Preface: General Chair

In my welcome to participants in this year's conference handbook, I especially welcomed those for which it was their first ACL. I expressed the hope that the conference fulfilled their expectations and remained in their memory as a great start. Trying to imagine the first experience of a present-day ACL, the magnitude of the whole event may be a bit overwhelming - our field is on an expanding trajectory, and even a selection of the best work fills a great number of parallel sessions over a number of days; plus, there are the workshops and tutorials to quench many topical thirsts. This ACL again promises to be a next peak in a progressive development.

ACL Conferences are the product of many people working together, kindly offering their services to the community at large. ACL-2016 is no exception to this. I would like to thank each and every person who has volunteered their time to make the event possible. I am deeply impressed with the sense of community that organizing an ACL brings about.

Priscilla Rasmussen, the ACL Business Manager, and the 2015 ACL Executive Committee (Chris Manning, Pushpak Bhattacharyya, Joakim Nivre, Graeme Hirst, Dragomir Radev, Gertjan van Nood, Min-Yen Kan, Herman Ney, and Yejin Choi) have been instrumental in setting ACL-2016 in motion and in guiding the ACL-2016 team along the path from concept to execution. Without the collective memory and hands-on guidance of the committee, an ACL conference will never happen.

The ACL-2016 team was formidable in building all the components of the conference and connecting them together in an impressive programme: Katrin Erk and Noah Smith (Programme Committee Chairs); Valia Kordoni, Markus Egg (Local Arrangements Chairs) who brought together a fantastic local organization team; Sabine Schulte im Walde and Jun Zhao (Workshop Chairs), Alexandra Birch and Willem Zuidema (Tutorial Chairs); Hai Zhao, Yusuke Miyao, and Yannick Versley (Publication Chairs); Tao Lei, He He, and Will Roberts (Student Research Workshop Chairs), Yang Liu, Chris Biemann, and Gosse Bouma (Faculty Advisors for the Student Research Workshop), Marianna Apidianaki and Sameer Pradhan (Demonstration Chairs), Barbara Plank (Publicity Chair), Florian Kunneman and Matt Post (Conference Handbook Team), and Yulia Grishina (Student Volunteer Coordinator).

The Program Chairs selected outstanding invited speakers: Mark Steedman (University of Edinburgh) and Amber Boydstun (University of California, Davis).

I am deeply grateful to our sponsors for their generous contributions, allowing the conference not to become prohibitively expensive: Google, Baidu, Amazon (Platinum Sponsors); Bloomberg, Facebook, eBay, Elsevier, Microsoft Research, and Maluuba (Gold Sponsors); Huawei Technologies, Zalando SE (Silver Sponsors); Nuance, Grammarly, Voicebox, Yandex, and Textkernel (Bronze Sponsors).

Finally, I would like to express my deep appreciation for the hard work carried out by all area chairs, workshop organizers, tutorial presenters, and the massive army of reviewers. Kudos to all.

Welcome to ACL-2016!

Antal van den Bosch
General Chair

Preface: Program Committee Co-Chairs

Welcome to the 54th Annual Meeting of the Association for Computational Linguistics! This year, ACL received 825 long paper submissions (a new record) and 463 short paper submissions.[1] Of the long papers, 231 were accepted for presentation at ACL—116 as oral presentations and 115 as poster presentations. 97 short papers were accepted—49 as oral and 48 as poster presentations. In addition, ACL also features 25 presentations of papers accepted in the *Transactions of the Association for Computational Linguistics* (TACL). With 353 paper presentations at the main conference, this is the largest ACL program to date.

In keeping with the tremendous growth of our field, we introduced some changes to the conference. Oral presentations were shortened to fifteen (twelve) minutes for long (short) papers, plus time for questions. While this places a greater demand on speakers to be concise, we believe it is worth the effort, allowing far more work to be presented orally. We also took advantage of the many halls available at Humboldt University and expanded the number of parallel talks during some conference sessions.

We introduced a category of outstanding papers to help recognize the highest quality work in the community this year. The 11 outstanding papers (9 long, 2 short, 0.85% of submissions) represent a broad spectrum of exciting contributions; they are recognized by especially prominent placement in the program. From these, a best paper and an IBM-sponsored best student paper have been selected; those will be announced in the awards session on Wednesday afternoon.

Following other recent ACL conferences, submissions were reviewed under different categories and using different review forms for empirical/data-driven, theoretical, applications/tools, resources/evaluation, and survey papers. We introduced special fields in the paper submission form for authors to explicitly note the release of open-source implementations to enable reproducibility, and to note freely available datasets. We also allowed authors to submit appendices of arbitrary length for details that would enable replication; reviewers were not expected to read this material.

Another innovation we explored during the review period was the scheduling of short paper review before long paper review. While this was planned to make the entire review period more compact (fitting between the constraints of NAACL 2016 and EMNLP 2016 at either end), we found that reviewing short papers first eliminated many of the surprises for the long paper review process.

We sought to follow recently-evolved best practices in planning the poster sessions, so that the many high-quality works presented in that format will be visible and authors and attendees benefit from the interactions during the two poster sessions.

ACL 2016 will have two distinguished invited speakers: Amber Boydstun (Associate Professor of Political Science at the University of California, Davis) and Mark Steedman (Professor of Cognitive Science at the University of Edinburgh). We are grateful that they accepted our invitations and look forward to their presentations.

There are many individuals we wish to thank for their contributions to ACL 2016, some multiple times:

[1] These numbers exclude papers that were not reviewed due to formatting, anonymity, or double submission violations (9 short and 21 long papers) or that were withdrawn prior to review (approximately 59 short and 52 long papers).

- The 38 area chairs who recruited reviewers, led the discussion about each paper, carefully assessed each submission, and authored meta-reviews to guide final decisions: Miguel Ballesteros, David Bamman, Steven Bethard, Jonathan Berant, Gemma Boleda, Ming-Wei Chang, Wanxiang Che, Chris Dyer, Ed Grefenstette, Hannaneh Hajishirzi, Minlie Huang, Mans Hulden, Heng Ji, Jing Jiang, Zornitsa Kozareva, Marco Kuhlmann, Yang Liu, Annie Louis, Wei Lu, Marie-Catherine de Marneffe, Gerard de Melo, David Mimno, Meg Mitchell, Daichi Mochihashi, Graham Neubig, Naoaki Okazaki, Simone Ponzetto, Matthew Purver, David Reitter, Nathan Schneider, Hinrich Schuetze, Thamar Solorio, Lucia Specia, Partha Talukdar, Ivan Titov, Lu Wang, Nianwen Xue, and Grace Yang.
- Our full program committee of 884 hard-working individuals who reviewed the conference's 1,288 submissions (including secondary reviewers).
- The ACL coordinating committee members, especially Yejin Choi, Graeme Hirst, Chris Manning, and Shiqi Zhao, who answered many questions as they arose during the year.
- TACL editors-in-chief Mark Johnson, Lillian Lee, and Kristina Toutanova, for coordinating with us on TACL presentations at ACL.
- Ani Nenkova and Owen Rambow, program co-chairs of NAACL 2016, and Michael Strube, program co-chair of ACL 2015, who were generous with advice.
- Yusuke Miyao, Yannick Versley, and Hai Zhao, our well-organized publication chairs, and the responsive team at Softconf led by Rich Gerber.
- Valia Kordoni and the local organization team, especially webmaster Kostadin Cholakov.
- Antal van den Bosch, our general chair, who kept us coordinated with the rest of the ACL 2016 team and offered guidance whenever we needed it.
- Antal van den Bosch, Claire Cardie, Pascale Fung, Ray Mooney, and Joakim Nivre, who carefully reviewed papers under consideration for outstanding and best paper recognition.
- Priscilla Rasmussen, who knows everything about how to make ACL a success.

We hope that you enjoy ACL 2016 in Berlin!

ACL 2016 program co-chairs
Katrin Erk, University of Texas
Noah A. Smith, University of Washington

ACL 2016 Organizing Committee

General Chair

Antal van den Bosch, Radboud University Nijmegen

Program Co-Chairs

Katrin Erk, University of Texas at Austin
Noah A. Smith, University of Washington

Local Organizing Committee

Valia Kordoni (local chair), Humboldt University
Markus Egg (local co-chair), Humboldt University
Kostadin Cholakov, Humboldt University
Maja Popović, Humboldt University
Manfred Stede, University of Potsdam
Anke Lüdeling, Humboldt University
Manfred Krifka, Humboldt University
Ulf Leser, Humboldt University
Yulia Grishina (Student Volunteer Coordinator), University of Potsdam

Workshop Chairs

Jun Zhao, Chinese Academy of Sciences
Sabine Schulte im Walde, IMS Stuttgart

Tutorial Chairs

Alexandra Birch, University of Edinburgh
Willem Zuidema, University of Amsterdam

Publication Chairs

Yannick Versley, Ruprecht-Karls-Universität Heidelberg
Hai Zhao, Shanghai Jiao Tong University
Yusuke Miyao, National Institute of Informatics, Japan

Demonstration Chairs

Sameer Pradhan, Boulder Learning
Marianna Apidianaki, LIMSI-CNRS

Student Research Workshop Chairs

Will Roberts, Humboldt-Universität zu Berlin
Tao Lei, Massachusetts Institute of Technology
He He, University of Maryland

Faculty Advisors to the Student Research Workshop

Yang Liu, Tsinghua University

Chris Biemann, Technische Universität Darmstadt

Invited Talk I: Same Policy Issue, Different Portrayal: The Importance of Tone and Framing in Language

Amber E. Boydstun, University of California at Davis

Many policy issues at the center of politics are relatively fixed; they tend to involve the same basic questions that do not vary over time (e.g., should abortion be legal? should we execute people convicted of horrific crimes?). Political candidates, too, are (like the rest of us) the same people year after year (e.g., Hillary Clinton in 2016 is just an older version of Hillary Clinton in 2015). Yet when citizens consider a given political item (be it a policy issue, a candidate, or something else), they tend not to perceive that item in a fixed way over time. Rather, peoples perceptions of the item tend to depend on how that item is portrayed at that moment. Policy issues and political candidates alike can be portrayed differently through the use of different visual imagery but even more pervasively through variance in the text used to describe them. In this talk, I give a general overview of the importance of issue and candidate portrayals in political communication. I outline the extensive research that has already been done trying to identify different portrayals in text. And I discuss the many opportunities available today to researchers interested in tracking issue and candidate portrayals in text and in examining the effects of issue and candidate portrayals on public attitudes and voting behavior.

Bio: Amber Boydstun is an Associate Professor of Political Science at the University of California, Davis. Her work bridges multiple disciplines, including psychology, journalism, and computer science. Her core research examines the interaction between media and politics, with a focus on how different media portrayals of the same policy issue can prompt citizens and policymakers to respond to that issue in different ways. She uses lab experiments, large-scale media studies, and manual and computational text analysis to study how issues make the news; how issues are "framed" in the news; the dynamics of "media storms"; and how media coverage can shape public opinion and public policy on issues like immigration, gun control, same-sex marriage, and capital punishment. She is author of *Making the News* (Chicago) and co-author of *The Decline of the Death Penalty and the Discovery of Innocence* (Cambridge), as well as many journal articles. Boydstun works with scholars across the globe as a member of the Comparative Agendas Project,[1] a collaborative enterprise by political science and policy scholars to measure international government outputs. She serves on the editorial boards for the journal Political Communication, the Text as Data Association, and the Women Also Know Stuff[2] initiative. Most recently, she co-chaired the 2016 Visions in Methodology Conference. [3]

Invited Talk II: On Distributional Semantics
Mark Steedman, University of Edinburgh

The central problem in open domain-question answering from text is the problem of *entailment*. Given enough text, the answer is almost certain to be there, but is likely to be expressed differently than in the question—either in a paraphrase, or in a sentence that entails or implies the answer. We cannot afford to bridge this gap by open-ended theorem-proving search. Instead we need a semantics for natural language that directly supports common-sense inference, such as that *arriving somewhere* implies subsequently *being there*, and *invading* a country implies *attacking* it. We would like this semantics to be compatible with traditional logical operator semantics including quantification, negation and tense, so that *not being there* implies *not having arrived*, and *not attacking* implies *not invading*.

There have been many attempts to build such a semantics of content words by hand, from the generative semantics of the '60s to WordNet and other resources of the present. The '60s saw attempts based on generative semantics, while more recently, they have exploited WordNet and other computational resources. However, such systems have been incomplete and language-specific in comparison to the vastness of human common-sense reasoning. One consequence has been renewed interest in the idea of treating the semantics as "hidden", to be discovered through machine learning, an idea that has its origins in the "semantic differential" of Osgood, Suci, and Tannenbaum in the '50s.

There are two distinct modern approaches to the problem of data-driven or "distributional" semantics. The first, which I will call "collocational", is the direct descendant of the semantic differential. In its most basic form, the meaning of a word is taken to be a vector in a space whose dimensions are defined by the lexicon of the language, and whose magnitude is defined by counts of those lexical items within a fixed window on the string (although in practice the dimensionality is reduced and the relation to frequency less direct). Crucially, semantic composition is defined in terms of linear algebraic operations such as vector addition.

The second approach, which I will call "denotational", defines the meaning of a word in terms of the entities (or rather their designators) that it is predicated over and the ensembles of predications over entities of the same types, obtained by machine-reading with wide coverage parsers. Semantic composition is can then be defined as an applicative system, as in traditional formal semantics.

The talk reviews recent work in both collocation- and denotation- based distributional semantics, including some hybrid approaches that interpolate grammatical features with collocational representations, or use probabilistic logics over relations whose arguments denote vectors, and asks for each what dimensions of meaning are actually being represented. It argues that the two approaches are largely orthogonal on these dimensions. Collocational representations are good for representing ambiguity, with linear algebraic composition most effective at disambiguation and representing distributional similarity. Denotational representations represent something more like a traditional compositional semantics, but one in which the primitive relations correspond to those of a hidden language of logical form representing paraphrase and common-sense entailment directly.

To make this point, I will discuss recent work in which collocational distributional representations such as embeddings have been used as proxies for semantic features in models such as LSTM, to guide disambiguation during parsing, while a lexicalized denotation-based distributional semantics is used to support inference of entailment. I will show that this hybrid approach can be applied with a number of parsing mod-

els, including transition-based and supertagging, to support entailment-based QA with denotation-based distributional representations. I will discuss work at Edinburgh and elsewhere in which the semantics of paraphrases is represented by a single cluster identifier and common-sense inference (derived from a learned entailment graph) is built into the lexicon and projected by syntactic derivation, rather than delegated to a later stage of inference. The method can be applied cross-linguistically, in support of machine translation. Ongoing work extends the method to extract multi-word items, light-verb constructions, and an aspect-based semantics for temporal/causal entailment, and to the creation and interrogation of Knowledge Graphs and Semantic Nets via natural language.

Bio: Mark Steedman is Professor of Cognitive Science in the School of Informatics at the University of Edinburgh. Previously, he taught as Professor in the Department of Computer and Information Science at the University of Pennsylvania, which he joined as Associate Professor in 1988, after teaching at the Universities of Warwick and Edinburgh. His PhD is in Artificial Intelligence from the University of Edinburgh. He was a Alfred P. Sloan Fellow at the University of Texas at Austin in 1980/81, and a Visiting Professor at Penn in 1986/87. He is a Fellow of the American Association for Artificial Intelligence, the British Academy, the Royal Society of Edinburgh, the Association for Computational Linguistics, and the Cognitive Science Society, and a Member of the European Academy.

His research interests cover issues in computational linguistics, artificial intelligence, computer science and cognitive science, including syntax and semantics of natural language, wide-coverage parsing and question-answering, comprehension of natural language discourse by humans and by machine, grammar-based language modeling, natural language generation, and the semantics of intonation in spoken discourse. Much of his current NLP research is addressed to probabilistic parsing and robust semantics for question-answering using the CCG grammar formalism, including the acquisition of language from paired sentences and meanings by child and machine. He sometimes works with colleagues in computer animation using these theories to guide the graphical animation of speaking virtual or simulated autonomous human agents. Some of his research concerns the analysis of music by humans and machines.

Table of Contents

Conference Program

Monday, August 8, 2016

8:45–9:00 ***Opening session***

9:00–10:10 ***Invited talk I: Amber Boydstun***

10:10–10:40 ***Coffee break***

Session 1A: Semantic parsing I

10:40–11:00 *Noise reduction and targeted exploration in imitation learning for Abstract Meaning Representation parsing*
James Goodman, Andreas Vlachos and Jason Naradowsky

11:00–11:20 *Data Recombination for Neural Semantic Parsing*
Robin Jia and Percy Liang

11:20–11:40 *Inferring Logical Forms From Denotations*
Panupong Pasupat and Percy Liang

11:40–12:00 *Language to Logical Form with Neural Attention*
Li Dong and Mirella Lapata

Session 1B: Information extraction

10:40–11:00 *Unsupervised Person Slot Filling based on Graph Mining*
Dian Yu and Heng Ji

11:20–11:40 *A Multi-media Approach to Cross-lingual Entity Knowledge Transfer*
Di Lu, Xiaoman Pan, Nima Pourdamghani, Shih-Fu Chang, Heng Ji and Kevin Knight

Session 1C: Machine translation I

10:40–11:00 *Models and Inference for Prefix-Constrained Machine Translation*
Joern Wuebker, Spence Green, John DeNero, Sasa Hasan and Minh-Thang Luong

11:00–11:20 *Modeling Coverage for Neural Machine Translation*
Zhaopeng Tu, Zhengdong Lu, Yang Liu, Xiaohua Liu and Hang Li

11:20–11:40 *Improving Neural Machine Translation Models with Monolingual Data*
Rico Sennrich, Barry Haddow and Alexandra Birch

11:40–12:00 *Graph-Based Translation Via Graph Segmentation*
Liangyou Li, Andy Way and Qun Liu

Session 1D: Word meaning I

10:40–11:00 *Incremental Acquisition of Verb Hypothesis Space towards Physical World Interaction*
Lanbo She and Joyce Chai

11:00–11:20 *Language Transfer Learning for Supervised Lexical Substitution*
Gerold Hintz and Chris Biemann

11:20–11:40 *Learning the Curriculum with Bayesian Optimization for Task-Specific Word Representation Learning*
Yulia Tsvetkov, Manaal Faruqui, Wang Ling, Brian MacWhinney and Chris Dyer

11:40–12:00 *Pointing the Unknown Words*
Caglar Gulcehre, Sungjin Ahn, Ramesh Nallapati, Bowen Zhou and Yoshua Bengio

Monday, August 8, 2016 (continued)

Session 1E: Parsing I

11:00–11:20 *Generalized Transition-based Dependency Parsing via Control Parameters*
Bernd Bohnet, Ryan McDonald, Emily Pitler and Ji Ma

11:20–11:40 *A Transition-Based System for Joint Lexical and Syntactic Analysis*
Matthieu Constant and Joakim Nivre

11:40–12:00 *Neural Greedy Constituent Parsing with Dynamic Oracles*
Maximin Coavoux and Benoit Crabbé

Session 1F: Noncompositionality

10:40–11:00 *Literal and Metaphorical Senses in Compositional Distributional Semantic Models*
E.Dario Gutierrez, Ekaterina Shutova, Tyler Marghetis and Benjamin Bergen

11:00–11:20 *Idiom Token Classification using Sentential Distributed Semantics*
Giancarlo Salton, Robert Ross and John Kelleher

11:20–11:40 *Adaptive Joint Learning of Compositional and Non-Compositional Phrase Embeddings*
Kazuma Hashimoto and Yoshimasa Tsuruoka

11:40–12:00 *Metaphor Detection with Topic Transition, Emotion and Cognition in Context*
Hyeju Jang, Yohan Jo, Qinlan Shen, Michael Miller, Seungwhan Moon and Carolyn Rose

12:00–13:40 ***Lunch break***

Session 2A: Word vectors I

14:00–14:20 *Compressing Neural Language Models by Sparse Word Representations*
Yunchuan Chen, Lili Mou, Yan Xu, Ge Li and Zhi Jin

14:20–14:40 *Intrinsic Subspace Evaluation of Word Embedding Representations*
Yadollah Yaghoobzadeh and Hinrich Schütze

14:40–15:00 *On the Role of Seed Lexicons in Learning Bilingual Word Embeddings*
Ivan Vulić and Anna Korhonen

Session 2B: Events and schemas

13:40–14:00 *Liberal Event Extraction and Event Schema Induction*
Lifu Huang, Taylor Cassidy, Xiaocheng Feng, Heng Ji, Clare R. Voss, Jiawei Han and Avirup Sil

14:00–14:20 *Jointly Event Extraction and Visualization on Twitter via Probabilistic Modelling*
Deyu Zhou, Tianmeng Gao and Yulan He

14:20–14:40 *Using Sentence-Level LSTM Language Models for Script Inference*
Karl Pichotta and Raymond J. Mooney

14:40–15:00 *Two Discourse Driven Language Models for Semantics*
Haoruo Peng and Dan Roth

Session 2C: Sentiment analysis

13:40–14:00 *Sentiment Domain Adaptation with Multiple Sources*
Fangzhao Wu and Yongfeng Huang

14:00–14:20 *Connotation Frames: A Data-Driven Investigation*
Hannah Rashkin, Sameer Singh and Yejin Choi

14:20–14:40 *Bi-Transferring Deep Neural Networks for Domain Adaptation*
Guangyou Zhou, Zhiwen Xie, Jimmy Xiangji Huang and Tingting He

14:40–15:00 *Document-level Sentiment Inference with Social, Faction, and Discourse Context*
Eunsol Choi, Hannah Rashkin, Luke Zettlemoyer and Yejin Choi

Session 2D: Parsing II

13:40–14:00 *Active Learning for Dependency Parsing with Partial Annotation*
Zhenghua Li, Min Zhang, Yue Zhang, Zhanyi Liu, Wenliang Chen, Hua Wu and Haifeng Wang

14:20–14:40 *Dependency Parsing with Bounded Block Degree and Well-nestedness via Lagrangian Relaxation and Branch-and-Bound*
Caio Corro, Joseph Le Roux, Mathieu Lacroix, Antoine Rozenknop and Roberto Wolfler Calvo

Session 2E: Information retrieval

13:40–14:00 *Query Expansion with Locally-Trained Word Embeddings*
Fernando Diaz, Bhaskar Mitra and Nick Craswell

14:00–14:20 *Together we stand: Siamese Networks for Similar Question Retrieval*
Arpita Das, Harish Yenala, Manoj Chinnakotla and Manish Shrivastava

14:20–14:40 *News Citation Recommendation with Implicit and Explicit Semantics*
Hao Peng, Jing Liu and Chin-Yew Lin

Monday, August 8, 2016 (continued)

Session 2F: Phonology and morphology

13:40–14:00 *Grapheme-to-Phoneme Models for (Almost) Any Language*
Aliya Deri and Kevin Knight

14:20–14:40 *Neural Word Segmentation Learning for Chinese*
Deng Cai and Hai Zhao

14:40–15:00 *Transition-Based Neural Word Segmentation*
Meishan Zhang, Yue Zhang and Guohong Fu

15:00–15:30 ***Coffee break***

Session 3A: Question answering I

15:30–15:50 *A Parallel-Hierarchical Model for Machine Comprehension on Sparse Data*
Adam Trischler, Zheng Ye, Xingdi Yuan, Jing He and Philip Bachman

15:50–16:10 *Combining Natural Logic and Shallow Reasoning for Question Answering*
Gabor Angeli, Neha Nayak and Christopher D. Manning

16:10–16:30 *Easy Questions First? A Case Study on Curriculum Learning for Question Answering*
Mrinmaya Sachan and Eric Xing

16:30–16:50 *Improved Representation Learning for Question Answer Matching*
Ming Tan, Cicero dos Santos, Bing Xiang and Bowen Zhou

16:50–17:10 *Tables as Semi-structured Knowledge for Question Answering*
Sujay Kumar Jauhar, Peter Turney and Eduard Hovy

Session 3B: Sentence vectors

15:30–15:50 *Neural Summarization by Extracting Sentences and Words*
Jianpeng Cheng and Mirella Lapata

16:10–16:30 *Neural Networks For Negation Scope Detection*
Federico Fancellu, Adam Lopez and Bonnie Webber

16:30–16:50 *CSE: Conceptual Sentence Embeddings based on Attention Model*
Yashen Wang, Heyan Huang, Chong Feng, Qiang Zhou, Jiahui Gu and Xiong Gao

Session 3C: Parsing III

Session 3D: Dialog

15:30–15:50 *DocChat: An Information Retrieval Approach for Chatbot Engines Using Unstructured Documents*
Zhao Yan, Nan Duan, Junwei Bao, Peng Chen, Ming Zhou, Zhoujun Li and Jianshe Zhou

15:50–16:10 *Investigating the Sources of Linguistic Alignment in Conversation*
Gabriel Doyle and Michael C. Frank

16:10–16:30 *Entropy Converges Between Dialogue Participants: Explanations from an Information-Theoretic Perspective*
Yang Xu and David Reitter

16:30–16:50 *Finding the Middle Ground - A Model for Planning Satisficing Answers*
Sabine Janzen, Wolfgang Maaß and Tobias Kowatsch

16:50–17:10 *A Sentence Interaction Network for Modeling Dependence between Sentences*
Biao Liu and Minlie Huang

Session 3E: Generation

15:30–15:50 *Towards more variation in text generation: Developing and evaluating variation models for choice of referential form*
Thiago Castro Ferreira, Emiel Krahmer and Sander Wubben

15:50–16:10 *How Much is 131 Million Dollars? Putting Numbers in Perspective with Compositional Descriptions*
Arun Chaganty and Percy Liang

16:10–16:30 *Generating Factoid Questions With Recurrent Neural Networks: The 30M Factoid Question-Answer Corpus*
Iulian Vlad Serban, Alberto García-Durán, Caglar Gulcehre, Sungjin Ahn, Sarath Chandar, Aaron Courville and Yoshua Bengio

16:30–16:50 *Latent Predictor Networks for Code Generation*
Wang Ling, Phil Blunsom, Edward Grefenstette, Karl Moritz Hermann, Tomáš Kočiský, Fumin Wang and Andrew Senior

16:50–17:10 *Easy Things First: Installments Improve Referring Expression Generation for Objects in Photographs*
Sina Zarrieß and David Schlangen

Session 3F: Entities and coreference

15:30–15:50 *Collective Entity Resolution with Multi-Focal Attention*
Amir Globerson, Nevena Lazic, Soumen Chakrabarti, Amarnag Subramanya, Michael Ringaard and Fernando Pereira

16:30–16:50 *Which Coreference Evaluation Metric Do You Trust? A Proposal for a Link-based Entity Aware Metric*
Nafise Sadat Moosavi and Michael Strube

16:50–17:10 *Improving Coreference Resolution by Learning Entity-Level Distributed Representations*
Kevin Clark and Christopher D. Manning

Session 3G: Topics

15:30–15:50 *Effects of Creativity and Cluster Tightness on Short Text Clustering Performance*
Catherine Finegan-Dollak, Reed Coke, Rui Zhang, Xiangyi Ye and Dragomir Radev

15:50–16:10 *Generative Topic Embedding: a Continuous Representation of Documents*
Shaohua Li, Tat-Seng Chua, Jun Zhu and Chunyan Miao

16:30–16:50 *Detecting Common Discussion Topics Across Culture From News Reader Comments*
Bei Shi, Wai Lam, Lidong Bing and Yinqing Xu

16:50–17:10 *A Discriminative Topic Model using Document Network Structure*
Weiwei Yang, Jordan Boyd-Graber and Philip Resnik

18:00–21:00 ***Poster and dinner session I (includes SRW)***

AraSenTi: Large-Scale Twitter-Specific Arabic Sentiment Lexicons
Nora Al-Twairesh, Hend Al-Khalifa and Abdulmalik AlSalman

Unsupervised Multi-Author Document Decomposition Based on Hidden Markov Model
Khaled Aldebei, Xiangjian He, Wenjing Jia and Jie Yang

Automatic Text Scoring Using Neural Networks
Dimitrios Alikaniotis, Helen Yannakoudakis and Marek Rei

Improved Semantic Parsers For If-Then Statements
I. Beltagy and Chris Quirk

Universal Dependencies for Learner English
Yevgeni Berzak, Jessica Kenney, Carolyn Spadine, Jing Xian Wang, Lucia Lam, Keiko Sophie Mori, Sebastian Garza and Boris Katz

Extracting token-level signals of syntactic processing from fMRI - with an application to PoS induction
Joachim Bingel, Maria Barrett and Anders Søgaard

Bidirectional Recurrent Convolutional Neural Network for Relation Classification
Rui Cai, Xiaodong Zhang and Houfeng Wang

Sentence Rewriting for Semantic Parsing
Bo Chen, Le Sun, Xianpei Han and Bo An

Chinese Zero Pronoun Resolution with Deep Neural Networks
Chen Chen and Vincent Ng

Constrained Multi-Task Learning for Automated Essay Scoring
Ronan Cummins, Meng Zhang and Ted Briscoe

CFO: Conditional Focused Neural Question Answering with Large-scale Knowledge Bases
Zihang Dai, Lei Li and Wei Xu

Verbs Taking Clausal and Non-Finite Arguments as Signals of Modality – Revisiting the Issue of Meaning Grounded in Syntax
Judith Eckle-Kohler

Tree-to-Sequence Attentional Neural Machine Translation
Akiko Eriguchi, Kazuma Hashimoto and Yoshimasa Tsuruoka

Coordination Annotation Extension in the Penn Tree Bank
Jessica Ficler and Yoav Goldberg

Analyzing Biases in Human Perception of User Age and Gender from Text
Lucie Flekova, Jordan Carpenter, Salvatore Giorgi, Lyle Ungar and Daniel Preoţiuc-Pietro

Modeling Social Norms Evolution for Personalized Sentiment Classification
Lin Gong, Mohammad Al Boni and Hongning Wang

Modeling Concept Dependencies in a Scientific Corpus
Jonathan Gordon, Linhong Zhu, Aram Galstyan, Prem Natarajan and Gully Burns

Normalized Log-Linear Interpolation of Backoff Language Models is Efficient
Kenneth Heafield, Chase Geigle, Sean Massung and Lane Schwartz

How well do Computers Solve Math Word Problems? Large-Scale Dataset Construction and Evaluation
Danqing Huang, Shuming Shi, Chin-Yew Lin, Jian Yin and Wei-Ying Ma

Embeddings for Word Sense Disambiguation: An Evaluation Study
Ignacio Iacobacci, Mohammad Taher Pilehvar and Roberto Navigli

Understanding Discourse on Work and Job-Related Well-Being in Public Social Media
Tong Liu, Christopher Homan, Cecilia Ovesdotter Alm, Megan Lytle, Ann Marie White and Henry Kautz

Achieving Open Vocabulary Neural Machine Translation with Hybrid Word-Character Models
Minh-Thang Luong and Christopher D. Manning

End-to-end Sequence Labeling via Bi-directional LSTM-CNNs-CRF
Xuezhe Ma and Eduard Hovy

Off-topic Response Detection for Spontaneous Spoken English Assessment
Andrey Malinin, Rogier van Dalen, Kate Knill, Yu Wang and Mark Gales

Synthesizing Compound Words for Machine Translation
Austin Matthews, Eva Schlinger, Alon Lavie and Chris Dyer

Harnessing Cognitive Features for Sarcasm Detection
Abhijit Mishra, Diptesh Kanojia, Seema Nagar, Kuntal Dey and Pushpak Bhattacharyya

End-to-End Relation Extraction using LSTMs on Sequences and Tree Structures
Makoto Miwa and Mohit Bansal

A short proof that O_2 is an MCFL
Mark-Jan Nederhof

Context-aware Argumentative Relation Mining
Huy Nguyen and Diane Litman

Leveraging Inflection Tables for Stemming and Lemmatization.
Garrett Nicolai and Grzegorz Kondrak

Scaling a Natural Language Generation System
Jonathan Pfeil and Soumya Ray

ALTO: Active Learning with Topic Overviews for Speeding Label Induction and Document Labeling
Forough Poursabzi-Sangdeh, Jordan Boyd-Graber, Leah Findlater and Kevin Seppi

Predicting the Rise and Fall of Scientific Topics from Trends in their Rhetorical Framing
Vinodkumar Prabhakaran, William L. Hamilton, Dan McFarland and Dan Jurafsky

Compositional Sequence Labeling Models for Error Detection in Learner Writing
Marek Rei and Helen Yannakoudakis

Neural Semantic Role Labeling with Dependency Path Embeddings
Michael Roth and Mirella Lapata

Prediction of Prospective User Engagement with Intelligent Assistants
Shumpei Sano, Nobuhiro Kaji and Manabu Sassano

Resolving References to Objects in Photographs using the Words-As-Classifiers Model
David Schlangen, Sina Zarrieß and Casey Kennington

RBPB: Regularization-Based Pattern Balancing Method for Event Extraction
Lei Sha, Jing Liu, Chin-Yew Lin, Sujian Li, Baobao Chang and Zhifang Sui

Neural Network-Based Model for Japanese Predicate Argument Structure Analysis
Tomohide Shibata, Daisuke Kawahara and Sadao Kurohashi

Addressing Limited Data for Textual Entailment Across Domains
Chaitanya Shivade, Preethi Raghavan and Siddharth Patwardhan

Annotating and Predicting Non-Restrictive Noun Phrase Modifications
Gabriel Stanovsky and Ido Dagan

Bilingual Segmented Topic Model
Akihiro Tamura and Eiichiro Sumita

Learning Semantically and Additively Compositional Distributional Representations
Ran Tian, Naoaki Okazaki and Kentaro Inui

Inner Attention based Recurrent Neural Networks for Answer Selection
Bingning Wang, Kang Liu and Jun Zhao

Relation Classification via Multi-Level Attention CNNs
Linlin Wang, Zhu Cao, Gerard de Melo and Zhiyuan Liu

Knowledge Base Completion via Coupled Path Ranking
Quan Wang, Jing Liu, Yuanfei Luo, Bin Wang and Chin-Yew Lin

Larger-Context Language Modelling with Recurrent Neural Network
Tian Wang and Kyunghyun Cho

The Creation and Analysis of a Website Privacy Policy Corpus
Shomir Wilson, Florian Schaub, Aswarth Abhilash Dara, Frederick Liu, Sushain Cherivirala, Pedro Giovanni Leon, Mads Schaarup Andersen, Sebastian Zimmeck, Kanthashree Mysore Sathyendra, N. Cameron Russell, Thomas B. Norton, Eduard Hovy, Joel Reidenberg and Norman Sadeh

Sequence-based Structured Prediction for Semantic Parsing
Chunyang Xiao, Marc Dymetman and Claire Gardent

Learning Word Meta-Embeddings
Wenpeng Yin and Hinrich Schütze

Towards Constructing Sports News from Live Text Commentary
Jianmin Zhang, Jin-ge Yao and Xiaojun Wan

A Continuous Space Rule Selection Model for Syntax-based Statistical Machine Translation
Jingyi Zhang, Masao Utiyama, Eiichro Sumita, Graham Neubig and Satoshi Nakamura

Probabilistic Graph-based Dependency Parsing with Convolutional Neural Network
Zhisong Zhang, Hai Zhao and Lianhui Qin

A Search-Based Dynamic Reranking Model for Dependency Parsing
Hao Zhou, Yue Zhang, Shujian Huang, Junsheng Zhou, Xin-Yu Dai and Jiajun Chen

Cross-Lingual Sentiment Classification with Bilingual Document Representation Learning
Xinjie Zhou, Xiaojun Wan and Jianguo Xiao

Segment-Level Sequence Modeling using Gated Recursive Semi-Markov Conditional Random Fields
Jingwei Zhuo, Yong Cao, Jun Zhu, Bo Zhang and Zaiqing Nie

Tuesday, August 9, 2016

9:00–10:10 ***Invited talk II: Mark Steedman***

10:10–10:40 ***Coffee break***

Session 4A: Relations and knowledge bases

10:40–11:00 *Identifying Causal Relations Using Parallel Wikipedia Articles*
Christopher Hidey and Kathy McKeown

11:00–11:20 *Compositional Learning of Embeddings for Relation Paths in Knowledge Base and Text*
Kristina Toutanova, Victoria Lin, Wen-tau Yih, Hoifung Poon and Chris Quirk

11:20–11:40 *Commonsense Knowledge Base Completion*
Xiang Li, Aynaz Taheri, Lifu Tu and Kevin Gimpel

Session 4B: Semantic parsing II

10:40–11:00 *Simpler Context-Dependent Logical Forms via Model Projections*
Reginald Long, Panupong Pasupat and Percy Liang

11:20–11:40 *A Fast Unified Model for Parsing and Sentence Understanding*
Samuel R. Bowman, Jon Gauthier, Abhinav Rastogi, Raghav Gupta, Christopher D. Manning and Christopher Potts

Session 4C: Word meaning II

11:20–11:40 *Investigating Language Universal and Specific Properties in Word Embeddings*
Peng Qian, Xipeng Qiu and Xuanjing Huang

11:40–12:00 *Diachronic Word Embeddings Reveal Statistical Laws of Semantic Change*
William L. Hamilton, Jure Leskovec and Dan Jurafsky

Session 4D: Tasks and datasets

10:40–11:00 *Beyond Plain Spatial Knowledge: Determining Where Entities Are and Are Not Located, and For How Long*
Alakananda Vempala and Eduardo Blanco

11:00–11:20 *LexSemTm: A Semantic Dataset Based on All-words Unsupervised Sense Distribution Learning*
Andrew Bennett, Timothy Baldwin, Jey Han Lau, Diana McCarthy and Francis Bond

11:20–11:40 *The LAMBADA dataset: Word prediction requiring a broad discourse context*
Denis Paperno, Germán Kruszewski, Angeliki Lazaridou, Ngoc Quan Pham, Raffaella Bernardi, Sandro Pezzelle, Marco Baroni, Gemma Boleda and Raquel Fernandez

11:40–12:00 *WikiReading: A Novel Large-scale Language Understanding Task over Wikipedia*
Daniel Hewlett, Alexandre Lacoste, Llion Jones, Illia Polosukhin, Andrew Fandrianto, Jay Han, Matthew Kelcey and David Berthelot

Session 4E: Parsing IV

11:00–11:20 *Optimizing Spectral Learning for Parsing*
Shashi Narayan and Shay B. Cohen

11:20–11:40 *Stack-propagation: Improved Representation Learning for Syntax*
Yuan Zhang and David Weiss

Session 4F: Document analysis

10:40–11:00 *Inferring Perceived Demographics from User Emotional Tone and User-Environment Emotional Contrast*
Svitlana Volkova and Yoram Bachrach

11:00–11:20 *Prototype Synthesis for Model Laws*
Matthew Burgess, Eugenia Giraudy and Eytan Adar

11:20–11:40 *Which argument is more convincing? Analyzing and predicting convincingness of Web arguments using bidirectional LSTM*
Ivan Habernal and Iryna Gurevych

11:40–12:00 *Discovery of Treatments from Text Corpora*
Christian Fong and Justin Grimmer

12:00–13:40 ***Lunch break***

Session 5A: Deep learning (short papers)

Session 5B: Semantics and generation (short papers)

Session 5C: Machine translation II (short papers)

Tuesday, August 9, 2016 (continued)

Session 5D: Text classification (short papers)

Session 5E: Potpourri I (short papers)

15:00–15:30 ***Coffee break***

Session 6A: Machine learning

15:30–15:50 *Learning Structured Predictors from Bandit Feedback for Interactive NLP*
Artem Sokolov, Julia Kreutzer, Christopher Lo and Stefan Riezler

16:10–16:30 *Deep Reinforcement Learning with a Natural Language Action Space*
Ji He, Jianshu Chen, Xiaodong He, Jianfeng Gao, Lihong Li, Li Deng and Mari Ostendorf

16:30–16:50 *Incorporating Copying Mechanism in Sequence-to-Sequence Learning*
Jiatao Gu, Zhengdong Lu, Hang Li and Victor O.K. Li

16:50–17:10 *Cross-domain Text Classification with Multiple Domains and Disparate Label Sets*
Himanshu Sharad Bhatt, Manjira Sinha and Shourya Roy

Session 6B: Word vectors II

15:50–16:10 *Morphological Smoothing and Extrapolation of Word Embeddings*
Ryan Cotterell, Hinrich Schütze and Jason Eisner

16:10–16:30 *Cross-lingual Models of Word Embeddings: An Empirical Comparison*
Shyam Upadhyay, Manaal Faruqui, Chris Dyer and Dan Roth

16:30–16:50 *Take and Took, Gaggle and Goose, Book and Read: Evaluating the Utility of Vector Differences for Lexical Relation Learning*
Ekaterina Vylomova, Laura Rimell, Trevor Cohn and Timothy Baldwin

Tuesday, August 9, 2016 (continued)

Session 6C: Machine translation III

15:30–15:50 *Minimum Risk Training for Neural Machine Translation*
Shiqi Shen, Yong Cheng, Zhongjun He, Wei He, Hua Wu, Maosong Sun and Yang Liu

16:10–16:30 *A Character-level Decoder without Explicit Segmentation for Neural Machine Translation*
Junyoung Chung, Kyunghyun Cho and Yoshua Bengio

16:30–16:50 *Target-Side Context for Discriminative Models in Statistical Machine Translation*
Aleš Tamchyna, Alexander Fraser, Ondřej Bojar and Marcin Junczys-Dowmunt

16:50–17:10 *Neural Machine Translation of Rare Words with Subword Units*
Rico Sennrich, Barry Haddow and Alexandra Birch

Session 6D: Discourse

15:30–15:50 *Implicit Discourse Relation Detection via a Deep Architecture with Gated Relevance Network*
Jifan Chen, Qi Zhang, Pengfei Liu, Xipeng Qiu and Xuanjing Huang

15:50–16:10 *Model Architectures for Quotation Detection*
Christian Scheible, Roman Klinger and Sebastian Padó

16:10–16:30 *Speech Act Modeling of Written Asynchronous Conversations with Task-Specific Embeddings and Conditional Structured Models*
Shafiq Joty and Enamul Hoque

16:30–16:50 *Situation entity types: automatic classification of clause-level aspect*
Annemarie Friedrich, Alexis Palmer and Manfred Pinkal

Session 6E: Language and vision

15:30–15:50 *Learning Prototypical Event Structure from Photo Albums*
Antoine Bosselut, Jianfu Chen, David Warren, Hannaneh Hajishirzi and Yejin Choi

15:50–16:10 *Cross-Lingual Image Caption Generation*
Takashi Miyazaki and Nobuyuki Shimizu

16:10–16:30 *Learning Concept Taxonomies from Multi-modal Data*
Hao Zhang, Zhiting Hu, Yuntian Deng, Mrinmaya Sachan, Zhicheng Yan and Eric Xing

16:30–16:50 *Generating Natural Questions About an Image*
Nasrin Mostafazadeh, Ishan Misra, Jacob Devlin, Margaret Mitchell, Xiaodong He and Lucy Vanderwende

16:50–17:10 *Physical Causality of Action Verbs in Grounded Language Understanding*
Qiaozi Gao, Malcolm Doering, Shaohua Yang and Joyce Chai

Session 6F: Summarization

16:30–16:50 *Optimizing an Approximation of ROUGE - a Problem-Reduction Approach to Extractive Multi-Document Summarization*
Maxime Peyrard and Judith Eckle-Kohler

Session 6G: Learner language

15:30–15:50 *Phrase Structure Annotation and Parsing for Learner English*
Ryo Nagata and Keisuke Sakaguchi

15:50–16:10 *A Trainable Spaced Repetition Model for Language Learning*
Burr Settles and Brendan Meeder

16:30–16:50 *User Modeling in Language Learning with Macaronic Texts*
Adithya Renduchintala, Rebecca Knowles, Philipp Koehn and Jason Eisner

16:50–17:10 *On the Similarities Between Native, Non-native and Translated Texts*
Ella Rabinovich, Sergiu Nisioi, Noam Ordan and Shuly Wintner

Tuesday, August 9, 2016 (continued)

17:30–19:00 ***Poster and dinner session II***

Learning Text Pair Similarity with Context-sensitive Autoencoders
Hadi Amiri, Philip Resnik, Jordan Boyd-Graber and Hal Daumé III

Linguistic Benchmarks of Online News Article Quality
Ioannis Arapakis, Filipa Peleja, Barla Berkant and Joao Magalhaes

Alleviating Poor Context with Background Knowledge for Named Entity Disambiguation
Ander Barrena, Aitor Soroa and Eneko Agirre

Mining Paraphrasal Typed Templates from a Plain Text Corpus
Or Biran, Terra Blevins and Kathleen McKeown

How to Train Dependency Parsers with Inexact Search for Joint Sentence Boundary Detection and Parsing of Entire Documents
Anders Björkelund, Agnieszka Faleńska, Wolfgang Seeker and Jonas Kuhn

MUTT: Metric Unit TesTing for Language Generation Tasks
William Boag, Renan Campos, Kate Saenko and Anna Rumshisky

N-gram language models for massively parallel devices
Nikolay Bogoychev and Adam Lopez

Cross-Lingual Morphological Tagging for Low-Resource Languages
Jan Buys and Jan A. Botha

Semi-Supervised Learning for Neural Machine Translation
Yong Cheng, Wei Xu, Zhongjun He, Wei He, Hua Wu, Maosong Sun and Yang Liu

Strategies for Training Large Vocabulary Neural Language Models
Wenlin Chen, David Grangier and Michael Auli

Predicting the Compositionality of Nominal Compounds: Giving Word Embeddings a Hard Time
Silvio Cordeiro, Carlos Ramisch, Marco Idiart and Aline Villavicencio

Learning-Based Single-Document Summarization with Compression and Anaphoricity Constraints
Greg Durrett, Taylor Berg-Kirkpatrick and Dan Klein

Set-Theoretic Alignment for Comparable Corpora
Thierry Etchegoyhen and Andoni Azpeitia

Jointly Learning to Embed and Predict with Multiple Languages
Daniel C. Ferreira, André F. T. Martins and Mariana S. C. Almeida

Supersense Embeddings: A Unified Model for Supersense Interpretation, Prediction, and Utilization
Lucie Flekova and Iryna Gurevych

Efficient techniques for parsing with tree automata
Jonas Groschwitz, Alexander Koller and Mark Johnson

A Vector Space for Distributional Semantics for Entailment
James Henderson and Diana Popa

Hidden Softmax Sequence Model for Dialogue Structure Analysis
Zhiyang He, Xien Liu, Ping Lv and Ji Wu

Summarizing Source Code using a Neural Attention Model
Srinivasan Iyer, Ioannis Konstas, Alvin Cheung and Luke Zettlemoyer

Continuous Profile Models in ASL Syntactic Facial Expression Synthesis
Hernisa Kacorri and Matt Huenerfauth

Evaluating Sentiment Analysis in the Context of Securities Trading

Noise reduction and targeted exploration in imitation learning for Abstract Meaning Representation parsing

James Goodman* **Andreas Vlachos†** **Jason Naradowsky***

Abstract

Semantic parsers map natural language statements into meaning representations, and must abstract over syntactic phenomena, resolve anaphora, and identify word senses to eliminate ambiguous interpretations. Abstract meaning representation (AMR) is a recent example of one such semantic formalism which, similar to a dependency parse, utilizes a graph to represent relationships between concepts (Banarescu et al., 2013). As with dependency parsing, transition-based approaches are a common approach to this problem. However, when trained in the traditional manner these systems are susceptible to the accumulation of errors when they find undesirable states during greedy decoding. Imitation learning algorithms have been shown to help these systems recover from such errors. To effectively use these methods for AMR parsing we find it highly beneficial to introduce two novel extensions: noise reduction and targeted exploration. The former mitigates the noise in the feature representation, a result of the complexity of the task. The latter targets the exploration steps of imitation learning towards areas which are likely to provide the most information in the context of a large action-space. We achieve state-of-the art results, and improve upon standard transition-based parsing by 4.7 F_1 points.

1 Introduction

Meaning representation languages and systems have been devised for specific domains, such as ATIS for air-travel bookings (Dahl et al., 1994) and database queries (Zelle and Mooney, 1996; Liang et al., 2013). Such machine-interpretable representations enable many applications relying on natural language understanding. The ambition of Abstract Meaning Representation (AMR) is that it is domain-independent and useful in a variety of applications (Banarescu et al., 2013).

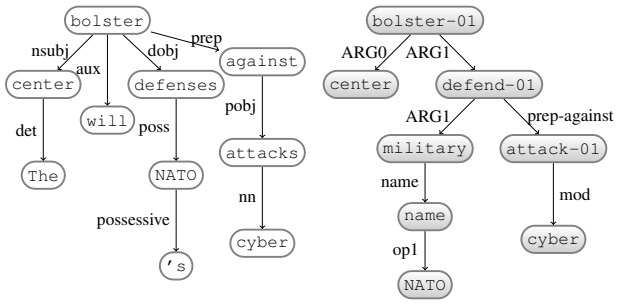

Figure 1: Dependency (left) and AMR graph (right) for: "The center will bolster NATO's defenses against cyber-attacks.'

The first AMR parser by Flanigan et al. (2014) used graph-based inference to find a highest-scoring maximum spanning connected acyclic graph. Later work by Wang et al. (2015b) was inspired by the similarity between the dependency parse of a sentence and its semantic AMR graph (Figure 1). Wang et al. (2015b) start from the dependency parse and learn a transition-based parser that converts it incrementally into an AMR graph using greedy decoding. An advantage of this approach is that the initial stage of dependency parsing is well-studied and trained using larger corpora than that for which AMR annotations exist.

Greedy decoding, where the parser builds the parse while maintaining only the best hypothesis at each step, has a well-documented disadvantage: error propagation (McDonald and Nivre, 2007). When the parser encounters states during parsing that are unlike those found during training, it is more likely to make mistakes, leading to states which are increasingly more foreign and causing errors to accumulate.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1–11,
Berlin, Germany, August 7-12, 2016.

One way to ameliorate this problem is to employ imitation learning algorithms for structured prediction. Algorithms such as SEARN (Daumé III et al., 2009), DAGGER (Ross et al., 2011), and LOLS (Chang et al., 2015) address the problem of error propagation by iteratively adjusting the training data to increasingly expose the model to training instances it is likely to encounter during test. Such algorithms have been shown to improve performance in a variety of tasks including information extraction(Vlachos and Craven, 2011), dependency parsing (Goldberg and Nivre, 2013), and feature selection (He et al., 2013). In this work we build on the transition-based parsing approach of Wang et al. (2015b) and explore the applicability of different imitation algorithms to AMR parsing, which has a more complex output space than those considered previously.

The complexity of AMR parsing affects transition-based methods that rely on features to represent structure, since these often cannot capture the information necessary to predict the correct transition according to the gold standard. In other words, the features defined are not sufficient to "explain" why different actions should preferred by the model. Such instances become noise during training, resulting in lower accuracy. To address this issue, we show that the α-bound Khardon and Wachman (2007), which drops consistently misclassified training instances, provides a simple and effective way of reducing noise and raising performance in perceptron-style classification training, and does so reliably across a range of parameter settings. This noise reduction is essential for imitation learning to gain traction in this task, and we gain 1.8 points of F_1-Score using the DAGGER imitation learning algorithm.

DAGGER relies on an externally specified expert (oracle) to define the correct action in each state; this defines a simple 0-1 loss function for each action. Other imitation learning algorithms (such as LOLS, SEARN) and the variant of DAGGER proposed by Vlachos and Clark (2014) (henceforth V-DAGGER) can leverage a task level loss function that does not decompose over the actions taken to construct the AMR graph. However these require extra computations to roll-out to an end-state AMR graph for each possible action *not* taken. The large action-space of our transition system makes these algorithms computationally infeasible, and roll-outs to an end-state for many of the possible actions will provide little additional information. Hence we modify the algorithms to target this exploration to actions where the classifier being trained is uncertain of the correct response, or disagrees with the expert. This provides a further gain of 2.7 F_1 points.

This paper extends imitation learning to structured prediction tasks more complex than previously attempted. In the process, we review and compare recently proposed algorithms and show how their components can be recombined and adjusted to construct a variant appropriate to the task in hand. Hence we invest some effort reviewing these algorithms and their common elements.

Overall, we obtain a final F-Score of 0.70 on the newswire corpus of LDC2013E117 (Knight et al., 2014). This is identical to the score obtained by Wang et al. (2015a), the highest so far published. Our gain of 4.5 F_1 points from imitation learning over standard transition-based parsing is orthogonal to that of Wang et al. (2015a) from additional trained analysers, including co-reference and semantic role labellers, incorporated in the feature set. We further test on five other corpora of AMR graphs, including weblog domains, and show a consistent improvement in all cases with the application of imitation learning using DAGGER and the targeted V-DAGGER we propose here.

2 Transition-based AMR parsing

AMR parsing is an example of the wider family of structured prediction problems, in which we seek a mapping from an input $\mathbf{x} \in \mathcal{X}$ to a structured output $\mathbf{y} \in \mathcal{Y}$. Here $\mathbf{x}$ is the dependency tree, and $\mathbf{y}$ the AMR graph; both are graphs and we notationally replace $\mathbf{x}$ with s_1 and $\mathbf{y}$ with s_T, with $s_{1\ldots T} \in \mathcal{S}$. s_i are the intermediate graph configurations (states) that the system transitions through.

A transition-based parser starts with an input s_1, and selects an action $a_1 \in \mathcal{A}$, using a classifier. a_i converts s_i into s_{i+1}, i.e. $s_{i+1} = a_i(s_i)$. We term the set of states and actions $\langle s_1, a_1, \ldots a_{T-1}, s_T \rangle$ a trajectory of length T. The classifier $\hat{\pi}$ is trained to predict a_i from s_i, with $\hat{\pi}(s) = \arg\max_{a \in \mathcal{A}} \mathbf{w_a} \cdot \Phi(s)$, assuming a linear classifier and a feature function $\Phi(s)$.

We require an expert, π^*, that can indicate what actions should be taken on each s_i to reach the target (gold) end state. In problems like POS-tagging these are directly inferable from gold, as the number of actions (T) equals the number of

Action Name	Param.	Pre-conditions	Outcome of action
NextEdge	l_r	β non-empty	Set label of edge (σ_0, β_0) to l_r. Pop β_0.
NextNode	l_c	β empty	Set concept of node σ_0 to l_c. Pop σ_0, and initialise β.
Swap		β non-empty	Make β_0 parent of σ_0 (reverse edge) and its sub-graph. Pop β_0 and insert β_0 as σ_1.
ReplaceHead		β non-empty	Pop σ_0 and delete it from the graph. Parents of σ_0 become parents of β_0. Other children of σ_0 become children of β_0. Insert β_0 at the head of σ and re-initialise β.
Reattach	κ	β non-empty	Pop β_0 and delete edge (σ_0, β_0). Attach β_0 as a child of κ. If κ has already been popped from σ then re-insert it as σ_1.
DeleteNode		β empty; leaf σ_0	Pop σ_0 and delete it from the graph.
Insert	l_c		Insert a new node δ with AMR concept l_c as the parent of σ_0, and insert δ into σ.
InsertBelow			Insert a new node δ with AMR concept l_c as a child of σ_0.

while $s_{current}$ *not terminal* **do**
  $a_{next} \leftarrow \pi(s_{current})$
  $s_{current} \leftarrow a_{next}(s_{current})$
$s_T \leftarrow s_{current}$

tokens with a 1:1 correspondence between them. In dependency parsing and AMR parsing this is not straightforward and dedicated transition systems are devised.

Given a labeled training dataset $\mathcal{D}$, algorithm 1 is first used to generate a trajectory for each of the inputs ($d \in D$) with $\pi = \pi^*$, the expert from which we wish to generalise. The data produced from all expert trajectories (i.e. $\langle s_{i,d}, a_{i,d} \rangle$ for all $i \in 1 \ldots T$ and all $d \in 1 \ldots D$), are used to train the classifier $\hat{\pi}$, the learned classifier, using standard supervised learning techniques. Algorithm 1 is reused to apply $\hat{\pi}$ to unseen data. Our transition system (defining $\mathcal{A}$, $\mathcal{S}$), and feature sets are based on Wang et al. (2015b), and are not the main focus of this paper. We introduce the key concepts here, with more details in the supplemental material.

We initialise the state with the stack of the nodes in the dependency tree, root node at the bottom. This stack is termed σ. A second stack, β is initialised with all children of the top node in σ. The state at any time is described by σ, β, and the current graph (which starts as the dependency tree with one node per token). At any stage before termination some of the nodes will be labelled with words from the sentence, and others with AMR concepts. Each action manipulates the top nodes in each stack, σ_0 and β_0. We reach a terminal state when σ is empty. The objective function to maximise is the Smatch score (Cai and Knight, 2013), which calculates an F_1-Score between the predicted and gold-target AMR graphs.

Table 1 summarises the actions in $\mathcal{A}$. NextNode and NextEdge form the core action set, labelling nodes and edges respectively without changing the graph structure. Swap, Reattach and ReplaceHead change graph structure, keeping it a tree. We permit a Reattach action to use parameter κ equal to any node within six edges from σ_0, excluding any that would disconnect the graph or create a cycle.

The Insert/InsertBelow actions insert a new node as a parent/child of σ_0. These actions are not used in Wang et al. (2015b), but Insert is very similar to the Infer action of Wang et al. (2015a). We do not use the Reentrance action of Wang et al. (2015b), as we found it not to add any benefit. This means that the output AMR is always a tree.

Our transition system has two characteristics which provide a particular challenge: given a sentence, the trajectory length T is theoretically unbounded; and $|\mathcal{A}|$ can be of the order 10^3 to 10^4. Commonly used transition-based systems have a fixed trajectory length T, which often arises naturally from the nature of the problem. In PoS-tagging each token requires a single action, and in syntactic parsing the total size of the graph is limited to the number of tokens in the input. The lack of a bound in T here is due to Insert actions that can grow the the graph, potentially *ad infinitum*, and actions like Reattach, which can move a sub-graph repeatedly back-and-forth. The action space size is due to the size of the AMR vocabulary, which for relations (edge-labels) is restricted to about 100 possible values, but for concepts (node-labels) is almost as broad as an En-

Algorithm 2: Generic Imitation Learning

Data: data D, expert π^*, Loss function $F(s)$
Result: learned classifier C, trained policy $\hat{\pi}$

1 Initialise C_0; **for** $n = 1$ **to** N **do**
2 Initialise $E_n = \phi$;
3 $\pi_{Rollin} = RollInPolicy(\pi^*, C_{0...n-1}, n)$;

5 **for** $d \in D$ **do**
6 Predict trajectory $\hat{s}_{1:T}$ with π_{Rollin};
7 **for** $\hat{s}_t \in \hat{s}_{1:T}$ **do**
8 **foreach** $a_t^j \in Explore(\hat{s}_t, \pi^*, \pi_{Rollin})$ **do**
9 $\Phi_t^j = \Phi(d, a_t^j, \hat{s}_{1:t})$;
10 Predict $\hat{s}'_{t+1:T}$ with $\pi_{Rollout}$;
11 $L_t^j = F(\hat{s}'_T)$;
12 **foreach** j **do**
13 $ActionCost_t^j = L_t^j - \min_k L_t^k$
14 Add $(\Phi_t, ActionCost_t)$ to E_n;
15 $\hat{\pi}_n, C_n = Train(C_{1...n-1}, E_1 \dots E_n)$;

glish dictionary. The large action space and unbounded T also make beam search difficult to apply since it relies on a fixed length T with commensurability of actions at the same index on different search trajectories.

3 Imitation Learning for Structured Prediction

Imitation learning originated in robotics, training a robot to follow the actions of a human expert (Schaal, 1999; Silver et al., 2008). The robot moves from state to state via actions, generating a trajectory in the same manner as the transition-based parser of Algorithm 1.

In the imitation learning literature, the learning of a policy $\hat{\pi}$ from just the expert generated trajectories is termed "exact imitation".As discussed, it is prone to error propagation, which arises because the implicit assumption of i.i.d. inputs (s_i) during training does not hold. The states in any trajectory are dependent on previous states, and on the policy used. A number of imitation learning algorithms have been proposed to mitigate error propagation, and share a common structure shown in Algorithm 2. Table 2 highlights some key differences between them.

The general algorithm firstly applies a policy π_{RollIn} (usually the expert, π^*, to start) to the data instances to generate a set of 'RollIn' trajectories in line 6 (we adopt the terminology of 'RollIn' and 'RollOut' trajectories from Chang et al. (2015)). Secondly a number of 'what if' scenarios are considered, in which a different action a_t^j is taken from a given s_t instead of the actual a_t in the RollIn trajectory (line 8). Each of these exploratory actions generates a RollOut trajectory (line 10) to a terminal state, for which a loss (L) is calculated using a loss function, $F(s_T^j)$, defined on the terminal states. For a number of different exploratory actions taken from a state s_t on a RollIn trajectory, the action cost (or relative loss) of each is calculated (line 13). Finally the generated $\langle s_t, a_t^j, ActionCost_t^j \rangle$ data are used to train a classifier, using any cost-sensitive classification (CSC) method (line 15). New π_{RollIn} and $\pi_{RollOut}$ are generated, and the process repeated over a number of iterations. In general the starting expert policy is progressively removed in each iteration, so that the training data moves closer and closer to the distribution encountered by just the trained classifier. This is required to reduce error propagation. For a general imitation learning algorithm we need to specify:

- the policy to generate the RollIn trajectory (the *RollInPolicy*)
- the policy to generate RollOut trajectories, including rules for interpolation of learned and expert policies (the *RollOutPolicy*)
- which one-step deviations to explore with a RollOut (the *Explore* function)
- how RollOut data are used in the classification learning algorithm to generate $\hat{\pi}_i$. (within the *Train* function)

Exact Imitation can be considered a single iteration of this algorithm, with π_{RollIn} equal to the expert policy, and a 0-1 binary loss for F (0 loss for $\pi^*(s_t)$, the expert action, and a loss of 1 for any other action); all one-step deviations from the expert trajectory are considered without explicit RollOut to a terminal state.

In **SEARN** (Daumé III et al., 2009), one of the first imitation learning algorithms in this framework, the π_{RollIn} and $\pi_{RollOut}$ policies are identical within each iteration, and are a stochastic blend of the expert and all classifiers trained in previous iterations. The $Explore$ function considers every possible one-step deviation from the RollIn trajectories, with a full RollOut to a terminal state. The

Algorithm	$\hat{\pi}$	RollIn	RollOut	Explore	Train
Exact Imitation	Deterministic	Expert only	None. 0/1 expert loss	All 1-step	E_1 only
SEARN	Stochastic	Mixture	Mixture, step-level stochastic	All 1-step	E_n only
LOLS	Deterministic	Learned only	Mixture, trajectory-level stoch.	All 1-step	$E_1 \dots E_n$
SCB-LOLS	Deterministic	Learned only	Mixture, trajectory-level stoch.	Random	$E_1 \dots E_n$
SMILE	Stochastic	Mixture	None. 0/1 expert loss	All 1-step	$E_1 \dots E_n$
DAGGER	Deterministic	Mixture	None. 0/1 expert loss	All 1-step	$E_1 \dots E_n$
V-DAGGER	Deterministic	Mixture	Mixture, step-level stochastic	All 1-step	$E_1 \dots E_n$
AGGREVATE	Deterministic	Learned only	Expert only	Random	$E_1 \dots E_n$

Table 2: Comparison of selected aspects of Imitation Learning algorithms.

$Train$ function uses only the training data from the most recent iteration (E_n) to train C_n.

LOLS extends this work to provide a deterministic learned policy (Chang et al., 2015), with $\hat{\pi}_n = C_n$. At each iteration $\hat{\pi}_n$ is trained on *all* previously gathered data $E_{1\dots n}$; π_{RollIn} uses the latest classifier $\hat{\pi}_{n-1}$, and each RollOut uses the same policy for all actions in the trajectory; either π^* with probability β, or $\hat{\pi}_{n-1}$ otherwise. Both LOLS and SEARN use an exhaustive search of alternative actions as an $Explore$ function. Chang et al. (2015) consider Structured Contextual Bandits (SCB) as a partial information case, the SCB modification of LOLS permits only one cost function call per RollIn (received from the external environment), so exhaustive RollOut exploration at each step is not possible. SCB-LOLS $Explore$ picks a single step $t \in \{1 \dots T\}$ at *random* at which to make a *random* single-step deviation.

Another strand of work uses only the expert policy when calculating the action cost. Ross and Bagnell (2010) introduce **SMILE**, and later **DAGGER** (Ross et al., 2011). These do not RollOut as such, but as in exact imitation consider all one-step deviations from the RollIn trajectory and obtain a $0/1$ action cost for each by asking the expert what it would do in that state. At the nth iteration the training trajectories are generated from an interpolation of π^* and $\hat{\pi}_{n-1}$, with the latter progressively increasing in importance; π^* is used with probability (1-δ)$^{n-1}$ for some decay rate δ. $\hat{\pi}_n$ is trained using all $E_{1\dots n}$. Ross et al. (2011) discuss and reject calculating an action cost by completing a RollOut from each one-step deviation to a terminal state. Three reasons given are:

1. Lack of real-world applicability, for example in robotic control.
2. Lack of knowledge of the final loss function, if we just have the expert's actions.
3. Time spent calculating RollOuts and calling the expert.

Ross and Bagnell (2014) *do* incorporate RollOuts to calculate an action cost in their **AGGREVATE** algorithm. These RollOuts use the expert policy only, and allow a cost-sensitive classifier to be trained that can learn that some mistakes are more serious than others. As with DAGGER, the trained policy cannot become better than the expert.

V-DAGGER is the variant proposed by Vlachos and Clark (2014) in a semantic parsing task. It is the same as DAGGER, but with RollOuts using the same policy as RollIn. For both V-DAGGER and SEARN, the stochasticity of the RollOut means that a number of independent samples are taken for each one-step deviation to reduce the variance of the action cost, and noise in the training data. This noise reduction comes at the expense of the time needed to compute additional RollOuts.

4 Adapting imitation learning to AMR

Algorithms with full RollOuts have particular value in the absence of an optimal (or near-optimal) expert able to pick the best action from any state. If we have a suitable loss function, then the benefit of RollOuts may become worth the computation expended on them. For AMR parsing we have both a loss function in Smatch, and the ability to generate arbitrary RollOuts.

We therefore use a heuristic expert. This reduces the computational cost at the expense of not always predicting the best action. An expert needs an alignment between gold AMR nodes and tokens in the parse-tree or sentence to determine the actions to convert to one from the other. These alignments are not provided in the gold AMR, and our expert uses the AMR node to token alignments of JAMR (Flanigan et al., 2014). These alignments are not trained, but generated using regex and string matching rules. However, trajectories are in the range 50-200 actions for most training sentences, which combined with the size of $|\mathcal{A}|$ makes an exhaustive search of all one-step deviations expensive. Compare this to unlabeled shift-

reduce parsers with 4 actions, or POS tagging with $|\mathcal{A}| \sim 30$.

4.1 Targeted exploration

To reduce this cost we note that exploring RollOuts for all possible alternative actions can be uninformative when the learned and expert policies agree on an action and none of the other actions score highly with the learned policy. Extending this insight we modify the $Explore$ function in Algorithm 2 to only consider the expert action, plus all actions scored by the current learned policy that are within a threshold τ of the score for the best rated action. In the first iteration, when there is no current learned policy, we pick a number of actions (usually 10) at random for exploration. Both SCB-LOLS and AGGREVATE use partial exploration, but select the step $t \in 1 \dots T$, and the action a_t at random. Here we optimise computational resources by directing the search to areas for which the trained policy is least sure of the optimal action, or disagrees with the expert.

Using imitation learning to address error propagation of transition-based parsing provides theoretical benefit from ensuring the distribution of s_t, a_t in the training data is consistent with the distribution on unseen test data. Using RollOuts that mix expert and learned policies additionally permits the learned policy to exceed the performance of a poor expert. Incorporating targeted exploration strategies in the $Explore$ function makes this computationally feasible.

4.2 Noise Reduction

Different samples for a RollOut trajectory using V-DAGGER or SEARN can give very different terminal states s_T (the final AMR graph) from the same starting s_t and a_t due to the step-level stochasticity. The resultant high variance in the reward signal hinders effective learning. Daumé III et al. (2009) have a similar problem, and note that an approximate cost function outperforms single Monte Carlo sampling, "likely due to the noise induced following a single sample".

To control noise we use the α-bound discussed by Khardon and Wachman (2007). This excludes a training example (i.e. an individual tuple s_i, a_i) from future training once it has been misclassified α times in training. We find that this simple idea avoids the need for multiple RollOut samples.

An attraction of LOLS is that it randomly selects either expert or learned policy for each RollOut, and then applies this consistently to the whole trajectory. Using LOLS should reduce noise without increasing the sample size. Unfortunately the unbounded T of our transition system leads to problems if we drop the expert from the RollIn or RollOut policy mix too quickly, with many trajectories never terminating. Ultimately $\hat{\pi}$ learns to stop doing this, but even with targeted exploration training time is prohibitive and our LOLS experiments failed to provide results. We find that V-DAGGER with an α-bound works as a good compromise, keeping the expert involved in RollIn, and speeding up learning overall.

Another approach we try is a form of *focused costing* (Vlachos and Craven, 2011). Instead of using the learned policy for $\beta\%$ of steps in the RollOut, we use it for the first b steps, and then revert to the expert. This has several potential advantages: the heuristic expert is faster than scoring all possible actions; it focuses the impact of the exploratory step on immediate actions/effects so that mistakes $\hat{\pi}$ makes on a distant part of the graph do not affect the action cost; it reduces noise for the same reason. We increase b in each iteration so that the expert is asymptotically removed from RollOuts, a function otherwise supported by the decay parameter, δ.

4.3 Transition System adaptations

Applying imitation learning to a transition system with unbounded T can and does cause problems in early iterations, with RollIn or RollOut trajectories failing to complete while the learned policy, $\hat{\pi}$, is still relatively poor. To ensure every trajectory completes we add action constraints to the system. These avoid the most pathological scenarios, such as disallowing a Reattach of a previously Reattached sub-graph. These constraints are only needed in the first few iterations until $\hat{\pi}$ learns, via the action costs, to avoid these scenarios. They are listed in the Supplemental Material. As a final failsafe we insert a hard-stop on any trajectory once $T > 300$.

To address the size of $|A|$, we only consider a subset of AMR concepts when labelling a node. Wang et al. (2015b) use all concepts that occur in the training data in the same sentence as the lemma of the node, leading to hundreds or thousands of possible actions from some states. We use the smaller set of concepts that were assigned by the expert to the lemma of the current node any-

	Exact Imitation			Imitation Learning				
Experiment	No α	α=1	α-Gain	No α	α=1	IL Gain (α)	IL Gain (No α)	Total Gain
AROW, C=10	65.5	66.8	1.3	65.5	67.4	0.6	0.0	1.9
AROW, C=100	66.4	66.6	0.2	66.4	67.7	1.1	0.0	1.3

PA, C=100	66.7	66.5	-0.2	67.2	68.7	2.2	0.5	2.0
Perceptron	65.5	65.3	-0.2	66.6	68.6	3.3	1.1	3.1

Table 3: DAGGER with α-bound. All figures are F-Scores on the validation set. 5 iterations of classifier training take place after each DAgger iteration. A decay rate (δ) for π^* of 0.3 was used.

where in the training data. We obtain these assignments from an initial application of the expert to the full training data.

We add actions to use the actual word or lemma of the current node to increase generalisation, plus an action to append '-01' to 'verbify' an unseen word. This is similar to the work of Werling et al. (2015) in word to AMR concept mapping, and is useful since 38% of the test AMR concepts do not exist in the training data (Flanigan et al., 2014).

Full details of the heuristics of the expert policy, features used and pre-processing are in Supplemental Material. All code is available at `https://github.com/hopshackle/dagger-AMR`.

4.4 Naïve Smatch as Loss Function

Smatch (Cai and Knight, 2013) uses heuristics to control the combinatorial explosion of possible mappings between the input and output graphs, but is still too computationally expensive to be calculated for every RollOut during training. We retain Smatch for reporting all final results, but use 'Naïve Smatch' as an approximation during training. This skips the combinatorial mapping of nodes between predicted and target AMR graphs. Instead, for each graph we compile a list of:

- Node labels, e.g. `name`
- Node-Edge-Node label concatenations, e.g. `leave-01:ARG0:room`
- Node-Edge label concatenations, e.g. `leave-01:ARG0`, `ARG0:room`

The loss is the number of entries that appear in only one of the lists. We do not convert to an F_1 score, as retaining the absolute number of mistakes is proportional to the size of the graph.

The flexibility of the transition system means multiple different actions from a given state s_i can lead, via different RollOut trajectories, to the same target s_T. This can result in many actions having the best action cost, reducing the signal in the training data and giving poor learning. To encourage short trajectories we break these ties with a penalty of $T/5$ to Naïve Smatch. Multiple routes of the same length still exist, and are preferred equally. Note that the ordering of the stack of dependency tree nodes in the transition system means we start at leaf nodes and move up the tree. This prevents sub-components of the output AMR graph being produced in an arbitrary order.

5 Experiments

The main dataset used is the newswire (proxy) section of LDC2014T12 (Knight et al., 2014). The data from years 1995-2006 form the training data, with 2007 as the validation set and 2008 as the test set. The data split is the same as that used by Flanigan et al. (2014) and Wang et al. (2015b). [1]

We first assess the impact of noise reduction using the alpha bound, and report these experiments without Rollouts (i.e. using DAGGER) to isolate the effect of noise reduction. Table 3 summarises results using exact imitation and DAGGER with the α-bound set to discard a training instance after one misclassification. This is the most extreme setting, and the one that gave best results. We try AROW (Crammer et al., 2013), Passive-Aggressive (PA) (Crammer et al., 2006), and perceptron (Collins, 2002) classifiers, with averaging in all cases. We see a benefit from the α-bound for exact imitation only with AROW, which is more noise-sensitive than PA or the simple perceptron. With DAGGER there is a benefit for all classifiers. In all cases the α-bound and DAGGER are synergistic; without the α-bound imitation learning works less well, if at all. α=1 was the optimal setting, with lesser benefit observed for larger values.

We now turn our attention to targeted exploration and focused costing, for which we use V-DAGGER as explained in section 4. For all V-

[1] Formally Flanigan et al. (2014; Wang et al. (2015b) use the pre-release version of this dataset (LDC2013E117). Werling et al. (2015) conducted comparative tests on the two versions, and found only a very minor changes of 0.1 to 0.2 points of F-score when using the final release.

Table 4: Comparison of previous work on the AMR task. R, P and F are Recall, Precision and F-Score.

DAGGER experiments we use AROW with regularisation parameter C=1000, and δ=0.3.

Figure 2 shows results by iteration of reducing the number of RollOuts explored. Only the expert action, plus actions that score close to the best-scoring action (defined by the threshold) are used for RollOuts. Using the action cost information from RollOuts does surpass simple DAGGER, and unsurprisingly more exploration is better.

Figure 3 shows the same data, but by total computational time spent[2]. This adjusts the picture, as small amounts of exploration give a faster benefit, albeit not always reaching the same peak performance. As a baseline, three iterations of V-DAGGER without targeted exploration (threshold = ∞) takes 9600 minutes on the same hardware to give an F-Score of 0.652 on the validation set.

Figure 4 shows the improvement using focused costing. The 'n/m' setting sets b, the number of initial actions taken by $\hat{\pi}$ in a RollOut to n, and then increases this by m at each iteration. We gain an increase of 2.9 points from 0.682 to 0.711. In all the settings tried, focused costing improves the results, and requires progressive removal of the expert to achieve the best score.

We use the classifier from the Focused Costing 5/5 run to achieve an F-Score on the held-out test set of 0.70, equal to the best published result so far (Wang et al., 2015a). Our gain of 4.7 points from imitation learning over standard transition-based parsing is orthogonal to that of Wang et al. (2015a) using exact imitation with additional trained analysers; they experience a gain of 2 points from using a Charniak parser (Charniak and Johnson, 2005) trained on the full OntoNotes corpus instead of the Stanford parser used here and in Wang et al. (2015b), and a further gain of 2 points from a semantic role labeller. Table 4 lists previous AMR work on the same dataset.

[2]experiments were run on 8-core Google Cloud n1-highmem-8 machines.

lpp	0.540	0.546	0.564	0.55	0.52

Table 5: Comparison of Exact Imitation (EI), DAGGER (D), V-DAGGER (V-D) on all components of the LDC2014T12 corpus.

Using DAGGER with this system we obtained an F-Score of 0.60 in the Semeval 2016 task on AMR parsing, one standard deviation above the mean of all entries. (Goodman et al., 2016)

Finally we test on all components of the LDC2014T12 corpus as shown in Table 5, which include both newswire and weblog data, as well as the freely available AMRs for *The Little Prince*, (lpp)[3]. For each we use exact imitation, DAGGER, and V-DAGGER on the train/validation/splits specified in the corpus. In all cases, imitation learning without RollOuts (DAGGER) improves on exact imitation, and incorporating RollOuts (V-DAGGER) provides an additional benefit. Rao et al. (2015) use SEARN on the same datasets, but with a very different transition system. We show their results for comparison.

Our expert achieves a Smatch F-Score of 0.94 on the training data. This explains why DAGGER, which assumes a good expert, is effective. Introducing RollOuts provides additional theoretical benefits from a non-decomposable loss function that can take into account longer-term impacts of an action. This provides much more information than the 0/1 binary action cost in DAGGER, and we can use Naïve Smatch as an approximation to our actual objective function during training. This informational benefit comes at the cost of increased noise and computational expense, which we control with targeted exploration and focused

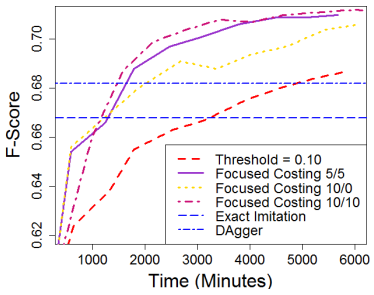

Figure 4: Focused costing with V-DAGGER. All runs use threshold of 0.10.

costing. We gain 2.7 points in F-Score, at the cost of 80-100x more computation. In problems with a less good expert, the gain from exploration could be much greater. Similarly, if designing an expert for a task is time-consuming, then it may be a better investment to rely on exploration with a poor expert to achieve the same result.

6 Related Work

Other strategies have been used to mitigate the error propagation problem in transition-based parsing. A common approach is to use beam search through state-space for each action choice to find a better approximation of the long-term score of the action, e.g. Zhang and Clark (2008). Goldberg and Elhadad (2010) remove the determinism of the sequence of actions to create *easy-first* parsers, which postpone uncertain, error-prone decisions until more information is available. This contrasts with working inflexibly left-to-right along a sentence, or bottom-to-top up a tree.

Goldberg and Nivre (2012) introduce *dynamic* experts that are *complete* in that they will respond from any state, not just those on the perfect trajectory assuming no earlier mistakes; any expert used with an imitation learning algorithm needs to be *complete* in this sense. Their algorithm takes exploratory steps off the expert trajectory to augment the training data collected in a fashion very similar to DAGGER.

Honnibal et al. (2013) use a *non-monotonic* parser that allows actions that are inconsistent with previous actions. When such an action is taken it amends the results of previous actions to ensure post-hoc consistency. Our parser is non-monotonic, and we have the same problem encountered by Honnibal et al. (2013) with many different actions from a state s_i able to reach the target s_T, following different "paths up the mountain". This leads to poor learning. To resolve this with fixed T they break ties with a monotonic parser, so that actions that do not require later correction are scored higher in the training data. In our variable T environment, adding a penalty to the size of T is sufficient (section 4.4).

Vlachos and Clark (2014) use V-DAGGER to give a benefit of 4.8 points of F-Score in a domain-specific semantic parsing problem similar to AMR. Their expert is sub-optimal, with no information on alignment between words in the input sentence, and nodes in the target graph. The parser learns to link words in the input to one of the 35 node types, with the 'expert' policy aligning completely at random. This is infeasible with AMR parsing due to the much larger vocabulary.

7 Conclusions

Imitation learning provides a total benefit of 4.5 points with our AMR transition-based parser over exact imitation. This is a more complex task than many previous applications of imitation learning, and we found that noise reduction was an essential pre-requisite. Using a simple 0/1 binary action cost using a heuristic expert provided a benefit of 1.8, with the remaining 2.7 points coming from RollOuts with targeted exploration, focused costing and a non-decomposable loss function that was a better approximation to our objective.

We have considered imitation learning algorithms as a toolbox that can be tailored to fit the characteristics of the task. An unbounded T meant that the LOLS RollIn was not ideal, but this could be modified to slow the loss of influence of the expert policy. We anticipate the approaches that we have found useful in the case of AMR to reduce the impact of noise, efficiently support large action spaces with targeted exploration, and cope with unbounded trajectories in the transition system will be of relevance to other structured prediction tasks.

Data Recombination for Neural Semantic Parsing

Abstract

Modeling crisp logical regularities is crucial in semantic parsing, making it difficult for neural models with no task-specific prior knowledge to achieve good results. In this paper, we introduce data recombination, a novel framework for injecting such prior knowledge into a model. From the training data, we induce a high-precision synchronous context-free grammar, which captures important conditional independence properties commonly found in semantic parsing. We then train a sequence-to-sequence recurrent network (RNN) model with a novel attention-based copying mechanism on datapoints sampled from this grammar, thereby teaching the model about these structural properties. Data recombination improves the accuracy of our RNN model on three semantic parsing datasets, leading to new state-of-the-art performance on the standard GeoQuery dataset for models with comparable supervision.

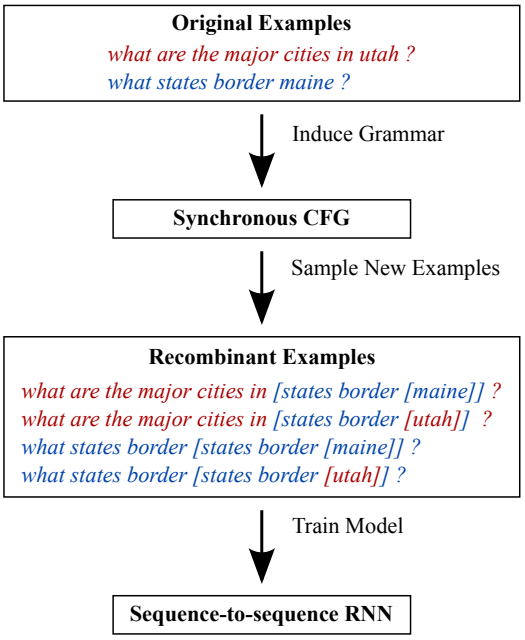

Figure 1: An overview of our system. Given a dataset, we induce a high-precision synchronous context-free grammar. We then sample from this grammar to generate new "recombinant" examples, which we use to train a sequence-to-sequence RNN.

1 Introduction

Semantic parsing—the precise translation of natural language utterances into logical forms—has many applications, including question answering (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Liang et al., 2011; Berant et al., 2013), instruction following (Artzi and Zettlemoyer, 2013b), and regular expression generation (Kushman and Barzilay, 2013). Modern semantic parsers (Artzi and Zettlemoyer, 2013a; Berant et al., 2013) are complex pieces of software, requiring hand-crafted features, lexicons, and grammars.

Meanwhile, recurrent neural networks (RNNs) have made swift inroads into many structured prediction tasks in NLP, including machine translation (Sutskever et al., 2014; Bahdanau et al., 2014) and syntactic parsing (Vinyals et al., 2015b; Dyer et al., 2015). Because RNNs make very few domain-specific assumptions, they have the potential to succeed at a wide variety of tasks with minimal feature engineering. However, this flexibility also puts RNNs at a disadvantage compared to standard semantic parsers, which can generalize naturally by leveraging their built-in awareness of logical compositionality.

In this paper, we introduce data recombination, a generic framework for declaratively inject-

Figure 2: One example from each of our domains. We tokenize logical forms as shown, thereby casting semantic parsing as a sequence-to-sequence task.

ing prior knowledge into a domain-general structured prediction model. In data recombination, prior knowledge about a task is used to build a high-precision generative model that expands the empirical distribution by allowing fragments of different examples to be combined in particular ways. Samples from this generative model are then used to train a domain-general model. In the case of semantic parsing, we construct a generative model by inducing a synchronous context-free grammar (SCFG), creating new examples such as those shown in Figure 1; our domain-general model is a sequence-to-sequence RNN with a novel attention-based copying mechanism. Data recombination boosts the accuracy of our RNN model on three semantic parsing datasets. On the GEO dataset, data recombination improves test accuracy by 4.3 percentage points over our baseline RNN, leading to new state-of-the-art results for models that do not use a seed lexicon for predicates.

2 Problem statement

We cast semantic parsing as a sequence-to-sequence task. The input utterance x is a sequence of words $x_1, \ldots, x_m \in \mathcal{V}^{(\text{in})}$, the input vocabulary; similarly, the output logical form y is a sequence of tokens $y_1, \ldots, y_n \in \mathcal{V}^{(\text{out})}$, the output vocabulary. A linear sequence of tokens might appear to lose the hierarchical structure of a logical form, but there is precedent for this choice: Vinyals et al. (2015b) showed that an RNN can reliably predict tree-structured outputs in a linear fashion.

We evaluate our system on three existing semantic parsing datasets. Figure 2 shows sample input-output pairs from each of these datasets.

- **GeoQuery** (GEO) contains natural language questions about US geography paired with corresponding Prolog database queries. We use the standard split of 600 training examples and 280 test examples introduced by Zettlemoyer and Collins (2005). We preprocess the logical forms to De Brujin index notation to standardize variable naming.
- **ATIS** (ATIS) contains natural language queries for a flights database paired with corresponding database queries written in lambda calculus. We train on 4473 examples and evaluate on the 448 test examples used by Zettlemoyer and Collins (2007).
- **Overnight** (OVERNIGHT) contains logical forms paired with natural language paraphrases across eight varied subdomains. Wang et al. (2015) constructed the dataset by generating all possible logical forms up to some depth threshold, then getting multiple natural language paraphrases for each logical form from workers on Amazon Mechanical Turk. We evaluate on the same train/test splits as Wang et al. (2015).

In this paper, we only explore learning from logical forms. In the last few years, there has an emergence of semantic parsers learned from denotations (Clarke et al., 2010; Liang et al., 2011; Berant et al., 2013; Artzi and Zettlemoyer, 2013b). While our system cannot directly learn from denotations, it could be used to rerank candidate derivations generated by one of these other systems.

3 Sequence-to-sequence RNN Model

Our sequence-to-sequence RNN model is based on existing attention-based neural machine translation models (Bahdanau et al., 2014; Luong et al., 2015a), but also includes a novel attention-based copying mechanism. Similar copying mechanisms have been explored in parallel by Gu et al. (2016) and Gulcehre et al. (2016).

3.1 Basic Model

Encoder. The encoder converts the input sequence $x_1, \ldots, x_m$ into a sequence of *context-*

sensitive embeddings $b_1, \ldots, b_m$ using a bidirectional RNN (Bahdanau et al., 2014). First, a word embedding function $\phi^{(\text{in})}$ maps each word x_i to a fixed-dimensional vector. These vectors are fed as input to two RNNs: a forward RNN and a backward RNN. The forward RNN starts with an initial hidden state h_0^{F}, and generates a sequence of hidden states $h_1^{\text{F}}, \ldots, h_m^{\text{F}}$ by repeatedly applying the recurrence

$$h_i^{\text{F}} = \text{LSTM}(\phi^{(\text{in})}(x_i), h_{i-1}^{\text{F}}). \quad (1)$$

The recurrence takes the form of an LSTM (Hochreiter and Schmidhuber, 1997). The backward RNN similarly generates hidden states $h_m^{\text{B}}, \ldots, h_1^{\text{B}}$ by processing the input sequence in reverse order. Finally, for each input position i, we define the context-sensitive embedding b_i to be the concatenation of h_i^{F} and h_i^{B}

Decoder. The decoder is an attention-based model (Bahdanau et al., 2014; Luong et al., 2015a) that generates the output sequence $y_1, \ldots, y_n$ one token at a time. At each time step j, it writes y_j based on the current hidden state s_j, then updates the hidden state to s_{j+1} based on s_j and y_j. Formally, the decoder is defined by the following equations:

$$s_1 = \tanh(W^{(s)}[h_m^{\text{F}}, h_1^{\text{B}}]). \quad (2)$$

$$e_{ji} = s_j^\top W^{(a)} b_i. \quad (3)$$

$$\alpha_{ji} = \frac{\exp(e_{ji})}{\sum_{i'=1}^{m} \exp(e_{ji'})}. \quad (4)$$

$$c_j = \sum_{i=1}^{m} \alpha_{ji} b_i. \quad (5)$$

$$P(y_j = w \mid x, y_{1:j-1}) \propto \exp(U_w[s_j, c_j]). \quad (6)$$

$$s_{j+1} = \text{LSTM}([\phi^{(\text{out})}(y_j), c_j], s_j). \quad (7)$$

When not specified, i ranges over $\{1, \ldots, m\}$ and j ranges over $\{1, \ldots, n\}$. Intuitively, the α_{ji}'s define a probability distribution over the input words, describing what words in the input the decoder is focusing on at time j. They are computed from the unnormalized attention scores e_{ji}. The matrices $W^{(s)}$, $W^{(a)}$, and U, as well as the embedding function $\phi^{(\text{out})}$, are parameters of the model.

3.2 Attention-based Copying

In the basic model of the previous section, the next output word y_j is chosen via a simple softmax over all words in the output vocabulary. However, this model has difficulty generalizing to the long tail of entity names commonly found in semantic parsing datasets. Conveniently, entity names in the input often correspond directly to tokens in the output (e.g., "*iowa*" becomes `iowa` in Figure 2).[1]

To capture this intuition, we introduce a new attention-based copying mechanism. At each time step j, the decoder generates one of two types of actions. As before, it can write any word in the output vocabulary. In addition, it can copy any input word x_i directly to the output, where the probability with which we copy x_i is determined by the attention score on x_i. Formally, we define a latent action a_j that is either $\texttt{Write}[w]$ for some $w \in \mathcal{V}^{(\text{out})}$ or $\texttt{Copy}[i]$ for some $i \in \{1, \ldots, m\}$. We then have

$$P(a_j = \texttt{Write}[w] \mid x, y_{1:j-1}) \propto \exp(U_w[s_j, c_j]), \quad (8)$$

$$P(a_j = \texttt{Copy}[i] \mid x, y_{1:j-1}) \propto \exp(e_{ji}). \quad (9)$$

The decoder chooses a_j with a softmax over all these possible actions; y_j is then a deterministic function of a_j and x. During training, we maximize the log-likelihood of y, marginalizing out a.

Attention-based copying can be seen as a combination of a standard softmax output layer of an attention-based model (Bahdanau et al., 2014) and a Pointer Network (Vinyals et al., 2015a); in a Pointer Network, the only way to generate output is to copy a symbol from the input.

4 Data Recombination

4.1 Motivation

The main contribution of this paper is a novel data recombination framework that injects important prior knowledge into our oblivious sequence-to-sequence RNN. In this framework, we induce a high-precision generative model from the training data, then sample from it to generate new training examples. The process of inducing this generative model can leverage any available prior knowledge, which is transmitted through the generated examples to the RNN model. A key advantage of our two-stage approach is that it allows us to declare desired properties of the task which might be hard to capture in the model architecture.

[1] On GEO and ATIS, we make a point not to rely on orthography for non-entities such as "*state*" to `_state`, since this leverages information not available to previous models (Zettlemoyer and Collins, 2005) and is much less language-independent.

Examples
("*what states border texas ?*",
`answer(NV, (state(V0), next_to(V0, NV), const(V0, stateid(texas))))`)
("*what is the highest mountain in ohio ?*",
`answer(NV, highest(V0, (mountain(V0), loc(V0, NV), const(V0, stateid(ohio)))))`)

Rules created by ABSENTITIES
ROOT → ⟨ "*what states border* STATEID *?*",
`answer(NV, (state(V0), next_to(V0, NV), const(V0, stateid(`STATEID`))))`⟩
STATEID → ⟨ "*texas*", `texas` ⟩
ROOT → ⟨ "*what is the highest mountain in* STATEID *?*",
`answer(NV, highest(V0, (mountain(V0), loc(V0, NV),`
`const(V0, stateid(`STATEID`)))))`⟩
STATEID → ⟨"*ohio*", `ohio`⟩

Rules created by ABSWHOLEPHRASES
ROOT → ⟨ "*what states border* STATE *?*", `answer(NV, (state(V0), next_to(V0, NV),` STATE `))`⟩
STATE → ⟨ "*states border texas*", `state(V0), next_to(V0, NV), const(V0, stateid(texas))`⟩
ROOT → ⟨ "*what is the highest mountain in* STATE *?*",
`answer(NV, highest(V0, (mountain(V0), loc(V0, NV),` STATE `)))`⟩

Rules created by CONCAT-2
ROOT → ⟨SENT$_1$ `</s>` SENT$_2$, SENT$_1$ `</s>` SENT$_2$⟩
SENT → ⟨ "*what states border texas ?*",
`answer(NV, (state(V0), next_to(V0, NV), const(V0, stateid(texas))))` ⟩
SENT → ⟨ "*what is the highest mountain in ohio ?*",
`answer(NV, highest(V0, (mountain(V0), loc(V0, NV), const(V0, stateid(ohio)))))` ⟩

Figure 3: Various grammar induction strategies illustrated on GEO. Each strategy converts the rules of an input grammar into rules of an output grammar. This figure shows the base case where the input grammar has rules ROOT → $\langle x, y \rangle$ for each (x, y) pair in the training dataset.

Our approach generalizes data augmentation, which is commonly employed to inject prior knowledge into a model. Data augmentation techniques focus on modeling invariances—transformations like translating an image or adding noise that alter the inputs x, but do not change the output y. These techniques have proven effective in areas like computer vision (Krizhevsky et al., 2012) and speech recognition (Jaitly and Hinton, 2013).

In semantic parsing, however, we would like to capture more than just invariance properties. Consider an example with the utterance "*what states border texas ?*". Given this example, it should be easy to generalize to questions where "*texas*" is replaced by the name of any other state: simply replace the mention of Texas in the logical form with the name of the new state. Underlying this phenomenon is a strong conditional independence principle: the meaning of the rest of the sentence is independent of the name of the state in question. Standard data augmentation is not sufficient to model such phenomena: instead of holding y fixed, we would like to apply simultaneous transformations to x and y such that the new x still maps to the new y. Data recombination addresses this need.

4.2 General Setting

In the general setting of data recombination, we start with a training set $\mathcal{D}$ of (x, y) pairs, which defines the empirical distribution $\hat{p}(x, y)$. We then fit a generative model $\tilde{p}(x, y)$ to $\hat{p}$ which generalizes beyond the support of $\hat{p}$, for example by splicing together fragments of different examples. We refer to examples in the support of $\tilde{p}$ as *recombinant* examples. Finally, to train our actual model $p_\theta(y \mid x)$, we maximize the expected value of $\log p_\theta(y \mid x)$, where (x, y) is drawn from $\tilde{p}$.

4.3 SCFGs for Semantic Parsing

For semantic parsing, we induce a synchronous context-free grammar (SCFG) to serve as the backbone of our generative model $\tilde{p}$. An SCFG consists of a set of production rules $X \to \langle \alpha, \beta \rangle$, where X is a category (non-terminal), and α and β are sequences of terminal and non-terminal symbols. Any non-terminal symbols in α must be aligned to the same non-terminal symbol in β, and vice versa. Therefore, an SCFG defines a set of joint derivations of aligned pairs of strings. In our case, we use an SCFG to represent joint deriva-

tions of utterances x and logical forms y (which for us is just a sequence of tokens). After we induce an SCFG G from $\mathcal{D}$, the corresponding generative model $\tilde{p}(x, y)$ is the distribution over pairs (x, y) defined by sampling from G, where we choose production rules to apply uniformly at random.

It is instructive to compare our SCFG-based data recombination with WASP (Wong and Mooney, 2006; Wong and Mooney, 2007), which uses an SCFG as the actual semantic parsing model. The grammar induced by WASP must have good coverage in order to generalize to new inputs at test time. WASP also requires the implementation of an efficient algorithm for computing the conditional probability $p(y \mid x)$. In contrast, our SCFG is only used to convey prior knowledge about conditional independence structure, so it only needs to have high precision; our RNN model is responsible for boosting recall over the entire input space. We also only need to forward sample from the SCFG, which is considerably easier to implement than conditional inference.

Below, we examine various strategies for inducing a grammar G from a dataset $\mathcal{D}$. We first encode $\mathcal{D}$ as an initial grammar with rules ROOT $\rightarrow \langle x, y \rangle$ for each $(x, y) \in \mathcal{D}$. Next, we will define each grammar induction strategy as a mapping from an input grammar G_{in} to a new grammar G_{out}. This formulation allows us to compose grammar induction strategies (Section 4.3.4).

4.3.1 Abstracting Entities

Our first grammar induction strategy, ABSENTITIES, simply abstracts entities with their types. We assume that each entity e (e.g., `texas`) has a corresponding type $e.t$ (e.g., `state`), which we infer based on the presence of certain predicates in the logical form (e.g. `stateid`). For each grammar rule $X \rightarrow \langle \alpha, \beta \rangle$ in G_{in}, where α contains a token (e.g., "*texas*") that string matches an entity (e.g., `texas`) in β, we add two rules to G_{out}: (i) a rule where both occurrences are replaced with the type of the entity (e.g., `state`), and (ii) a new rule that maps the type to the entity (e.g., STATEID $\rightarrow \langle$"*texas*", `texas`$\rangle$; we reserve the category name STATE for the next section). Thus, G_{out} generates recombinant examples that fuse most of one example with an entity found in a second example. A concrete example from the GEO domain is given in Figure 3.

4.3.2 Abstracting Whole Phrases

Our second grammar induction strategy, ABSWHOLEPHRASES, abstracts both entities and whole phrases with their types. For each grammar rule $X \rightarrow \langle \alpha, \beta \rangle$ in G_{in}, we add up to two rules to G_{out}. First, if α contains tokens that string match to an entity in β, we replace both occurrences with the type of the entity, similarly to rule (i) from ABSENTITIES. Second, if we can infer that the entire expression β evaluates to a set of a particular type (e.g. `state`) we create a rule that maps the type to $\langle \alpha, \beta \rangle$. In practice, we also use some simple rules to strip question identifiers from α, so that the resulting examples are more natural. Again, refer to Figure 3 for a concrete example.

This strategy works because of a more general conditional independence property: the meaning of any semantically coherent phrase is conditionally independent of the rest of the sentence, the cornerstone of compositional semantics. Note that this assumption is not always correct in general: for example, phenomena like anaphora that involve long-range context dependence violate this assumption. However, this property holds in most existing semantic parsing datasets.

4.3.3 Concatenation

The final grammar induction strategy is a surprisingly simple approach we tried that turns out to work. For any $k \geq 2$, we define the CONCAT-k strategy, which creates two types of rules. First, we create a single rule that has ROOT going to a sequence of k SENT's. Then, for each root-level rule ROOT $\rightarrow \langle \alpha, \beta \rangle$ in G_{in}, we add the rule SENT $\rightarrow \langle \alpha, \beta \rangle$ to G_{out}. See Figure 3 for an example.

Unlike ABSENTITIES and ABSWHOLEPHRASES, concatenation is very general, and can be applied to any sequence transduction problem. Of course, it also does not introduce additional information about compositionality or independence properties present in semantic parsing. However, it does generate harder examples for the attention-based RNN, since the model must learn to attend to the correct parts of the now-longer input sequence. Related work has shown that training a model on more difficult examples can improve generalization, the most canonical case being dropout (Hinton et al., 2012; Wager et al., 2013).

```
function TRAIN(dataset D, number of epochs T,
      number of examples to sample n)
    Induce grammar G from D
    Initialize RNN parameters θ randomly
    for each iteration t = 1, ..., T do
        Compute current learning rate η_t
        Initialize current dataset D_t to D
        for i = 1, ..., n do
            Sample new example (x', y') from G
            Add (x', y') to D_t
        end for
        Shuffle D_t
        for each example (x, y) in D_t do
            θ ← θ + η_t ∇ log p_θ(y | x)
        end for
    end for
end function
```

Figure 4: The training procedure with data recombination. We first induce an SCFG, then sample new recombinant examples from it at each epoch.

4.3.4 Composition

We note that grammar induction strategies can be composed, yielding more complex grammars. Given any two grammar induction strategies f_1 and f_2, the composition $f_1 \circ f_2$ is the grammar induction strategy that takes in G_{in} and returns $f_1(f_2(G_{\text{in}}))$. For the strategies we have defined, we can perform this operation symbolically on the grammar rules, without having to sample from the intermediate grammar $f_2(G_{\text{in}})$.

5 Experiments

We evaluate our system on three domains: GEO, ATIS, and OVERNIGHT. For ATIS, we report logical form exact match accuracy. For GEO and OVERNIGHT, we determine correctness based on denotation match, as in Liang et al. (2011) and Wang et al. (2015), respectively.

5.1 Choice of Grammar Induction Strategy

We note that not all grammar induction strategies make sense for all domains. In particular, we only apply ABSWHOLEPHRASES to GEO and OVERNIGHT. We do not apply ABSWHOLEPHRASES to ATIS, as the dataset has little nesting structure.

5.2 Implementation Details

We tokenize logical forms in a domain-specific manner, based on the syntax of the formal language being used. On GEO and ATIS, we disallow copying of predicate names to ensure a fair comparison to previous work, as string matching between input words and predicate names is not commonly used. We prevent copying by prepending underscores to predicate tokens; see Figure 2 for examples.

On ATIS alone, when doing attention-based copying and data recombination, we leverage an external lexicon that maps natural language phrases (e.g., "*kennedy airport*") to entities (e.g., `jfk:ap`). When we copy a word that is part of a phrase in the lexicon, we write the entity associated with that lexicon entry. When performing data recombination, we identify entity alignments based on matching phrases and entities from the lexicon.

We run all experiments with 200 hidden units and 100-dimensional word vectors. We initialize all parameters uniformly at random within the interval $[-0.1, 0.1]$. We maximize the log-likelihood of the correct logical form using stochastic gradient descent. We train the model for a total of 30 epochs with an initial learning rate of 0.1, and halve the learning rate every 5 epochs, starting after epoch 15. We replace word vectors for words that occur only once in the training set with a universal `<unk>` word vector. Our model is implemented in Theano (Bergstra et al., 2010).

When performing data recombination, we sample a new round of recombinant examples from our grammar at each epoch. We add these examples to the original training dataset, randomly shuffle all examples, and train the model for the epoch. Figure 4 gives pseudocode for this training procedure. One important hyperparameter is how many examples to sample at each epoch: we found that a good rule of thumb is to sample as many recombinant examples as there are examples in the training dataset, so that half of the examples the model sees at each epoch are recombinant.

At test time, we use beam search with beam size 5. We automatically balance missing right parentheses by adding them at the end. On GEO and OVERNIGHT, we then pick the highest-scoring logical form that does not yield an executor error when the corresponding denotation is computed. On ATIS, we just pick the top prediction on the beam.

5.3 Impact of the Copying Mechanism

First, we measure the contribution of the attention-based copying mechanism to the model's overall

performance. On each task, we train and evaluate two models: one with the copying mechanism, and one without. Training is done without data recombination. The results are shown in Table 1.

On GEO and ATIS, the copying mechanism helps significantly: it improves test accuracy by 10.4 percentage points on GEO and 6.4 points on ATIS. However, on OVERNIGHT, adding the copying mechanism actually makes our model perform slightly worse. This result is somewhat expected, as the OVERNIGHT dataset contains a very small number of distinct entities. It is also notable that both systems surpass the previous best system on OVERNIGHT by a wide margin.

We choose to use the copying mechanism in all subsequent experiments, as it has a large advantage in realistic settings where there are many distinct entities in the world. The concurrent work of Gu et al. (2016) and Gulcehre et al. (2016), both of whom propose similar copying mechanisms, provides additional evidence for the utility of copying on a wide range of NLP tasks.

5.4 Main Results

For our main results, we train our model with a variety of data recombination strategies on all three datasets. These results are summarized in Tables 2 and 3. We compare our system to the baseline of not using any data recombination, as well as to state-of-the-art systems on all three datasets.

We find that data recombination consistently improves accuracy across the three domains we evaluated on, and that the strongest results come from composing multiple strategies. Combining ABSWHOLEPHRASES, ABSENTITIES, and CONCAT-2 yields a 4.3 percentage point improvement over the baseline without data recombination on GEO, and an average of 1.7 percentage points on OVERNIGHT. In fact, on GEO, we achieve test accuracy of 89.3%, which surpasses the previous state-of-the-art, excluding Liang et al. (2011), which used a seed lexicon for predicates. On ATIS, we experiment with concatenating more than 2 examples, to make up for the fact that we cannot apply ABSWHOLEPHRASES, which generates longer examples. We obtain a test accuracy of 83.3 with ABSENTITIES composed with CONCAT-3, which beats the baseline by 7 percentage points and is competitive with the state-of-the-art.

Data recombination without copying. For completeness, we also investigated the effects of data recombination on the model without attention-based copying. We found that recombination helped significantly on GEO and ATIS, but hurt the model slightly on OVERNIGHT. On GEO, the best data recombination strategy yielded test accuracy of 82.9%, for a gain of 8.3 percentage points over the baseline with no copying and no recombination; on ATIS, data recombination gives test accuracies as high as 74.6%, a 4.7 point gain over the same baseline. However, no data recombination strategy improved average test accuracy on OVERNIGHT; the best one resulted in a 0.3 percentage point decrease in test accuracy. We hypothesize that data recombination helps less on OVERNIGHT in general because the space of possible logical forms is very limited, making it more like a large multiclass classification task. Therefore, it is less important for the model to learn good compositional representations that generalize to new logical forms at test time.

[2]The method of Liang et al. (2011) is not comparable to ours, as they as they used a seed lexicon mapping words to predicates. We explicitly avoid using such prior knowledge in our system.

Figure 5: A sample of our artificial data.

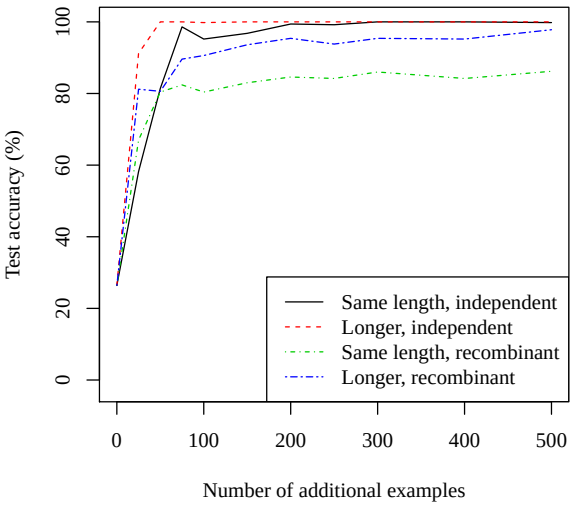

Figure 6: The results of our artificial data experiments. We see that the model learns more from longer examples than from same-length examples.

5.5 Effect of Longer Examples

Interestingly, strategies like ABSWHOLEPHRASES and CONCAT-2 help the model even though the resulting recombinant examples are generally not in the support of the test distribution. In particular, these recombinant examples are on average longer than those in the actual dataset, which makes them harder for the attention-based model. Indeed, for every domain, our best accuracy numbers involved some form of concatenation, and often involved ABSWHOLEPHRASES as well. In comparison, applying ABSENTITIES alone, which generates examples of the same length as those in the original dataset, was generally less effective.

We conducted additional experiments on artificial data to investigate the importance of adding longer, harder examples. We experimented with adding new examples via data recombination, as well as adding new independent examples (e.g. to simulate the acquisition of more training data). We constructed a simple world containing a set of entities and a set of binary relations. For any n, we can generate a set of depth-n examples, which involve the composition of n relations applied to a single entity. Example data points are shown in Figure 5. We train our model on various datasets, then test it on a set of 500 randomly chosen depth-2 examples. The model always has access to a small seed training set of 100 depth-2 examples. We then add one of four types of examples to the training set:

- **Same length, independent**: New randomly chosen depth-2 examples.[3]
- **Longer, independent**: Randomly chosen depth-4 examples.
- **Same length, recombinant**: Depth-2 examples sampled from the grammar induced by applying ABSENTITIES to the seed dataset.
- **Longer, recombinant**: Depth-4 examples sampled from the grammar induced by applying ABSWHOLEPHRASES followed by ABSENTITIES to the seed dataset.

To maintain consistency between the independent and recombinant experiments, we fix the recombinant examples across all epochs, instead of resampling at every epoch. In Figure 6, we plot accuracy on the test set versus the number of additional examples added of each of these four types. As

[3]Technically, these are not completely independent, as we sample these new examples without replacement. The same applies to the longer "independent" examples.

expected, independent examples are more helpful than the recombinant ones, but both help the model improve considerably. In addition, we see that even though the test dataset only has short examples, adding longer examples helps the model more than adding shorter ones, in both the independent and recombinant cases. These results underscore the importance training on longer, harder examples.

6 Discussion

In this paper, we have presented a novel framework we term data recombination, in which we generate new training examples from a high-precision generative model induced from the original training dataset. We have demonstrated its effectiveness in improving the accuracy of a sequence-to-sequence RNN model on three semantic parsing datasets, using a synchronous context-free grammar as our generative model.

There has been growing interest in applying neural networks to semantic parsing and related tasks. Dong and Lapata (2016) concurrently developed an attention-based RNN model for semantic parsing, although they did not use data recombination. Grefenstette et al. (2014) proposed a non-recurrent neural model for semantic parsing, though they did not run experiments. Mei et al. (2016) use an RNN model to perform a related task of instruction following.

Our proposed attention-based copying mechanism bears a strong resemblance to two models that were developed independently by other groups. Gu et al. (2016) apply a very similar copying mechanism to text summarization and single-turn dialogue generation. Gulcehre et al. (2016) propose a model that decides at each step whether to write from a "shortlist" vocabulary or copy from the input, and report improvements on machine translation and text summarization. Another piece of related work is Luong et al. (2015b), who train a neural machine translation system to copy rare words, relying on an external system to generate alignments.

Prior work has explored using paraphrasing for data augmentation on NLP tasks. Zhang et al. (2015) augment their data by swapping out words for synonyms from WordNet. Wang and Yang (2015) use a similar strategy, but identify similar words and phrases based on cosine distance between vector space embeddings. Unlike our data recombination strategies, these techniques only change inputs x, while keeping the labels y fixed. Additionally, these paraphrasing-based transformations can be described in terms of grammar induction, so they can be incorporated into our framework.

In data recombination, data generated by a high-precision generative model is used to train a second, domain-general model. Generative oversampling (Liu et al., 2007) learns a generative model in a multiclass classification setting, then uses it to generate additional examples from rare classes in order to combat label imbalance. Uptraining (Petrov et al., 2010) uses data labeled by an accurate but slow model to train a computationally cheaper second model. Vinyals et al. (2015b) generate a large dataset of constituency parse trees by taking sentences that multiple existing systems parse in the same way, and train a neural model on this dataset.

Some of our induced grammars generate examples that are not in the test distribution, but nonetheless aid in generalization. Related work has also explored the idea of training on altered or out-of-domain data, often interpreting it as a form of regularization. Dropout training has been shown to be a form of adaptive regularization (Hinton et al., 2012; Wager et al., 2013). Guu et al. (2015) showed that encouraging a knowledge base completion model to handle longer path queries acts as a form of structural regularization.

Language is a blend of crisp regularities and soft relationships. Our work takes RNNs, which excel at modeling soft phenomena, and uses a highly structured tool—synchronous context free grammars—to infuse them with an understanding of crisp structure. We believe this paradigm for simultaneously modeling the soft and hard aspects of language should have broader applicability beyond semantic parsing.

Inferring Logical Forms From Denotations

Abstract

A core problem in learning semantic parsers from denotations is picking out consistent logical forms—those that yield the correct denotation—from a combinatorially large space. To control the search space, previous work relied on restricted set of rules, which limits expressivity. In this paper, we consider a much more expressive class of logical forms, and show how to use dynamic programming to efficiently represent the complete set of consistent logical forms. Expressivity also introduces many more spurious logical forms which are consistent with the correct denotation but do not represent the meaning of the utterance. To address this, we generate fictitious worlds and use crowdsourced denotations on these worlds to filter out spurious logical forms. On the WIKITABLEQUESTIONS dataset, we increase the coverage of answerable questions from 53.5% to 76%, and the additional crowdsourced supervision lets us rule out 92.1% of spurious logical forms.

1 Introduction

Consider the task of learning to answer complex natural language questions (e.g., "*Where did the last 1st place finish occur?*") using only question-answer pairs as supervision (Clarke et al., 2010; Liang et al., 2011; Berant et al., 2013; Artzi and Zettlemoyer, 2013). Semantic parsers map the question into a logical form (e.g., $\mathbf{R}[\texttt{Venue}].\texttt{argmax}(\texttt{Position.1st}, \texttt{Index})$) that can be executed on a knowledge source to obtain the answer (denotation). Logical forms are very expressive since they can be recursively composed, but this very expressivity makes it more difficult to search over the space of logical forms. Previous work sidesteps this obstacle by restricting the set of possible logical form compositions, but this is limiting. For instance, for the system in Pasupat and Liang (2015), in only 53.5% of the examples was the correct logical form even in the set of generated logical forms.

The goal of this paper is to solve two main challenges that prevent us from generating more expressive logical forms. The first challenge is computational: the number of logical forms grows exponentially as their size increases. Directly enumerating over all logical forms becomes infeasible, and pruning techniques such as beam search can inadvertently prune out correct logical forms.

The second challenge is the large increase in *spurious* logical forms—those that do not reflect the semantics of the question but coincidentally execute to the correct denotation. For example, while logical forms $z_1, \ldots, z_5$ in Figure 1 are all *consistent* (they execute to the correct answer y), the logical forms z_4 and z_5 are spurious and would give incorrect answers if the table were to change.

We address these two challenges by solving two interconnected tasks. The first task, which addresses the computational challenge, is to enumerate the set Z of all consistent logical forms given a question x, a knowledge source w ("world"), and the target denotation y (Section 4). Observing that the space of possible denotations grows much more slowly than the space of logical forms, we perform *dynamic programming on denotations* (DPD) to make search feasible. Our method is guaranteed to find all consistent logical forms up to some bounded size.

Given the set Z of consistent logical forms, the second task is to filter out spurious logical forms from Z (Section 5). Using the property that spurious logical forms ultimately give a wrong answer when the data in the world w changes, we create

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 23–32,
Berlin, Germany, August 7-12, 2016.

Year	Venue	Position	Event	Time
2001	Hungary	2nd	400m	47.12
2003	Finland	1st	400m	46.69
2005	Germany	11th	400m	46.62
2007	Thailand	1st	relay	182.05
2008	China	7th	relay	180.32

x: "*Where did the last 1st place finish occur?*"
y: Thailand

Consistent

Correct

z_1: $\mathbf{R}$[Venue].argmax(Position.1st, Index)
Among rows with Position = 1st, pick the one with maximum index, then return the Venue of that row.

z_2: $\mathbf{R}$[Venue].Index.max($\mathbf{R}$[Index].Position.1st)
Find the maximum index of rows with Position = 1st, then return the Venue of the row with that index.

z_3: $\mathbf{R}$[Venue].argmax(Position.Number.*1*, $\mathbf{R}[\lambda x.\mathbf{R}$[Date].$\mathbf{R}$[Year].$x]$)
Among rows with Position number 1, pick one with latest date in the Year column and return the Venue.

Spurious

z_4: $\mathbf{R}$[Venue].argmax(Position.Number.*1*, $\mathbf{R}[\lambda x.\mathbf{R}$[Number].$\mathbf{R}$[Time].$x]$)
Among rows with Position number 1, pick the one with maximum Time number. Return the Venue.

z_5: $\mathbf{R}$[Venue].Year.Number.($\mathbf{R}$[Number].$\mathbf{R}$[Year].argmax(Type.Row, Index) $-$ *1*)
Subtract 1 from the Year in the last row, then return the Venue of the row with that Year.

Inconsistent

$\tilde{z}$: $\mathbf{R}$[Venue].argmin(Position.1st, Index)
Among rows with Position = 1st, pick the one with minimum index, then return the Venue. (= Finland)

Figure 1: Six logical forms generated from the question x. The first five are *consistent*: they execute to the correct answer y. Of those, *correct* logical forms z_1, z_2, and z_3 are different ways to represent the semantics of x, while *spurious* logical forms z_4 and z_5 get the right answer y for the wrong reasons.

fictitious worlds to test the denotations of the logical forms in Z. We use crowdsourcing to annotate the correct denotations on a subset of the generated worlds. To reduce the amount of annotation needed, we choose the subset that maximizes the expected information gain. The pruned set of logical forms would provide a stronger supervision signal for training a semantic parser.

We test our methods on the WIKITABLEQUESTIONS dataset of complex questions on Wikipedia tables. We define a simple, general set of deduction rules (Section 3), and use DPD to confirm that the rules generate a correct logical form in

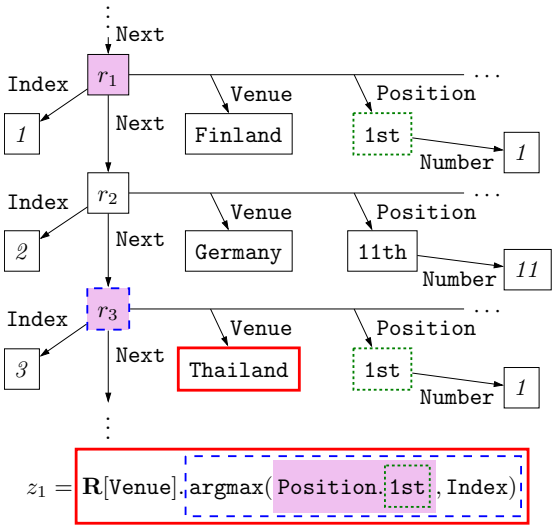

Figure 2: The table in Figure 1 is converted into a graph. The recursive execution of logical form z_1 is shown via the different colors and styles.

76% of the examples, up from the 53.5% in Pasupat and Liang (2015). Moreover, unlike beam search, DPD is guaranteed to find all consistent logical forms up to a bounded size. Finally, by using annotated data on fictitious worlds, we are able to prune out 92.1% of the spurious logical forms.

2 Setup

The overarching motivation of this work is allowing people to ask questions involving computation on semi-structured knowledge sources such as tables from the Web. This section introduces how the knowledge source is represented, how the computation is carried out using *logical forms*, and our task of inferring correct logical forms.

Worlds. We use the term *world* to refer to a collection of entities and relations between entities. One way to represent a world w is as a directed graph with nodes for entities and directed edges for relations. (For example, a world about geography would contain a node `Europe` with an edge `Contains` to another node `Germany`.)

In this paper, we use data tables from the Web as knowledge sources, such as the one in Figure 1. We follow the construction in Pasupat and Liang (2015) for converting a table into a directed graph (see Figure 2). Rows and cells become nodes (e.g., r_0 = first row and `Finland`) while columns become labeled directed edges between them (e.g., `Venue` maps r_1 to `Finland`). The graph is augmented with additional edges `Next` (from each

row to the next) and Index (from each row to its index number). In addition, we add normalization edges to cell nodes, including Number (from the cell to the first number in the cell), Num2 (the second number), Date (interpretation as a date), and Part (each list item if the cell represents a list). For example, a cell with content "*3-4*" has a Number edge to the integer *3*, a Num2 edge to *4*, and a Date edge to *XX-03-04*.

Logical forms. We can perform computation on a world w using a *logical form* z, a small program that can be executed on the world, resulting in a *denotation* $[\![z]\!]_w$.

We use lambda DCS (Liang, 2013) as the language of logical forms. As a demonstration, we will use z_1 in Figure 2 as an example. The smallest units of lambda DCS are entities (e.g., 1st) and relations (e.g., Position). Larger logical forms can be constructed using logical operations, and the denotation of the new logical form can be computed from denotations of its constituents. For example, applying the *join* operation on Position and 1st gives Position.1st, whose denotation is the set of entities with relation Position pointing to 1st. With the world in Figure 2, the denotation is $[\![\texttt{Position.1st}]\!]_w = \{r_1, r_3\}$, which corresponds to the 2nd and 4th rows in the table. The partial logical form Position.1st is then used to construct argmax(Position.1st, Index), the denotation of which can be computed by mapping the entities in $[\![\texttt{Position.1st}]\!]_w = \{r_1, r_3\}$ using the relation Index ($\{r_0 : 0, r_1 : 1, \dots\}$), and then picking the one with the largest mapped value (r_3, which is mapped to *3*). The resulting logical form is finally combined with $\mathbf{R}[\texttt{Venue}]$ with another *join* operation. The relation $\mathbf{R}[\texttt{Venue}]$ is the *reverse* of Venue, which corresponds to traversing Venue edges in the reverse direction.

Semantic parsing. A semantic parser maps a natural language utterance x (e.g., "*Where did the last 1st place finish occur?*") into a logical form z. With denotations as supervision, a semantic parser is trained to put high probability on z's that are *consistent*—logical forms that execute to the correct denotation y (e.g., Thailand). When the space of logical forms is large, searching for consistent logical forms z can become a challenge.

As illustrated in Figure 1, consistent logical forms can be divided into two groups: *correct* logical forms represent valid ways for computing the answer, while *spurious* logical forms accidentally get the right answer for the wrong reasons (e.g., z_4 picks the row with the maximum time but gets the correct answer anyway).

Tasks. Denote by Z and Z_c the sets of all consistent and correct logical forms, respectively. The first task is to efficiently compute Z given an utterance x, a world w, and the correct denotation y (Section 4). With the set Z, the second task is to infer Z_c by pruning spurious logical forms from Z (Section 5).

3 Deduction rules

The space of logical forms given an utterance x and a world w is defined recursively by a set of *deduction rules* (Table 1). In this setting, each constructed logical form belongs to a *category* (*Set*, *Rel*, or *Map*). These categories are used for type checking in a similar fashion to categories in syntactic parsing. Each deduction rule specifies the categories of the arguments, category of the resulting logical form, and how the logical form is constructed from the arguments.

Deduction rules are divided into base rules and compositional rules. A base rule follows one of the following templates:

$$\textit{TokenSpan}[span] \rightarrow c\,[f(span)] \quad (1)$$

$$\emptyset \rightarrow c\,[f()] \quad (2)$$

A rule of Template 1 is triggered by a span of tokens from x (e.g., to construct z_1 in Figure 2 from x in Figure 1, Rule B1 from Table 1 constructs 1st of category *Set* from the phrase "*1st*"). Meanwhile, a rule of Template 2 generates a logical form without any trigger (e.g., Rule B5 generates Position of category *Rel* from the graph edge Position without a specific trigger in x).

Compositional rules then construct larger logical forms from smaller ones:

$$c_1\,[z_1] + c_2\,[z_2] \rightarrow c\,[g(z_1, z_2)] \quad (3)$$

$$c_1\,[z_1] \rightarrow c\,[g(z_1)] \quad (4)$$

A rule of Template 3 combines partial logical forms z_1 and z_2 of categories c_1 and c_2 into $g(z_1, z_2)$ of category c (e.g., Rule C1 uses 1st of category *Set* and Position of category *Rel* to construct Position.1st of category *Set*). Template 4 works similarly.

Most rules construct logical forms without requiring a trigger from the utterance x. This is

	Rule	Semantics
	Base Rules	
B1	*TokenSpan* → *Set*	fuzzymatch($span$)
	(entity fuzzily matching the text: "*chinese*" → `China`)	
B2	*TokenSpan* → *Set*	val($span$)
	(interpreted value: "*march 2015*" → *2015-03-XX*)	
B3	$\emptyset$ → *Set*	`Type.Row`
	(the set of all rows)	
B4	$\emptyset$ → *Set*	$c \in$ ClosedClass
	(any entity from a column with few unique entities)	
	(e.g., `400m` or `relay` from the Event column)	
B5	$\emptyset$ → *Rel*	$r \in$ GraphEdges
	(any relation in the graph: `Venue`, `Next`, `Num2`, ...)	
B6	$\emptyset$ → *Rel*	`!=` | `<` | `<=` | `>` | `>=`
	Compositional Rules	
C1	*Set* + *Rel* → *Set*	$z_2.z_1 \mid \mathbf{R}[z_2].z_1$
	($\mathbf{R}[z]$ is the reverse of z; i.e., flip the arrow direction)	
C2	*Set* → *Set*	$a(z_1)$
	($a \in \{\texttt{count}, \texttt{max}, \texttt{min}, \texttt{sum}, \texttt{avg}\}$)	
C3	*Set* + *Set* → *Set*	$z_1 \sqcap z_2 \mid z_1 \sqcup z_2 \mid z_1 - z_2$
	(subtraction is only allowed on numbers)	
	Compositional Rules with Maps	
	Initialization	
M1	*Set* → *Map*	(z_1, x) (identity map)
	Operations on Map	
M2	*Map* + *Rel* → *Map*	$(u_1, z_2.b_1) \mid (u_1, \mathbf{R}[z_2].b_1)$
M3	*Map* → *Map*	$(u_1, a(b_1))$
	($a \in \{\texttt{count}, \texttt{max}, \texttt{min}, \texttt{sum}, \texttt{avg}\}$)	
M4	*Map* + *Set* → *Map*	$(u_1, b_1 \sqcap z_2) \mid \ldots$
M5	*Map* + *Map* → *Map*	$(u_1, b_1 \sqcap b_2) \mid \ldots$
	(Allowed only when $u_1 = u_2$)	
	(Rules M4 and M5 are repeated for $\sqcup$ and $-$)	
	Finalization	
M6	*Map* → *Set*	$\texttt{argmin}(u_1, \mathbf{R}[\lambda x.b_1])$ | $\texttt{argmax}(u_1, \mathbf{R}[\lambda x.b_1])$

Table 1: Deduction rules define the space of logical forms by specifying how partial logical forms are constructed. The logical form of the i-th argument is denoted by z_i (or (u_i, b_i) if the argument is a *Map*). The set of final logical forms contains any logical form with category *Set*.

crucial for generating implicit relations (e.g., generating `Year` from "*what's the venue in 2000?*" without a trigger "*year*"), and generating operations without a lexicon (e.g., generating `argmax` from "*where's the longest competition*"). However, the downside is that the space of possible logical forms becomes very large.

The *Map* category. The technique in this paper requires execution of partial logical forms. This poses a challenge for `argmin` and `argmax` operations, which take a set and a binary relation as arguments. The binary could be a complex function (e.g., in z_3 from Figure 1). While it is possible to build the binary independently from the set, executing a complex binary is sometimes impossible (e.g., the denotation of $\lambda x.\texttt{count}(x)$ is impossible to write explicitly without knowledge of x).

We address this challenge with the *Map* category. A *Map* is a pair (u, b) of a finite set u (unary) and a binary relation b. The denotation of (u, b) is $([\![u]\!]_w, [\![b]\!]'_w)$ where the binary $[\![b]\!]'_w$ is $[\![b]\!]_w$ with the domain restricted to the set $[\![u]\!]_w$. For example, consider the construction of $\texttt{argmax}(\texttt{Position.1st}, \texttt{Index})$. After constructing `Position.1st` with denotation $\{r_1, r_3\}$, Rule M1 initializes $(\texttt{Position.1st}, x)$ with denotation $(\{r_1, r_3\}, \{r_1 : \{r_1\}, r_3 : \{r_3\}\})$. Rule M2 is then applied to generate $(\texttt{Position.1st}, \mathbf{R}[\texttt{Index}].x)$ with denotation $(\{r_1, r_3\}, \{r_1 : \{1\}, r_3 : \{3\}\})$. Finally, Rule M6 converts the *Map* into the desired `argmax` logical form with denotation $\{r_3\}$.

Generality of deduction rules. Using domain knowledge, previous work restricted the space of logical forms by manually defining the categories c or the semantic functions f and g to fit the domain. For example, the category *Set* might be divided into *Records*, *Values*, and *Atomic* when the knowledge source is a table (Pasupat and Liang, 2015). Another example is when a compositional rule g (e.g., $\texttt{sum}(z_1)$) must be triggered by some phrase in a lexicon (e.g., words like "*total*" that align to `sum` in the training data). Such restrictions make search more tractable but greatly limit the scope of questions that can be answered.

Here, we have increased the coverage of logical forms by making the deduction rules simple and general, essentially following the syntax of lambda DCS. The base rules only generates entities that approximately match the utterance, but all possible relations, and all possible further combinations.

Beam search. Given the deduction rules, an utterance x and a world w, we would like to generate all derived logical forms Z. We first present the floating parser (Pasupat and Liang, 2015), which uses beam search to generate $Z_\text{b} \subseteq Z$, a usually incomplete subset. Intuitively, the algorithm first constructs base logical forms based on spans of the utterance, and then builds larger logical forms of increasing size in a "floating" fashion—without requiring a trigger from the utterance.

Formally, partial logical forms with category c and size s are stored in a *cell* (c, s). The algorithm first generates base logical forms from base deduction rules and store them in cells $(c, 0)$ (e.g., the cell $(\textit{Set}, 0)$ contains `1st`, `Type.Row`, and so on). Then for each size $s = 1, \ldots, s_\text{max}$, we populate

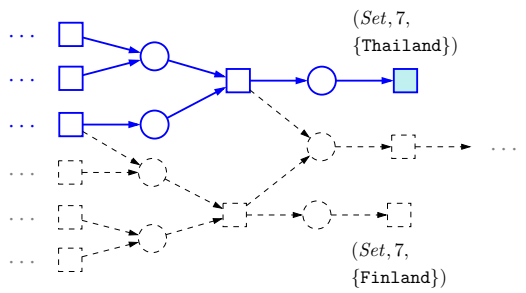

Figure 3: The first pass of DPD constructs cells (c, s, d) (square nodes) using denotationally invariant semantic functions (circle nodes). The second pass enumerates all logical forms along paths that lead to the correct denotation y (solid lines).

the cells (c, s) by applying compositional rules on partial logical forms with size less than s. For instance, when $s = 2$, we can apply Rule C1 on logical forms `Number`.*1* from cell $(\textit{Set}, s_1 = 1)$ and `Position` from cell $(\textit{Rel}, s_2 = 0)$ to create `Position.Number`.*1* in cell $(\textit{Set}, s_0 + s_1 + 1 = 2)$. After populating each cell (c, s), the list of logical forms in the cell is pruned based on the model scores to a fixed beam size in order to control the search space. Finally, the set Z_{b} is formed by collecting logical forms from all cells $(\textit{Set}, s)$ for $s = 1, \ldots, s_{\max}$.

Due to the generality of our deduction rules, the number of logical forms grows quickly as the size s increases. As such, partial logical forms that are essential for building the desired logical forms might fall off the beam early on. In the next section, we present a new search method that compresses the search space using denotations.

4 Dynamic programming on denotations

Our first step toward finding all correct logical forms is to represent all consistent logical forms (those that execute to the correct denotation). Formally, given x, w, and y, we wish to generate the set Z of all logical forms z such that $[\![z]\!]_w = y$.

As mentioned in the previous section, beam search does not recover the full set Z due to pruning. Our key observation is that while the number of logical forms explodes, the number of *distinct denotations* of those logical forms is much more controlled, as multiple logical forms can share the same denotation. So instead of directly enumerating logical forms, we use *dynamic programming on denotations* (DPD), which is inspired by similar methods from program induction (Lau et al., 2003; Liang et al., 2010; Gulwani, 2011).

The main idea of DPD is to collapse logical forms with the same denotation together. Instead of using cells (c, s) as in beam search, we perform dynamic programming using cells (c, s, d) where d is a denotation. For instance, the logical form `Position.Number`.*1* will now be stored in cell $(\textit{Set}, 2, \{r_1, r_3\})$.

For DPD to work, each deduction rule must have a *denotationally invariant* semantic function g, meaning that the denotation of the resulting logical form $g(z_1, z_2)$ only depends on the denotations of z_1 and z_2:

$$[\![z_1]\!]_w = [\![z_1']\!]_w \ \wedge \ [\![z_2]\!]_w = [\![z_2']\!]_w \\ \Rightarrow [\![g(z_1, z_2)]\!]_w = [\![g(z_1', z_2')]\!]_w$$

All of our deduction rules in Table 1 are denotationally invariant, but a rule that, for instance, returns the argument with the larger logical form size would not be. Applying a denotationally invariant deduction rule on any pair of logical forms from (c_1, s_1, d_1) and (c_2, s_2, d_2) always results in a logical form with the same denotation d in the same cell $(c, s_1 + s_2 + 1, d)$.[1] (For example, the cell $(\textit{Set}, 4, \{r_3\})$ contains $z_1 :=$ `argmax(Position.1st, Index)` and $z_1' :=$ `argmin(Event.Relay, Index)`. Combining each of these with `Venue` using Rule C1 gives $\mathbf{R}[\texttt{Venue}].z_1$ and $\mathbf{R}[\texttt{Venue}].z_1'$, which belong to the same cell $(\textit{Set}, 5, \{\texttt{Thailand}\})$).

Algorithm. DPD proceeds in two forward passes. The first pass finds the possible combinations of cells (c, s, d) that lead to the correct denotation y, while the second pass enumerates the logical forms in the cells found in the first pass. Figure 3 illustrates the DPD algorithm.

In the first pass, we are only concerned about finding relevant cell combinations and not the actual logical forms. Therefore, any logical form that belongs to a cell could be used as an argument of a deduction rule to generate further logical forms. Thus, we keep at most one logical form per cell; subsequent logical forms that are generated for that cell are discarded.

After populating all cells up to size $s_{\max}$, we list all cells $(\textit{Set}, s, y)$ with the correct denotation y, and then note all possible rule combinations $(\text{cell}_1, \text{rule})$ or $(\text{cell}_1, \text{cell}_2, \text{rule})$ that lead to those

[1] Semantic functions f with one argument work similarly.

final cells, including the combinations that yielded discarded logical forms.

The second pass retrieves the actual logical forms that yield the correct denotation. To do this, we simply populate the cells (c, s, d) with all logical forms, using only rule combinations that lead to final cells. This elimination of irrelevant rule combinations effectively reduces the search space. (In Section 6.2, we empirically show that the number of cells considered is reduced by 98.7%.)

The parsing chart is represented as a hypergraph as in Figure 3. After eliminating unused rule combinations, each of the remaining hyperpaths from base predicates to the target denotation corresponds to a single logical form. making the remaining parsing chart a compact implicit representation of all consistent logical forms. This representation is guaranteed to cover all possible logical forms under the size limit $s_{\max}$ that can be constructed by the deduction rules.

In our experiments, we apply DPD on the deduction rules in Table 1 and explicitly enumerate the logical forms produced by the second pass. For efficiency, we prune logical forms that are clearly redundant (e.g., applying `max` on a set of size 1). We also restrict a few rules that might otherwise create too many denotations. For example, we restricted the union operation ($\sqcup$) except unions of two entities (e.g., we allow `Germany` $\sqcup$ `Finland` but not `Venue.Hungary` $\sqcup \ldots$), subtraction when building a *Map*, and `count` on a set of size 1.[2]

5 Fictitious worlds

After finding the set Z of all consistent logical forms, we want to filter out spurious logical forms. To do so, we observe that semantically correct logical forms should also give the correct denotation in worlds w' other than than w. In contrast, spurious logical forms will fail to produce the correct denotation on some other world.

Generating fictitious worlds. With the observation above, we generate *fictitious worlds* $w_1, w_2, \ldots$, where each world w_i is a slight alteration of w. As we will be executing logical forms $z \in Z$ on w_i, we should ensure that all entities and relations in $z \in Z$ appear in the fictitious world w_i (e.g., z_1 in Figure 1 would be meaningless if the entity `1st` does not appear in w_i). To this end, we impose that all predicates present in the original world w should also be present in w_i as well.

[2]While we technically can apply `count` on sets of size 1, the number of spurious logical forms explodes as there are too many sets of size 1 generated.

Year	Venue	Position	Event	Time
2001	Finland	7th	relay	46.62
2003	Germany	1st	400m	180.32
2005	China	1st	relay	47.12
2007	Hungary	7th	relay	182.05

Figure 4: From the example in Figure 1, we generate a table for the fictitious world w_1.

	w	w_1	w_2	$\cdots$	
z_1	Thailand	China	Finland	$\cdots$	q_1
z_2	Thailand	China	Finland	$\cdots$	
z_3	Thailand	China	Finland	$\cdots$	
z_4	Thailand	Germany	China	$\cdots$	q_2
z_5	Thailand	China	China	$\cdots$	q_3
z_6	Thailand	China	China	$\cdots$	
$\vdots$	$\vdots$	$\vdots$	$\vdots$		

Figure 5: We execute consistent logical forms $z_i \in Z$ on fictitious worlds to get denotation tuples. Logical forms with the same denotation tuple are grouped into the same equivalence class q_j.

In our case where the world w comes from a data table t, we construct w_i from a new table t_i as follows: we go through each column of t and resample the cells in that column. The cells are sampled using random draws without replacement if the original cells are all distinct, and with replacement otherwise. Sorted columns are kept sorted. To ensure that predicates in w exist in w_i, we use the same set of table columns and enforce that any entity fuzzily matching a span in the question x must be present in t_i (e.g., for the example in Figure 1, the generated t_i must contain "1st"). Figure 4 shows an example fictitious table generated from the table in Figure 1.

Fictitious worlds are similar to test suites for computer programs. However, unlike manually designed test suites, we do not yet know the correct answer for each fictitious world or whether a world is helpful for filtering out spurious logical forms. The next subsections introduce our method for choosing a subset of useful fictitious worlds to be annotated.

Equivalence classes. Let $W = (w_1, \ldots, w_k)$ be the list of all possible fictitious worlds. For each $z \in Z$, we define the denotation tuple $[\![z]\!]_W = ([\![z]\!]_{w_1}, \ldots, [\![z]\!]_{w_k})$. We observe that some logical forms produce the same denotation across all

fictitious worlds. This may be due to an algebraic equivalence in logical forms (e.g., z_1 and z_2 in Figure 1) or due to the constraints in the construction of fictitious worlds (e.g., z_1 and z_3 in Figure 1 are equivalent as long as the Year column is sorted). We group logical forms into equivalence classes based on their denotation tuples, as illustrated in Figure 5. When the question is unambiguous, we expect at most one equivalence class to contain correct logical forms.

Annotation. To pin down the correct equivalence class, we acquire the correct answers to the question x on some subset $W' = (w'_1, \ldots, w'_\ell) \subseteq W$ of ℓ fictitious worlds, as it is impractical to obtain annotations on all fictitious worlds in W. We compile equivalence classes that agree with the annotations into a set Z_c of correct logical forms.

We want to choose W' that gives us the most information about the correct equivalence class as possible. This is analogous to standard practices in active learning (Settles, 2010).[3] Let $\mathcal{Q}$ be the set of all equivalence classes q, and let $[\![q]\!]_{W'}$ be the denotation tuple computed by executing an arbitrary $z \in q$ on W'. The subset W' divides $\mathcal{Q}$ into partitions $F_t = \{q \in \mathcal{Q} : [\![q]\!]_{W'} = t\}$ based on the denotation tuples t (e.g., from Figure 5, if W' contains just w_2, then q_2 and q_3 will be in the same partition $F_{(\text{China})}$). The annotation t^*, which is also a denotation tuple, will mark one of these partitions F_{t^*} as correct. Thus, to prune out many spurious equivalence classes, the partitions should be as numerous and as small as possible.

More formally, we choose a subset W' that maximizes the expected information gain (or equivalently, the reduction in entropy) about the correct equivalence class given the annotation. With random variables $Q \in \mathcal{Q}$ representing the correct equivalence class and $T^*_{W'}$ for the annotation on worlds W', we seek to find $\arg\min_{W'} \mathrm{H}(Q \mid T^*_{W'})$. Assuming a uniform prior on Q ($p(q) = 1/|\mathcal{Q}|$) and accurate annotation ($p(t^* \mid q) = \mathbf{I}[q \in F_{t^*}]$):

$$\begin{aligned}\mathrm{H}(Q \mid T^*_{W'}) &= \sum_{q,t} p(q,t) \log \frac{p(t)}{p(q,t)} \\ &= \frac{1}{|\mathcal{Q}|} \sum_t |F_t| \log |F_t|. \qquad (*)\end{aligned}$$

[3]The difference is that we are obtaining partial information about an individual example rather than partial information about the parameters.

We exhaustively search for W' that minimizes (*). The objective value follows our intuition since $\sum_t |F_t| \log |F_t|$ is small when the terms $|F_t|$ are small and numerous.

In our experiments, we approximate the full set W of fictitious worlds by generating $k = 30$ worlds to compute equivalence classes. We choose a subset of $\ell = 5$ worlds to be annotated.

6 Experiments

For the experiments, we use the training portion of the WIKITABLEQUESTIONS dataset (Pasupat and Liang, 2015), which consists of 14,152 questions on 1,679 Wikipedia tables gathered by crowd workers. Answering these complex questions requires different types of operations. The same operation can be phrased in different ways (e.g., "*best*", "*top ranking*", or "*lowest ranking number*") and the interpretation of some phrases depend on the context (e.g., "*number of*" could be a table lookup or a count operation). The lexical content of the questions is also quite diverse: even excluding numbers and symbols, the 14,152 training examples contain 9,671 unique words, only 10% of which appear more than 10 times.

We attempted to manually annotate the first 300 examples with lambda DCS logical forms. We successfully constructed correct logical forms for 84% of these examples, which is a good number considering the questions were created by humans who could use the table however they wanted. The remaining 16% reflect limitations in our setup—for example, non-canonical table layouts, answers appearing in running text or images, and common sense reasoning (e.g., knowing that "Quarterfinal" is better than "Round of 16").

6.1 Generality of deduction rules

We compare our set of deduction rules with the one given in Pasupat and Liang (2015) (henceforth PL15). PL15 reported generating the annotated logical form in 53.5% of the first 200 examples. With our more general deduction rules, we use DPD to verify that the rules are able to generate the annotated logical form in 76% of the first 300 examples, within the logical form size limit $s_{\max}$ of 7. This is 90.5% of the examples that were successfully annotated. Figure 6 shows some examples of logical forms we cover that PL15 could not. Since DPD is guaranteed to find all consistent logical forms, we can be sure that the logical

"*which opponent has the most wins*" $z = \texttt{argmax}(\mathbf{R}[\texttt{Opponent}].\texttt{Type.Row},$ $\mathbf{R}[\lambda x.\texttt{count}(\texttt{Opponent}.x \sqcap \texttt{Result.Lost}])$
"*how long did ian armstrong serve?*" $z = \mathbf{R}[\texttt{Num2}].\mathbf{R}[\texttt{Term}].\texttt{Member.IanArmstrong}$ $- \mathbf{R}[\texttt{Number}].\mathbf{R}[\texttt{Term}].\texttt{Member.IanArmstrong}$
"*which players came in a place before lukas bauer?*" $z = \mathbf{R}[\texttt{Name}].\texttt{Index.<}.\mathbf{R}[\texttt{Index}].\texttt{Name.LukasBauer}$
"*which players played the same position as ardo kreek?*" $z = \mathbf{R}[\texttt{Player}].\texttt{Position}.\mathbf{R}[\texttt{Position}].\texttt{Player.Ardo}$ $\sqcap \texttt{!=.Ardo}$

Figure 6: Several example logical forms our system can generated that are not covered by the deduction rules from the previous work PL15.

forms not covered are due to limitations of the deduction rules. Indeed, the remaining examples either have logical forms with size larger than 7 or require other operations such as addition, union of arbitrary sets, etc.

6.2 Dynamic programming on denotations

Search space. To demonstrate the savings gained by collapsing logical forms with the same denotation, we track the growth of the number of unique logical forms and denotations as the logical form size increases. The plot in Figure 7 shows that the space of logical forms explodes much more quickly than the space of denotations.

The use of denotations also saves us from considering a significant amount of irrelevant partial logical forms. On average over 14,152 training examples, DPD generates approximately 25,000 consistent logical forms. The first pass of DPD generates $\approx$ 153,000 cells (c, s, d), while the second pass generates only $\approx$ 2,000 cells resulting from $\approx$ 8,000 rule combinations, resulting in a 98.7% reduction in the number of cells that have to be considered.

Comparison with beam search. We compare DPD to beam search on the ability to generate (but not rank) the annotated logical forms. We consider two settings: when the beam search parameters are uninitialized (i.e., the beams are pruned randomly), and when the parameters are trained using the system from PL15 (i.e., the beams are pruned based on model scores). The plot in Figure 8 shows that DPD generates more annotated logical forms (76%) compared to beam search (53.7%), even when beam search is guided heuristically by learned parameters. Note that DPD is an exact algorithm and does not require a heuristic.

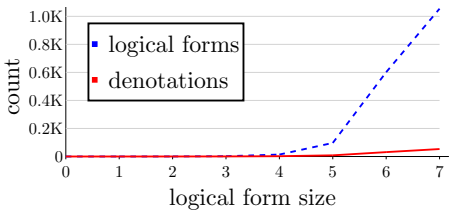

Figure 7: The median of the number of logical forms (dashed) and denotations (solid) as the formula size increases. The space of logical forms grows much faster than the space of denotations.

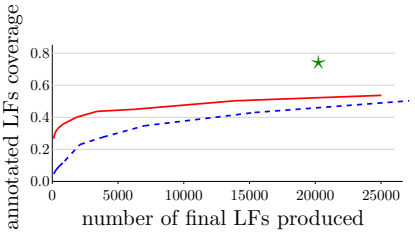

Figure 8: The number of annotated logical forms that can be generated by beam search, both uninitialized (dashed) and initialized (solid), increases with the number of candidates generated (controlled by beam size), but lacks behind DPD (star).

6.3 Fictitious worlds

We now explore how fictitious worlds divide the set of logical forms into equivalence classes, and how the annotated denotations on the chosen worlds help us prune spurious logical forms.

Equivalence classes. Using 30 fictitious worlds per example, we produce an average of 1,237 equivalence classes. One possible concern with using a limited number of fictitious worlds is that we may fail to distinguish some pairs of non-equivalent logical forms. We verify the equivalence classes against the ones computed using 300 fictitious worlds. We found that only 5% of the logical forms are split from the original equivalence classes.

Ideal Annotation. After computing equivalence classes, we choose a subset W' of 5 fictitious worlds to be annotated based on the information-theoretic objective. For each of the 252 examples with an annotated logical form z^*, we use the denotation tuple $t^* = [\![z^*]\!]_{W'}$ as the annotated answers on the chosen fictitious worlds. We are able to rule out 98.7% of the spurious equivalence classes and 98.3% of spurious logical forms. Furthermore, we are able to filter down to just one equivalence class in 32.7% of the examples, and

at most three equivalence classes in 51.3% of the examples. If we choose 5 fictitious worlds randomly instead of maximizing information gain, then the above statistics are 22.6% and 36.5%, respectively. When more than one equivalence classes remain, usually only one class is a dominant class with many equivalent logical forms, while other classes are small and contain logical forms with unusual patterns (e.g., z_5 in Figure 1).

The average size of the correct equivalence class is $\approx$ 3,000 with the standard deviation of $\approx$ 8,000. Because we have an expressive logical language, there are fundamentally many equivalent ways of computing the same quantity.

Crowdsourced Annotation. Data from crowdsourcing is more susceptible to errors. From the 252 annotated examples, we use 177 examples where at least two crowd workers agree on the answer of the original world w. When the crowdsourced data is used to rule out spurious logical forms, the entire set Z of consistent logical forms is pruned out in 11.3% of the examples, and the correct equivalent class is removed in 9% of the examples. These issues are due to annotation errors, inconsistent data (e.g., having date of death before birth date), and different interpretations of the question on the fictitious worlds. For the remaining examples, we are able to prune out 92.1% of spurious logical forms (or 92.6% of spurious equivalence classes).

To prevent the entire Z from being pruned, we can relax our assumption and keep logical forms z that disagree with the annotation in at most 1 fictitious world. The number of times Z is pruned out is reduced to 3%, but the number of spurious logical forms pruned also decreases to 78%.

7 Related Work and Discussion

This work evolved from a long tradition of learning executable semantic parsers, initially from annotated logical forms (Zelle and Mooney, 1996; Kate et al., 2005; Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2010), but more recently from denotations (Clarke et al., 2010; Liang et al., 2011; Berant et al., 2013; Kwiatkowski et al., 2013; Pasupat and Liang, 2015). A central challenge in learning from denotations is finding consistent logical forms (those that execute to a given denotation).

As Kwiatkowski et al. (2013) and Berant and Liang (2014) both noted, a chief difficulty with executable semantic parsing is the "schema mismatch"—words in the utterance do not map cleanly onto the predicates in the logical form. This mismatch is especially pronounced in the WIKITABLEQUESTIONS of Pasupat and Liang (2015). In the second example of Figure 6, "*how long*" is realized by a logical form that computes a difference between two dates. The ramification of this mismatch is that finding consistent logical forms cannot solely proceed from the language side. This paper is about using annotated denotations to drive the search over logical forms.

This takes us into the realm of program induction, where the goal is to infer a program (logical form) from input-output pairs (for us, world-denotation pairs). Here, previous work has also leveraged the idea of dynamic programming on denotations (Lau et al., 2003; Liang et al., 2010; Gulwani, 2011), though for more constrained spaces of programs. Continuing the program analogy, generating fictitious worlds is similar in spirit to fuzz testing for generating new test cases (Miller et al., 1990), but the goal there is coverage in a single program rather than identifying the correct (equivalence class of) programs. This connection can potentially improve the flow of ideas between the two fields.

Finally, the effectiveness of dynamic programming on denotations relies on having a manageable set of denotations. For more complex logical forms and larger knowledge graphs, there are many possible angles worth exploring: performing abstract interpretation to collapse denotations into equivalence classes (Cousot and Cousot, 1977), relaxing the notion of getting the correct denotation (Steinhardt and Liang, 2015), or working in a continuous space and relying on gradient descent (Guu et al., 2015; Neelakantan et al., 2016; Yin et al., 2016; Reed and de Freitas, 2016). This paper, by virtue of exact dynamic programming, sets the standard.

Abstract

Semantic parsing aims at mapping natural language to machine interpretable meaning representations. Traditional approaches rely on high-quality lexicons, manually-built templates, and linguistic features which are either domain- or representation-specific. In this paper we present a general method based on an attention-enhanced encoder-decoder model. We encode input utterances into vector representations, and generate their logical forms by conditioning the output sequences or trees on the encoding vectors. Experimental results on four datasets show that our approach performs competitively without using hand-engineered features and is easy to adapt across domains and meaning representations.

1 Introduction

Semantic parsing is the task of translating text to a formal meaning representation such as logical forms or structured queries. There has recently been a surge of interest in developing machine learning methods for semantic parsing (see the references in Section 2), due in part to the existence of corpora containing utterances annotated with formal meaning representations. Figure 1 shows an example of a question (left hand-side) and its annotated logical form (right hand-side), taken from JOBS (Tang and Mooney, 2001), a well-known semantic parsing benchmark. In order to predict the correct logical form for a given utterance, most previous systems rely on predefined templates and manually designed features, which often render the parsing model domain- or representation-specific. In this work, we aim to use a simple yet effective method to bridge the gap between natural language and logical form with minimal domain knowledge.

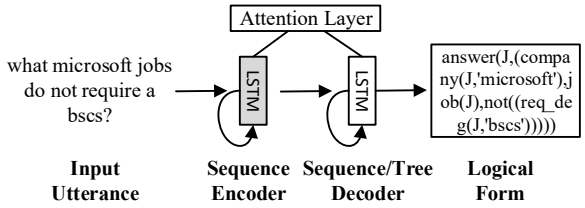

Figure 1: Input utterances and their logical forms are encoded and decoded with neural networks. An attention layer is used to learn soft alignments.

Encoder-decoder architectures based on recurrent neural networks have been successfully applied to a variety of NLP tasks ranging from syntactic parsing (Vinyals et al., 2015a), to machine translation (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014), and image description generation (Karpathy and Fei-Fei, 2015; Vinyals et al., 2015b). As shown in Figure 1, we adapt the general encoder-decoder paradigm to the semantic parsing task. Our model learns from natural language descriptions paired with meaning representations; it encodes sentences and decodes logical forms using recurrent neural networks with long short-term memory (LSTM) units. We present two model variants, the first one treats semantic parsing as a vanilla sequence transduction task, whereas our second model is equipped with a hierarchical tree decoder which explicitly captures the compositional structure of logical forms. We also introduce an attention mechanism (Bahdanau et al., 2015; Luong et al., 2015b) allowing the model to learn soft alignments between natural language and logical forms and present an argument identification step to handle rare mentions of entities and numbers.

Evaluation results demonstrate that compared to previous methods our model achieves similar or better performance across datasets and meaning representations, despite using no hand-engineered domain- or representation-specific features.

2 Related Work

Our work synthesizes two strands of research, namely semantic parsing and the encoder-decoder architecture with neural networks.

The problem of learning semantic parsers has received significant attention, dating back to Woods (1973). Many approaches learn from sentences paired with logical forms following various modeling strategies. Examples include the use of parsing models (Miller et al., 1996; Ge and Mooney, 2005; Lu et al., 2008; Zhao and Huang, 2015), inductive logic programming (Zelle and Mooney, 1996; Tang and Mooney, 2000; Thompson and Mooney, 2003), probabilistic automata (He and Young, 2006), string/tree-to-tree transformation rules (Kate et al., 2005), classifiers based on string kernels (Kate and Mooney, 2006), machine translation (Wong and Mooney, 2006; Wong and Mooney, 2007; Andreas et al., 2013), and combinatory categorial grammar induction techniques (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2010; Kwiatkowski et al., 2011). Other work learns semantic parsers without relying on logical-from annotations, e.g., from sentences paired with conversational logs (Artzi and Zettlemoyer, 2011), system demonstrations (Chen and Mooney, 2011; Goldwasser and Roth, 2011; Artzi and Zettlemoyer, 2013), question-answer pairs (Clarke et al., 2010; Liang et al., 2013), and distant supervision (Krishnamurthy and Mitchell, 2012; Cai and Yates, 2013; Reddy et al., 2014).

Our model learns from natural language descriptions paired with meaning representations. Most previous systems rely on high-quality lexicons, manually-built templates, and features which are either domain- or representation-specific. We instead present a general method that can be easily adapted to different domains and meaning representations. We adopt the general encoder-decoder framework based on neural networks which has been recently repurposed for various NLP tasks such as syntactic parsing (Vinyals et al., 2015a), machine translation (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014), image description generation (Karpathy and Fei-Fei, 2015; Vinyals et al., 2015b), question answering (Hermann et al., 2015), and summarization (Rush et al., 2015).

Mei et al. (2016) use a sequence-to-sequence model to map navigational instructions to actions. Our model works on more well-defined meaning representations (such as Prolog and lambda calculus) and is conceptually simpler; it does not employ bidirectionality or multi-level alignments. Grefenstette et al. (2014) propose a different architecture for semantic parsing based on the combination of two neural network models. The first model learns shared representations from pairs of questions and their translations into knowledge base queries, whereas the second model generates the queries conditioned on the learned representations. However, they do not report empirical evaluation results.

3 Problem Formulation

Our aim is to learn a model which maps natural language input $q = x_1 \cdots x_{|q|}$ to a logical form representation of its meaning $a = y_1 \cdots y_{|a|}$. The conditional probability $p(a|q)$ is decomposed as:

$$p(a|q) = \prod_{t=1}^{|a|} p(y_t|y_{<t}, q) \tag{1}$$

where $y_{<t} = y_1 \cdots y_{t-1}$.

Our method consists of an **encoder** which encodes natural language input q into a vector representation and a **decoder** which learns to generate $y_1, \cdots, y_{|a|}$ conditioned on the encoding vector. In the following we describe two models varying in the way in which $p(a|q)$ is computed.

3.1 Sequence-to-Sequence Model

This model regards both input q and output a as sequences. As shown in Figure 2, the encoder and decoder are two different L-layer recurrent neural networks with long short-term memory (LSTM) units which recursively process tokens one by one. The first $|q|$ time steps belong to the encoder, while the following $|a|$ time steps belong to the decoder. Let $\mathbf{h}_t^l \in \mathbb{R}^n$ denote the hidden vector at time step t and layer l. $\mathbf{h}_t^l$ is then computed by:

$$\mathbf{h}_t^l = \text{LSTM}\left(\mathbf{h}_{t-1}^l, \mathbf{h}_t^{l-1}\right) \tag{2}$$

where LSTM refers to the LSTM function being used. In our experiments we follow the architecture described in Zaremba et al. (2015), however other types of gated activation functions are possible (e.g., Cho et al. (2014)). For the encoder, $\mathbf{h}_t^0 = \mathbf{W}_q \mathbf{e}(x_t)$ is the word vector of the current input token, with $\mathbf{W}_q \in \mathbb{R}^{n \times |V_q|}$ being a parameter matrix, and $\mathbf{e}(\cdot)$ the index of the corresponding

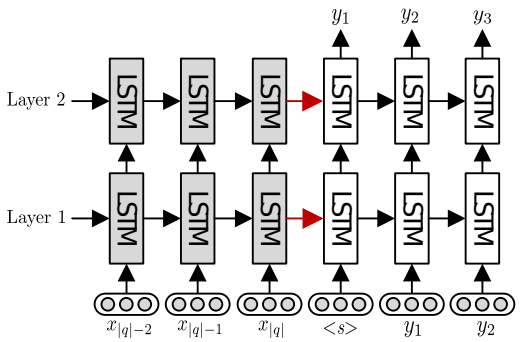

Figure 2: Sequence-to-sequence (SEQ2SEQ) model with two-layer recurrent neural networks.

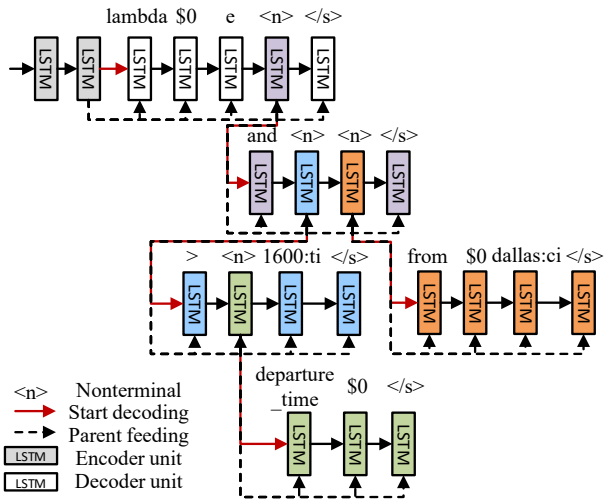

Figure 3: Sequence-to-tree (SEQ2TREE) model with a hierarchical tree decoder.

token. For the decoder, $\mathbf{h}_t^0 = \mathbf{W}_a \mathbf{e}(y_{t-1})$ is the word vector of the previous predicted word, where $\mathbf{W}_a \in \mathbb{R}^{n \times |V_a|}$. Notice that the encoder and decoder have different LSTM parameters.

Once the tokens of the input sequence $x_1, \cdots, x_{|q|}$ are encoded into vectors, they are used to initialize the hidden states of the first time step in the decoder. Next, the hidden vector of the topmost LSTM $\mathbf{h}_t^L$ in the decoder is used to predict the t-th output token as:

$$p\left(y_t | y_{<t}, q\right) = \text{softmax}\left(\mathbf{W}_o \mathbf{h}_t^L\right)^\intercal \mathbf{e}\left(y_t\right) \quad (3)$$

where $\mathbf{W}_o \in \mathbb{R}^{|V_a| \times n}$ is a parameter matrix, and $\mathbf{e}\left(y_t\right) \in \{0,1\}^{|V_a|}$ a one-hot vector for computing y_t's probability from the predicted distribution.

We augment every sequence with a "start-of-sequence" <*s*> and "end-of-sequence" </*s*> token. The generation process terminates once </*s*> is predicted. The conditional probability of generating the whole sequence $p\left(a|q\right)$ is then obtained using Equation (1).

3.2 Sequence-to-Tree Model

The SEQ2SEQ model has a potential drawback in that it ignores the hierarchical structure of logical forms. As a result, it needs to memorize various pieces of auxiliary information (e.g., bracket pairs) to generate well-formed output. In the following we present a hierarchical tree decoder which is more faithful to the compositional nature of meaning representations. A schematic description of the model is shown in Figure 3.

The present model shares the same encoder with the sequence-to-sequence model described in Section 3.1 (essentially it learns to encode input q as vectors). However, its decoder is fundamentally different as it generates logical forms in a top-down manner. In order to represent tree structure, we define a "nonterminal" <*n*> token which indicates subtrees. As shown in Figure 3, we preprocess the logical form "*lambda $0 e (and (>(departure_time $0) 1600:ti) (from $0 dallas:ci))*" to a tree by replacing tokens between pairs of brackets with nonterminals. Special tokens <*s*> and <*(*> denote the beginning of a sequence and nonterminal sequence, respectively (omitted from Figure 3 due to lack of space). Token </*s*> represents the end of sequence.

After encoding input q, the hierarchical tree decoder uses recurrent neural networks to generate tokens at depth 1 of the subtree corresponding to parts of logical form a. If the predicted token is <*n*>, we decode the sequence by conditioning on the nonterminal's hidden vector. This process terminates when no more nonterminals are emitted. In other words, a sequence decoder is used to hierarchically generate the tree structure.

In contrast to the sequence decoder described in Section 3.1, the current hidden state does not only depend on its previous time step. In order to better utilize the parent nonterminal's information, we introduce a *parent-feeding* connection where the hidden vector of the parent nonterminal is concatenated with the inputs and fed into LSTM.

As an example, Figure 4 shows the decoding tree corresponding to the logical form "*A B (C)*", where $y_1 \cdots y_6$ are predicted tokens, and $t_1 \cdots t_6$ denote different time steps. Span "*(C)*" corresponds to a subtree. Decoding in this example has two steps: once input q has been encoded, we first generate $y_1 \cdots y_4$ at depth 1 until token </*s*> is

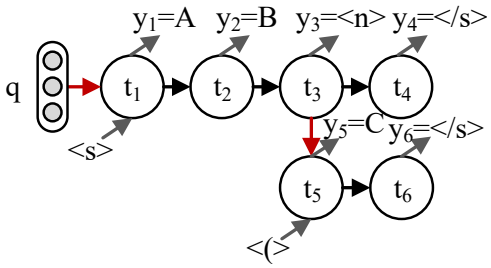

Figure 4: A SEQ2TREE decoding example for the logical form "*A B (C)*".

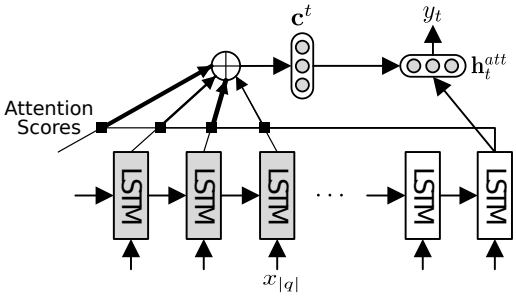

Figure 5: Attention scores are computed by the current hidden vector and all the hidden vectors of encoder. Then, the encoder-side context vector $\mathbf{c}^t$ is obtained in the form of a weighted sum, which is further used to predict y_t.

predicted; next, we generate y_5, y_6 by conditioning on nonterminal t_3's hidden vectors. The probability $p(a|q)$ is the product of these two sequence decoding steps:

$$p(a|q) = p(y_1 y_2 y_3 y_4|q)\, p(y_5 y_6|y_{\leq 3}, q) \quad (4)$$

where Equation (3) is used for the prediction of each output token.

3.3 Attention Mechanism

As shown in Equation (3), the hidden vectors of the input sequence are not directly used in the decoding process. However, it makes intuitively sense to consider relevant information from the input to better predict the current token. Following this idea, various techniques have been proposed to integrate encoder-side information (in the form of a context vector) at each time step of the decoder (Bahdanau et al., 2015; Luong et al., 2015b; Xu et al., 2015).

As shown in Figure 5, in order to find relevant encoder-side context for the current hidden state $\mathbf{h}_t^L$ of decoder, we compute its attention score with the k-th hidden state in the encoder as:

$$s_k^t = \frac{\exp\{\mathbf{h}_k^L \cdot \mathbf{h}_t^L\}}{\sum_{j=1}^{|q|} \exp\{\mathbf{h}_j^L \cdot \mathbf{h}_t^L\}} \quad (5)$$

where $\mathbf{h}_1^L, \cdots, \mathbf{h}_{|q|}^L$ are the top-layer hidden vectors of the encoder. Then, the context vector is the weighted sum of the hidden vectors in the encoder:

$$\mathbf{c}^t = \sum_{k=1}^{|q|} s_k^t \mathbf{h}_k^L \quad (6)$$

In lieu of Equation (3), we further use this context vector which acts as a summary of the encoder to compute the probability of generating y_t as:

$$\mathbf{h}_t^{att} = \tanh\left(\mathbf{W}_1 \mathbf{h}_t^L + \mathbf{W}_2 \mathbf{c}^t\right) \quad (7)$$

$$p(y_t|y_{<t}, q) = \text{softmax}\left(\mathbf{W}_o \mathbf{h}_t^{att}\right)^{\mathsf{T}} \mathbf{e}(y_t) \quad (8)$$

where $\mathbf{W}_o \in \mathbb{R}^{|V_a| \times n}$ and $\mathbf{W}_1, \mathbf{W}_2 \in \mathbb{R}^{n \times n}$ are three parameter matrices, and $\mathbf{e}(y_t)$ is a one-hot vector used to obtain y_t's probability.

3.4 Model Training

Our goal is to maximize the likelihood of the generated logical forms given natural language utterances as input. So the objective function is:

$$\text{minimize} - \sum_{(q,a)\in\mathcal{D}} \log p(a|q) \quad (9)$$

where $\mathcal{D}$ is the set of all natural language-logical form training pairs, and $p(a|q)$ is computed as shown in Equation (1).

The RMSProp algorithm (Tieleman and Hinton, 2012) is employed to solve this non-convex optimization problem. Moreover, dropout is used for regularizing the model (Zaremba et al., 2015). Specifically, dropout operators are used between different LSTM layers and for the hidden layers before the softmax classifiers. This technique can substantially reduce overfitting, especially on datasets of small size.

3.5 Inference

At test time, we predict the logical form for an input utterance q by:

$$\hat{a} = \arg\max_{a'} p\left(a'|q\right) \quad (10)$$

where a' represents a candidate output. However, it is impractical to iterate over all possible results to obtain the optimal prediction. According to Equation (1), we decompose the probability $p(a|q)$ so that we can use greedy search (or beam search) to generate tokens one by one.

Algorithm 1 Decoding for SEQ2TREE

Input: q: Natural language utterance
Output: $\hat{a}$: Decoding result

$\triangleright$ *Push the encoding result to a queue*
$Q.init(\{hid : \mathsf{SeqEnc}(q)\})$
$\triangleright$ *Decode until no more nonterminals*
while $(c \leftarrow Q.pop()) \neq \varnothing$ **do**
    $\triangleright$ *Call sequence decoder*
    $c.child \leftarrow \mathsf{SeqDec}(c.hid)$
    $\triangleright$ *Push new nonterminals to queue*
    for $n \leftarrow$ nonterminal in $c.child$ **do**
        $Q.push(\{hid : \mathsf{HidVec}(n)\})$
$\hat{a} \leftarrow$ convert decoding tree to output sequence

Algorithm 1 describes the decoding process for SEQ2TREE. The time complexity of both decoders is $\mathcal{O}(|a|)$, where $|a|$ is the length of output. The extra computation of SEQ2TREE compared with SEQ2SEQ is to maintain the nonterminal queue, which can be ignored because most of time is spent on matrix operations. We implement the hierarchical tree decoder in a batch mode, so that it can fully utilize GPUs. Specifically, as shown in Algorithm 1, every time we pop multiple nonterminals from the queue and decode these nonterminals in one batch.

3.6 Argument Identification

The majority of semantic parsing datasets have been developed with question-answering in mind. In the typical application setting, natural language questions are mapped into logical forms and executed on a knowledge base to obtain an answer. Due to the nature of the question-answering task, many natural language utterances contain entities or numbers that are often parsed as arguments in the logical form. Some of them are unavoidably rare or do not appear in the training set at all (this is especially true for small-scale datasets). Conventional sequence encoders simply replace rare words with a special unknown word symbol (Luong et al., 2015a; Jean et al., 2015), which would be detrimental for semantic parsing.

We have developed a simple procedure for argument identification. Specifically, we identify entities and numbers in input questions and replace them with their type names and unique IDs. For instance, we pre-process the training example "*jobs with a salary of 40000*" and its logical form "*job(ANS), salary_greater_than(ANS, 40000, year)*" as "*jobs with a salary of* $\underline{num_0}$" and "*job(ANS), salary_greater_than(ANS,* $\underline{num_0}$*, year)*". We use the pre-processed examples as training data. At inference time, we also mask entities and numbers with their types and IDs. Once we obtain the decoding result, a post-processing step recovers all the markers $\underline{type_i}$ to their corresponding logical constants.

4 Experiments

We compare our method against multiple previous systems on four datasets. We describe these datasets below, and present our experimental settings and results. Finally, we conduct model analysis in order to understand what the model learns. The code is available at `https://github.com/donglixp/lang2logic`.

4.1 Datasets

Our model was trained on the following datasets, covering different domains and using different meaning representations. Examples for each domain are shown in Table 1.

JOBS This benchmark dataset contains 640 queries to a database of job listings. Specifically, questions are paired with Prolog-style queries. We used the same training-test split as Zettlemoyer and Collins (2005) which contains 500 training and 140 test instances. Values for the variables company, degree, language, platform, location, job area, and number are identified.

GEO This is a standard semantic parsing benchmark which contains 880 queries to a database of U.S. geography. GEO has 880 instances split into a training set of 680 training examples and 200 test examples (Zettlemoyer and Collins, 2005). We used the same meaning representation based on lambda-calculus as Kwiatkowski et al. (2011). Values for the variables city, state, country, river, and number are identified.

ATIS This dataset has 5,410 queries to a flight booking system. The standard split has 4,480 training instances, 480 development instances, and 450 test instances. Sentences are paired with lambda-calculus expressions. Values for the variables date, time, city, aircraft code, airport, airline, and number are identified.

IFTTT Quirk et al. (2015) created this dataset by extracting a large number of if-this-then-that

Dataset	Length	Example
JOBS	9.80	*what microsoft jobs do not require a bscs?*
	22.90	answer(company(J,'microsoft'),job(J),not((req_deg(J,'bscs'))))
GEO	7.60	*what is the population of the state with the largest area?*
	19.10	(population:i (argmax $0 (state:t $0) (area:i $0)))
ATIS	11.10	*dallas to san francisco leaving after 4 in the afternoon please*
	28.10	(lambda $0 e (and (>(departure_time $0) 1600:ti) (from $0 dallas:ci) (to $0 san_francisco:ci)))
IFTTT	6.95	*Turn on heater when temperature drops below 58 degree*
	21.80	TRIGGER: Weather - Current_temperature_drops_below - ((Temperature (58)) (Degrees_in (f)))
		ACTION: WeMo_Insight_Switch - Turn_on - ((Which_switch? ("")))

Table 1: Examples of natural language descriptions and their meaning representations from four datasets. The average length of input and output sequences is shown in the second column.

recipes from the IFTTT website[1]. Recipes are simple programs with exactly one trigger and one action which users specify on the site. Whenever the conditions of the trigger are satisfied, the action is performed. Actions typically revolve around home security (e.g., "*turn on my lights when I arrive home*"), automation (e.g., "*text me if the door opens*"), well-being (e.g., "*remind me to drink water if I've been at a bar for more than two hours*"), and so on. Triggers and actions are selected from different channels (160 in total) representing various types of services, devices (e.g., Android), and knowledge sources (such as ESPN or Gmail). In the dataset, there are 552 trigger functions from 128 channels, and 229 action functions from 99 channels. We used Quirk et al.'s (2015) original split which contains $77,495$ training, $5,171$ development, and $4,294$ test examples. The IFTTT programs are represented as abstract syntax trees and are paired with natural language descriptions provided by users (see Table 1). Here, numbers and URLs are identified.

4.2 Settings

Natural language sentences were lowercased; misspellings were corrected using a dictionary based on the Wikipedia list of common misspellings. Words were stemmed using NLTK (Bird et al., 2009). For IFTTT, we filtered tokens, channels and functions which appeared less than five times in the training set. For the other datasets, we filtered input words which did not occur at least two times in the training set, but kept all tokens in the logical forms. Plain string matching was employed to identify augments as described in Section 3.6. More sophisticated approaches could be used, however we leave this future work.

Model hyper-parameters were cross-validated on the training set for JOBS and GEO. We used the standard development sets for ATIS and IFTTT. We used the RMSProp algorithm (with batch size set to 20) to update the parameters. The smoothing constant of RMSProp was 0.95. Gradients were clipped at 5 to alleviate the exploding gradient problem (Pascanu et al., 2013). Parameters were randomly initialized from a uniform distribution $\mathcal{U}(-0.08, 0.08)$. A two-layer LSTM was used for IFTTT, while a one-layer LSTM was employed for the other domains. The dropout rate was selected from $\{0.2, 0.3, 0.4, 0.5\}$. Dimensions of hidden vector and word embedding were selected from $\{150, 200, 250\}$. Early stopping was used to determine the number of epochs. Input sentences were reversed before feeding into the encoder (Sutskever et al., 2014). We use greedy search to generate logical forms during inference. Notice that two decoders with shared word embeddings were used to predict triggers and actions for IFTTT, and two softmax classifiers are used to classify channels and functions.

Method	Accuracy

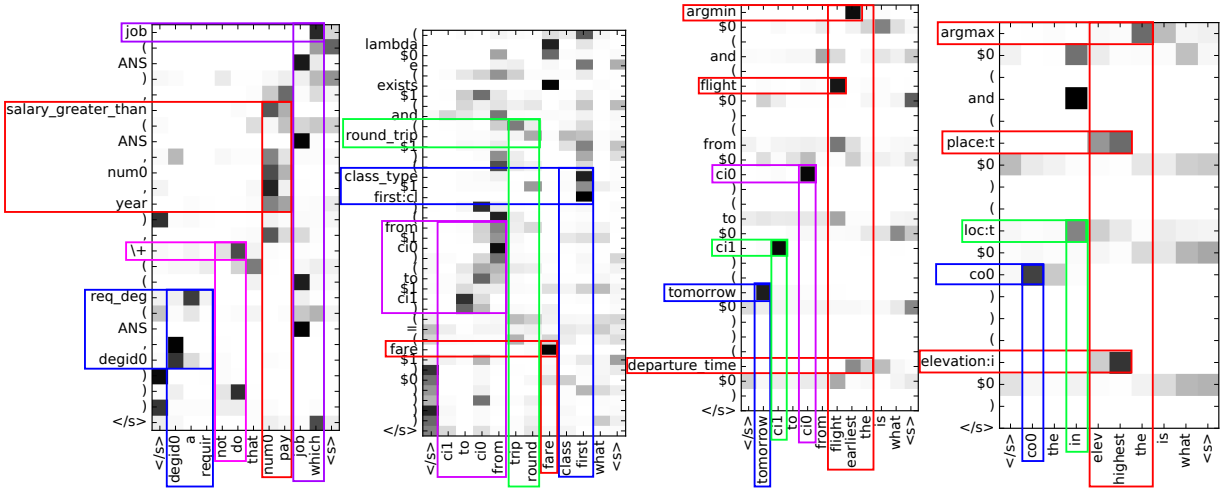
Table 5: Evaluation results on IFTTT.

in the literature. We report results with the full models (SEQ2SEQ, SEQ2TREE) and two ablation variants, i.e., without an attention mechanism (−attention) and without argument identification (−argument). We report accuracy which is defined as the proportion of the input sentences that are correctly parsed to their gold standard logical forms. Notice that DCS+L, KCAZ13 and GUSP output answers directly, so accuracy in this setting is defined as the percentage of correct answers.

Overall, SEQ2TREE is superior to SEQ2SEQ. This is to be expected since SEQ2TREE explicitly models compositional structure. On the JOBS and GEO datasets which contain logical forms with nested structures, SEQ2TREE outperforms SEQ2SEQ by 2.9% and 2.5%, respectively. SEQ2TREE achieves better accuracy over SEQ2SEQ on ATIS too, however, the difference is smaller, since ATIS is a simpler domain without complex nested structures. We find that adding attention substantially improves performance on all three datasets. This underlines the importance of utilizing soft alignments between inputs and outputs. We further analyze what the attention layer learns in Figure 6. Moreover, our results show that argument identification is critical for small-scale datasets. For example, about 92% of city names appear less than 4 times in the GEO training set, so it is difficult to learn reliable parameters for these words. In relation to previous work, the proposed models achieve comparable or better performance. Importantly, we use the same framework (SEQ2SEQ or SEQ2TREE) across datasets and meaning representations (Prolog-style logical forms in JOBS and lambda calculus in the other two datasets) without modification. Despite this relatively simple approach, we observe that SEQ2TREE ranks second on JOBS, and is tied for first place with ZC07 on ATIS.



(a) which jobs pay num0 that do not require a degid0

Figure 6: Alignments (same color rectangles) produced by the attention mechanism (darker color represents higher attention score). Input sentences are reversed and stemmed. Model output is shown for SEQ2SEQ (a, b) and SEQ2TREE (c, d).

We illustrate examples of alignments produced by SEQ2SEQ in Figures 6a and 6b. Alignments produced by SEQ2TREE are shown in Figures 6c and 6d. Matrices of attention scores are computed using Equation (5) and are represented in grayscale. Aligned input words and logical form predicates are enclosed in (same color) rectangles whose overlapping areas contain the attention scores. Also notice that attention scores are computed by LSTM hidden vectors which encode context information rather than just the words in their current positions. The examples demonstrate that the attention mechanism can successfully model the correspondence between sentences and logical forms, capturing reordering (Figure 6b), many-to-many (Figure 6a), and many-to-one alignments (Figures 6c,d).

For IFTTT, we follow the same evaluation protocol introduced in Quirk et al. (2015). The dataset is extremely noisy and measuring accuracy is problematic since predicted abstract syntax trees (ASTs) almost never exactly match the gold standard. Quirk et al. view an AST as a set of productions and compute balanced F1 instead which we also adopt. The first column in Table 5 shows the percentage of channels selected correctly for both triggers and actions. The second column measures accuracy for *both* channels and functions. The last column shows balanced F1 against the gold tree over all productions in the proposed derivation. We compare our model against posclass, the method introduced in Quirk et al. and several of their baselines. posclass is reminiscent of KRISP (Kate and Mooney, 2006), it learns distributions over productions given input sentences represented as a bag of linguistic features. The retrieval baseline finds the closest description in the training data based on character string-edit-distance and returns the recipe for that training program. The phrasal method uses phrase-based machine translation to generate the recipe, whereas sync extracts synchronous grammar rules from the data, essentially recreating WASP (Wong and Mooney, 2006). Finally, they use a binary classifier to predict whether a production should be present in the derivation tree corresponding to the description.

Quirk et al. (2015) report results on the full test data and smaller subsets after noise filtering, e.g., when non-English and unintelligible descriptions are removed (Tables 5a and 5b). They also ran their system on a high-quality subset of description-program pairs which were found in the gold standard and at least three humans managed to independently reproduce (Table 5c). Across all subsets our models outperforms posclass and related baselines. Again we observe that SEQ2TREE consistently outperforms SEQ2SEQ, albeit with a small margin. Compared to the previous datasets, the attention mechanism and our argument iden-

tification method yield less of an improvement. This may be due to the size of Quirk et al. (2015) and the way it was created – user curated descriptions are often of low quality, and thus align very loosely to their corresponding ASTs.

4.4 Error Analysis

Finally, we inspected the output of our model in order to identify the most common causes of errors which we summarize below.

Under-Mapping The attention model used in our experiments does not take the alignment history into consideration. So, some question words, expecially in longer questions, may be ignored in the decoding process. This is a common problem for encoder-decoder models and can be addressed by explicitly modelling the decoding coverage of the source words (Tu et al., 2016; Cohn et al., 2016). Keeping track of the attention history would help adjust future attention and guide the decoder towards untranslated source words.

Argument Identification Some mentions are incorrectly identified as arguments. For example, the word *may* is sometimes identified as a month when it is simply a modal verb. Moreover, some argument mentions are ambiguous. For instance, *6 o'clock* can be used to express either *6 am* or *6 pm*. We could disambiguate arguments based on contextual information. The execution results of logical forms could also help prune unreasonable arguments.

Rare Words Because the data size of JOBS, GEO, and ATIS is relatively small, some question words are rare in the training set, which makes it hard to estimate reliable parameters for them. One solution would be to learn word embeddings on unannotated text data, and then use these as pretrained vectors for question words.

5 Conclusions

In this paper we presented an encoder-decoder neural network model for mapping natural language descriptions to their meaning representations. We encode natural language utterances into vectors and generate their corresponding logical forms as sequences or trees using recurrent neural networks with long short-term memory units. Experimental results show that enhancing the model with a hierarchical tree decoder and an attention mechanism improves performance across the board. Extensive comparisons with previous methods show that our approach performs competitively, without recourse to domain- or representation-specific features. Directions for future work are many and varied. For example, it would be interesting to learn a model from question-answer pairs without access to target logical forms. Beyond semantic parsing, we would also like to apply our SEQ2TREE model to related structured prediction tasks such as constituency parsing.

Acknowledgments We would like to thank Luke Zettlemoyer and Tom Kwiatkowski for sharing the ATIS dataset. The support of the European Research Council under award number 681760 "Translating Multiple Modalities into Text" is gratefully acknowledged.

Unsupervised Person Slot Filling based on Graph Mining

{yud2,jih}@rpi.edu

Abstract

Slot filling aims to extract the values (*slot fillers*) of specific attributes (*slots types*) for a given entity (*query*) from a large-scale corpus. Slot filling remains very challenging over the past seven years. We propose a simple yet effective unsupervised approach to extract slot fillers based on the following two observations: (1) a trigger is usually a salient node relative to the query and filler nodes in the dependency graph of a context sentence; (2) a relation is likely to exist if the query and candidate filler nodes are strongly connected by a relation-specific trigger. Thus we design a graph-based algorithm to automatically identify triggers based on personalized PageRank and Affinity Propagation for a given (*query*, *filler*) pair and then label the slot type based on the identified triggers. Our approach achieves 11.6%-25% higher F-score over state-of-the-art English slot filling methods. Our experiments also demonstrate that as long as a few trigger seeds, name tagging and dependency parsing capabilities exist, this approach can be quickly adapted to any language and new slot types. Our promising results on Chinese slot filling can serve as a new benchmark.

1 Introduction

The goal of the Text Analysis Conference Knowledge Base Population (TAC-KBP) Slot Filling (SF) task (McNamee and Dang, 2009; Ji et al., 2010; Ji et al., 2011; Surdeanu and Ji, 2014) is to extract the values (***fillers***) of specific attributes (***slot types***) for a given entity (***query***) from a large-scale corpus and provide justification sentences to support these slot fillers. KBP defines 25 slot types for persons (*e.g.*, *spouse*) and 16 slots for organizations (*e.g.*, *founder*). For example, given a person query "*Dominich Dunne*" and slot type *spouse*, a SF system may extract a slot filler "*Ellen Griffin*" and its justification sentence $E1$ as shown in Figure 1.

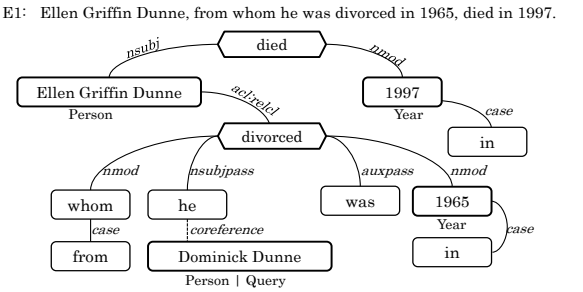

Figure 1: Extended dependency tree for E1.

Slot filling remains a very challenging task. The two most successful state-of-the-art techniques are as follows.

(1) Supervised classification. Considering any pair of query and candidate slot filler as an instance, these approaches train a classifier from manually labeled data through active learning (Angeli et al., 2014b) or noisy labeled data through distant supervision (Angeli et al., 2014a; Surdeanu et al., 2010) to predict the existence of a specific relation between them.

(2) Pattern matching. These approaches extract and generalize lexical and syntactic patterns automatically or semi-automatically (Sun et al., 2011; Li et al., 2012; Yu et al., 2013; Hong et al., 2014). They usually suffer from low recall due to numerous different ways to express a certain relation type (Surdeanu and Ji, 2014). For example, none of the top-ranked patterns (Li et al., 2012) based on dependency paths in Table 1 can capture the *spouse* slot in *E1*.

Query	nsubj^{-1} **married** dobj	Slot Filler
Query	appos **wife** prep_of	Slot Filler
Query	nsubjpass^{-1} **survived** agent	Slot Filler

Table 1: Dependency patterns for slot *spouse*.

Both of the previous methods have poor portability to a new language or a new slot type. Furthermore, both methods focus on the flat relation representation between the query and the candidate slot filler, while ignoring the global graph structure among them and other facts in the context.

When multiple facts about a person entity are presented in a sentence, the author (e.g., a news reporter or a discussion forum poster) often uses explicit *trigger* words or phrases to indicate their relations with the entity. As a result, these interdependent facts and query entities are strongly connected via syntactic or semantic relations.

Many slot types, especially when the queries are person entities, are indicated by such *triggers*. We call these slots ***trigger-driven*** slots. In this paper, we define a ***trigger*** as the smallest extent of a text which most clearly indicates a slot type. For example, in *E1*, "*divorced*" is a trigger for *spouse* while "*died*" is a trigger for death-related slots.

Considering the limitations of previous flat representations for the relations between a query (Q) and a candidate slot filler (F), we focus on analyzing the whole dependency tree structure that connects Q, F and other semantically related words or phrases in each context sentence. Our main observation is that there often exists a trigger word (T) which plays an important role in connecting Q and F in the dependency tree for trigger-driven slots. From the extended dependency tree shown in Figure 1, we can clearly see that "*divorced*" is most strongly connected to the query mention ("*he*") and the slot filler ("*Ellen Griffin Dunne*"). Therefore we can consider it as a trigger word which explicitly indicates a particular slot type.

Based on these observations, we propose a novel and effective **unsupervised graph mining** approach for person slot filling by deeply exploring the structures of dependency trees. It consists of the following three steps:

- **Step 1 - Candidate Relation Identification:** Construct an extended dependency tree for each sentence including any mention referring to the query entity. Identify candidate slot fillers based on slot type constraints (*e.g.*, the *spouse* fillers are limited to person entities) (Section 2).
- **Step 2 - Trigger Identification:** Measure the importance of each node in the extended dependency tree relative to Q and F, rank them and select the most important ones as the trigger set (Section 3).
- **Step 3 - Slot Typing:** For any given new slot type, automatically expand a few trigger seeds using the Paraphrase Database (Ganitkevitch et al., 2013). Then we use the expanded trigger set to label the slot types of identified triggers (Section 4).

This framework only requires name tagging and dependency parsing as pre-processing, and a few trigger seeds as input, and thus it can be easily adapted to a new language or a new slot type. Experiments on English and Chinese demonstrate that our approach dramatically advances state-of-the-art results for both pre-defined KBP slot types and new slot types.

2 Candidate Relation Identification

We first present how to build an extended dependency graph for each evidence sentence (Section 2.1) and generate query and filler candidate mentions (Section 2.2).

2.1 Extended Dependency Tree Construction

Given a sentence containing N words, we construct an undirected graph $G = (V, E)$, where $V = \{v_1, \ldots, v_N\}$ represents the words in a sentence, E is an edge set, associated with each edge e_{ij} representing a dependency relation between v_i and v_j. We first apply a dependency parser to generate basic uncollapsed dependencies by ignoring the direction of edges. Figure 1 shows the dependency tree built from the example sentence. In addition, we annotate an entity, time or value mention node with its type. For example, in Figure 1, "*Ellen Griffin Dunne*" is annotated as a person, and "*1997*" is annotated as a year. Finally we perform co-reference resolution, which introduces implicit links between nodes that refer to the same entity. We replace any nominal or pronominal entity mention with its coreferential name mention. For example, "*he*" is replaced by "*Dominick Dunne*" in Figure 1. Formally, an extended dependency tree is an annotated tree of entity mentions, phrases and their links.

2.2 Query Mention and Filler Candidate Identification

Given a query q and a set of relevant documents, we construct a dependency tree for each sentence. We identify a person entity e as a query mention if e matches the last name of q or e shares two or more tokens with q. For example, "*he/Dominick Dunne*" in Figure 1 is identified as a mention referring to the query *Dominick Dunne*. For each sentence which contains at least one query mention, we regard all other entities, values and time expressions as candidate fillers and generate a set of entity pairs (q, f), where q is a query mention, and f is a candidate filler. In Example $E1$, we can extract three entity pairs (*i.e.*, {*Dominick Dunne*} $\times$ {*Ellen Griffin Dunne*, 1997, 1965}). For each entity pair, we represent the query mention and the filler candidate as two sets of nodes Q and F respectively, where $Q, F \subseteq V$.

3 Trigger Identification

In this section, we proceed to introduce an unsupervised graph-based method to identify triggers for each query and candidate filler pair. We rank all trigger candidates (Section 3.1) and then keep the top ones as the trigger set (Section 3.2).

3.1 Trigger Candidate Ranking

As we have discussed in Section 1, we can consider trigger identification problem as finding the important nodes relative to Q and F in G. Algorithms such as Pagerank (Page et al., 1999) are designed to compute the global importance of each node relative to all other nodes in a graph. By redefining the importance according to our preference toward F and Q, we can extend PageRank to generate relative importance scores.

We use the random surfer model (Page et al., 1999) to explain our motivation. Suppose a random surfer keeps visiting adjacent nodes in G at random. The expected percentage of surfers visiting each node converges to the PageRank score. We extend PageRank by introducing a "back probability" β to determine how often surfers jump back to the ***preferred nodes*** (*i.e.*, Q or F) so that the converged score can be used to estimate the relative probability of visiting these preferred nodes.

Given G and a set of preferred nodes R where $R \subseteq V$, we denote the relative importance for all $v \in V$ with respect to R as $I(v \mid R)$, following the work of White and Smyth (2003).

For a node v_k, we denote $N(k)$ as the set of neighbors of v_k. We use $\pi(k)$, the k-th component of the vector $\boldsymbol{\pi}$, to denote the stationary distribution of v_k where $1 \leq k \leq |V|$. We define a preference vector $\boldsymbol{p_R} = \{p_1, ..., p_{|V|}\}$ such that the probabilities sum to 1, and p_k denotes the relative importance attached to v_k. p_k is set to $1/|R|$ for $v_k \in R$, otherwise 0. Let $\boldsymbol{A}$ be the matrix corresponding to the graph G where $A_{jk} = 1/|N(k)|$ and $A_{jk} = 0$ otherwise.

For a given $\boldsymbol{p_R}$, we can obtain the personalized PageRank equation (Jeh and Widom, 2003):

$$\boldsymbol{\pi} = (1 - \beta)\boldsymbol{A\pi} + \beta\boldsymbol{p_R} \quad (1)$$

where $\beta \in [0, 1]$ determines how often surfers jump back to the nodes in R. We set $\beta = 0.3$ in our experiment. The solution π to Equation 1 is a steady-state importance distribution induced by $\boldsymbol{p_R}$. Based on a theorem of Markov Theory, a solution π with $\sum_{k=1}^{|V|} \pi(k) = 1$ always exists and is unique (Motwani and Raghavan, 1996).

We define relative importance scores based on the personalized ranks described above, *i.e.*, $I(v \mid R) = \pi(v)$ after convergence, and we compute the importance scores for all the nodes in V relative to Q and F respectively.

A query mention in a sentence is more likely to be involved in multiple relations while a filler is usually associated with only one slot type. Therefore we combine two relative importance scores by assigning a higher priority to $I(v \mid F)$ as follows.

$$\mathcal{I}(v \mid \{Q, F\}) = I(v \mid F) + I(v \mid F) \cdot I(v \mid Q) \quad (2)$$

We discard a trigger candidate if it is (or part of) an entity which can only act as a query or a slot filler. We assume a trigger can only be a noun, verb, adjective, adverb or preposition. In addition, verbs, nouns and adjectives are more informative to be triggers. Thus, we remove any trigger candidate v if it has a higher $\mathcal{I}(v \mid \{Q, F\})$ than the first top-ranked verb/noun/adjective trigger candidate.

For example, we rank the candidate triggers based on the query and slot filler pair ("*Dominick Dunne*", "*Ellen Griffin Dunne*") as shown in Figure 2.

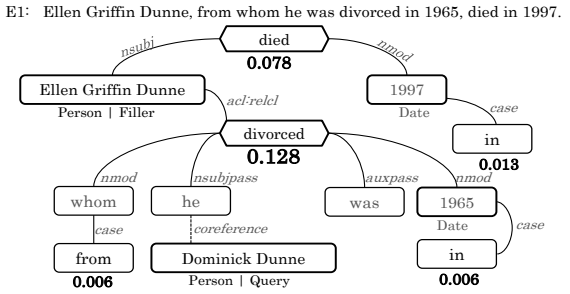

Figure 2: Importance scores of trigger candidates relative to query and filler in E1.

3.2 Trigger Candidate Selection

Given Q and F, we can obtain a relative importance score $\mathcal{I}(v \mid \{Q, F\})$ for each candidate trigger node v in V as shown in Section 3.1. We denote the set of trigger candidates as $T = \{t_1, \cdots, t_n\}$ where $n \leq |V|$.

Since a relation can be indicated by a single trigger word, a trigger phrase or even multiple non-adjacent trigger words, it is difficult to set a single threshold even for one slot type. Instead, we aim to automatically classify top ranked candidates into one group (*i.e.*, a trigger set) so that they all have similar higher scores compared to other candidates.

Therefore, we define this problem as a clustering task. We mainly consider clustering algorithms which do not require pre-specified number of clusters.

We apply the affinity propagation approach to take as input a collection of real-valued similarity scores between pairs of candidate triggers. Real-valued ***messages*** are exchanged between candidate triggers until a high-quality set of ***exemplars*** (centers of clusters), and corresponding clusters gradually emerges (Frey and Dueck, 2007).

There are two kinds of messages exchanged between candidate triggers: one is called ***responsibility*** $\gamma(i, j)$, sent from t_i to a candidate exemplar t_j; the other is ***availability*** $\alpha(i, j)$, sent from the candidate exemplar t_j to t_i.

The calculation of each procedure iterates until convergence. To begin with, the availabilities are initialized to zero: $\alpha(i, j) = 0$. Then the responsibilities are computed using the following rule:

$$\gamma(i, j) \leftarrow s(i, j) - \max_{j's.t.j' \neq j} \{\alpha(i, j') + s(i, j')\} \quad (3)$$

where the similarity score $s(i, j)$ indicates how well t_j is suited to be the exemplar for t_i. Whereas the above responsibility update lets all candidate exemplars compete for the ownership of a trigger candidate t_i, the following availability update gathers evidence from trigger candidates as to whether each candidate exemplar would make a good exemplar:

$$\alpha(i, j) \leftarrow \min \Big\{0, \gamma(j, j) + \sum_{i's.t.i' \notin \{i,j\}} \max\{0, \gamma(i', j)\}\Big\} \quad (4)$$

Given T, we can generate an $n \times n$ affinity matrix $\boldsymbol{M}$ which serves as the input of the affinity propagation. M_{ij} represents the negative squared difference in relative importance score between t_i and t_j (Equation 5).

$$M_{ij} = -(\mathcal{I}(i \mid \{Q, F\}) - \mathcal{I}(j \mid \{Q, F\}))^2 \quad (5)$$

We compute the average importance score for all the clusters after convergence and keep the one with the highest average score as the trigger set. For example, given the query and slot filler pair in Figure 3, we obtain trigger candidates $T = \{died, divorced, from, in, in\}$ and their corresponding relative importance scores. After the above clustering, we obtain three clusters and choose the cluster $\{divorced\}$ with the highest average relative importance score (0.128) as the trigger set.

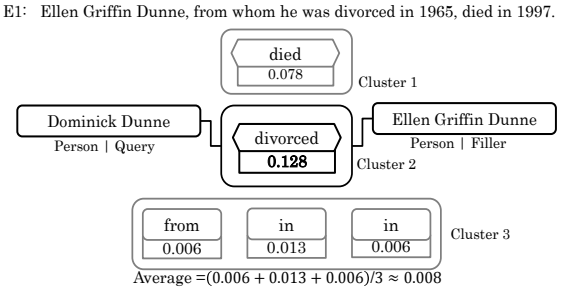

Figure 3: Trigger candidate filtering for E1.

4 Slot Type Labeling

In this section, we will introduce how to label the slot type for an identified relation tuple (Q, T, F). The simplest solution is to match T against existing trigger gazetteers for certain types of slots. For

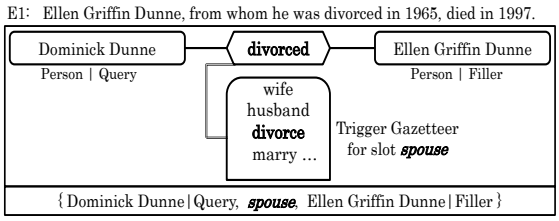

Figure 4: Example of slot type labeling.

example, Figure 4 shows how we label the relation as a *spouse* slot type.

In fact, some trigger gazetteers have already been constructed by previous work such as (Yu et al., 2015). However, manual construction of these triggers heavily rely upon labeled training data and high-quality patterns, which would be unavailable for a new language or a new slot type.

Inspired by the trigger-based event extraction work (Bronstein et al., 2015), we propose to extract trigger seeds from the slot filling annotation guideline [1] and then expand them by paraphrasing techniques. For each slot type we manually select two trigger seeds from the guideline and then use the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013; Pavlick et al., 2015) to expand these seeds. Specifically, we select top-20 lexical paraphrases based on similarity scores as our new triggers for each slot type. Some examples are shown in Table 2.

Seeds	Slot Types	Expanded Triggers
assassinate	*death*	kill, die, slay, murder
graduate	*schools*	PhD, supervisor, diploma
sister	*siblings*	twin, half-brother, sibling
marriage	*spouse*	married, spouse, matrimony

Table 2: PPDB-based trigger expansion examples.

5 Filler Validation

After we label each relation tuple, we perform the following validation steps to filter noise and remove redundancy. For many slot types, there are some specific constraints on entity types of slot fillers defined in the task specification. For example, *employee_or_member_of* fillers should be either organizations or geopolitical entities, while family slots (*e.g.*, *spouse* and *children*) expect person entities. We apply these constraints to further validate all relation tuples.

[1] http://www.nist.gov/tac/2015/KBP/ColdStart/guidelines/TAC_KBP_2015_Slot_Descriptions_V1.0.pdf

Moreover, ***single-value*** slots can only have a single filler (*e.g.*, *date_of_birth*), while ***list-value*** slots can take multiple fillers (*e.g.*, *cities_of_residence*). However, we might extract conflicting relation tuples from multiple sentences and sources. For each relation tuple, it can also be extracted from multiple sentences, and thus it may receive multiple relative importance scores. We aim to keep the most reliable relation tuple for a single-value slot.

For a single-value slot, suppose we have a collection of relation tuples R which share the same query. Given $r \in R$ with a set of relative importance scores $\mathcal{I} = \{i_1, i_2, \cdots, i_n\}$, we can regard the average score of $\mathcal{I}$ as the credibility score of r. The reason is that the higher the relative importance score, the more likely the tuple is to be correct. In our experiments, we use the weighted arithmetic mean as follows so that higher scores can contribute more to the final average:

$$\bar{i} = \frac{\sum_{k=1}^{n} w_k \cdot i_k}{\sum_{k=1}^{n} w_k} \quad (6)$$

where w_k denotes the non-negative weight of i_k. When we regard the weight w_k equal to the score i_k, Equation 6 can be simplified as:

$$\bar{i} = \frac{\sum_{k=1}^{n} w_k^2}{\sum_{k=1}^{n} w_k} \quad (7)$$

We calculate the weighted mean $\bar{i}$ for each $r \in R$ and keep the relation tuple with the highest $\bar{i}$.

6 Experiments

6.1 Data and Scoring Metric

In order to evaluate the quality of our proposed framework and its portability to a new language, we use TAC-KBP2013 English Slot Filling (ESF), TAC-KBP 2015 English Cold Start Slot Filling (CSSF) and TAC-KBP2015 Chinese Slot Filling (CSF) data sets for which we can compare with the ground truth and state-of-the-art results reported in previous work. The source collection includes news documents, web blogs and discussion forum posts. In ESF there are 50 person queries and on average 20 relevant documents per query; while in CSF there are 51 person queries, and on average 5 relevant documents per query.

Overall	**39.2**	27.6

Table 4: English Cold Start Slot Filling F_1 (%) (KBP2015 CSSF data set).

We only test our method on 18 trigger-driven person slot types shown in Table 3. Some other slot types (*e.g.*, *age*, *origin*, *religion* and *title*) do not rely on lexical triggers in most cases; instead the query mention and the filler are usually adjacent or seperated by a comma. In addition, we do not deal with the two remaining trigger-driven person slot types (*i.e.*, *cause_of_death* and *charges*) since these slots often expect other types of concepts (*e.g.*, a disease or a crime phrase).

We use the official TAC-KBP slot filling evaluation scoring metrics: *Precision* (P), *Recall* (R) and *F-score* (F_1) (Ji et al., 2010) to evaluate our results.

6.2 English Slot Filling

We apply Stanford CoreNLP (Manning et al., 2014) for English part-of-speech (POS) tagging, name tagging, time expression extraction, dependency parsing and coreference resolution. In Table 3 we compare our approach with two state-of-the-art English slot filling methods: a distant supervision method (Roth et al., 2013) and a hybrid method that combines distant and partial supervision (Angeli et al., 2014b). Our method outperforms both methods dramatically. KBP2015 English cold start slot filling is a task which combines entity mention extraction and slot filling (Surdeanu and Ji, 2014). Based on the released evaluation queries from KBP2015 Cold Start Slot Filling, our approach achieves 39.2% overall F-score on 18 person trigger-driven slot types, which is significantly better than state-of-the-art (Angeli et al., 2015) on the same set of news documents (Table 4).

Compared to the previous work, our method discards a trigger-driven relation tuple if it is not supported by triggers. For example, "*Poland*" is mistakenly extracted as the country of residence of "*Mandelbrot*" by distant supervision (Roth et al., 2013) from the following sentence:

A professor emeritus at Yale University, ***Mandelbrot*** *was born in* ***Poland*** *but as a child moved with his family to* ***France*** *where he was educated.*

maybe because the relation tuple (*Mandelbrot*, *live_in*, *Poland*) indeed exists in external knowledge bases. Given the same entity pair, our method identifies "*born*" as the trigger word and labels the slot type as *country_of_birth*.

When there are several triggers indicating different slot types in a sentence, our approach performs better in associating each trigger with the filler it dominates by analyzing the whole dependency tree. For example, given a sentence:

Haig *is survived by his wife of 60 years, Patricia; his children Alexander, Brian and* ***Barbara****; eight grandchildren; and his brother, the Rev. Francis R. Haig.*

(*Haig*, *sibling*, *Barbara*) is the only relation tuple extracted from the above sentence by the previous method. Given the entity pair (*Haig*, *Barbara*), the relative importance score of "*children*" (0.1) is higher than the score of "*brother*" (0.003),

and "*children*" is kept as the only trigger candidate after clustering. Therefore, we extract the tuple (*Haig*, *children*, *Barbara*) instead. In addition, we successfully identify the missing fillers for other slot types: *spouse* (*Patricia*), *children* (*Alexander, Brian and Barbara*) and *siblings* (*Francis R. Haig*) by identifying their corresponding triggers.

In addition, flat relation representations fail to extract the correct relation (*i.e.*, *alternate_names*) between "*Dandy Don*" and "*Meredith*" since "*brother*" is close to both of them in the following sentence:

In high school and at Southern Methodist University, where, already known as ***Dandy Don*** *(a nickname bestowed on him by his brother) ,* ***Meredith*** *became an all-American.*

6.3 Adapting to New Slot Types

Our framework can also be easily adapted to new slot types. We evaluate it on three new person list-value slot types: *friends*, *colleagues* and *collaborators*.

We use "*friend*" as the slot-specific trigger for the slot *friends* and "*colleague*" for the slot *colleagues*. "*collaborate*", "*cooperate*" and "*partner*" are used to type the slot *collaborators*.

We manually annotate ground truth for evaluation. It is difficult to find all the correct fillers for a given query from millions of documents. Therefore, we only calculate precision. Experiments show we can achieve 56.3% for *friends*, 100% for *colleagues* and 60% for *collaborators* (examples shown in Table 5).

6.4 Impact of Trigger Mining

In Section 3.2, we keep top-ranked trigger candidates based on clustering rather than threshold tuning. We explore a range of thresholds for comparison, as shown in Figure 5. Our approach achieves 57.4% F-score, which is comparable to the highest F-score 58.1% obtained by threshold tuning.

We also measure the impact of the size of the trigger gazetteer. We already outperform state-of-the-art by using PPDB to expand triggers mined from guidelines as shown in Table 6. As the size of the trigger gazetteer increases, our method (marked with a $\star$) achieves better performance.

6.5 Chinese Slot Filling

As long as we have the following resources: (1) a POS tagger, (2) a name tagger, (3) a dependency parser and (4) slot-specific trigger gazetteers, we can apply the framework to a new language. Coreference resolution is optional.

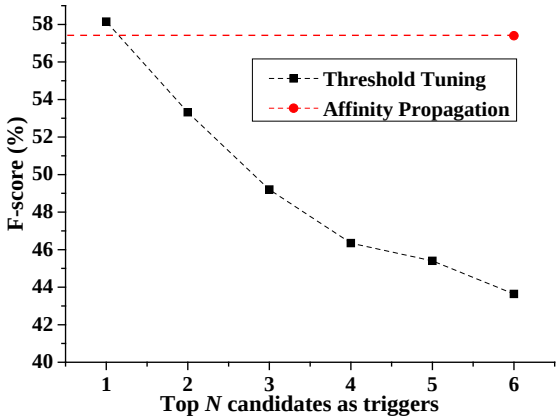

Figure 5: The effect of the number of trigger candidates on ESF.

Method	Size	F_1 (%)
State-of-the-art (Roth et al., 2013)	–	32.3
Guideline seeds*	20	27.3
Guideline seeds + PPDB expansion*	220	**38.9**
Manually Constructed Trigger Gazetteers*	7,463	**57.4**

Table 6: The effect of trigger gazetteers on ESF (size: the number of triggers).

We demonstrate the portability of our framework to Chinese since all the resources mentioned above are available. We apply Stanford CoreNLP (Manning et al., 2014) for Chinese POS tagging, name tagging (Wang et al., 2013) and dependency parsing (Levy and Manning, 2003). To explore the impact of the quality of annotation resources, we also use a Chinese language analysis tool: Language Technology Platform (LTP) (Che et al., 2010). We use the full set of Chinese trigger gazetteers published by Yu et al. (2015). Experimental results (Table 7) demonstrate that our approach can serve as a new and promising benchmark. As far as we know, there are no results available for comparison.

However, the performance of Chinese SF is heavily influenced by the relatively low performance of name tagging since our method returns an empty result if it fails to find any query metnion. About 20% and 16% queries cannot be recognized by CoreNLP and LTP respectively. One reason is that many Chinese names are also common words. For example, a buddhist monk's name "觉醒"(*wake*) is identified as a verb rather than a person entity.

Evidence Sentence	Slot Type	Query	Extracted Fillers
Many of ***his*** subjects were friends from his previous life , such as ***Elizabeth Taylor*** and ***Gloria Vanderbilt*** .	*friends*	Dominick Dunne	Gloria Vanderbilt; Elizabeth Taylor
Toby Keith hit an emotional note with a performance of "Cryin' For Me (Wayman's Song)," dedicated to ***his*** late friend, jazz artist and former basketball star ***Wayman Tisdale***, who died last May.	*friends*	Wayman Tisdale	Toby Keith
"I think all of her writing came from ***her*** heart," ***Michael Glaser***, a longtime colleague at St. Mary's and former Maryland poet laureate, said last week.	*colleagues*	Lucille Clifton	Michael Glaser
Cunningham has collaborated on two books: "Changes: Notes on Choreography," with Frances Starr, and "The Dancer and the Dance," with ***Jacqueline Lesschaeve***.	*collaborators*	Merce Cunningham	Jacqueline Lesschaeve

Table 5: Examples for new slot types.

A dependency parser is indispensable to produce reliable rankings of trigger candidates. Unfortunately, a high-quality parser for a new language is often not available because of language-specific features. For example, in Chinese a single sentence about a person's biography often contains more than five co-ordinated clauses, each of which includes a trigger. Therefore a dependency parser adapted from English often mistakenly identifies one of the triggers as a main predicate of the sentence.

In addition, Chinese is a very concise language. For example, a "[Person Name][Organization Suffix]"structure can indicate various different types of relations between the person name and the organization: "杨明牙医诊所"(*Yang Ming Clinic*) indicates ownership, "邵逸夫图书馆"(*Shao Yifu Library*) indicates sponsorship, "丰子恺研究中心"(*Feng Zikai Research Center*) indicates research theme, and "罗京治丧委员会"(*Luojing Commemoration Committee*) indicates commemoration. None of them includes an explicit trigger nor indicates employment relation. It requires more fine-grained dependency relation types to distinguish them.

Finally, compared to English, Chinese tends to have more variants for some types of triggers (e.g., there are at least 31 different titles for "*wife*"in Chinese). Some of them are implicit and require shallow inference. For example, "投奔"(*to seek shelter or asylum*) indicates a residence relation in most cases.

Slot Type	CoreNLP-based	LTP-based
siblings	40.0	**57.1**
other_family	**40.0**	0.0
spouse	40.0	**48.0**
children	19.0	**21.4**
parents	0.0	**25.0**
schools_attended	11.1	**17.1**
date_of_birth	**42.4**	0.0
date_of_death	**48.5**	0.0
state_of_birth	38.1	**52.2**
state_of_death	55.6	**70.0**
city_of_birth	**28.6**	26.7
city_of_death	33.3	**42.9**
country_of_birth	11.8	11.8
country_of_death	0.0	0.0
states_of_residence	**30.8**	29.6
cities_of_residence	27.3	**34.8**
country_of_residence	**6.5**	0.0
employee_of	31.0	**31.2**
Overall	**29.6**	28.3

Table 7: Chinese Slot Filling F_1 (%) (KBP2015 CSF data set).

7 Related Work

Besides the methods based on distant supervision (*e.g.*, (Surdeanu et al., 2010; Roth et al., 2013; Angeli et al., 2014b)) discussed in Section 6.2, pattern-based methods have also been proven to be effective in SF in the past years (Sun et al., 2011; Li et al., 2012; Yu et al., 2013). Dependency-based patterns achieve better performance since they can capture long-distance relations. Most of these approaches assume that a relation exists between Q and F if there is a dependency path connecting Q and F and all the words on the path are equally regarded as trigger candidates. We explore the complete graph structure of a sentence rather than chains/subgraphs as in previous work. Our previous research focused on identifying the relation between F and T by extracting filler candidates from the identified scope of a trigger (*e.g.*, (Yu et al., 2015)). We found that each slot-specific trigger has its own scope, and corresponding fillers seldom appear outside its scope. We did not compare with results from this previous approach which did not consider redundancy removal required in the official evaluations.

Soderland et al. (2013) built their SF system based on Open Information Extraction (IE) technology. Our method achieves much higher recall since dependency trees can capture the relations among query, slot filler and trigger in more complicated long sentences. In addition, our triggers are automatically labeled so that we do not need to design manual rules to classify relation phrases as in Open IE.

8 Conclusions and Future Work

In this paper, we demonstrate the importance of deep mining of dependency structures for slot filling. Our approach outperforms state-of-the-art and can be rapidly portable to a new language or a new slot type, as long as there exists capabilities of name tagging, POS tagging, dependency parsing and trigger gazetteers.

In the future we aim to label slot types based on contextual information as well as sentence structures instead of trigger gazetteers only. There are two primary reasons. First, a trigger can serve for multiple slot types. For example, slot *children* and its inverse slot *parents* share a subset of triggers. Second, a trigger word can have multiple different meanings. For example, a *sibling* trigger word "*sister*" can also represent a female member of a religious community. We attempt to combine multi-prototype approaches (*e.g.*, (Reisinger and Mooney, 2010)) to better disambiguate senses of trigger words.

Besides considering the cross-sentence conflicts, we also want to investigate the within-sentence conflicts caused by the competition of triggers. A trigger identified by our approach is the most important node in the dependency tree relative to the given entity pair. However, this trigger might be more important to another entity pair, which shares the same filler, in the same sentence. A promising solution is to rank all the entities in the sentence based on their importance relative to the identified trigger and the filler candidate.

Abstract

When a large-scale incident or disaster occurs, there is often a great demand for rapidly developing a system to extract detailed and new information from low-resource languages (LLs). We propose a novel approach to discover comparable documents in high-resource languages (HLs), and project Entity Discovery and Linking results from HLs documents back to LLs. We leverage a wide variety of language-independent forms from multiple data modalities, including image processing (image-to-image retrieval, visual similarity and face recognition) and sound matching. We also propose novel methods to learn entity priors from a large-scale HL corpus and knowledge base. Using Hausa and Chinese as the LLs and English as the HL, experiments show that our approach achieves 36.1% higher Hausa name tagging F-score over a costly supervised model, and 9.4% higher Chinese-to-English Entity Linking accuracy over state-of-the-art.

1 Introduction

In many situations such as disease outbreaks and natural calamities, we often need to develop an Information Extraction (IE) component (e.g., a name tagger) within a very limited time to extract information from low-resource languages (LLs) (e.g., locations where Ebola outbreaks from Hausa documents). The main challenge lies in the lack of labeled data and linguistic processing tools in these languages. A potential solution is to extract and project knowledge from high-resource languages (HLs) to LLs.

A large amount of non-parallel, domain-rich, topically-related comparable corpora naturally exist across LLs and HLs for breaking incidents, such as coordinated news streams (Wang et al., 2007) and code-switching social media (Voss et al., 2014; Barman et al., 2014). However, without effective Machine Translation techniques, even just identifying such data in HLs is not a trivial task. Fortunately many of such comparable documents are presented in multiple data modalities (text, image and video), because press releases with multimedia elements generate up to 77% more views than text-only releases (Newswire, 2011). In fact, they often contain the same or similar images and videos, which are language-independent.

In this paper we propose to use images as a hub to automatically discover comparable corpora. Then we will apply Entity Discovery and Linking (EDL) techniques in HLs to extract entity knowledge, and project results back to LLs by leveraging multi-source multi-media techniques. In the following we will elaborate motivations and detailed methods for two most important EDL components: name tagging and Cross-lingual Entity Linking (CLEL). For CLEL we choose Chinese as the LL and English as HL because Chinese-to-English is one of the few language pairs for which we have ground-truth annotations from official shared tasks (e.g., TAC-KBP (Ji et al., 2015)). Since Chinese name tagging is a well-studied problem, we choose Hausa instead of Chinese as the LL for name tagging experiment, because we can use the ground truth from the DARPA LORELEI program[1] for evaluation.

Entity and Prior Transfer for Name Tagging: In the first case study, we attempt to use HL extraction results directly to validate and correct names

[1] http://www.darpa.mil/program/low-resource-languages-for-emergent-incidents

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 54–65,
Berlin, Germany, August 7-12, 2016.

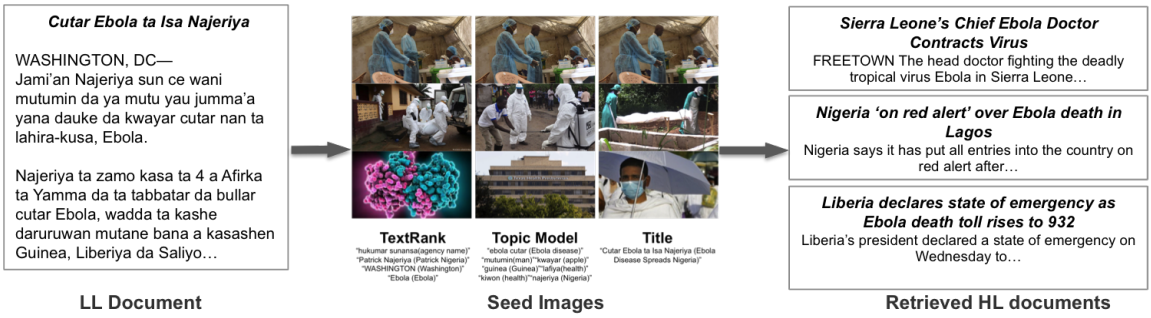

Figure 1: Image Anchored Comparable Corpora Retrieval.

extracted from LLs. For example, in the Hausa document in Figure 1, it would be challenging to identify the location name "*Najeriya*" directly from the Hausa document because it's different from its English counterpart. But since its translation "*Nigeria*" appears in the topically-related English document, we can use it to infer and validate its name boundary.

Even if topically-related documents don't exist in an HL, similar scenarios (e.g., disease outbreaks) and similar activities of the same entity (e.g., meetings among politicians) often repeat over time. Moreover, by running a high-performing HL name tagger on a large amount of documents, we can obtain ***entity prior*** knowledge which shows the probability of a related name appearing in the same context. For example, if we already know that "*Nigeria*", "*Borno*", "*Goodluck Jonathan*", "*Boko Haram*" are likely to appear, then we could also expect "*Mouhammed Ali Ndume*" and "*Mohammed Adoke*" might be mentioned because they were both important politicians appointed by Goodluck Jonathan to consider opening talks with Boko Haram. Or more generally if we know the LL document is about politics in China in 1990s, we could estimate that famous politicians during that time such as "*Deng Xiaoping*" are likely to appear in the document.

Next we will project these names extracted from HL documents directly to LL documents to identify and verify names. In addition to textual evidence, we check visual similarity to match an HL name with its equivalent in LL. And we apply face recognition techniques to verify person names by image search. This idea matches human knowledge acquisition procedure as well. For example, when a child is watching a cartoon and shifting between versions in two languages, s/he can easily infer translation pairs for the same concept whose images appear frequently (e.g., "宝宝 (*baby*)" and "螃蟹 (*crab*)" in "*Dora Exploration*", "海盗 (*pirate*)" in "*the Garden Guardians*", and "亨利 (*Henry*)" in "*Thomas Train*"), as illustrated in Figure 2.

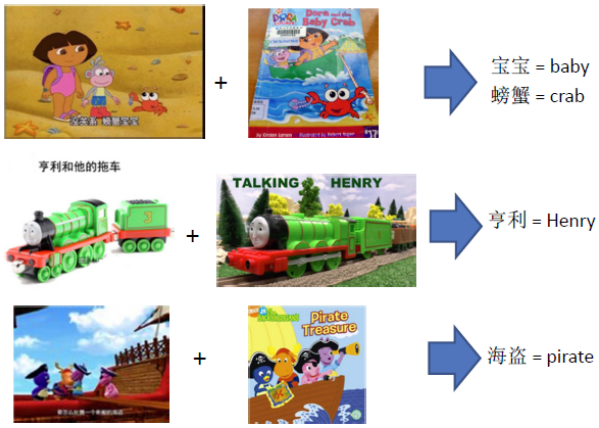

Figure 2: Examples of Cartoons in Chinese (left) and English (right).

Representation and Structured Knowledge Transfer for Entity Linking: Besides data sparsity, another challenge for low-resource language IE lies in the lack of knowledge resources. For example, there are advanced knowledge representation parsing tools available (e.g., Abstract Meaning Representation (AMR) (Banarescu et al., 2013)) and large-scale knowledge bases for English Entity Linking, but not for other languages, including some medium-resource ones such as Chinese. For example, the following documents are both about the event of Pistorius killing his girl friend Reeva:

- **LL document:** 南非残疾运动员皮斯托瑞斯被指控杀害女友瑞娃于其茨瓦内的家中。皮斯托瑞斯是南非著名的残疾人田径选手，有"刀锋战士"之称。...(*The disabled South African sportsman Oscar Pis-*

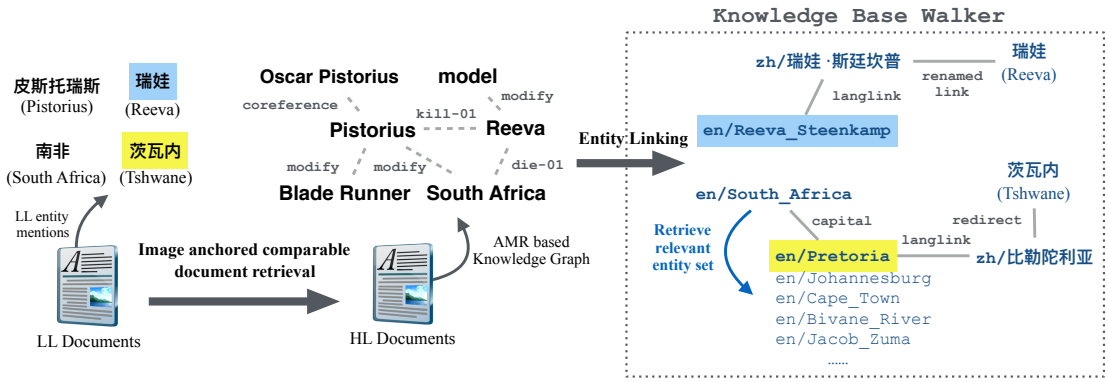

Figure 3: Cross-lingual Knowledge Transfer for Entity Linking.

torius was charged to killing his girl friend Reeva at his home in Tshwane. Pistorius is a famous runner in South Africa, also named as "Blade Runner"...)

- **HL document:** *In the early morning of Thursday, 14 February 2013, "Blade Runner" Oscar Pistorius shot and killed South African model Reeva Steenkamp...*

From the LL documents we may only be able to construct co-occurrence based knowledge graph and thus it's difficult to link rare entity mentions such as "瑞娃 (*Reeva*)" and "茨瓦内 (*Tshwane*)" to an English knowledge base (KB). But if we apply an HL (e.g., English) entity linker, we could construct much richer knowledge graphs from HL documents using deep knowledge representations such as AMR, as shown in Figure 3, and link all entity mentions to the KB accurately. Moreover, if we start to *walk* through the KB, we can easily reach from English related entities to the entities mentioned in LL documents. For example, we can walk from "*South Africa*" to its capital "*Pretoria*" in the KB, which is linked to its LL form "比勒陀利亚" through a language link and then is re-directed to "茨瓦内" mentioned in the LL document through a redirect link. Therefore we can infer that "茨瓦内" should be linked to "*Pretoria*" in the KB.

Compared to most previous cross-lingual projection methods, our approach does not require domain-specific parallel corpora or lexicons, or in fact, any parallel data at all. It also doesn't require any labeled data in LLs. Using Hausa and Chinese as the LLs and English as HL for case study, experiments demonstrate that our approach can achieve 36.1% higher Hausa name tagging over a costly supervised model trained from 337 documents, and 9.4% higher Chinese-to-English Entity Linking accuracy over a state-of-the-art system.

2 Approach Overview

Figure 4 illustrates the overall framework. It consists of two steps: (1) Apply language-independent key phrase extraction methods on each LL document, then use key phrases as a query to retrieve seed images, and then use the seed images to retrieve matching images, and retrieve HL documents containing these images (Section 3); (2) Extract knowledge from HL documents, and design knowledge transfer methods to refine LL extraction results.

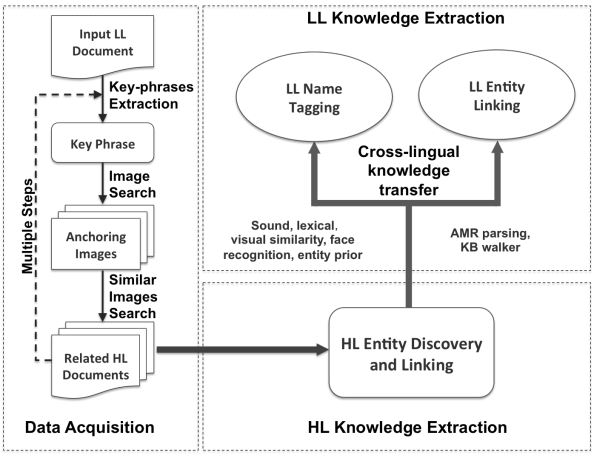

Figure 4: Overall Framework.

We will present two case studies on name tagging (Section 5) and cross-lingual entity linking (CLEL) (Section 6) respectively. Our projection approach consists of a series of non-traditional multi-media multi-source methods based on textual and visual similarity, face recognition, as well as entity priors learned from both unstructured data and structured KB.

3 Comparable Corpora Discovery

In this section we will describe the detailed steps of acquiring HL documents for a given LL document via anchoring images. Using a cluster of images as a hub, we attempt to connect topically-related documents in LL and HL. We will walk through each step for the motivating example in Figure 1.

3.1 Key Phrase Extraction

For an LL document (e.g., Figure 1 for the walk-through example), we start by extracting its key phrases using the following three language-independent methods: (1) TextRank (Mihalcea and Tarau, 2004), which is a graph-based ranking model to determine key phrases. (2) Topic modeling based on Latent Dirichlet allocation (LDA) model (Blei et al., 2003), which can generate a small number of key phrases representing the main topics of each document. (3) The title of the document if it's available.

3.2 Seed Image Retrieval

Using the extracted key phrases together as one single query, we apply Google Image Search to retrieve top 15 ranked images as seeds. To reduce the noise introduced by image search, we filter out images smaller than 100×100 pixels because they are unlikely to appear in the main part of web pages. We also filter out an image if its web page contains less than half of the tokens in the query. Figure 1 shows the anchoring images retrieved for the walk-through example.

3.3 HL Document Retrieval

Using each seed image, we apply Google image-to-image search to retrieve more matching images, and then use the TextCat tool (Cavnar et al., 1994) as a language identifier to select HL documents containing these images. It shows three English documents retrieved for the first image in Figure 1.

For related topics, more images may be available in HLs than LLs. To compensate this data sparsity problem, using the HL documents retrieved as a seed set, we repeat the above steps one more time by extracting key phrases from the HL seed set to retrieve more images and gather more HL documents. For example, a Hausa document about "*Arab Spring*" includes protests that happened in Algeria, Bahrain, Iran, Libya, Yemen and Jordan. The HL documents retrieved by LL key phrases and images in the first step missed the detailed information about protests in Iran. However the second step based on key phrases and images from HL successfully retrieved detailed related documents about protests in Iran.

Applying the above multimedia search, we automatically discover domain-rich non-parallel data. Next we will extract facts from HLs and project them to LLs.

4 HL Entity Discovery and Linking

4.1 Name Tagging

After we acquire HL (English in this paper) comparable documents, we apply a state-of-the-art English name tagger (Li et al., 2014) based on structured perceptron to extract names. From the output we filter out uninformative names such as news agencies. If the same name receives multiple types across documents, we use the majority one.

4.2 Entity Linking

We apply a state-of-the-art Abstract Meaning Representation (AMR) parser (Wang et al., 2015a) to generate rich semantic representations. Then we apply an AMR based entity linker (Pan et al., 2015) to link all English entity mentions to the corresponding entities in the English KB. Given a name n_h, this entity linker first constructs a Knowledge Graph $g(n_h)$ with n_h at the hub and leaf nodes obtained from names reachable by AMR graph traversal from n_h. A subset of the leaf nodes are selected as collaborators of n_h. Names connected by AMR conjunction relations are grouped into sets of coherent names. For each name n_h, an initial ranked list of entity candidates $\mathcal{E} = \{e_1, ..., e_M\}$ is generated based on a salience measure (Medelyan and Legg, 2008). Then a Knowledge Graph $g(e_m)$ is generated for each entity candidate e_m in n_h's entity candidate list $\mathcal{E}$. The entity candidates are then re-ranked according to Jaccard Similarity, which computes the similarity between $g(n_h)$ and $g(e_m)$: $J(g(n_h), g(e_m)) = \frac{|g(n_h)\cap g(e_m)|}{|g(n_h)\cup g(e_m)|}$. Finally, the entity candidate with the highest score is selected as the appropriate entity for n_h. Moreover, the Knowledge Graphs of coherent mentions will be merged and linked collectively.

4.3 Entity Prior Acquisition

Given the English entities discovered from the above, we aim to automatically mine related en-

tities to further expand the expected entity set. We use a large English corpus and English knowledge base respectively as follows.

If a name n_h appears frequently in these retrieved English documents,[2] we further mine other related names n'_h which are very likely to appear in the same context as n_h in a large-scale news corpus (we use English Gigaword V5.0 corpus[3] in our experiment). For each pair of names $\langle n'_h, n_h \rangle$, we compute $P(n'_h|n_h)$ based on their co-occurrences in the same sentences. If $P(n'_h|n_h)$ is larger than a threshold,[4] and n'_h is a person name, then we add n'_h into the expected English name set.

Let $\mathcal{E}^0 = \{e_1, ..., e_N\}$ be the set of entities in the KB that all mentions in English documents are linked to. For each $e_i \in \mathcal{E}^0$, we 'walk' one step from it in the KB to retrieve all of its neighbors $\mathcal{N}(e_i)$. We denote the set of neighbor nodes as $\mathcal{E}^1 = \{\mathcal{N}(e_1), ..., \mathcal{N}(e_N)\}$. Then we extend the expected English entity set as $\mathcal{E}^0 \cup \mathcal{E}^1$. Table 1 shows some retrieved neighbors for entity "*Elon Musk*".

Relation	Neighbor
is founder of	SpaceX
is founder of	Tesla Motors
is spouse of	Justine Musk
birth place	Pretoria
alma mater	University of Pennsylvania
parents	Errol Musk
relatives	Kimbal Musk

Table 1: Neighbors of Entity "*Elon Musk*".

5 Knowledge Transfer for Name Tagging

In this section we will present the first case study on name tagging, using English as HL and Hausa as LL.

5.1 Name Projection

After expanding the English expected name set using entity prior, next we will try to carefully select, match and project each expected name (n_h) from English to the one (n_l) in Hausa documents. We scan through every n-gram (n in the order 3, 2, 1) in Hausa documents to see if any of them match an English name based on the following multi-media language-independent low-cost heuristics.

Spelling: If n_h and n_l are identical (e.g., "*Brazil*"), or with an edit distance of one after lower-casing and removing punctuation (e.g., n_h = "*Mogadishu*" and n_l = "*Mugadishu*"), or substring match (n_h = "*Denis Samsonov*" and n_l = "*Samsonov*").

Pronunciation: We check the pronunciations of n_h and n_l based on Soundex (Odell, 1956), Metaphone (Philips, 1990) and NYSIIS (Taft, 1970) algorithms. We consider two codes match if they are exactly the same or one code is a part of the other. If at least two coding systems match between n_h and n_l, we consider they are equivalents.

Visual Similarity: When two names refer to the same entity, they usually share certain visual patterns in their related images. For example, using the textual clues above is not sufficient to find the Hausa equivalent "*Majalisar Dinkin Duniya*" for "*United Nations*", because their pronunciations are quite different. However, Figure 5 shows the images retrieved by "*Majalisar Dinkin Duniya*" and "*United Nations*" are very similar.[5]

We first retrieve top 50 images for each mention using Google image search. Let $\mathcal{I}_h$ and $\mathcal{I}_l$ denote two sets of images retrieved by an n_h and a candidate n_l (e.g., n_h = "*United Nations*" and n_l = "*Majalisar Dinkin Duniya*" in Figure 5), $i_h \in \mathcal{I}_h$ and $i_l \in \mathcal{I}_l$. We apply the Scale-invariant feature transform (SIFT) detector (Lowe, 1999) to count the number of matched key points between two images, $K(i_h, i_l)$, as well as the key points in each image, $P(i_h)$ and $P(i_l)$. SIFT key point is a circular image region with an orientation, which can provide feature description of the object in the image. Key points are maxima/minima of the Difference of Gaussians after the image is convolved with Gaussian filters at different scales. They usually lie in high-contrast regions. Then we define the similarity ($0 \sim 1$) between two phrases as:

$$S(n_h, n_l) = \max_{i_h \in \mathcal{I}_h} \max_{i_l \in \mathcal{I}_l} \frac{K(i_h, i_l)}{\min(P(i_h), P(i_l))} \quad (1)$$

Based on empirical results from a separate small development set, we decide two phrases match if $S(n_h, n_l) > 10\%$. This visual similarity computation method, though seemingly simple, has been

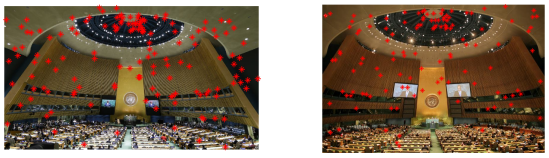
[2] for our experiment we choose those that appear more than 10 times

[3] https://catalog.ldc.upenn.edu/LDC2011T07

[4] 0.02 in our experiment.

[5] Although existing Machine Translation (MT) tools like Google Translate can correctly translate this example phrase from Hausa to English, here we use it as an example to illustrate the low-resource setting when direct MT is not available.

one of the principal techniques in detecting near-duplicate visual content (Ke et al., 2004).



(a) Majalisar Dinkin Duniya (b) United Nations

Figure 5: Matched SIFT Key points.

5.2 Person Name Verification through Face Recognition

For each name candidate, we apply Google image search to retrieve top 10 images (examples in Figure 6). If more than 5 images contain and only contain 1-2 faces, we classify the name as a person. We apply face detection technique based on Haar Feature (Viola and Jones, 2001). This technique is a machine learning based approach where a cascade function is trained from a large amount of positive and negative images. In the future we will try other alternative methods using different feature sets such as Histograms of Oriented Gradients (Dalal and Triggs, 2005).

Figure 6: Face Recognition for Validating Person Name 'Nawaz Shariff'.

6 Knowledge Transfer for Entity Linking

In this section we will present the second case study on Entity Linking, using English as HL and Chinese as LL. We choose this language pair because its ground-truth Entity Linking annotations are available through the TAC-KBP program (Ji et al., 2015).

6.1 Baseline LL Entity Linking

We apply a state-of-the-art language-independent cross-lingual entity linking approach (Wang et al., 2015b) to link names from Chinese to an English KB. For each name n, this entity linker uses the cross-lingual surface form dictionary $\langle f, \{e_1, e_2, ..., e_M\}\rangle$, where $\mathcal{E} = \{e_1, e_2, ..., e_M\}$ is the set of entities with surface form f in the KB according to their properties (e.g., labels, names, aliases), to locate a list of candidate entities $e \in \mathcal{E}$ and compute the importance score by an entropy based approach.

6.2 Representation and Structured Knowledge Transfer

Then for each expected English entity e_h, if there is a cross-lingual link to link it to an LL (Chinese) entry e_l in the KB, we added the title of the LL entry or its redirected/renamed page c_l as its LL translation. In this way we are able to collect a set of pairs of $\langle c_l, e_h\rangle$, where c_l is an expected LL name, and e_h is its corresponding English entity in the KB. For example, in Figure 3, we can collect pairs including "(瑞娃, *Reeva Steenkamp*)", "(瑞娃·斯廷坎普, *Reeva Steenkamp*)", "(茨瓦内, *Pretoria*)" and "(比勒陀利亚, *Pretoria*)". For each mention in an LL document, we then check whether it matches any c_l, if so then use e_h to override the baseline LL Entity Linking result. Table 2 shows some $\langle c_l, e_h\rangle$ pairs with frequency. Our approach not only successfully retrieves translation variants of "*Beijing*" and "*China Central TV*", but also alias and abbreviations.

e_h	e_l	c_l	Freq.
Beijing	北京市	北京(Beijing)	553
		北京市(Beijing City)	227
		燕京(Yanjing)	15
		京师(Jingshi)	3
		北平(Beiping)	2
		首都(Capital)	1
		蓟(Ji)	1
		燕都(Yan capital)	1
China Central TV	中国中央电视台	央视(Central TV)	19
		CCTV	16
		中央电视台(Central TV)	13
		中国央视(China Central TV)	3

Table 2: Representation and Structured Knowledge Transfer for Expected English Entities "*Beijing*" and "*China Central TV*".

7 Experiments

In this section we will evaluate our approach on name tagging and Cross-lingual Entity Linking.

7.1 Data

For name tagging, we randomly select 30 Hausa documents from the DARPA LORELEI program as our test set. It includes 63 person names (PER), 64 organizations (ORG) 225 geo-political entities

(GPE) and locations (LOC). For this test set, in total we retrieved 810 topically-related English documents. We found that 80% names in the ground truth appear at least once in the retrieved English documents, which shows the effectiveness of our image-anchored comparable data discovery method.

For comparison, we trained a supervised Hausa name tagger based on Conditional Random Fields (CRFs) from the remaining 337 labeled documents, using lexical features (character ngrams, adjacent tokens, capitalization, punctuations, numbers and frequency in the training data).

We learn entity priors by running the Stanford name tagger (Manning et al., 2014) on English Gigaword V5.0 corpus.[6] The corpus includes 4.16 billion tokens and 272 million names (8.28 million of which are unique).

For Cross-lingual Entity Linking, we use 30 Chinese documents from the TAC-KBP2015 Chinese-to-English Entity Linking track (Ji et al., 2015) as our test set. It includes 678 persons, 930 geo-political names, 437 organizations and 88 locations. The English KB is derived from BaseKB, a cleaned version of English Freebase. 89.7% of these mentions can be linked to the KB. Using the multi-media approach, we retrieved 235 topically-related English documents.

7.2 Name Tagging Performance

Table 3 shows name tagging performance. We can see that our approach dramatically outperforms the supervised model. We conduct the Wilcoxon Matched-Pairs Signed-Ranks Test on ten folders. The results show that the improvement using visual evidence is significant at a 95% confidence level and the improvement using entity prior is significant at a 99% confidence level. Visual Evidence greatly improves organization tagging because most of them cannot be matched by spelling or pronunciation.

Face detection helps identify many person names missed by the supervised name tagger. For example, in the following sentence, "*Nawaz Shariff*" is mistakenly classified as a location by the supervised model due to the designator "*kasar (country)*" appearing in its left context. Since faces can be detected from all of the top 10 retrieved images (Figure 6), we fix its type to person.

- **Hausa document**: "*Yansanda sun dauki wannan matakin ne kwana daya bayanda PM kasar* ***Nawaz Shariff*** *ya fidda sanarwar inda ya bukaci...* (*The Police took this step a day after the PM of the country* ***Nawaz Shariff*** *threw out the statement in which he demanded that...*)"

[6] https://catalog.ldc.upenn.edu/LDC2011T07

Face detection is also effective to resolve classification ambiguity. For example, the common person name "*Haiyan*" can also be used to refer to the Typhoon in Southeast Asia. Both of our HL and LL name taggers mistakenly label "*Haiyan*" as a person in the following documents:

- **Hausa document**: "*...a yayinda mahaukaciyar guguwar teku da aka lakawa suna* ***Haiyan*** *ta fada tsibiran Leyte da Samar.* (*...as the violent typhoon, which has been given the name,* ***Haiyan****, has swept through the island of Leyte and Samar.*)"

- **Retrieved English comparable document**: "*As* ***Haiyan*** *heads west toward Vietnam, the Red Cross is at the forefront of an international effort to provide food, water, shelter and other relief...*"

In contrast using face detection results we successfully remove it based on processing the retrieved images as shown in Figure 7.

Figure 7: Top 9 Retrieved Images for 'Haiyan'.

Entity priors successfully provide more detailed and richer background knowledge than the comparable English documents. For example, the main topic of one Hausa document is the former president of Nigeria *Olusegun Obasanjo* accusing the current President *Goodluck Jonathan*, and a comment by the former 1990s military administrator of Kano *Bawa Abdullah Wase* is quoted. But *Bawa Abdullah Wase* is not mentioned in any related English documents. However, based on entity priors we observe that "*Bawa Abdullah Wase*" appears frequently in the same contexts as "*Nigeria*" and "*Kano*", and thus we successfully project it back to the Hausa sentence: "*Haka ma* ***Bawa Abdullahi Wase*** *ya ce akawai abun dubawa a kalamun*

System	Identification F-score				Classification Accuracy	Overall F-score
	PER	ORG	LOC[7]	ALL		
Supervised	36.52	38.64	42.38	40.25	76.84	30.93
Our Approach	**77.69**	**60.00**	**70.55**	**70.59**	**95.00**	**67.06**
Our Approach w/o Visual Evidence	73.77	46.58	70.74	67.98	94.77	64.43
Our Approach w/o Entity Prior	64.91	60.00	70.55	67.59	94.71	64.02

Table 3: Name Tagging Performance (%).

tsohon shugaban kasa kuma tsohon jamiin tsaro. (*In the same vein, Bawa Abdullahi Wase said that there were things to take away from the former President's words.*)". The impact of entity priors on person names is much more significant than other categories because multiple person entities often co-occur in some certain events or related topics which might not be fully covered in the retrieved English documents. In contrast most expected organizations and locations already exist in the retrieved English documents.

For the same local topic, Hausa documents usually describe more details than English documents, and include more unsalient entities. For example, for the president election in Ivory Coast, a Hausa document mentions the officials of the electoral body such as "*Damana Picasse*": "*Wani wakilin hukumar zaben daga jamiyyar shugaba Gbagbo,* ***Damana Picasse****, ya kekketa takardun sakamakon a gaban yan jarida, ya kuma ce ba na halal ba ne.* (*An official of the electoral body from president Gbagbo's party, Damana Picasse, tore up the result document in front of journalists, and said it is not legal.*)". In contrast, no English comparable documents mention their names. The entity prior method is able to extract many names which appear frequently together with the president name "*Gbagbo*".

7.3 Entity Linking Performance

Table 4 presents the Cross-lingual Entity Linking performance. We can see that our approach significantly outperforms our baseline and the best reported results on the same test set (Ji et al., 2015). Our approach is particularly effective for rare nicknames (e.g., "*C罗*" (C Luo) is used to refer to *Cristiano Ronaldo*) or ambiguous abbreviations (e.g., "*邦联*" (federal) can refer to *Confederate States of America*, *邦联制* (*Confederation*) and many other entities) for which the contexts in LLs are not sufficient for making correct linking decisions due to the lack of rich knowledge representation. Our approach produces worse linking results than the baseline for a few cases when the same abbreviation is used to refer to multiple entities in the same document. For example, when "*巴*" is used to refer to both "*巴西* (*Brazil*)" or "*巴勒斯坦* (*Palestine*)" in the same document, our approach mistakenly links all mentions to the same entity.

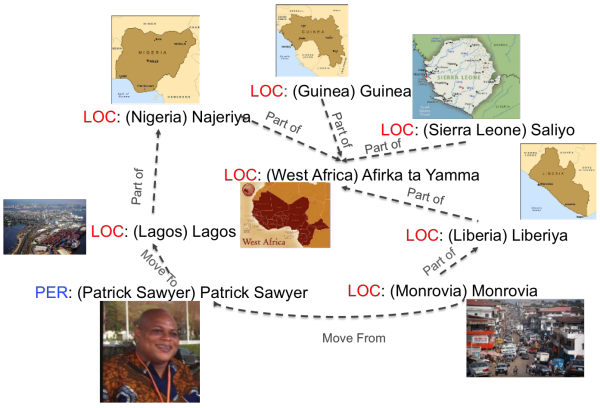


Figure 8: An Example of Cross-lingual Cross-media Knowledge Graph.

7.4 Cross-lingual Cross-media Knowledge Graph

As an end product, our framework will construct cross-lingual cross-media knowledge graphs. An example about the Ebola scenario is presented in Figure 8, including entity nodes extracted from both Hausa (LL) and English (HL), anchored by images; and edges extracted from English.

8 Related Work

Some previous cross-lingual projection methods focused on transferring data/annotation (e.g., (Padó and Lapata, 2009; Kim et al., 2010; Faruqui and Kumar, 2015)), shared feature representation/model (e.g., (McDonald et al., 2011; Kozhevnikov and Titov, 2013; Kozhevnikov and Titov, 2014)), or expectation (e.g., (Wang and Manning, 2014)). Most of them relied on a large

Table 4: Cross-lingual Entity Linking Accuracy (%).

amount of parallel data to derive word alignment and translations, which are inadequate for many LLs. In contrast, we do not require any parallel data or bi-lingual lexicon. We introduce new cross-media techniques for projecting HLs to LLs, by inferring projections using domain-rich, non-parallel data automatically discovered by image search and processing. Similar image-mediated approaches have been applied to other tasks such as cross-lingual document retrieval (Funaki and Nakayama, 2015) and bilingual lexicon induction (Bergsma and Van Durme, 2011). Besides visual similarity, their method also relied on distributional similarity computed from a large amount of unlabeled data, which might not be available for some LLs.

Our name projection and validation approaches are similar to other previous work on bi-lingual lexicon induction from non-parallel corpora (e.g., (Fung and Yee, 1998; Rapp, 1999; Shao and Ng, 2004; Munteanu and Marcu, 2005; Sproat et al., 2006; Klementiev and Roth, 2006; Hassan et al., 2007; Udupa et al., 2009; Ji, 2009; Darwish, 2010; Noeman and Madkour, 2010; Bergsma and Van Durme, 2011; Radford et al., ; Irvine and Callison-Burch, 2013; Irvine and Callison-Burch, 2015)) and name translation mining from multilingual resources such as Wikipedia (e.g. (Sorg and Cimiano, 2008; Adar et al., 2009; Nabende, 2010; Lin et al., 2011)). We introduce new multimedia evidence such as visual similarity and face recognition for name validation, and also exploit a large amount of monolingual HL data for mining entity priors to expand the expected entity set.

For Cross-lingual Entity Linking, some recent work (Finin et al., 2015) also found cross-lingual coreference resolution can greatly reduce ambiguity. Some other methods also utilized global knowledge in the English KB to improve linking accuracy via quantifying link types (Wang et al., 2015b), computing pointwise mutual information for the Wikipedia categories of consecutive pairs of entities (Sil et al., 2015), or using linking as feedback to improve name classification (Sil and Yates, 2013; Heinzerling et al., 2015; Besancon et al., 2015; Sil et al., 2015).

9 Conclusions and Future Work

We describe a novel multi-media approach to effectively transfer entity knowledge from high-resource languages to low-resource languages. In the future we will apply visual pattern recognition and concept detection techniques to perform deep content analysis of the retrieved images, so we can do matching and inference on concept/entity level instead of shallow visual similarity. We will also extend anchor image retrieval from document-level into phrase-level or sentence-level to obtain richer background information. Furthermore, we will exploit edge labels while walking through a knowledge base to retrieve more relevant entities. Our long-term goal is to extend this framework to other knowledge extraction and population tasks such as event extraction and slot filling to construct multimedia knowledge bases effectively from multiple languages with low cost.

Abstract

We apply phrase-based and neural models to a core task in interactive machine translation: suggesting how to complete a partial translation. For the phrase-based system, we demonstrate improvements in suggestion quality using novel objective functions, learning techniques, and inference algorithms tailored to this task. Our contributions include new tunable metrics, an improved beam search strategy, an n-best extraction method that increases suggestion diversity, and a tuning procedure for a hierarchical joint model of alignment and translation. The combination of these techniques improves next-word suggestion accuracy dramatically from 28.5% to 41.2% in a large-scale English-German experiment. Our recurrent neural translation system increases accuracy yet further to 53.0%, but inference is two orders of magnitude slower. Manual error analysis shows the strengths and weaknesses of both approaches.

1 Introduction

A core prediction task in interactive machine translation (MT) is to complete a partial translation (Ortiz-Martínez et al., 2009; Koehn et al., 2014). Sentence completion enables interfaces that are richer than basic post-editing of MT output. For example, the translator can receive updated suggestions after each word typed (Langlais et al., 2000). However, we show that completing partial translations by naïve constrained decoding—the standard in prior work—yields poor suggestion quality. We describe new phrase-based objective functions, learning techniques, and inference algorithms for the sentence completion task.[1] We then compare this improved phrase-based system to a state-of-the-art recurrent neural translation system in large-scale English-German experiments.

A system for completing partial translations takes as input a source sentence and a prefix of the target sentence. It predicts a suffix: a sequence of tokens that extends the prefix to form a full sentence. In an interactive setting, the first words of the suffix are critical; these words are the focus of the user's attention and can typically be appended to the translation with a single keystroke. We introduce a tuning metric that scores correctness of the whole suffix, but is particularly sensitive to these first words.

Phrase-based inference for this task involves aligning the prefix to the source, then generating the suffix by translating the unaligned words. We describe a beam search strategy and a hierarchical joint model of alignment and translation that together improve suggestions dramatically. For English-German news, next-word accuracy increases from 28.5% to 41.2%.

An interactive MT system could also display multiple suggestions to the user. We describe an algorithm for efficiently finding the n-best next words directly following a prefix and their corresponding best suffixes. Our experiments show that this approach to n-best list extraction, combined with our other improvements, increased next-word suggestion accuracy of 10-best lists from 33.4% to 55.5%.

We also train a recurrent neural translation system to maximize the conditional likelihood of the next word following a translation prefix, which is both a standard training objective in neural translation and an ideal fit for our task. This neural system provides even more accurate predictions than our improved phrase-based system. However, inference is two orders of magnitude slower, which is prob-

Berlin, Germany, August 7-12, 2016.

lematic for an interactive setting. We conclude with a manual error analysis that reveals the strengths and weaknesses of both the phrase-based and neural approaches to suffix prediction.

2 Evaluating Suffix Prediction

Let $\mathcal{F}$ and $\mathcal{E}$ denote the set of all source and target language strings, respectively. Given a source sentence $f \in \mathcal{F}$ and target prefix $e_p \in \mathcal{E}$, a predicted suffix $e_s \in \mathcal{E}$ can be evaluated by comparing the full sentence $e = e_p e_s$ to a reference e^*. Let e^*_s denote the suffix of the reference that follows e_p.

We define three metrics below that score translations by the characteristics that are most relevant in an interactive setting: the accuracy of the first words of the suffix and the overall quality of the suffix. Each metric takes example triples (f, e_p, e^*) produced during an interactive MT session in which e_p was generated in the process of constructing e^*.

A *simulated* corpus of examples can be produced from a parallel corpus of (f, e^*) pairs by selecting prefixes of each e^*. An *exhaustive* simulation selects all possible prefixes, while a *sampled* simulation selects only k prefixes uniformly at random for each e^*. Computing metrics for exhaustive simulations is expensive because it requires performing suffix prediction inference for every prefix: $|e^*|$ times for each reference.

Word Prediction Accuracy (WPA) or *next-word accuracy* (Koehn et al., 2014) is 1 if the first word of the predicted suffix e_s is also the first word of reference suffix e^*_s, and 0 otherwise. Averaging over examples gives the frequency that the word following the prefix was predicted correctly. In a sampled simulation, all reference words that follow the first word of a sampled suffix are ignored by the metric, so most reference information is unused.

Number of Predicted Words (#prd) is the maximum number of contiguous words at the start of the predicted suffix that match the reference. Like WPA, this metric is 0 if the first word of e_s is not also the first word of e^*_s. In a sampled simulation, all reference words that follow the first mis-predicted word in the sampled suffix are ignored. While it is possible that the metric will require the full reference suffix, most reference information is unused in practice.

Prefix-BLEU (pxBLEU): BLEU (Papineni et al., 2002) is computed from the geometric mean of clipped n-gram precisions $prec_n(\cdot, \cdot)$ and a brevity penalty $BP(\cdot, \cdot)$. Given a sequence of references $E^* = e^*_1, \ldots, e^*_t$ and corresponding predictions $E = e_1, \ldots, e_t$,

$$\textsc{Bleu}(E, E^*) = BP(E, E^*) \cdot \prod_{n=1}^{4} prec_n(E, E^*)^{\frac{1}{4}}$$

Ortiz-Martínez et al. (2010) use BLEU directly for training an interactive system, but we propose a variant that only scores the predicted suffix and not the input prefix. The pxBLEU metric computes $\textsc{Bleu}(\hat{E}, \hat{E}^*)$ for the following constructed sequences $\hat{E}$ and $\hat{E}^*$:

- For each (f, e_p, e^*) and suffix prediction e_s, $\hat{E}$ includes the full sentence $e = e_p e_s$.
- For each (f, e_p, e^*), $\hat{E}^*$ is a masked copy of e^* in which all prefix words that do not match any word in e are replaced by null tokens.

This construction maintains the original computation of the brevity penalty, but does not include the prefix in the precision calculations. Unlike the two previous metrics, the pxBLEU metric uses all available reference information.

In order to account for boundary conditions, the reference e^* is masked by the prefix e_p as follows: we replace each of the first $|e_p - 3|$ words with a null token e_{null}, unless the word also appears in the suffix e^*_s. Masking retains the last three words of the prefix so that the first words after the prefix can contribute to the precision of all n-grams that overlap with the prefix, up to $n = 4$. Words that also appear in the suffix are retained so that their correct prediction in the suffix can contribute to those precisions, which would otherwise be clipped.

2.1 Loss Functions for Learning

All of these metrics can be used as the tuning objective of a phrase-based machine translation system. Tuning toward a sampled simulation that includes one or two prefixes per reference is much faster than using an exhaustive set of prefixes. A linear combination of these metrics can be used to trade off the relative importance of the full suffix and the words immediately following the prefix. With a combined metric, learning can focus on these words while using all available information in the references.

2.2 Keystroke Ratio (KSR)

In addition to these metrics, suffix prediction can be evaluated by the widely used keystroke ratio (KSR) metric (Och et al., 2003). This ratio assumes that

any number of characters from the beginning of the suggested suffix can be appended to the user prefix using a single keystroke. It computes the ratio of key strokes required to enter the reference interactively to the character count of the reference. Our MT architecture does not permit tuning to KSR.

Other methods of quantifying effort in an interactive MT system are more appropriate for user studies than for direct evaluation of MT predictions. For example, measuring pupil dilation, pause duration and frequency (Schilperoord, 1996), mouse-action ratio (Sanchis-Trilles et al., 2008), or source difficulty (Bernth and McCord, 2000) would certainly be relevant for evaluating a full interactive system, but are beyond the scope of this work.

3 Phrase-Based Inference

In the log-linear approach to phrase-based translation (Och and Ney, 2004), the distribution of translations $e \in \mathcal{E}$ given a source sentence $f \in \mathcal{F}$ is:

$$p(e|f;w) = \sum_{\substack{r: \\ src(r)=f \\ tgt(r)=e}} \frac{1}{Z(f)} \exp\left[w^\top \phi(r)\right] \quad (1)$$

Here, r is a phrasal derivation with source and target projections $src(r)$ and $tgt(r)$, $w \in \mathbb{R}^d$ is the vector of model parameters, $\phi(\cdot) \in \mathbb{R}^d$ is a feature map, and $Z(f)$ is an appropriate normalizing constant.

For the same model, the distribution over suffixes $e_s \in \mathcal{E}$ must also condition on a prefix $e_p \in \mathcal{E}$:

$$p(e_s|e_p, f;w) = \sum_{\substack{r: \\ src(r)=f \\ tgt(r)=e_p e_s}} \frac{1}{Z(f)} \exp\left[w^\top \phi(r)\right] \quad (2)$$

In phrase-based decoding, the best scoring derivation r given a source sentence f and weights w is found efficiently by beam search, with one beam for every count of source words covered by a partial derivation (known as the *source coverage cardinality*). To predict a suffix conditioned on a prefix by constrained decoding, Barrachina et al. (2008) and Ortiz-Martínez et al. (2009) modify the beam search by discarding hypotheses (partial derivations) that do not match the prefix e_p.

We propose *target beam search*, a two-step inference procedure. The first step is to produce a phrase-based alignment between the target prefix and a subset of the source words. The target is aligned left-to-right by appending aligned phrase pairs. However, each beam is associated with a target word count, rather than a source word count. Therefore, each beam contains hypotheses for a fixed prefix of target words. Phrasal translation candidates are bundled and sorted with respect to each target phrase rather than each source phrase. Crucially, the source distortion limit is not enforced during alignment, so that long-range reorderings can be analyzed correctly.

The second step generates the suffix using standard beam search.[2] Once the target prefix is completely aligned, each hypothesis from the final target beam is copied to an appropriate source beam. Search starts with the lowest-count source beam that contains at least one hypothesis. Here, we re-instate the distortion limit with the following modification to avoid search failures: The decoder can always translate any source position before the last source position that was covered in the alignment phase.

3.1 Synthetic Phrase Pairs

The phrase pairs available during decoding may not be sufficient to align the target prefix to the source. Pre-compiled phrase tables (Koehn et al., 2003) are typically pruned, and dynamic phrase tables (Levenberg et al., 2010) require sampling for efficient lookup.

To improve alignment coverage, we include additional *synthetic phrases* extracted from word-level alignments between the source sentence and target prefix inferred using unpruned lexical statistics.

We first find the intersection of two directional word alignments. The directional alignments are obtained similar to IBM Model 2 (Brown et al., 1993) by aligning the most likely source word to each target word. Given a source sequence $f = f_1 \dots f_{|f|}$ and a target sequence $e = e_1 \dots e_{|e|}$, we define the alignment $a = a_1 \dots a_{|e|}$, where $a_i = j$ means that e_i is aligned to f_j. The likelihood is modeled by a single-word lexicon probability that is provided by our translation model and an alignment probability modeled as a Poisson distribution $Poisson(k, \lambda)$ in the distance to the diagonal.

$$a_i = \operatorname*{arg\,max}_{j \in \{1,\dots,|f|\}} p(a_i = j|f, e) \quad (3)$$

$$p(a_i = j|f, e) = p(e_i|f_j) \cdot p(a_i|j) \quad (4)$$

$$p(e_i|f_j) = \frac{cnt(e_i, f_j)}{cnt(f_j)} \quad (5)$$

$$p(a_i|j) = Poisson(|a_i - j|, 1.0) \quad (6)$$

[2] We choose cube pruning (Huang and Chiang, 2007) as the beam-filling strategy.

Here, $cnt(e_i, f_j)$ is the count of all word alignments between e_i and f_j in the training bitext, and $cnt(f_j)$ the monolingual occurrence count of f_j.

We perform standard phrase extraction (Och et al., 1999; Koehn et al., 2003) to obtain our synthetic phrases, whose translation probabilities are again estimated based on the single-word probabilities $p(e_i|f_j)$ from our translation model. Given a synthetic phrase pair (e, f), the phrase translation probability is computed as

$$p(e|f) = \prod_{1 \leq i \leq |e|} \max_{1 \leq j \leq |f|} p(e_i|f_j) \quad (7)$$

Additionally, we introduce three indicator features that count the number of synthetic phrase pairs, source words and target words, respectively.

4 Tuning

In order to tune the model for suffix prediction, we optimize the weights w in Equation 2 to maximize the metrics introduced in Section 2. Model tuning is performed with AdaGrad (Duchi et al., 2011), an online subgradient method. It features an adaptive learning rate and comes with good theoretical guarantees. See Green et al. (2013) for the details of applying AdaGrad to phrase-based translation.

The same model scores both alignment of the prefix and translation of the suffix. However, different feature weights may be appropriate for scoring each step of the inference process. In order to learn different weights for alignment and translation within a unified joint model, we apply the hierarchical adaptation method of Wuebker et al. (2015), which is based on *frustratingly easy domain adaptation* (FEDA) (Daumé III, 2007). We define three sub-segment domains: PREFIX, OVERLAP and SUFFIX. The PREFIX domain contains all phrases that are used for aligning the prefix with the source sentence. Phrases that span both prefix and suffix additionally belong to the OVERLAP domain. Finally, once the prefix has been completely covered, the SUFFIX domain applies to all phrases that are used to translate the remainder of the sentence. The ROOT domain spans the entire phrasal derivation.

Formally, given a set of domains $\mathcal{D} = \{\text{ROOT}, \text{PREFIX}, \text{OVERLAP}, \text{SUFFIX}\}$, each feature is replicated for each domain $d \in \mathcal{D}$. These replicas can be interpreted as domain-specific "offsets" to the baseline weights. For an original feature vector ϕ with a set of domains $D \subseteq \mathcal{D}$, the replicated feature vector contains $|\mathcal{D}|$ copies f_d of each feature $f \in \phi$, one for each $d \in \mathcal{D}$.

$$f_d = \begin{cases} f, & d \in D \\ 0, & \text{otherwise.} \end{cases} \quad (8)$$

The weights of the replicated feature space are initialized with 0 except for the ROOT domain, where we copy the baseline weights w.

$$w_d = \begin{cases} w, & d \text{ is ROOT} \\ 0, & \text{otherwise.} \end{cases} \quad (9)$$

All our phrase-based systems are first tuned without prefixes or domains to maximize BLEU. When tuning for suffix prediction, we keep these baseline weights w_{ROOT} fixed to maintain baseline translation quality and only update the weights corresponding to the PREFIX, OVERLAP and SUFFIX domains.

5 Diverse n-best Extraction

Consider the interactive MT application setting in which the user is presented with an autocomplete list of alternative translations (Langlais et al., 2000). The user query may be satisfied if the machine predicts the correct completion in its top-n output. However, it is well-known that n-best lists are poor approximations of MT structured output spaces (Macherey et al., 2008; Gimpel et al., 2013). Even very large values of n can fail to produce alternatives that differ in the first words of the suffix, which limits n-best KSR and WPA improvements at test time. For tuning, WPA is often zero for every item on the n-best list, which prevents learning.

Fortunately, the prefix can help efficiently enumerate diverse next-word alternatives. If we can find all edges in the decoding lattice that span the prefix e_p and suffix e_s, then we can generate diverse alternatives in precisely the right location in the target. Let $G = (V, E)$ be the search lattice created by decoding, where V are nodes and E are the edges produced by rule applications. For any $w \in V$, let $\text{parent}(w)$ return v s.t. $v, w \in E$, $\text{target}(w)$ return the target sequence e defined by following the next pointers from w, and $\text{length}(w)$ be the length of the target sequence up to w. During decoding, we set parent pointers and also assign monotonically increasing integer ids to each w.

To extract a full sentence completion given an edge $v, w \in E$ that spans the prefix/suffix boundary, we must find the best path to a goal node efficiently. To do this, we sort V in reverse topological order and set forward pointers from each node v to the

Algorithm 1 Diverse n-best list extraction

child node on the best goal path. During this traversal, we also mark all child nodes of edges that span the prefix/suffix boundary. Finally, we use the parent and child pointers to extract an n-best list of translations. Algorithm 1 shows the full procedure.

6 Neural machine translation

Neural machine translation (NMT) models the conditional probability $p(e|f)$ of translating a source sentence f to a target sentence e. In the *encoder-decoder* NMT framework (Sutskever et al., 2014; Cho et al., 2014), an *encoder* computes a representation $\boldsymbol{s}$ for each source sentence. From that source representation, the *decoder* generates a translation one word at a time by maximizing:

$$\log p(e|f) = \sum_{i=1}^{|e|} \log p\left(e_i|e_{<i}, f, \boldsymbol{s}\right) \qquad (10)$$

The individual probabilities in Equation 10 are often parameterized by a recurrent neural network which repeatedly predicts the next word e_i given all previous target words $e_{<i}$. Since this model generates translations by repeatedly predicting next words, it is a natural choice for the sentence completion task. Even in unconstrained decoding, it predicts one word at a time conditioned on the most likely prefix.

We modified the state-of-the-art English-German NMT system described in (Luong et al., 2015) to conduct a beam search that constrains the translation to match a fixed prefix.[3] As we decode from left to right, the decoder transitions from a constrained prefix decoding mode to unconstrained beam search. In the constrained mode—the next word to predict e_i is known—we set the beam size to 1, aggregate the score of predicting e_i immediately without having to sort the softmax distribution over all words, and feed e_i directly to the next time step. Once the prefix has been consumed, the decoder switches to standard beam search with a larger beam size (12 in our experiments). In this mode, the most probable word e_i is passed to the next time step.

7 Experimental Results

We evaluate our models and methods for English-French and English-German on two domains: *software* and *news*.

The phrase-based systems are built with Phrasal (Green et al., 2014), an open source toolkit. We use a dynamic phrase table (Levenberg et al., 2010) and tune parameters with AdaGrad. All systems have 42 dense baseline features. We align the bitexts with *mgiza* (Gao and Vogel, 2008) and estimate 5-gram language models (LMs) with *KenLM* (Heafield et al., 2013).

The English-French bilingual training data consists of 4.9M sentence pairs from the Common Crawl and Europarl corpora from WMT 2015 (Bojar et al., 2015). The LM was estimated from the target side of the bitext.

For English-German we run large-scale experiments. The bitext contains 19.9M parallel segments collected from WMT 2015 and the OPUS collection (Skadiņš et al., 2014). The LM was estimated from the target side of the bitext and the monolingual Common Crawl corpus (Buck et al., 2014), altogether 37.2B running words.

The software test set includes 10k sentence pairs from the Autodesk post editing corpus[4]. For the news domain we chose the English-French *newstest2014* and English-German *newstest2015* sets provided for the WMT 2016[5] shared task. The translation systems were tuned towards the specific domain, using another 10k segments from the Autodesk data or the *newstest2013* data set, respectively. On the English-French tune set we randomly select one target prefix from each sentence pair for rapid experimentation. On all other test and tune sets we select two target prefixes at random.[6] The

[3] We used the trained models provided by the authors of (Luong et al., 2015) using the codebase at `https://github.com/lmthang/nmt.matlab`.

[4] `https://autodesk.app.box.com/Autodesk-PostEditing`

[5] `http://www.statmt.org/wmt16`

[6] We briefly experimented with larger sets of prefixes and also exhaustive simulation in tuning, but did not observe significant improvements.

selected prefixes remain fixed throughout all experiments.

For NMT, we report results both using a single network and an ensemble of eight models using various attention mechanisms (Luong et al., 2015).

7.1 Phrase-based Results

Tables 1 and 2 show the main phrase-based results. The baseline system corresponds to constrained beam search, which performed best in (Ortiz-Martínez et al., 2009) and (Barrachina et al., 2008), where it was referred to as *phrase-based (PB)* and *phrase-based model (PBM)*, respectively. Our *target beam search* strategy improves all metrics on both test sets.

For English-French, we observe absolute improvements of up to 3.2% pxBLEU, 11.4% WPA and 10.6% KSR. We experimented with four different prefix-constrained tuning criteria: pxBLEU, WPA, #prd, and the linear combination $\frac{(\text{pxBLEU}+\text{WPA})}{2}$. We see that tuning towards prefix decoding increases all metrics. Across our two test sets, the combined metric yielded the most stable results. Here, we obtain gains of up to 3.0% pxBLEU, 3.1% WPA and 2.1% KSR. We continue using the linear combination criterion for all subsequent experiments.

For English-German—the large-scale setting—we observe similar total gains of up to 3.9% pxBLEU, 11.2% WPA and 8.2% KSR. The target beam search procedure contributes the most gain among our various improvements. Table 3 illustrates the differences in the translation output on three example sentences taken from the *newstest2015* test set. It is clearly visible that both target beam search and prefix tuning improve the prefix alignment, which results in better translation suffixes.

7.2 Diverse n-best Results

To improve recall in interactive MT, the user can be presented with multiple alternative sentence completions (Langlais et al., 2000), which correspond to an n-best list of translation hypotheses generated by the prefix-constrained inference procedure. The diverse extraction scheme introduced in section 5 is particularly designed for next-word prediction recall. Table 4 shows results for 10-best lists.

We see that WPA is increased by up to 15.3% by including the 10-best candidates, 11.3% being contributed by our novel diverse n-best extraction. Jointly, target beam search, prefix tuning and diverse n-best extraction lead to an absolute improvement of up to 23.5% over the baseline 10-best oracle. We believe that $n = 10$ suggestions are the maximum number of candidates that should be presented to a user, but we also ran experiments with $n = 3$ and $n = 5$, which would result in an interface with reduced cognitive load. These settings yield 5.5% and 10.0% WPA gains respectively on English-German news.

7.3 Comparison with NMT

We compare this phrase-based system to the NMT system described in Section 6 for English-German. Table 5 shows the results. We observe a clear advantage of NMT over our best phrase-based system when comparing WPA. For pxBLEU, the phrase-based model outperforms the single neural network system on the Autodesk set, but underperforms the ensemble. This stands in contrast to unconstrained full-sentence translation quality, where the phrase-based system is slightly better than the ensemble. The neural system substantially outperforms the phrase-based system for all metrics in the *news* domain.

In an interactive setting, the system must make predictions in near real-time, so we report average decoding times. We observe a clear time vs. accuracy trade-off; the phrase-based is 10.6 to 31.3 times faster than the single network NMT system and more than 100 times faster than the ensemble. Crucially, the phrase-based system runs on a CPU, while NMT requires a GPU for these speeds. Further, the 10-best oracle WPA of the phrase-based system is higher than the NMT ensemble in both genres.

Following the example of Neubig et al. (2015), we performed a manual analysis of the first 100 segments on the newstest2015 data set in order to qualitatively compare the constrained translations produced by the phrase-based and single network NMT systems. We observe four main error categories in which the translations differ, for which we have given examples in Table 6. NMT is generally better with long-range verb reorderings, which often lead to the verb being dropped by the phrase-based system. E.g. the word *erscheinen* in Ex. 1 and *veröffentlicht* in Ex. 2 are missing in the phrase-based translation. Also, the NMT engine often produces better German grammar and morphological agreement, e.g. *kein* vs. *keine* in Ex. 3 or the verb conjugations in Ex. 4. Especially interesting is that the NMT system generated the negation *nicht* in the second half of Ex. 3. This word does not have

a direct correspondence in the English source, but makes the sentence feel more natural in German. On the other hand, NMT sometimes drops content words, as in Ex. 5, where *middle-class jobs*, *Minnesota* and *Progressive Caucus co-chair* remain entirely untranslated by NMT. Finally, incorrect prefix alignment sometimes leads to incorrect portions of the source sentence being translated after the prefix or even superfluous output by the phrase-based engine, like *, die* in Ex. 6. Table 7 summarizes how many times each of the systems produced a better output than the other, broken down by category.

8 Related Work

Target-mediated interactive MT was first proposed by Foster et al. (1997) and then further developed within the TransType (Langlais et al., 2000) and TransType2 (Esteban et al., 2004; Barrachina et al., 2008) projects. In TransType2, several different approaches were evaluated. Barrachina et al. (2008) reports experimental results that show the superiority of phrase-based models over stochastic finite state transducers and alignment templates, which were extended for the interactive translation paradigm by Och et al. (2003). Ortiz-Martínez et al. (2009) confirm this observation, and find that their own suggested method using partial statistical phrase-based alignments performs on a similar level on most tasks. The approach using phrase-based models is used as the baseline in this paper.

In order to make the interaction sufficiently responsive, Barrachina et al. (2008) resort to search within a word graph, which is generated by the translation decoder without constraints at the beginning of the workflow. A given prefix is then matched to the paths within the word graph. This approach was recently refined with more permissive matching criteria by Koehn et al. (2014), who report strong improvements in prediction accuracy.

Instead of using a word graph, it is also possible to perform a new search for every interaction (Bender et al., 2005; Ortiz-Martínez et al., 2009), which is the approach we have adopted. Ortiz-Martínez et al. (2009) perform the most similar study to our work in the literature. The authors also define prefix decoding as a two-stage process, but focus on investigating different smoothing techniques, while our work includes new metrics, models, and inference.

9 Conclusion

We have shown that both phrase-based and neural translation approaches can be used to complete partial translations. The recurrent neural system provides higher word prediction accuracy, but requires lengthy inference on a GPU. The phrase-based system is fast, produces diverse n-best lists, and provides reasonable prefix-BLEU performance. The complementary strengths of both systems suggest future work in combining these techniques.

We have also shown decisively that simply performing constrained decoding for a phrase-based model is not an effective approach to the task of completing translations. Instead, the learning objective, model, and inference procedure should all

We also report unconstrained full-sentence BLEU scores. The phrase-based timing results include prefix alignment and synthetic phrase extraction.

be tailored to the task. The combination of these changes can adapt a phrase-based translation system to perform prefix alignment and suffix prediction jointly with fewer search errors and greater accuracy for the critical first words of the suffix. In light of the dramatic improvements in prediction quality that result from the techniques we have described, we look forward to investigating the effect on user experience for interactive translation systems that employ these methods.

Abstract

Attention mechanism has enhanced state-of-the-art Neural Machine Translation (NMT) by jointly learning to align and translate. It tends to ignore past alignment information, however, which often leads to over-translation and under-translation. To address this problem, we propose coverage-based NMT in this paper. We maintain a coverage vector to keep track of the attention history. The coverage vector is fed to the attention model to help adjust future attention, which lets NMT system to consider more about untranslated source words. Experiments show that the proposed approach significantly improves both translation quality and alignment quality over standard attention-based NMT.[1]

1 Introduction

The past several years have witnessed the rapid progress of end-to-end Neural Machine Translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015). Unlike conventional Statistical Machine Translation (SMT) (Koehn et al., 2003; Chiang, 2007), NMT uses a single and large neural network to model the entire translation process. It enjoys the following advantages. First, the use of distributed representations of words can alleviate the curse of dimensionality (Bengio et al., 2003). Second, there is no need to explicitly design features to capture translation regularities, which is quite difficult in SMT. Instead, NMT is capable of learning representations directly from the training data. Third, Long Short-Term Memory (Hochreiter and Schmidhuber, 1997) enables NMT to capture long-distance reordering, which is a significant challenge in SMT.

NMT has a serious problem, however, namely lack of *coverage*. In phrase-based SMT (Koehn et al., 2003), a decoder maintains a coverage vector to indicate whether a source word is translated or not. This is important for ensuring that each source word is translated in decoding. The decoding process is completed when all source words are "covered" or translated. In NMT, there is no such coverage vector and the decoding process ends only when the end-of-sentence mark is produced. We believe that lacking coverage might result in the following problems in conventional NMT:

1. Over-translation: some words are unnecessarily translated for multiple times;

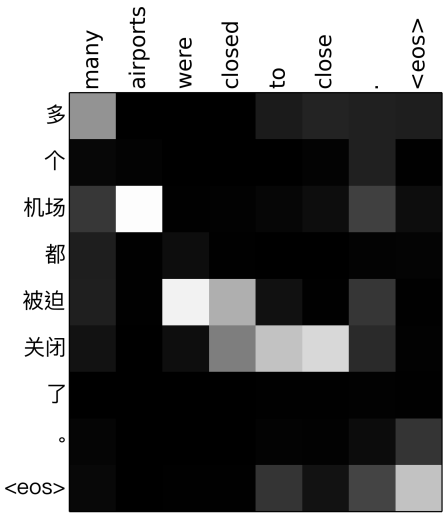
2. Under-translation: some words are mistakenly untranslated.

Specifically, in the state-of-the-art attention-based NMT model (Bahdanau et al., 2015), generating a target word heavily depends on the relevant parts of the source sentence, and a source word is involved in generation of all target words. As a result, over-translation and under-translation inevitably happen because of ignoring the "coverage" of source words (i.e., number of times a source word is translated to a target word). Figure 1(a) shows an example: the Chinese word "*guānbì*" is over translated to "*close*(*d*)" twice, while "*bèipò*" (means "*be forced to*") is mistakenly untranslated.

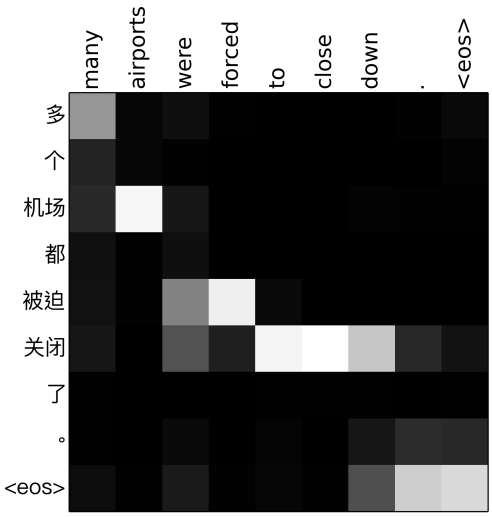
In this work, we propose a coverage mechanism to NMT (NMT-COVERAGE) to alleviate the over-translation and under-translation problems. Basically, we append a coverage vector to the intermediate representations of an NMT model, which are sequentially updated after each attentive read

[1]Our code is publicly available at https://github.com/tuzhaopeng/NMT-Coverage.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 76–85,
Berlin, Germany, August 7-12, 2016.



(a) Over-translation and under-translation generated by NMT.



(b) Coverage model alleviates the problems of over-translation and under-translation.

Figure 1: Example translations of (a) NMT without coverage, and (b) NMT with coverage. In conventional NMT without coverage, the Chinese word "*guānbì*" is over translated to "*close*(*d*)" twice, while "*bèipò*" (means "*be forced to*") is mistakenly untranslated. Coverage model alleviates these problems by tracking the "coverage" of source words.

during the decoding process, to keep track of the attention history. The coverage vector, when entering into attention model, can help adjust the future attention and significantly improve the overall alignment between the source and target sentences. This design contains many particular cases for coverage modeling with contrasting characteristics, which all share a clear linguistic intuition and yet can be trained in a data driven fashion. Notably, we achieve significant improvement even by simply using the sum of previous alignment probabilities as coverage for each word, as a successful example of incorporating linguistic knowledge into neural network based NLP models.

Experiments show that NMT-COVERAGE significantly outperforms conventional attention-based NMT on both translation and alignment tasks. Figure 1(b) shows an example, in which NMT-COVERAGE alleviates the over-translation and under-translation problems that NMT without coverage suffers from.

2 Background

Our work is built on attention-based NMT (Bahdanau et al., 2015), which simultaneously conducts dynamic alignment and generation of the target sentence, as illustrated in Figure 2. It

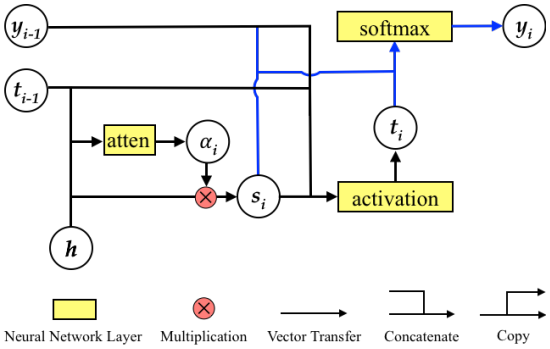


Figure 2: Architecture of attention-based NMT. Whenever possible, we omit the source index j to make the illustration less cluttered.

produces the translation by generating one target word y_i at each time step. Given an input sentence $\mathbf{x} = \{x_1, \ldots, x_J\}$ and previously generated words $\{y_1, \ldots, y_{i-1}\}$, the probability of generating next word y_i is

$$P(y_i|y_{<i}, \mathbf{x}) = softmax\big(g(y_{i-1}, \mathbf{t}_i, \mathbf{s}_i)\big) \quad (1)$$

where g is a non-linear function, and $\mathbf{t}_i$ is a decoding state for time step i, computed by

$$\mathbf{t}_i = f(\mathbf{t}_{i-1}, y_{i-1}, \mathbf{s}_i) \quad (2)$$

Here the activation function $f(\cdot)$ is a Gated Recurrent Unit (GRU) (Cho et al., 2014b), and $\mathbf{s}_i$ is

a distinct source representation for time i, calculated as a weighted sum of the source annotations:

$$\mathbf{s}_i = \sum_{j=1}^{J} \alpha_{i,j} \cdot \mathbf{h}_j \quad (3)$$

where $\mathbf{h}_j = [\overrightarrow{h}_j^\top; \overleftarrow{h}_j^\top]^\top$ is the annotation of x_j from a bi-directional Recurrent Neural Network (RNN) (Schuster and Paliwal, 1997), and its weight $\alpha_{i,j}$ is computed by

$$\alpha_{i,j} = \frac{\exp(e_{i,j})}{\sum_{k=1}^{J} \exp(e_{i,k})} \quad (4)$$

and

$$\begin{aligned} e_{i,j} &= a(\mathbf{t}_{i-1}, \mathbf{h}_j) \\ &= v_a^\top \tanh(W_a \mathbf{t}_{i-1} + U_a \mathbf{h}_j) \end{aligned} \quad (5)$$

is an *attention model* that scores how well y_i and $\mathbf{h}_j$ match. With the attention model, it avoids the need to represent the entire source sentence with a single vector. Instead, the decoder selects parts of the source sentence to pay attention to, thus exploits an *expected annotation* $\mathbf{s}_i$ over possible alignments $\alpha_{i,j}$ for each time step i.

However, the attention model fails to take advantage of past alignment information, which is found useful to avoid over-translation and under-translation problems in conventional SMT (Koehn et al., 2003). For example, if a source word is translated in the past, it is less likely to be translated again and should be assigned a lower alignment probability.

3 Coverage Model for NMT

In SMT, a coverage set is maintained to keep track of which source words have been translated ("covered") in the past. Let us take $\mathbf{x} = \{x_1, x_2, x_3, x_4\}$ as an example of input sentence. The initial coverage set is $\mathcal{C} = \{0, 0, 0, 0\}$ which denotes that no source word is yet translated. When a translation rule $bp = (x_2 x_3, y_m y_{m+1})$ is applied, we produce one hypothesis labelled with coverage $\mathcal{C} = \{0, 1, 1, 0\}$. It means that the second and third source words are translated. The goal is to generate translation with full coverage $\mathcal{C} = \{1, 1, 1, 1\}$. A source word is translated when it is covered by one translation rule, and it is not allowed to be translated again in the future (i.e., *hard coverage*). In this way, each source word is guaranteed to be translated and only be translated once. As shown, coverage is essential for SMT since it avoids gaps and overlaps in translation of source words.

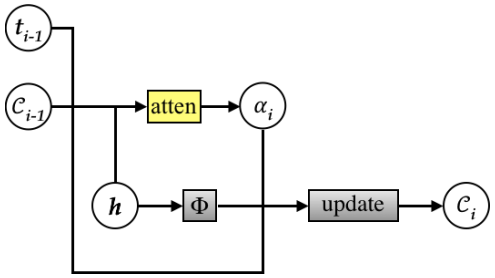

Figure 3: Architecture of coverage-based attention model. A coverage vector $\mathcal{C}_{i-1}$ is maintained to keep track of which source words have been translated before time i. Alignment decisions α_i are made jointly taking into account past alignment information embedded in $\mathcal{C}_{i-1}$, which lets the attention model to consider more about untranslated source words.

Modeling coverage is also important for attention-based NMT models, since they generally lack a mechanism to indicate whether a certain source word has been translated, and therefore are prone to the "coverage" mistakes: some parts of source sentence have been translated more than once or not translated. For NMT models, directly modeling coverage is less straightforward, but the problem can be significantly alleviated by keeping track of the attention signal during the decoding process. The most natural way for doing that would be to append a coverage vector to the annotation of each source word (i.e., $\mathbf{h}_j$), which is initialized as a zero vector but updated after every attentive read of the corresponding annotation. The coverage vector is fed to the attention model to help adjust future attention, which lets NMT system to consider more about untranslated source words, as illustrated in Figure 3.

3.1 Coverage Model

Since the coverage vector summarizes the attention record for $\mathbf{h}_j$ (and therefore for a small neighbor centering at the j^{th} source word), it will discourage further attention to it if it has been heavily attended, and implicitly push the attention to the less attended segments of the source sentence since the attention weights are normalized to one. This can potentially solve both coverage mistakes mentioned above, when modeled and learned properly.

Formally, the coverage model is given by

$$\mathcal{C}_{i,j} = g_{update}\big(\mathcal{C}_{i-1,j}, \alpha_{i,j}, \Phi(\mathbf{h}_j), \Psi\big) \quad (6)$$

where

- $g_{update}(\cdot)$ is the function that updates $\mathcal{C}_{i,j}$ after the new attention $\alpha_{i,j}$ at time step i in the decoding process;
- $\mathcal{C}_{i,j}$ is a d-dimensional coverage vector summarizing the history of attention till time step i on $\mathbf{h}_j$;
- $\Phi(\mathbf{h}_j)$ is a word-specific feature with its own parameters;
- Ψ are auxiliary inputs exploited in different sorts of coverage models.

Equation 6 gives a rather general model, which could take different function forms for $g_{update}(\cdot)$ and $\Phi(\cdot)$, and different auxiliary inputs Ψ (e.g., previous decoding state $\mathbf{t}_{i-1}$). In the rest of this section, we will give a number of representative implementations of the coverage model, which either leverage more linguistic information (Section 3.1.1) or resort to the flexibility of neural network approximation (Section 3.1.2).

3.1.1 Linguistic Coverage Model

We first consider at linguistically inspired model which has a small number of parameters, as well as clear interpretation. While the linguistically-inspired coverage in NMT is similar to that in SMT, there is one key difference: it indicates what percentage of source words have been translated (i.e., *soft coverage*). In NMT, each target word y_i is generated from all source words with probability $\alpha_{i,j}$ for source word x_j. In other words, the source word x_j is involved in generating all target words and the probability of generating target word y_i at time step i is $\alpha_{i,j}$. Note that unlike in SMT in which each source word is *fully translated* at one decoding step, the source word x_j is *partially translated* at each decoding step in NMT. Therefore, the coverage at time step i denotes the translated ratio of that each source word is translated.

We use a scalar ($d = 1$) to represent linguistic coverage for each source word and employ an accumulate operation for g_{update}. The initial value of linguistic coverage is zero, which denotes that the corresponding source word is not translated yet. We iteratively construct linguistic coverages through accumulation of alignment probabilities generated by the attention model, each of which is normalized by a distinct context-dependent weight. The coverage of source word x_j at time step i is computed by

$$\mathcal{C}_{i,j} = \mathcal{C}_{i-1,j} + \frac{1}{\Phi_j}\alpha_{i,j} = \frac{1}{\Phi_j}\sum_{k=1}^{i}\alpha_{k,j} \quad (7)$$

where Φ_j is a pre-defined weight which indicates the number of target words x_j is expected to generate. The simplest way is to follow Xu et al. (2015) in image-to-caption translation to fix $\Phi = 1$ for all source words, which means that we directly use the sum of previous alignment probabilities without normalization as coverage for each word, as done in (Cohn et al., 2016).

However, in machine translation, different types of source words may contribute differently to the generation of target sentence. Let us take the sentence pairs in Figure 1 as an example. The noun in the source sentence "*jīchǎng*" is translated into one target word "*airports*", while the adjective "*bèipò*" is translated into three words "*were forced to*". Therefore, we need to assign a distinct Φ_j for each source word. Ideally, we expect $\Phi_j = \sum_{i=1}^{I}\alpha_{i,j}$ with I being the total number of time steps in decoding. However, such desired value is not available before decoding, thus is not suitable in this scenario.

Fertility To predict Φ_j, we introduce the concept of *fertility*, which is firstly proposed in word-level SMT (Brown et al., 1993). Fertility of source word x_j tells how many target words x_j produces. In SMT, the fertility is a random variable Φ_j, whose distribution $p(\Phi_j = \phi)$ is determined by the parameters of word alignment models (e.g., IBM models). In this work, we simplify and adapt fertility from the original model and compute the fertility Φ_j by[2]

$$\Phi_j = \mathcal{N}(x_j|\mathbf{x}) = N \cdot \sigma(U_f\mathbf{h}_j) \quad (8)$$

where $N \in \mathbb{R}$ is a predefined constant to denote the maximum number of target words one source

[2]Fertility in SMT is a random variable with a set of fertility probabilities, $n(\Phi_j|x_j) = p(\Phi_{<j}, \mathbf{x})$, which depends on the fertilities of previous source words. To simplify the calculation and adapt it to the attention model in NMT, we define the fertility in NMT as a constant number, which is independent of previous fertilities.

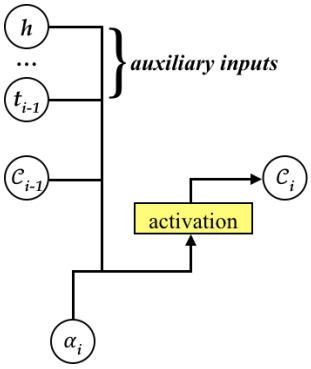

Figure 4: NN-based coverage model.

word can produce, $\sigma(\cdot)$ is a logistic sigmoid function, and $U_f \in \mathbb{R}^{1\times 2n}$ is the weight matrix. Here we use $\mathbf{h}_j$ to denote $(x_j|\mathbf{x})$ since $\mathbf{h}_j$ contains information about the whole input sentence with a strong focus on the parts surrounding x_j (Bahdanau et al., 2015). Since Φ_j does not depend on i, we can pre-compute it before decoding to minimize the computational cost.

3.1.2 Neural Network Based Coverage Model

We next consider Neural Network (NN) based coverage model. When $\mathcal{C}_{i,j}$ is a vector ($d > 1$) and $g_{update}(\cdot)$ is a neural network, we actually have an RNN model for coverage, as illustrated in Figure 4. In this work, we take the following form:

$$\mathcal{C}_{i,j} = f(\mathcal{C}_{i-1,j}, \alpha_{i,j}, \mathbf{h}_j, \mathbf{t}_{i-1})$$

where $f(\cdot)$ is a nonlinear activation function and $\mathbf{t}_{i-1}$ is the auxiliary input that encodes past translation information. Note that we leave out the word-specific feature function $\Phi(\cdot)$ and only take the input annotation $\mathbf{h}_j$ as the input to the coverage RNN. It is important to emphasize that the NN-based coverage model is able to be fed with arbitrary inputs, such as the previous attentional context $\mathbf{s}_{i-1}$. Here we only employ $\mathcal{C}_{i-1,j}$ for past alignment information, $\mathbf{t}_{i-1}$ for past translation information, and $\mathbf{h}_j$ for word-specific bias.[3]

Gating The neural function $f(\cdot)$ can be either a simple activation function $\tanh$ or a gating function that proves useful to capture long-distance dependencies. In this work, we adopt GRU for the gating activation since it is simple yet powerful (Chung et al., 2014). Please refer to (Cho et al., 2014b) for more details about GRU.

Discussion Intuitively, the two types of models summarize coverage information in "different languages". Linguistic models summarize coverage information in human language, which has a clear interpretation to humans. Neural models encode coverage information in "neural language", which can be "understood" by neural networks and let them to decide how to make use of the encoded coverage information.

3.2 Integrating Coverage into NMT

Although attention based model has the capability of jointly making alignment and translation, it does not take into consideration translation history. Specifically, a source word that has significantly contributed to the generation of target words in the past, should be assigned lower alignment probabilities, which may not be the case in attention based NMT. To address this problem, we propose to calculate the alignment probabilities by incorporating past alignment information embedded in the coverage model.

Intuitively, at each time step i in the decoding phase, coverage from time step $(i-1)$ serves as an additional input to the attention model, which provides complementary information of that how likely the source words are translated in the past. We expect the coverage information would guide the attention model to focus more on untranslated source words (i.e., assign higher alignment probabilities). In practice, we find that the coverage model does fulfill the expectation (see Section 5). The translated ratios of source words from linguistic coverages negatively correlate to the corresponding alignment probabilities.

More formally, we rewrite the attention model in Equation 5 as

$$\begin{aligned} e_{i,j} &= a(\mathbf{t}_{i-1}, \mathbf{h}_j, \mathcal{C}_{i-1,j}) \\ &= v_a^\top \tanh(W_a \mathbf{t}_{i-1} + U_a \mathbf{h}_j + V_a \mathcal{C}_{i-1,j}) \end{aligned}$$

where $\mathcal{C}_{i-1,j}$ is the coverage of source word x_j before time i. $V_a \in \mathbb{R}^{n\times d}$ is the weight matrix for coverage with n and d being the numbers of hidden units and coverage units, respectively.

[3] In our preliminary experiments, considering more inputs (e.g., current and previous attentional contexts, unnormalized attention weights $e_{i,j}$) does not always lead to better translation quality. Possible reasons include: 1) the inputs contains duplicate information, and 2) more inputs introduce more back-propagation paths and therefore make it difficult to train. In our experience, one principle is to only feed the coverage model inputs that contain distinct information, which are complementary to each other.

4 Training

We take end-to-end learning for the NMT-COVERAGE model, which learns not only the parameters for the "original" NMT (i.e., θ for encoding RNN, decoding RNN, and attention model) but also the parameters for coverage modeling (i.e., η for annotation and guidance of attention) . More specifically, we choose to maximize the likelihood of reference sentences as most other NMT models (see, however (Shen et al., 2016)):

$$(\theta^*, \eta^*) = \arg\max_{\theta,\eta} \sum_{n=1}^{N} \log P(\mathbf{y}_n|\mathbf{x}_n; \theta, \eta) \quad (9)$$

No auxiliary objective For the coverage model with a clearer linguistic interpretation (Section 3.1.1), it is possible to inject an auxiliary objective function on some intermediate representation. More specifically, we may have the following objective:

$$(\theta^*, \eta^*) = \arg\max_{\theta,\eta} \sum_{n=1}^{N} \Bigg\{ \log P(\mathbf{y}_n|\mathbf{x}_n; \theta, \eta) - \lambda \Big\{ \sum_{j=1}^{J} (\Phi_j - \sum_{i=1}^{I} \alpha_{i,j})^2; \eta \Big\} \Bigg\}$$

where the term $\{ \sum_{j=1}^{J} (\Phi_j - \sum_{i=1}^{I} \alpha_{i,j})^2; \eta \}$ penalizes the discrepancy between the sum of alignment probabilities and the expected fertility for linguistic coverage. This is similar to the more explicit training for fertility as in Xu et al. (2015), which encourages the model to pay equal attention to every part of the image (i.e., $\Phi_j = 1$). However, our empirical study shows that the combined objective consistently worsens the translation quality while slightly improves the alignment quality.

Our training strategy poses less constraints on the dependency between Φ_j and the attention than a more explicit strategy taken in (Xu et al., 2015). We let the objective associated with the translation quality (i.e., the likelihood) to drive the training, as in Equation 9. This strategy is arguably advantageous, since the attention weight on a hidden state $\mathbf{h}_j$ cannot be interpreted as the proportion of the corresponding word being translated in the target sentence. For one thing, the hidden state $\mathbf{h}_j$, after the transformation from encoding RNN, bears the contextual information from other parts of the source sentence, and thus loses the rigid correspondence with the corresponding word. Therefore, penalizing the discrepancy between the sum of alignment probabilities and the expected fertility does not hold in this scenario.

5 Experiments

5.1 Setup

We carry out experiments on a Chinese-English translation task. Our training data for the translation task consists of 1.25M sentence pairs extracted from LDC corpora[4] , with 27.9M Chinese words and 34.5M English words respectively. We choose NIST 2002 dataset as our development set, and the NIST 2005, 2006 and 2008 datasets as our test sets. We carry out experiments of the alignment task on the evaluation dataset from (Liu and Sun, 2015), which contains 900 manually aligned Chinese-English sentence pairs. We use the case-insensitive 4-gram NIST BLEU score (Papineni et al., 2002) for the translation task, and the alignment error rate (AER) (Och and Ney, 2003) for the alignment task. To better estimate the quality of the soft alignment probabilities generated by NMT, we propose a variant of AER, naming *SAER*:

$$SAER = 1 - \frac{|M_A \times M_S| + |M_A \times M_P|}{|M_A| + |M_S|}$$

where A is a candidate alignment, and S and P are the sets of sure and possible links in the reference alignment respectively ($S \subseteq P$). M denotes alignment matrix, and for both M_S and M_P we assign the elements that correspond to the existing links in S and P with probabilities 1 while assign the other elements with probabilities 0. In this way, we are able to better evaluate the quality of the soft alignments produced by attention-based NMT. We use *sign-test* (Collins et al., 2005) for statistical significance test.

For efficient training of the neural networks, we limit the source and target vocabularies to the most frequent 30K words in Chinese and English, covering approximately 97.7% and 99.3% of the two corpora respectively. All the out-of-vocabulary words are mapped to a special token UNK. We set $N = 2$ for the fertility model in the linguistic coverages. We train each model with the sentences of length up to 80 words in the training data. The word embedding dimension is 620 and the size of a hidden layer is 1000. All the other settings are the same as in (Bahdanau et al., 2015).

[4]The corpora include LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06.

#	System	#Params	MT05	MT06	MT08	Avg.
1	Moses	–	31.37	30.85	23.01	28.41

7	+ NN-based coverage w/ gating ($d = 10$)	+100K	**32.73**†‡	**32.47**†‡	**25.23**†‡	**30.14**

Table 1: Evaluation of translation quality. d denotes the dimension of NN-based coverages, and † and ‡ indicate statistically significant difference ($p < 0.01$) from GroundHog and Moses, respectively. "+" is on top of the baseline system GroundHog.

We compare our method with two state-of-the-art models of SMT and NMT[5]:

- **Moses** (Koehn et al., 2007): an open source phrase-based translation system with default configuration and a 4-gram language model trained on the target portion of training data.
- **GroundHog** (Bahdanau et al., 2015): an attention-based NMT system.

5.2 Translation Quality

Table 1 shows the translation performances measured in BLEU score. Clearly the proposed NMT-COVERAGE significantly improves the translation quality in all cases, although there are still considerable differences among different variants.

Parameters Coverage model introduces few parameters. The baseline model (i.e., GroundHog) has 84.3M parameters. The linguistic coverage using fertility introduces 3K parameters (2K for fertility model), and the NN-based coverage with gating introduces 10K$\times d$ parameters (6K$\times d$ for gating), where d is the dimension of the coverage vector. In this work, the most complex coverage model only introduces 0.1M additional parameters, which is quite small compared to the number of parameters in the existing model (i.e., 84.3M).

Speed Introducing the coverage model slows down the training speed, but not significantly. When running on a single GPU device Tesla K80, the speed of the baseline model is 960 target words per second. System 4 ("+Linguistic coverage with fertility") has a speed of 870 words per second, while System 7 ("+NN-based coverage (d=10)") achieves a speed of 800 words per second.

[5]There are recent progress on aggregating multiple models or enlarging the vocabulary(e.g., in (Jean et al., 2015)), but here we focus on the generic models.

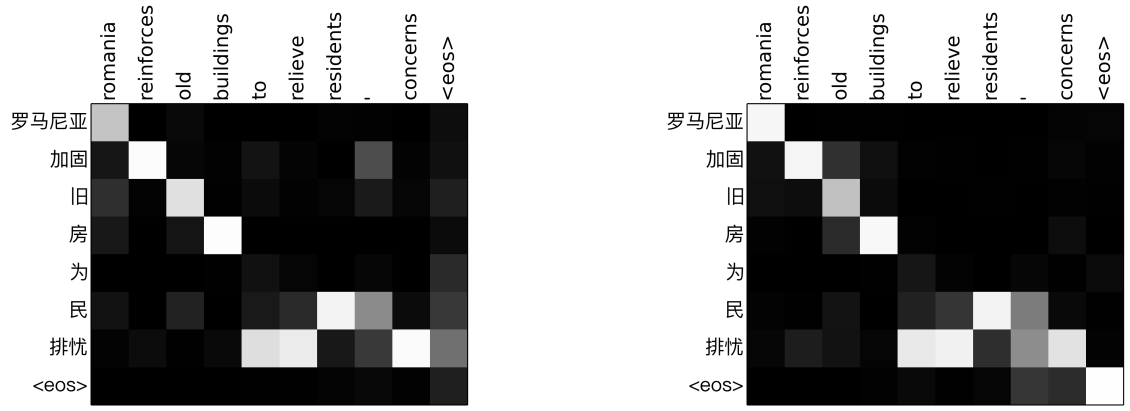
Linguistic Coverages (Rows 3 and 4): Two observations can be made. First, the simplest linguistic coverage (Row 3) already significantly improves translation performance by 1.1 BLEU points, indicating that coverage information is very important to the attention model. Second, incorporating fertility model boosts the performance by better estimating the covered ratios of source words.

NN-based Coverages (Rows 5-7): (1) *Gating* (Rows 5 and 6): Both variants of NN-based coverages outperform GroundHog with averaged gains of 0.8 and 1.3 BLEU points, respectively. Introducing gating activation function improves the performance of coverage models, which is consistent with the results in other tasks (Chung et al., 2014). (2) *Coverage dimensions* (Rows 6 and 7): Increasing the dimension of coverage models further improves the translation performance by 0.6 point in BLEU score, at the cost of introducing more parameters (e.g., from 10K to 100K).[6]

5.3 Alignment Quality

Table 2 lists the alignment performances. We find that coverage information improves attention model as expected by maintaining an annotation summarizing attention history on each source word. More specifically, linguistic coverage with fertility significantly reduces alignment errors under both metrics, in which fertility plays an important role. NN-based coverages, however, does not significantly reduce alignment errors until increasing the coverage dimension from 1 to 10. It indicates that NN-based models need slightly more

[6]In a pilot study, further increasing the coverage dimension only slightly improved the translation performance. One possible reason is that encoding the relatively simple coverage information does not require too many dimensions.



(a) Groundhog

(b) + NN cov. w/ gating ($d = 10$)

Figure 5: Example alignments. Using coverage mechanism, translated source words are less likely to contribute to generation of the target words next (e.g., top-right corner for the first four Chinese words.).

System	SAER	AER
GroundHog	67.00	54.67
+ Ling. cov. w/o fertility	66.75	53.55
+ Ling. cov. w/ fertility	64.85	52.13
+ NN cov. w/o gating ($d = 1$)	67.10	54.46
+ NN cov. w/ gating ($d = 1$)	66.30	53.51
+ NN cov. w/ gating ($d = 10$)	**64.25**	**50.50**

Table 2: Evaluation of alignment quality. The lower the score, the better the alignment quality.

dimensions to encode the coverage information.

Figure 5 shows an example. The coverage mechanism does meet the expectation: the alignments are more concentrated and most importantly, translated source words are less likely to get involved in generation of the target words next. For example, the first four Chinese words are assigned lower alignment probabilities (i.e., darker color) after the corresponding translation "*romania reinforces old buildings*" is produced.

5.4 Effects on Long Sentences

Following Bahdanau et al. (2015), we group sentences of similar lengths together and compute BLEU score and averaged length of translation for each group, as shown in Figure 6. Cho et al. (2014a) show that the performance of Groundhog drops rapidly when the length of input sentence increases. Our results confirm these findings. One main reason is that Groundhog produces much shorter translations on longer sentences (e.g., > 40, see right panel in Figure 6), and thus faces a serious under-translation problem. NMT-COVERAGE alleviates this problem by incorporating coverage information into the attention model, which in general pushes the attention to untranslated parts of the source sentence and implicitly discourages early stop of decoding. It is worthy to emphasize that both NN-based coverages (with gating, $d = 10$) and linguistic coverages (with fertility) achieve similar performances on long sentences, reconfirming our claim that the two variants improve the attention model in their own ways.

As an example, consider this source sentence in the test set:

> *qiáodān běn sàijì píngjūn défēn 24.3fēn , tā zài sān zhōu qián jiēshòu shǒushù , qiúduì zài cǐ qījiān 4 shèng 8 fù .*

Groundhog translates this sentence into:

> *jordan achieved an average score of eight weeks ahead with a surgical operation three weeks ago .*

in which the sub-sentence "*, qiúduì zài cǐ qījiān 4 shèng 8 fù*" is under-translated. With the (NN-based) coverage mechanism, NMT-COVERAGE translates it into:

> *jordan 's average score points to UNK this year . he received surgery before three weeks , with a team in the period of 4 to 8 .*

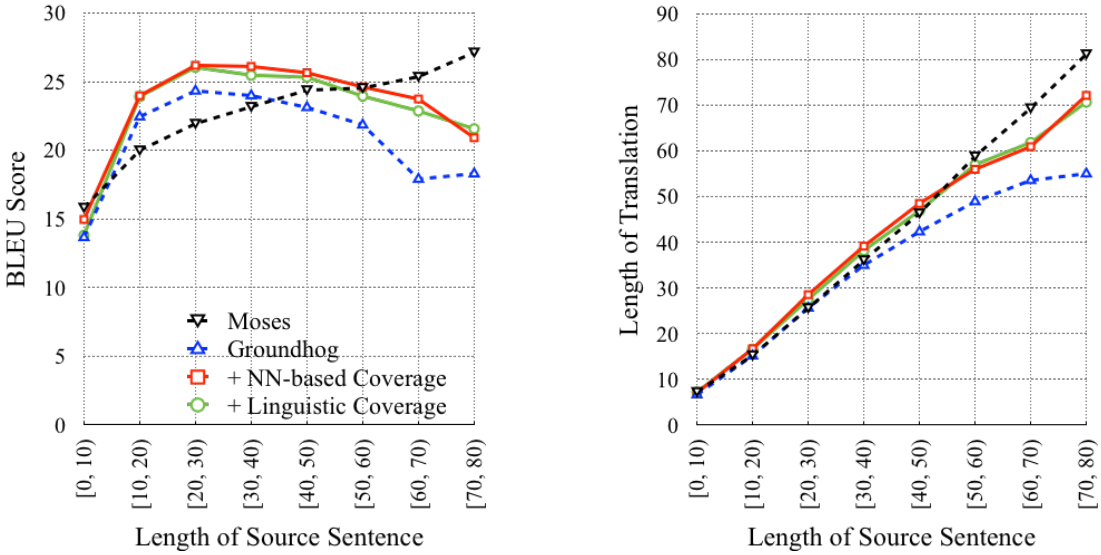


Figure 6: Performance of the generated translations with respect to the lengths of the input sentences. Coverage models alleviate under-translation by producing longer translations on long sentences.

in which the under-translation is rectified.

The quantitative and qualitative results show that the coverage models indeed help to alleviate under-translation, especially for long sentences consisting of several sub-sentences.

6 Related Work

Our work is inspired by recent works on improving attention-based NMT with techniques that have been successfully applied to SMT. Following the success of Minimum Risk Training (MRT) in SMT (Och, 2003), Shen et al. (2016) proposed MRT for end-to-end NMT to optimize model parameters directly with respect to evaluation metrics. Based on the observation that attention-based NMT only captures partial aspects of attentional regularities, Cheng et al. (2016) proposed agreement-based learning (Liang et al., 2006) to encourage bidirectional attention models to agree on parameterized alignment matrices. Along the same direction, inspired by the coverage mechanism in SMT, we propose a coverage-based approach to NMT to alleviate the over-translation and under-translation problems.

Independent from our work, Cohn et al. (2016) and Feng et al. (2016) made use of the concept of "fertility" for the attention model, which is similar in spirit to our method for building the linguistically inspired coverage with fertility. Cohn et al. (2016) introduced a feature-based fertility that includes the total alignment scores for the surrounding source words. In contrast, we make prediction of fertility before decoding, which works as a normalizer to better estimate the coverage ratio of each source word. Feng et al. (2016) used the previous attentional context to represent *implicit fertility* and passed it to the attention model, which is in essence similar to the input-feed method proposed in (Luong et al., 2015). Comparatively, we predict *explicit fertility* for each source word based on its encoding annotation, and incorporate it into the linguistic-inspired coverage for attention model.

7 Conclusion

We have presented an approach for enhancing NMT, which maintains and utilizes a coverage vector to indicate whether each source word is translated or not. By encouraging NMT to pay less attention to translated words and more attention to untranslated words, our approach alleviates the serious over-translation and under-translation problems that traditional attention-based NMT suffers from. We propose two variants of coverage models: *linguistic coverage* that leverages more linguistic information and *NN-based coverage* that resorts to the flexibility of neural network approximation . Experimental results show that both variants achieve significant improvements in terms of translation quality and alignment quality over NMT without coverage.

Improving Neural Machine Translation Models with Monolingual Data

Rico Sennrich and **Barry Haddow** and **Alexandra Birch**
School of Informatics, University of Edinburgh
{rico.sennrich,a.birch}@ed.ac.uk, bhaddow@inf.ed.ac.uk

Abstract

Neural Machine Translation (NMT) has obtained state-of-the art performance for several language pairs, while only using parallel data for training. Target-side monolingual data plays an important role in boosting fluency for phrase-based statistical machine translation, and we investigate the use of monolingual data for NMT. In contrast to previous work, which combines NMT models with separately trained language models, we note that encoder-decoder NMT architectures already have the capacity to learn the same information as a language model, and we explore strategies to train with monolingual data without changing the neural network architecture. By pairing monolingual training data with an automatic back-translation, we can treat it as additional parallel training data, and we obtain substantial improvements on the WMT 15 task English↔German (+2.8–3.7 BLEU), and for the low-resourced IWSLT 14 task Turkish→English (+2.1–3.4 BLEU), obtaining new state-of-the-art results. We also show that fine-tuning on in-domain monolingual and parallel data gives substantial improvements for the IWSLT 15 task English→German.

1 Introduction

Neural Machine Translation (NMT) has obtained state-of-the art performance for several language pairs, while only using parallel data for training. Target-side monolingual data plays an important role in boosting fluency for phrase-based statistical machine translation, and we investigate the use of monolingual data for NMT.

Language models trained on monolingual data have played a central role in statistical machine translation since the first IBM models (Brown et al., 1990). There are two major reasons for their importance. Firstly, word-based and phrase-based translation models make strong independence assumptions, with the probability of translation units estimated independently from context, and language models, by making different independence assumptions, can model how well these translation units fit together. Secondly, the amount of available monolingual data in the target language typically far exceeds the amount of parallel data, and models typically improve when trained on more data, or data more similar to the translation task.

In (attentional) encoder-decoder architectures for neural machine translation (Sutskever et al., 2014; Bahdanau et al., 2015), the decoder is essentially an RNN language model that is also conditioned on source context, so the first rationale, adding a language model to compensate for the independence assumptions of the translation model, does not apply. However, the data argument is still valid in NMT, and we expect monolingual data to be especially helpful if parallel data is sparse, or a poor fit for the translation task, for instance because of a domain mismatch.

In contrast to previous work, which integrates a separately trained RNN language model into the NMT model (Gülçehre et al., 2015), we explore strategies to include monolingual training data in the training process without changing the neural network architecture. This makes our approach applicable to different NMT architectures.

The main contributions of this paper are as follows:

- we show that we can improve the machine translation quality of NMT systems by mixing monolingual target sentences into the

The research presented in this publication was conducted in cooperation with Samsung Electronics Polska sp. z o.o. - Samsung R&D Institute Poland.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 86–96,
Berlin, Germany, August 7-12, 2016.

training set.

- we investigate two different methods to fill the source side of monolingual training instances: using a dummy source sentence, and using a source sentence obtained via back-translation, which we call synthetic. We find that the latter is more effective.

- we successfully adapt NMT models to a new domain by fine-tuning with either monolingual or parallel in-domain data.

2 Neural Machine Translation

We follow the neural machine translation architecture by Bahdanau et al. (2015), which we will briefly summarize here. However, we note that our approach is not specific to this architecture.

The neural machine translation system is implemented as an encoder-decoder network with recurrent neural networks.

The encoder is a bidirectional neural network with gated recurrent units (Cho et al., 2014) that reads an input sequence $x = (x_1, ..., x_m)$ and calculates a forward sequence of hidden states $(\overrightarrow{h}_1, ..., \overrightarrow{h}_m)$, and a backward sequence $(\overleftarrow{h}_1, ..., \overleftarrow{h}_m)$. The hidden states $\overrightarrow{h}_j$ and $\overleftarrow{h}_j$ are concatenated to obtain the annotation vector h_j.

The decoder is a recurrent neural network that predicts a target sequence $y = (y_1, ..., y_n)$. Each word y_i is predicted based on a recurrent hidden state s_i, the previously predicted word y_{i-1}, and a context vector c_i. c_i is computed as a weighted sum of the annotations h_j. The weight of each annotation h_j is computed through an *alignment model* α_{ij}, which models the probability that y_i is aligned to x_j. The alignment model is a single-layer feedforward neural network that is learned jointly with the rest of the network through backpropagation.

A detailed description can be found in (Bahdanau et al., 2015). Training is performed on a parallel corpus with stochastic gradient descent. For translation, a beam search with small beam size is employed.

3 NMT Training with Monolingual Training Data

In machine translation, more monolingual data (or monolingual data more similar to the test set) serves to improve the estimate of the prior probability $p(T)$ of the target sentence T, before taking the source sentence S into account. In contrast to (Gülçehre et al., 2015), who train separate language models on monolingual training data and incorporate them into the neural network through shallow or deep fusion, we propose techniques to train the main NMT model with monolingual data, exploiting the fact that encoder-decoder neural networks already condition the probability distribution of the next target word on the previous target words. We describe two strategies to do this: providing monolingual training examples with an empty (or dummy) source sentence, or providing monolingual training data with a synthetic source sentence that is obtained from automatically translating the target sentence into the source language, which we will refer to as *back-translation*.

3.1 Dummy Source Sentences

The first technique we employ is to treat monolingual training examples as parallel examples with empty source side, essentially adding training examples whose context vector c_i is uninformative, and for which the network has to fully rely on the previous target words for its prediction. This could be conceived as a form of dropout (Hinton et al., 2012), with the difference that the training instances that have the context vector dropped out constitute novel training data. We can also conceive of this setup as multi-task learning, with the two tasks being translation when the source is known, and language modelling when it is unknown.

During training, we use both parallel and monolingual training examples in the ratio 1-to-1, and randomly shuffle them. We define an epoch as one iteration through the parallel data set, and resample from the monolingual data set for every epoch. We pair monolingual sentences with a single-word dummy source side *<null>* to allow processing of both parallel and monolingual training examples with the same network graph.[1] For monolingual minibatches[2], we freeze the network parameters of the encoder and the attention model.

One problem with this integration of monolin-

[1] One could force the context vector c_i to be 0 for monolingual training instances, but we found that this does not solve the main problem with this approach, discussed below.

[2] For efficiency, Bahdanau et al. (2015) sort sets of 20 minibatches according to length. This also groups monolingual training instances together.

gual data is that we cannot arbitrarily increase the ratio of monolingual training instances, or fine-tune a model with only monolingual training data, because different output layer parameters are optimal for the two tasks, and the network 'unlearns' its conditioning on the source context if the ratio of monolingual training instances is too high.

3.2 Synthetic Source Sentences

To ensure that the output layer remains sensitive to the source context, and that good parameters are not unlearned from monolingual data, we propose to pair monolingual training instances with a synthetic source sentence from which a context vector can be approximated. We obtain these through back-translation, i.e. an automatic translation of the monolingual target text into the source language.

During training, we mix synthetic parallel text into the original (human-translated) parallel text and do not distinguish between the two: no network parameters are frozen. Importantly, only the source side of these additional training examples is synthetic, and the target side comes from the monolingual corpus.

4 Evaluation

We evaluate NMT training on parallel text, and with additional monolingual data, on English↔German and Turkish→English, using training and test data from WMT 15 for English↔German, IWSLT 15 for English→German, and IWSLT 14 for Turkish→English.

4.1 Data and Methods

We use Groundhog[3] as the implementation of the NMT system for all experiments (Bahdanau et al., 2015; Jean et al., 2015a). We generally follow the settings and training procedure described by Sennrich et al. (2016).

For English↔German, we report case-sensitive BLEU on detokenized text with mteval-v13a.pl for comparison to official WMT and IWSLT results. For Turkish→English, we report case-sensitive BLEU on tokenized text with multi-bleu.perl for comparison to results by Gülçehre et al. (2015).

Gülçehre et al. (2015) determine the network vocabulary based on the parallel training data, and replace out-of-vocabulary words with a special UNK symbol. They remove monolingual sentences with more than 10% UNK symbols. In contrast, we represent unseen words as sequences of subword units (Sennrich et al., 2016), and can represent any additional training data with the existing network vocabulary that was learned on the parallel data. In all experiments, the network vocabulary remains fixed.

$\text{WIT}_{\text{parallel}}$	200 000
$\text{WMT}_{\text{mono\_de}}$	160 000 000
$\text{WMT}_{\text{synth\_de}}$	3 600 000
$\text{WMT}_{\text{mono\_en}}$	118 000 000
$\text{WMT}_{\text{synth\_en}}$	4 200 000

Table 1: English↔German training data.

4.1.1 English↔German

We use all parallel training data provided by WMT 2015 (Bojar et al., 2015)[4]. We use the News Crawl corpora as additional training data for the experiments with monolingual data. The amount of training data is shown in Table 1.

Baseline models are trained for a week. Ensembles are sampled from the last 4 saved models of training (saved at 12h-intervals). Each model is fine-tuned with fixed embeddings for 12 hours.

For the experiments with synthetic parallel data, we back-translate a random sample of 3 600 000 sentences from the German monolingual data set into English. The German→English system used for this is the baseline system (`parallel`). Translation took about a week on an NVIDIA Titan Black GPU. For experiments in German→English, we back-translate 4 200 000 monolingual English sentences into German, using the English→German system `+synthetic`. Note that we always use single models for back-translation, not ensembles. We leave it to future work to explore how sensitive NMT training with synthetic data is to the quality of the back-translation.

We tokenize and truecase the training data, and represent rare words via BPE (Sennrich et al., 2016). Specifically, we follow Sennrich et al. (2016) in performing BPE on the joint vocabulary with 89 500 merge operations. The network vo-

Table 2: Turkish→English training data.

cabulary size is 90 000.

We also perform experiments on the IWSLT 15 test sets to investigate a cross-domain setting.[5] The test sets consist of TED talk transcripts. As in-domain training data, IWSLT provides the WIT[3] parallel corpus (Cettolo et al., 2012), which also consists of TED talks.

4.1.2 Turkish→English

We use data provided for the IWSLT 14 machine translation track (Cettolo et al., 2014), namely the WIT[3] parallel corpus (Cettolo et al., 2012), which consists of TED talks, and the SETimes corpus (Tyers and Alperen, 2010).[6] After removal of sentence pairs which contain empty lines or lines with a length ratio above 9, we retain 320 000 sentence pairs of training data. For the experiments with monolingual training data, we use the English LDC Gigaword corpus (Fifth Edition). The amount of training data is shown in Table 2. With only 320 000 sentences of parallel data available for training, this is a much lower-resourced translation setting than English↔German.

Gülçehre et al. (2015) segment the Turkish text with the morphology tool Zemberek, followed by a disambiguation of the morphological analysis (Sak et al., 2007), and removal of non-surface tokens produced by the analysis. We use the same preprocessing[7]. For both Turkish and English, we represent rare words (or morphemes in the case of Turkish) as character bigram sequences (Sennrich et al., 2016). The 20 000 most frequent words (morphemes) are left unsegmented. The networks have a vocabulary size of 23 000 symbols.

To obtain a synthetic parallel training set, we back-translate a random sample of 3 200 000 sentences from Gigaword. We use an English→Turkish NMT system trained with the same settings as the Turkish→English baseline system.

We found overfitting to be a bigger problem than with the larger English↔German data set, and follow Gülçehre et al. (2015) in using Gaussian noise (stddev 0.01) (Graves, 2011), and dropout on the output layer (p=0.5) (Hinton et al., 2012). We also use early stopping, based on BLEU measured every three hours on tst2010, which we treat as development set. For Turkish→English, we use gradient clipping with threshold 5, following Gülçehre et al. (2015), in contrast to the threshold 1 that we use for English↔German, following Jean et al. (2015a).

4.2 Results

4.2.1 English→German WMT 15

Table 3 shows English→German results with WMT training and test data. We find that mixing parallel training data with monolingual data with a dummy source side in a ratio of 1-1 improves quality by 0.4–0.5 BLEU for the single system, 1 BLEU for the ensemble. We train the system for twice as long as the baseline to provide the training algorithm with a similar amount of parallel training instances. To ensure that the quality improvement is due to the monolingual training instances, and not just increased training time, we also continued training our baseline system for another week, but saw no improvements in BLEU.

Including synthetic data during training is very effective, and yields an improvement over our baseline by 2.8–3.4 BLEU. Our best ensemble system also outperforms a syntax-based baseline (Sennrich and Haddow, 2015) by 1.2–2.1 BLEU. We also substantially outperform NMT results reported by Jean et al. (2015a) and Luong et al. (2015), who previously reported SOTA result.[8] We note that the difference is particularly large for single systems, since our ensemble is not as diverse as that of Luong et al. (2015), who used 8 independently trained ensemble components, whereas we sampled 4 ensemble components from the same training run.

4.2.2 English→German IWSLT 15

Table 4 shows English→German results on IWSLT test sets. IWSLT test sets consist of TED talks, and are thus very dissimilar from the WMT

[8] Luong et al. (2015) report 20.9 BLEU (tokenized) on newstest2014 with a single model, and 23.0 BLEU with an ensemble of 8 models. Our best single system achieves a *tokenized* BLEU (as opposed to untokenized scores reported in Table 3) of 23.8, and our ensemble reaches 25.0 BLEU.

5	2+$WIT_{parallel}$	WIT	200k	**30.4**	**25.9**	**28.4**

Table 4: English→German translation performance (BLEU) on IWSLT test sets (TED talks). Single models.

test sets, which are news texts. We investigate if monolingual training data is especially valuable if it can be used to adapt a model to a new genre or domain, specifically adapting a system trained on WMT data to translating TED talks.

Systems 1 and 2 correspond to systems in Table 3, trained only on WMT data. System 2, trained on parallel and synthetic WMT data, obtains a BLEU score of 25.5 on tst2015. We observe that even a small amount of fine-tuning[9], i.e. continued training of an existing model, on WIT data can adapt a system trained on WMT data to the TED domain. By back-translating the monolingual WIT corpus (using a German→English system trained on WMT data, i.e. without in-domain knowledge), we obtain the synthetic data set WIT_{synth}. A single epoch of fine-tuning on WIT_{synth} (system 4) results in a BLEU score of 26.7 on tst2015, or an improvement of 1.2 BLEU. We observed no improvement from fine-tuning on WIT_{mono}, the monolingual TED corpus with dummy input (system 3).

These adaptation experiments with monolingual data are slightly artificial in that parallel training data is available. System 5, which is fine-tuned with the original WIT training data, obtains a BLEU of 28.4 on tst2015, which is an improvement of 2.9 BLEU. While it is unsurprising that in-domain parallel data is most valuable, we find it encouraging that NMT domain adaptation with monolingual data is also possible, and effective, since there are settings where only monolingual in-domain data is available.

[9]We leave the word embeddings fixed for fine-tuning.

name	BLEU 2014	BLEU 2015

NMT (Gülçehre et al., 2015)	23.6	-
+shallow fusion	23.7	-
+deep fusion	24.0	-
parallel	25.9	26.7
+synthetic	**29.5**	**30.4**
+synthetic (ensemble of 4)	30.8	31.6

Table 5: German→English translation performance (BLEU) on WMT training/test sets (newstest2014; newstest2015).

The best results published on this dataset are by Luong and Manning (2015), obtained with an ensemble of 8 independently trained models. In a comparison of single-model results, we outperform their model on tst2013 by 1 BLEU.

4.2.3 German→English WMT 15

Results for German→English on the WMT 15 data sets are shown in Table 5. Like for the reverse translation direction, we see substantial improvements (3.6–3.7 BLEU) from adding monolingual training data with synthetic source sentences, which is substantially bigger than the improvement observed with deep fusion (Gülçehre et al., 2015); our ensemble outperforms the previous state of the art on newstest2015 by 2.3 BLEU.

4.2.4 Turkish→English IWSLT 14

Table 6 shows results for Turkish→English. On average, we see an improvement of 0.6 BLEU on the test sets from adding monolingual data with a dummy source side in a 1-1 ratio[10], although we note a high variance between different test sets.

With synthetic training data ($\text{Gigaword}_{\text{synth}}$), we outperform the baseline by 2.7 BLEU on average, and also outperform results obtained via shallow or deep fusion by Gülçehre et al. (2015) by 0.5 BLEU on average. To compare to what extent synthetic data has a regularization effect, even without novel training data, we also back-translate the target side of the parallel training text to obtain the training corpus $\text{parallel}_{\text{synth}}$. Mixing the original parallel corpus with $\text{parallel}_{\text{synth}}$ (ratio 1-1) gives some improvement over the baseline (1.7 BLEU on average), but the novel monolingual training data ($\text{Gigaword}_{\text{mono}}$) gives higher improvements, despite being out-of-domain in relation to the test sets. We speculate that novel in-domain monolingual data would lead to even higher improvements.

4.2.5 Back-translation Quality for Synthetic Data

One question that our previous experiments leave open is how the quality of the automatic back-translation affects training with synthetic data. To investigate this question, we back-translate the same German monolingual corpus with three different German→English systems:

- with our baseline system and greedy decoding
- with our baseline system and beam search (beam size 12). This is the same system used for the experiments in Table 3.
- with the German→English system that was itself trained with synthetic data (beam size 12).

[10] We also experimented with higher ratios of monolingual data, but this led to decreased BLEU scores.

	BLEU		
	DE→EN	EN→DE	
back-translation	2015	2014	2015
none	-	20.4	23.6
parallel (greedy)	22.3	23.2	26.0
parallel (beam 12)	25.0	23.8	26.5
synthetic (beam 12)	28.3	23.9	26.6
ensemble of 3	-	24.2	27.0
ensemble of 12	-	24.7	27.6

Table 7: English→German translation performance (BLEU) on WMT training/test sets (newstest2014; newstest2015). Systems differ in how the synthetic training data is obtained. Ensembles of 4 models (unless specified otherwise).

BLEU scores of the German→English systems, and of the resulting English→German systems that are trained on the different back-translations, are shown in Table 7. The quality of the German→English back-translation differs substantially, with a difference of 6 BLEU on newstest2015. Regarding the English→German systems trained on the different synthetic corpora, we find that the 6 BLEU difference in back-translation quality leads to a 0.6–0.7 BLEU difference in translation quality. This is balanced by the fact that we can increase the speed of back-translation by trading off some quality, for instance by reducing beam size, and we leave it to future research to explore how much the amount of synthetic data affects translation quality.

We also show results for an ensemble of 3 models (the best single model of each training run), and 12 models (all 4 models of each training run). Thanks to the increased diversity of the ensemble components, these ensembles outperform the ensembles of 4 models that were all sampled from the same training run, and we obtain another improvement of 0.8–1.0 BLEU.

4.3 Contrast to Phrase-based SMT

The back-translation of monolingual target data into the source language to produce synthetic parallel text has been previously explored for phrase-based SMT (Bertoldi and Federico, 2009; Lambert et al., 2011). While our approach is technically similar, synthetic parallel data fulfills novel roles

name	training data	instances	BLEU tst2011	tst2012	tst2013	tst2014
baseline (Gülçehre et al., 2015)			18.4	18.8	19.9	18.7
deep fusion (Gülçehre et al., 2015)			20.2	20.2	21.3	**20.6**
baseline	parallel	7.2m	18.6	18.2	18.4	18.3
$\text{parallel}_{\text{synth}}$	parallel/$\text{parallel}_{\text{synth}}$	6m/6m	19.9	20.4	20.1	20.0
$\text{Gigaword}_{\text{mono}}$	parallel/$\text{Gigaword}_{\text{mono}}$	7.6m/7.6m	18.8	19.6	19.4	18.2
$\text{Gigaword}_{\text{synth}}$	parallel/$\text{Gigaword}_{\text{synth}}$	8.4m/8.4m	**21.2**	**21.1**	**21.8**	20.4

Table 6: Turkish→English translation performance (*tokenized* BLEU) on IWSLT test sets (TED talks). Single models. Number of training instances varies due to early stopping.

system	BLEU WMT	IWSLT
parallel	20.1	21.5
+synthetic	20.8	21.6
PBSMT gain	+0.7	+0.1
NMT gain	+2.9	+1.2

Table 8: Phrase-based SMT results (English→German) on WMT test sets (average of newstest201{4,5}), and IWSLT test sets (average of tst201{3,4,5}), and average BLEU gain from adding synthetic data for both PBSMT and NMT.

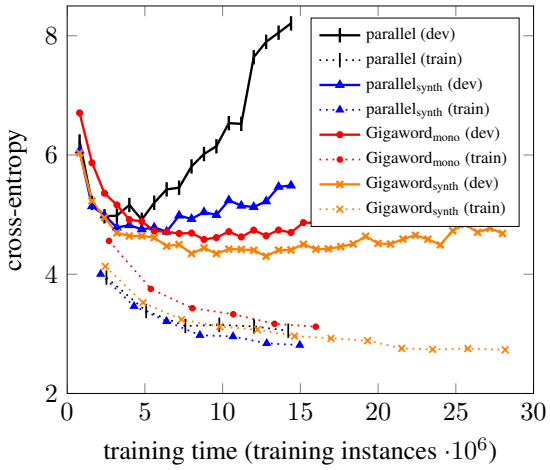

Figure 1: Turkish→English training and development set (tst2010) cross-entropy as a function of training time (number of training instances) for different systems.

in NMT.

To explore the relative effectiveness of back-translated data for phrase-based SMT and NMT, we train two phrase-based SMT systems with Moses (Koehn et al., 2007), using only $\text{WMT}_{\text{parallel}}$, or both $\text{WMT}_{\text{parallel}}$ and $\text{WMT}_{\text{synth\_de}}$ for training the translation and reordering model. Both systems contain the same language model, a 5-gram Kneser-Ney model trained on all available WMT data. We use the baseline features described by Haddow et al. (2015).

Results are shown in Table 8. In phrase-based SMT, we find that the use of back-translated training data has a moderate positive effect on the WMT test sets (+0.7 BLEU), but not on the IWSLT test sets. This is in line with the expectation that the main effect of back-translated data for phrase-based SMT is domain adaptation (Bertoldi and Federico, 2009). Both the WMT test sets and the News Crawl corpora which we used as monolingual data come from the same source, a web crawl of newspaper articles.[11] In contrast, News Crawl is out-of-domain for the IWSLT test sets.

In contrast to phrase-based SMT, which can make use of monolingual data via the language model, NMT has so far not been able to use monolingual data to great effect, and without requiring architectural changes. We find that the effect of synthetic parallel data is not limited to domain adaptation, and that even out-of-domain synthetic data improves NMT quality, as in our evaluation on IWSLT. The fact that the synthetic data is more effective on the WMT test sets (+2.9 BLEU) than on the IWSLT test sets (+1.2 BLEU) supports the hypothesis that domain adaptation contributes to the effectiveness of adding synthetic data to NMT training.

It is an important finding that back-translated data, which is mainly effective for domain adaptation in phrase-based SMT, is more generally useful in NMT, and has positive effects that go beyond domain adaptation. In the next section, we will investigate further reasons for its effectiveness.

[11] The WMT test sets are held-out from News Crawl.

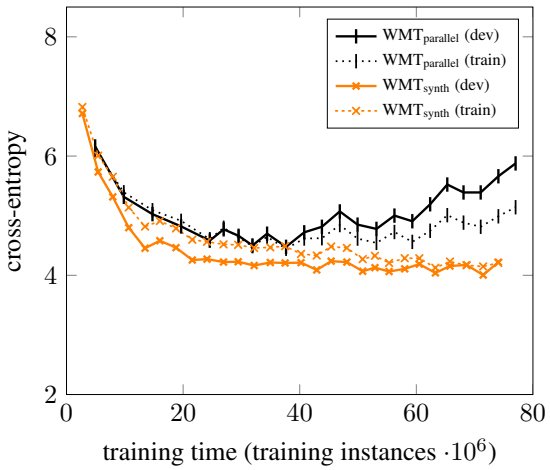

Figure 2: English→German training and development set (newstest2013) cross-entropy as a function of training time (number of training instances) for different systems.

4.4 Analysis

We previously indicated that overfitting is a concern with our baseline system, especially on small data sets of several hundred thousand training sentences, despite the regularization employed. This overfitting is illustrated in Figure 1, which plots training and development set cross-entropy by training time for Turkish→English models. For comparability, we measure training set cross-entropy for all models on the same random sample of the parallel training set. We can see that the model trained on only parallel training data quickly overfits, while all three monolingual data sets (parallel$_{synth}$, Gigaword$_{mono}$, or Gigaword$_{synth}$) delay overfitting, and give better perplexity on the development set. The best development set cross-entropy is reached by Gigaword$_{synth}$.

Figure 2 shows cross-entropy for English→German, comparing the system trained on only parallel data and the system that includes synthetic training data. Since more training data is available for English→German, there is no indication that overfitting happens during the first 40 million training instances (or 7 days of training); while both systems obtain comparable training set cross-entropies, the system with synthetic data reaches a lower cross-entropy on the development set. One explanation for this is the domain effect discussed in the previous section.

A central theoretical expectation is that monolingual target-side data improves the model's fluency, its ability to produce natural target-language sentences. As a proxy to sentence-level fluency, we investigate word-level fluency, specifically words produced as sequences of subword units, and whether NMT systems trained with additional monolingual data produce more natural words. For instance, the English→German systems translate the English phrase *civil rights protections* as a single compound, composed of three subword units: *Bürger|rechts|schutzes*[12], and we analyze how many of these multi-unit words that the translation systems produce are well-formed German words.

system	produced	attested	natural
parallel	1078	53.4%	74.9%
+mono	994	61.6%	84.6%
+synthetic	1217	56.4%	82.5%

Table 9: Number of words in system output that do not occur in parallel training data (count$_{ref}$ = 1168), and proportion that is attested in data, or natural according to native speaker. English→German; newstest2015; ensemble systems.

We compare the number of words in the system output for the newstest2015 test set which are produced via subword units, and that do not occur in the parallel training corpus. We also count how many of them are attested in the full monolingual corpus or the reference translation, which we all consider 'natural'. Additionally, the main authors, a native speaker of German, annotated a random subset ($n = 100$) of unattested words of each system according to their naturalness[13], distinguishing between natural German words (or names) such as *Literatur|klassen* 'literature classes', and nonsensical ones such as **As|best|atten* (a misspelling of *Astbestmatten* 'asbestos mats').

In the results (Table 9), we see that the systems trained with additional monolingual or synthetic data have a higher proportion of novel words attested in the non-parallel data, and a higher proportion that is deemed natural by our annotator. This supports our expectation that additional monolingual data improves the (word-level) fluency of the NMT system.

[12] Subword boundaries are marked with '|'.

[13] For the annotation, the words were blinded regarding the system that produced them.

5 Related Work

To our knowledge, the integration of monolingual data for pure neural machine translation architectures was first investigated by (Gülçehre et al., 2015), who train monolingual language models independently, and then integrate them during decoding through rescoring of the beam (*shallow fusion*), or by adding the recurrent hidden state of the language model to the decoder state of the encoder-decoder network, with an additional controller mechanism that controls the magnitude of the LM signal (*deep fusion*). In deep fusion, the controller parameters and output parameters are tuned on further parallel training data, but the language model parameters are fixed during the fine-tuning stage. Jean et al. (2015b) also report on experiments with reranking of NMT output with a 5-gram language model, but improvements are small (between 0.1–0.5 BLEU).

The production of synthetic parallel texts bears resemblance to data augmentation techniques used in computer vision, where datasets are often augmented with rotated, scaled, or otherwise distorted variants of the (limited) training set (Rowley et al., 1996).

Another similar avenue of research is self-training (McClosky et al., 2006; Schwenk, 2008). The main difference is that self-training typically refers to scenario where the training set is enhanced with training instances with artificially produced output labels, whereas we start with human-produced output (i.e. the translation), and artificially produce an input. We expect that this is more robust towards noise in the automatic translation. Improving NMT with monolingual source data, following similar work on phrase-based SMT (Schwenk, 2008), remains possible future work.

Domain adaptation of neural networks via continued training has been shown to be effective for neural language models by (Ter-Sarkisov et al., 2015), and in work parallel to ours, for neural translation models (Luong and Manning, 2015). We are the first to show that we can effectively adapt neural translation models with monolingual data.

6 Conclusion

In this paper, we propose two simple methods to use monolingual training data during training of NMT systems, with no changes to the network architecture. Providing training examples with dummy source context was successful to some extent, but we achieve substantial gains in all tasks, and new SOTA results, via back-translation of monolingual target data into the source language, and treating this synthetic data as additional training data. We also show that small amounts of in-domain monolingual data, back-translated into the source language, can be effectively used for domain adaptation. In our analysis, we identified domain adaptation effects, a reduction of overfitting, and improved fluency as reasons for the effectiveness of using monolingual data for training.

While our experiments did make use of monolingual training data, we only used a small random sample of the available data, especially for the experiments with synthetic parallel data. It is conceivable that larger synthetic data sets, or data sets obtained via data selection, will provide bigger performance benefits.

Because we do not change the neural network architecture to integrate monolingual training data, our approach can be easily applied to other NMT systems. We expect that the effectiveness of our approach not only varies with the quality of the MT system used for back-translation, but also depends on the amount (and similarity to the test set) of available parallel and monolingual data, and the extent of overfitting of the baseline model. Future work will explore the effectiveness of our approach in more settings.

Graph-Based Translation Via Graph Segmentation

Abstract

One major drawback of phrase-based translation is that it segments an input sentence into continuous phrases. To support linguistically informed source discontinuity, in this paper we construct graphs which combine bigram and dependency relations and propose a graph-based translation model. The model segments an input graph into connected subgraphs, each of which may cover a discontinuous phrase. We use beam search to combine translations of each subgraph left-to-right to produce a complete translation. Experiments on Chinese–English and German–English tasks show that our system is significantly better than the phrase-based model by up to +1.5/+0.5 BLEU scores. By explicitly modeling the graph segmentation, our system obtains further improvement, especially on German–English.

1 Introduction

Statistical machine translation (SMT) starts from sequence-based models. The well-known phrase-based (PB) translation model (Koehn et al., 2003) has significantly advanced the progress of SMT by extending translation units from single words to phrases. By using phrases, PB models can capture local phenomena, such as word order, word deletion, and word insertion. However, one of the significant weaknesses in conventional PB models is that only continuous phrases are used, so generalizations such as French *ne ... pas* to English *not* cannot be learned. To solve this, syntax-based models (Galley et al., 2004; Chiang, 2005; Liu et al., 2006; Marcu et al., 2006) take tree structures into consideration to learn translation patterns by using non-terminals for generalization.

Model	C	D	S

This work	•	•	graph

Table 1: Comparison between our work and previous work in terms of three aspects: keeping continuous phrases (C), allowing discontinuous phrases (D), and input structures (S).

However, the expressiveness of these models is confined by hierarchical constraints of the grammars used (Galley and Manning, 2010) since these patterns still cover continuous spans of an input sentence.

By contrast, Quirk et al. (2005), Menezes and Quirk (2005) and Xiong et al. (2007) take treelets from dependency trees as the basic translation units. These treelets are connected and may cover discontinuous phrases. However, their models lack the ability to handle continuous phrases which are not connected in trees but could in fact be extremely important to system performance (Koehn et al., 2003). Galley and Manning (2010) directly extract discontinuous phrases from input sequences. However, without imposing additional restrictions on discontinuity, the amount of extracted rules can be very large and unreliable.

Different from previous work (as shown in Table 1), in this paper we use graphs as input structures and propose a graph-based translation model to translate a graph into a target string. The basic translation unit in this model is a connected subgraph which may cover discontinuous phrases. The main contributions of this work are summarized as follows:

- We propose to use a graph structure to combine a sequence and a tree (Section 3.1). The

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 97–107,
Berlin, Germany, August 7-12, 2016.

graph contains both local relations between words from the sequence and long-distance relations from the tree.

- We present a translation model to translate a graph (Section 3). The model segments the graph into subgraphs and uses beam search to generate a complete translation from left to right by combining translation options of each subgraph.
- We present a set of sparse features to explicitly model the graph segmentation (Section 4). These features are based on edges in the input graph, each of which is either inside a subgraph or connects the subgraph with a previous subgraph.
- Experiments (Section 5) on Chinese–English and German–English tasks show that our model is significantly better than the PB model. After incorporating the segmentation model, our system achieves still further improvement.

2 Review: Phrase-based Translation

We first review the basic PB translation approach, which will be extended to our graph-based translation model. Given a pair of sentences $\langle S, T \rangle$, the conventional PB model is defined as Equation (1):

$$p(\bar{t}_1^I \mid \bar{s}_1^I) = \prod_{i=1}^{I} p(\bar{t}_i|\bar{s}_{a_i}) d(\bar{s}_{a_i}, \bar{s}_{a_{i-1}}) \quad (1)$$

The target sentence T is broken into I phrases $\bar{t}_1 \cdots \bar{t}_I$, each of which is a translation of a source phrase $\bar{s}_{a_i}$. d is a distance-based reordering model. Note that in the basic PB model, the phrase segmentation is not explicitly modeled which means that different segmentations are treated equally (Koehn, 2010).

The performance of PB translation relies on the quality of phrase pairs in a translation table. Conventionally, a phrase pair $\langle \bar{s}, \bar{t} \rangle$ has two properties: (i) $\bar{s}$ and $\bar{t}$ are continuous phrases. (ii) $\langle \bar{s}, \bar{t} \rangle$ is consistent with a word alignment A (Och and Ney, 2004): $\forall (i,j) \in A, s_i \in \bar{s} \Leftrightarrow t_j \in \bar{t}$ and $\exists s_i \in \bar{s}, t_j \in \bar{t}, (i,j) \in A$.

PB decoders generate hypotheses (partial translations) from left to right. Each hypothesis maintains a *coverage vector* to indicate which source words have been translated so far. A hypothesis can be extended on the right by translating an uncovered source phrase. The translation process ends when all source words have been translated.

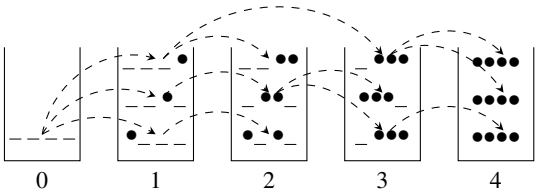

Figure 1: Beam search for phrase-based MT. • denotes a covered source position while _ indicates an uncovered position (Liu and Huang, 2014).

Beam search (as in Figure 1) is taken as an approximate search strategy to reduce the size of the decoding space. Hypotheses which cover the same number of source words are grouped in a stack. Hypotheses can be pruned according to their partial translation cost and an estimated future cost.

3 Graph-Based Translation

Our graph-based translation model extends PB translation by translating an input graph rather than a sequence to a target string. The graph is segmented into a sequence of connected subgraphs, each of which corresponds to a target phrase, as in Equation (2):

$$\begin{aligned} & p(\bar{t}_1^I \mid G(\tilde{s}_1^I)) \\ & = \prod_{i=1}^{I} p(\bar{t}_i|G(\tilde{s}_{a_i})) d(G(\tilde{s}_{a_i}), G(\tilde{s}_{a_{i-1}})) \\ & \approx \prod_{i=1}^{I} p(\bar{t}_i|G(\tilde{s}_{a_i})) d(\tilde{s}_{a_i}, \tilde{s}_{a_{i-1}}) \end{aligned} \quad (2)$$

where $G(\tilde{s}_i)$ denotes a connected source subgraph which covers a (discontinuous) phrase $\tilde{s}_i$.

3.1 Building Graphs

As a more powerful and natural structure for sentence modeling, a graph can model various kinds of word-relations together in a unified representation. In this paper, we use graphs to combine two commonly used relations: bigram relations and dependency relations. Figure 2 shows an example of a graph. Each edge in the graph denotes either a dependency relation or a bigram relation. Note that the graph we use in this paper is directed, connected, node-labeled and may contain cycles.

Bigram relations are implied in sequences and provide local and sequential information on pairs

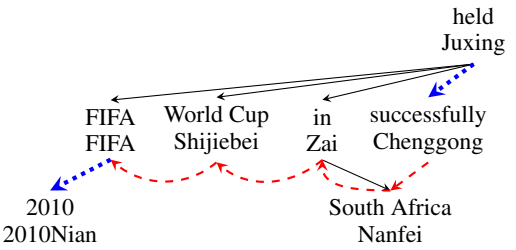

Figure 2: An example graph for a Chinese sentence. Each node includes a Chinese word and its English meaning. Dashed red lines are bigram relations. Solid lines are dependency relations. Dotted blue lines are shared by bigram and dependency relations.

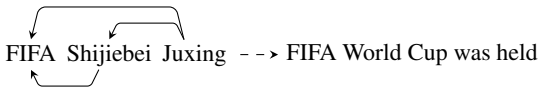
of continuous words. Phrases connected by bigram relations (i.e. continuous phrases) are known to be useful to improve phrase coverage (Hanneman and Lavie, 2009). By contrast, dependency relations come from dependency structures which model syntactic and semantic relations between words. Phrases whose words are connected by dependency relations (also known as treelets) are linguistic-motivated and thus more reliable (Quirk et al., 2005).

By combining these two relations together in graphs, we can make use of both continuous and linguistic-informed discontinuous phrases as long as they are connected subgraphs.

3.2 Training

Different from PB translation, the basic translation units in our model are subgraphs. Thus, during training, we extract subgraph–phrase pairs instead of phrase pairs on parallel graph–string sentences associated with word alignments.[1] An example of a translation rule is as follows:



Note that the source side of a rule in our model is a graph which can be used to cover either a continuous phrase or a discontinuous phrase according to its match in an input graph during decoding.

The algorithm for extracting translation rules is shown in Algorithm 1. This algorithm traverses each phrase pair $\langle \tilde{s}, \bar{t} \rangle$, which is within a length limit and consistent with a given word alignment

[1]Different from translation rules in conventional syntax-based MT, rules in our model are not learned based on synchronous grammars and so non-terminals are disallowed.

Algorithm 1: Algorithm for extracting translation rules from a graph-string pair.

Data: A word-aligned graph–string pair $(G(S), T, A)$
Result: A set of translation pairs R

```
1  for each phrase t̄ in T: | t̄ | ≤ L do
2      find the minimal (may be discontinuous) phrase s̃ in S so that | s̃ | ≤ L and ⟨s̃, t̄⟩ is consistent with A ;
3      Queue Q = {s̃};
4      while Q is not empty do
5          pop an element s̃ off;
6          if G(s̃) is connected then
7              add ⟨G(s̃), t⟩ to R;
8          end
9          if | s̃ | < L then
10             for each unaligned word s_i adjacent to s̃ do
11                 s̃′ = extend s̃ with s_i;
12                 add s̃′ to Q;
13             end
14         end
15     end
16 end
```

(lines 1–2), and outputs $\langle G(\tilde{s}), \bar{t} \rangle$ if $\tilde{s}$ is covered by a connected subgraph $G(\tilde{s})$ (lines 6–8). A source phrase can be extended with unaligned source words which are adjacent to the phrase (lines 9–14). We use a queue Q to store all phrases which are consistently aligned to the same target phrase (line 3).

3.3 Model and Decoding

We define our model in the log-linear framework (Och and Ney, 2002) over a derivation $D = r_1 r_2 \cdots r_N$, as in Equation (3):

$$p(D) \propto \prod_i \phi_i(D)^{\lambda_i} \tag{3}$$

where r_i are translation rules, ϕ_i are features defined on derivations and λ_i are feature weights. In our experiments, we use the standard 9 features: two translation probabilities $p(G(s)|t)$ and $p(t|G(s))$, two lexical translation probabilities $p_{lex}(s|t)$ and $p_{lex}(t|s)$, a language model $lm(t)$ over a translation t, a rule penalty, a word penalty, an unknown word penalty and a distortion feature d for distance-based reordering.

The calculation of the distortion feature d in our

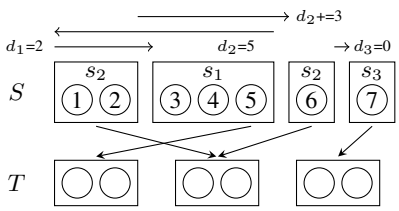


Figure 3: Distortion calculation for both continuous and discontinuous phrases in a derivation.

model is different from the one used in conventional PB models, as we need to take discontinuity into consideration. In this paper, we use a distortion function defined in Galley and Manning (2010) to penalize discontinuous phrases that have relatively long gaps. Figure 3 shows an example of calculating distortion for discontinuous phrases.

Our graph-based decoder is very similar to the PB decoder except that, in our decoder, each hypothesis is extended by translating an uncovered subgraph instead of a phrase. Positions covered by the subgraph are then marked as translated.

4 Graph Segmentation Model

Each derivation in our graph-based translation model implies a sequence of subgraphs (also called a segmentation). By default, similar to PB translation, our model treats each segmentation equally as shown in Equation (2). However, previous work on PB translation has suggested that such segmentations provide useful information which can improve translation performance. For example, boundary information in a phrase segmentation can be used for reordering models (Xiong et al., 2006; Cherry, 2013).

In this paper, we are interested in directly modeling the segmentation using information from graphs. By making the assumption that each subgraph is only dependent on previous subgraphs, we define a generative process over a graph segmentation as in Equation (4):

$$\begin{aligned} &p(G(\tilde{s}_1)\cdots G(\tilde{s}_I)) \\ &= \prod_{i=1}^{I} P(G(\tilde{s}_i)|G(\tilde{s}_1)\cdots G(\tilde{s}_{i-1})) \end{aligned} \quad (4)$$

Instead of training a stand-alone discriminative segmentation model to assign each subgraph a probability given previous subgraphs, we implement the model via sparse features, each of which is extracted at run-time during decoding and then directly added to the log-linear framework, so that these features can be tuned jointly with other features (of Section 3.3) to directly maximize the translation quality.

ZH–EN	#Sents

DE–EN	#Sents
Train	2M+
WMT11 (Dev)	3,003
WMT12	3,003
WMT13	3,000

Table 2: The number of sentences in our corpora.

Since a segmentation is obtained by breaking up the connectivity of an input graph, it is intuitive to use edges to model the segmentation. According to Equation (4), for a current subgraph G_i, we only consider those edges which are either inside G_i or connect G_i with a previous subgraph. Based on these edges, we extract sparse features for each node in the subgraph. The set of sparse features is defined as follows:

$$\begin{Bmatrix} n.w \\ n.c \end{Bmatrix} \times \begin{Bmatrix} n'.w \\ n'.c \end{Bmatrix} \times \begin{Bmatrix} C \\ P \\ H \end{Bmatrix} \times \begin{Bmatrix} in \\ out \end{Bmatrix}$$

where $n.w$ and $n.c$ are the word and class of the current node n, and $n'.w$ and $n'.c$ are the word and class of a node n' connected to n. C, P, and H denote that the node n' is in the current subgraph G_i or the adjacent previous subgraph G_{i-1} or other previous subgraphs, respectively. Note that we treat the adjacent previous subgraph differently from others since information from the last previous unit is quite useful (Xiong et al., 2006; Cherry, 2013). *in* and *out* denote that the edge is an incoming edge or outgoing edge for the current node n. Figure 4 shows an example of extracting sparse features for a subgraph.

Inspired by success in using sparse features in SMT (Cherry, 2013), in this paper we lexicalize only on the top-100 most frequent words. In addition, we group source words into 50 classes by using *mkcls* which should provide useful generalization (Cherry, 2013) for our model.

5 Experiment

We conduct experiments on Chinese–English (ZH–EN) and German–English (DE–EN) translation tasks. Table 2 provides a summary of our corpra. Our ZH–EN training corpus contains 1.5M+ sentences from LDC. NIST 2002 (MT02) is taken as a development set to tune weights, and NIST

Figure 4: An illustration of extracting sparse features for each node in a subgraph during decoding. The decoder segments the graph in Figure 2 into three subgraphs (solid rectangles) and produces a complete translation by combining translations of each subgraph (dashed rectangles). In this figure, the class of a word is randomly assigned.

2004 (MT04) and NIST 2005 (MT05) are two test sets used to evaluate the systems. The Stanford Chinese word segmenter (Chang et al., 2008) is used to segment Chinese sentences. The Stanford dependency parser (Chang et al., 2009) parses a Chinese sentence into a projective dependency tree which is then converted to a graph by adding bigram relations.

The DE–EN training corpus is from WMT 2014, including Europarl V7 and News Commentary. News-Test 2011 (WMT11) is taken as a development set while News-Test 2012 (WMT12) and News-Test 2013 (WMT13) are test sets. We use mate-tools[2] to perform morphological analysis and parse German sentences (Bohnet, 2010). Then, MaltParser[3] converts a parse result into a projective dependency tree (Nivre and Nilsson, 2005).

5.1 Settings

In this paper, we mainly report results from five systems under the same configuration. **PBMT** is built by the PB model in Moses (Koehn et al., 2007). **Treelet** extends PBMT by taking treelets as the basic translation units (Quirk et al., 2005; Menezes and Quirk, 2005). We implement a Treelet model in Moses which produces translations from left to right and uses beam search for decoding. **DTU** extends the PB model by allowing discontinuous phrases (Galley and Manning, 2010). We implement DTU with source discontinuity in Moses.[4] **GBMT** is our basic graph-based translation system while **GSM** adds the graph segmentation model into GBMT. Both systems are implemented in Moses.

Word alignment is performed by GIZA++ (Och and Ney, 2003) with the heuristic function *grow-diag-final-and*. We use SRILM (Stolcke, 2002) to train a 5-gram language model on the Xinhua portion of the English Gigaword corpus 5th edition with modified Kneser-Ney discounting (Chen and Goodman, 1996). Batch MIRA (Cherry and Foster, 2012) is used to tune weights. BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011), and TER (Snover et al., 2006) are used for evaluation.

[2] http://code.google.com/p/mate-tools/
[3] http://www.maltparser.org/

[4] The re-implementation of DTU in Moses makes it easier to meaningfully compare systems under the same settings.

Metric	System	ZH–EN		DE–EN	
		MT04	MT05	WMT12	WMT13
BLEU ↑	PBMT	33.2	31.8	19.5	21.9
	Treelet	33.8*	31.7	19.6	22.1*
	DTU	**34.5***	32.3*	**19.8***	**22.3***
	GBMT	**34.7***	**32.4***	**19.8***	**22.4***
	GSM	**34.9**$^{*+}$	**32.7**$^{*+}$	**20.3**$^{*+}$	**22.9**$^{*+}$
METEOR ↑	PBMT	32.1	32.3	28.0	29.2
	Treelet	31.9	31.8	28.0	29.1
	DTU	**32.3***	**32.4**	**28.2***	**29.5***
	GBMT	**32.4**$^{*+}$	**32.5***	**28.2***	**29.4***
	GSM	**32.7**$^{*+}$	**32.6**$^{*+}$	**28.5**$^{*+}$	**29.8**$^{*+}$
TER ↓	PBMT	60.6	61.6	63.7	60.2
	Treelet	60.1*	61.4	63.2*	59.6*
	DTU	60.0*	61.5	63.5*	59.8*
	GBMT	59.8^{*+}	61.3*	63.5*	59.8*
	GSM	60.5	62.1	63.1^{*+}	**59.3**$^{*+}$

Table 3: Metric scores for all systems on Chinese–English (ZH–EN) and German–English (DE–EN). Each score is an average over three MIRA runs (Clark et al., 2011). $*$ means a system is significantly better than PBMT at $p \leq 0.01$. Bold figures mean a system is significantly better than Treelet at $p \leq 0.01$. $+$ means a system is significantly better than DTU at $p \leq 0.01$. In this table, we mark a system by comparing it with previous ones.

5.2 Results and Discussion

Table 3 shows our evaluation results. We find that our GBMT system is significantly better than PBMT as measured by all three metrics across all test sets. Specifically, the improvements are up to +1.5/+0.5 BLEU, +0.3/+0.2 METEOR, and -0.8/-0.4 TER on ZH–EN and DE–EN, respectively. This improvement is reasonable as our system allows discontinuous phrases which can reduce data sparsity and handle long-distance relations (Galley and Manning, 2010). Another argument for discontinuous phrases is that they allow the decoder to use larger translation units which tend to produce better translations (Galley and Manning, 2010). However, this argument was only verified on ZH–EN. Therefore, we are interested in seeing whether we have the same observation in our experiments on both language pairs.

We count the used translation rules in MT02 and WMT11 based on different target lengths. The results are shown in Figure 5. We find that both DTU and GBMT indeed tend to use larger translation units on ZH–EN. However, more smaller translation units are used on DE–EN.[5] We presume this is because long-distance reordering is performed more often on ZH–EN than on DE–EN. Based on the fact that the distortion function d measures the reordering distance, we find that the average distortion value in PB on ZH–EN MT02 is 18.4 and 3.5 on DE–EN WMT11. Our observations suggest that the argument that discontinuous phrases allow decoders to use larger translation units should be considered with caution when we explain the benefit of discontinuity on different language pairs.

[5]We have the same finding on all test sets.

System	# Rules	
	ZH–EN	DE–EN
DTU	224M+	352M+
GBMT	99M+	153M+

Table 4: The number of rules in DTU and GBMT.

Compared to PBMT, the Treelet system does not show consistent improvements. Our system achieves significantly better BLEU and METEOR scores than Treelet on both ZH–EN and DE–EN, and a better TER score on DE–EN. This suggests that continuous phrases are essential for system robustness since it helps to improve phrase coverage (Hanneman and Lavie, 2009). Lower phrase coverage in Treelet results in more short phrases being used, as shown in Figure 5. In addition, we find that both DTU and our systems do not achieve consistent improvements over Treelet in terms of TER. We observed that both DTU and our systems tend to produce longer translations than Treelet, which might cause unreliable TER evaluation in our experiments as TER favours shorter sentences (He and Way, 2010).

Since discontinuous phrases produced by using syntactic information are fewer in number but

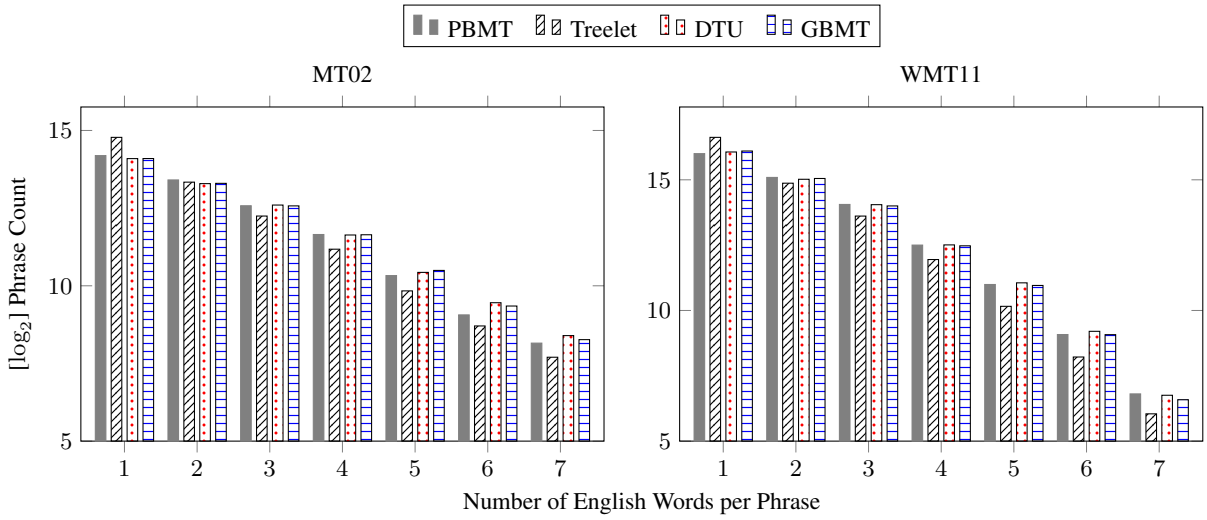

Figure 5: Phrase Length Histogram for MT02 and WMT11.

more reliable (Koehn et al., 2003), our GBMT system achieves comparable performance with DTU but uses significantly fewer rules, as shown in Table 4. After integrating the graph segmentation model to help subgraph selection, GBMT is further improved and the resulted system G2S has significantly better evaluation scores than DTU on both language pairs. However, our segmentation model is more helpful on DE–EN than ZH–EN. We find that the number of features learned on ZH–EN (25K+) is much less than on DE–EN (49K+). This may result in a lower feature coverage during decoding. The lower number of features in ZH–EN could be caused by the fact that the development set MT02 has many fewer sentences than WMT11. Accordingly, we suggest to use a larger development set during tuning to achieve better translation performance when the segmentation model is integrated.

Our current model is more akin to addressing problems in phrase-based and treelet-based models by segmenting graphs into pieces rather than extracting a recursive grammar. Therefore, similar to those models, our model is weak at phrase reordering as well. However, we are interesting in the potential power of our model by incorporating lexical reordering (LR) models and comparing it with syntax-based models.

Table 5 shows BLEU scores of the hierarchical phrase-based (HPB) system (Chiang, 2005) in Moses[6] and GBMT combined with a word-based LR model (Koehn et al., 2005). We find that the LR model significantly improves our system. GBMT+LR is comparable with the Moses HPB model on Chinese–English and better than HPB on German–English.

System	ZH–EN		DE–EN	
	MT04	MT05	WMT12	WMT13
GBMT+LR	36.0	33.9	20.6	23.6
HPB	36.1	34.1	20.3	22.8

Table 5: BLEU scores of a Moses hierarchical phrase-based system (HPB) and our system (GBMT) with a word-based lexical reordering model (LR).

5.3 Examples

Figure 6 shows three examples from MT04 to better explain the differences of each system. Example 1 shows that systems which allow discontinuous phrases (namely Treelet, DTU, GBMT, and GSM) successfully translate a Chinese collocation "*Yu . . . Wuguan*" to "*have nothing to do with*" while PBMT fails to catch the generalization since it only allows continuous phrases.

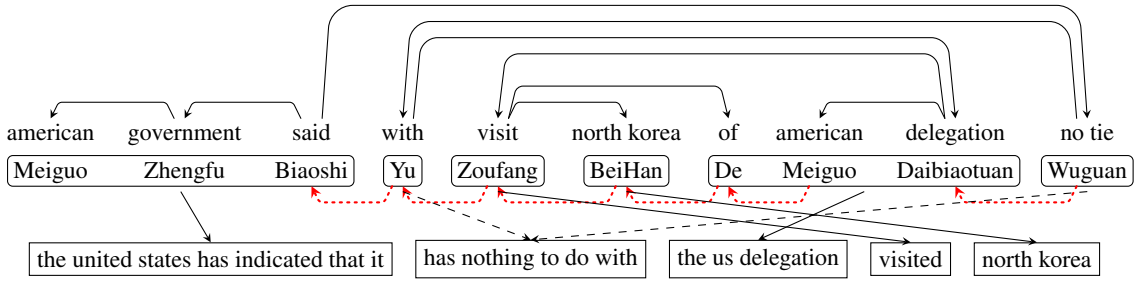
In Example 2, Treelet translates a discontinuous phrase "*Dui . . . Zuofa*" (to . . . practice) only as "*to*" where an important target word "*practice*" is dropped. By contrast, bigram relations allow our systems (GBMT and GSM) to find a better phrase to translate: "*De Zuofa*" to "*of practice*". In addition, DTU translates a discontinuous phrase "*De Zuofa . . . Buman*" to "*dissatisfaction with the approach of*". However, the phrase is actually not

[6]For a fairer comparison, we disallow target discontinuity in HPB rules. This means that a non-terminal on the target side is either the first symbol or the last symbol.

Example 1

PBMT: the united states has indicated that the united states and north korea delegation has visited	*Treelet*: the united states has indicated that it has nothing to do with the us delegation visited the north korea	*DTU*: the united states has indicated that it has nothing to do with the us delegation visited north korea	*GBMT*: the united states has indicated that it has nothing to do with the us delegation visited north korea	*GSM*: the united states has indicated that it has nothing to do with the us delegation visited north korea

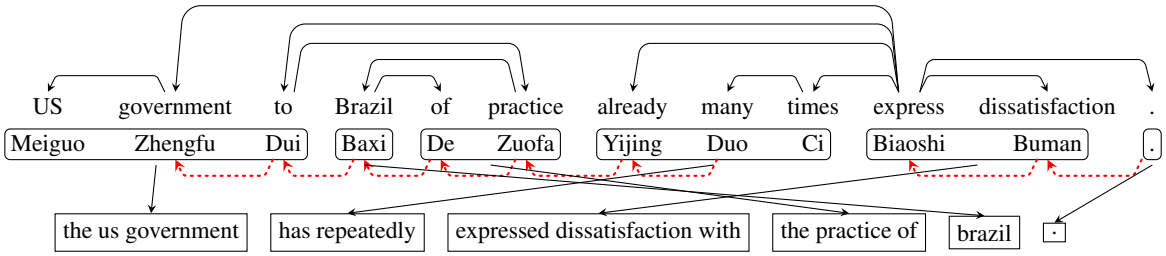
REF: the american government said that it has nothing to do with the american delegation to visit north korea



Example 2

PBMT: the united states government to brazil has repeatedly expressed its dissatisfaction .	*Treelet*: the government of brazil to the united states has on many occasions expressed their discontent .	*DTU*: the united states has repeatedly expressed its dissatisfaction with the approach of the government to brazil .	*GBMT*: the us government has repeatedly expressed dissatisfaction with the practice of brazil .	*GSM*: the us government has repeatedly expressed dissatisfaction with the practice of brazil .

REF: the us government has expressed their resentment against this practice of brazil on many occasions .



Example 3

PBMT: the government and all sectors of society should continue to explore in depth and draw on collective wisdom .	*Treelet*: the government must continue to make in-depth discussions with various sectors of the community and the collective wisdom .	*DTU*: the government must continue to work together with various sectors of the community to make an in-depth study and draw on collective wisdom .	*GBMT*: the government must continue to work together with various sectors of the community in-depth study and draw on collective wisdom .	*GSM*: the government must continue to make in-depth discussions with various sectors of the community and draw on collective wisdom .

REF: the government must continue to hold thorough discussions with all walks of life to pool the wisdom of the masses .

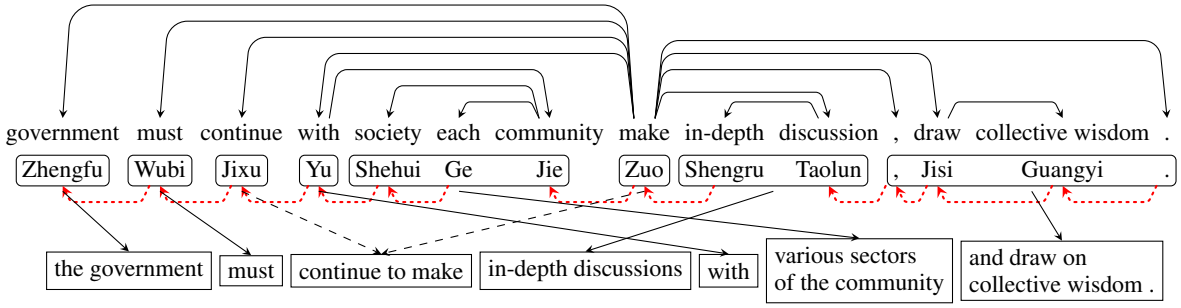


Figure 6: Translation examples from MT04 produced by different systems. Each source sentence is annotated by dependency relations and additional bigram relations (dotted red edges). We also annotate phrase alignments produced by our system GSM.

linguistically motivated and could be unreliable. By disallowing phrases which are not connected in the input graph, GBMT and GSM produce better translations.

Example 3 illustrates that our graph segmentation model helps to select better subgraphs. After obtaining a partial translation "*the government must*", GSM chooses to translate a subgraph which covers a discontinuous phrase "*Jixu ... Zuo*" to "*continue to make*" while GBMT translates "*Jixu Yu*" (continue ... with) to "*continue to work together with*". By selecting the proper subgraph to translate, GSM performs a better reordering on the translation.

6 Related Work

Starting from sequence-based models, SMT has been benefiting increasingly from complex structures.

Sequence-based MT: Since the breakthrough made by IBM on word-based models in the 1990s (Brown et al., 1993), SMT has developed rapidly. The PB model (Koehn et al., 2003) advanced the state-of-the-art by translating multi-word units, which makes it better able to capture local phenomena. However, a major drawback in PBMT is that only continuous phrases are considered. Galley and Manning (2010) extend PBMT by allowing discontinuity. However, without linguistic structure information such as syntax trees, sequence-based models can learn a large amount of phrases which may be unreliable.

Tree-based MT: Compared to sequences, trees provide recursive structures over sentences and can handle long-distance relations. Typically, trees used in SMT are either phrasal structures (Galley et al., 2004; Liu et al., 2006; Marcu et al., 2006) or dependency structures (Menezes and Quirk, 2005; Xiong et al., 2007; Xie et al., 2011; Li et al., 2014). However, conventional tree-based models only use linguistically well-formed phrases. Although they are more reliable in theory, discarding all phrase pairs which are not linguistically motivated is an overly harsh decision. Therefore, exploring more translation rules usually can significantly improve translation performance (Marcu et al., 2006; DeNeefe et al., 2007; Wang et al., 2007; Mi et al., 2008).

Graph-based MT: Compared to sequences and trees, graphs are more general and can represent more relations between words. In recent years, graphs have been drawing quite a lot of attention from researchers. Jones et al. (2012) propose a hypergraph-based translation model where hypergraphs are taken as a meaning representation of sentences. However, large corpora with annotated hypergraphs are not readily available for MT. Li et al. (2015) use an edge replacement grammar to translate dependency graphs which are converted from dependency trees by labeling edges. However, their model only focuses on subgraphs which cover continuous phrases.

7 Conclusion

In this paper, we extend the conventional phrase-based translation model by allowing discontinuous phrases. We use graphs which combine bigram and dependency relations together as inputs and present a graph-based translation model. Experiments on Chinese–English and German–English show our model to be significantly better than the phrase-based model as well as other more sophisticated models. In addition, we present a graph segmentation model to explicitly guide the selection of subgraphs. In experiments, this model further improves our system.

In the future, we will extend this model to allow discontinuity on target sides and explore the possibility of directly encoding reordering information in translation rules. We are also interested in using graphs for neural machine translation to see how it can translate and benefit from graphs.

Incremental Acquisition of Verb Hypothesis Space towards Physical World Interaction

{shelanbo, jchai}@cse.msu.edu

Abstract

As a new generation of cognitive robots start to enter our lives, it is important to enable robots to follow human commands and to learn new actions from human language instructions. To address this issue, this paper presents an approach that explicitly represents verb semantics through hypothesis spaces of fluents and automatically acquires these hypothesis spaces by interacting with humans. The learned hypothesis spaces can be used to automatically plan for lower-level primitive actions towards physical world interaction. Our empirical results have shown that the representation of a hypothesis space of fluents, combined with the learned hypothesis selection algorithm, outperforms a previous baseline. In addition, our approach applies incremental learning, which can contribute to life-long learning from humans in the future.

1 Introduction

As a new generation of cognitive robots start to enter our lives, it is important to enable robots to follow human commands (Tellex et al., 2014; Thomason et al., 2015) and to learn new actions from human language instructions (Cantrell et al., 2012; Mohan et al., 2013). To achieve such a capability, one of the fundamental challenges is to link higher-level concepts expressed by human language to lower-level primitive actions the robot is familiar with. While grounding language to perception (Gorniak and Roy, 2007; Chen and Mooney, 2011; Kim and Mooney, 2012; Artzi and Zettlemoyer, 2013; Tellex et al., 2014; Liu et al., 2014; Liu and Chai, 2015) has received much attention in recent years, less work has addressed grounding language to robotic action. Actions are often expressed by verbs or verb phrases. Most semantic representations for verbs are based on argument frames (e.g., thematic roles which capture participants of an action). For example, suppose a human directs a robot to "*fill the cup with milk*". The robot will need to first create a semantic representation for the verb "*fill*" where "*the cup*" and "*milk*" are grounded to the respective objects in the environment (Yang et al., 2016). Suppose the robot is successful in this first step, it still may not be able to execute the action "*fill*" as it does not know how this higher-level action corresponds to its lower-level primitive actions.

In robotic systems, operations usually consist of multiple segments of lower-level primitive actions (e.g., *move to*, *open gripper*, and *close gripper*) which are executed both sequentially and concurrently. Task scheduling provides the order or schedule for executions of different segments of actions and action planning provides the plan for executing each individual segment. Primitive actions are often predefined in terms of how they change the state of the physical world. Given a goal, task scheduling and action planning will derive a sequence of primitive actions that can change the initial environment to the goal state. The goal state of the physical world becomes a driving force for robot actions. Thus, beyond semantic frames, modeling verb semantics through their effects on the state of the world may provide a link to connect higher-level language and lower-level primitive actions.

Motivated by this perspective, we have developed an approach where each verb is explicitly represented by a hypothesis space of fluents (i.e., desired goal states) of the physical world, which is incrementally acquired and updated through interacting with humans. More specifically, given a human command, if there is no knowledge about the

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 108–117,
Berlin, Germany, August 7-12, 2016.

corresponding verb (i.e., no existing hypothesis space for that verb), the robot will initiate a learning process by asking human partners to demonstrate the sequence of actions that is necessary to accomplish this command. Based on this demonstration, a hypothesis space of fluents for that verb frame will be automatically acquired. If there is an existing hypothesis space for the verb, the robot will select the best hypothesis that is most relevant to the current situation and plan for the sequence of lower-level actions. Based on the outcome of the actions (e.g., whether it has successfully executed the command), the corresponding hypothesis space will be updated. Through this fashion, a hypothesis space for each encountered verb frame is incrementally acquired and updated through continuous interactions with human partners. In this paper, to focus our effort on representations and learning algorithms, we adopted an existing benchmark dataset (Misra et al., 2015) to simulate the incremental learning process and interaction with humans.

Compared to previous works (She et al., 2014b; Misra et al., 2015), our approach has three unique characteristics. First, rather than a single goal state associated with a verb, our approach captures a space of hypotheses which can potentially account for a wider range of novel situations when the verb is applied. Second, given a new situation, our approach can automatically identify the best hypothesis that fits the current situation and plan for lower-level actions accordingly. Third, through incremental learning and acquisition, our approach has a potential to contribute to life-long learning from humans. This paper provides details on the hypothesis space representation, the induction and inference algorithms, as well as experiments and evaluation results.

2 Related Work

Our work here is motivated by previous linguistic studies on verbs, action modeling in AI, and recent advances in grounding language to actions.

Previous linguistic studies (Hovav and Levin, 2008; Hovav and Levin, 2010) propose action verbs can be divided into two types: ***manner verbs*** that "specify as part of their meaning a manner of carrying out an action" (e.g., *nibble, rub, laugh, run, swim*), and ***result verbs*** that "specify the coming about of a result state" (e.g., *clean, cover, empty, fill, chop, cut, open, enter*). Recent work has shown that explicitly modeling resulting change of state for action verbs can improve grounded language understanding (Gao et al., 2016). Motivated by these studies, this paper focuses on result verbs and uses hypothesis spaces to explicitly represent the result states associated with these verbs.

In AI literature on action modeling, action schemas are defined with preconditions and effects. Thus, representing verb semantics for action verbs using resulting states can be connected to the agent's underlying planning modules. Different from earlier works in the planning community that learn action models from example plans (Wang, 1995; Yang et al., 2007) and from interactions (Gil, 1994), our goal here is to explore the representation of verb semantics and its acquisition through language and action.

There has been some work in the robotics community to translate natural language to robotic operations (Kress-Gazit et al., 2007; Jia et al., 2014; Sung et al., 2014; Spangenberg and Henrich, 2015), but not for the purpose of learning new actions. To support action learning, previously we have developed a system where the robot can acquire the meaning of a new verb (e.g., *stack*) by following human's step-by-step language instructions (She et al., 2014a; She et al., 2014b). By performing the actions at each step, the robot is able to acquire the desired goal state associated with the new verb. Our empirical results have shown that representing acquired verbs by resulting states allow the robot to plan for primitive actions in novel situations. Moreover, recent work (Misra et al., 2014; Misra et al., 2015) has presented an algorithm for grounding higher-level commands such as "microwave the cup" to lower-level robot operations, where each verb lexicon is represented as the desired resulting states. Their empirical evaluations once again have shown the advantage of representing verbs as desired states in robotic systems. Different from these previous works, we represent verb semantics through a hypothesis space of fluents (rather than a single hypothesis). In addition, we present an incremental learning approach for inducing the hypothesis space and selecting the best hypothesis.

3 An Incremental Learning Framework

An overview of our incremental learning framework is shown in Figure 1. Given a language

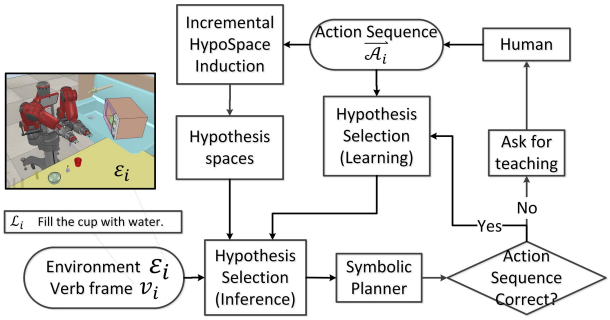

Figure 1: An incremental process of verb acquisition (i.e. learning) and application (i.e. inference).

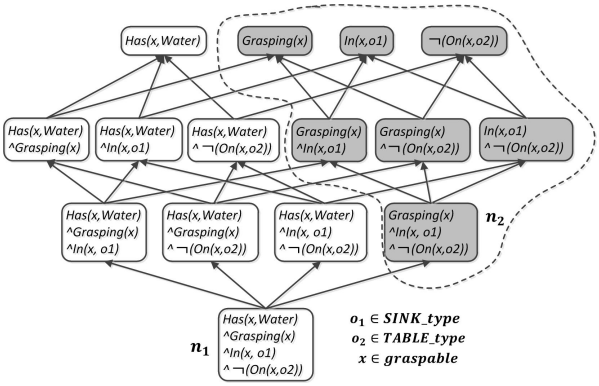

Figure 2: An example hypothesis space for the verb frame `fill(x)`. The bottom node captures the state changes after executing the *fill* command in the environment. Anchored by the bottom node, the hypothesis space is generated in a bottom-up fashion. Each node represents a potential goal state. The highlighted nodes are pruned during induction, as they are not consistent with the bottom node.

command $\mathcal{L}_i$ (e.g. *"fill the cup with water."*) and an environment $\mathcal{E}_i$ (e.g. a simulated environment shown in Figure 1), the goal is to identify a sequence of lower-level robotic actions to perform the command. Similar to previous works (Pasula et al., 2007; Mouro et al., 2012), the environment $\mathcal{E}_i$ is represented by a conjunction of grounded state fluents, where each fluent describes either the property of an object or relations (e.g. spatial) between objects. The language command $\mathcal{L}_i$ is first translated to an intermediate representation of grounded verb frame v_i through semantic parsing and referential grounding (e.g. for "*fill the cup*", the argument *the cup* is grounded to `Cup1` in the scene). The system knowledge of each verb frame (e.g., `fill(x)`) is represented by a *Hypothesis Space* $\mathcal{H}$, where each hypothesis (i.e. a node) is a description of possible fluents - or, in other words, resulting states - that are attributed to executing the verb command. Given a verb frame v_i and an environment $\mathcal{E}_i$, a *Hypothesis Selector* will choose an optimal hypothesis from space $\mathcal{H}$ to describe the expected resulting state of executing v_i in $\mathcal{E}_i$. Given this goal state and the current environment, a symbolic planner such as the STRIPS planner (Fikes and Nilsson, 1971) is used to generate an action sequence for the agent to execute. If the action sequence correctly performs the command (e.g. as evaluated by a human partner), the hypothesis selector will be updated with the success of its prediction. On the other hand, if the action has never been encountered (i.e., the system has no knowledge about this verb and thus the corresponding space is empty) or the predicted action sequence is incorrect, the human partner will provide an action sequence $\vec{A}_i$ that can correctly perform command v_i in the current environment. Using $\vec{A}_i$ as the ground truth information, the system will not only update the hypothesis selector, but will also update the existing space of v_i. The updated hypothesis space is treated as system knowledge of v_i, which will be used in future interaction. Through this procedure, a hypothesis space for each verb frame v_i is continually and incrementally updated through human-robot interaction.

4 State Hypothesis Space

To bridge human language and robotic actions, previous works have studied representing the semantics of a verb with a single resulting state (She et al., 2014b; Misra et al., 2015). One problem of this representation is that when the verb is applied in a new situation, if any part of the resulting state cannot be satisfied, the symbolic planner will not be able to generate a plan for lower-level actions to execute this verb command. The planner is also not able to determine whether the failed part of state representation is even necessary. In fact, this effect is similar to the over-fitting problem. For example, given a sequence of actions of performing `fill(x)`, the induced hypothesis could be "$Has(x, Water) \wedge Grasping(x) \wedge In(x, o_1) \wedge \neg(On(x, o_2))$", where x is a graspable object (e.g. a cup or bowl), o_1 is any type of sink, and o_2 is any table. However, during inference, when applied to a new situation that does not have any type of sink or table, this hypothesis will not

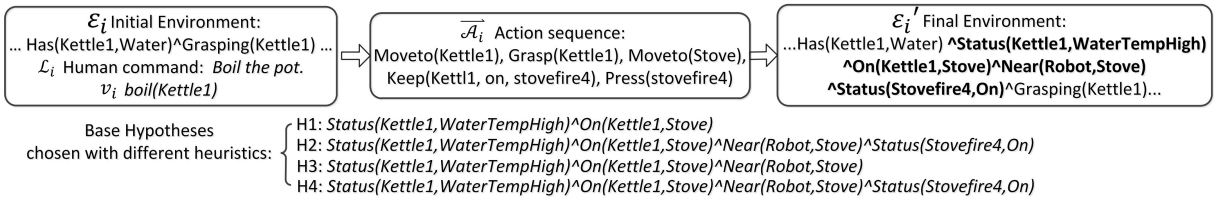

Figure 3: A training instance $\{\mathcal{E}_i, v_i, \vec{\mathcal{A}}_i\}$ for hypothesis space induction. $\mathcal{E}_i'$ is the resulting environment of executing $\vec{\mathcal{A}}_i$ in $\mathcal{E}_i$. The change of state in $\mathcal{E}_i'$ compared to $\mathcal{E}_i$ is highlighted in bold. Different heuristics generate different Base Hypotheses as shown at the bottom.

be applicable. Nevertheless, the first two terms $Has(x, Water) \wedge Grasping(x)$ may already be sufficient to generate a plan for completing the verb command.

To handle this over-fitting problem, we propose a hierarchical hypothesis space to represent verb semantics, as shown in Figure 2. The space is organized based on a specific-to-general hierarchical structure. Formally, a hypothesis space $\mathcal{H}$ for a verb frame is defined as: $\langle \mathbb{N}, \mathbb{E} \rangle$, where each $n_i \in \mathbb{N}$ is a hypothesis node and each $e_{ij} \in \mathbb{E}$ is a directed edge pointing from parent n_i to child n_j, meaning node n_j is more general than n_i and has one less constraint.

In Figure 2, the bottom hypothesis (n_1) is $Has(x, Water) \wedge Grasping(x) \wedge In(x, o1) \wedge \neg(On(x, o2))$. A hypothesis n_i represents a conjunction of parameterized state fluents l_k:

$$n_i := \wedge l_k, and\, l_k := [\neg]\, pred_k(x_{k_1}[, x_{k_2}])$$

A fluent l_k is composed of a predicate (e.g. object status: *Has,* or spatial relation: *On*) and a set of argument variables. It can be positive or negative. Take the bottom node in Figure 2 as an example, it contains four fluents including one negative term (i.e. $\neg(On(x, o_2))$) and three positive terms. During inference, the parameters will be grounded to the environment to check whether this hypothesis is applicable.

5 Hypothesis Space Induction

Given an initial environment $\mathcal{E}_i$, a language command which contains the verb frame v_i, and a corresponding action sequence $\vec{\mathcal{A}}_i$, $\{\mathcal{E}_i, v_i, \vec{\mathcal{A}}_i\}$ forms a training instance for hypothesis space induction. First, based on different heuristics, a base hypothesis is generated by comparing the state difference between the final and the initial environment. Second, a hypothesis space $\mathcal{H}$ is induced on top of this *Base Hypothesis* in a bottom-up fashion. And during induction some nodes are pruned. Third, if the system has existing knowledge for the same verb frame (i.e. an existing hypothesis space $\mathcal{H}_t$ for the same verb frame), this newly induced space will be merged with previous knowledge. Next we explain each step in detail.

5.1 Base Hypothesis Induction

One key concept in the space induction is the *Base Hypothesis* (e.g. the bottom node in Figure 2), which provides a foundation for building a space. As shown in Figure 3, given a verb frame v_i and a working environment $\mathcal{E}_i$, the action sequence $\vec{\mathcal{A}}_i$ given by a human will change the initial environment $\mathcal{E}_i$ to a final environment $\mathcal{E}_i'$. The state changes are highlighted in Figure 3. Suppose a state change can be described by n fluents. Then the first question is which of these n fluents should be included in the base hypothesis. To gain some understanding on what would be a good representation, we applied different heuristics of choosing fluents to form a base hypothesis as shown in Figure 3:

- $H1_{argonly}$: only includes the changed states associated with the argument objects specified in the frame (e.g., in Figure 3, `Kettle1` is the only argument).
- $H2_{manip}$: includes the changed states of all the objects that have been manipulated in the action sequence taught by the human.
- $H3_{argrelated}$: includes the changed states of all the objects related to the argument objects in the final environment. An object o is considered as "related to" an argument object if there is a state fluent that includes both o and an argument object in one predicate. (e.g. `Stove` is related to the argument object `Kettle1` through $On(Kettle1, Stove)$).

Input: A Base Hypothesis h
Initialization: Set initial space $\mathcal{H}$: $\langle \mathbb{N}, \mathbb{E} \rangle$ with $\mathbb{N}$:[h] and $\mathbb{E}$:[ ],
Set a set of temporary hypotheses T:[h]
while T is not empty **do**
  Pop an element t from T
  Generate children [$t^{(0)}$,...,$t^{(k)}$] from t by removing each single fluent
  foreach i = 0 ... k **do**
    if $t^{(i)}$ is consistent with t **then**
      Append $t^{(i)}$ to T;
      Add $t^{(i)}$ to $\mathbb{N}$ if not already in;
      Add link $t \rightarrow t^{(i)}$ to $\mathbb{E}$ if not already in;
    else
      Prune $t^{(i)}$ and any node that can be generalized from $t^{(i)}$
    end
  end
end
Output: Hypothesis space $\mathcal{H}$

Algorithm 1: A single hypothesis space induction algorithm. $\mathcal{H}$ is a space initialized with a base hypothesis and an empty set of links. T is a temporary container of candidate hypotheses.

- $H4_{all}$: includes all the fluents whose values are changed from $\mathcal{E}_i$ to $\mathcal{E}_i'$ (e.g. all the four highlighted state fluents in $\mathcal{E}_i'$).

5.2 Single Space Induction

First we define the ***consistency*** between two hypotheses:

Definition. Hypotheses h_1 and h_2 are ***consistent***, if and only if the action sequence $\vec{\mathcal{A}}_1$ generated from a symbolic planner based on goal state h_1 is exactly the same as the action sequence $\vec{\mathcal{A}}_2$ generated based on goal state h_2.

Given a base hypothesis, the space induction process is a while-loop generalizing hypotheses in a bottom-up fashion, which stops when no hypotheses can be further generalized. As shown in Algorithm 1, a hypothesis node t can firstly be generalized to a set of immediate children [$t^{(0)}$,...,$t^{(k)}$] by removing a single fluent from t. For example, the base hypothesis n_1 in Figure 2 is composed of 4 fluents, such that 4 immediate children nodes can potentially be generated. If a child node $t^{(i)}$ is consistent with its parent t (i.e. determined based on the *consistency* defined previously), node $t^{(i)}$ and a link $t \rightarrow t^{(i)}$ are added to the space $\mathcal{H}$. The node $t^{(i)}$ is also added to a temporary hypothesis container waiting to be further generalized. On the other hand, some children hypotheses can be inconsistent with their parents. For example, the gray node (n_2) in Figure 2 is a child node that is inconsistent with its parent (n_1). As n_2 does not explicitly specify $Has(x, Water)$ as part of its goal state, the symbolic planner generates less steps to achieve goal state n_2 than goal state n_1. This implies that the semantics of achieving n_2 may be different than those for achieving n_1. Such hypotheses that are inconsistent with their parents are pruned. In addition, if $t^{(i)}$ is inconsistent with its parent t, any children of $t^{(i)}$ are also inconsistent with t (e.g. children of n_2 in Figure 2 are also gray nodes, meaning they are inconsistent with the base hypothesis). Through pruning, the size of entire space can be greatly reduced.

In the resulting hypothesis space, every single hypothesis is consistent with the base hypothesis. By only keeping consistent hypotheses via pruning, we can remove fluents that are not representative of the main goal associated with the verb.

5.3 Space Merging

If the robot has existing knowledge (i.e. hypothesis space $\mathcal{H}_t$) for a verb frame, the induced hypothesis space $\mathcal{H}$ from a new instance of the same verb will be merged with the existing space $\mathcal{H}_t$. Currently, a new space $\mathcal{H}_{t+1}$ is generated where the nodes of $\mathcal{H}_{t+1}$ are the union of $\mathcal{H}$ and $\mathcal{H}_t$, and links in $\mathcal{H}_{t+1}$ are generated by checking the parent-child relationship between nodes. In future work, more space merging operations will be explored, and human feedback will be incorporated into the induction process.

6 Hypothesis Selection

Hypothesis selection is applied when the agent intends to execute a command. Given a verb frame extracted from the language command, the agent will first select the best hypothesis (describing the goal state) from the existing knowledge base, and then apply a symbolic planner to generate an action sequence to achieve the goal. In our framework, the model of selecting the best hypothesis is incrementally learned throughout continuous interaction with humans. More specifically, given a correct action sequence (whether performed by the robot or provided by the human), a regression model is trained to capture the fitness of a hypothesis given a particular situation.

Inference: Given a verb frame v_i and a working environment $\mathcal{E}_i$, the goal of inference is to estimate how well each hypothesis h_k from a space $\mathcal{H}_t$ describes the expected result of performing v_i

in $\mathcal{E}_i$. The best fit hypothesis will be used as the goal state to generate the action sequence. Specifically, the "goodness" of describing command v_i with hypothesis h_k in environment $\mathcal{E}_i$ is formulated as follows:

$$f(h_k \mid v_i; \mathcal{E}_i; \mathcal{H}_t) = W^T \cdot \Phi(h_k, v_i, \mathcal{E}_i, \mathcal{H}_t) \quad (1)$$

where $\Phi(h_k, v_i, \mathcal{E}_i, \mathcal{H}_t)$ is a feature vector capturing multiple aspects of relations between $h_k, v_i, \mathcal{E}_i$ and $\mathcal{H}_t$ as shown in Table 1; and W captures the weight associated with each feature. Example global features include whether the candidate goal h_k is in the top level of entire space $\mathcal{H}_t$ and whether h_k has the highest frequency. Example local features include if most of the fluents in h_k are already satisfied in current scene $\mathcal{E}_i$ (as this h_k is unlikely to be a desired goal state). The features also include whether the same verb frame v_i has been performed in a similar scene during previous interactions, as the corresponding hypotheses induced during that experience are more likely to be relevant and are thus preferred.

Parameter Estimation: Given an action sequence $\vec{\mathcal{A}}_i$ that illustrates how to correctly perform command v_i in environment $\mathcal{E}_i$ during interaction, the model weights will be incrementally updated with[1]:

$$W_{t+1} = W_t - \eta(\alpha \frac{\partial R(W_t)}{\partial W_t} + \frac{\partial L(J_{ki}, f_{ki})}{\partial W_t})$$

where $f_{ki} := f(h_k|v_i; \mathcal{E}_i; \mathcal{H}_t)$ is defined in Equation 1. J_{ki} is the dependent variable the model should approximate, where $J_{ki} := J(s_i, h_k)$ is the Jaccard Index (details in Section 7) between hypothesis h_k and a set of changed states s_i (i.e. the changed states of executing the illustration action sequence $\vec{\mathcal{A}}_i$ in current environment). $L(J_{ki}, f_{ki})$ is a squared loss function. $\alpha R(W_t)$ is the penalty term, and η is the constant learning rate.

7 Experiment Setup

Dataset Description. To evaluate our approach, we applied the dataset made available by (Misra et al., 2015). To support incremental learning, each utterance from every original paragraph is extracted so that each command/utterance only contains one verb and its arguments. The corresponding initial environment and an action sequence taught by a human for each command are also extracted. An example is shown in Figure 3, where $\mathcal{L}_i$ is a language command, $\mathcal{E}_i$ is the initial working environment, and $\vec{\mathcal{A}}_i$ is a sequence of primitive actions to complete the command given by the human. In the original data, some sentences are not aligned with any actions, and thus cannot be used for either the learning or the evaluation. Removing these unaligned sentences resulted in a total of 991 data instances, including 165 different verb frames.

Features on candidate hypothesis h_k and the space $\mathcal{H}_t$ 1. If h_k belongs to the top level of $\mathcal{H}_t$. 2. If h_k has the highest frequency in $\mathcal{H}_t$.
Features on h_k and current situation $\mathcal{E}_i$ 3. Portion of fluents in h_k that are already satisfied by $\mathcal{E}_i$. 4. Portion of non-argument objects in h_k. Examples of non-argument objects are o_1 and o_2 in Figure 2.
Features on relations between a testing verb frame v_i and previous interaction experience 5. Whether the same verb frame v_i has been executed previously with the same argument objects. 6. Similarities between noun phrase descriptions used in current command and commands from interaction history.

Table 1: Current features used for incremental learning of the regression model. The first two are binary features and the rest are real-valued features.

Among the 991 data instances, 793 were used for incremental learning (i.e., space induction and hypothesis selector learning). Specifically, given a command, if the robot correctly predicts an action sequence[2], this correct prediction is used to update the hypothesis selector. Otherwise, the agent will require a correct action sequence from the human, which is used for hypothesis space induction as well as updating the hypothesis selector.

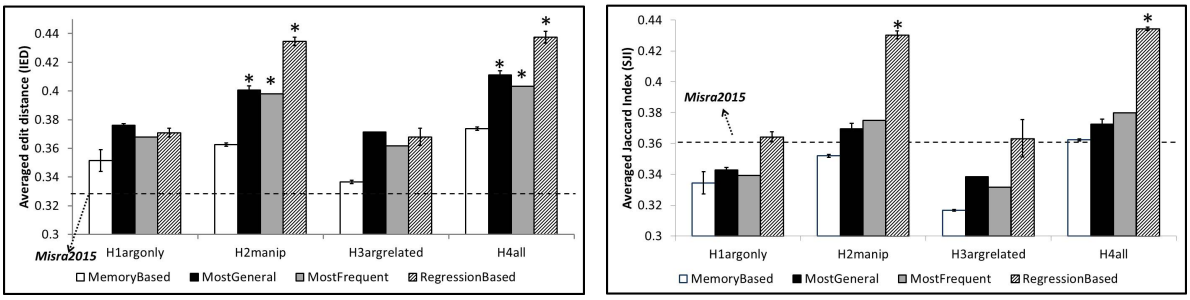
The hypothesis spaces and regression based selectors acquired at each run were evaluated on the other 20% (198) testing instances. Specifically, for each testing instance, the induced space and the hypothesis selector were applied to identify a desired goal state. Then a symbolic planner[3] was applied to predict an action sequence $\vec{\mathcal{A}}^{(p)}$ based on this predicted goal state. We then compared $\vec{\mathcal{A}}^{(p)}$ with the ground truth action sequence $\vec{\mathcal{A}}^{(g)}$ using the following two metrics.

- IED (*Instruction Edit Distance*) measures

[1]The SGD regressor in the scikit-learn (Pedregosa et al., 2011) is used to perform the linear regression with L2 regularization.

[2]Currently, a prediction is considered correct if the predicted result ($c^{(p)}$) is similar to a human labeled action sequence ($c^{(g)}$) (i.e., $SJI(c^{(g)}, c^{(p)}) > 0.5$).

[3]The symbolic planner implemented by (Rintanen, 2012) was utilized to generate action sequences.



(a) IED results for different configurations

(b) SJI results for different configurations

Figure 4: The overall performance on the testing set with different configurations in generating the base hypothesis and in hypothesis selection. Each configuration runs five times by randomly shuffling the order of learning instances, and the averaged performance is reported. The result from *Misra2015* is shown as a line. Results that are statistically significant better than *Misra2015* are marked with $*$ (*paired t-test,* $p< 0.05$).

similarity between the ground truth action sequence $\vec{\mathcal{A}}^{(g)}$ and the predicted sequence $\vec{\mathcal{A}}^{(p)}$. Specifically, the edit distance d between two action sequences $\vec{\mathcal{A}}^{(g)}$ and $\vec{\mathcal{A}}^{(p)}$ is first calculated. Then d is rescaled as $IED = 1 - d/max(\vec{\mathcal{A}}^{(g)}, \vec{\mathcal{A}}^{(p)})$, such that IED ranges from 0 to 1 and a larger IED means the two sequences are more similar.

- SJI (*State Jaccard Index*). Because different action sequences could lead to a same goal state, we also use Jaccard Index to check the overlap between the changed states. Specifically, executing the ground truth action sequence $\vec{\mathcal{A}}^{(g)}$ in the initial scene $\mathcal{E}_i$ results in a final environment $\mathcal{E}_i'$. Suppose the changed states between $\mathcal{E}_i$ and $\mathcal{E}_i'$ is $c^{(g)}$. For the predicted action sequence, we can calculate another set of changed states $c^{(p)}$. The Jaccard Index between $c^{(g)}$ and $c^{(p)}$ is evaluated, which also ranges from 0 to 1 and a larger SJI means the predicted state changes are more similar to the ground truth.

Configurations. We also compared the results of using the regression based selector to select a hypothesis (i.e., *RegressionBased*) with the following different strategies for selecting the hypothesis:

- *Misra2015*: The state of the art system reported in (Misra et al., 2015) on the command/utterance level evaluation[4].

- *MemoryBased*: Given the induced space, only the base hypotheses h_ks from each learning instances are used. Because these h_ks don't have any relaxation, they represent purely learning from memorization.

- *MostGeneral*: In this case, only those hypotheses from the top level of the hypothesis space are used, which contain the least number of fluents. These nodes are the most relaxed hypotheses in the space.

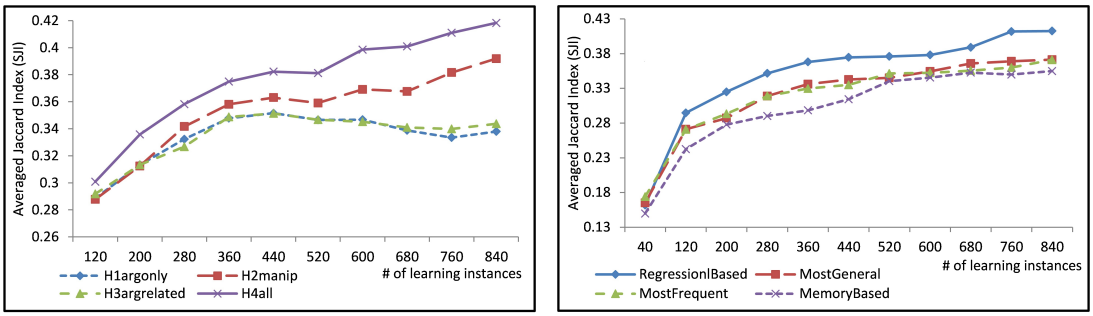
- *MostFrequent*: In this setting, the hypotheses that are most frequently observed in the learning instances are used.

8 Results

8.1 Overall performance

The results of the overall performance across different configurations are shown in Figure 4. For both of the IED and SJI (i.e. Figure 4(a) and Figure 4(b)), the hypothesis spaces with the regression model based hypothesis selector always achieve the best performance across different configurations, and outperforms the previous approach (Misra et al., 2015). For different base hypothesis induction strategies, the $H4_{all}$ considering all the changed states achieves the best performance across all configurations. This is because $H4_{all}$ keeps all of the state change information compared with other heuristics. The performance of $H2_{manip}$ is similar to $H4_{all}$. The reason is that, when all the manipulated objects are considered, the resulted set of changed states will cover most of the fluents in $H4_{all}$. On the other dimension,

[4]We applied the same system described in (Misra et al., 2015) to predict action sequences. The only difference is here we report the performance at the command level, not at the paragraph level.



(a) Use regression based selector to select hypothesis, and compare each base hypothesis induction heuristics.

(b) Induce the base hypothesis with $H4_{all}$, and compare different hypothesis selection strategies.

Figure 5: Incremental learning results. The spaces and regression models acquired at different incremental learning cycles are evaluated on testing set. The averaged Jaccard Index is reported.

the regression based hypothesis selector achieves the best performance and the *MemoryBased* strategy has the lowest performance. Results for *MostGeneral* and *MostFrequent* are between the regression based selector and *MemoryBased*.

8.2 Incremental Learning Results

Figure 5 presents the incremental learning results on the testing set. To better present the results, we show the performance based on each learning cycle of 40 instances. The averaged Jaccard Index (SJI) is reported. Specifically, Figure 5(a) shows the results of configurations comparing different base hypothesis induction heuristics using regression model based hypothesis selection. After using 200 out of 840 (23.8%) learning instances, all the four curves achieve more than 80% of the overall performance. For example, for the heuristic $H4_{all}$, the final average Jaccard Index is 0.418. When 200 instances are used, the score is 0.340 ($0.340/0.418 \approx 81\%$). The same number holds for the other heuristics. After 200 instances, $H4_{all}$ and $H2_{manip}$ consistently achieve better performance than $H1_{argonly}$ and $H3_{argrelated}$. This result indicates that while change of states mostly affect the arguments of the verbs, other state changes in the environment cannot be ignored. Modeling them actually leads to better performance. Using $H4_{all}$ for base hypothesis induction, Figure 5(b) shows the results of comparing different hypothesis selection strategies. The regression model based selector always outperforms other selection strategies.

8.3 Results on Frequently Used Verb Frames

Beside overall evaluation, we have also taken a closer look at individual verb frames. Most of the verb frames in the data have a very low frequency, which cannot produce statistically significant results. So we only selected verb frames with frequency larger than 40 in this evaluation. For each verb frame, 60% data are used for incremental learning and 40% are for testing. For each frame, a regression based selector is trained separately. The resulting SJI curves are shown in Figure 6.

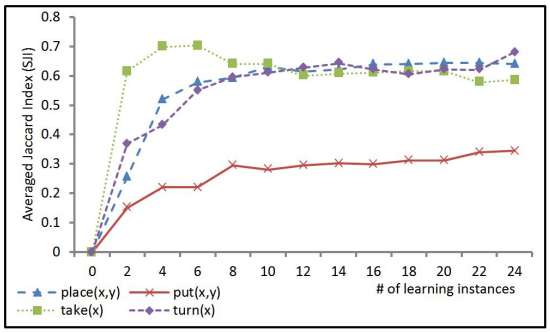


Figure 6: Incremental evaluation for individual verb frames. Four frequently used verb frames are examined: $place(x, y)$, $put(x, y)$, $take(x)$, and $turn(x)$. X-axis is the number of incremental learning instances, and Y-axis is the averaged SJI computed with $H4_{all}$ base hypothesis induction and regression based hypothesis selector.

As shown in Figure 6, all the four curves become steady after 8 learning instances are used. However, while some verb frames have final SJIs of more than 0.55 (i.e. $take(x)$ and $turn(x)$), others have relatively lower results (e.g. results for $put(x, y)$ are lower than 0.4). After examining the learning instances for $put(x, y)$, we found these data are more noisy than the training data for other frames. One source of errors is the incorrect object grounding results. For example, a problematic

training instance is "*put the pillow on the couch*", where the object grounding module cannot correctly ground the "*couch*" to the target object. As a result, the changed states of the second argument (i.e. the "*couch*") are incorrectly identified, which leads to incorrect prediction of desired states during inference. Another common error source is from automated parsing of utterances. The action frames generated from the parsing results could be incorrect in the first place, which would contribute to a hypothesis space for a wrong frame. These different types of errors are difficult to be recognized by the system itself. This points to the future direction of involving humans in a dialogue to learn a more reliable hypothesis space for verb semantics.

9 Conclusion

This paper presents an incremental learning approach that represents and acquires semantics of action verbs based on state changes of the environment. Specifically, we propose a hierarchical hypothesis space, where each node in the space describes a possible effect on the world from the verb. Given a language command, the induced hypothesis space, together with a learned hypothesis selector, can be applied by the agent to plan for lower-level actions. Our empirical results have demonstrated a significant improvement in performance compared to a previous leading approach. More importantly, as our approach is based on incremental learning, it can be potentially integrated in a dialogue system to support life-long learning from humans. Our future work will extend the current approach with dialogue modeling to learn more reliable hypothesis spaces of resulting states for verb semantics.

Abstract

We propose a framework for lexical substitution that is able to perform transfer learning across languages. Datasets for this task are available in at least three languages (English, Italian, and German). Previous work has addressed each of these tasks in isolation. In contrast, we regard the union of three shared tasks as a combined multilingual dataset. We show that a supervised system can be trained effectively, even if training and evaluation data are from different languages. Successful transfer learning between languages suggests that the learned model is in fact independent of the underlying language. We combine state-of-the-art unsupervised features obtained from syntactic word embeddings and distributional thesauri in a supervised delexicalized ranking system. Our system improves over state of the art in the full lexical substitution task in all three languages.

1 Introduction

The lexical substitution task is defined as replacing a target word in a sentence context with a synonym, which does not alter the meaning of the utterance. Although this appears easy to humans, automatically performing such a substitution is challenging, as it implicitly addresses the problem of both determining semantically similar substitutes, as well as resolving the ambiguity of polysemous words. In fact, lexical substitution was originally conceived as an extrinsic evaluation of Word Sense Disambiguation (WSD) when first proposed by McCarthy & Navigli (2007). However, a system capable of replacing words by appropriate meaning-preserving substitutes can be utilized in downstream tasks that require paraphrasing of input text. Examples of such use cases include text simplification, text shortening, and summarization. Furthermore, lexical substitution can be regarded as an alternative to WSD in downstream tasks requiring word disambiguation. For example, it was successfully applied in Semantic Textual Similarity (Bär et al., 2012). A given list of substitution words can be regarded as a vector representation modeling the meaning of a word in context. As opposed to WSD systems, this is not reliant on a predefined sense inventory, and therefore does not have to deal with issues of coverage, or sense granularity. On the other hand, performing lexical substitution is more complex than WSD, as a system has to both generate and rank a list of substitution candidates per instance.

Over the last decade, a number of shared tasks in lexical substitution has been organized and a wide range of methods have been proposed. Although many approaches are in fact language-independent, most existing work is tailored to a single language and dataset. In this work, we investigate lexical substitution as a multilingual task, and report experimental results for English, German and Italian datasets. We consider a supervised approach to lexical substitution, which casts the task as a ranking problem (Szarvas et al., 2013b). We adapt state-of-the-art unsupervised features (Biemann and Riedl, 2013; Melamud et al., 2015a) in a delexicalized ranking framework and perform transfer learning experiments by training a ranker model from a different language. Finally, we demonstrate the utility of aggregating data from different languages and train our model on this single multilingual dataset. We are able to improve the state of the art for the full task on all datasets.

The remainder of this paper is structured as follows. In Section 2 we elaborate on the lexical sub-

Berlin, Germany, August 7-12, 2016.

stitution task and datasets. Section 3 shows related work of systems addressing each of these tasks. In Section 4 we describe our method for building a supervised system capable of transfer learning. Section 5 shows our experimental results and discussion. Finally in Section 6 we give a conclusion and outlook to future work.

2 Lexical substitution datasets and evaluation

The lexical substitution task was first defined at *SemEval 2007* (McCarthy and Navigli, 2007, "SE07"). A lexical sample of target word is selected from different word classes (nouns, verbs, and adjectives). Through annotation, a set of valid substitutes was collected for 10-20 contexts per target. Whereas in the original SE07 task, annotators were free to provide "up to three, but all equally good" substitutes, later tasks dropped this restriction. Substitutes were subsequently aggregated by annotator frequency, creating a ranking of substitutes. The use of SE07 has become a de-facto standard for system comparison, however equivalent datasets have been produced for other languages. *Evalita 2009* posed a lexical substitution task for Italian (Toral, 2009, "EL09"). Participants were free to obtain a list of substitution candidates in any way, most commonly *Italian WordNet*[1] was used. A *WeightedSense* baseline provided by the organizers proved very strong, as all systems scored below it. This baseline is obtained by aggregating differently weighted semantic relations from multiple human-created lexical resources (Ruimy et al., 2002). A German version of the lexical substitution task was organized at *GermEval 2015* (Cholakov et al., 2014; Miller et al., 2015, "GE15"). Likewise, *WeightedSense* was able to beat both of two participating systems in *oot* evaluations (Miller et al., 2015).

A variation for *cross-lingual lexical substitution* was proposed by Mihalcea et al. (2010), in which substitute words are required in a different language than the source sentence. The sentence context as well as the target word were given in English, whereas the substitute words should be provided in Spanish (annotators were fluent in both languages). This variant is motivated by direct application in Machine Translation systems, or as an aid for human-based translation. There also exists a larger crowd-sourced dataset of 1012 nouns (Biemann, 2013, "TWSI"), as well as an all-words dataset in which all words in each sentence are annotated with lexical expansions (Kremer et al., 2014). Evaluation of lexical substitution adheres to metrics defined by SE07 (McCarthy and Navigli, 2007), who provide two evaluation settings[2]; *best* evaluating only a system's "best guess" of a single target substitute and *oot,* an unordered evaluation of up to ten substitutes. Thater et. al (2009) proposed to use *Generalized Average Precision* (GAP), to compare an output *ranking* rather than unordered sets of substitutes.

Dataset comparison The proposed lexical substitution datasets (SE07, EL09, GE15) differ in their degree of ambiguity of target items. If a dataset contains mostly target words that are unambiguous, substitution lists of different instances of the same target are similar, despite occurring in different context. We can quantify this degree of variation by measuring the overlap of gold substitutes of each target across all contexts. For this, we adapt the *pairwise agreement* (PA) metric defined by McCarthy & Navigli (2009). Instead of inter-annotator agreement we measure agreement across different context instances. Let T be a set of lexical target words, and D dataset of instances $(t_i, S_i) \in D$, in which target $t_i \in T$ is annotated with a set of substitutes S_i. Then we regard for each target word t the substitute sets $S_t \subset D$ for t. We define a *substitute agreement* as $SA(t)$ as the mean pairwise dice coefficient between all $s_1, s_2 \in S_t$ where $s_1 \neq s_2$. For each dataset D we list the substitute variance $SV = 1 - \frac{1}{|T|} \sum_{t \in T} SA(t)$. Table 1 shows this metric for the three datasets, as well as for subsets of the dataset according to target part of speech. It can be seen that the variance in gold substitutes differs substantially between datasets, but not much between target word type within a dataset. *EL09* has the highest degree of variance, suggesting that targets tend to be more ambiguous, whereas *GE15* has the lowest degree of variance, suggesting less ambiguity.

3 Related Work

Lexical substitution has been addressed extensively in recent years. Early systems, having only very few training instances available, use un-

[1] Italian WordNet has later been migrated into MultiWordNet (MWN), which is used in this work.

[2] The original SE07 task had a third evaluation setting MWE, in which systems had to correctly identify which target words were part of a multiword expression.

supervised approaches for determining appropriate substitutes. For the English SE07 task, systems mostly consider substitution candidates from *WordNet* (Fellbaum, 1998) and cast lexical substitution into a ranking task. Experiments may also be performed by pooling the set of candidates from the gold data, evaluating a pure ranking variant. Early approaches use a contextualized word instance representation and rank candidates according to their similarity to this representation. Effective representations are *syntactic vector space models* (Erk and Padó, 2008; Thater et al., 2011), which use distributional sparse vector representations based on the syntactic context of words. Performance improvement could be shown for different models, including the use of graph centrality algorithms on directional word similarity graphs (Sinha and Mihalcea, 2011), and clustering approaches on word instance representations (Erk and Padó, 2010). Multiple systems have built upon the distributional approach. Extensions include the use of LDA topic models (Ó Séaghdha and Korhonen, 2014), and probabilistic graphical models (Moon and Erk, 2013). The current state of the art combines a distributional model with the use of n-gram language models (Melamud et al., 2015a). They define the context vector of each word in a background corpus as a *substitute vector*, which is a vector of suitable filler words for the current n-gram context. They then obtain a contextualized *paraphrase vector* by computing a weighted average of substitute vectors in the background corpus, based on their similarity to the current target instance. In contrast to traditional sparse vector representations obtained through distributional methods, a recent trend is the use of low-dimensional dense vector representations. The use of such vector representations or word embeddings has been popularized by the *continuous bag-of-words* (CBOW) and *Skip-gram* model (Mikolov et al., 2013a). Melamud et al. (2015b) show a simple and knowledge-lean model for lexical substitution based solely on syntactic word embeddings. As we leverage this model as a feature in our approach, we will elaborate on this in Section 4. Another approach for applying word embeddings to lexical substitution is their direct extension with multiple word senses, which can be weighted according to target context (Neelakantan et al., 2014).

Biemann (2013) first showed that the lexical substitution task can be solved very well when sufficient amount of training data is collected per target. An approach based on crowdsourcing human judgments achieved the best performance on the S07 dataset to day. However, judgments had to be collected for each lexical item, and as a consequence the approach can not scale to an open vocabulary. As an alternative to *per-word* supervised systems trained on target instances per lexeme, *all-words* systems aim to generalize over all lexical items. Szarvas et al. (2013a) proposed such a system by using *delexicalization*: features are generalized in such a way that they are independent of lexical items, and thus generalize beyond the training set and across targets. Originally, a maximum entropy classifier was trained on target-substitute instances and used for pointwise ranking of substitution candidates. In a follow-up work it was shown that learning-to-rank methods could drastically improve this approach, achieving state-of-the-art performance with a *LambdaMART* ranker (Szarvas et al., 2013b). In this work we will build upon this model and further generalize not only across lexical items but across different languages.

For both EL09 and GE15, existing approaches have been adapted. For the Italian dataset, a distributional method was combined with LSA (De Cao and Basili, 2009). The best performing system applied a WSD system and language models (Basile and Semeraro, 2009). For the German dataset, Hintz and Biemann (2015) adapted the supervised approach by (Szarvas et al., 2013a), achieving best performance for nouns and adjectives. Jackov (2015) used a deep semantic analysis framework employing an internal dependency relation knowledge base, which achieved the best performance for verbs.

4 Method description

We subdivide lexical substitution into two subtasks; *candidate selection* and *ranking*. For a given target t, we consider a list of possible substi-

tutes $s \in C_t$, where C_t is a static per-target candidate list. Our method is agnostic to the creation of this static resource, which can be obtained either by an unsupervised similarity-based approach, or from a lexical resource. In particular, candidates obtained at this stage do not disambiguate possible multiple senses of t, and are filtered and ordered in the ranking stage by a supervised model.

In modeling a supervised system, we have experimented with two learning setups. The first is applying a standard classification / regression learner. Here, lexical substitution is cast into a pointwise ranking task by training on target-substitute pairs generated from the gold standard. For each sentence context c, target word t and substitute s, we regard the tuple (c,t,s) as a training instance. We obtain these training instances for each lexsub instance (c,t) by considering all substitutes $s \in G_t \cup C_t$ where G_t are all candidates for target t pooled from the gold data and C_t are obtained from lexical resources. We then experiment with two labeling alternatives for a binary classification and a regression setup, respectively. For binary classification we label each instance (c,t,s) as *positive* if s has been suggested as a substitute for t by at least one annotator, and as *negative* otherwise. For regression, we normalize the annotation counts for each substitute to obtain a score in $(0,1]$ if a substitute s occurs in the gold data, 0 otherwise. The ranking of substitutes per target is obtained by considering the posterior likelihood of the *positive* label as yielded by a classifier model. We have tried multiple classifiers but have found no significant improvement over a *maximum entropy* baseline[3]. Our second setup is a learning-to-rank framework, adapted from (Szarvas et al., 2013b). Here, we are not restricted to a pointwise ranking model, but consider pairwise and listwise models[4].

We base our feature model on existing research. In addition to basic syntactic and frequency-based features, we obtained sophisticated features from trigram and syntactic thesauri, motivated by the findings of Biemann and Riedl (2013), as well as syntactic embedding features motivated by Melamud et al. (2015b).

[3]For classification setup we use *Mallet*: `http://mallet.cs.umass.edu/`

[4]For learning-to-rank we use *RankLib*: `http://mallet.cs.umass.edu/`

all	0.242	0.223

Table 2: Upper bound for substitute recall based on lexical resources *WordNet*, *MultiWordNet*, *GermaNet*

4.1 Candidate selection

We confirm earlier research (Sinha and Mihalcea, 2009) on the high quality of selecting candidates from lexical resources. We thus base our candidate selection on prevalently used resources: *WordNet* (Fellbaum, 1998) for English, *GermaNet* (Hamp and Feldweg, 1997) for German and *MultiWordNet* (Pianta et al., 2002) for Italian. For all resources, we consider all possible senses for a given target word and obtain all *synonyms*, *hypernyms* and *hyponyms* and their transitive hull. Thus, for the *hypernymy* and *hyponymy* relation, we follow the respective edges in the graph collecting all nodes (synsets) along the path. For each synset, we extract all lemmas as substitution candidates. Although restricting candidates incurs a relatively low upper bound on system recall, we still obtain best results using this rather conservative filter. Table 2 shows the upper bound for system recall for each of the datasets, evaluated with and without removing all multiword expressions from both candidate lists and gold data. A higher coverage of *WordNet* is a plausible explanation for the much higher recall on the English data.

4.2 Supervised ranking

Learning-to-rank methods train a supervised model for ranking a list of items by *relevance*. A basic *pointwise* approach applies regression techniques to obtain a relevance scores for each item in isolation. More advanced models are based on *pairwise* preference information for instance pairs, and *listwise* approaches, which are optimized on a global metric of a given ranking output. An extensive overview of learning-to-rank models can be found in (Burges, 2010). For lexical substitution, *LambdaMART* (Wu et al., 2010) has been found to be particularly effective. *LambdaMART* is a listwise method based on gradient boosting of regression trees. Its two main hyperparameters are

the number of leaves in each regression tree and the number of iterations and trees. We have not performed extensive tuning of these hyperparameters and used default settings, an ensemble of 1000 trees with 10 leaves.

4.3 Delexicalized features

The idea of delexicalization has been proposed, for instance, by Bergsma et al. (2007). They propose to use statistical measures based solely on the frequency of different expansions of the same target term. Their feature set has motivated a large subset of the feature model, which we adapt in this work. The idea of generalizing features for lexical substitution in such a way that they work across lexical items has been shown by Moon and Erk (2013), and made explicit by Szarvas et al. (2013a). Instances are characterized using non-lexical features from heterogeneous evidence. The intuition of this feature model is to exploit redundant signals of substitutability from different sources and methods.

In cases where background corpora are required, the following data is used throughout all features: For English, a newspaper corpus compiled from 105 million sentences from the Leipzig Corpora Collection (Richter et al., 2006) and the Gigaword corpus (Parker et al., 2011) was used. For German a 70M sentence newswire corpus (Biemann et al., 2007) was used. For Italian, a subset of 40M sentences of *itWac*, a large web-crawl, was used (Baroni et al., 2009).

Shallow syntactic features We apply a part-of-speech tagger trained on universal POS tags (Petrov et al., 2012), which we simplify into the classes *noun*, *verb*, *adjective* and *adverb*. Using these simplified tags we construct an n-gram sliding window, with $n \in [1..5]$, of POS around the target. We could also reduce window sizes drastically to $n = 1{,}2$ without sacrificing performance.

Frequency features We use language models for each of the languages to obtain *frequency ratio* features. An n-gram sliding window around a target t is used to generate a set of features $\frac{freq(c_l,s,c_r)}{freq(c_l,t,c_r)}$, where c_l and c_r are the left and right context words around t. Here, we normalize the frequency of the substitute with the frequency of the n-gram with original target t. As a variant, we further normalize frequencies by the set of all substitutes, to obtain frequencies features $\frac{freq(c_l,s,c_r)}{\sum_{s' \in C_t} freq(c_l,s',c_r)}$ where C_t is the set of candidate substitutes for t. In our experiments we used sliding windows of size $[1..5]$. We obtain 5-gram counts from *web1t* (Brants and Franz, 2009).

Conjunction ratio features Based on the n-gram resources above, we further define a conjunctive phrase ratio feature, which measures how often the construct $(c_l, t, conjunction, s, c_r)$ occurs in a background corpus; i.e. how often t and s co-occur with a *conjunction* word ("*and*", "*or*", ","), within the context of the sentence. As there is a different set of conjunction words for each language, we first aggregate the mean over all conjunction words:

$$conj_{l,r}(t,s) = \frac{1}{|CONJ|} \sum_{con \in CONJ} freq(c_l,t,con,s,c_r)$$

where l and r is the size of the left and right context window, and $CONJ$ is a set of conjunction words per-language[5]. For left and right context size $l = r = 0$ this feature also captures a context-independent conjunction co-occurrence between only t and s. Again, we normalize this feature over the set of all candidates:

$$\frac{conj_{l,r}(t,s)}{\sum_{s' \in C_t} conj_{l,r}(t,s)}$$

Distributional features We construct a *distributional thesaurus* (DT) for each of the languages by following Biemann and Riedl (2013) and obtain first-order word-to-context measures, as well as second-order word-to-word similarity measures. As context features we have experimented with both syntactic dependencies as well as left and right neighboring words, and have found them to perform equivalently. As a salience measure we use *Lexicographer's Mutual Information* (Bordag, 2008) and prune the data, keeping only the 1000 most salient features per word. Word similarity is obtained from an overlap count in the pruned context features. We model features for the *contextualized* distributional similarity between t and s as

- percentage of shared context features for the top-k context features of t and s, globally and restricted to sentence context (k =5, 20, 50, 100, 200)

[5] Conjunction words used are *and*, *or*, (*comma*), for English; *und*, *oder*, (*comma*) for German and *e*, *ed*, *o*, *od*, (*comma*) for Italian.

- percentage of shared words for the top-k similar words of t and s (k =200)
- sum of salience score of context features of s overlapping with the sentence context
- binary occurrence of s in top-k similar words of t (k =100, 200)

With the exception of the last feature, these measures are scaled to $[0,1]$ over the set of all substitute candidates.

Syntactic word embeddings We adapt the unsupervised approach by (Melamud et al., 2015a) as a set of features. We follow (Levy and Goldberg, 2014) to construct dependency-based word embeddings; we obtain syntactic contexts by running a syntactic dependency parser[6], and computing word embeddings using dependency edges as context features[7]. The resulting dense vector representations for words and context live within the same vector space. We compute the semantic similarity between a target and a substitute word from the cosine similarity in the word embedding space, as well as the first-order target-to-context similarity. For a given target word t and substitute s, let C_t be the syntactic context of t and $c \in C_t$ a single context – i.e. a dependency edge attached to t; let v_t, v_s be the vector representations of t and s in the word embedding space, and v_c the vector representation of c in the context embedding space. Then $Sim_1 = \cos(v_s, v_c)$ and $Sim_2 = \cos(v_s, v_t)$ are the first-order and second-order substitutability measures considered by Melamud et al. (2015a). In contrast to their approach, we do not just consider an unsupervised combination of these two measures, but instead use both Sim_1 and Sim_2 as single features. We also use their combinations of a *balanced* / *unbalanced*, *arithmetic* / *geometrical* mean, to obtain six numeric features in total. Importantly, these features are independent of the underlying embedding vectors and can therefore generalize across arbitrary embeddings between languages.

Semantic resource features To generalize across multiple languages we minimize the complexity of features obtained from semantic resources – which may differ notably in size and structure. From the resources listed in Section 4.1 we extract binary features for the semantic relations *synonymy*, *hypernymy* and *hyponymy*, occurring between t and s. We have also experimented with graded variants for transitive relations, such as encoding n-th level hypernymy, but have not observed any gain from this feature variation.

[6] We trained models for *Mate* (`https://code.google.com/p/mate-tools/`) based on *universal dependencies* (`http://universaldependencies.org/`)

[7] We used *word2vecf* (`https://bitbucket.org/yoavgo/word2vecf`) for computing syntactic word embeddings

4.4 Transfer learning

Transfer learning is made feasible by a fully lexeme-independent and language-independent feature space. Language-specific knowledge resides only within the respective resources for each language, and gets abstracted in feature extraction. Figure 1 illustrates this process at the example of two entirely unrelated sentences in different languages (English and German). A further mediator for transfer learning is a model based on boosted decision trees. As opposed to linear models, which could not be reasonably learned across languages, a *LambdaMART* ranker is able to learn feature interaction across languages. To give an example of what the resulting model can pick up on, we can regard conditionally strong features. Consider the n-gram pair frequency ratio feature of window size $(l,r) = (1,0)$, which compares the frequency ratio of the target and substitute including a single left context word. Depending on the POS window, this feature can be highly informative in some cases, where it is less informative in others. For *adjective-noun* pairs, in which the noun is the substitution target, the model can learn that this frequency ratio is strongly positively correlated; in this case, the substitute frequently occurs with the same adjective than the original target. For other POS windows, for example *determiner-noun* pairs, the same frequency ratio may be less indicative, as most nouns frequently occur with a determiner. This property works across languages, as long as as attributive adjectives are prepositioned. In our subset of languages, this is the case for English and German, but not for Italian, which uses postpositive adjectives. Nevertheless, we are able to learn such universal feature interactions.

5 Results and discussion

Evaluation of lexical substitution requires special care, as different evaluation settings are used

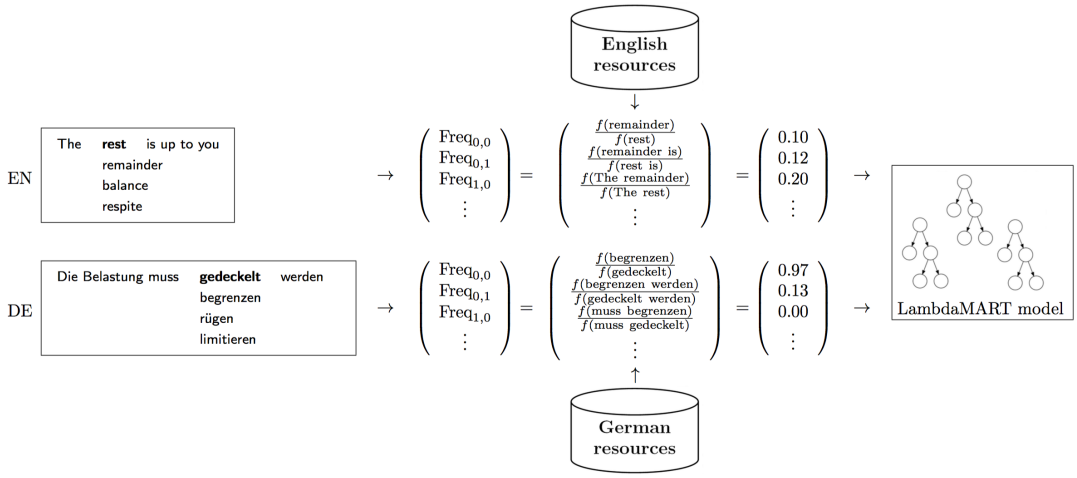

Figure 1: Visualization of feature extraction and delexicalization. Two unrelated sentences in English and German (translation: "*the strain has to be **limited***") are shown. Language-specific knowledge is obtained from resources for each language respectively. The resulting feature space is delexicalized and language independent.

throughout previous work and comparability is not always guaranteed. We follow the convention of reporting the full lexical substitution task (both generating and ranking candidates) with the metrics *P-best* and *P-oot* and report the ranking-only task (candidates pooled from the gold standard) with the *GAP* score. We further observe that previous work commonly discards multiword expressions from both the candidate lists as well as the gold data[8]. We follow this convention, but note that our system is in fact capable of successfully ranking multiword expansions out of the box. System performance slightly decreases when including MWE, as there is virtually no overlap between those provided by the system and those in the gold standard.

For ranking we experiment with different pointwise classifiers as provided by *Mallet* (MaxEnt classification and regression) as well learning-to-rank models provided by *RankLib* (RankBoost, RankNet, LambdaMART). In line with findings in (Szarvas et al., 2013b), we observe that learning-to-rank approaches work better than a pointwise classification / regression setup throughout all languages and feature subsets. Among different rankers, we confirm LambdaMART to yield the best performance, and will only report numbers using this model. As optimization metric we have explored both *NDCG@10* and *MAP*. The *NDCG* metric can incorporate different scoring weights based on annotator overlap, however MAP directly correlates with evaluation score. We have found optimizing on MAP to yield slightly better results, even if this disregards the relative score weights between gold substitutes. For the ranking-only task, we also extended the pooled training data with additional negative examples (i.e. adding all candidates as for the full task) but observed a minor decrease in system performance.

[8]The omission of MWE by multiple authors has been confirmed by the authors of (Melamud et al., 2015a).

Table 4: Transfer learning results on the ranking-only task (candidates pooled from gold)

We report transfer learning results across all three datasets. Table 3 shows a transfer-learning matrix for the full lexical substitution task, whereas Table 4 shows results for the ranking-only task. For evaluation, we consistently use the complete datasets, which are roughly equal in size for all languages (~ 2000 instances). For the identity entries in this matrix, as well as training on the complete dataset ("all") we follow previous supervised work and perform 10-fold cross-validation. Splits are based on the target lexeme, so that no two instances for the same target word are in different sets. Tables 3 and 4 suggest the feasibility of transfer learning. Although models trained on the original language (identity entries of the matrix) perform best, training on a different language still yields reasonable results. Training only on a single other language, not surprisingly, yields worse results for each dataset, however combining the data from the two remaining languages ("others") can mitigate this issue to some degree. Importantly, adding the data from two additional languages consistently improves system performance throughout all datasets for the open candidate task (Table 3). It is interesting to note that in case of SE07, training on only other languages performs surprisingly well for the *best-P* score, beating even a model trained on English. A possible explanation for this is that the SE07 dataset appears to be somewhere in the middle between EL09 and GE15 in terms of substitute variance. For the ranking-only task, transfer learning seems to work a little less effectively. In case of German, adding foreign language data in fact hurts *GAP* performance. This potentially originates from a much smaller set of training instances and inconsistency of the amount and overlap of pooled candidates across different tasks (as described in Table 1). We also observe that a learning-to-rank model is essential for performing transfer learning. In case of LambdaMART, an ensemble of decision trees is constructed, which is well suited to exploit redundant signals across multiple features. Linear models resulted in worse performance for transfer learning, as the resulting weights seem to be language-specific.

Feature ablation experiments are performed for various feature groups in the full and ranking-only task (Table 5). The ablation groups correspond to the feature categories defined in Section 4.3. The *frequency* group includes plain frequency features as well as conjunction ratio features. We consider only our universal model trained on all language data (with 10-fold CV for each dataset). In case of English, the full system performs best and all feature groups improve overall performance. For other languages these results are mixed. In case of the German data, embedding features and semantic relation features seem to work well on their own, so that results for other ablation groups are slightly better. For ranking-only, embedding features seem to be largely subsumed by the combination of the other groups. Ablation of embeddings differs vastly between the full and ranking-only task; they seem to more more crucial for the full task. For all languages, semantic relations are the best feature in the full task, acting as a strong filter for candidates; in ranking-only they are more dispensable.

In summary, we observe that delexicalized transfer learning for lexical substitution is possible. Existing supervised approaches can be extended to generalize across multiple languages without much effort. Training a supervised system on different language data emphasizes that the learned model is sufficiently generic to be language independent. Our feature space constructed from heterogeneous evidence consists of many features that perform relatively weakly on their own. The resulting ranking model captures redundancy between these signals. Finally, Table 6 shows our results in comparison to previous work. Note that we omit some participating systems from the original SE07 task. The reason we did not list IRST2 (Giuliano et al., 2007) is that for out-of-ten results, the system outputs the same substitute multiple times and the evaluation scheme gives credit for each copy of the substitute. Our (and other) systems do not tamper with the metric in this way, and only yield a set of substitutes. UNT (Hassan et al., 2007) uses a much richer set of knowledge bases, not all of them easily available, to achieve slightly better *oot* scores. From our experiments, we list both a model trained per language, as well as a universal model trained on all data. The latter beats nearly all other approaches on the full lexical substitution task, despite not being optimized for a single language. Although omission of MWEs is common practice for SE07, it is unclear if this was

[9] State of the art baseline, according to previous reported results, c.f. Table 6

	English		German		Italian

Table 5: Feature ablation results for the full and ranking-only task (universal model trained on all data)

done for EL09 and GE15. However, re-inclusion of MWE does not drastically alter results[10]. In the ranking-only variant, we are not able to beat the learning-to-rank approach by Szarvas et. al (2013b), we note however that they have performed extensive hyperparameter optimization of their ranker, which we have omitted. We are also not able to achieve *GAP* scores reported by Melamud at al. (2015b). Although we used their exact embeddings, we could not reproduce their results[11].

6 Conclusion

We are the first to model lexical substitution as a language-independent task by considering not just a single-language dataset, but by merging data from distinct tasks in English, German and Italian. We have shown that a supervised, delexicalized approach can successfully learn a single model across languages – and thus perform transfer learning for lexical substitution. We observe that a listwise ranker model such as LambdaMART facilitates this transfer learning. We have further shown that incorporating more data helps training a more robust model and can consistently improve system performance by adding foreign language training data. We extended an existing supervised learning-to-rank approach for lexical substitution (Szarvas et al., 2013b) with state-of-the-art embedding features (Melamud et al., 2015b). In our experiments, a single model trained on all data performed best on each language. In all three datasets we were able to improve the current state of the art for the full lexical substitution task. The resulting model can be regarded as language-independent; given an unannotated background corpus for computing language-specific resources and a source of substitution candidates, the system can be used almost out of the box. For obtaining substitution candidates, we still rely on lexical resources such as *WordNet*, which have to be available for each language. As future work we aim to make our approach completely knowledge-free by eliminating this dependency. We can consider substitution candidates based on their distributional similarity. First experiments confirm that this already yields a much better coverage, i.e. upper bound on recall, while introducing more noise. The remaining key challenge is to better characterize possible substitutes from bad substitutes in ranked lists of distributionally similar words, which frequently contain antonyms and co-hyponyms. We will explore unsupervised acquisition of relational similarity (Mikolov et al., 2013b) for this task.

Abstract

We use Bayesian optimization to learn curricula for word representation learning, optimizing performance on downstream tasks that depend on the learned representations as features. The curricula are modeled by a linear ranking function which is the scalar product of a learned weight vector and an engineered feature vector that characterizes the different aspects of the complexity of each instance in the training corpus. We show that learning the curriculum improves performance on a variety of downstream tasks over random orders and in comparison to the natural corpus order.

1 Introduction

It is well established that in language acquisition, there are robust patterns in the order by which phenomena are acquired. For example, prototypical concepts are acquired earlier; concrete words tend to be learned before abstract ones (Rosch, 1978). The acquisition of lexical knowledge in artificial systems proceeds differently. In general, models will improve during the course of parameter learning, but the time course of acquisition is not generally studied beyond generalization error as a function of training time or data size. We revisit this issue of choosing the order of learning—**curriculum learning**—framing it as an optimization problem so that a rich array of factors—including nuanced measures of difficulty, as well as prototypicality and diversity—can be exploited.

Prior research focusing on curriculum strategies in NLP is scarce, and has conventionally been following a paradigm of "starting small" (Elman, 1993), i.e., initializing the learner with "simple" examples first, and then gradually increasing data complexity (Bengio et al., 2009; Spitkovsky et al., 2010). In language modeling, this preference for increasing complexity has been realized by curricula that increase the entropy of training data by growing the size of the training vocabulary from frequent to less frequent words (Bengio et al., 2009). In unsupervised grammar induction, an effective curriculum comes from increasing length of training sentences as training progresses (Spitkovsky et al., 2010). These case studies have demonstrated that carefully designed curricula can lead to better results. However, they have relied on heuristics in selecting curricula or have followed the intuitions of human and animal learning (Kail, 1990; Skinner, 1938). Had different heuristics been chosen, the results would have been different. In this paper, we use curriculum learning to create improved word representations. However, rather than testing a small number of curricula, we search for an optimal curriculum using Bayesian optimization. A curriculum is defined to be the ordering of the training instances, in our case it is the ordering of paragraphs in which the representation learning model reads the corpus. We use a linear ranking function to conduct a systematic exploration of interacting factors that affect curricula of representation learning models. We then analyze our findings, and compare them to human intuitions and learning principles.

We treat curriculum learning as an outer loop in the process of learning and evaluation of vector-space representations of words; the iterative procedure is (1) predict a curriculum; (2) train word embeddings; (3) evaluate the embeddings on tasks that use word embeddings as the sole features. Through this model we analyze the impact of curriculum on word representation models and on extrinsic tasks. To quantify curriculum properties, we define three groups of features aimed at analyzing statistical and linguistic content and structure

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 130–139,
Berlin, Germany, August 7-12, 2016.

of training data: (1) diversity, (2) simplicity, and (3) prototypicality. A function of these features is computed to score each paragraph in the training data, and the curriculum is determined by sorting corpus paragraphs by the paragraph scores. We detail the model in §2. Word vectors are learned from the sorted corpus, and then evaluated on part-of-speech tagging, parsing, named entity recognition, and sentiment analysis (§3). Our experiments confirm that training data curriculum affects model performance, and that models with optimized curriculum consistently outperform baselines trained on shuffled corpora (§4). We analyze our findings in §5.

The contributions of this work are twofold. First, this is the first framework that formulates curriculum learning as an optimization problem, rather then shuffling data or relying on human intuitions. We experiment with optimizing the curriculum of word embeddings, but in principle the curriculum of other models can be optimized in a similar way. Second, to the best of our knowledge, this study is the first to analyze the impact of distributional and linguistic properties of training texts on the quality of task-specific word embeddings.

2 Curriculum Learning Model

We are considering the problem of maximizing a performance of an NLP task through sequentially optimizing the curriculum of training data of word vector representations that are used as features in the task.

Let $\mathcal{X} = \{x_1, x_2, \ldots, x_n\}$ be the training corpus with n lines (sentences or paragraphs). The curriculum of word representations is quantified by scoring each of the paragraphs according to the linear function $\mathbf{w}^\intercal \boldsymbol{\phi}(\mathcal{X})$, where $\boldsymbol{\phi}(\mathcal{X}) \in \mathbb{R}^{\ell \times 1}$ is a real-valued vector containing ℓ linguistic features extracted for each paragraph, and $\mathbf{w} \in \mathbb{R}^{\ell \times 1}$ denote the weights learned for these features. The feature values $\boldsymbol{\phi}(\mathcal{X})$ are z-normalized across all paragraphs. These scores are used to specify the order of the paragraphs in the corpus—the curriculum: we sort the paragraphs by their scores.

After the paragraphs are curriculum-ordered, the reordered training corpus is used to generate word representations. These word representations are then used as features in a subsequent NLP task. We define the objective function $eval : \mathcal{X} \rightarrow \mathbb{R}$, which is the quality estimation metric for this NLP task performed on a held-out dataset (e.g., correlation, accuracy, F_1 score, BLEU). Our goal is to define the features $\boldsymbol{\phi}(\mathcal{X})$ and to find the optimal weights $\mathbf{w}$ that maximize $eval$.

We optimize the feature weights using Bayesian optimization; we detail the model in §2.1. Distributional and linguistic features inspired by prior research in language acquisition and second language learning are described in §2.2. Figure 1 shows the computation flow diagram.

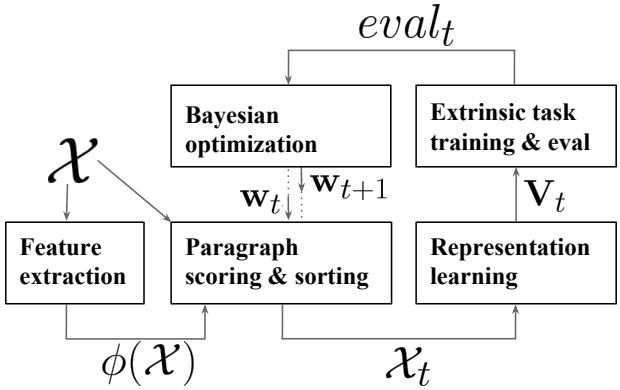

Figure 1: Curriculum optimization framework.

2.1 Bayesian Optimization for Curriculum Learning

As no assumptions are made regarding the form of $eval(\mathbf{w})$, gradient-based methods cannot be applied, and performing a grid search over parameterizations of $\mathbf{w}$ would require a exponentially growing number of parameterizations to be traversed. Thus, we propose to use Bayesian Optimization (BayesOpt) as the means to maximize $eval(\mathbf{w})$. BayesOpt is a methodology to globally optimize *expensive*, multimodal black-box functions (Shahriari et al., 2016; Bergstra et al., 2011; Snoek et al., 2012). It can be viewed as a sequential approach to performing a regression from high-level model parameters (e.g., learning rate, number of layers in a neural network, and in our model–curriculum weights $\mathbf{w}$) to the loss function or the performance measure ($eval$).

An arbitrary objective function, $eval$, is treated as a black-box, and BayesOpt uses Bayesian inference to characterize a posterior distribution over functions that approximate $eval$. This model of $eval$ is called the **surrogate model**. Then, the BayesOpt exploits this model to make decisions about $eval$, e.g., where is the expected maximum of the function, and what is the expected improvement that can be obtained over the best iteration so far. The strategy function, estimating the next set

of parameters to explore given the current beliefs about $eval$ is called the **acquisition function**. The surrogate model and the acquisition function are the two key components in the BayesOpt framework; their interaction is shown in Algorithm 1.

The surrogate model allows us to cheaply approximate the quality of a set of parameters $\mathbf{w}$ without running $eval(\mathbf{w})$, and the acquisition function uses this surrogate to choose a new value of $\mathbf{w}$. However, a trade-off must be made: should the acquisition function move $\mathbf{w}$ into a region where the surrogate believes an optimal value will be found, or should it explore regions of the space that reveal more about how $eval$ behaves, perhaps discovering even better values? That is, acquisition functions balance a tradeoff between exploration—by selecting $\mathbf{w}$ in the regions where the uncertainty of the surrogate model is high, and exploitation—by querying the regions where the model prediction is high.

Popular choices for the surrogate model are Gaussian Processes (Rasmussen, 2006; Snoek et al., 2012, GP), providing convenient and powerful prior distribution on functions, and tree-structured Parzen estimators (Bergstra et al., 2011, TPE), tailored to handle conditional spaces. Choices of the acquisition functions include probability of improvement (Kushner, 1964), expected improvement (EI) (Močkus et al., 1978; Jones, 2001), GP upper confidence bound (Srinivas et al., 2010), Thompson sampling (Thompson, 1933), entropy search (Hennig and Schuler, 2012), and dynamic combinations of the above functions (Hoffman et al., 2011); see Shahriari et al. (2016) for an extensive comparison. Yogatama et al. (2015) found that the combination of EI as the acquisition function and TPE as the surrogate model performed favorably in Bayesian optimization of text representations; we follow this choice in our model.

Algorithm 1 Bayesian optimization

$\mathcal{H} \leftarrow \emptyset$ ▷ Initialize observation history
$\mathcal{A} \leftarrow EI$ ▷ Initialize acquisition function
$\mathcal{S}_0 \leftarrow TPE$ ▷ Initialize surrogate model
for t $\leftarrow$ 1 to T **do**
  $\mathbf{w}_t \leftarrow \text{argmax}_{\mathbf{w}} \mathcal{A}(\mathbf{w}; \mathcal{S}_{t-1}, \mathcal{H})$ ▷ Predict $\mathbf{w}_t$ by optimizing acquisition function
  $eval(\mathbf{w}_t)$ ▷ Evaluate $\mathbf{w}_t$ on extrinsic task
  $\mathcal{H} \leftarrow \mathcal{H} \cup (\mathbf{w}_t, eval(\mathbf{w}_t))$ ▷ Update observation history
  Estimate $\mathcal{S}_t$ given $\mathcal{H}$
end for
return $\mathcal{H}$

2.2 Distributional and Linguistic Features

To characterize and quantify a curriculum, we define three categories of features, focusing on various distributional, syntactic, and semantic aspects of training data. We now detail the feature categories along with motivations for feature selection.

DIVERSITY. Diversity measures capture the distributions of types in data. Entropy is the best-known measure of diversity in statistical research, but there are many others (Tang et al., 2006; Gimpel et al., 2013). Common measures of diversity are used in many contrasting fields, from ecology and biology (Rosenzweig, 1995; Magurran, 2013), to economics and social studies (Stirling, 2007). Diversity has been shown effective in related research on curriculum learning in language modeling, vision, and multimedia analysis (Bengio et al., 2009; Jiang et al., 2014).

Let p_i and p_j correspond to empirical frequencies of word types t_i and t_j in the training data. Let d_{ij} correspond to their semantic similarity, calculated as the cosine similarity between embeddings of t_i and t_j learned from the training data. We annotate each paragraph with the following diversity features:

- Number of word types: $\#types$
- Type-token ratio: $\frac{\#types}{\#tokens}$
- Entropy: $-\sum_i p_i \ln(p_i)$
- Simpson's index (Simpson, 1949): $\sum_i {p_i}^2$
- Quadratic entropy (Rao, 1982):[1] $\sum_{i,j} d_{ij} p_i p_j$

SIMPLICITY. Spitkovsky et al. (2010) have validated the utility of syntactic simplicity in curriculum learning for unsupervised grammar induction by showing that training on sentences in order of increasing lengths outperformed other orderings. We explore the simplicity hypothesis, albeit without prior assumptions on specific ordering of data, and extend it to additional simplicity/complexity measures of training data. Our features are inspired by prior research in second language acquisition, text simplification, and readability assessment (Schwarm and Ostendorf, 2005; Heilman et al., 2007; Pitler and Nenkova, 2008; Vajjala and

[1] Intuitively, this feature promotes paragraphs that contain semantically similar high-probability words.

Meurers, 2012). We use an off-the-shelf syntactic parser[2] (Zhang and Clark, 2011) to parse our training corpus. Then, the following features are used to measure phonological, lexical, and syntactic complexity of training paragraphs:

- Language model score
- Character language model score
- Average sentence length
- Verb-token ratio
- Noun-token ratio
- Parse tree depth
- Number of noun phrases: $\#NPs$
- Number of verb phrases: $\#VBs$
- Number of prepositional phrases: $\#PPs$

PROTOTYPICALITY. This is a group of semantic features that use insights from cognitive linguistics and child language acquisition. The goal is to characterize the curriculum of representation learning in terms of the curriculum of human language learning. We resort to the Prototype theory (Rosch, 1978), which posits that semantic categories include more central (or prototypical) as well as less prototypical words. For example, in the ANIMAL category, *dog* is more prototypical than *sloth* (because *dog* is more frequent); *dog* is more prototypical than *canine* (because *dog* is more concrete); and *dog* is more prototypical than *bull terrier* (because *dog* is less specific). According to the theory, more prototypical words are acquired earlier. We use lexical semantic databases to operationalize insights from the prototype theory in the following semantic features; the features are computed on token level and averaged over paragraphs:

- Age of acquisition (AoA) of words was extracted from the crowd-sourced database, containing over 50 thousand English words (Kuperman et al., 2012). For example, the AoA of *run* is 4.47 (years), of *flee* is 8.33, and of *abscond* is 13.36. If a word was not found in the database it was assigned the maximal age of 25.
- Concreteness ratings on the scale of 1–5 (1 is most abstract) for 40 thousand English lemmas (Brysbaert et al., 2014). For example, *cookie* is rated as 5, and *spirituality* as 1.07.
- Imageability ratings are taken from the MRC psycholinguistic database (Wilson, 1988). Following Tsvetkov et al. (2014), we used the MRC annotations as seed, and propagated the ratings to all vocabulary words using the word embeddings as features in an ℓ_2-regularized logistic regression classifier.
- Conventionalization features count the number of "conventional" words and phrases in a paragraph. Assuming that a Wikipedia title is a proxy to a conventionalized concept, we counted the number of existing titles (from a database of over 4.5 million titles) in the paragraph.
- Number of syllables scores are also extracted from the AoA database; out-of-database words were annotated as 5-syllable words.
- Relative frequency in a supersense was computed by marginalizing the word frequencies in the training corpus over coarse semantic categories defined in the WordNet (Fellbaum, 1998; Ciaramita and Altun, 2006). There are 41 supersense types: 26 for nouns and 15 for verbs, e.g., NOUN.ANIMAL and VERB.MOTION. For example, in NOUN.ANIMAL the relative frequency of *human* is 0.06, of *dog* is 0.01, of *bird* is 0.01, of *cattle* is 0.009, and of *bumblebee* is 0.0002.
- Relative frequency in a synset was calculated similarly to the previous feature category, but word frequencies were marginalized over WordNet synsets (more fine-grained synonym sets). For example, in the synset {*vet, warhorse, veteran, oldtimer, seasoned stager*}, *veteran* is the most prototypical word, scoring 0.87.

3 Evaluation Benchmarks

We evaluate the utility of the pretrained word embeddings as features in downstream NLP tasks. We choose the following off-the-shelf models that utilize pretrained word embeddings as features:

Sentiment Analysis (Senti). Socher et al. (2013) created a treebank of sentences annotated with fine-grained sentiment labels on phrases and sentences from movie review excerpts. The coarse-grained treebank of positive and negative classes has been split into training, development, and test datasets containing 6,920, 872, and 1,821 sentences, respectively. We use the average of the word vectors of a given sentence as a feature vector for classification (Faruqui et al., 2015; Sedoc

[2] http://http://people.sutd.edu.sg/~yue_zhang/doc

et al., 2016). The ℓ_2-regularized logistic regression classifier is tuned on the development set and accuracy is reported on the test set.

Named Entity Recognition (NER). Named entity recognition is the task of identifying proper names in a sentence, such as names of persons, locations etc. We use the recently proposed LSTM-CRF NER model (Lample et al., 2016) which trains a forward-backward LSTM on a given sequence of words (represented as word vectors), the hidden units of which are then used as (the only) features in a CRF model (Lafferty et al., 2001) to predict the output label sequence. We use the CoNLL 2003 English NER dataset (Tjong Kim Sang and De Meulder, 2003) to train our models and present results on the test set.

Part of Speech Tagging (POS). For POS tagging, we again use the LSTM-CRF model (Lample et al., 2016), but instead of predicting the named entity tag for every word in a sentence, we train the tagger to predict the POS tag of the word. The tagger is trained and evaluated with the standard Penn TreeBank (PTB) (Marcus et al., 1993) training, development and test set splits as described in Collins (2002).

Dependency Parsing (Parse). Dependency parsing is the task of identifying syntactic relations between the words of a sentence. For dependency parsing, we train the stack-LSTM parser of Dyer et al. (2015) for English on the universal dependencies v1.1 treebank (Agić et al., 2015) with the standard development and test splits, reporting unlabeled attachment scores (UAS) on the test data. We remove all part-of-speech and morphology features from the data, and prevent the model from optimizing the word embeddings used to represent each word in the corpus, thereby forcing the parser to rely completely on the pretrained embeddings.

4 Experiments

Data. All models were trained on Wikipedia articles, split to paragraph-per-line. Texts were cleaned, tokenized, numbers were normalized by replacing each digit with "DG", all types that occur less than 10 times were replaces by the "UNK" token, the data was not lowercased. We list data sizes in table 1.

# paragraphs	# tokens	# types
2,532,361	100,872,713	156,663

Table 1: Training data sizes.

Setup. 100-dimensional word embeddings were trained using the `cbow` model implemented in the word2vec toolkit (Mikolov et al., 2013).[3] All training data was used, either shuffled or ordered by a curriculum. As described in §3, we modified the extrinsic tasks to learn solely from word embeddings, without additional features. All models were learned under same conditions, across curricula: in Parse, NER, and POS we limited the number of training iterations to 3, 3, and 1, respectively. This setup allowed us to evaluate the effect of curriculum without additional interacting factors.

Experiments. In all the experiments we first train word embedding models, then the word embeddings are used as features in four extrinsic tasks (§3). We tune the tasks on development data, and report results on the test data. The only component that varies across the experiments is order of paragraphs in the training corpus—the curriculum. We compare the following experimental setups:

- **Shuffled** baselines: the curriculum is defined by random shuffling the training data. We shuffled the data 10 times, and trained 10 word embeddings models, each model was then evaluated on downstream tasks. Following Bengio et al. (2009), we report test results for the system that is closest to the median in dev scores. To evaluate variability and a range of scores that can be obtained from shuffling the data, we also report test results for systems that obtained the highest dev scores.
- **Sorted** baselines: the curriculum is defined by sorting the training data by sentence length in increasing/decreasing order, similarly to (Spitkovsky et al., 2010).
- **Coherent** baselines: the curriculum is defined by just concatenating Wikipedia articles. The goal of this experiment is to evaluate the importance of semantic coherence in training data.

[3]To evaluate the impact of curriculum learning, we enforced sequential processing of data organized in a predefined order of training examples. To control for sequential processing, word embedding were learned by running the `cbow` using a single thread for one iteration.

Our intuition is that a coherent curriculum can improve models, since words with similar meanings and similar contexts are grouped when presented to the learner.

- **Optimized curriculum** models: the curriculum is optimized using the BayesOpt. We evaluate and compare models optimized using features from one of the three feature groups (§2.2). As in the shuffled baselines, we fix the number of trials (here, BayesOpt iterations) to 10, and we report test results of systems that obtained best dev scores.

Results. Experimental results are listed in table 2. Most systems trained with curriculum substantially outperform the strongest of all baselines. These results are encouraging, given that all word embedding models were trained on the same set of examples, only in different order, and display the indirect influence of the data curriculum on downstream tasks. These results support our assumption that curriculum matters. Albeit not as pronounced as with optimized curriculum, sorting paragraphs by length can also lead to substantial improvements over random baselines, but there is no clear recipe on whether the models prefer curricula sorted in an increasing or decreasing order. These results also support the advantage of a task-specific optimization framework over a general, intuition-guided recipe. An interesting result, also, that shuffling is not essential: systems trained on coherent data are on par (or better) than the shuffled systems.[4] In the next section, we analyze these results qualitatively.

5 Analysis

What are task-specific curriculum preferences? We manually inspect learned features and curriculum-sorted corpora, and find that best systems are obtained when their embeddings are learned from curricula appropriate to the downstream tasks. We discuss below several examples.

POS and Parse systems converge to the same set of weights, when trained on features that provide various measures of syntactic simplicity. The features with highest coefficients (and thus the most important features in sorting) are $\#NPs$, Parse tree depth, $\#VPs$, and $\#PPs$ (in this order). The sign in the $\#NPs$ feature weight, however, is the opposite from the other three feature weights (i.e., sorted in different order). $\#NPs$ is sorted in the increasing order of the number of noun phrases in a paragraph, and the other features are sorted in the decreasing order. Since Wikipedia corpus contains a lot of partial phrases (titles and headings), such curriculum promotes more complex, full sentences, and demotes partial sentences.

Best Senti system is sorted by prototypicality features. Most important features (with the highest coefficients) are Concreteness, Relative frequency in a supersense, and the Number of syllables. First two are sorted in decreasing order (i.e. paragraphs are sorted from more to less concrete, and from more to less prototypical words), and the Number of syllables is sorted in increasing order (this also promotes simpler, shorter words which are more prototypical). We hypothesize that this sorting reflects the type of data that Sentiment analysis task is trained on: it is trained on movie reviews, that are usually written in a simple, colloquial language.

Unlike POS, Parse, and Senti systems, all NER systems prefer curricula in which texts are sorted from short to long paragraphs. The most important features in the best (simplicity-sorted) system are $\#PPs$ and Verb-token ratio, both sorted from less to more occurrences of prepositional and verb phrases. Interestingly, most of the top lines in the NER system curricula contain named entities, although none of our features mark named entities explicitly. We show top lines in the simplicity-optimized system in figure 2.

Finally, in all systems sorted by prototypicality, the last line is indeed not a prototypical word *Donaudampfschiffahrtselektrizitätenhauptbetriebswerkbauunterbeamtengesellschaft*, which is an actual word in German, frequently used as an example of compounding in synthetic languages, but rarely (or never?) used by German speakers.

Weighting examples according to curriculum. Another way to integrate curriculum in word em-

[4]Note that in the shuffled NER baselines, best dev results yield lower performance on the test data. This implies that in the standard development/test splits the development and test sets are not fully compatible or not large enough. We also observe this problem in the curriculum-optimized Parse-prototypicality and Senti-diversity systems. The dev scores for the Parse systems are 76.99, 76.47, 76.47 for diversity, prototypicality, and simplicity, respectively, but the prototypicality-sorted parser performs poorly on test data. Similarly in the sentiment analysis task, the dev scores are 69.15, 69.04, 69.49 for diversity, prototypicality, and simplicity feature groups. Senti-diversity scores, however, are lower on the test data, although the dev results are better than in Senti-simplicity. This limitation of the standard dev/test splits is beyond the scope of this paper.

		Senti	NER	POS	Parse
Shuffled	median	66.01	85.88	96.35	75.08
	best	66.61	85.50	96.38	76.40
Sorted	long→short	66.78	85.22	96.47	75.85
	short→long	66.12	85.49	96.20	75.31
Coherent	original order	66.23	85.99	96.47	76.08
Optimized curriculum	diversity	66.06	86.09	96.59	**76.63**
	prototypicality	**67.44**	85.96	96.53	75.81
	simplicity	67.11	**86.42**	**96.62**	76.54

bedding training is to weight training examples according to curriculum during word representation training. We modify the `cbow` objective $\sum_{t=1}^{T} \log p(w_t|w_{t-c}..w_{t+c})$ as follows:[5]

$$\sum_{t=1}^{T}(\frac{1}{1+e^{-weight(w_t)}}+\lambda)\log p(w_t|w_{t-c}..w_{t+c})$$

Here, $weight(w_t)$ denotes the score attributed to the token w_t, which is the z-normalized score of the paragraph; λ=0.5 is determined empirically. $\log p(w_t)|w_{t-c}..w_{t+c})$ computes the probability of predicting word w_t, using the context of c words to the left and right of w_t. Notice that this quantity is no longer a proper probability, as we are not normalizing over the weights $weight(w_t)$ over all tokens. However, the optimization in word2vec is performed using stochastic gradient descent, optimizing for a single token at each iteration. This yields a normalizer of 1 for each iteration, yielding the same gradient as the original `cbow` model.

We retrain our best curriculum-sorted systems with the modified objective, also controlling for curriculum. The results are shown in table 3. We find that the benefit of integrating curriculum in training objective of word representations is not evident across tasks: Senti and NER systems trained on vectors with the modified objective substantially outperform best results in table 2; POS and Parse perform better than the baselines but worse than the systems with the original objective.

	Senti	NER	POS	Parse
curriculum	67.44	86.42	**96.62**	**76.63**
`cbow`+curric	**68.26**	**86.49**	96.48	76.54

Table 3: Evaluation of the impact of curriculum integrated in the `cbow` objective.

Are we learning task-specific curricula? One way to assess whether we learn meaningful task-specific curriculum preferences is to compare curricula learned by one downstream task across different feature groups. If learned curricula are similar in, say, NER system, despite being optimized once using diversity features and once using prototypicality features—two disjoint feature sets—we can infer that the NER task prefers word embeddings learned from examples presented in a certain order, regardless of specific optimization features. For each downstream task, we thus measure Spearman's rank correlation between the curricula optimized using diversity (D), or prototypicality (P), or simplicity (S) feature sets. Prior to measuring correlations, we remove duplicate lines from

[5]The modified word2vec tool is located at `https://github.com/wlin12/wang2vec`.

the training corpora. Correlation results across tasks and across feature sets are shown in table 4.

The general pattern of results is that if two systems score higher than baselines, training sentences of their feature embeddings have similar curricula (i.e., the Spearman's ρ is positive), and if two systems disagree (one is above and one is below the baseline), then their curricula also disagree (i.e., the Spearman's ρ is negative or close to zero). NER systems all outperform the baselines and their curricula have high correlations. Moreover, NER sorted by diversity and simplicity have better scores than NER sorted by prototypicality, and in line with these results $\rho(\text{S,D})_{NER} > \rho(\text{P,S})_{NER}$ and $\rho(\text{S,D})_{NER} > \rho(\text{D,P})_{NER}$. Similar pattern of results is in POS correlations. In Parse systems, also, diversity and simplicity features yielded best parsing results, and $\rho(\text{S,D})_{Parse}$ has high positive correlation. The prototypicality-optimized parser performed poorly, and its correlations with better systems are negative. The best parser was trained using the diversity-optimized curriculum, and thus $\rho(\text{D,P})_{Parse}$ is the lowest. Senti results follow similar pattern of curricula correlations.

	Senti	**NER**	**POS**	**Parse**
ρ(D, P)	-0.68	0.76	0.66	-0.76
ρ(P, S)	0.33	0.75	0.75	-0.45
ρ(S, D)	-0.16	0.81	0.51	0.67

Table 4: Curricula correlations across feature groups.

Curriculum learning vs. data selection. We compare the task of curriculum learning to the task of data selection (reducing the set of training instances to more important or cleaner examples). We reduce the training data to the subset of 10% of tokens, and train downstream tasks on the reduced training sets. We compare system performance trained using the top 10% of tokens in the best curriculum-sorted systems (Senti-prototypicality, NER-implicity, POS-simplicity, Parse-diversity) to the systems trained using the top 10% of tokens in a corpus with randomly shuffled paragraphs.[6] The results are listed in table 5.

The curriculum-based systems are better in POS and in Parse systems, mainly because these tasks prefer vectors trained on curricula that promote well-formed sentences (as discussed above). Conversely, NER prefers vectors trained on corpora that begin with named entities, so most of the tokens in the reduced training data are constituents in short noun phrases. These results suggest that the tasks of data selection and curriculum learning are different. Curriculum is about strong initialization of the models and time-course learning, which is not necessarily sufficient for data reduction.

	Senti	**NER**	**POS**	**Parse**
random	63.97	**82.35**	96.22	69.11
curriculum	**64.47**	76.96	**96.55**	**72.93**

6 Related Work

Two prior studies on curriculum learning in NLP are discussed in the paper (Bengio et al., 2009; Spitkovsky et al., 2010). Curriculum learning and related research on self-paced learning has been explored more deeply in computer vision (Bengio et al., 2009; Kumar et al., 2010; Lee and Grauman, 2011) and in multimedia analysis (Jiang et al., 2015). Bayesian optimization has also received little attention in NLP. GPs were used in the task of machine translation quality estimation (Cohn and Specia, 2013) and in temporal analysis of social media texts (Preotiuc-Pietro and Cohn, 2013); TPEs were used by Yogatama et al. (2015) for optimizing choices of feature representations—n-gram size, regularization choice, etc.—in supervised classifiers.

7 Conclusion

We used Bayesian optimization to optimize curricula for training dense distributed word representations, which, in turn, were used as the sole features in NLP tasks. Our experiments confirmed that better curricula yield stronger models. We also conducted an extensive analysis, which sheds better light on understanding of text properties that are beneficial for model initialization. The proposed novel technique for finding an optimal curriculum is general, and can be used with other datasets and models.

[6] Top $n\%$ tokens are used rather than top $n\%$ paragraphs because in all tasks except NER curriculum-sorted corpora begin with longer paragraphs. Thus, with top $n\%$ paragraphs our systems would have an advantage over random systems due to larger vocabulary sizes and not necessarily due to a better subset of data.

Abstract

The problem of rare and unknown words is an important issue that can potentially effect the performance of many NLP systems, including traditional count-based and deep learning models. We propose a novel way to deal with the rare and unseen words for the neural network models using attention. Our model uses two softmax layers in order to predict the next word in conditional language models: one predicts the location of a word in the source sentence, and the other predicts a word in the shortlist vocabulary. At each timestep, the decision of which softmax layer to use is adaptively made by an MLP which is conditioned on the context. We motivate this work from a psychological evidence that humans naturally have a tendency to point towards objects in the context or the environment when the name of an object is not known. Using our proposed model, we observe improvements on two tasks, neural machine translation on the Europarl English to French parallel corpora and text summarization on the Gigaword dataset.

1 Introduction

Words are the basic input/output units in most of the NLP systems, and thus the ability to cover a large number of words is a key to building a robust NLP system. However, considering that (i) the number of all words in a language including named entities is very large and that (ii) language itself is an evolving system (people create new words), this can be a challenging problem.

A common approach followed by the recent neural network based NLP systems is to use a softmax output layer where each of the output dimension corresponds to a word in a predefined word-shortlist. Because computing high dimensional softmax is computationally expensive, in practice the shortlist is limited to have only top-K most frequent words in the training corpus. All other words are then replaced by a special word, called the *unknown word (UNK)*.

The shortlist approach has two fundamental problems. The first problem, which is known as the *rare word* problem, is that some of the words in the shortlist occur less frequently in the training set and thus are difficult to learn a good representation, resulting in poor performance. Second, it is obvious that we can lose some important information by mapping different words to a single dummy token UNK. Even if we have a very large shortlist including all unique words in the training set, it does not necessarily improve the test performance, because there still exists a chance to see an unknown word at test time. This is known as the *unknown word* problem. In addition, increasing the shortlist size mostly leads to increasing rare words due to Zipf's Law.

These two problems are particularly critical in language understanding tasks such as factoid question answering (Bordes et al., 2015) where the words that we are interested in are often named entities which are usually unknown or rare words.

In a similar situation, where we have a limited information on how to call an object of interest, it seems that humans (and also some primates) have an efficient behavioral mechanism of drawing attention to the object: *pointing* (Matthews et al., 2012). Pointing makes it possible to deliver information and to associate context to a particular object without knowing how to call it. In particular, human infants use pointing as a fundamental communication tool (Tomasello et al., 2007).

In this paper, inspired by the pointing behavior of humans and recent advances in the atten-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 140–149,
Berlin, Germany, August 7-12, 2016.

tion mechanism (Bahdanau et al., 2014) and the pointer networks (Vinyals et al., 2015), we propose a novel method to deal with the rare or unknown word problem. The basic idea is that we can see many NLP problems as a task of predicting target text given context text, where some of the target words appear in the context as well. We observe that in this case we can make the model *learn to point* a word in the context and copy it to the target text, as well as *when to point*. For example, in machine translation, we can see the source sentence as the context, and the target sentence as what we need to predict. In Figure 1, we show an example depiction of how words can be copied from source to target in machine translation. Although the source and target languages are different, many of the words such as named entities are usually represented by the same characters in both languages, making it possible to copy. Similarly, in text summarization, it is natural to use some words in the original text in the summarized text as well.

Specifically, to predict a target word at each timestep, our model first determines the source of the word generation, that is, whether to take one from a predefined shortlist or to copy one from the context. For the former, we apply the typical softmax operation, and for the latter, we use the attention mechanism to obtain the pointing softmax probability over the context words and pick the one of high probability. The model learns this decision so as to use the pointing only when the context includes a word that can be copied to the target. This way, our model can predict even the words which are not in the shortlist, as long as it appears in the context. Although some of the words still need to be labeled as UNK, i.e., if it is neither in the shortlist nor in the context, in experiments we show that this *learning when and where to point* improves the performance in machine translation and text summarization.

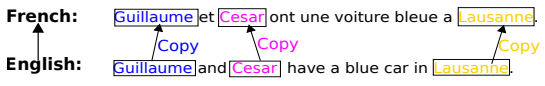

Figure 1: An example of how copying can happen for machine translation. Common words that appear both in source and the target can directly be copied from input to source. The rest of the unknown in the target can be copied from the input after being translated with a dictionary.

The rest of the paper is organized as follows. In the next section, we review the related works including pointer networks and previous approaches to the rare/unknown problem. In Section 3, we review the neural machine translation with attention mechanism which is the baseline in our experiments. Then, in Section 4, we propose our method dealing with the rare/unknown word problem, called the **Pointer Softmax (PS)**. The experimental results are provided in the Section 5 and we conclude our work in Section 6.

2 Related Work

The attention-based pointing mechanism is introduced first in the pointer networks (Vinyals et al., 2015). In the pointer networks, the output space of the target sequence is constrained to be the observations in the input sequence (not the input space). Instead of having a fixed dimension softmax output layer, softmax outputs of varying dimension is dynamically computed for each input sequence in such a way to maximize the attention probability of the target input. However, its applicability is rather limited because, unlike our model, there is no option to choose whether to point or not; it always points. In this sense, we can see the pointer networks as a special case of our model where we always choose to point a context word.

Several approaches have been proposed towards solving the rare words/unknown words problem, which can be broadly divided into three categories. The first category of the approaches focuses on improving the computation speed of the softmax output so that it can maintain a very large vocabulary. Because this only increases the shortlist size, it helps to mitigate the unknown word problem, but still suffers from the rare word problem. The hierarchical softmax (Morin and Bengio, 2005), importance sampling (Bengio and Senécal, 2008; Jean et al., 2014), and the noise contrastive estimation (Gutmann and Hyvärinen, 2012; Mnih and Kavukcuoglu, 2013) methods are in the class.

The second category, where our proposed method also belongs to, uses information from the context. Notable works are (Luong et al., 2015) and (Hermann et al., 2015). In particular, applying to machine translation task, (Luong et al., 2015) learns to point some words in source sentence and copy it to the target sentence, similarly to our method. However, it does not use attention mechanism, and by having fixed sized soft-

max output over the relative pointing range (e.g., -7, ..., -1, 0, 1, ..., 7), their model (the Positional All model) has a limitation in applying to more general problems such as summarization and question answering, where, unlike machine translation, the length of the context and the pointing locations in the context can vary dramatically. In question answering setting, (Hermann et al., 2015) have used placeholders on named entities in the context. However, the placeholder id is directly predicted in the softmax output rather than predicting its location in the context.

The third category of the approaches changes the unit of input/output itself from words to a smaller resolution such as characters (Graves, 2013) or bytecodes (Sennrich et al., 2015; Gillick et al., 2015). Although this approach has the main advantage that it could suffer less from the rare/unknown word problem, the training usually becomes much harder because the length of sequences significantly increases.

Simultaneously to our work, (Gu et al., 2016) and (Cheng and Lapata, 2016) proposed models that learn to copy from source to target and both papers analyzed their models on summarization tasks.

3 Neural Machine Translation Model with Attention

As the baseline neural machine translation system, we use the model proposed by (Bahdanau et al., 2014) that learns to (soft-)align and translate jointly. We refer this model as NMT.

The encoder of the NMT is a bidirectional RNN (Schuster and Paliwal, 1997). The forward RNN reads input sequence $\mathbf{x} = (x_1, \ldots, x_T)$ in left-to-right direction, resulting in a sequence of hidden states $(\overrightarrow{\mathbf{h}}_1, \ldots, \overrightarrow{\mathbf{h}}_T)$. The backward RNN reads $\mathbf{x}$ in the reversed direction and outputs $(\overleftarrow{\mathbf{h}}_1, \ldots, \overleftarrow{\mathbf{h}}_T)$. We then concatenate the hidden states of forward and backward RNNs at each time step and obtain a sequence of *annotation* vectors $(\mathbf{h}_1, \ldots, \mathbf{h}_T)$ where $\mathbf{h}_j = \left[\overrightarrow{\mathbf{h}}_j || \overleftarrow{\mathbf{h}}_j\right]$. Here, $||$ denotes the concatenation operator. Thus, each annotation vector $\mathbf{h}_j$ encodes information about the j-th word with respect to all the other surrounding words in both directions.

In the decoder, we usually use gated recurrent unit (GRU) (Cho et al., 2014; Chung et al., 2014). Specifically, at each time-step t, the soft-alignment mechanism first computes the relevance weight e_{tj} which determines the contribution of annotation vector $\mathbf{h}_j$ to the t-th target word. We use a non-linear mapping f (e.g., MLP) which takes $\mathbf{h}_j$, the previous decoder's hidden state $\mathbf{s}_{t-1}$ and the previous output y_{t-1} as input:

$$e_{tj} = f(\mathbf{s}_{t-1}, \mathbf{h}_j, y_{t-1}).$$

The outputs e_{tj} are then normalized as follows:

$$l_{tj} = \frac{\exp(e_{tj})}{\sum_{k=1}^{T} \exp(e_{tk})}. \quad (1)$$

We call l_{tj} as the relevance score, or the alignment weight, of the j-th annotation vector.

The relevance scores are used to get the *context vector* $\mathbf{c}_t$ of the t-th target word in the translation:

$$\mathbf{c}_t = \sum_{j=1}^{T} l_{tj} \mathbf{h}_j \ ,$$

The hidden state of the decoder $\mathbf{s}_t$ is computed based on the previous hidden state $\mathbf{s}_{t-1}$, the context vector $\mathbf{c}_t$ and the output word of the previous time-step y_{t-1}:

$$\mathbf{s}_t = f_r(\mathbf{s}_{t-1}, y_{t-1}, \mathbf{c}_t), \quad (2)$$

where f_r is GRU.

We use a deep output layer (Pascanu et al., 2013) to compute the conditional distribution over words:

$$p(y_t = a | y_{<t}, \mathbf{x}) \propto \exp\left(\psi^a_{(\mathbf{W}_o, \mathbf{b}_o)} f_o(\mathbf{s}_t, y_{t-1}, \mathbf{c}_t)\right), \quad (3)$$

where $\mathbf{W}$ is a learned weight matrix and $\mathbf{b}$ is a bias of the output layer. f_o is a single-layer feed-forward neural network. $\psi_{(\mathbf{W}_o, \mathbf{b}_o)}(\cdot)$ is a function that performs an affine transformation on its input. And the superscript a in ψ^a indicates the a-th column vector of ψ.

The whole model, including both the encoder and the decoder, is jointly trained to maximize the (conditional) log-likelihood of target sequences given input sequences, where the training corpus is a set of $(\mathbf{x}_n, \mathbf{y}_n)$'s. Figure 2 illustrates the architecture of the NMT.

4 The Pointer Softmax

In this section, we introduce our method, called as the pointer softmax (PS), to deal with the rare and unknown words. The pointer softmax can be

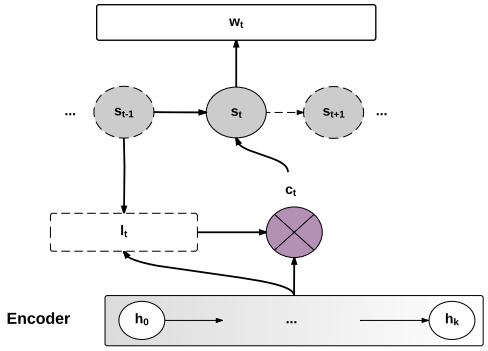

Figure 2: A depiction of neural machine translation architecture with attention. At each timestep, the model generates the attention weights $\mathbf{l}_t$. We use $\mathbf{l}_t$ the encoder's hidden state to obtain the context $\mathbf{c}_t$. The decoder uses $\mathbf{c}_t$ to predict a vector of probabilities for the words $\mathbf{w}_t$ by using softmax.

applicable approach to many NLP tasks, because it resolves the limitations about unknown words for neural networks. It can be used in parallel with other existing techniques such as the large vocabulary trick (Jean et al., 2014). Our model learns two key abilities jointly to make the pointing mechanism applicable in more general settings: (i) to predict whether it is required to use the pointing or not at each time step and (ii) to point any location of the context sequence whose length can vary widely over examples. Note that the pointer networks (Vinyals et al., 2015) are in lack of the ability (i), and the ability (ii) is not achieved in the models by (Luong et al., 2015).

To achieve this, our model uses two softmax output layers, the *shortlist* softmax and the *location* softmax. The shortlist softmax is the same as the typical softmax output layer where each dimension corresponds a word in the predefined word shortlist. The location softmax is a pointer network where each of the output dimension corresponds to the location of a word in the context sequence. Thus, the output dimension of the location softmax varies according to the length of the given context sequence.

At each time-step, if the model decides to use the shortlist softmax, we generate a word w_t from the shortlist. Otherwise, if it is expected that the context sequence contains a word which needs to be generated at the time step, we obtain the location of the context word l_t from the location softmax. The key to making this possible is deciding when to use the shortlist softmax or the location softmax at each time step. In order to accomplish this, we introduce a switching network to the model. The switching network, which is a multilayer perceptron in our experiments, takes the representation of the context sequence (similar to the input annotation in NMT) and the previous hidden state of the output RNN as its input. It outputs a binary variable z_t which indicates whether to use the shortlist softmax (when $z_t = 1$) or the location softmax (when $z_t = 0$). Note that if the word that is expected to be generated at each timestep is neither in the shortlist nor in the context sequence, the switching network selects the shortlist softmax, and then the shortlist softmax predicts UNK. The details of the pointer softmax model can be seen in Figure 3 as well.

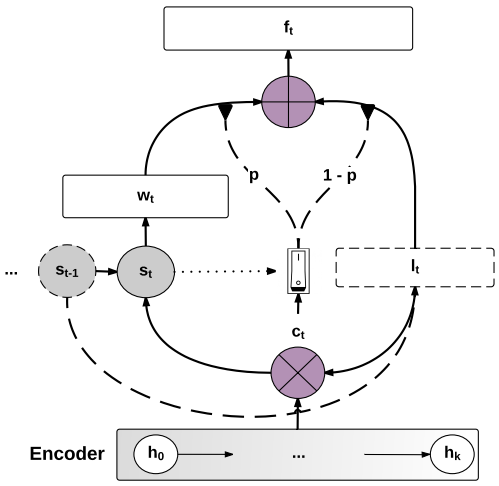

Figure 3: A simple depiction of the Pointer Softmax(PS) architecture. At each timestep as usual$\mathbf{l}_t$, $\mathbf{c}_t$ and the $\mathbf{w}_t$ for the words over the limited vocabulary(shortlist) is being generated. We have an additional switching variable z_t that decides whether to use $\mathbf{w}_t$ or copy the word from the input via $\mathbf{l}_t$. The final word prediction will be performed via pointer softmax $\mathbf{f}_t$ which can either copy the word from the source or predict the word from the shortlist vocabulary.

More specifically, our goal is to maximize the probability of observing the target word sequence $\mathbf{y} = (y_1, y_2, \ldots, y_{T_y})$ and the word generation source $\mathbf{z} = (z_1, z_2, \ldots, z_{T_y})$, given the context sequence $\mathbf{x} = (x_1, x_2, \ldots, x_{T_x})$:

$$p_\theta(\mathbf{y}, \mathbf{z}|\mathbf{x}) = \prod_{t=1}^{T_y} p_\theta(y_t, z_t|y_{<t}, z_{<t}, \mathbf{x}). \quad (4)$$

Note that the word observation y_t can be either a word w_t from the shortlist softmax or a location l_t from the location softmax, depending on the switching variable z_t.

Considering this, we can factorize the above equation further

$$p(\mathbf{y}, \mathbf{z}|\mathbf{x}) = \prod_{t \in \mathcal{T}_w} p(w_t, z_t|(y,z)_{<t}, \mathbf{x}) \times \prod_{t' \in \mathcal{T}_l} p(l_{t'}, z_{t'}|(y,z)_{<t'}, \mathbf{x}). \quad (5)$$

Here, $\mathcal{T}_w$ is a set of time steps where $z_t = 1$, and $\mathcal{T}_l$ is a set of time-steps where $z_t = 0$. And, $\mathcal{T}_w \cup \mathcal{T}_l = \{1, 2, \ldots, T_y\}$ and $\mathcal{T}_w \cap \mathcal{T}_l = \emptyset$. We denote all previous observations at step t by $(y,z)_{<t}$. Note also that $\mathbf{h}_t = f((y,z)_{<t})$.

Then, the joint probabilities inside each product can be further factorized as follows:

$$p(w_t, z_t|(y,z)_{<t}) = p(w_t|z_t = 1, (y,z)_{<t}) \times p(z_t = 1|(y,z)_{<t}) \quad (6)$$

$$p(l_t, z_t|(y,z)_{<t}) = p(l_t|z_t = 0, (y,z)_{<t}) \times p(z_t = 0|(y,z)_{<t}) \quad (7)$$

here, we omitted $\mathbf{x}$ which is conditioned on all probabilities in the above.

The switch probability is modeled as a multilayer perceptron with binary output:

$$p(z_t = 1|(y,z)_{<t}, \mathbf{x}) = \sigma(f(\mathbf{x}, \mathbf{h}_{t-1}; \theta)) \quad (8)$$

$$p(z_t = 0|(y,z)_{<t}, \mathbf{x}) = 1 - \sigma(f(\mathbf{x}, \mathbf{h}_{t-1}; \theta)). \quad (9)$$

And $p(w_t|z_t = 1, (y,z)_{<t}, \mathbf{x})$ is the shortlist softmax and $p(l_t|z_t = 0, (y,z)_{<t}, \mathbf{x})$ is the location softmax which can be a pointer network. $\sigma(\cdot)$ stands for the sigmoid function, $\sigma(x) = \frac{1}{\exp(-x)+1}$.

Given N such context and target sequence pairs, our training objective is to maximize the following log likelihood w.r.t. the model parameter θ

$$\arg\max_{\theta} \frac{1}{N} \sum_{n=1}^{N} \log p_\theta(y_n, z_n|x_n). \quad (10)$$

4.1 Basic Components of the Pointer Softmax

In this section, we discuss practical details of the three fundamental components of the pointer softmax. The interactions between these components and the model is depicted in Figure 3.

Location Softmax $\mathbf{l}_t$: The location of the word to copy from source text to the target is predicted by the location softmax $\mathbf{l}_t$. The location softmax outputs the conditional probability distribution $p(l_t|z_t = 0, (y,z)_{<t}, \mathbf{x})$. For models using the attention mechanism such as NMT, we can reuse the probability distributions over the source words in order to predict the location of the word to point. Otherwise we can simply use a pointer network of the model to predict the location.

Shortlist Softmax $\mathbf{w}_t$: The subset of the words in the vocabulary V is being predicted by the shortlist softmax $\mathbf{w}_t$.

Switching network d_t : The switching network d_t is an MLP with sigmoid output function that outputs a scalar probability of switching between $\mathbf{l}_t$ and $\mathbf{w}_t$, and represents the conditional probability distribution $p(z_t|(y,z)_{<t}, \mathbf{x})$. For NMT model, we condition the MLP that outputs the switching probability on the representation of the context of the source text $\mathbf{c}_t$ and the hidden state of the decoder $\mathbf{h}_t$. Note that, during the training, d_t is observed, and thus we do not have to sample.

The output of the pointer softmax, $\mathbf{f}_t$ will be the concatenation of the the two vectors, $d_t \times \mathbf{w}_t$ and $(1 - d_t) \times \mathbf{l}_t$.

At test time, we compute Eqn. (6) and (7) for all shortlist word w_t and all location l_t, and pick the word or location of the highest probability.

5 Experiments

In this section, we provide our main experimental results with the pointer softmax on machine translation and summarization tasks. In our experiments, we have used the same baseline model and just replaced the softmax layer with pointer softmax layer at the language model. We use the Adadelta (Zeiler, 2012) learning rule for the training of NMT models. The code for pointer softmax model is available at `https://github.com/caglar/pointer_softmax`.

5.1 The Rarest Word Detection

We construct a synthetic task and run some preliminary experiments in order to compare the results with the pointer softmax and the regular softmax's performance for the rare-words. The vocabulary size of our synthetic task is $|V| = 600$ using sequences of length 7. The words in the sequences are sampled according to their unigram distribu-

tion which has the form of a geometric distribution. The task is to predict the least frequent word in the sequence according to unigram distribution of the words. During the training, the sequences are generated randomly. Before the training, validation and test sets are constructed with a fixed seed.

We use a GRU layer over the input sequence and take the last-hidden state, in order to get the summary $\mathbf{c}_t$ of the input sequence. The $\mathbf{w}_t$, $\mathbf{l}_t$ are only conditioned on $\mathbf{c}_t$, and the MLP predicting the d_t is conditioned on the latent representations of $\mathbf{w}_t$ and $\mathbf{l}_t$. We use minibatches of size 250 using adam adaptive learning rate algorithm (Kingma and Adam, 2015) using the learning rate of 8×10^{-4} and hidden layers with 1000 units.

We train a model with pointer softmax where we assign pointers for the rarest 60 words and the rest of the words are predicted from the shortlist softmax of size 540. We observe that increasing the inverse temperature of the sigmoid output of d_t to 2, in other words making the decisions of d_t to become sharper, works better, i.e. $d_t = \sigma(2x)$.

At the end of training with pointer softmax we obtain the error rate of 17.4% and by using softmax over all 600 tokens, we obtain the error-rate of 48.2%.

5.2 Summarization

In these series of experiments, we use the annotated Gigaword corpus as described in (Rush et al., 2015). Moreover, we use the scripts that are made available by the authors of (Rush et al., 2015) [1] to preprocess the data, which results to approximately 3.8M training examples. This script generates about 400K validation and an equal number of test examples, but we use a randomly sampled subset of 2000 examples each for validation and testing. We also have made small modifications to the script to extract not only the tokenized words, but also system-generated named-entity tags. We have created two different versions of training data for pointers, which we call UNK-pointers data and entity-pointers data respectively.

For the UNK-pointers data, we trim the vocabulary of the source and target data in the training set and replace a word by the UNK token whenever a word occurs less than 5 times in either source or target data separately. Then, we create pointers from each UNK token in the target data to the position in the corresponding source document where the same word occurs in the source, as seen in the data before UNKs were created. It is possible that the source can have an UNK in the matching position, but we still created a pointer in this scenario as well. The resulting data has 2.7 pointers per 100 examples in the training set and 9.1 pointers rate in the validation set.

In the entity-pointers data, we exploit the named-entity tags in the annotated corpus and first anonymize the entities by replacing them with an integer-id that always starts from 1 for each document and increments from left to right. Entities that occur more than once in a single document share the same id. We create the anonymization at token-level, so as to allow partial entity matches between the source and target for multi-token entities. Next, we create a pointer from the target to source on similar lines as before, but only for exact matches of the anonymized entities. The resulting data has 161 pointers per 100 examples in the training set and 139 pointers per 100 examples in the validation set.

If there are multiple matches in the source, either in the UNK-pointers data or the entity-pointers data, we resolve the conflict in favor of the first occurrence of the matching word in the source document. In the UNK data, we model the UNK tokens on the source side using a single placeholder embedding that is shared across all documents, and in the entity-pointers data, we model each entity-id in the source by a distinct placeholder, each of which is shared across all documents.

In all our experiments, we use a bidirectional GRU-RNN (Chung et al., 2014) for the encoder and a uni-directional RNN for the decoder. To speed-up training, we use the large-vocabulary trick (Jean et al., 2014) where we limit the vocabulary of the softmax layer of the decoder to 2000 words dynamically chosen from the words in the source documents of each batch and the most common words in the target vocabulary. In both experiments, we fix the embedding size to 100 and the hidden state dimension to 200. We use pretrained word2vec vectors trained on the same corpus to initialize the embeddings, but we finetuned them by backpropagating through the embeddings during training. Our vocabulary sizes are fixed to 125K for source and 75K for target for both exper-

[1] https://github.com/facebook/NAMAS

iments.

We use the reference data for pointers for the model only at the training time. During the test time, the switch makes a decision at every timestep on which softmax layer to use.

For evaluation, we use full-length Rouge F1 using the official evaluation tool [2]. In their work, the authors of (Bahdanau et al., 2014) use full-length Rouge Recall on this corpus, since the maximum length of limited-length version of Rouge recall of 75 bytes (intended for DUC data) is already long for Gigaword summaries. However, since full-length Recall can unfairly reward longer summaries, we also use full-length F1 in our experiments for a fair comparison between our models, independent of the summary length.

The experimental results comparing the Pointer Softmax with NMT model are displayed in Table 1 for the UNK pointers data and in Table 2 for the entity pointers data. As the experiments show, pointer softmax improves over the baseline NMT on both UNK data and entities data. Our hope was that the improvement would be larger for the entities data since the incidence of pointers was much greater. However, it turns out this is not the case, and we suspect the main reason is anonymization of entities which removed data-sparsity by converting all entities to integer-ids that are shared across all documents. We believe that on de-anonymized data, our model could help more, since the issue of data-sparsity is more acute in this case.

Table 1: Results on Gigaword Corpus when pointers are used for UNKs in the training data, using Rouge-F1 as the evaluation metric.

	Rouge-1	Rouge-2	Rouge-L
NMT + lvt	34.87	16.54	32.27
NMT + lvt + PS	**35.19**	**16.66**	**32.51**

Table 2: Results on anonymized Gigaword Corpus when pointers are used for entities, using Rouge-F1 as the evaluation metric.

	Rouge-1	Rouge-2	Rouge-L
NMT + lvt	34.89	**16.78**	32.37
NMT + lvt + PS	**35.11**	16.76	**32.55**

[2] http://www.berouge.com/Pages/default.aspx

Table 3: Results on Gigaword Corpus for modeling UNK's with pointers in terms of recall.

	Rouge-1	Rouge-2	Rouge-L
NMT + lvt	36.45	17.41	33.90
NMT + lvt + PS	**37.29**	**17.75**	**34.70**

In Table 3, we provide the results for summarization on Gigaword corpus in terms of recall as also similar comparison done by (Rush et al., 2015). We observe improvements on all the scores with the addition of pointer softmax. Let us note that, since the test set of (Rush et al., 2015) is not publicly available, we sample 2000 texts with their summaries without replacement from the validation set and used those examples as our test set.

In Table 4 we present a few system generated summaries from the Pointer Softmax model trained on the UNK pointers data. From those examples, it is apparent that the model has learned to accurately point to the source positions whenever it needs to generate rare words in the summary.

5.3 Neural Machine Translation

In our neural machine translation (NMT) experiments, we train NMT models with attention over the Europarl corpus (Bahdanau et al., 2014) over the sequences of length up to 50 for English to French translation. [3]. All models are trained with early-stopping which is done based on the negative log-likelihood (NLL) on the development set. Our evaluations to report the performance of our models are done on `newstest2011` by using BLUE score. [4]

We use $30,000$ tokens for both the source and the target language shortlist vocabularies (1 of the token is still reserved for the unknown words). The whole corpus contains $134,831$ unique English words and $153,083$ unique French words. We have created a word-level dictionary from French to English which contains translation of 15,953 words that are neither in shortlist vocabulary nor dictionary of common words for both the source and the target. There are about $49,490$ words shared between English and French parallel corpora of Europarl.

[3] In our experiments, we use an existing code, provided in https://github.com/kyunghyuncho/dl4mt-material, and on the original model we only changed the last softmax layer for our experiments

[4] We compute the BLEU score using the multi-blue.perl script from Moses on tokenized sentence pairs.

During the training, in order to decide whether to pick a word from the source sentence using attention/pointers or to predict the word from the short-list vocabulary, we use a simple heuristic. If the word is not in the short-list vocabulary, we first check if the word $\mathbf{y}_t$ itself appears in the source sentence. If it is not, we check if the word itself is in the source sentence by using the shared words lookup table for the source and the target language. If the word is in the source sentence, we then use the location of the word in the source as the target. Otherwise we check if one of the English senses from the cross-language dictionary of the French word is in the source. If it is in the source sentence, then we use the location of that word as our translation. Otherwise we just use the argmax of $\mathbf{l}_t$ as the target.

For switching network d_t, we observed that using a two-layered MLP with noisy-tanh activation (Gulcehre et al., 2016) function with residual connection from the lower layer (He et al., 2015) activation function to the upper hidden layers improves the BLEU score about 1 points over the d_t using ReLU activation function. We initialized the biases of the last sigmoid layer of d_t to -1 such that if d_t becomes more biased toward choosing the shortlist vocabulary at the beginning of the training. We renormalize the gradients if the norm of the gradients exceed 1 (Pascanu et al., 2012).

In Table 5, we provided the result of NMT with pointer softmax and we observe about 3.6 BLEU score improvement over our baseline.

Table 5: Europarl Dataset (EN-FR)

	BLEU-4
NMT	20.19
NMT + PS	**23.76**

In Figure 4, we show the validation curves of the NMT model with attention and the NMT model with shortlist-softmax layer. Pointer softmax converges faster in terms of number of minibatch updates and achieves a lower validation negative-log-likelihood (NLL) (63.91) after $200k$ updates over the Europarl dataset than the NMT model with shortlist softmax trained for $400k$ minibatch updates (65.26). Pointer softmax converges faster than the model using the shortlist softmax, because the targets provided to the pointer softmax also acts like guiding hints to the attention.

6 Conclusion

In this paper, we propose a simple extension to the traditional soft attention-based shortlist softmax by using pointers over the input sequence. We show that the whole model can be trained jointly with single objective function. We observe noticeable improvements over the baselines on machine translation and summarization tasks by using pointer softmax. By doing a very simple mod-

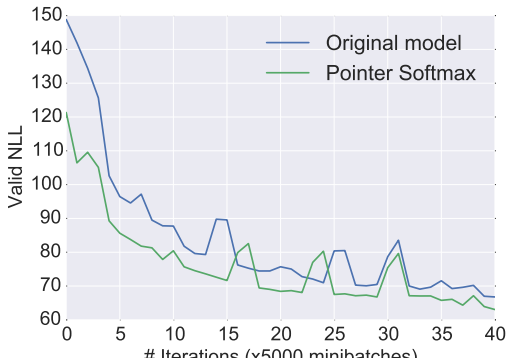

Figure 4: A comparison of the validation learning-curves of the same NMT model trained with pointer softmax and the regular softmax layer. As can be seen from the figures, the model trained with pointer softmax converges faster than the regular softmax layer. Switching network for pointer softmax in this Figure uses ReLU activation function.

ification over the NMT, our model is able to generalize to the unseen words and can deal with rare-words more efficiently. For the summarization task on Gigaword dataset, the pointer softmax was able to improve the results even when it is used together with the large-vocabulary trick. In the case of neural machine translation, we observed that the training with the pointer softmax is also improved the convergence speed of the model as well. For French to English machine translation on Europarl corpora, we observe that using the pointer softmax can also improve the training convergence of the model.

Generalized Transition-based Dependency Parsing via Control Parameters

Abstract

In this paper, we present a generalized transition-based parsing framework where parsers are instantiated in terms of a set of control parameters that constrain transitions between parser states. This generalization provides a unified framework to describe and compare various transition-based parsing approaches from both a theoretical and empirical perspective. This includes well-known transition systems, but also previously unstudied systems.

1 Introduction

Transition-based dependency parsing is perhaps the most successful parsing framework in use today (Nivre, 2008). This is due to the fact that it can process sentences in linear time (Nivre, 2003); is highly accurate (Zhang and Nivre, 2011; Bohnet and Nivre, 2012; Weiss et al., 2015); and has elegant mechanisms for parsing non-projective sentences (Nivre, 2009). As a result, there have been numerous studies into different transition systems, each with varying properties and complexities (Nivre, 2003; Attardi, 2006; Nivre, 2008; Nivre, 2009; Gómez-Rodríguez and Nivre, 2010; Choi and Palmer, 2011; Pitler and McDonald, 2015).

While connections between these transition systems have been noted, there has been little work on developing frameworks that generalize the phenomena parsed by these diverse systems. Such a framework would be beneficial for many reasons: It would provide a language from which we can theoretically compare known transition systems; it can give rise to new systems that could have favorable empirical properties; and an implementation of the generalization allows for comprehensive empirical studies.

In this work we provide such a generalized transition-based parsing framework. Our framework can be cast as transition-based parsing as it contains both parser states as well as transitions between these states that construct dependency trees. As in traditional transition-based parsing, the state maintains two data structures: a set of *unprocessed tokens* (normally called the *buffer*); and a set of *operative tokens* (often called the *stack*). Key to our generalization is the notion of *active* tokens, which is the set of tokens in which new arcs can be created and/or removed from consideration. A parser instantiation is defined by a set of control parameters, which dictate: the types of transitions that are permitted and their properties; the capacity of the active token set; and the maximum arc distance.

We show that a number of different transition systems can be described via this framework. Critically the two most common systems are covered – arc-eager and arc-standard (Nivre, 2008). But also Attardi's non-projective (Attardi, 2006), Kuhlmann's hybrid system (Kuhlmann et al., 2011), the directed acyclic graph (DAG) parser of Sagae and Tsujii (2008), and likely others. More interestingly, the easy-first framework of Goldberg and Elhadad (2010) can be described as an arc-standard system with an unbounded active token capacity.

We present a number of experiments with an implementation of our generalized framework. One major advantage of our generalization (and its implementation) is that it allows for easy exploration of novel systems not previously studied. In Section 5 we discuss some possibilities and provide experiments for these in Section 6.

2 Related Work

Transition-based dependency parsing can be characterized as any parsing system that maintains a

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 150–160,
Berlin, Germany, August 7-12, 2016.

state as well as a finite set of operations that move the system from one state to another (Nivre, 2008). In terms of modern statistical models that dominate the discourse today, the starting point is likely the work of Kudo and Matsumoto (2000) and Yamada and Matsumoto (2003), who adopted the idea of cascaded chunking from Abney (1991) in a greedy dependency parsing framework.

From this early work, transition-based parsing quickly grew in scope with the formalization of the arc-eager versus arc-standard paradigms (Nivre, 2003; Nivre, 2008), the latter largely being based on well-known shift-reduce principles in the phrase-structure literature (Ratnaparkhi, 1999). The speed and empirical accuracy of these systems – as evident in the widely used MaltParser software (Nivre et al., 2006a) – led to the study of a number of different transition systems.

Many of these new transition systems attempted to handle phenomena not covered by arc-eager or arc-standard transition systems, which inherently could only produce projective dependency trees. The work of Attardi (2006), Nivre (2009), Gómez-Rodríguez and Nivre (2010), Choi and Palmer (2011), and Pitler and McDonald (2015) derived transition systems that could parse non-projective trees. Each of these systems traded-off complexity for empirical coverage. Additionally, Sagae and Tsujii (2008) developed transition systems that could parse DAGs by augmentating the arc-standard and the arc-eager system. Bohnet and Nivre (2012) derived a system that could produce both labeled dependency trees as well as part-of-speech tags in a joint transition system. Taking this idea further Hatori et al. (2012) defined a transition system that performed joint segmentation, tagging and parsing.

In terms of empirical accuracy, from the early success of Nivre and colleagues (Nivre et al., 2006b; Hall et al., 2007; Nivre, 2008), there has been an succession of improvements in training and decoding, including structured training with beam search (Zhang and Clark, 2008; Zhang and Nivre, 2011), incorporating graph-based rescoring features (Bohnet and Kuhn, 2012), the aformentioned work on joint parsing and tagging (Bohnet and Nivre, 2012), and more recently the adoption of neural networks and feature embeddings (Chen and Manning, 2014; Weiss et al., 2015; Dyer et al., 2015; Alberti et al., 2015).

In terms of abstract generalizations of transition systems, the most relevant work is that of Gómez-Rodríguez and Nivre (2013) – which we abbreviate GR&N13. In that work, a generalized framework is defined by first defining a set of base transitions, and then showing that many transition-based systems can be constructed via composition of these base transitions. Like our framework, this covers common systems such as arc-eager and arc-standard, as well as easy-first parsing. In particular, arc construction in easy-first parsing can be seen as an action composed of a number of shifts, an arc action, and a number of un-shift actions. The primary conceptual difference between that work and the present study is the distinction between complex actions versus control parameters. In terms of theoretical coverage, the frameworks are not equivalent. For instance, our generalization covers the system of Attardi (2006), whereas GR&N13 cover transition systems where multiple arcs can be created in tandem. In Section 7 we compare the two generalizations.

3 Generalized Transition-based Parsing

A transition system must define a parser state as well as a set of transitions that move the system from one state to the next. Correct sequences of transitions create valid parse trees. A parser state is typically a tuple of data structures and variables that represent the dependency tree constructed thus far and, implicitly, possible valid transitions to the next state.

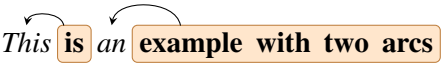
In order to generalize across the parser states of transition-based parsing systems, we preserve their common parts and make the specific parts configurable. In order to generalize across the transitions, we divide the transitions into their basic operations. Each specific transition is then defined by composition of these basic operations. By defining the properties of the data structures and the composition of the basic operations, different transition systems can be defined and configured within one single unified system. As a consequence, we obtain a generalized parser that is capable of executing a wide range of different transition systems by setting a number of control parameters without changing the specific implementation of the generalized parser.

3.1 Basic Notation

In the following, we use a directed unlabeled dependency tree $T = \langle V, A \rangle$ for a sentence $x =$

(a) Arc-standard: *is* and *example* are eligible for arcs.

(b) Arc-eager: *example* and *with* are eligible for arcs.



(c) Easy-first: All unreduced tokens are active (bolded).

Figure 1: A partially processed dependency tree after having just added the arc *(example, an)* in the arc-standard, arc-eager, and easy-first systems. Tokens in the operative token set O are shaded orange, while tokens in the unordered buffer U are in an unshaded box. The bolded tokens are in ACTIVE(O) and eligible for arcs (Section 3.4).

$w_1, ..., w_n$, where $V_x = \{1, ..., n\}$ and $V_x^r = V_x \cup \{r\}$, $A_x \subset V_x^r \times V_x$. r is a placeholder for the root node and set either to 0 (root to the left of the sentence) or $n + 1$ (root to the right). The definition is mostly equivalent to that of Kübler et al. (2009) but deviates in the potential handling of the root on the right (Ballesteros and Nivre, 2013).

The set of nodes V_x index the words of a sentence x and V_x^r includes in addition the artificial root node r. Let A be the arc set, i.e., $(i, j) \in A$ iff there is a dependency from i to j. We use as alternative notation $(i \rightarrow j)$. This is the arc set the algorithm will create.

For ease of exposition, we will only address unlabeled parsing. However, for our experiments we do implement a labeled parsing variant using the standard convention of composing arc transitions with corresponding arc labels.

3.2 Generalized Parser State

Let U be an unordered set of buffered unprocessed tokens. This set is identical to the buffer from transition-based parsing. Following standard notation, we will use $i|U$ to indicate that i is the leftmost element of the set.

Let O be an ordered set of operative tokens. Specifically, O is the set of tokens that 1) have been moved out of U, and 2) are not themselves reduced. The set O is similar in nature to the traditional stack of transition-based parsing, but is not restricted to stack operations. As in transition-based parsing we will use the notation $O|i$ to indicate that i is the rightmost element of the set; $O[n]$ is the n-th rightmost element of the set. Figure 1 shows the set of tokens in O within shaded boxes and U within unshaded boxes.

Transitions

"Adds an arc from j to i, both $\in$ ACTIVE(O)."	
$\leftarrow_{i,j}$	$(O, U, A) \Rightarrow (O, U, A \cup (j \rightarrow i))$
"Adds an arc from i to j, both $\in$ ACTIVE(O)."	
$\rightarrow_{i,j}$	$(O, U, A) \Rightarrow (O, U, A \cup (i \rightarrow j))$
"Removes token $i \in$ ACTIVE(O) from O."	
$-_i$	$(O...\text{i}..., U, A) \Rightarrow (O, U, A)$
"Moves the top token from U to the top of O."	
$+$	$(O, i\|U, A) \Rightarrow (O\|i, U, A)$

Figure 2: Base generalized transitions over parser states.

3.3 Generalized Transitions

The above discussion describes what a generalized transition-based parser state looks like; it does not describe any transitions between these states, which is the core of transition-based parsing. In this section we present a set of basic transitions, which themselves can be composed to make more complex transitions (similar to Gómez-Rodríguez and Nivre (2013)).

Let $\mathcal{T} = \{\leftarrow_{i,j}, \rightarrow_{i,j}, -_i, +\}$ be the set of basic transitions (Figure 2), which have analogues to standard transition-based parsing. These transitions come with the standard preconditions, i.e., a root cannot be a modifier; each token can modify at most one word[1]; a token can only be reduced if it has a head; and a shift can only happen if the unoperative buffer is non-empty. We will often refer to these as LEFT-ARC ($\leftarrow_{i,j}$), RIGHT-ARC ($\rightarrow_{i,j}$), REDUCE ($-_i$), and SHIFT ($+$). We additionally refer to LEFT-ARC and RIGHT-ARC together as *arc-creation* actions.

3.4 Control Parameters

Instantiations of a transition system are defined via *control parameters*. We defined two sets of such parameters. The first, we call *global parameters*, dictates system wide behaviour. The second, we call *transition parameters*, dictates a specific behaviour for each transition.

[1]This precondition is not needed for DAG transition systems.

Global Control Parameters

We have two parameters for the broader behaviour of the system.

1. Active token capacity K. The active set of tokens ACTIVE(O) that can be operated on by the transitions is the set $\{O[min(|O|, K)], ..., O[1]\}$. K additionally determines the size of O at the start of parsing. E.g., if $K = 2$, then we populate O with the first two tokens. This is equivalent to making SHIFT deterministic while $|O| < K$.

2. Max arc distance D. I.e., arcs can only be created between two active tokens $O[i]$ and $O[j]$ if $|i - j| \leq D$.

Transition Control Paramters

Let $\mathcal{M}(\mathcal{T})$ be a *multiset* of transitions, such that if $t \in \mathcal{M}(\mathcal{T})$, then $t \in \mathcal{T}$. Note that $\mathcal{M}(\mathcal{T})$ is a multiset, and thus can have multiple transitions of the same type. For each $t \in \mathcal{M}(\mathcal{T})$, our generalization requires the following control parameters to be set (default in bold):

1. Bottom-up: $B \in \{[\mathbf{t}]\mathbf{rue}, [f]alse\}$. Whether creating an arc also reduces it. Specifically we will have two parameters, B_L and B_R, which specify whether LEFT/RIGHT-ARC actions are bottom up. We use the notation and say $B = true$ to mean $B_L = B_R = true$. For example $B_L = true$ indicates that $\leftarrow_{i,j}$ is immediately followed by a reduce $-_i$.

2. Arc-Shift: $S \in \{[t]rue, [\mathbf{f}]\mathbf{alse}\}$. Whether creating an arc also results in SHIFT. Specifically we will have two parameters, S_L and S_R, which specify whether LEFT/RIGHT-ARC actions are joined with a SHIFT. We use the notation and say $S = true$ to mean $S_L = S_R = true$. For example $S_L = true$ indicates that $\leftarrow_{i,j}$ is immediately followed by $+$.

3. Periphery: $P \in \{[l]eft, [r]ight, \mathbf{na}\}$. If a transition must operate on the left or right periphery of the active token set ACTIVE(O). For arc-creation transitions, this means that at least one of the head or modifier is on the specified periphery. If the value is na, that means that the action is not constrained to be on the periphery. Note, that when K ≤ 2, all arc-creation actions by default are on the periphery.

Each of these control parameters has a default value, which will be assumed if unspecified. Note that the relevance of these parameters is transition dependent. E.g., a SHIFT requires no such control parameters and a REDUCE needs neither B nor S.

These control parameters allow *limited* compositionality of the basic transitions in Figure 2. Unlike Gómez-Rodríguez and Nivre (2013), each transition includes at most one SHIFT, at most one REDUCE, and at most one LEFT-ARC or RIGHT-ARC. I.e., the most compositional transition is a LEFT/RIGHT-ARC with a REDUCE and/or a SHIFT. Even with this restriction, all of the transition systems covered by Gómez-Rodríguez and Nivre (2013) can still be expressed in our generalization.

3.5 Generalized Transition System

To summarize, a generalized transition is defined as follows:

1. A parser state: $\Gamma = \langle O, U, A \rangle$.

2. A set of basic transitions: $\mathcal{T} = \{\leftarrow_{i,j}, \rightarrow_{i,j}, -_i, +\}$.

And each transition system instantiation must further define:

1. Values for global control parameters: K and D.

2. A multiset of valid transitions $\mathcal{M}(\mathcal{T})$, where $\forall t \in \mathcal{M}(\mathcal{T})$, then $t \in \mathcal{T}$.

3. For each $t \in \mathcal{M}(\mathcal{T})$ values for B, S, and P.

4 Transition System Instantiations

The instantiation of the transition system consists of setting the capacity K and distance D as well as the transition control parameters. In order to make the comparison clearer, we will define typical transition systems using the notation of Kuhlmann et al. (2011). Here, a parser state is a triple (σ, β, A), where $\sigma|i$ is a stack with top element i, $j|\beta$ is a buffer whose next element is j, and A the set of created arcs. To make notation cleaner, we will drop indexes whenever the context makes it clear. E.g., if the active token capacity is 2 ($K = 2$), then necessarily for $\leftarrow_{i,j}$, $i = 2$ and $j = 1$ and we can write $\leftarrow$. When $K > 2$ or $D > 1$, a base arc-creation action can be instantiated into multiple transitions that only differ by the indexes. E.g., when $K = 3$ and $D = 2$, $\leftarrow$ with $P = na$ can have three instantiations: $\leftarrow_{3,2}$, $\leftarrow_{2,1}$ and

$\leftarrow_{3,1}$. To keep exposition compact, in such circumstances we use $\star$ to denote the set of index-pairs allowed by the given K, D and P values.

4.1 Arc-standard

Arc-standard parsing is a form of shift-reduce parsing where arc-creations actions happen between the top two elements on the stack:

LEFT-ARC: $(\sigma|i|j, \beta, A) \Rightarrow (\sigma|j, \beta, A \cup (j \rightarrow i))$

RIGHT-ARC: $(\sigma|i|j, \beta, A) \Rightarrow (\sigma|i, \beta, A \cup (i \rightarrow j))$

SHIFT: $(\sigma, i|\beta, A) \Rightarrow (\sigma|i, \beta, A)$

This is easily handled in our generalization by having only two active tokens. $\leftarrow$ and $\rightarrow$ actions with default parameter values are used to simulate LEFT-ARC and RIGHT-ARC respectively, and $+$ is used to shift tokens from U to O.

$\mathcal{M}(\mathcal{T})$	base	parameter values
LEFT-ARC	$\leftarrow$	$\{$*default*$\}$
RIGHT-ARC	$\rightarrow$	$\{$*default*$\}$
SHIFT	$+$	
capacity K		2
arc distance D		1

Note that when $K = 2$, arc-creations are by definition always on the periphery.

4.2 Arc-eager

Arc-eager transition systems have been described in various ways. Kuhlmann et al. (2011) defines it as operations between tokens at the top of the stack and front of the buffer.

LEFT-ARC: $(\sigma|i, j|\beta, A) \Rightarrow (\sigma, j|\beta, A \cup (j \rightarrow i))$

RIGHT-ARC: $(\sigma|i, j|\beta, A) \Rightarrow (\sigma|i|j, \beta, A \cup (i \rightarrow j))$

REDUCE: $(\sigma|i, \beta, A) \Rightarrow (\sigma, \beta, A)$

SHIFT: $(\sigma, i|\beta, A) \Rightarrow (\sigma|i, \beta, A)$

In our generalization, we can simulate this by having two active tokens on the operative set, representing the top of the stack and front of the buffer. SHIFT and LEFT-ARC are handled in the same way as in the arc-standard system. The RIGHT-ARC action is simulated by $\rightarrow$ with modified parameters to account for the fact that the action keeps the modifier in O and also shifts a token from U to O. The REDUCE action is handled by $-$ with the periphery set to left so as to remove the second rightmost token from O.

$\mathcal{M}(\mathcal{T})$	base	parameter values
LEFT-ARC	$\leftarrow$	$\{$*default*$\}$
RIGHT-ARC	$\rightarrow$	$\{B = f, S = t\}$
REDUCE	$-$	$\{P = l\}$
SHIFT	$+$	
K		2
D		1

Note that the artificial root must be on the right of the sentence to permit the reduce to operate at the left periphery of the active token set.

4.3 Easy-first

For easy-first parsing (Goldberg and Elhadad, 2010), the number of active tokens is infinite or, more precisely, equals to the number of tokens in the input sentence, and arc-creation actions can happen between any two adjacent tokens.

$\mathcal{M}(\mathcal{T})$	base	parameter values
LEFT-ARC	$\leftarrow_\star$	$\{$*default*$\}$
RIGHT-ARC	$\rightarrow_\star$	$\{$*default*$\}$
K		∞
D		1

Note here $\star$ denotes the set of indexes $\{(i, j)|i \leq |O|, j \geq 1, i = j + 1\}$. Thus, at each time step there are $2 * |O|$ actions that need to be considered. Additionally, reduce is always composed with arc-creation and since $K = \infty$, then there is never a SHIFT operation as O is immediately populated with all tokens on the start of parsing.

4.4 Kuhlmann et al. (2011)

Kuhlmann et al. present a 'hybrid' transition system where the RIGHT-ARC action is arc-standard in nature, but LEFT-ARC actions is arc-eager in nature, which is equivalent to the system of Yamada and Matsumoto (2003). We can get the same effect as their system by allowing three active tokens, representing the top two tokens of the stack and the front of the buffer. Transitions can be handled similarly as the arc-standard system where only the periphery parameter need to be changed accordingly. This change also requires the root to be on the right of the sentence.

$\mathcal{M}(\mathcal{T})$	base	parameter values
LEFT-ARC	$\leftarrow$	$\{P = r\}$
RIGHT-ARC	$\rightarrow$	$\{P = l\}$
SHIFT	$+$

4.5 Sagae and Tsujii (2008)

Sagae and Tsuji present a model for projective DAG parsing by modifying the LEFT-ARC and RIGHT-ARC transitions of the arc-eager system. In their system, the LEFT-ARC transition does not remove the dependent, and RIGHT-ARC transition does not shift any token from the input to the stack.

LEFT-ARC: $(\sigma|i,j|\beta,A) \Rightarrow (\sigma|i,j|\beta,A \cup (j \rightarrow i))$

RIGHT-ARC: $(\sigma|i,j|\beta,A) \Rightarrow (\sigma|i,j|\beta,A \cup (i \rightarrow j))$

REDUCE: $(\sigma|i,\beta,A) \Rightarrow (\sigma,\beta,A)$

SHIFT: $(\sigma,i|\beta,A) \Rightarrow (\sigma|i,\beta,A)$

This can be easily simulated by modifying arc-eager system mentioned in Sec. 4.2 such that both the LEFT-ARC and RIGHT-ARC transition keep the stack/buffer untouched.

$\mathcal{M}(\mathcal{T})$	base	parameter values
LEFT-ARC	$\leftarrow$	$\{B = f\}$
RIGHT-ARC	$\rightarrow$	$\{B = f\}$
REDUCE	$-$	$\{P = l\}$
SHIFT	$+$	
K		2
D		1

4.6 Attardi (2006)

Now we show how our framework can extend to non-projective systems. This is primarily controlled by the arc-distance parameter D.

The base of the Attardi non-projective transition system is the arc-standard system. Attardi modifies RIGHT/LEFT-ARC actions that operate over larger contexts in the stack. For simplicity of exposition below we model the variant of the Attardi system described in Cohen et al. (2011).

RIGHT-ARCN: $(\sigma|i_{1+N}|\ldots|i_2|i_1,\beta,A) \Rightarrow (\sigma|i_N|\ldots|i_2|i_1,\beta,A \cup (i_1 \rightarrow i_{1+N}))$

LEFT-ARCN: $(\sigma|i_{1+N}|\ldots|i_2|i_1,\beta,A) \Rightarrow (\sigma|i_{1+N}|\ldots|i_2,\beta,A \cup (i_{1+N} \rightarrow i_1))$

SHIFT: $(\sigma,i|\beta,A) \Rightarrow (\sigma|i,\beta,A)$

Conceptually the Attardi system can be generalized to any value of N[2], and Attardi specifically allows N=1,2,3. Actions that create arcs between non-adjacent tokens permit limited non-projectivity.

Thus, for Attardi, we set the number of active tokens to N+1, to simulate the top N+1 tokens of the stack, and set the max distance D to N to indicate that tokens up to N positions below the top of the stack can add arcs with the top of the stack.

$\mathcal{M}(\mathcal{T})$	base	parameter values
LEFT-ARC	$\leftarrow_\star$	$\{P = r\}$
RIGHT-ARC	$\rightarrow_\star$	$\{P = r\}$
K		$N + 1$
D		N (3 for Attardi (2006))

The critical parameter for each arc action is that $P = r$. This means that the right peripheral active token always must participate in the action, as does the right-most token of the stack for the original Attardi. Here $\star$ denotes $\{(i,j)|j = 1, i - j \leq D\}$.

5 Novel Transition Systems

Any valid setting of the control parameters could theoretically define a new transition system, however not all such combinations will be empirically reasonable. We outline two potential novel transition systems suggested by our framework, which we will experiment with in Section 6. This is a key advantage of our framework (and implementation) – it provides an easy experimental solution to explore novel transition systems.

5.1 Bounded Capacity Easy-first

Easy-first and arc-standard are similar since they are both bottom-up and both create arcs between adjacent nodes. The main difference lies in the capacity K, which is 2 for arc-standard and ∞ for easy-first. In addition, the shift action is needed by the arc-standard system. Each system has some advantages: arc-standard is faster, and somewhat easier to train, while easy-first can be more accurate (under identical learning settings). Seen this way, it is natural to ask: what happens if the active token range K is set to k, with $2 < k < \infty$? We explore various values in the region between arc-standard and easy-first in Section 6.

$\mathcal{M}(\mathcal{T})$	base	parameter values
LEFT-ARC	$\leftarrow_\star$	$\{default\}$
RIGHT-ARC	$\rightarrow_\star$	$\{default\}$
SHIFT	$+$	
K		k
D		1

5.2 Non-projective Easy-first

A simple observation is that by allowing $D > 1$ makes any transition system naturally non-

[2] Attardi (2006) also introduces Extract/Insert actions to a temporary buffer that he argues generalizes to all values of N. We don't account for that specific generalization here.

projective. One example would be a non-projective variant of easy-first parsing:

$\mathcal{M}(\mathcal{T})$	base	parameter values
LEFT-ARC	$\leftarrow_\star$	$\{default\}$
RIGHT-ARC	$\rightarrow_\star$	$\{default\}$
K		∞
D		any value of N

Here N denotes the maximum arc-creation distance.

We also note that one could potentially vary both K and D simultaneously, giving a non-projective limited capacity easy-first system.

6 Implementation and Experiments

Our implementation uses a linear model $\sum_{y_i \in y} \mathbf{w} \cdot \mathbf{f}(x, y_1, \ldots, y_i)$ to assign a score to a sequence $y = y_1, y_2, \ldots y_m$ of parser transitions, given sentence x. Model parameters are trained using the structured perceptron with "early update" (Collins and Roark, 2004) and features follow that of Zhang and Nivre (2011).

For the arc-standard and arc-eager transition systems, we use the static oracle to derive a single gold sequence for a given sentence and its gold tree. For systems where there is no such static oracle, for example the easy-first system, we use the method proposed by Ma et al. (2013) to select a gold sequence such that, for each update, the condition $\mathbf{w} \cdot \mathbf{f}(x, \hat{y}_k) < \mathbf{w} \cdot \mathbf{f}(x, \overline{y}_k)$ always holds, which is required for perceptron convergence. Here $\hat{y}_k$ denotes the length k prefix of a correct sequence and $\overline{y}_k$ denotes the highest scoring sequence in the beam.

We carry out the experiments on the Wall Street Journal using the standard splits for the training set (section 2-21), development set (section 22) and test set (section 23). We converted the constituency trees to Stanford dependencies version 3.3.0 (de Marneffe et al., 2006). We used a CRF-based Part-of-Speech tagger to generate 5-fold jack-knifed Part-of-Speech tag annotation of the training set and used predicted tags on the development and test set. The tagger reaches accuracy scores similar to the Stanford tagger (Toutanova et al., 2003) with 97.44% on the test set. The unlabeled and labeled accuracy scores exclude punctuation marks.

Obviously, there are many interesting instantiations for the generalized transition system. In particular, it would be interesting to investigate parsing performance of systems with different active token size and arc-distance. Before we investigate these system in the next subsections, we present the performance on standard systems.

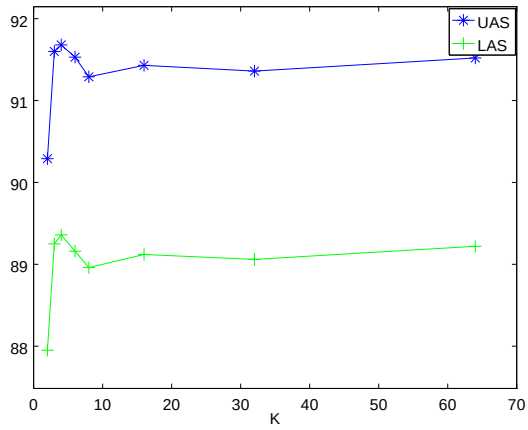

Figure 3: Labeled/unlabeled attachment scores with respect to the active capacity K.

6.1 Common Systems

The results for arc-standard, arc-eager and easy-first (bottom of Table 1) show how standard systems perform within our framework. Easy-first's labeled attachment score (LAS) is 0.46 higher than the LAS of arc-eager when using the same feature set. These results are competitive with the state-of-the-art linear parsers, but below recent work on neural network parsers. A future line of work is to adopt such training into our generalization.

System	UAS	LAS	b

Arc-standard (gen.)	92.81	90.68	32
Arc-eager (gen.)	92.88	90.73	32
Easy-first (gen.)	93.31	91.19	32

Table 1: State-of-the-art comparison. $\star$ denotes our own re-implementation. The systems in the first block on the top use neural networks.

6.2 Bounded Capacity Easy-first

Table 1 shows that easy-first is more accurate than arc-standard. However, it is also more computationally expensive. By varying the number of active tokens, we can investigate whether there is a sweet spot in the accuracy vs. speed trade-off.

Figure 3 shows labeled/unlabeled accuracy scores on the development set for active token

sizes ranging from 2 to 32, all with beam size 1. Different from the original easy-first system where all tokens are initialized as active tokens, in the bounded capacity system, a token can be active only after it has been shifted from U to O. We observe that the accuracy score increases remarkably by over a point when active token capacity gets increased from 2 to 3, and peaks at a active token capacity of 4. Generally, more active tokens allows the parser to delay "difficult" decisions to later steps and choose the "easy" ones at early steps. Such behavior has the effect of limiting the extent of error propagation. The result also suggests that a modification as simple as adding one more active token to the arc-standard system can yield significant improvement.

With a larger active token capacity, we see a slight drop of accuracy. This is likely related to the parser having to predict when to perform a shift transition. In comparison, the vanilla easy-first parser does not need to model this.

6.3 Non-projective Easy-first

For the experiments with non-projective easy-first, we use the Dutch and Danish CoNLL 2006 corpora. To assess the performance, we applied the evaluation rules of the 2006 shared task. In order to make the non-projective systems perform well, we added to all feature templates the arc-distance D. In these experiments, we included in the training an artificial root node on the right since Dutch as well a few sentences of the Danish corpus have more than one root node.

In the experiments, we use the easy-first setting with infinite set of active tokens K and increase stepwise the arc-distance D. For training, we filter out the sentences which contain non-projective arcs not parseable with the selected setting. Table 2 provides an overview of the performance with increasing arc-distance. At the bottom of the table, we added accuracy scores for the bounded capacity non-projective easy-first parser since we think these settings provide attractive trade-offs between accuracy and complexity.

The original easy-first performs $O(n)$ feature extractions and has a runtime of $O(n\log(n))$ assuming a heap is used to extract the argmax at each step and feature extraction is done over local contexts only (Goldberg and Elhadad, 2010). For the non-projective variant of easy-first with $D = d$, $O(dn)$ feature extractions are required. Thus, for the unrestricted variant where $K = D = \infty$, $O(n^2)$ feature extractions are required. Table 2 explored more practical settings: when $K = \infty$, $D \leq 7$, the number of feature extractions is back to $O(n)$ with a runtime of $O(n\log(n))$, matching the original easy-first complexity. When both K and D are small constants as in the lower portion of Table 2, the runtime is $O(n)$.

Table 2: Experiments with non-projective easy-first and bounded capacity easy-first with D the arc-distance, K the active token capacity (∞ = all tokens of a sentence), UAS and LAS are the unlabeled and labeled accuracy scores, CUR is the recall of crossing edges and NPS shows the percentage of sentences covered in the training set where 100% means all non-projective (and projective) sentences in the training can be parsed and are included in training.

7 Comparison with GR&N13

The work most similar to ours is that of Gómez-Rodríguez and Nivre (2013) (GR&N13). They define a *divisible transition system* with the principle to divide the transitions into elementary transitions and then to compose from these elementary transitions complex transitions. GR&N13 identified the following five elementary transitions:

SHIFT: $(\sigma, i|\beta, A) \Rightarrow (\sigma|i, \beta, A)$

UNSHIFT: $(\sigma|i, \beta, A) \Rightarrow (\sigma, i|\beta, A)$

REDUCE: $(\sigma|i, \beta, A) \Rightarrow (\sigma, \beta, A)$

LEFT-ARC: $(\sigma|i, j|\beta, A) \Rightarrow (\sigma|i, j|\beta, A \cup (j \rightarrow i))$

RIGHT-ARC: $(\sigma|i, j|\beta, A) \Rightarrow (\sigma|i, j|\beta, A \cup (i \rightarrow j))$

The notion of function composition is used to combine the elementary transitions to the complex ones. For instance, arc-standard would have three actions: SHIFT; RIGHT-ARC $\oplus$REDUCE; LEFT-ARC $\oplus$REDUCE.

The first difference we can note is the GR&N13 cannot instantiate transition systems that produce non-projective trees. This is surely a superficial

difference, as GR&N13 could easily add transitions with larger arc-distance or even SWAP actions (Nivre, 2009).

However, a less superficial difference is that our generalization uses control parameters to construct instantiations of transition systems, instead of solely via transition composition like GR&N13. Through this, our generalization results in a minimal departure from 'standard' representations of these systems. While this may seem like a notational difference, this is particularly a benefit with respect to implementation, as previous techniques for classification and feature extraction can largely be reused.

For example, in GR&N13, the definition of the easy-first transition system (Goldberg and Elhadad, 2010) is complex, e.g., a RIGHT-ARC at position i requires a compositional transition of i SHIFT actions, a RIGHT-ARC, a SHIFT, a REDUCE, then i UNSHIFT actions. Note, that this means in any implementation of this generalization, the output space for a classifier will be very large. Furthermore, the feature space would ultimately need to take the entire sentence into consideration, considering that all compositional actions are centered on the same state.

In our transition system, on the other hand, easy-first operates almost as it does in its native form, where n LEFT-ARC and n RIGHT-ARC actions are ranked relative to each other. There are only two actions, each instantiated for every location in the state. Thus the output space and feature extraction are quite natural.

This leads to straight-forward implementations allowing for easy experimentation and discovery. Unlike GR&N13, we present empirical results for both known transition systems as well as some novel systems (Section 6).

8 Conclusion

We presented a generalized transition system that is capable of representing and executing a wide range of transition systems within one single implementation. These transition systems include systems such as arc-standard, arc-eager, easy-first.

Transitions can be freely composed of elementary operations. The transition system shows perfect alignment between the elementary operations on one hand and their preconditions and the oracle on the other hand. We adjust the transition system to work on a stack in a uniform way starting at a node on the stack and ending with the top node of the stack. The results produced by this system are more comparable as they can be executed with the same classifier and feature extraction system.

Finally, we would like to highlight two insights that the experiments provide. First, a few more active tokens than two can boost the accuracy level of an arc-standard transition system towards the level of an easy-first transition system. These parsing systems maintain very nicely the linear complexity of the arc-standard transition system while they provide a higher accuracy similar to those of easy-first. Second, non-projective trees can be parsed by allowing a larger arc-distance which is a simple way to allow for non-projective edges.

We think that the transition systems with more active tokens or the combination with edges that span over more words provide very attractive transition systems for possible future parsers.

Acknowledgments

Abstract

We present a transition-based system that jointly predicts the syntactic structure and lexical units of a sentence by building two structures over the input words: a syntactic dependency tree and a forest of lexical units including multiword expressions (MWEs). This combined representation allows us to capture both the syntactic and semantic structure of MWEs, which in turn enables deeper downstream semantic analysis, especially for semi-compositional MWEs. The proposed system extends the arc-standard transition system for dependency parsing with transitions for building complex lexical units. Experiments on two different data sets show that the approach significantly improves MWE identification accuracy (and sometimes syntactic accuracy) compared to existing joint approaches.

1 Introduction

Multiword expressions (MWEs) are sequences of words that form non-compositional semantic units. Their identification is crucial for semantic analysis, which is traditionally based on the principle of compositionality. For instance, the meaning of *cut the mustard* cannot be compositionally derived from the meaning of its elements and the expression therefore has to be treated as a single unit. Since Sag et al. (2002), MWEs have attracted growing attention in the NLP community.

Identifying MWEs in running text is challenging for several reasons (Baldwin and Kim, 2010; Seretan, 2011; Ramisch, 2015). First, MWEs encompass very diverse linguistic phenomena, such as complex grammatical words (*in spite of*, *because of*), nominal compounds (*light house*), non-canonical prepositional phrases (*above board*), verbal idiomatic expressions (*burn the midnight oil*), light verb constructions (*have a bath*), multiword names (*New York*), and so on. They can also be discontiguous in the sense that the sequence can include intervening elements (*John **pulled** Mary's **leg***). They may also vary in their morphological forms (*hot dog, hot dogs*), in their lexical elements (*lose one's mind/head*), and in their syntactic structure (*he took a step*, *the step he took*).

The semantic processing of MWEs is further complicated by the fact that there exists a continuum between entirely non-compositional expressions (*piece of cake*) and almost free expressions (*traffic light*). Many MWEs are indeed semi-compositional. For example, the compound *white wine* denotes a type of wine, but the color of the wine is not white, so the expression is only partially transparent. In the light verb construction *take a nap*, *nap* keeps its usual meaning but the meaning of the verb *take* is bleached. In addition, the noun can be compositionally modified as in *take a long nap*. Such cases show that MWEs may be decomposable and partially analyzable, which implies the need for predicting their internal structure in order to compute their meaning.

From a syntactic point of view, MWEs often have a regular structure and do not need special syntactic annotation. Some MWEs have an irregular structure, such as *by and large* which on the surface is a coordination of a preposition and an adjective. They are syntactically as well as semantically non-compositional and cannot be represented with standard syntactic structures, as stated in Candito and Constant (2014). Many of these irregular MWEs are complex grammatical words like *because of*, *in spite of* and *in order to* – fixed (grammatical) MWEs in the sense of Sag et al. (2002). In some treebanks, these are annotated using special structures and labels because they can-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 161–171,
Berlin, Germany, August 7-12, 2016.

not be modified or decomposed. We hereafter use the term *fixed MWE* to refer to either fixed or irregular MWEs.

In this paper, we present a novel representation that allows both regular and irregular MWEs to be adequately represented without compromising the syntactic representation. We then show how this representation can be processed using a transition-based system that is a mild extension of a standard dependency parser. This system takes as input a sentence consisting of a sequence of tokens and predicts its syntactic dependency structure as well as its lexical units (including MWEs). The resulting structure combines two factorized substructures: (i) a standard tree representing the syntactic dependencies between the lexical elements of the sentence and (ii) a forest of lexical trees including MWEs identified in the sentence. Each MWE is represented by a constituency-like tree, which permits complex lexical units like MWE embeddings (for example, [[*Los Angeles*] *Lakers*], I will [*take a* [*rain check*]]). The syntactic and lexical structures are factorized in the sense that they share lexical elements: both tokens and fixed MWEs.

The proposed parsing model is an extension of a classical arc-standard parser, integrating specific transitions for MWE detection. In order to deal with the two linguistic dimensions separately, it uses two stacks (instead of one). It is synchronized by using a single buffer, in order to handle the factorization of the two structures. It also includes different hard constraints on the system in order to reduce ambiguities artificially created by the addition of new transitions. To the best of our knowledge, this system is the first transition-based parser that includes a specific mechanism for handling MWEs in two dimensions. Previous related research has usually proposed either pipeline approaches with MWE identification performed either before or after dependency parsing (Kong et al., 2014; Vincze et al., 2013a) or workaround joint solutions using off-the-shelf parsers trained on dependency treebanks where MWEs are annotated by specific subtrees (Nivre and Nilsson, 2004; Eryiğit et al., 2011; Vincze et al., 2013b; Candito and Constant, 2014; Nasr et al., 2015).

2 Syntactic and Lexical Representations

A standard dependency tree represents syntactic structure by establishing binary syntactic relations between words. This is an adequate representation of both syntactic and lexical structure on the assumption that words and lexical units are in a one-to-one correspondence. However, as argued in the introduction, this assumption is broken by the existence of MWEs, and we therefore need to distinguish lexical units as distinct from words.

In the new representation, each lexical unit – whether a single word or an MWE – is associated with a *lexical node*, which has linguistic attributes such as surface form, lemma, part-of-speech tag and morphological features. With an obvious reuse of terminology from context-free grammar, lexical nodes corresponding to MWEs are said to be *non-terminal*, because they have other lexical nodes as children, while lexical nodes corresponding to single words are *terminal* (and do not have any children).

Some lexical nodes are also *syntactic nodes*, that is, nodes of the syntactic dependency tree. These nodes are either non-terminal nodes corresponding to (complete) fixed MWEs or terminal nodes corresponding to words that do not belong to a fixed MWE. Syntactic nodes are connected into a tree structure by binary, asymmetric dependency relations pointing from a *head* node to a *dependent* node.

Figure 1 shows the representation of the sentence *the prime minister made a few good decisions*. It contains three non-terminal lexical nodes: one fixed MWE (*a few*), one contiguous non-fixed MWE (*prime minister*) and one discontiguous non-fixed MWE (*made decisions*). Of these, only the first is also a syntactic node. Note that, for reasons of clarity, we have suppressed the lexical children of the fixed MWE in Figure 1. (The non-terminal node corresponding to *a few* has the lexical children *a* and *few*.) For the same reason, we are not showing the linguistic attributes of lexical nodes. For example, the node *made-decisions* has the following set of features: surface-form='made decisions', lemma='make decision', POS='V'. Non-fixed MWEs have regular syntax and their components might have some autonomy. For example, in the light verb construction *made-decisions*, the noun *decisions* is modified by the adjective *good* that is not an element of the MWE.

The proposed representation of fixed MWEs is an alternative to using special dependency labels as has often been the case in the past (Nivre and Nilsson, 2004; Eryiğit et al., 2011). In addition

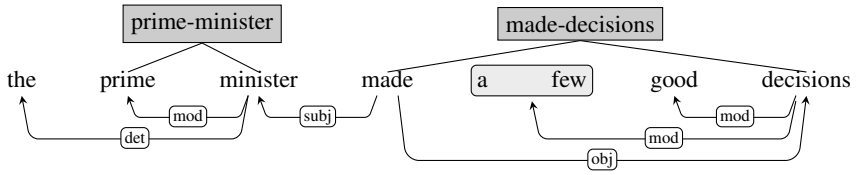

Figure 1: Representation of syntactic and lexical structure.

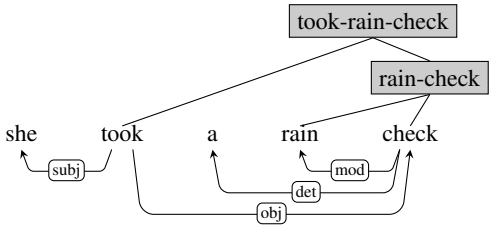

Figure 2: Lexical structure of embedded MWEs.

to special labels, MWEs are then represented as a flat subtree of the syntactic tree. The root of the subtree is the left-most or right-most element of the MWE, and all the other elements are attached to this root with dependencies having special labels. Despite the special labels, these subtrees look like ordinary dependency structures and may confuse a syntactic parser. In our representation, fixed MWEs are instead represented by nodes that are atomic with respect to syntactic structure (but complex with respect to lexical structure), which makes it easier to store linguistic attributes that belong to the fixed MWE and cannot be derived from its components. The new representation also allows us to represent the hierarchical structure of embedded MWEs. Figure 2 provides an analysis of *she took a rain check* that includes such an embedding. The lexical node *took-rain-check* corresponds to a light verb construction where the object is a compound noun that keeps its semantic interpretation whereas the verb has a neutral value. One of its children is the lexical node *rain-check* corresponding to a compound noun.

Let us now define the representation formally. Given a sentence $x = x_1, \ldots, x_n$ consisting of n tokens, the syntactic and lexical representation is a quadruple (V, F, N, A), where

1. V is the set of *terminal nodes*, corresponding one-to-one to the tokens $x_1, \ldots, x_n$,
2. F is a set of n-ary trees on V, with each tree corresponding to a fixed MWE and the root labeled with the part-of-speech tag for the MWE,
3. N is a set of n-ary trees on F, with each tree corresponding to a non-fixed MWE and the root labeled with the part-of-speech tag for the MWE,
4. A is a set of labeled dependency arcs defining a tree over F.

This is a generalization of the standard definition of a dependency tree (see, for example, Kübler et al. (2009)), where the dependency structure is defined over an intermediate layer of lexical nodes (F) instead of directly on the terminal nodes (V), with an additional layer of non-fixed MWEs added on top. To exemplify the definition, here are the formal structures corresponding to the representation visualized in Figure 1.

$$\begin{array}{lcl} V & = & \{1,2,3,4,5,6,7,8\} \\ F & = & \{1,2,3,4,\mathrm{A}(5,6),7,8\} \\ N & = & \{1,\mathrm{N}(2,3),\mathrm{V}(4,8),\mathrm{A}(5,6),7\} \\ A & = & \{(3,\mathrm{det},1),(3,\mathrm{mod},2), \\ & & (4,\mathrm{subj},3),(4,\mathrm{obj},8), \\ & & (8,\mathrm{mod},\mathrm{A}(5,6)),(8,\mathrm{mod},7)\} \end{array}$$

Terminal nodes are represented by integers corresponding to token positions, while trees are represented by n-ary terms $t(c_1, \ldots, c_n)$, where t is a part-of-speech tag and $c_1, \ldots, c_n$ are the subtrees immediately dominated by the root of the tree. The total set of lexical nodes is $L = V \cup F \cup N$, where V contains the terminal and $(F \cup N) - V$ the non-terminal lexical nodes. The set of syntactic nodes is simply F.

It is worth noting that the representation imposes some limitations on what MWEs can be represented. In particular, we can only represent overlapping MWEs if they are cases of embedding, that is, cases where one MWE is properly contained in the other. For example, in an example like *she took a walk then a bath*, it might be argued that *took* should be part of two lexical units: *took-walk* and *took-bath*. This cannot currently be represented. By contrast, we can accommodate cases where two lexical units are interleaved, as in the French example *il prend un cachet et demi*, with the two units *prend-cachet* and *un-et-demi*, which occur in the crossed pattern A1 B1 A2 B2. However, while these cases can be represented in

principle, the parsing model we propose will not be capable of processing them.

Finally, it is worth noting that, although our representation in general allows lexical nodes with arbitrary branching factor for flat MWEs, it is often convenient for parsing to assume that all trees are binary (Crabbé, 2014). For the rest of the paper, we therefore assume that non-binary trees are always transformed into equivalent binary trees using either right or left binarization. Such transformations add intermediate temporary nodes that are only used for internal processing.

3 Transition-Based Model

A transition-based parser is based on three components: a transition system for mapping sentences to their representation, a model for scoring different transition sequences (derivations), and a search algorithm for finding the highest scoring transition sequence for a given input sentence. Following Nivre (2008), we define a transition system as a quadruple $S = (C, T, c_s, C_t)$ where:

1. C is a set of configurations,
2. T is a set of transitions, each of which is a partial function $t : C \rightarrow C$,
3. c_s is an initialization function that maps each input sentence x to an initial configuration $c_s(x) \in C$,
4. $C_t \subseteq C$ is a set of terminal configurations.

A *transition sequence* for a sentence x is a sequence of configurations $C_{0,m} = c_0, \ldots, c_m$ such that $c_0 = c_s(x)$, $c_m \in C_t$, and for every c_i $(0 \leq i < m)$ there is some transition $t \in T$ such that $t(c_i) = c_{i+1}$. Every transition sequence defines a representation for the input sentence.

Training a transition-based parser means training the model for scoring transition sequences. This requires an *oracle* that determines what is an optimal transition sequence given an input sentence and the correct output representation (as given by treebank). Static oracles define a single unique transition sequence for each input-output pair. Dynamic oracles allow more than one optimal transition sequence and can also score non-optimal sequences (Goldberg and Nivre, 2013). Once a scoring model has been trained, parsing is usually performed as best-first search under this model, using greedy search or beam search.

3.1 Arc-Standard Dependency Parsing

Our starting point is the arc-standard transition system for dependency parsing first defined in Nivre (2004) and represented schematically in Figure 3. A configuration in this system consists of a triple $c = (\sigma, \beta, A)$, where σ is a stack containing partially processed nodes, β is a buffer containing remaining input nodes, and A is a set of dependency arcs. The initialization function maps $x = x_1, \ldots, x_n$ to $c_s(x) = ([\,], [1, \ldots, n], \{\,\})$, and the set C_t of terminal configurations contains any configuration of the form $c = ([i], [\,], A)$. The dependency tree defined by such a terminal configuration is $(\{1, \ldots, n\}, A)$. There are three possible transitions:

- **Shift** takes the first node in the buffer and pushes it onto the stack.
- **Right-Arc(**k**)** adds a dependency arc (i, k, j) to A, where j is the first and i the second element of the stack, and removes j from the stack.
- **Left-Arc(**k**)** adds a dependency arc (j, k, i) to A, where j is the first and i the second element of the stack, and removes i from the stack.

A transition sequence in the arc-standard system builds a projective dependency tree over the set of terminal nodes in V. The tree is built bottom-up by attaching dependents to their head and removing them from the stack until only the root of the tree remains on the stack.

3.2 Joint Syntactic and Lexical Analysis

To perform joint syntactic and lexical analysis we need to be able to build structure in two parallel dimensions: the syntactic dimension, represented by a dependency tree, and the lexical dimension, represented by a forest of (binary) trees. The two dimensions share the token-level representation, as well as the level of fixed MWEs, but the syntactic tree and the non-fixed MWEs are independent.

We extend the parser configuration to use two stacks, one for each dimension, but only one buffer. In addition, we need not only a set of dependency arcs, but also a set of lexical units. A configuration in the new system therefore consists of a quintuple $c = (\sigma_1, \sigma_2, \beta, A, L)$, where σ_1 and σ_2 are stacks containing partially processed nodes (which may now be complex MWEs), β is a buffer containing remaining input nodes (which

Initial:	$([\,], [0, \ldots, n], \{\,\})$		
Terminal:	$([i], [\,], A)$		
Shift:	$(\sigma, i\|\beta, A)$	$\Rightarrow$	$(\sigma\|i, \beta, A)$
Right-Arc(k):	$(\sigma\|i\|j, \beta, A)$	$\Rightarrow$	$(\sigma\|i, \beta, A \cup \{(i, k, j)\})$
Left-Arc(k):	$(\sigma\|i\|j, \beta, A)$	$\Rightarrow$	$(\sigma\|j, \beta, A \cup \{(j, k, i)\})$

Figure 3: Arc-standard transition system.

Initial:	$([\,], [\,], [0, \ldots, n], \{\,\}, \{\,\})$		
Terminal:	$([x], [\,], [\,], A, L)$		
Shift:	$(\sigma_1, \sigma_2, i\|\beta, A, L)$	$\Rightarrow$	$(\sigma_1\|i, \sigma_2\|i, \beta, A, L)$
Right-Arc(k):	$(\sigma_1\|x\|y, \sigma_2, \beta, A, L)$	$\Rightarrow$	$(\sigma_1\|x, \sigma_2, \beta, A \cup \{(x, k, y)\}, L)$
Left-Arc(k):	$(\sigma_1\|x\|y, \sigma_2, \beta, A, L)$	$\Rightarrow$	$(\sigma_1\|y, \sigma_2, \beta, A \cup \{(y, k, x)\}, L)$
Merge$_F$(t):	$(\sigma_1\|x\|y, \sigma_2\|x\|y, \beta, A, L)$	$\Rightarrow$	$(\sigma_1\|t(x, y), \sigma_2\|t(x, y), \beta, A, L)$
Merge$_N$(t):	$(\sigma_1, \sigma_2\|x\|y, \beta, A, L)$	$\Rightarrow$	$(\sigma_1, \sigma_2\|t(x, y), \beta, A, L)$
Complete:	$(\sigma_1, \sigma_2\|x, \beta, A, L)$	$\Rightarrow$	$(\sigma_1, \sigma_2, \beta, A, L \cup \{x\})$

Figure 4: Transition system for joint syntactic and lexical analysis.

are always tokens), A is a set of dependency arcs, and L is a set of lexical units (tokens or MWEs). The initialization function maps $x = x_1, \ldots, x_n$ to $c_s(x) = ([\,], [\,], [1, \ldots, n], \{\,\}, \{\,\})$, and the set C_t of terminal configurations contains any configuration of the form $c = ([x], [\,], [\,], A, L)$. The dependency tree defined by such a terminal configuration is (F, A), and the set of lexical units is $V \cup L$. Note that the set F of syntactic nodes is not explicitly represented in the configuration but is implicitly defined by A. Similarly, the set L only contains $F \cup N$.

The new transition system is shown in Figure 4. There are now six possible transitions:

- **Shift** takes the first node in the buffer and pushes it onto both stacks. This guarantees that the two dimensions are synchronized at the token level.
- **Right-Arc(k)** adds a dependency arc (x, k, y) to A, where y is the first and x the second element of the syntactic stack (σ_1), and removes y from this stack. It does not affect the lexical stack (σ_2).[1]
- **Left-Arc(k)** adds a dependency arc (y, k, x) to A, where y is the first and x the second element of the syntactic stack (σ_1), and removes x from this stack. Like **Right-Arc(k)**, it does not affect the lexical stack (σ_2).
- **Merge$_F$(t)** applies in a configuration where the two top elements x and y are identical on both stacks and combines these elements into a tree $t(x, y)$ representing a fixed MWE with part-of-speech tag t. Since it operates on both stacks, the new element will be a syntactic node as well as a lexical node.
- **Merge$_N$(t)** combines the two top elements x and y on the lexical stack (σ_2) into a tree $t(x, y)$ representing a non-fixed MWE with part-of-speech tag t. Since it only operates on the lexical stack, the new element will not be a syntactic node.
- **Complete** moves the top element x on the lexical stack (σ_2) to L, making it a final lexical unit in the output representation. Note that x can be a simple token, a fixed MWE (created on both stacks), or a non-fixed MWE (created only on the lexical stack).

A transition sequence in the new system derives the set of lexical nodes and simultaneously builds a projective dependency tree over the set of syntactic nodes. By way of example, Figure 5 shows the transition sequence for the example in Figure 1.

3.3 Implicit Completion

The system presented above has one potential drawback: it needs a separate Complete transition for every lexical unit, even in the default case

[1] We use the variables x and y, instead of i and j, because the stack elements can now be complex lexical units as well as simple tokens.

Transition		Configuration
		$([\,],[\,],[1,2,3,4,5,6,7,8],A_0=\{\,\},L_0=\{\,\})$
Shift	$\Rightarrow$	$([1],[1],[2,3,4,5,6,7,8],A_0,L_0)$
Complete	$\Rightarrow$	$([1],[\,],[2,3,4,5,6,7,8],A_0,L_1=L_0\cup\{1\})$
Shift	$\Rightarrow$	$([1,2],[2],[3,4,5,6,7,8],A_0,L_1)$
Shift	$\Rightarrow$	$([1,2,3],[2,3],[4,5,6,7,8],A_0,L_1)$
Merge$_N$(N)	$\Rightarrow$	$([1,2,3],[\mathrm{N}(2,3)],[4,5,6,7,8],A_1,L_1)$

Merge$_N$(V)	$\Rightarrow$	$([4,8],[\mathrm{V}(4,8)],[\,],A_5,L_4)$
Complete	$\Rightarrow$	$([4,8],[\,],[\,],A_5,L_5=L_4\cup\{\mathrm{V}(4,8)\})$
Right-Arc(obj)	$\Rightarrow$	$([4],[\,],[\,],A_6=A_5\cup\{(4,\mathrm{obj},8)\},L_5)$

Figure 5: Transition sequence for joint syntactic and lexical analysis.

when a lexical unit is just a token. This makes sequences much longer and increases the inherent ambiguity. One way to deal with this problem is to make the Complete transition implicit and deterministic, so that it is not scored by the model (or predicted by a classifier in the case of deterministic parsing) but is performed as a side effect of the Right-Arc and Left-Arc transitions. Every time we apply one of these transitions, we check whether the dependent x of the new arc is part of a unit y on the lexical stack satisfying one of the following conditions: (i) $x = y$; (ii) x is a lexical child of y and every lexical node z in y either has a syntactic head in A or is the root of the dependency tree. If (i) or (ii) is satisfied, we move y from the lexical stack to the set L of lexical units as a side effect of the arc transition.

4 Experiments

This section provides experimental results obtained with a simple implementation of our system using a greedy search parsing algorithm and a linear model trained with an averaged perceptron with shuffled examples and a static oracle. More precisely, the static oracle is defined using the following transition priorities: Merge$_F$ > Merge$_N$ > Complete > LeftArc > RightArc > Shift. At each state of the training phase, the static oracle selects the valid transition that has the higher priority.

We evaluated the two variants of the system, namely *Explicit* and *Implicit*, with explicit and implicit completion, respectively. They were compared against the joint approach proposed in Candito and Constant (2014) that we applied to an arc-standard parser, instead of a graph-based parser. The parser is trained on a treebank where MWE status and grammatical function are concatenated in arc labels. We consider it as the *Baseline*. We used classical transition-based parsing features consisting of patterns combining linguistic attributes of nodes on the stacks and the buffer, as well as processed subtrees and transition history. We can note that the joint systems do not contain features sharing elements of both stacks. Preliminary tuning experiments did not show gains when using such features.

We also compared these systems against weaker ones, obtained by disabling some transitions and using one stack only. Two systems, namely *Syntactic-baseline* and *Syntactic* only predict the syntactic nodes and the dependency structure by using respectively a baseline parser and our system where neither the lexical stack nor the Merge$_N$ and Complete transitions are used. The latter one is an implementation of the proposal in Nivre (2014). Two systems are devoted only to the lexical layer: *Lexical* only recognizes the lexical units (only the lexical stack and the Merge$_N$ and Complete transitions are activated); *Fixed* only identifies the fixed expressions.

Corpus	EWT		FTB

# MWEs	2,996	401	23,556	2,119	4,043
# fixed	-	-	10,987	925	1,992

Table 1: Dataset statistics.

We also implemented pipeline systems where: (i) fixed MWEs are identified by applying only the *Fixed* system; (ii) elements of predicted MWEs are merged into single tokens; (iii) the retokenized text is parsed using the *Baseline* or *Implicit* systems trained on a dataset where fixed MWEs consist of single tokens.

We carried out our experiments on two different datasets annotating both the syntactic structure and the MWEs: the French Treebank [FTB] (Abeillé et al., 2003) and the STREUSLE corpus (Schneider et al., 2014b) combined with the English Web Treebank [EWT] (Bies et al., 2012). They are commonly used for evaluating the most recent MWE-aware dependency parsers and supervised MWE identification systems. Concerning the FTB, we used the dependency version developed in Candito and Constant (2014) derived from the SPMRL shared task version (Seddah et al., 2013). Fixed and non-fixed MWEs are distinguished, but are limited to contiguous ones only. The STREUSLE corpus (Schneider et al., 2014b) corresponds to a subpart of the English Web Treebank (EWT). It consists of reviews and is comprehensively annotated in contiguous and discontiguous MWEs. Fixed and non-fixed expressions are not distinguished though the distinction between non-compositional and collocational MWEs is made. This implies that the Merge$_F$ transition is not used on this dataset. Practically, we used the LTH converter (Johansson and Nugues, 2007) to obtain the dependency version of the EWT constituent version. We also used the predicted linguistic attributes used in Constant and Le Roux (2015) and in Constant et al. (2016). Both datasets include predicted POS tags, lemmas and morphology, as well as features computed from compound dictionary lookup. None of them is entirely satisfying with respect to our model, but they allow us to evaluate the feasibility of the approach. Statistics on the two datasets are provided in Table 1.

Results are provided in Table 2 for French and in Table 3 for English. In order to evaluate the syntactic layer, we used classical UAS and LAS metrics. Before evaluation, merged units were automatically decomposed in the form of flat subtrees using specific arcs as in Seddah et al. (2013), so all systems can be evaluated and compared at the token level. MWE identification is evaluated with the F-score of the MWE segmentation, namely *MWE* for all MWEs and *FMWE* for fixed MWEs only. An MWE segment corresponds to the set of its component positions in the input token sequence.

First, results show that our joint system consistently and significantly outperforms the baseline in terms of MWE identification on both datasets. The merge transitions play a key role. In terms of syntax, the *Explicit* system does not have any positive impact (on par or degraded scores), whereas the *Implicit* system allows us to obtain slightly better results on French and a significant improvement on English. The very good performances on English might be explained by the fact that it contains a non-negligeable set of discontiguous MWEs which complicates the prediction of explicit Complete transitions.

When compared with weaker systems, we can see that the addition of the lexical layer helps improve the prediction of the syntactic layer, which confirms results on symbolic parsing (Wehrli, 2014). The syntactic layer does not seem to impact the lexical layer prediction: we observe comparable results. This might be due to the fact that syntax is helpful for long-distance discontiguity only, which does not appear in our datasets (the English dataset contains MWEs with small gaps). Another explanation could also be that syntactic parsing accuracy is rather low due to the use of a simple greedy algorithm. Developing more advanced transition-based parsing methods like beam-search may help improve both syntactic parsing accuracy and MWE identification. When comparing joint systems with pipeline ones, we can see that preidentifying fixed MWEs seems to help MWE identification whereas syntactic parsing accuracy tends to be slightly lower. One hypothesis could be that Merge$_F$ transitions may confuse the prediction of Merge$_N$ transitions.

When compared with existing state-of-the-art systems, we can see that the proposed systems achieve MWE identification scores that are comparable with the pipeline and joint approaches used in Candito and Constant (2014) with a graph-

based parser for French, and the base sequence tagger using a perceptron model with rich MWE-dedicated features of Schneider et al. (2014a) for English. It reaches lower scores than the best simple CRF-based MWE tagging system of Le Roux et al. (2014). These scores are obtained on the SPMRL shared task version, though they are not entirely comparable with our system as they do not distinguish fixed from non-fixed MWEs.

5 Related work

The present paper proposes a new representation for lexical and syntactic analysis in the framework of syntactic dependency parsing. Most existing MWE-aware dependency treebanks represent an MWE as a flat subtree of the syntactic tree with special labels, like in the UD treebanks (Nivre et al., 2016) or in the SPMRL shared task (Seddah et al., 2013), or in other individual treebanks (Nivre and Nilsson, 2004; Eryiğit et al., 2011). Such representation enables MWE discontinuity, but the internal syntactic structure is not annotated. Candito and Constant (2014) proposed a representation where the irregular and regular MWEs are distinguished: irregular MWEs are integrated in the syntactic tree as above; regular MWEs are annotated in their component attributes while their internal structure is annotated in the syntactic tree. The Prague Dependency Treebank (Bejček et al., 2013) has several interconnected annotation layers: morphological (*m*-layer), syntactic (*a*-layer) and semantic (*t*-layer). All these layers are trees that are interconnected. MWEs are annotated on the *t*-layer and are linked to an MWE lexicon (Bejček and Straňák, 2010). Constant and Le Roux (2015) proposed a dependency representation of lexical segmentation allowing annotations of deeper phenomena like MWE nesting. More details on MWE-aware treebanks (including constituent ones) can be found in Rosén et al. (2015).

Statistical MWE-aware dependency parsing has received a growing interest since Nivre and Nilsson (2004). The main challenge resides in finding the best orchestration strategy. Past research has explored either pipeline or joint approaches. Pipeline strategies consist in positioning the MWE recognition either before or after the parser itself, as in Nivre and Nilsson (2004), Eryiğit et al. (2011), Constant et al. (2013), and Kong et al. (2014) for pre-identification and as in Vincze et al. (2013a) for post-identification. Joint strategies have mainly consisted in using off-the-shelf

parsers and integrating MWE annotation in the syntactic structure, so that MWE identification is blind for the parser (Nivre and Nilsson, 2004; Eryiğit et al., 2011; Seddah et al., 2013; Vincze et al., 2013b; Candito and Constant, 2014; Nasr et al., 2015).

Our system includes a special treatment of MWEs using specific transitions in a classical transition-based system, in line with the proposal of Nivre (2014). Constant et al. (2016) also proposed a two-dimensional representation in the form of dependency trees anchored by the same words. The annotation of fixed MWEs is redundant on both dimensions, while they are shared in our representation. They propose, along with this representation, an adaptation of an easy-first parser able to predict both dimensions. Contrary to our system, there are no special mechanisms for treating MWEs.

The use of multiple stacks to capture partly independent dimensions is inspired by the multiplanar dependency parser of Gómez-Rodríguez and Nivre (2013). Our parsing strategy for (hierarchical) MWEs is very similar to the deterministic constituency parsing method of Crabbé (2014).

6 Conclusion

This paper proposes a transition-based system that extends a classical arc-standard parser to handle both lexical and syntactic analysis. It is based on a new representation having two linguistic layers sharing lexical nodes. Experimental results show that MWE identification is greatly improved with respect to the mainstream joint approach. This can be a useful starting point for several lines of research: implementing more advanced transition-based techniques (beam search, dynamic oracles, deep learning); extending other classical transition systems like arc-eager and hybrid as well as handling non-projectivity.

Abstract

Dynamic oracle training has shown substantial improvements for dependency parsing in various settings, but has not been explored for constituent parsing. The present article introduces a dynamic oracle for transition-based constituent parsing. Experiments on the 9 languages of the SPMRL dataset show that a neural greedy parser with morphological features, trained with a dynamic oracle, leads to accuracies comparable with the best non-reranking and non-ensemble parsers.

1 Introduction

Constituent parsing often relies on search methods such as dynamic programming or beam search, because the search space of all possible predictions is prohibitively large. In this article, we present a greedy parsing model. Our main contribution is the design of a dynamic oracle for transition-based constituent parsing. In NLP, dynamic oracles were first proposed to improve greedy dependency parsing training without involving additional computational costs at test time (Goldberg and Nivre, 2012; Goldberg and Nivre, 2013).

The training of a transition-based parser involves an oracle, that is a function mapping a configuration to the best transition. Transition-based parsers usually rely on a static oracle, only well-defined for gold configurations, which transforms trees into sequences of gold actions. Training against a static oracle restricts the exploration of the search space to the gold sequence of actions. At test time, due to error propagation, the parser will be in a very different situation than at training time. It will have to infer good actions from noisy configurations. To alleviate error propagation, a solution is to train the parser to predict the best action given any configuration, by allowing it to explore a greater part of the search space at train time. Dynamic oracles are non-deterministic oracles well-defined for any configuration. They give the best possible transitions for any configuration. Although dynamic oracles are widely used in dependency parsing and available for most standard transition systems (Goldberg and Nivre, 2013; Goldberg et al., 2014; Gómez-Rodríguez et al., 2014; Straka et al., 2015), no dynamic oracle parsing model has yet been proposed for phrase structure grammars.

The model we present aims at parsing morphologically rich languages (MRL). Recent research has shown that morphological features are very important for MRL parsing (Björkelund et al., 2013; Crabbé, 2015). However, traditional linear models (such as the structured perceptron) need to define rather complex feature templates to capture interactions between features. Additional morphological features complicate this task (Crabbé, 2015). Instead, we propose to rely on a neural network weighting function which uses a non-linear hidden layer to automatically capture interactions between variables, and embeds morphological features in a vector space, as is usual for words and other symbols (Collobert and Weston, 2008; Chen and Manning, 2014).

The article is structured as follows. In Section 2, we present neural transition-based parsing. Section 3 motivates learning with a dynamic oracle and presents an algorithm to do so. Section 4 introduces the dynamic oracle. Finally, we present parsing experiments in Section 5 to evaluate our proposal.

2 Transition-Based Constituent Parsing

Transition-based parsers for phrase structure grammars generally derive from the work of Sagae

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 172–182,
Berlin, Germany, August 7-12, 2016.

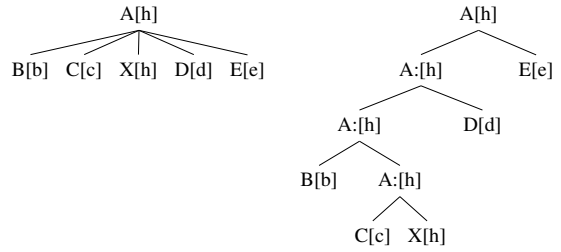

Figure 1: Order-0 head markovization.

and Lavie (2005). In the present paper, we extend Crabbé (2015)'s transition system.

Grammar form We extract the grammar from a head-annotated preprocessed constituent treebank (cf Section 5). The preprocessing involves two steps. First, unary chains are merged, except at the preterminal level, where at most one unary production is allowed. Second, an order-0 head-markovization is performed (Figure 1). This step introduces temporary symbols in the binarized grammar, which are suffixed by ":". The resulting productions have one the following form:

$$X[h] \rightarrow A[a]\ B[b] \quad X[h] \rightarrow A[a]\ b$$
$$X[h] \rightarrow h \quad X[h] \rightarrow a\ B[b]$$

where X, A, B are delexicalised non-terminals, a, b and $h \in \{a, b\}$ are tokens, and $X[h]$ is a lexicalized non-terminal. The purpose of lexicalization is to allow the extraction of features involving the heads of phrases together with their tags and morphological attributes.

Transition System In the transition-based framework, parsing relies on two data structures: a **buffer** containing the sequence of tokens to parse and a **stack** containing partial instantiated trees. A **configuration** $C = \langle j, S, b, \gamma \rangle$ is a tuple where j is the index of the next token in the buffer, S is the current stack, b is a boolean, and γ is the set of constituents constructed so far.[1]

Constituents are instantiated non-terminals, i.e. tuples (X, i, j) such that X is a non-terminal and (i, j) are two integers denoting its span. Although the content of γ could be retrieved from the stack, we make it explicit because it will be useful for the design of the oracle in Section 4.

From an initial configuration $C_0 = \langle 0, \epsilon, \bot, \emptyset \rangle$, the parser incrementally derives new configurations by performing actions until a final configuration is reached. S(HIFT) pops an element from the buffer and pushes it on the stack. R(EDUCE)(X) pops two elements from the stack, and pushes a new non-terminal X on the stack with the two elements as its children. There are two kinds of binary reductions, left (RL) or right (RR), depending on the position of the head. Finally, unary reductions (RU(X)) pops only one element from the stack and pushes a new non-terminal X. A **derivation** $C_{0 \Rightarrow \tau} = C_0 \overset{a_0}{\Rightarrow} \ldots \overset{a_{\tau-1}}{\Rightarrow} C_\tau$ is a sequence of configurations linked by actions and leading to a final configuration. Figure 2 presents the algorithm as a deductive system. G(HOST)R(EDUCE) actions and boolean b ($\top$ or $\bot$) are used to ensure that unary reductions (RU) can only take place once after a SHIFT action.[2]

Constraints on the transitions make sure that predicted trees can be unbinarized. Figure 3 shows two examples of trees that could not have been obtained by the binarization process. In the first tree, a temporary symbol rewrites as two tempo-

Stack: $S\|(C,l,i)\|(B,i,k)\|(A,k,j)$	
Action	Constraints
RL(X) or RR(X), X$\in N$	A$\notin N_{tmp}$ and B $\notin N_{tmp}$
RL(X:) or RR(X:), X:$\in N_{tmp}$	C$\notin N_{tmp}$ or $j < n$
RR(X)	B$\notin N_{tmp}$
RL(X)	A$\notin N_{tmp}$

Table 1: Constraints to ensure that binary trees can be unbinarized. n is the sentence length.

Input $\quad w_0 w_1 \ldots w_{n-1}$

Axiom $\quad \langle 0, \epsilon, \bot, \emptyset \rangle$

S $\quad \dfrac{\langle j, S, \bot, \gamma \rangle}{\langle j+1, S\|(t_j, j, j+1), \top, \gamma \rangle}$

RL(X) $\quad \dfrac{\langle j, S\|(A,i,k)\|(B,k,j), \bot, \gamma \rangle}{\langle j, S\|(X,i,j), \bot, \gamma \cup \{(X,i,j)\} \rangle}$

RU(X) $\quad \dfrac{\langle j, S\|(t_{j-1}, j-1, j), \top, \gamma \rangle}{\langle j, S\|(X, j-1, j), \bot, \gamma \cup \{(X,j-1,j)\} \rangle}$

GR $\quad \dfrac{\langle j, S, \top, \gamma \rangle}{\langle j, S, \bot, \gamma \rangle}$

Figure 2: Transition system, the transition RR(X) and the lexicalization of symbols are omitted.

[1] The introduction of γ is the main difference with Crabbé (2015)'s transition system.

[2] This transition system is similar to the extended system of Zhu et al. (2013). The main difference is the strategy used to deal with unary reductions. Our strategy ensures that derivations for a sentence all have the same number of steps, which can have an effect when using beam search. We use a GHOST-REDUCE action, whereas they use a padding strategy with an IDLE action.

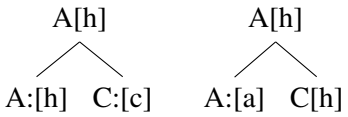

Figure 3: Examples of ill-formed binary trees

rary symbols. In the second one, the head of a temporary symbol is not the head of its direct parent. Table 1 shows a summary of the constraints used to ensure that any predicted tree is a well-formed binarized tree.[3] In this table, N is the set of non-terminals and $N_{tmp} \subset N$ is the set of temporary non-terminals.

Weighted Parsing The deductive system is inherently non-deterministic. Determinism is provided by a scoring function

$$s(C_{0 \Rightarrow \tau}) = \sum_{i=1}^{\tau} f_{\boldsymbol{\theta}}(C_{i-1}, a_i)$$

where $\boldsymbol{\theta}$ is a set of parameters. The score of a derivation decomposes as a sum of scores of actions. In practice, we used a feed-forward neural network very similar to the scoring model of Chen and Manning (2014). The input of the network is a sequence of typed symbols. We consider three main types (non-terminals, tags and terminals) plus a language-dependent set of morphological attribute types, for example, gender, number, or case (Crabbé, 2015). The first layer $\mathbf{h}^{(0)}$ is a lookup layer which concatenates the embeddings of each typed symbol extracted from a configuration. The second layer $\mathbf{h}^{(1)}$ is a non-linear layer with a rectifier activation (ReLU). Finally, the last layer $\mathbf{h}^{(2)}$ is a softmax layer giving a distribution over possible actions, given a configuration. The score of an action is its log probability.

Assuming $\mathbf{v_1}, \mathbf{v_2} \ldots, \mathbf{v}_\alpha$ are the embeddings of the sequence of symbols extracted from a configuration, the forward pass is summed up by the following equations:

$$\begin{aligned}
\mathbf{h}^{(0)} &= [\mathbf{v_1}; \mathbf{v_2}; \ldots; \mathbf{v}_\alpha] \\
\mathbf{h}^{(1)} &= \max\{0, \mathbf{W}^{(h)} \cdot \mathbf{h}^{(0)} + \mathbf{b}^{(h)}\} \\
\mathbf{h}^{(2)} &= \text{Softmax}(\mathbf{W}^{(o)} \cdot \mathbf{h}^{(1)} + \mathbf{b}^{(o)}) \\
f_{\boldsymbol{\theta}}(C, a) &= \log(\mathbf{h}^{(2)}_a)
\end{aligned}$$

[3]There are additional constraints which are not presented here. For example, SHIFT assumes that the buffer is not empty. A full description of constraints typically used in a slightly different transition system can be found in Zhang and Clark (2009)'s appendix section.

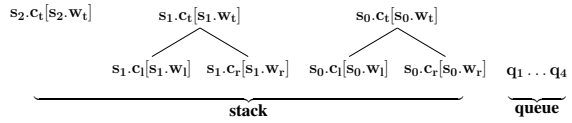

Figure 4: Schematic representation of local elements in a configuration.

Thus, $\boldsymbol{\theta}$ includes the weights and biases for each layer ($\mathbf{W}^{(h)}$, $\mathbf{W}^{(o)}$, $\mathbf{b}^{(h)}, \mathbf{b}^{(o)}$), and the embedding lookup table for each symbol type.

We perform greedy search to infer the best-scoring derivation. Note that this is not an exact inference. Most propositions in phrase structure parsing rely on dynamic programming (Durrett and Klein, 2015; Mi and Huang, 2015) or beam search (Crabbé, 2015; Watanabe and Sumita, 2015; Zhu et al., 2013). However we found that with a scoring function expressive enough and a rich feature set, greedy decoding can be surprisingly accurate (see Section 5).

Features Each terminal is a tuple containing the word form, its part-of-speech tag and an arbitrary number of language-specific morphological attributes, such as CASE, GENDER, NUMBER, ASPECT and others (Seddah et al., 2013; Crabbé, 2015). The representation of a configuration depends on symbols at the top of the two data structures, including the first tokens in the buffer, the first lexicalised non-terminals in the stack and possibly their immediate descendants (Figure 4). The full set of templates is specified in Table 6 of Annex A. The sequence of symbols that forms the input of the network is the instanciation of each position described in this table with a discrete symbol.

3 Training a Greedy Parser with an Oracle

An important component for the training of a parser is an oracle, that is a function mapping a gold tree and a configuration to an action. The oracle is used to generate local training examples from trees, and feed them to the local classifier.

A **static oracle** (Goldberg and Nivre, 2012) is an incomplete and deterministic oracle. It is only well-defined for gold configurations (the configurations derived by the gold action sequence) and returns the unique gold action. Usually, parsers use a static oracle to transform the set of binarized trees into a set $\mathcal{D} = \{C^{(i)}, a^{(i)}\}_{1 \leq i \leq T}$ of training examples. Training consists in minimiz-

ing the negative log likelihood of these examples. The limitation of this training method is that only gold configurations are seen during training. At test time, due to error propagation, the parser will have to predict good actions from noisy configurations, and will have much difficulty to recover after mistakes.

To alleviate this problem, a line of work (Daumé III et al., 2006; Ross et al., 2011) has cast the problem of structured prediction as a search problem and developed training algorithms aiming at exploring a greater part of the search space. These methods require an oracle well-defined for every search state, that is, for every parsing configuration.

A **dynamic oracle** is a complete and non-deterministic oracle (Goldberg and Nivre, 2012). It returns the non-empty set of the best transitions given a configuration and a gold tree. In dependency parsing, starting from Goldberg and Nivre (2012), dynamic oracle algorithms and training methods have been proposed for a variety of transition systems and led to substantial improvements in accuracy (Goldberg and Nivre, 2013; Goldberg et al., 2014; Gómez-Rodríguez et al., 2014; Straka et al., 2015; Gómez-Rodríguez and Fernández-González, 2015).

Online training An online trainer iterates several times over each sentence in the treebank, and updates its parameters until convergence. When a static oracle is used, the training examples can be pregenerated from the sentences. When we use a dynamic oracle instead, we generate training examples on the fly, by following the prediction of the parser (given the current parameters) instead of the gold action, with probability p, where p is a hyperparameter which controls the degree of exploration. The online training algorithm for a single sentence s, with an oracle function o is shown in Figure 5. It is a slightly modified version of Goldberg and Nivre (2013)'s algorithm 3, an approach they called *learning with exploration*.

In particular, as our neural network uses a cross-entropy loss, and not the perceptron loss used in Goldberg and Nivre (2013), updates are performed even when the prediction is correct. When $p = 0$, the algorithm acts identically to a static oracle trainer, as the parser always follows the gold transition. When the set of actions predicted by the oracle has more than one element, the best scoring element among them is chosen as the reference

action to update the parameters of the neural network.

4 A Dynamic Oracle for Transition-Based Parsing

This section introduces a dynamic oracle algorithm for the parsing model presented in the previous 2 sections, that is the function o used in the algorithm in Figure 5.

The dynamic oracle must minimize a cost function $\mathcal{L}(c; t, T)$ computing the cost of applying transition t in configuration c, with respect to a gold parse T. As is shown by Goldberg and Nivre (2013), the oracle's correctness depends on the cost function. A correct dynamic oracle o will have the following general formulation:

$$o(c, T) = \{t | \mathcal{L}(c; t, T) = \min_{t'} \mathcal{L}(c; t', T)\} \quad (1)$$

The correctness of the oracle is not necessary to improve training. The oracle needs only to be good enough (Daumé et al., 2009), which is confirmed by empirical results (Straka et al., 2015). Goldberg and Nivre (2013) identified *arc-decomposability*, a powerful property of certain dependency parsing transition systems for which we can easily derive correct efficient oracles. When this property holds, we can infer whether a tree is reachable from the reachability of individual arcs. This simplifies the calculation of each transition cost. We rely on an analogue property we call **constituent decomposition**. A

set of constituents is **tree-consistent** if it is a subset of a set corresponding to a well-formed tree. A phrase structure transition system is constituent-decomposable iff *for any configuration C and any tree-consistent set of constituents γ, if every constituent in γ is reachable from C, then the whole set is reachable from C* (constituent reachability will be formally defined in Section 4.1).

The following subsections are structured as follows. First of all, we present a cost function (Section 4.1). Then, we derive a correct dynamic oracle algorithm for an ideal case where we assume that there is no temporary symbols in the grammar (Section 4.2). Finally, we present some heuristics to define a dynamic oracle for the general case (Section 4.3).

4.1 Cost Function

The cost function we use ignores the lexicalization of the symbols. For the sake of simplicity, we momentarily leave apart the headedness of the binary reductions (until the last paragraph of Section 4) and assume a unique binary REDUCE action.

For the purpose of defining a cost function for transitions, we adopt a representation of trees as sets of constituents. For example, `(S (NP (D the) (N cat)) (VP (V sleeps)))` corresponds to the set $\{(\text{S}, 0, 3), (\text{NP}, 0, 2), (\text{VP}, 2, 3)\}$. As is shown in Figure 2, every reduction action (unary or binary) adds a new constituent to the set γ of already predicted constituents, which was introduced in Section 2. We define the cost of a predicted set of constituents $\hat{\gamma}$ with respect to a gold set γ^* as the number of constituents in γ^* which are not in $\hat{\gamma}$ penalized by the number of predicted unary constituents which are not in the gold set:

$$\mathcal{L}_r(\hat{\gamma}, \gamma^*) = |\gamma^* - \hat{\gamma}| + |\{(X, i, i+1) \in \hat{\gamma} | (X, i, i+1) \notin \gamma^*\}| \quad (2)$$

The first term penalizes false negatives and the second one penalizes unary false positives. The number of binary constituents in γ^* and $\hat{\gamma}$ depends only on the sentence length n, thus binary false positives are implicitly taken into account by the fist term.

The cost of a transition and that of a configuration are based on **constituent reachability**. The relation $C \vdash C'$ holds iff C' can be deduced from C by performing a transition. Let $\vdash^*$ denote the reflexive transitive closure of $\vdash$. A set of constituents γ (possibly a singleton) is reachable from a configuration C iff there is a configuration $C' = \langle j, S, b, \gamma' \rangle$ such that $C \vdash^* C'$ and $\gamma \subseteq \gamma'$, which we write $C \rightsquigarrow \gamma$.

Then, the cost of an action t for a configuration C is the cost difference between the best tree reachable from $t(C)$ and the best tree reachable from C:

$$\mathcal{L}_r(t; C, \gamma^*) = \min_{\gamma : t(C) \rightsquigarrow \gamma} \mathcal{L}(\gamma, \gamma^*) - \min_{\gamma : C \rightsquigarrow \gamma} \mathcal{L}(\gamma, \gamma^*)$$

This cost function is easily decomposable (as a sum of costs of transitions) whereas F1 measure is not.

By definition, for each configuration, there is at least one transition with cost 0 with respect to the gold parse. Otherwise, it would entail that there is a tree reachable from C but unreachable from $t(C)$, for any t. Therefore, we reformulate equation 1:

$$o(C, \gamma^*) = \{t | \mathcal{L}_r(C; t, \gamma^*) = 0\} \quad (3)$$

In the transition system, the grammar is left implicit: any reduction is allowed (even if the corresponding grammar rule has never been seen in the training corpus). However, due to the introduction of temporary symbols during binarization, there are constraints to ensure that any derivation corresponds to a well-formed unbinarized tree. These constraints make it difficult to test the reachability of constituents. For this reason, we instantiate two transition systems. We call SR-TMP the transition system in Figure 2 which enforces the constraints in Table 1, and SR-BIN, the same transition system without any of such constraints. SR-BIN assumes an idealized case where the grammar contains no temporary symbols, whereas SR-TMP is the actual system we use in our experiments.

4.2 A Correct Oracle for SR-BIN Transition System

SR-BIN transition system provides no guarantees that predicted trees are unbinarisable. The only condition for a binary reduction to be allowed is that the stack contains at least two symbols. If so, any non-terminal in the grammar could be used. In such a case, we can define a simple necessary and sufficient condition for constituent reachability.

Constituent reachability Let γ^* be a tree-consistent constituent set, and $C = \langle j, S, b, \gamma \rangle$ a

parsing configuration, such that:

$$S = (X_1, i_0, i_1) \dots (X_p, i_{p-1}, i)|(A, i, k)|(B, k, j)$$

A binary constituent (X, m, n) is reachable iff it satisfies one of the three following properties :

1. $(X, m, n) \in \gamma$
2. $j < m < n$
3. $m \in \{i_0, \dots i_{p-1}, i, k\}, n \geq j$ and $(m, n) \neq (k, j)$

The first two cases are trivial and correspond respectively to a constituent already constructed and to a constituent spanning words which are still in the buffer.

In the third case, (X, m, n) can be constructed by performing $n - j$ times the transitions SHIFT and GHOST-REDUCE (or REDUCE-UNARY), and then a sequence of binary reductions ended by an X reduction. Note that as the index j in the configuration is non-decreasing during a derivation, the constituents whose span end is inferior to j are not reachable if they are not already constructed. For a unary constituent, the condition for reachability is straightforward: a constituent $(X, i-1, i)$ is reachable from configuration $C = \langle j, S, b, \gamma \rangle$ iff $(X, i-1, i) \in \gamma$ or $i > j$ or $i = j \wedge b = \top$.

Constituent decomposability SR-BIN is constituent decomposable. In this paragraph, we give some intuition about why this holds. Reasoning by contradiction, let's assume that every constituent of a tree-consistent set γ^* is reachable from $C = \langle j, S|(A, i, k)|(B, k, j), b, \gamma \rangle$ and that γ^* is not reachable (contraposition). This entails that at some point during a derivation, there is no possible transition which maintains reachability for all constituents of γ^*. Let's assume C is in such a case. If some constituent of γ^* is reachable from C, but not from SHIFT(C), its span must have the form (m, j), where $m \leq i$. If some constituent of γ^* is reachable from C, but not from REDUCE(X)(C), for any label X, its span must have the form (k, n), where $n > j$. If both conditions hold, γ^* contains incompatible constituents (crossing brackets), which contradicts the assumption that γ^* is tree-consistent.

Computing the cost of a transition The conditions on constituent reachability makes it easy to compute the cost of a transition t for a given configuration $C = \langle j, S|(A, i, k)|(B, k, j), b, \gamma \rangle$ and a gold set γ^*:

```
1: function O(⟨j, S|(A, i, k)|(B, k, j), b, γ⟩, γ*)
2:     if b = ⊤ then                    ▷ Last action was SHIFT
3:         if (X, j − 1, j) ∈ γ* then
4:             return {REDUCEUNARY(X)}
5:         else
6:             return {GHOSTREDUCE}
7:     if ∃n > j, (X, k, n) ∈ γ* then
8:         return {SHIFT}
9:     if (X, i, j) ∈ γ* then
10:        return {REDUCE(X)}
11:    if ∃m < i, (X, m, j) ∈ γ* then
12:        return {REDUCE(Y), ∀Y}
13:    return {a ∈ A|a is a possible action}
```

Figure 6: Oracle algorithm for SR-BIN.

- The cost of a SHIFT is the number of constituents not in γ, reachable from C and whose span ends in j.
- The cost of a binary reduction REDUCE(X) is a sum of two terms. The first one is the number of constituents of γ^* whose span has the form (k, n) with $n > j$. These are no longer compatible with (X, i, j) in a tree. The second one is one if $(Y, i, j) \in \gamma^*$ and $Y \neq X$ and zero otherwise. It is the cost of mislabelling a constituent with a gold span.
- The cost of a unary reduction or that of a ghost reduction can be computed straightforwardly by looking at the gold set of constituents.

We present in Figure 6 an oracle algorithm derived from these observations.

4.3 A Heuristic-based Dynamic Oracle for SR-TMP transition system

The conditions for constituent reachability for SR-BIN do not hold any longer for SR-TMP. In particular, constituent reachability depends crucially on the distinction between temporary and non-temporary symbols. The algorithm in Figure 6 is not correct for this transition system. In Figure 7, we give an illustration of a prototypical case in which the algorithm in Figure 6 will fail. The constituent (C:, i, j) is in the gold set of constituents and could be constructed with REDUCE(C:). The third symbol on the stack being temporary symbol D:, the reduction to a temporary symbol will jeopardize the reachability of (C, m, j) because reduc-

tions are not possible when the two symbols at the top of the stack are temporary symbols. The best course of action is then a reduction to any non-temporary symbol, so as to keep (C, m, j) reachable. Note that in this case, the cost of REDUCE(C:) cannot be smaller than that of a single mislabelled constituent.

In fact, this example shows that the constraints inherent to SR-TMP makes it non constituent-decomposable. In the example in Figure 7, both constituents in the set $\{(\mathrm{C}, m, j), (\mathrm{C}{:}, i, j)\}$, a tree-consistent constituent set, is reachable. However, the whole set is not reachable, as REDUCE(C:) would make (C, m, j) not reachable.

In dependency parsing, several exact dynamic oracles have been proposed for non arc-decomposable transition systems (Goldberg et al., 2014), including systems for non-projective parsing (Gómez-Rodríguez et al., 2014). These oracles rely on tabular methods to compute the cost of transitions and have (high-degree) polynomial worst case running time. Instead, to avoid resorting to more computationally expensive exact methods, we adapt the algorithm in Figure 6 to the constraints involving temporary symbols using the following heuristics:

- If the standard oracle predicts a reduction, make sure to choose its label so that every reachable constituent $(X, m, j) \in \gamma^*$ $(m < i)$ is still reachable after the transition. Practically, if such constituent exists and if the third symbol on the stack is a temporary symbol, then do not predict a temporary symbol.
- When reductions to both temporary symbols and non-temporary symbols have cost zero, only predict temporary symbols. This should not harm training and improve precision for the unbinarized tree, as any non temporary symbol in the binarized tree corresponds to a constituent in the n-ary tree.

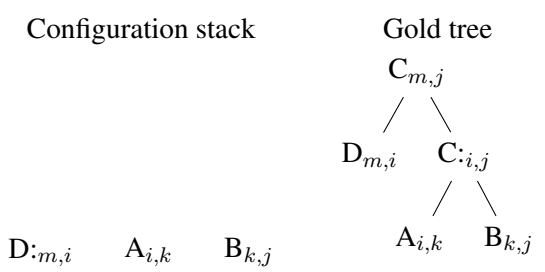

Figure 7: Problematic case. Due to the temporary symbol constraints enforced by SR-TMP, the algorithm in Figure 6 will fail on this example.

Head choice In some cases, namely when reducing two non-temporary symbols to a new constituent (X, i, j), the oracle must determine the head position in the reduction (REDUCE-RIGHT or REDUCE-LEFT). We used the following heuristic: if (X, i, j) is in the gold set, choose the same head position, otherwise, predict both RR(X) and RL(X) to keep the non-determinism.

5 Experiments

We conducted parsing experiments to evaluate our proposal. We compare two experimental settings. In the 'static' setting, the parser is trained only on gold configurations; in the 'dynamic' setting, we use the dynamic oracle and the training method in Figure 5 to explore non-gold configurations. We used both the SPMRL dataset (Seddah et al., 2013) in the 'predicted tag' scenario, and the Penn Treebank (Marcus et al., 1993), to compare our proposal to existing systems. The tags and morphological attributes were predicted using Marmot (Mueller et al., 2013), by 10-fold jackknifing for the train and development sets. For the SPMRL dataset, the head annotation was carried out with the procedures described in Crabbé

Table 2: Results on development and test corpora. Metrics are provided by `evalb_spmrl` with `spmrl.prm` parameters (`http://www.spmrl.org/spmrl2013-sharedtask.html`). † use clusters or word vectors learned on unannotated data. * Björkelund et al. (2013).

(2015), using the alignment between dependency treebanks and constituent treebanks. For English, we used Collins' head annotation rules (Collins, 2003). Our system is entirely supervised and uses no external data. Every embedding was initialised randomly (uniformly) in the interval $[-0.01, 0.01]$. Word embeddings have 32 dimensions, tags and non-terminal embeddings have 16 dimensions. The dimensions of the morphological attributes depend on the number of values they can have (Table 4). The hidden layer has 512 units.[4]

For the 'dynamic' setting, we trained every other k sentence with the dynamic oracle and the other sentences with the static oracle. This method, used by Straka et al. (2015), allows for high values of p, without slowing or preventing convergence. We used several hyperparameters combinations (see Table 5 of Annex A). For each language, we present the model with the combination which maximizes the developement set F-score. We used Averaged Stochastic Gradient Descent (Polyak and Juditsky, 1992) to minimize the negative log likelihood of the training examples. We shuffled the sentences in the training set before each iteration.

Results Results for English are shown in Table 3. The use of the dynamic oracle improves F-score by 0.4 on the development set and 0.6 on the test set. The resulting parser, despite using greedy decoding and no additional data, is quite accurate. For example, it compares well with Hall et al. (2014)'s span based model and is much faster.

For the SPMRL dataset, we report results on the development sets and test sets in Table 2. The metrics take punctuation and unparsed sentences into account (Seddah et al., 2013). We compare our results with the SPMRL shared task baselines (Seddah et al., 2013) and several other parsing models. The model of Björkelund et al. (2014) obtained the best results on this dataset. It is based on a product grammar and a discriminative reranker, together with morphological features and word clusters learned on unannotated data. Durrett and Klein (2015) use a neural CRF based on CKY decoding algorithm, with word embeddings pretrained on unannotated data. Fernández-González and Martins (2015) use a parsing-as-reduction approach, based on a dependency parser with a label set rich enough to reconstruct constituent trees from dependency trees. Finally, Crabbé (2015) uses a structured perceptron with rich features and beam-search decoding. Both Crabbé (2015) and Björkelund et al. (2014) use MARMOT-predicted morphological tags (Mueller et al., 2013), as is done in our experiments.

Our results show that, despite using a very simple greedy inference and being strictly supervised, our base model (static oracle training) is competitive with the best single parsers on this dataset.

[4]We did not tune these hyperparameters for each language. Instead, we chose a set of hyperparameters which achieved a tradeoff between training time and model accuracy. The effect of the morphological features and their dimensionality are left to future work.

We hypothesize that these surprising results come both from the neural scoring model and the morphological attribute embeddings (especially for Basque, Hebrew, Polish and Swedish). We did not test these hypotheses systematically and leave this investigation for future work.

Furthermore, we observe that the dynamic oracle improves training by up to 0.6 F-score (averaged over all languages). The improvement depends on the language. For example, Swedish, Arabic, Basque and German are the languages with the most important improvement. In terms of absolute score, the parser also achieves very good results on Korean and Basque, and even outperforms Björkelund et al. (2014)'s reranker on Korean.

Combined effect of beam and dynamic oracle Although initially, dynamic oracle training was designed to improve parsing without relying on more complex search methods (Goldberg and Nivre, 2012), we tested the combined effects of dynamic oracle training and beam search decoding. In Table 2, we provide results for beam decoding with the already trained local models in the 'dynamic' setting. The transition from greedy search to a beam of size two brings an improvement comparable to that of the dynamic oracle. Further increase in beam size does not seem to have any noticeable effect, except for Arabic. These results show that effects of the dynamic oracle and beam decoding are complementary and suggest that a good tradeoff between speed and accuracy is already achieved in a greedy setting or with a very small beam size

6 Conclusion

We have described a dynamic oracle for constituent parsing. Experiments show that training a parser against this oracle leads to an improvement in accuracy over a static oracle. Together with morphological features, we obtain a greedy parser as accurate as state-of-the-art (non reranking) parsers for morphologically-rich languages.

			$\mathbf{q_4.form}$
$\mathbf{s_0.w_t.m} \forall m \in M$		$\mathbf{q_0.m} \forall m \in M$	
$\mathbf{s_1.w_t.m} \forall m \in M$		$\mathbf{q_1.m} \forall m \in M$	

Table 6: These templates specify a list of addresses in a configuration. The input of the neural network is the instanciation of each address by a discrete typed symbol. Each $\mathbf{v_i}$ (Section 2) is the embedding of the i^{th} instantiated symbol of this list. M is the set of all available morphological attributes for a given language. We use the following notations (cf Figure 4): $\mathbf{s}_i$ is the i^{th} item in the stack, $\mathbf{c}$ denotes non-terminals, **t**op, **l**eft and **r**ight, indicate the position of an element in the subtree. Finally, $\mathbf{w}$ and $\mathbf{q}$ are respectively stack and buffer tokens.

Literal and Metaphorical Senses in Compositional Distributional Semantic Models

Abstract

Metaphorical expressions are pervasive in natural language and pose a substantial challenge for computational semantics. The inherent compositionality of metaphor makes it an important test case for compositional distributional semantic models (CDSMs). This paper is the first to investigate whether metaphorical composition warrants a distinct treatment in the CDSM framework. We propose a method to learn metaphors as linear transformations in a vector space and find that, across a variety of semantic domains, explicitly modeling metaphor improves the resulting semantic representations. We then use these representations in a metaphor identification task, achieving a high performance of 0.82 in terms of F-score.

1 Introduction

An extensive body of behavioral and corpus-linguistic studies suggests that metaphors are pervasive in everyday language (Cameron, 2003; Steen et al., 2010) and play an important role in how humans define and understand the world. According to Conceptual Metaphor Theory (CMT) (Lakoff and Johnson, 1981), individual metaphorical expressions, or *linguistic metaphors* (LMs), are instantiations of broader generalizations referred to as *conceptual metaphors* (CMs). For example, the phrases *half-baked idea*, *food for thought*, and *spoon-fed information* are LMs that instantiate the CM IDEAS ARE FOOD. These phrases reflect a mapping from the *source domain* of FOOD to the *target domain* of IDEAS (Lakoff, 1989). Two central claims of the CMT are that this mapping is systematic, in the sense that it consists of a fixed set of ontological correspondences, such as *thinking is preparing*, *communication is feeding*, *understanding is digestion*; and that this mapping can be productively extended to produce novel LMs that obey these correspondences.

Recent years have seen the rise of statistical techniques for metaphor detection. Several of these techniques leverage distributional statistics and vector-space models of meaning to classify utterances as literal or metaphorical (Utsumi, 2006; Shutova et al., 2010; Hovy et al., 2013; Tsvetkov et al., 2014). An important insight of these studies is that metaphorical meaning is not merely a property of individual words, but rather arises through cross-domain composition. The meaning of *sweet*, for instance, is not intrinsically metaphorical. Yet this word may exhibit a range of metaphorical meanings—e.g., *sweet dreams, sweet person, sweet victory*–that are created through the interplay of source and target domains. If metaphor is compositional, how do we represent it, and how can we use it in a compositional framework for meaning?

Compositional distributional semantic models (CDSMs) provide a compact model of compositionality that produces vector representations of phrases while avoiding the sparsity and storage issues associated with storing vectors for each phrase in a language explicitly. One of the most popular CDSM frameworks (Baroni and Zamparelli, 2010; Guevara, 2010; Coecke et al., 2010) represents nouns as vectors, adjectives as matrices that act on the noun vectors, and transitive verbs as third-order tensors that act on noun or noun phrase vectors. The meaning of a phrase is then derived by composing these lexical representations. The vast majority of such models build a single representation for all senses of a word, collapsing distinct senses together. One exception is the work of Kartsaklis and Sadrzadeh (2013a), who investigated homonymy, in which lexical items

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 183–193,
Berlin, Germany, August 7-12, 2016.

have identical form but unrelated meanings (e.g., *bank*). They found that deriving verb tensors from all instances of a homonymous form (as compared to training a separate tensor for each distinct sense) loses information and degrades the resultant phrase vector representations. To the best of our knowledge, there has not yet been a study of regular polysemy (i.e. metaphorical or metonymic sense distinctions) in the context of compositional distributional semantics. Yet, due to systematicity in metaphorical cross-domain mappings, there are likely to be systematic contextual sense distinctions that can be captured by a CDSM, improving the resulting semantic representations.

In this paper, we investigate whether metaphor, as a case of regular polysemy, warrants distinct treatment under a compositional distributional semantic framework. We propose a new approach to CDSMs, in which metaphorical meanings are distinct but structurally related to literal meanings. We then extend the generalizability of our approach by proposing a method to automatically learn metaphorical mappings as linear transformations in a CDSM. We focus on modeling adjective senses and evaluate our methods on a new data set of 8592 adjective-noun pairs annotated for metaphoricity, which we will make publicly available. Finally, we apply our models to classify unseen adjective-noun (AN) phrases as literal or metaphorical and obtain state-of-the-art performance in the metaphor identification task.

2 Background & Related Work

Metaphors as Morphisms. The idea of metaphor as a systematic mapping has been formalized in the framework of category theory (Goguen, 1999; Kuhn and Frank, 1991). In category theory, morphisms are transformations from one object to another that preserve some essential structure of the original object. Category theory provides a general formalism for analyzing relationships as morphisms in a wide range of systems (see Spivak (2014)). Category theory has been used to formalize the CM hypothesis with applications to user interfaces, poetry, and information visualization (Kuhn and Frank, 1991; Goguen and Harrell, 2010; Goguen and Harrell, 2005). Although these formal treatments of metaphors as morphisms are rigorous and well-formalized, they have been applied at a relatively limited scale. This is because this work does not suggest a straightforward and data-driven way to quantify semantic domains or morphisms, but rather focuses on the transformations and relations between semantic domains and morphisms, assuming some appropriate quantification has already been established. In contrast, our methods can learn representations of source-target domain mappings from corpus data, and so are inherently more scalable.

Compositional DSMs. Similar issues arose in modeling compositional semantics. Formal semantics has dealt with compositional meaning for decades, by using mathematical structures from abstract algebra, logic, and category theory (Montague, 1970; Partee, 1994; Lambek, 1999). However, formal semantics requires manual crafting of features. The central insight of CDSMs is to model the composition of words as algebraic operations on their vector representations, as provided by a conventional DSM (Mitchell and Lapata, 2008). Guevara (2010) and Baroni and Zamparelli (2010) were the first to treat adjectives and verbs differently from nouns. In their models, adjectives are represented by matrices that act on noun vectors. Adjective matrices can be learned using regression techniques. Other CDSMs have also been proposed and successfully applied to tasks such as sentiment analysis and paraphrase (Socher et al., 2011; Socher et al., 2012; Tsubaki et al., 2013; Turney, 2013).

Handling Polysemy in CDSMs. Several researchers argue that terms with ambiguous senses can be handled by DSMs without any recourse to additional disambiguation steps, as long as contextual information is available (Boleda et al., 2012; Erk and Padó, 2010; Pantel and Lin, 2002; Schütze, 1998; Tsubaki et al., 2013). Baroni et al. (2014) conjecture that CDSMs might largely avoid problems handling adjectives with multiple senses because the matrices for adjectives implicitly incorporate contextual information. However, they do draw a distinction between two ways in which the meaning of a term can vary. Continuous *polysemy*—the subtle and continuous variations in meaning resulting from the different contexts in which a word appears—is relatively tractable, in their opinion. This contrasts with discrete *homonymy*—the association of a single term with completely independent meanings (e.g., *light house* vs. *light work*). Baroni et al. concede that homonymy is more difficult to handle in

CDSMs. Unfortunately, they do not propose a definite way to determine whether any given variation in meaning is polysemy or homonymy, and offer no account of regular polysemy (i.e., metaphor and metonymy) or whether it would pose similar problems as homonymy for CDSMs.

To handle the problematic case of homonymy, Kartsaklis and Sadrzadeh (2013b) adapt a clustering technique to disambiguate the senses of verbs, and then train separate tensors for each sense, using the previously mentioned CDSM framework of Coecke et al. (2010). They found that prior disambiguation resulted in semantic similarity measures that correlated more closely with human judgments.

In principle, metaphor, as a type of regular polysemy, is different from the sort of semantic ambiguity described above. General ambiguity or vagueness in meaning (e.g. *bright light* vs *bright color*) is generally context-dependent in an unsystematic manner. In contrast, in regular polysemy meaning transfer happens in a systematic way (e.g. *bright light* vs. *bright idea*), which can be explicitly modeled within a CDSM. The above CDSMs provide no account of such systematic polysemy, which is the gap this paper aims to fill.

Computational Work on Metaphor. There is now an extensive literature on statistical approaches to metaphor detection. The investigated methods include clustering (Birke and Sarkar, 2006; Shutova et al., 2010; Li and Sporleder, 2010); topic modeling (Bethard et al., 2009; Li et al., 2010; Heintz et al., 2013); topical structure and imageability analysis (Strzalkowski et al., 2013); semantic similarity graphs (Sporleder and Li, 2009), and feature-based classifiers (Gedigian et al., 2006; Li and Sporleder, 2009; Turney et al., 2011; Dunn, 2013a; Dunn, 2013b; Hovy et al., 2013; Mohler et al., 2013; Neuman et al., 2013; Tsvetkov et al., 2013; Tsvetkov et al., 2014). We refer readers to the survey by Shutova (2015) for a more thorough review.

Most relevant to the present work are approaches that attempt to identify whether adjective-noun phrases are metaphorical or literal. Krishnakumaran and Zhu (2007) use AN co-occurrence counts and WordNet hyponym/hypernym relations for this task. If the noun and its hyponyms/hypernyms do not occur frequently with the given adjective, then the AN phrase is labeled as metaphorical. Krishnakumaran and Zhu's system achieves a precision of 0.67. Turney et al. (2011) classify verb and adjective phrases based on their level of concreteness or abstractness in relation to the noun they appear with. They learn concreteness rankings for words automatically (starting from a set of examples) and then search for expressions where a concrete adjective or verb is used with an abstract noun (e.g., *dark humor* is tagged as a metaphor; *dark hair* is not). They measure performance on a set of 100 phrases involving one of five adjectives, attaining an average accuracy of 0.79. Tsvetkov et al. (2014) train a random-forest classifier using several features, including abstractness and imageability rankings, WordNet supersenses, and DSM vectors. They report an accuracy of 0.81 on the Turney et al. (2011) AN phrase set. They also introduce a new set of 200 AN phrases, on which they measure an F-score of 0.85.

3 Experimental Data

Corpus. We trained our DSMs from a corpus of 4.58 billion tokens. Our corpus construction procedure is modeled on that of Baroni and Zamparelli (2010). The corpus consisted of a 2011 dump of English Wikipedia, the UKWaC (Baroni et al., 2009), the BNC (BNC Consortium, 2007), and the English Gigaword corpus (Graff et al., 2003). The corpus was tokenized, lemmatized, and POS-tagged using the NLTK toolkit (Bird and Loper, 2004) for Python.

Metaphor Annotations. We created an annotated dataset of 8592 AN phrases (3991 literal, 4601 metaphorical). Our choice of adjectives was inspired by the test set of Tsvetkov et al. (2014), though our annotated dataset is considerably larger. We focused on 23 adjectives that can have both metaphorical and literal senses, and which function as source-domain words in relatively productive CMs: TEMPERATURE (*cold*, *heated*, *icy*, *warm*), LIGHT (*bright*, *brilliant*, *dim*), TEXTURE (*rough*, *smooth*, *soft*); SUBSTANCE (*dense*, *heavy*, *solid*), CLARITY (*clean*, *clear*, *murky*), TASTE (*bitter*, *sour*, *sweet*), STRENGTH (*strong*, *weak*), and DEPTH (*deep*, *shallow*). We extracted all AN phrases involving these adjectives that occur in our corpus at least 10 times. We filtered out all phrases that require wider context to establish their meaning or metaphoricity—e.g., *bright side*, *weak point*.

The remaining phrases were annotated using a

procedure based on Shutova et al. (2010). Annotators were encouraged to rely on their own intuition of metaphor, but were provided with the following guidance:

- For each phrase, establish the meaning of the adjective in the context of the phrase.
- Try to imagine a more basic meaning of this adjective in other contexts. Basic meanings tend to be: more concrete; related to embodied actions/perceptions/sensations; more precise; historically older/more "original".
- If you can establish a basic meaning distinct from the meaning of the adjective in this context, it is likely to be used metaphorically.

If requested, a randomly sampled sentence from the corpus that contained the phrase in question was also provided. The annotation was performed by one of the authors. The author's annotations were compared against those of a university graduate native English-speaking volunteer who was not involved in the research, on a sample of 500 phrases. Interannotator reliability (Cohen, 1960; Fleiss et al., 1969) was $\kappa = 0.80$ ($SE = .02$). Our annotated data set is publicly available at `http://bit.ly/1TQ5czN`

4 Representing Metaphorical Senses in a Compositional DSM

In this section we test whether separate treatment of literal and metaphorical senses is justified in a CDSM framework. In that case, training adjective matrix representations on literal and metaphorical subsets separately may result in systematically improved phrase vector representations, despite each matrix making use of fewer training examples.

4.1 Method

Our goal is to learn accurate vector representations for unseen adjective-noun (AN) phrases, where adjectives can take on metaphorical or literal senses. Our models build off the CDSM framework of Baroni and Zamparelli (2010), as extended by Li et al. (2014). Each adjective a is treated as a linear map from nouns to AN phrases:

$$\mathbf{p} = \mathbf{A}_a \mathbf{n},$$

where $\mathbf{p}$ is a vector for the phrase, $\mathbf{n}$ is a vector for the noun, and $\mathbf{A}_a$ is a matrix for the adjective.

Contextual Variation Model. The traditional representations do not account for the differences in meaning of an adjective in literal vs metaphorical phrases. Their assumption is that the contextual variations in meaning that are encoded by literal and metaphorical senses may be subtle enough that they can be handled by a single catch-all matrix per adjective, $\mathbf{A}_{\text{BOTH}(a)}$. In this model, every phrase i can be represented by

$$\mathbf{p}_i = \mathbf{A}_{\text{BOTH}(a)} \mathbf{n}_i \quad (1)$$

regardless of whether a is used metaphorically or literally in i. This model has the advantage of simplicity and requires no information about whether an adjective is being used literally or metaphorically. In fact, to our knowledge, all previous literature has handled metaphor in this way.

Discrete Polysemy Model Alternatively, the metaphorical and literal senses of an adjective may be distinct enough that averaging the two senses together in a single adjective matrix produces representations that are not well-suited for either metaphorical or literal phrases. Thus, the literal-metaphorical distinction could be problematic for CDSMs in the way that Baroni et al. (2014) suggested that homonyms are. Just as Kartsaklis and Sadrzadeh (2013a) solve this problem by representing each sense of a homonym by a different adjective matrix, we represent literal and metaphorical senses by different adjective matrices. Each literal phrase i is represented by

$$\mathbf{p}_i = \mathbf{A}_{\text{LIT}(a)} \mathbf{n}_i, \quad (2)$$

where $\mathbf{A}_{\text{LIT}(a)}$ is the literal matrix for adjective a. Likewise, a metaphorical phrase is represented by

$$\mathbf{p}_i = \mathbf{A}_{\text{MET}(a)} \mathbf{n}_i, \quad (3)$$

where $\mathbf{A}_{\text{MET}(a)}$ is the metaphorical matrix for a.

Learning. Given a data set of noun and phrase vectors $\mathcal{D}(a) = \{(\mathbf{n}_i, \mathbf{p}_i)\}_{i=1}^{N}$ for AN phrases involving adjective a extracted using a conventional DSM, our goal is to learn $\mathbf{A}_{\mathcal{D}(a)}$. This can be treated as an optimization problem, of learning an estimate $\hat{\mathbf{A}}_{\mathcal{D}(a)}$ that minimizes a specified loss function. In the case of the squared error loss, $L(\mathbf{A}_{\mathcal{D}(a)}) = \sum_{i \in \mathcal{D}(a)} \|\mathbf{p}_i - \mathbf{A}_{\mathcal{D}(a)} \mathbf{n}_i\|_2^2$, the optimal solution can be found precisely using ordinary least-squares regression. However, this may result in overfitting because of the large number of parameters relative to the number of samples (i.e., phrases). Regularization parameters $\lambda = (\lambda_1, \lambda_2)$ can be introduced to keep $\hat{\mathbf{A}}_{\mathcal{D}(a)}$ small:

$$\sum_{i \in \mathcal{D}(a)} \|\mathbf{p}_i - \hat{\mathbf{A}}_{\mathcal{D}(a)}\mathbf{n}_i\|_2^2 + R(\lambda; \hat{\mathbf{A}}_{\mathcal{D}(a)}),$$

where $R(\lambda; \hat{\mathbf{A}}_{\mathcal{D}}) = \lambda_1\|\hat{\mathbf{A}}_{\mathcal{D}}\|_1 + \lambda_2\|\hat{\mathbf{A}}_{\mathcal{D}}\|_2$. This approach, known as elastic-net regression (Zou and Hastie, 2005), produces better adjective matrices than unregularized regression (Li et al., 2014). Note that the same procedure can be used to learn the adjective representations in both the Contextual Variation model and the Discrete Polysemy model by varying what phrases are included in the training set $\mathcal{D}(a)$. In the Contextual Variation model $\mathcal{D}(a)$ includes both metaphorical and literal phrases, while in the Discrete Polysemy model it includes only metaphorical phrases when learning $\hat{\mathbf{A}}_{\text{MET}(a)}$ and testing on metaphorical phrases (and only literal phrases when learning $\hat{\mathbf{A}}_{\text{LIT}(a)}$ and testing on literal phrases).

4.2 Experimental Setup

Extracting Noun & Phrase Vectors. Our approach for constructing term vector representations is similar to that of Dinu et al. (2013). We first selected the 10K most frequent nouns, adjectives, and verbs to serve as context terms. We then constructed a co-occurrence matrix that recorded term-context co-occurrence within a symmetric 5-word context window of the 50K most frequent POS-tagged terms in the corpus. We then used these co-occurrences to compute the positive pointwise mutual information (PPMI) between every pair of terms, and collected these into a term-term matrix. Next, we reduced the dimensionality of this matrix to 100 dimensions using singular-value decomposition. Additionally, we computed "ground truth" distributional vectors for all the annotated AN phrases in our data set by treating the phrases as single terms and computing their PPMI with the 50K single-word terms, and then projecting them onto the same 100-dimensional basis.

Training Adjective Matrices. For each adjective a that we are testing, we split the phrases involving that adjective into two subsets, the literal (LIT) subset and the metaphorical (MET) subset. We then split the subsets into 10 folds, so that we do not train and test any matrices on the same phrases. For each fold k, we train three adjective matrices: $\hat{\mathbf{A}}_{\text{MET}(a)}$ using all phrases from the MET set not in fold k; $\hat{\mathbf{A}}_{\text{LIT}(a)}$ using all phrases from the LIT set not in fold k; and $\hat{\mathbf{A}}_{\text{BOTH}(a)}$ using all the phrases from either subset not in fold k. Within each fold, we use nested cross-validation as outlined in Li et al. (2014) to determine the regularization parameters for each regression problem.

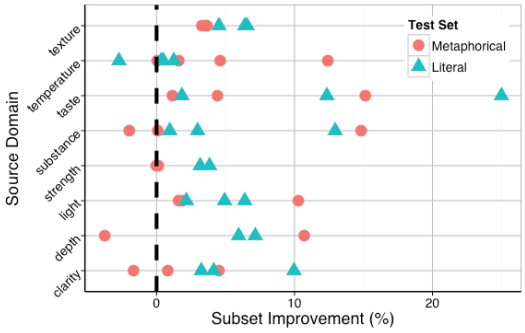

Figure 1: Reduction in error from training on targeted subset (MET/LIT) rather than on all phrases.

4.3 Evaluating Vector Representations

Evaluation. Our goal is to produce a vector prediction of each phrase that will be close to its ground truth distributional vector. Phrase vectors directly extracted from the corpus by treating the phrase as a single term are the gold standard for predicting human judgment and producing paraphrases (Dinu et al., 2013), so we use these as our ground truth. The quality of the vector prediction for phrase i is measured using the cosine distance between the phrase's ground truth vector $\mathbf{p}_i$ and the vector prediction $\hat{\mathbf{p}}_i$:

$$err(\hat{\mathbf{p}}_i) = 1 - \cos(\hat{\mathbf{p}}_i, \mathbf{p}_i).$$

We then analyze the benefit of training on a reduced subset by calculating a "subset improvement" (SI) score for the MET and LIT subsets of each adjective a. We define the SI for each subset $\mathcal{D}(a) \in \{\text{LIT}(a), \text{MET}(a)\}$ as:

$$SI(\mathcal{D}(a)) = 1 - \frac{\sum_{i \in \mathcal{D}(a)} err(\hat{\mathbf{A}}_{\mathcal{D}(a)}\mathbf{n}_i)}{\sum_{i \in \mathcal{D}(a)} err(\hat{\mathbf{A}}_{\text{BOTH}(a)}\mathbf{n}_i)}$$

Positive values of SI thus indicate improved performance when trained on a reduced subset compared to the full set of phrases. For example $SI_{\text{LIT}(a)} = 5\%$ tells us that predicting the phrase vectors for LIT phrases of adjective a using the LIT matrix resulted in a 5% reduction in mean cosine error compared to predicting the phrase vectors using the BOTH matrix.

Results. The results are summarized in Fig. 1. Each point indicates the SI for a single adjective and for a single subset. Adjectives are grouped by source domain along the y-axis. Overall, almost every item shows a subset improvement; and, for every source domain, the majority of adjectives show a subset improvement.

We analyzed per-adjective SI by fitting a linear mixed-effects model, with a fixed intercept, a fixed effect of test subset (MET vs. LIT), a random effect of source domain, and the maximal converging random effects structure (uncorrelated random intercepts and slopes) (Barr et al., 2013). Training on a targeted subset improved performance by $4.4\% \pm 0.009(SE)$ ($p = .002$). There was no evidence that this differed by test subset (i.e., metaphorical vs. literal senses, $p = .35$). The positive SI from training on a targeted subset suggests that metaphorical and literal uses of the same adjective are semantically distinct.

4.4 Metaphor Classification

Method. The results of the previous section suggest a straightforward classification rule: classify unseen phrase i involving adjective a as metaphorical if $\cos(\mathbf{p}_i, \hat{\mathbf{A}}_{\text{MET}(a)}\mathbf{n}_i) < \cos(\hat{\mathbf{A}}_{\text{LIT}(a)}\mathbf{n}_i)$. Otherwise, we classify it as literal.

Evaluation. We test this method on our data set of 8593 annotated AN phrases using 10-fold cross validation. It is possible that our method's classification performance is not due to the compositional aspect of the model, but rather to some semantic coherence property among the nouns in the AN phrases that we are testing. To control for this possibility, we compare the performance of our method against four baselines. The first baseline, NOUN-NN, measures the cosine distance between the vector for the noun of the AN phrase being tested and the noun vectors of the nouns participating in an AN phrase in the training folds. The test phrase is then assigned the label of the AN phrase whose noun vector is nearest. PHRASE-NN proceeds similarly, but using the ground-truth phrase vectors for the test phrase and the training phrases. The test phrase is then assigned the label of the AN phrase whose vector is nearest. The baseline NOUN-CENT first computes the centroid of the noun vectors of the training phrases that are literal, and the centroid of the noun vectors of the training phrases that are metaphorical. It then assigns the test phrase the label of the centroid whose cosine distance from the test phrase's noun vector is smallest. PHRASE-CENT, proceeds similarly, but using phrase vectors. We measure performance against the manual annotations.

Results. Our classification method achieved a held-out F-score of 0.817, recall of 0.793, precision of 0.842, and accuracy of 0.809. These results were superior to those of the baselines (Table 1). These results are competitive with the state of the art and demonstrate the importance of compositionality in metaphor identification.

Method	F-score	Precision	Recall	Accuracy
MET-LIT	0.817	0.842	0.793	0.809
NOUN-NN	0.709	0.748	0.675	0.703
PHRASE-NN	0.590	0.640	0.547	0.592
NOUN-CENT	0.717	0.741	0.695	0.706
PHRASE-CENT	0.629	0.574	0.695	0.559

Table 1: Performance of the method of §4.4 (MET-LIT) against various baselines.

5 Metaphors as Linear Transformations

One of the principal claims of the CM hypothesis is that CMs are productive: A CM (i.e., mapping) can generate endless new LMs (i.e., linguistic expressions). Cases where the LMs involve an adjective that has already been used metaphorically and for which we have annotated metaphorical and literal examples can be handled by the methods of §4, but when the novel LM involves an adjective that has only been observed in literal usage, we need a more elaborate model. According to the CM hypothesis, an adjective's metaphorical meaning is a result of the action of a source-to-target CM mapping on the adjective's literal sense. If so, then given an appropriate representation of this mapping it should be possible to infer the metaphorical sense of an adjective without ever seeing metaphorical exemplars—that is, using only the adjective's literal sense. Our next experiments seek to determine whether it is possible to represent and learn CM mappings as linear maps in distributional vector space.

5.1 Model

We model each CM mapping $\mathcal{M}$ from source to target domain as a linear transformation $\mathbf{C}_{\mathcal{M}}$:

$$\mathbf{A}_{\text{MET}(a)}\mathbf{n}_i \approx \mathbf{C}_{\mathcal{M}}\mathbf{A}_{\text{LIT}(a)}\mathbf{n}_i \tag{4}$$

We can apply a two-step regression to learn $\mathbf{C}_{\mathcal{M}}$. First we apply elastic-net regression to learn the literal adjective matrix $\hat{\mathbf{A}}_{\text{LIT}(a)}$ as in §4.2. Then we can substitute this estimate into Eq. (4), and apply elastic-net regression to learn the $\hat{\mathbf{C}}_{\mathcal{M}}$ that minimizes the regularized squared error loss:

$$\sum_{a \in \mathcal{M}} \sum_{i \in \mathcal{D}(a)} \|\mathbf{p}_i - \hat{\mathbf{C}}_{\mathcal{M}}\hat{\mathbf{A}}_{\text{LIT}(a_i)}\mathbf{n}_i\|_2^2 + R(\lambda; \hat{\mathbf{C}}_{\mathcal{M}}).$$

To learn $C_{\mathcal{M}}$ in this regression problem, we can pool together and train on phrases from many different adjectives that participate in $\mathcal{M}$.

5.2 Experimental Setup

We used a cross-validation scheme where we treated each adjective in a source domain as a fold in training the domain's metaphor transformation matrix. The nested cross-validation procedure we use to set regularization parameters λ and evaluate performance requires at least 3 adjectives in a source domain, so we evaluate on the 6 source domain classes containing at least 3 adjectives. The total number of phrases for these 19 adjectives is 6987 (3659 metaphorical, 3328 literal).

5.3 Evaluating Vector Representations

Evaluation. We wish to test whether CM mappings learned from one set of adjectives are transferable to new adjectives for which metaphorical phrases are unseen. As in §4, models were evaluated using cosine error compared to the ground truth phrase vector representation. Since our goal is to improve the vector representation of metaphorical phrases given no metaphorical annotations, we measure performance on the MET phrase subset for each adjective. We compare the performance of the transformed LIT matrix $\mathbf{C}_{\mathcal{M}}\mathbf{A}_{\text{LIT}(a)}$ against the performance of the original LIT matrix $\mathbf{A}_{\text{LIT}(a)}$ by defining the metaphor transformation improvement (MTI) as:

$$MTI(a) = 1 - \frac{\sum_{i \in \text{MET}} err(\mathbf{C}_{\mathcal{M}}\hat{\mathbf{A}}_{\text{LIT}(a)})}{\sum_{i \in \text{MET}} err(\hat{\mathbf{A}}_{\text{LIT}(a)})}.$$

Results. Per-adjective MTI was analyzed with a linear mixed-effects model, with a fixed intercept, a random effect of source domain, and random intercepts. Transforming the LIT matrix using the CM mapping matrix improved performance by $11.5\% \pm 0.023(SE)$ ($p < .001$). On average, performance improved for 18 of 19 adjectives and for every source domain ($p = .03$, binomial test; Fig. 2). Thus, mapping structure is indeed shared across adjectives participating in the same CM.

5.4 Metaphor Classification

Method. Once again our results suggest a procedure for metaphor classification. This procedure can classify phrases involving adjectives without seeing any metaphorical annotations. For any unseen phrase i involving an adjective a_i, we classify the phrase as metaphorical if $\cos(\mathbf{p}_i, \hat{\mathbf{C}}_{\mathcal{M}}\hat{\mathbf{A}}_{\text{LIT}(a_i)}\mathbf{n}_i) < \cos(\mathbf{p}_i, \hat{\mathbf{A}}_{\text{LIT}(a_i)}\mathbf{n}_i)$. Otherwise, we classify it as literal. We used the same procedure as in §4.2 to learn $\hat{\mathbf{A}}_{\text{LIT}(a_i)}$.

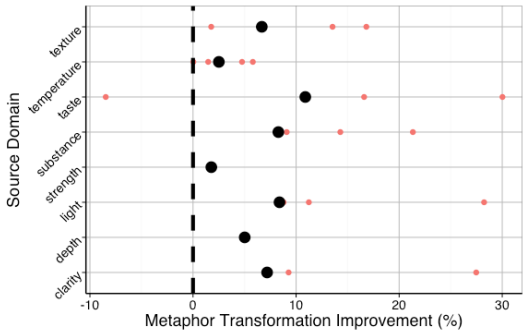

Figure 2: Reduction in error from transforming LIT matrix using metaphorical mapping. Mean change was positive for every domain (large black), and for all but one adjective (small red).

Method	F-score	Precision	Recall	Accuracy
TRANS-LIT	0.793	0.716	0.819	0.804
MET-LIT	0.838	0.856	0820	0.833
NOUN-NN	0.692	0.732	0.655	0.693
PHRASE-NN	0.575	0.625	0.532	0.587
NOUN-CENT	0.703	0.722	0.685	0.696
PHRASE-CENT	0.610	0.552	0.681	0.542

Table 2: Performance of method of §5.4 (TRANS-LIT) against method of §4.4 (MET-LIT) and various baselines.

Results. Our method achieved an F-score of 0.793 on the classification of phrases involving unseen adjectives. On this same set of phrases, the method of §4.4 achieved an F-score of 0.838. Once again, the performance of our method was superior to the performance of the baselines (Table 2; the MET-LIT figures in Table 2 differ slightly from those in Table 1 because only 19 of 23 adjectives are tested). For comparison, we also include the classification performance using the MET-LIT method of §4.4. While MET-LIT slightly outperforms TRANS-LIT, the latter has the benefit of not needing annotations for metaphorical phrases for the test adjective. Hence, our approach is generalizable to cases where such annotations are unavailable with only slight performance reduction.

6 Discussion

Overall, our results show that taking metaphor into account has the potential to improve CDSMs and expand their domain of applicability. The findings of §4 suggest that collapsing across metaphorical and literal uses may hurt accuracy of vector rep-

resentations in CDSMs. While the method in §4 depends on explicit annotations of metaphorical and literal senses, the method in §5 provides a way to generalize these representations to adjectives for which metaphorical training data is unavailable, by showing that metaphorical mappings are transferable across adjectives from the same source domain. Note that an accurate matrix representation of the literal sense of each adjective is still required in the experimental setup of §5. This particular choice of setup allowed a proof of concept of the hypothesis that metaphors function as cross-domain transformations, but in principle it would be desirable to learn transformations from a general BOTH matrix representation for any adjective in a source domain to its MET matrix representation. This would enable improved vector representations of metaphorical AN phrases without annotation for unseen adjectives.

The success of our models on the metaphor classification tasks demonstrates that there is information about metaphoricity of a phrase inherent in the composition of the meanings of its components. Notably, our results show that this metaphorical compositionality can be captured from corpus-derived distributional statistics. We also noticed some trends at the level of individual phrases. In particular, classification performance and vector accuracy tended to be lower for metaphorical phrases whose nouns are distributionally similar to nouns that tend to participate in literal phrases (e.g., *reception* is similar to *foyer* and *refreshment* in our corpus; *warm reception* is metaphorical while *warm foyer* is literal). Another area where classification accuracy is low is in phrases with low corpus occurrence frequency. The ground truth vectors for these phrases exhibit high sample variance and sparsity. Many such phrases sound paradoxical (e.g., *bitter sweetness*).

Our results could also inform debates within cognitive science. First, cognitive scientists debate whether words that are used both literally and figuratively (e.g., *long road*, *long meeting*) are best understood as having a single, abstract meaning that varies with context or two distinct but related meanings. For instance, some argue that domains like space, time, and number operate over a shared, generalized magnitude system, yet others maintain that our mental representation of time and number is distinct from our mental representation of space, yet inherited metaphorically from it (Winter et al., 2015). Our results suggest that figurative and literal senses involve quite different patterns of use. This is statistical evidence that adjectives that are used metaphorically have distinct related senses, not a single abstract sense.

Second, the Conceptual Metaphor Theory account hypothesizes that LMs are an outgrowth of metaphorical thought, which is in turn an outgrowth of embodied experiences that conflate source and target domains—experience structures thought, and thought structures language (Lakoff, 1993). However, recent critics have argued for the opposite causal direction: Linguistic regularities may drive the mental mapping between source and target domains (Hutchinson and Louwerse, 2013; Casasanto, 2014; Hutchinson and Louwerse, 2014). Our results show that, at least for AN pairs, the semantic structure of a source domain and its mapping to a metaphorical target domain are available in the distributional statistics of language itself. There may be no need, therefore, to invoke embodied experience to explain the prevalence of metaphorical thought in adult language users. A lifetime of experience with literal and metaphorical language may suffice.

7 Conclusion

We have shown that modeling metaphor explicitly within a CDSM can improve the resulting vector representations. According to our results, the systematicity of metaphor can be exploited to learn linear transformations that represent the action of metaphorical mappings across many different adjectives in the same semantic domain. Our classification results suggest that the compositional distributional semantics of a phrase can inform classification of the phrase for metaphoricity.

Beyond improvements to the applications we presented, the principles underlying our methods also show potential for other tasks. For instance, the LIT and MET adjective matrices and the CM mapping matrix learned with our methods could be applied to improve automated paraphrasing of AN phrases. Our work is also directly extendable to other syntactic constructions. In the CDSM framework we apply, verbs would be represented as third-order tensors. Tractable and efficient methods for estimating these verb tensors are now available (Fried et al., 2015). It may also be possible to extend the coverage of our system by using automated word-sense disambiguation to bootstrap annotations and therefore construct LIT

and MET matrices in a minimally supervised fashion (Kartsaklis et al., 2013b). Finally, it would be interesting to investigate modeling metaphorical mappings as nonlinear mappings within the deep learning framework.

Abstract

Idiom token classification is the task of deciding for a set of potentially idiomatic phrases whether each occurrence of a phrase is a literal or idiomatic usage of the phrase. In this work we explore the use of Skip-Thought Vectors to create distributed representations that encode features that are predictive with respect to idiom token classification. We show that classifiers using these representations have competitive performance compared with the state of the art in idiom token classification. Importantly, however, our models use only the sentence containing the target phrase as input and are thus less dependent on a potentially inaccurate or incomplete model of discourse context. We further demonstrate the feasibility of using these representations to train a competitive general idiom token classifier.

1 Introduction

Idioms are a class of multiword expressions (MWEs) whose meaning cannot be derived from their individual constituents (Sporleder et al., 2010). Idioms often present idiosyncratic behaviour such as violating selection restrictions or changing the default semantic roles of syntactic categories (Sporleder and Li, 2009). Consequently, they present many challenges for Natural Language Processing (NLP) systems. For example, in Statistical Machine Translation (SMT) it has been shown that translations of sentences containing idioms receive lower scores than translations of sentences that do not contain idioms (Salton et al., 2014).

Idioms are pervasive across almost all languages and text genres and as a result broad coverage NLP systems must explicitly handle idioms (Villavicencio et al., 2005). A complicating factor, however, is that many idiomatic expressions can be used both literally or figuratively. In general, idiomatic usages are more frequent, but for some expressions the literal meaning may be more common (Li and Sporleder, 2010a). As a result, there are two fundamental tasks in NLP idiom processing: *idiom type* classification is the task of identifying expressions that have possible idiomatic interpretations and *idiom token* classification is the task of distinguishing between idiomatic and literal usages of potentially idiomatic phrases (Fazly et al., 2009). In this paper we focus on this second task, *idiom token* classification.

Previous work on idiom token classification, such as (Sporleder and Li, 2009) and (Peng et al., 2014), often frame the problem in terms of modelling the global lexical context. For example, these models try to capture the fact that the idiomatic expression *break the ice* is likely to have a literal meaning in a context containing words such as *cold*, *frozen* or *water* and an idiomatic meaning in a context containing words such as *meet* or *discuss* (Li and Sporleder, 2010a). Frequently these global lexical models create a different idiom token classifier for each phrase. However, a number of papers on idiom type and token classification have pointed to a range of other features that could be useful for idiom token classification; including local syntactic and lexical patterns (Fazly et al., 2009) and cue words (Li and Sporleder, 2010a). However, in most cases these non-global features are specific to a particular phrase. So a key challenge is to identify from a range of features which features are the correct features to use for idiom token classification for a specific expression.

Meanwhile, in recent years there has been an explosion in the use of neural networks for learning distributed representations for language (e.g.,

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 194–204,
Berlin, Germany, August 7-12, 2016.

Socher et al. (2013), Kalchbrenner et al. (2014) and Kim (2014)). These representations are automatically trained from data and can simultaneously encode multiple linguistics features. For example, word embeddings can encode gender distinctions and plural-singular distinctions (Mikolov et al., 2013b) and the representations generated in sequence to sequence mappings have been shown to be sensitive to word order (Sutskever et al., 2014). The recent development of Skip-Thought Vectors (or Sent2Vec) (Kiros et al., 2015) has provided an approach to learn distributed representations of sentences in an unsupervised manner.

In this paper we explore whether the representations generated by Sent2Vec encodes features that are useful for idiom token classification. This question is particularly interesting because the Sent2Vec based models only use the sentence containing the phrase as input whereas the baselines systems use full the paragraph surrounding the sentence. We further investigate the construction of a "general" classifier that can predict if a sentence contains literal or idiomatic language (independent of the expression) using just the distributed representation of the sentence. This approach contrasts with previous work that has primarily adopted a "per expression" classifier approach and has been based on more elaborate context features, such as discourse and lexical cohesion between and sentence and the larger context. We show that our method needs less contextual information than the state-of-the-art method and achieves competitive results, making it an important contribution to a range of applications that do not have access to a full discourse context. We proceed by introducing that previous work in more detail.

2 Previous Work

One of the earliest works on idiom token classification was on Japanese idioms (Hashimoto and Kawahara, 2008). This work used a set of features, commonly used in Word Sense Disambiguation (WSD) research, that were defined over the text surrounding a phrase, as well as a number of idiom specific features, which were in turn used to train an SVM classifier based on a corpus of sentences tagged as either containing an idiomatic usage or a literal usage of a phrase. Their results indicated that the WSD features worked well on idiom token classification but that their idioms specific features did not help on the task.

Focusing on idiom token classification in English, Fazly et al. (2009) developed the concept of a canonical form (defined in terms of local syntactic and lexical patterns) and argued that for each idiom there is a distinct canonical form (or small set of forms) that mark idiomatic usages of a phrase. Meanwhile Sporleder and Li (2009) proposed a model based on how strongly an expression is linked to the overall cohesive structure of the discourse. Strong links result in a literal classification, otherwise an idiomatic classification is returned. In related work, Li and Sporleder (2010a) experimented with a range of features for idiom token classification models, including: global lexical context, discourse cohesion, syntactic structures based on dependency parsing, and local lexical features such as cue words, occurring just before or after a phrase. An example of a local lexical feature is when the word *between* occurs directly after *break the ice*; here this could mark an idiomatic usage of the phrase: *it helped to break the ice between Joe and Olivia*. The results of this work indicated that features based on global lexical context and discourse cohesion were the best features to use for idiom token classification. The inclusion of syntactic structures in the feature set provided a boost to the performance of the model trained on global lexical context and discourse cohesion. Interestingly, unlike the majority of previous work on idiom token classification Li and Sporleder (2010a) also investigated building general models that could work across multiple expressions. Again they found that global lexical context and discourse cohesion were the best features in their experiments.

Continuing work on this topic, Li and Sporleder (2010b) present research based on the assumption that literal and figurative language are generated by two different Gaussians. The model representation is based on semantic relatedness features similar to those used earlier in (Sporleder and Li, 2009). A Gaussian Mixture Model was trained using an Expectation Maximization method with the classification of instances performed by choosing the category which maximises the probability of fitting either of the Gaussian components. Li and Sporleder (2010b)'s results confirmed the findings from previous work that figurative language exhibits less cohesion with the surrounding context then literal language.

More recently, Feldman and Peng (2013) describes an approach to idiom token identification that frames the problem as one of outlier detection. The intuition behind this work is that because idiomatic usages of phrases have weak cohesion with the surrounding context they are semantically distant from local topics. As a result, phrases that are semantic outliers with respect to the context are likely to be idioms. Feldman and Peng (2013) explore two different approaches to outlier detection based on principle component analysis (PCA) and linear discriminant analysis (LDA) respectively. Building on this work, Peng et al. (2014) assume that phrases within a given text segment (e.g., a paragraph) that are semantically similar to the main topic of discussion in the segment are likely to be literal usages. They use Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to extract a topic representation, defined as a topic term document matrix, of each text segment within a corpus. They then trained a number of models that classify a phrase in a given text segment as a literal or idiomatic usage by using the topic term document matrix to project the phrase into a topic space representation and label outliers within the topic space as idiomatic. To the best of our knowledge, Peng et al. (2014) is currently the best performing approach to idiom token classification and we use their models as our baseline[1].

3 Skip-Thought Vectors

While idiom token classification based on long range contexts, such as is explored in a number of the models outlined in the previous section, generally achieve good performance, an NLP system may not always have access to the surrounding context, or may indeed find it challenging to construct a reliable interpretation of that context. Moreover, the construction of classifiers for each individual idiom case is resource intensive, and we argue fails to easily scale to under-resourced languages. In light of this, in our work we are exploring the potential of distributed compositional semantic models to produce reliable estimates of idiom token classification.

Skip-Thought Vectors (Sent2Vec) (Kiros et al., 2015) are a recent prominent example of such distributed models. Skip-Thought Vectors are an application of the Encoder/Decoder framework (Sutskever et al., 2014), a popular architecture for NMT (Bahdanau et al., 2015) based on recurrent neural networks (RNN). The encoder takes an input sentence and maps it into a distributed representation (a vector of real numbers). The decoder is a language model that is conditioned on the distributed representation and, in Sent2Vec, is used to "predict" the sentences surrounding the input sentence. Consequently, the Sent2Vec encoder learns (among other things) to encode information about the context of an input sentence without the need of explicit access to it. Figure 1 presents the architecture of Sent2Vec.

More formally, assume a given tuple (s_{i-1}, s_i, s_{i+1}) where s_i is the input sentence, s_{i-1} is the previous sentence to s_i and s_{i+1} is the next sentence to s_i. Let w_i^t denote the t-th word for s_i and $\mathbf{x}_i^t$ denote its word embedding. We follow Kiros et al. (2015) and describe the model in three parts: encoder, decoder and objective function.

Encoder. Given the sentence s_i of length N, let $w_i^1, \ldots, w_i^N$ denote the words in s_i. At each timestep t, the encoder (in this case an RNN with Gated Recurrent Units - GRUs (Cho et al., 2014)) produces a hidden state $\mathbf{h}_i^t$ that represents the sequence $w_i^1, \ldots, w_i^t$. Therefore, $\mathbf{h}_i^N$ represents the full sentence. Each $\mathbf{h}_i^N$ is produced by iterating the following equations (without the subscript i):

$$\mathbf{r}^t = \sigma(\mathbf{W}_r^e \mathbf{x}^t + \mathbf{U}_r^e \mathbf{h}^{t-1}) \quad (1)$$

$$\mathbf{z}^t = \sigma(\mathbf{W}_z^e \mathbf{x}^t + \mathbf{U}_z^e \mathbf{h}^{t-1}) \quad (2)$$

$$\tilde{\mathbf{h}}^t = tanh(\mathbf{W}^e \mathbf{x}^t + \mathbf{U}^{\mathbf{e}}(\mathbf{r}^t \odot \mathbf{h}^{t-1})) \quad (3)$$

$$\mathbf{h}^t = (1 - \mathbf{z}^t) \odot \mathbf{h}^{t-1} + \mathbf{z}^t \odot \tilde{\mathbf{h}}^t \quad (4)$$

where $\mathbf{r}^t$ is the reset gate, $\mathbf{z}^t$ is the update gate, $\tilde{\mathbf{h}}^t$ is the proposed update state at time t and $\odot$ denotes a component-wise product.

Decoder. The decoder is essentially a neural language model conditioned on the input sentence representation $\mathbf{h}_i^N$. However, two RNNs are used (one for the sentence s_{i-1} and the other for the sentence s_{i+1}) with different parameters except the embedding matrix ($\mathbf{E}$), and a new set of matrices ($\mathbf{C}_r$, $\mathbf{C}_z$ and $\mathbf{C}$) are introduced to condition the GRU on $\mathbf{h}_i^N$. Let $\mathbf{h}_{i+1}^t$ denote the hidden state of the decoder of the sentence s_{i+1} at time t. De-

[1]However, it is not possible for us to reproduce their results directly as they "apply the (modified) Google stop list before extracting the topics" (Peng et al., 2014, p. 2023) and, to date, we do not have access to the modified list. So in our experiments we compare our results with the results they report on the same data.

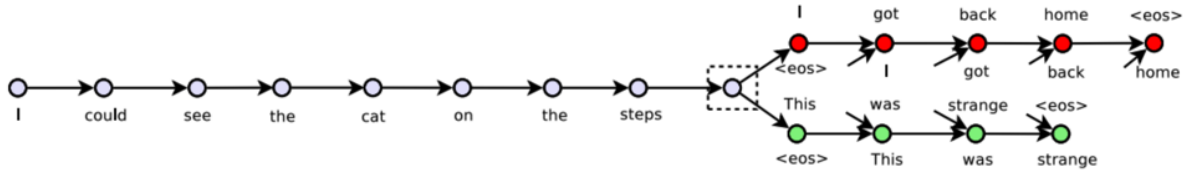

Figure 1: Picture representing the Encoder/Decoder architecture used in the Sent2Vec as shown in Kiros et al. (2015). The gray circles represent the Encoder unfolded in time, the red and the green circles represent the Decoder for the previous and the next sentences respectively also unfolded in time. In this example, the input sentence presented to the Encoder is *I could see the cat on the steps*. The previous sentence is *I got back home* and the next sentence is *This was strange*. Unattached arrows are connected to the encoder output (which is the last gray circle).

coding s_{i+1} requires iterating the following equations:

$$\mathbf{r}^t = \sigma(\mathbf{W}_r^d \mathbf{x}^t + \mathbf{U}_r^d \mathbf{h}^{t-1} + \mathbf{C}_r \mathbf{h}_i^N) \quad (5)$$

$$\mathbf{z}^t = \sigma(\mathbf{W}_z^d \mathbf{x}^t + \mathbf{U}_z^d \mathbf{h}^{t-1} + \mathbf{C}_z \mathbf{h}_i^N) \quad (6)$$

$$\tilde{\mathbf{h}}^t = tanh(\mathbf{W}^d \mathbf{x}^t + \mathbf{U}^{\mathbf{d}}(\mathbf{r}^t \odot \mathbf{h}^{t-1}) + \mathbf{C}\mathbf{h}_i^N) \quad (7)$$

$$\mathbf{h}_{i+1}^t = (1 - \mathbf{z}^t) \odot \mathbf{h}^{t-1} + \mathbf{z}^t \odot \tilde{\mathbf{h}}^t \quad (8)$$

where $\mathbf{r}^t$ is the reset gate, $\mathbf{z}^t$ is the update gate, $\tilde{\mathbf{h}}^t$ is the proposed update state at time t and $\odot$ denotes a component-wise product. An analogous computation is required to decode s_{i-1}.

Given $\mathbf{h}_{i+1}^t$, the probability of the word w_{i+1}^t conditioned on the previous $w_{i+1}^{<t}$ words and the encoded representation produced by the encoder (h_i^N) is:

$$P(w_{i+1}^t | w_{i+1}^{<t}, h_i^N) \propto exp(\mathbf{E}_{w_{i+1}^t} \mathbf{h}_{i+1}^t) \quad (9)$$

where $\mathbf{E}_{w_{i+1}^t}$ denotes the embedding for the word w_{i+1}^t. An analogous computation is performed to find the probability of s_{i-1}.

Objective. Given the tuple (s_{i-1}, s_i, s_{i+1}), the objective is to optimize the sum of the log-probabilities of the next (s_{i+1}) and previous (s_{i-1}) sentences given the distributed representation ($\mathbf{h}_i^N$) of s_i:

$$\sum \log P(w_{i+1}^t | w_{i+1}^{<t}, h_i^N) + P(w_{i-1}^t | w_{i-1}^{<t}, h_i^N) \quad (10)$$

where the total objective is summed over all training tuples (s_{i-1}, s_i, s_{i+1}).

The utility of Sent2Vec is that it is possible to infer properties of the surrounding context only from the input sentence. Therefore, we can assume that the Sent2Vec distributed representation is also carrying information regarding its context (without the need to explicitly access it). Following that intuition, we can train a supervised classifier only using the labelled sentences containing examples of idiomatic or literal language use without modelling long windows of context or using methods to extract topic representations.

4 Experiments

In the following we describe a study that evaluates the predictiveness of the distributed representations generated by Sent2Vec for idiom token classifier. We first evaluate these representations using a "per expression" study design (i.e., one classifier per expression) and compare our results to those of Peng et al. (2014) who applied multi-paragraphs contexts to generate best results. We also experiment with a "general" classifier trained and tested on a set of mixed expressions.

4.1 Dataset

In order to make our results comparable with (Peng et al., 2014) we used the same VNC-Tokens dataset (Cook et al., 2008) that they used in their experiments. The dataset used is a collection of sentences containing 53 different Verb Noun Constructions[2] (VNCs) extracted from the British National Corpus (BNC) (Burnard, 2007). In total, the VNC-Token dataset has 2984 sentences where each sample sentence is labelled with one of three labels: *I* (idiomatic); *L* (literal); or *Q* (unknown).

[2]This verb-noun constructions can be used either idiomatically or literally.

Of the 56 VNCs in the dataset 28 of these expressions have a reasonably balanced representation (with similar numbers of idiomatic and literal occurrences in the corpus) and the other 28 expressions have a skewed representation (with one class much more common then the other). Following the approach taken by (Peng et al., 2014), in this study we use the "balanced" part of the dataset and considered only those sentences labelled as "I" and "L" (1205 sentences - 749 labelled as "I" and 456 labelled as "L").

Peng et al. (2014) reported the precision, recall and f1-score of their models on 4 of the expressions from the balanced section of dataset: **BlowWhistle**; **MakeScene**; **LoseHead**; and **TakeHeart**. So, our first experiment is designed to compare our models with these baseline systems on a "per-expression" basis. For this experiment we built a training and test set for each of these expressions by randomly sampling expressions following the same distributions presented in Peng et al. (2014). In Table 1 we present those distribution and the split into training and test sets. The numbers in parentheses denote the number of samples labelled as "I".

Expression	Samples	Train Size	Test Size
BlowWhistle	78 (27)	40 (20)	38 (7)
LoseHead	40 (21)	30 (15)	10 (6)
MakeScene	50 (30)	30 (15)	20 (15)
TakeHeart	81 (61)	30 (15)	51 (46)

Table 1: The sizes of the samples for each expression and the split into training and test set. The numbers in parentheses indicates the number of idiomatic labels within the set. We follow the same split as described in Peng et al. (2014).

While we wish to base our comparison on the work of Peng et al. (2014) as it is the current state of the art, this is not without its own challenges. In particular we see the choice of these 4 expression as a somewhat random decision as other expressions could also be selected for the evaluation with similar ratios to those described in Table 1. Moreover, the choosen expressions are all semi-compositional and do not consider fully non-compositional expressions (although we believe the task of classifying non-compositional expressions would be easier for any method aimed at idiom token classification as these expressions are high-fixed) .A better evaluation would consider all the 28 expressions of the balanced part of the VNC-tokens dataset. In addition, we also see this choice of training and test splits as somewhat arbitrary. For two of the expressions the test set contain samples in a way that one of the classes outnumber the other by a great amount: for *BlowWhistle*, the literal class contains roughly 4 times more samples than the idiomatic class; and for *TakeHeart* the idiomatic class contains roughly 9 times more samples than the literal class. Our concerns with these very skewed test set ratios is that it is very easy when applying a per expression approach (i.e., a separate model for each expression) for a model to achieve good performance (in terms of precision, recall, ad f1) if the positive class is the majority class in the test set. However, despite these concerns, in our first experiment in order to facilitate comparison with the prior art we follow the expression selections and training/test splits described in Peng et al. (2014).

Studies on the characteristics of distributed semantic representations of words have shown that similar words tend to be represented by points that are close to each other in the semantic feature space (e.g. Mikolov et al. (2013a)). Inspired by these results we designed a second experiment to test whether the Sent2Vec representations would cluster idiomatic sentences in one part of the feature space and literal sentences in another part of the space. For this experiment we used the entire "balanced" part of the VNC-tokens dataset to train and test our "general" (multi-expression) models. In this experiment we wanted the data to reflect, as much as possible, the real distribution of the idiomatic and literal usages of each expression. So, in constructing our training and test set we tried to maintain for each expression the same ratio of idiomatic and literal examples across the training and test set. To create the training and test sets, we split the dataset into roughly 75% for training (917 samples) and 25% for testing (288 samples). We randomly sample the expressions ensuring that the ratio of idiomatic to literal expressions of each expression were maintained across both sets. In Table 2 we show the expressions used and their split into training and testing. The numbers in parentheses are the number of samples labelled as "I".

4.2 Sent2Vec Models

To encode the sentences into their distributed representations we used the code and models made available[3] by Kiros et al. (2015). Using their

Table 2: The sizes of the samples for each expression and the split into training and test set. The numbers in parentheses indicates the number of idiomatic labels within the set.

models it is possible to encode the sentences into three different formats: *uni-skip* (which uses a regular RNN to encode the sentence into a 2400-dimensional vector); *bi-skip* (that uses a bidirectional RNN to encode the sentence also into a 2400-dimensional vector); and the *comb-skip* (a concatenation of *uni-skip* and *bi-skip* which has 4800 dimensions). Their models were trained using the BookCorpus dataset (Zhu et al., 2015) and has been tested in several different NLP tasks as semantic relatedness, paraphrase detection and image-sentence ranking. Although we experimented with all the three models, in this paper we only report the results of classifiers trained and tested using the *comb-skip* features.

4.3 Classifiers

4.3.1 "Per-expression" models

The idea behind Sent2Vec is similar to those of word embeddings experiments: sentences containing similar meanings should be represented by points close to each other in the feature space. Following this intuition we experiment first with a similarity based classifier, the K-Nearest Neighbours (k-NN). For the k-NNs we experimented with $k = \{2, 3, 5, 10\}$.

We also experimented with a more advanced algorithm, namely the Support Vector Machine (SVM) (Vapnik, 1995). We trained the SVM under three different configurations:

Linear-SVM-PE[4]. This model used a "linear" kernel with $C = 1.0$ on all the classification setups.

Grid-SVM-PE. For this model we performed a grid search for the best parameters for each expression. The parameters are: *BlowWhiste* $=$ { kernel: 'rbf', $C = 100$}; *LoseHead* $=$ { kernel: 'rbf', $C = 1$ }; *MakeSene* $=$ { kernel: 'rbf', $C = 100$ }; *TakeHeart* $=$ { kernel: 'rbf', $C = 1000$ }.

SGD-SVM-PE. This model is a SVM with linear kernel but trained using stochastic gradient descent (Bottou, 2010). We set the SGD's learning rates (α) using a grid search: *BlowWhiste* $= \{\alpha = 0.001\}$; *LoseHead* $= \{\alpha = 0.01\}$; *MakeSene* $= \{\alpha = 0.0001\}$; *TakeHeart* $= \{\alpha = 0.0001\}$; *FullDataset* $= \{\alpha = 0.0001\}$. We trained these classifiers for 15 epochs.

4.3.2 "General" models

We consider the task of creating a "general" classifier that takes an example of any potential idiom and classifying it into idiomatic or literal usage more difficult than the "per-expression" classification task. Hence we executed this part of the study with the SVM models only. We trained the same three types of SVM models used in the "per-expression" approach but with the following parameters:

Linear-SVM-GE[5]. This model used a linear kernel with $C = 1.0$ for all the classification sets.

Grid-SVM-GE. For this model we also performed a grid search and set the kernel to "polynomial kernel" of $degree = 2$ with $C = 1000$.

SGD-SVM-GE. We also experimented with a SVM with linear kernel trained using stochastic gradient descent. We set the SGD's learning rate $\alpha = 0.0001$ after performing a grid search. We trained this classifier for 15 epochs.

5 Results and Discussion

We first present the results for the per expression comparison with Peng et al. (2014) and then in

[4]PE stands for "per-expression"

[5]GE stands for "general".

Table 3: Results in terms of precision (P.), recall (R.) and f1-score (F1) on the four chosen expressions. The results of (Peng et al., 2014) are those of the multi-paragraphs method. The bold values indicates the best results for that expression in terms of f1-score.

Section 5.2 we present the results for the "general' classifier approach.

5.1 Per-Expression Classification

The averaged results over 10 runs in terms of precision, recall and f1-score are presented in Table 3. When calculating these metrics, we considered the positive class to be the "I" (idiomatic) label. We used McNemar's test (McNemar, 1947) to check the statistical significance of our models' results and found all our results to be significant at $p < 0.05$.

We can see in Table 3 that some of our models outperform the baselines on 1 expression (*BlowWhistle*) and achieved the same f1-scores on 2 expressions (*LoseHead* and *MakeScene*). For theses 3 expressions, our best models generally had higher precision than the baselines, finding more idioms on the test sets. In addition, for *MakeScene*, 2 of our models achieved the same f1-scores (*KNN-3* and *SGD-SVM-PE*), although they have different precision and recall.

The only expression on which a baseline model outperformed all our models was *TakeHeart* where it achieved higher precision, recall and f1-scores. Nevertheless, this expression had the most imbalanced test set, with roughly 9 times more idioms than literal samples. Therefore, if the baseline label all the test set samples as idiomatic (including the literal examples), it would still have the best results. It is thus worth emphasizing that the choices of distributions for training and test sets in Peng et al's work seems arbitrary and does not reflect the real distribution of the data in a balanced corpus. Also, Peng et al. (2014) did not provide the confusion matrices for their models so we cannot analyse their model behaviour across the classes.

That aside, while our best models share the same f1-score with the baseline on 2 of the expressions, we believe that our method is more powerful if we take into account that we do not explicitly access the context surrounding our input sentences. We can also consider that our method is cheaper than the baseline in the sense that we do not need to process words other than the words in the input sentence.

In addition, we note that the SVMs generally outperform the KNNs, although no single model perform best across all expressions. Regardless of the fact that the KNN-3 achieved the same f1-score as SGD-SVM on *MakeScene*, the SVM consistently scored higher than the KNNs on all expressions. This is an interesting finding if we consider that our feature vector is 4800-dimensional and the SVMs are projecting these features into a space that has much more than 4800 dimensions and not incurring into the "curse of dimensionality". Furthermore, other work using Sent2vec have shown the capabilities of the Sent2Vec representations to capture features that are suited to various NLP tasks where semantics is involved (e.g., paraphrase detection and semantic relatedness (Kiros et al., 2015)). These results together with our findings suggests that the factors in-

Table 4: Precision (P.), recall (R.) and f1-scores (F1) calculated on the expressions of the balanced part of the VNC-Tokens dataset. The expressions marked with * indicate the expressions also evaluated with the "per-expression" classifiers.

volved in distinguishing between the semantics of idiomatic and literal language are deeply entrenched in language generation and only a high-dimensional representation can enable a classifier to make that distinction. This observation also implies that the contribution of each feature (generated by the distributed representation) is very small, given the fact that we need that many dimensions and the space needed to unpack the components of literal and idiomatic language has many more dimensions than the input space. Therefore, the current manually engineered features (i.e., the features used in previous idiom token classification) are only capturing a small portion of these dimensions and assigning more weight to these dimensions while other dimensions (not captured) are not considered (i.e., as they are not considered, the features represented by these dimensions have their weight equal to 0)

Another point for consideration is the fact that the combination of our model with the work of Peng et al. (2014) may result in a stronger model on this "per-expression" setting. Nevertheless, as previously highlighted, it was not possible for us to directly re-implement their work.

5.2 General Classification

Moving on to the general classification case, we present the average results (in terms of precision, recall and f1-score) over 10 runs to our "general" classifiers on the balanced part of the VNC-Tokens dataset. Once again, the positive class is assumed to be the "I" (idiomatic) label and we split the outcomes per expression. It should be noted that the "per-expression" evaluation was performed using a balanced set to train the classifiers while in this experiment we maintained the ratio of idiomatic to literal usages for each expression across the training and test sets. Our motivation for maintaining this ratio was to simulate the real distribution of the classes in the corpus.

We present results for the four individual MWEs used in the per-sentence based evaluation as well as a set of averages made over all 28 expression in the "balanced" portion of the dataset. Referring to the results we first of all note the overall performance of the "general" classifiers is

fairly high with 2 classifiers (Linear-SVM-GE and Grid-SVM-GE) sharing the same precision, recall and f1-scores. While averages here are the same across the two classifiers, it is worth noting that deviations occured across individual MWE types, though these deviations balanced out across the data set. Although not displayed in this table due to space limitations, it should be noted that all the 3 classifier had a extremely low performance on *SeeStar* (f1 = 0.15, 0.15 and 0.17 respectively).

If we compare the performance of the 4 expressions analysed in the "per-expression" experiment we can observe that all the "general" classifiers had a better performance over *BlowWhistle* and the Linear-SVM-GE also performed better on *MakeScene*. Nevertheless we should emphasize that the "general" classifier's evaluation is closer to what we would expect in a real data distribution than the evaluation presented on the "per-expression" section. This does not invalidate the evaluation of the latter but when we have access to a real data distribution it should also be taken into account when performing a ML evaluation.

In general, the results look promising. It is interesting to see how the classifiers trained on a set of mixed expressions ("general" classifiers) had a performance close to the "per-expression" classifiers, even though the latter were trained and tested on "artificial" training and test sets that do not reflect the real data distributions. We believe that these results indicate that the distributed representations generated by Sent2Vec are indeed clustering together sentences within the same class (idiomatic or literal) in feature space.

6 Conclusions and Future Work

In this paper we have investigated the use of distributed compositional semantics in literal and idiomatic language classification, more specifically using Skip-Thought Vectors (Sent2Vec). We followed the intuition that the distributed representations generated by Sent2Vec also include information regarding the context where the potential idiomatic expression is inserted and therefore is sufficient for distinguishing between idiomatic and literal language use.

We tested this approach with different Machine Learning (ML) algorithms (K-Nearest Neighbours and Support Vector Machines) and compared our work against a topic model representation that include the full paragraph or the surrounding paragraphs where the potential idiom is inserted. We have shown that using the Sent2Vec representations our classifiers achieve better results in 3 out of 4 expressions tested. We have also shown that our models generally present better precision and/or recall than the baselines.

We also investigated the capability of Sent2Vec clustering representations of sentences within the same class in feature space. We followed the intuition presented by previous experiments with distributed representations that words with similar meaning are clustered together in feature space and experimented with a "general" classifier that is trained on a dataset of mixed expressions. We have shown that the "general" classifier is feasible but the traditional "per-expression" does achieve better results in some cases.

In future work we plan to investigate the use of Sent2Vec to encode larger samples of text - not only the sentence containing idioms. We also plan to further analyse the errors made by our "general" model and investigate the "general" approach on the skewed part of the VNC-tokens dataset. We also plan to investigate an end-to-end approach based on deep learning-based representations to classify literal and idiomatic language use.

In addition, we also plan to compare our work to the method of Sporleder et al. (2010) as well apply our work on the IDX Corpus (Sporleder et al., 2010) and to other languages. The focus of these future experiments will be to test how our approach which is relatively less dependent on NLP resources compares with these other methods for idiom token classification.

Adaptive Joint Learning of Compositional and Non-Compositional Phrase Embeddings

Kazuma Hashimoto and Yoshimasa Tsuruoka
The University of Tokyo, 3-7-1 Hongo, Bunkyo-ku, Tokyo, Japan
{hassy,tsuruoka}@logos.t.u-tokyo.ac.jp

Abstract

We present a novel method for jointly learning compositional and non-compositional phrase embeddings by adaptively weighting both types of embeddings using a compositionality scoring function. The scoring function is used to quantify the level of compositionality of each phrase, and the parameters of the function are jointly optimized with the objective for learning phrase embeddings. In experiments, we apply the adaptive joint learning method to the task of learning embeddings of transitive verb phrases, and show that the compositionality scores have strong correlation with human ratings for verb-object compositionality, substantially outperforming the previous state of the art. Moreover, our embeddings improve upon the previous best model on a transitive verb disambiguation task. We also show that a simple ensemble technique further improves the results for both tasks.

1 Introduction

Representing words and phrases in a vector space has proven effective in a variety of language processing tasks (Pham et al., 2015; Sutskever et al., 2014). In most of the previous work, phrase embeddings are computed from word embeddings by using various kinds of composition functions. Such composed embeddings are called *compositional embeddings*. An alternative way of computing phrase embeddings is to treat phrases as single units and assigning a unique embedding to each candidate phrase (Mikolov et al., 2013; Yazdani et al., 2015). Such embeddings are called *non-compositional embeddings*.

Relying solely on non-compositional embeddings has the obvious problem of data sparsity (i.e. rare or unknown phrase problems). At the same time, however, using compositional embeddings is not always the best option since some phrases are inherently non-compositional. For example, the phrase "bear fruits" means "to yield results"[1] but it is hard to infer its meaning by composing the meanings of "bear" and "fruit". Treating all phrases as compositional also has a negative effect in learning the composition function because the words in those idiomatic phrases are not just uninformative but can serve as noisy samples in the training. These problems have motivated us to adaptively combine both types of embeddings.

Most of the existing methods for learning phrase embeddings can be divided into two approaches. One approach is to learn compositional embeddings by regarding all phrases as compositional (Pham et al., 2015; Socher et al., 2012). The other approach is to learn both types of embeddings separately and use the better ones (Kartsaklis et al., 2014; Muraoka et al., 2014). Kartsaklis et al. (2014) show that non-compositional embeddings are better suited for a phrase similarity task, whereas Muraoka et al. (2014) report the opposite results on other tasks. These results suggest that we should not stick to either of the two types of embeddings unconditionally and could learn better phrase embeddings by considering the compositionality levels of the individual phrases in a more flexible fashion.

In this paper, we propose a method that jointly learns compositional and non-compositional embeddings by adaptively weighting both types of phrase embeddings using a compositionality scoring function. The scoring function is used to quantify the level of compositionality of each phrase

Berlin, Germany, August 7-12, 2016.

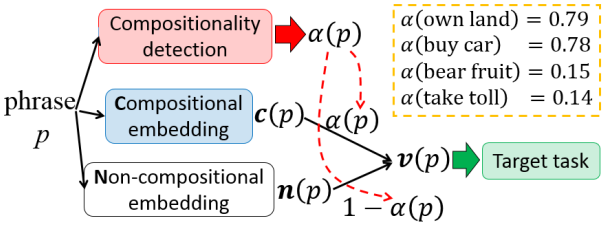

Figure 1: The overview of our method and examples of the compositionality scores. Given a phrase p, our method first computes the compositionality score $\alpha(p)$ (Eq. (3)), and then computes the phrase embedding $\boldsymbol{v}(p)$ using the compositional and non-compositional embeddings, $\boldsymbol{c}(p)$ and $\boldsymbol{n}(p)$, respectively (Eq. (2)).

and learned in conjunction with the target task for learning phrase embeddings. In experiments, we apply our method to the task of learning transitive verb phrase embeddings and demonstrate that it allows us to achieve state-of-the-art performance on standard datasets for compositionality detection and verb disambiguation.

2 Method

In this section, we describe our approach in the most general form, without specifying the function to compute the compositional embeddings or the target task for optimizing the embeddings.

Figure 1 shows the overview of our proposed method. At each iteration of the training (i.e. gradient calculation) of a certain target task (e.g. language modeling or sentiment analysis), our method first computes a compositionality score for each phrase. Then the score is used to weight the compositional and non-compositional embeddings of the phrase in order to compute the expected embedding of the phrase which is to be used in the target task. Some examples of the compositionality scores are also shown in the figure.

2.1 Compositional Phrase Embeddings

The compositional embedding $\boldsymbol{c}(p) \in \mathbb{R}^{d \times 1}$ of a phrase $p = (w_1, \cdots, w_L)$ is formulated as

$$\boldsymbol{c}(p) = f(\boldsymbol{v}(w_1), \cdots, \boldsymbol{v}(w_L)), \qquad (1)$$

where d is the dimensionality, L is the phrase length, $\boldsymbol{v}(\cdot) \in \mathbb{R}^{d \times 1}$ is a word embedding, and $f(\cdot)$ is a composition function. The function can be simple ones such as element-wise addition or multiplication (Mitchell and Lapata, 2008). More complex ones such as recurrent neural networks (Sutskever et al., 2014) are also commonly used. The word embeddings and the composition function are jointly learned on a certain target task. Since compositional embeddings are built on word-level (i.e. unigram) information, they are less prone to the data sparseness problem.

2.2 Non-Compositional Phrase Embeddings

In contrast to the compositional embedding, the non-compositional embedding of a phrase $\boldsymbol{n}(p) \in \mathbb{R}^{d \times 1}$ is independently parameterized, i.e., the phrase p is treated just like a single word. Mikolov et al. (2013) show that non-compositional embeddings are preferable when dealing with idiomatic phrases. Some recent studies (Kartsaklis et al., 2014; Muraoka et al., 2014) have discussed the (dis)advantages of using compositional or non-compositional embeddings. However, in most cases, a phrase is neither completely compositional nor completely non-compositional. To the best of our knowledge, there is no method that allows us to jointly learn both types of phrase embeddings by incorporating the levels of compositionality of the phrases as real-valued scores.

2.3 Adaptive Joint Learning

To simultaneously consider both compositional and non-compositional aspects of each phrase, we compute a phrase embedding $\boldsymbol{v}(p)$ by adaptively weighting $\boldsymbol{c}(p)$ and $\boldsymbol{n}(p)$ as follows:

$$\boldsymbol{v}(p) = \alpha(p)\boldsymbol{c}(p) + (1 - \alpha(p))\boldsymbol{n}(p), \qquad (2)$$

where $\alpha(\cdot)$ is a scoring function that quantifies the compositionality levels, and outputs a real value ranging from 0 to 1. What we expect from the scoring function is that large scores indicate high levels of compositionality. In other words, when $\alpha(p)$ is close to 1, the compositional embedding is mainly considered, and vice versa. For example, we expect $\alpha(\text{buy car})$ to be large and $\alpha(\text{bear fruit})$ to be small as shown in Figure 1.

We parameterize the scoring function $\alpha(p)$ as logistic regression:

$$\alpha(p) = \sigma(\boldsymbol{W} \cdot \boldsymbol{\phi}(p)), \qquad (3)$$

where $\boldsymbol{\phi}(p) \in \mathbb{R}^{N \times 1}$ is a feature vector of the phrase p, $\boldsymbol{W} \in \mathbb{R}^{N \times 1}$ is a weight vector, N is the number of features, and $\sigma(\cdot)$ is the logistic function. The weight vector $\boldsymbol{W}$ is jointly optimized in conjunction with the objective J for the target task of learning phrase embeddings $\boldsymbol{v}(p)$.

Updating the model parameters Given the partial derivative $\boldsymbol{\delta}_p = \frac{\partial J}{\partial \boldsymbol{v}(p)} \in \mathbb{R}^{d \times 1}$ for the target task, we can compute the partial derivative for updating $\boldsymbol{W}$ as follows:

$$\delta_\alpha = \alpha(p)(1-\alpha(p))\{\boldsymbol{\delta}_p \cdot (\boldsymbol{c}(p) - \boldsymbol{n}(p))\} \quad (4)$$

$$\frac{\partial J}{\partial \boldsymbol{W}} = \delta_\alpha \boldsymbol{\phi}(p). \quad (5)$$

If $\boldsymbol{\phi}(p)$ is not constructed by static features but is computed by a feature learning model such as neural networks, we can propagate the error term δ_α into the feature learning model by the following equation:

$$\frac{\partial J}{\partial \boldsymbol{\phi}(p)} = \delta_\alpha \boldsymbol{W}. \quad (6)$$

When we use only static features, as in this work, we can simply compute the partial derivatives of J with respect to $\boldsymbol{c}(p)$ and $\boldsymbol{n}(p)$ as follows:

$$\frac{\partial J}{\partial \boldsymbol{c}(p)} = \alpha(p)\boldsymbol{\delta}_p \quad (7)$$

$$\frac{\partial J}{\partial \boldsymbol{n}(p)} = (1-\alpha(p))\boldsymbol{\delta}_p. \quad (8)$$

As mentioned above, Eq. (7) and (8) show that the non-compositional embeddings are mainly updated when $\alpha(p)$ is close to 0, and vice versa. The partial derivative $\frac{\partial J}{\partial \boldsymbol{c}(p)}$ is used to update the model parameters in the composition function via the backpropagation algorithm. Any differentiable composition functions can be used in our method.

Expected behavior of our method The training of our method depends on the target task; that is, the model parameters are updated so as to minimize the cost function as described above. More concretely, $\alpha(p)$ for each phrase p is adaptively adjusted so that the corresponding parameter updates contribute to minimizing the cost function. As a result, different phrases will have different $\alpha(p)$ values depending on their compositionality. If the size of the training data were almost infinitely large, $\alpha(p)$ for all phrases would become nearly zero, and the non-compositional embeddings $\boldsymbol{n}(p)$ are dominantly used (since that would allow the model to better fit the data). In reality, however, the amount of the training data is limited, and thus the compositional embeddings $\boldsymbol{c}(p)$ are effectively used to overcome the data sparseness problem.

3 Learning Verb Phrase Embeddings

This section describes a particular instantiation of our approach presented in the previous section, focusing on the task of learning the embeddings of transitive verb phrases.

3.1 Word and Phrase Prediction in Predicate-Argument Relations

Acquisition of selectional preference using embeddings has been widely studied, where word and/or phrase embeddings are learned based on syntactic links (Bansal et al., 2014; Hashimoto and Tsuruoka, 2015; Levy and Goldberg, 2014; Van de Cruys, 2014). As with language modeling, these methods perform word (or phrase) prediction using (syntactic) contexts.

In this work, we focus on verb-object relationships and employ a phrase embedding learning method presented in Hashimoto and Tsuruoka (2015). The task is a plausibility judgment task for predicate-argument tuples. They extracted Subject-Verb-Object (*SVO*) and SVO-Preposition-Noun (*SVOPN*) tuples using a probabilistic HPSG parser, *Enju* (Miyao and Tsujii, 2008), from the training corpora. Transitive verbs and prepositions are extracted as predicates with two arguments. For example, the extracted tuples include (S, V, O) = ("importer", "make", "payment") and (SVO, P, N) = ("importer make payment", "in", "currency"). The task is to discriminate between observed and unobserved tuples, such as the (S, V, O) tuple mentioned above and (S, V', O) = ("importer", "*eat*", "payment"), which is generated by replacing "make" with "eat". The (S, V', O) tuple is unlikely to be observed.

For each tuple (p, a_1, a_2) observed in the training data, a cost function is defined as follows:

$$\begin{aligned} -\log\sigma(s(p,a_1,a_2)) &- \log\sigma(-s(p',a_1,a_2)) \\ &- \log\sigma(-s(p,a_1',a_2)) \\ &- \log\sigma(-s(p,a_1,a_2')), \end{aligned} \quad (9)$$

where $s(\cdot)$ is a plausibility scoring function, and p, a_1 and a_2 are a predicate and its arguments, respectively. Each of the three unobserved tuples (p', a_1, a_2), (p, a_1', a_2), and (p, a_1, a_2') is generated by replacing one of the entries with a random sample.

In their method, each predicate p is represented with a matrix $\boldsymbol{M}(p) \in \mathbb{R}^{d \times d}$ and each argument a with an embedding $\boldsymbol{v}(a) \in \mathbb{R}^{d \times 1}$. The matrices and embeddings are learned by minimizing the cost function using *AdaGrad* (Duchi et al., 2011). The scoring function is parameterized as

$$s(p, a_1, a_2) = \boldsymbol{v}(a_1) \cdot (\boldsymbol{M}(p)\boldsymbol{v}(a_2)), \quad (10)$$

and the VO and SVO embeddings are computed as

$$\boldsymbol{v}(VO) = \boldsymbol{M}(V)\boldsymbol{v}(O) \quad (11)$$

$$\boldsymbol{v}(SVO) = \boldsymbol{v}(S) \odot \boldsymbol{v}(VO), \quad (12)$$

as proposed by Kartsaklis et al. (2012). The operator $\odot$ denotes element-wise multiplication. In summary, the scores are computed as

$$s(V, S, O) = \boldsymbol{v}(S) \cdot \boldsymbol{v}(VO) \quad (13)$$

$$s(P, SVO, N) = \boldsymbol{v}(SVO) \cdot (\boldsymbol{M}(P)\boldsymbol{v}(N)). \quad (14)$$

With this method, the word and composed phrase embeddings are jointly learned based on co-occurrence statistics of predicate-argument structures. Using the learned embeddings, they achieved state-of-the-art accuracy on a transitive verb disambiguation task (Grefenstette and Sadrzadeh, 2011).

3.2 Applying the Adaptive Joint Learning

In this section, we apply our adaptive joint learning method to the task described in Section 3.1. We here redefine the computation of $\boldsymbol{v}(VO)$ by first replacing $\boldsymbol{v}(VO)$ in Eq. (11) with $\boldsymbol{c}(VO)$ as,

$$\boldsymbol{c}(VO) = \boldsymbol{M}(V)\boldsymbol{v}(O), \quad (15)$$

and then assigning VO to p in Eq. (2) and (3):

$$\boldsymbol{v}(VO) = \alpha(VO)\boldsymbol{c}(VO) + (1 - \alpha(VO))\boldsymbol{n}(VO), \quad (16)$$

$$\alpha(VO) = \sigma(\boldsymbol{W} \cdot \boldsymbol{\phi}(VO)). \quad (17)$$

The $\boldsymbol{v}(VO)$ in Eq. (16) is used in Eq. (12) and (13). We assume that the candidates of the phrases are given in advance. For the phrases not included in the candidates, we set $\boldsymbol{v}(VO) = \boldsymbol{c}(VO)$. This is analogous to the way a human guesses the meaning of an idiomatic phrase she does not know. We should note that $\boldsymbol{\phi}(VO)$ can be computed for phrases not included in the candidates, using partial features among the features described below. If any features do not fire, $\boldsymbol{\phi}(VO)$ becomes 0.5 according to the logistic function.

For the feature vector $\boldsymbol{\phi}(VO)$, we use the following simple binary and real-valued features:

- indices of V, O, and VO
- frequency and Pointwise Mutual Information (PMI) values of VO.

More concretely, the first set of the features (indices of V, O, and VO) is the concatenation of traditional one-hot vectors. The second set of features, frequency and PMI (Church and Hanks, 1990) features, have proven effective in detecting the compositionality of transitive verbs in McCarthy et al. (2007) and Venkatapathy and Joshi (2005). Given the training corpus, the frequency feature for a VO pair is computed as

$$freq(VO) = \log(count(VO)), \quad (18)$$

where $count(VO)$ counts how many times the VO pair appears in the training corpus, and the PMI feature is computed as

$$\mathrm{PMI}(VO) = \log \frac{count(VO)count(*)}{count(V)count(O)}, \quad (19)$$

where $count(V)$, $count(O)$, and $count(*)$ are the counts of the verb V, the object O, and all VO pairs in the training corpus, respectively. We normalize the frequency and PMI features so that their maximum absolute value becomes 1.

4 Experimental Settings

4.1 Training Data

As the training data, we used two datasets, one small and one large: the British National Corpus (BNC) (Leech, 1992) and the English Wikipedia. More concretely, we used the publicly available data[2] preprocessed by Hashimoto and Tsuruoka (2015). The BNC data consists of 1.38 million SVO tuples and 0.93 million SVOPN tuples. The Wikipedia data consists of 23.6 million SVO tuples and 17.3 million SVOPN tuples. Following the provided code[3], we used exactly the same train/development/test split (0.8/0.1/0.1) for training the overall model. As the third training data, we also used the concatenation of the two data, which is hereafter referred to as *BNC-Wikipedia*.

We applied our adaptive joint learning method to verb-object phrases observed more than K times in each corpus. K was set to 10 for the BNC data and 100 for the Wikipedia and BNC-Wikipedia data. Consequently, the non-compositional embeddings were assigned to 17,817, 28,933, and 30,682 verb-object phrase types in the BNC, Wikipedia, and BNC-Wikipedia data, respectively.

[2] http://www.logos.t.u-tokyo.ac.jp/~hassy/publications/cvsc2015/

[3] https://github.com/hassyGo/SVOembedding

4.2 Training Details

The model parameters consist of d-dimensional word embeddings for nouns, non-compositional phrase embeddings, $d \times d$-dimensional matrices for verbs and prepositions, and a weight vector $\boldsymbol{W}$ for $\alpha(VO)$. All the model parameters are jointly optimized. We initialized the embeddings and matrices with zero-mean gaussian random values with a variance of $\frac{1}{d}$ and $\frac{1}{d^2}$, respectively, and $\boldsymbol{W}$ with zeros. Initializing $\boldsymbol{W}$ with zeros forces the initial value of each $\alpha(VO)$ to be 0.5 since we use the logistic function to compute $\alpha(VO)$.

The optimization was performed via mini-batch AdaGrad (Duchi et al., 2011). We fixed d to 25 and the mini-batch size to 100. We set candidate values for the learning rate ε to $\{0.01, 0.02, 0.03, 0.04, 0.05\}$. For the weight vector $\boldsymbol{W}$, we employed L2-norm regularization and set the coefficient λ to $\{10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}, 0\}$. For selecting the hyperparameters, each training process was stopped when the evaluation score on the development split decreased. Then the best performing hyperparameters were selected for each training dataset. Consequently, ε was set to 0.05 for all training datasets, and λ was set to 10^{-6}, 10^{-3}, and 10^{-5} for the BNC, Wikipedia, and BNC-Wikipedia data, respectively. Once the training is finished, we can use the learned embeddings and the scoring function in downstream target tasks.

5 Evaluation on the Compositionality Detection Function

5.1 Evaluation Settings

Datasets First, we evaluated the learned compositionality detection function on two datasets, **VJ'05**[4] and **MC'07**[5], provided by Venkatapathy and Joshi (2005) and McCarthy et al. (2007), respectively. VJ'05 consists of 765 verb-object pairs with human ratings for the compositionality. MC'07 is a subset of VJ'05 and consists of 638 verb-object pairs. For example, the rating of "buy car" is 6, which is the highest score, indicating the phrase is highly compositional. The rating of "bear fruit " is 1, which is the lowest score, indicating the phrase is highly non-compositional.

Human agreement	0.702	0.716

Table 1: Compositionality detection task.

Evaluation metric The evaluation was performed by calculating Spearman's rank correlation scores[6] between the averaged human ratings and the learned compositionality scores $\alpha(VO)$.

Ensemble technique We also produced the result by employing an *ensemble* technique. More concretely, we used the averaged compositionality scores from the results of the BNC and Wikipedia data for the ensemble result.

5.2 Results and Discussion

5.2.1 Result Overview

Table 1 shows our results and the state of the art. Our method outperforms the previous state of the art in all settings. The result denoted as *Ensemble* is the one that employs the ensemble technique, and achieves the strongest correlation with the human-annotated datasets. Even without the ensemble technique, our method performs better than all of the previous methods.

Kiela and Clark (2013) used window-based co-occurrence vectors and improved their score using WordNet hypernyms. By contrast, our method does not rely on such external resources, and only needs parsed corpora. We should note that Kiela and Clark (2013) reported that their score did not improve when using parsed corpora. Our method also outperforms DSPROTO+, which used a small amount of the labeled data, while our method is fully unsupervised.

We calculated confidence intervals ($P < 0.05$) using bootstrap resampling (Noreen, 1989). For example, for the results using the BNC-Wikipedia data, the intervals on MC'07 and VJ'05 are (0.455, 0.574) and (0.475, 0.579), respectively. These results show that our method significantly outperforms the previous state-of-the-art results.

[6] We used the Scipy 0.12.0 implementation in Python.

Phrase		Gold standard	(a) BNC	(b) Wikipedia	BNC-Wikipedia	Ensemble ((a)+(b))×0.5
(A)	buy car	6	0.78	0.71	0.80	0.74
	own land	6	0.79	0.73	0.76	0.76
	take toll	1.5	0.14	0.11	0.06	0.13
	shed light	1	0.21	0.07	0.07	0.14
	bear fruit	1	0.15	0.19	0.17	0.17
(B)	make noise	6	0.37	0.33	0.30	0.35
	have reason	5	0.26	0.39	0.33	0.33
(C)	smoke cigarette	6	0.56	0.90	0.78	0.73
	catch eye	1	0.48	0.14	0.17	0.31

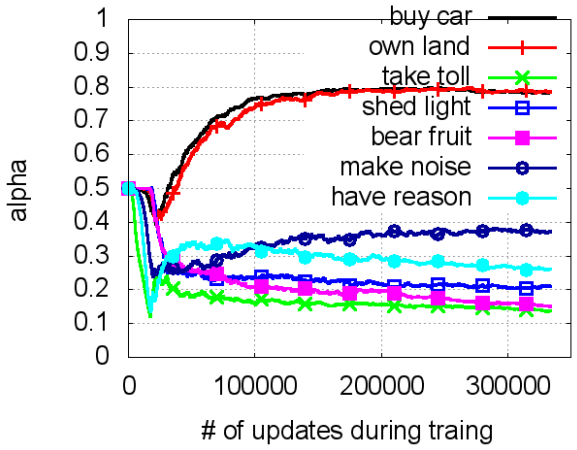

Figure 2: Trends of $\alpha(VO)$ during the training on the BNC data.

Highest average scores		Lowest average scores	
approve	0.83	bear	0.37
reject	0.72	play	0.38
discuss	0.71	have	0.38
visit	0.70	make	0.39
want	0.70	break	0.40
describe	0.70	take	0.40
involve	0.69	raise	0.41
own	0.68	reach	0.41
attend	0.68	gain	0.42
reflect	0.67	draw	0.42

Table 3: The 10 highest and lowest average compositionality scores with the corresponding verbs on the BNC data.

5.2.2 Analysis of Compositionality Scores

Figure 2 shows how $\alpha(VO)$ changes for the seven phrases during the training on the BNC data. As shown in the figure, starting from 0.5, $\alpha(VO)$ for each phrase converges to its corresponding value. The differences in the trends indicate that our method can adaptively learn compositionality levels for the phrases. Table 2 shows the learned compositionality scores for the three groups of the examples along with the gold-standard scores given by the annotators. The group (A) is considered to be consistent with the gold-standard scores, the group (B) is not, and the group (C) shows examples for which the difference between the compositionality scores of our results is large.

Characteristics of light verbs The verbs "take", "make", and "have" are known as *light verbs* [7], and the scoring function tends to assign low scores to light verbs. In other words, our method can recognize that the light verbs are frequently used to form idiomatic (i.e. non-compositional) phrases. To verify the assumption, we calculated the average compositionality score for each verb by averaging the compositionality scores paired with its candidate objects. Here we used 135 verbs which take more than 30 types of objects in the BNC data. Table 3 shows the 10 highest and lowest average scores with the corresponding verbs. We see that relatively low scores are assigned to the light verbs as well as other verbs which often form idiomatic phrases. As shown in the group (B) in Table 2, however, light verb phrases are not always non-compositional. Despite this, the learned function assigns low scores to compositional phrases formed by the light verbs. These results suggest that using a more flexible scoring function may further strengthen our method.

Context dependence Both our method and the two datasets, VJ'05 and MC'07, assume that the compositionality score can be computed for each phrase with no contextual information. However, in general, the compositionality level of a phrase depends on its contextual information. For example, the meaning of the idiomatic phrase "bear

[7] In Section 5.2.2 in Newton (2006), the term *light verb* is used to refer to verbs which can be used in combination with some other element where their contribution to the meaning of the whole construction is reduced in some way.

fruit" can be compositionaly interpreted as "to yield fruit" for a plant or tree. We manually inspected the BNC data to check whether the phrase "bear fruit" is used as the compositional meaning or the idiomatic meaning ("to yield results"). As a result, we have found that most of the usage was its idiomatic meaning. In the model training, our method is affected by the majority usage and fits the evaluation datasets where the phrase "bear fruit" is regarded as highly non-compositional. Incorporating contextual information into the compositionality scoring function is a promising direction of future work.

5.2.3 Effects of Ensemble

We used the two different corpora for constructing the training data, and our method achieves the state-of-the-art results in all settings. To inspect the results on VJ'05, we calculated the correlation score between the outputs from our results of the BNC and Wikipedia data. The correlation score is 0.674 and that is, the two different corpora lead to reasonably consistent results, which indicates the robustness of our method. However, the correlation score is still much lower than perfect correlation; in other words, there are disagreements between the outputs learned with the corpora. The group (C) in Table 2 shows such two examples. In these cases, the ensemble technique is helpful in improving the results as shown in the examples.

Another interesting observation in our results is that the result of the ensemble technique outperforms that of the BNC-Wikipedia data as shown in Table 1. This shows that separately using the training corpora of different nature and then performing the ensemble technique can yield better results. By contrast, many of the previous studies on embedding-based methods combine different corpora into a single dataset, or use multiple corpora just separately and compare them (Hashimoto and Tsuruoka, 2015; Muraoka et al., 2014; Pennington et al., 2014). It would be worth investigating whether the results in the previous work can be improved by ensemble techniques.

6 Evaluation on the Phrase Embeddings

6.1 Evaluation Settings

Dataset Next, we evaluated the learned embeddings on the transitive verb disambiguation dataset **GS'11**[8] provided by Grefenstette and Sadrzadeh (2011). GS'11 consists of 200 pairs of transitive verbs and each verb pair takes the same subject and object. For example, the transitive verb "run" is known as a polysemous word and this task requires one to identify the meanings of "run" and "operate" as similar to each other when taking "people" as their subject and "company" as their object. In the same setting, however, the meanings of "run" and "move" are not similar to each other. Each pair has multiple human ratings indicating how similar the phrases of the pair are.

Evaluation metric The evaluation was performed by calculating Spearman's rank correlation scores between the human ratings and the cosine similarity scores of $\boldsymbol{v}(SVO)$ in Eq. (12). Following the previous studies, we used the gold-standard ratings in two ways: averaging the human ratings for each SVO tuple (GS'11a) and treating each human rating separately (GS'11b).

Ensemble technique We used the same ensemble technique described in Section 5.1. In this task we produced two ensemble results: *Ensemble A* and *Ensemble B*. The former used the averaged cosine similarity from the results of the BNC and Wikipedia data, and the latter further incorporated the result of the BNC-Wikipedia data.

Baselines We compared our adaptive joint learning method with two baseline methods. One is the method in Hashimoto and Tsuruoka (2015) and it is equivalent to fixing $\alpha(VO)$ to 1 in our method. The other is fixing $\alpha(VO)$ to 0.5 in our method, which serves as a baseline to evaluate how effective the proposed adaptive weighting method is.

6.2 Results and Discussion

6.2.1 Result Overview

Table 4 shows our results and the state of the art, and our method outperforms almost all of the previous methods in both datasets. Again, the ensemble technique further improves the results, and overall, Ensemble B yields the best results.

The scores in Hashimoto and Tsuruoka (2015), the baseline results with $\alpha(VO) = 1$ in our method, have been the best to date. As shown in Table 4, our method outperforms the baseline results with $\alpha(VO) = 0.5$ as well as those

[8] http://www.cs.ox.ac.uk/activities/compdistmeaning/GS2011data.txt

	Proposed method		$\alpha(VO) = 1$	$\alpha(VO) = 0.5$
take toll	$\alpha(\text{take toll}) = 0.11$	put strain place strain cause strain have affect exacerbate injury	deplete division necessitate monitoring deplete pool create pollution deplete field	put strain cause lack befall army exacerbate weakness cause strain

Table 5: Examples of the closest neighbors in the learned embedding space. All of the results were obtained by using the Wikipedia data, and the values of $\alpha(VO)$ are the same as those in Table 2.

Method	GS'11a	GS'11b
Proposed method (Wikipedia)	0.598	0.461
Proposed method (BNC)	0.595	0.463
Proposed method (BNC-Wikipedia)	0.623	0.483
Proposed method (Ensemble A)	0.661	0.511
Proposed method (Ensemble B)	0.680	0.524
$\alpha(VO) = 0.5$ (Wikipedia)	0.491	0.386
$\alpha(VO) = 0.5$ (BNC)	0.599	0.462
$\alpha(VO) = 0.5$ (BNC-Wikipedia)	0.610	0.477
$\alpha(VO) = 0.5$ (Ensemble A)	0.612	0.474
$\alpha(VO) = 0.5$ (Ensemble B)	0.638	0.495
$\alpha(VO) = 1$ (Wikipedia)	0.576	n/a
$\alpha(VO) = 1$ (BNC)	0.574	n/a
Milajevs et al. (2014)	0.456	n/a
Polajnar et al. (2014)	n/a	0.370
Hashimoto et al. (2014)	0.420	0.340
Polajnar et al. (2015)	n/a	0.330
Grefenstette and Sadrzadeh (2011)	n/a	0.210
Human agreement	0.750	0.620

Table 4: Transitive verb disambiguation task. The results for $\alpha(VO) = 1$ are reported in Hashimoto and Tsuruoka (2015).

with $\alpha(VO) = 1$. We see that our method improves the baseline scores by adaptively combining compositional and non-compositional embeddings. Along with the results in Table 1, these results show that our method allows us to improve the composition function by jointly learning non-compositional embeddings and the scoring function for compositionality detection.

6.2.2 Analysis of the Learned Embeddings

We inspected the effects of adaptively weighting the compositional and non-compositional embeddings. Table 5 shows the five closest neighbor phrases in terms of the cosine similarity for the three idiomatic phrases "take toll", "catch eye", and "bear fruit" as well as the two non-idiomatic phrases "make noise" and "buy car". The examples trained with the Wikipedia data are shown for our method and the two baselines, i.e., $\alpha(VO) = 1$ and $\alpha(VO) = 0.5$. As shown in Table 2, the compositionality levels of the first three phrases are low and their non-compositional embeddings are dominantly used to represent their meaning.

One observation with $\alpha(VO) = 1$ is that head words (i.e. verbs) are emphasized in the shown examples except "take toll" and "make noise". As with other embedding-based methods, the compositional embeddings are highly affected by their component words. As a result, the phrases consisting of the same verb and the similar objects are often listed as the closest neighbors. By contrast, our method flexibly allows us to adaptively omit the information about the component words. Therefore, our method puts more weight on capturing the idiomatic aspects of the example phrases by

adaptively using the non-compositional embeddings.

The results of $\alpha(VO) = 0.5$ are similar to those with our proposed method, but we can see some differences. For example, the phrase list for "make noise" of our proposed method captures offensive meanings, whereas that of $\alpha(VO) = 0.5$ is somewhat ambiguous. As another example, the phrase lists for "buy car" show that our method better captures the semantic similarity between the objects than $\alpha(VO) = 0.5$. This is achieved by adaptively assigning a relatively large compositionality score (0.71) to the phrase to use the information about the object "car".

We should note that "make noise" is highly compositional but our method outputs $\alpha(\text{make noise}) = 0.33$, and the phrase list of $\alpha(VO) = 1$ is the most appropriate in this case. Improving the compositionality detection function should thus further improve the learned embeddings.

7 Related Work

Learning embeddings of words and phrases has been widely studied, and the phrase embeddings have proven effective in many language processing tasks, such as machine translation (Cho et al., 2014; Sutskever et al., 2014), sentiment analysis and semantic textual similarity (Tai et al., 2015). Most of the phrase embeddings are constructed by word-level information via various kinds of composition functions like long short-term memory (Hochreiter and Schmidhuber, 1997) recurrent neural networks. Such composition functions should be powerful enough to efficiently encode information about all the words into the phrase embeddings. By simultaneously considering the compositionality of the phrases, our method would be helpful in saving the composition models from having to be powerful enough to perfectly encode the non-compositional phrases. As a first step towards this purpose, in this paper we have shown the effectiveness of our method on the task of learning verb phrase embeddings.

Many studies have focused on detecting the compositionality of a variety of phrases (Lin, 1999), including the ones on verb phrases (Diab and Bhutada, 2009; McCarthy et al., 2003) and compound nouns (Farahmand et al., 2015; Reddy et al., 2011). Compared to statistical feature-based methods (McCarthy et al., 2007; Venkatapathy and Joshi, 2005), recent methods use word and phrase embeddings (Kiela and Clark, 2013; Yazdani et al., 2015). The embedding-based methods assume that word embeddings are given in advance and as a post-processing step, learn or simply employ composition functions to compute phrase embeddings. In other words, there is no distinction between compositional and non-compositional phrases. Yazdani et al. (2015) further proposed to incorporate latent annotations (binary labels) for the compositionality of the phrases. However, binary judgments cannot consider numerical scores of the compositionality. By contrast, our method adaptively weights the compositional and non-compositional embeddings using the compositionality scoring function.

8 Conclusion and Future Work

We have presented a method for adaptively learning compositional and non-compositional phrase embeddings by jointly detecting compositionality levels of phrases. Our method achieves the state of the art on a compositionality detection task of verb-object pairs, and also improves upon the previous state-of-the-art method on a transitive verb disambiguation task. In future work, we will apply our method to other kinds of phrases and tasks.

Abstract

Metaphor is a common linguistic tool in communication, making its detection in discourse a crucial task for natural language understanding. One popular approach to this challenge is to capture semantic incohesion between a metaphor and the dominant topic of the surrounding text. While these methods are effective, they tend to overclassify target words as metaphorical when they deviate in meaning from its context. We present a new approach that (1) distinguishes literal and non-literal use of target words by examining sentence-level topic transitions and (2) captures the motivation of speakers to express emotions and abstract concepts metaphorically. Experiments on an online breast cancer discussion forum dataset demonstrate a significant improvement in metaphor detection over the state-of-the-art. These experimental results also reveal a tendency toward metaphor usage in personal topics and certain emotional contexts.

1 Introduction

Figurative language is commonly used in human communication ranging from literature to everyday speech. One of the most common forms of non-literal language is *metaphor*, in which two dissimilar concepts are compared. In the utterance, "Time is money" (Lakoff and Johnson, 1980), for example, the concept of "time" is compared to "money" to emphasize that time is valuable. Bringing in information from another domain allows more effective ways of expressing thoughts, feelings, and ideas than only using literal language.

Previous approaches to modeling metaphor have used either the semantic and syntactic information in just the sentence that contains a metaphor (Turney et al., 2011; Tsvetkov et al., 2014), or the context beyond a single sentence (Broadwell et al., 2013; Strzalkowski et al., 2013; Schulder and Hovy, 2014; Klebanov et al., 2015; Jang et al., 2015) to detect topical discrepancy between a candidate metaphor and the dominant theme (See Section 2 for more detailed literature review).

Although previous approaches were effective at capturing some aspects of the governing context of a metaphor, the space of how to best use the contextual information is still wide open. Previous context-based models tend to overclassify literal words as metaphorical if they find semantic contrast with the governing context. These cases manifested in the work by Schulder and Hovy (2014) and Jang et al. (2015) as high recall but low precision for metaphorical instances.

We present a new approach that uses lexical and topical context to resolve the problem of low precision on metaphor detection. To better capture the relevant context surrounding a metaphor, we approach the problem in two directions. First, we hypothesize that topic transition patterns between sentences containing metaphors and their contexts are different from that of literal sentences. To this end, we incorporate several indicators of sentence-level topic transitions as features, such as topic similarity between a sentence and its neighboring sentences, measured by Sentence LDA. Second, we observe that metaphor is often used to express speakers' emotional experiences; we therefore model a speaker's motivation in using metaphor by detecting emotion and cognition words in metaphorical and literal sentences and their contexts.

To demonstrate the efficacy of our approach, we

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 216–225,
Berlin, Germany, August 7-12, 2016.

evaluate our system on the metaphor detection task presented by Jang et al. (2015) using a breast cancer discussion forum dataset. This dataset is distinct in that it features metaphors occurring in conversational text, unlike news corpora or other formal texts typical in computational linguistics.

Our contributions are three-fold: (1) We extend the previous approaches for contextually detecting metaphor by exploring topic transitions between a metaphor and its context rather than only detecting lexical discrepancies. In addition, (2) we propose to capture emotional and cognitive content to better uncover speakers' motivation for using metaphors. Lastly, (3) through our empirical evaluation, we find that metaphor occurs more frequently around personal topics.

2 Relation to Prior Work

Research in automatic metaphor detection has spanned from detecting metaphor in limited sets of syntactic constructions to studying the use of metaphor in discourse, with approaches ranging from rule-based methods using lexical resources to statistical machine learning models. Here, we focus in particular on approaches that use context wider than a sentence for metaphor detection. For a more thorough review of metaphor processing systems, refer to Shutova (2015).

The main idea behind using context in metaphor detection is that metaphorically used words tend to violate lexical cohesion in text. Different methods, however, approach the problem of detecting semantic outliers in different ways.

Li and Sporleder (2009; 2010) identify metaphorical idioms using the idea that non-literal expressions break lexical cohesion of a text. Li and Sporleder (2009) approached the problem by constructing a *lexical cohesion graph*. In the graph, content words in a text are represented as vertices, which are connected by edges representing semantic relatedness. The intuition behind their approach was that non-literal expressions would lower the average semantic relatedness of the graph. To classify a word as literal or metaphorical, Li and Sporleder (2010) use Gaussian Mixture Models with semantic similarity features, such as the relatedness between this target word and words in its context.

Broadwell et al. (2013) and Strzalkowski et al. (2013) base their approach on the idea that metaphors are likely to be concrete words that are not semantically associated with the surrounding context. Broadwell et al. (2013) implemented this idea using *topic chains*, which consist of noun phrases that are connected by pronominal mention, repetition, synonym, or hyponym relations. Strzalkowski et al. (2013) build on this idea by taking nouns and adjectives around the target concept as candidate source relations. They filtered out candidate sources that were in the same topical chain as the target concept or were not linked to the word being classified by a direct dependency path.

Schulder and Hovy (2014) also hypothesize that novel metaphors are marked by their unusualness in a given context. They use a domain-specific *term relevance* metric, which measures how typical a term is for the domain associated with the literal usage of a word, and *common relevance*, which measures how common a word is across domains. If a term is neither typical for a text's domain nor common, it is taken as a metaphor candidate. A particular strength of this approach is its accommodation of common words without discriminative power, which often confuse context-based models.

Jang et al. (2015) model context by using both *global context*, the context of an entire post, and *local context*, the context within a sentence, in relationship to a word being classified as metaphorical or literal. They used word categories from FrameNet, topic distribution, and lexical chain information (similar in concept to the topic chain information in (Broadwell et al., 2013)) to model the contrast between a word and its global context. To model the contrast between a word and its local context, they used lexical concreteness, word categories and semantic relatedness features.

Mohler et al. (2013) built a domain-aware semantic signature for a text to capture the context surrounding a metaphorical candidate. Unlike other approaches that try to discriminate metaphors from their context, their approach uses binary classifiers to compare the semantic signature for a text with that of known metaphors.

The above approaches attempted to capture governing context in various ways and were effective when applied to the problem of metaphor detection. However, these methods tend to overclassify literal instances as metaphorical when semantic cohesion is violated within their governing contexts. Additionally, these methods could

fail to detect extended metaphors, which span over wider contexts. In this paper, we specifically focus on the problem of discriminating literal instances from metaphorical instances by expanding the scope of what is captured within a context. Like (Mohler et al., 2013), we share the intuition that there could be associations between specific metaphors and their contexts, but we relax the assumption that metaphors must be similar to known metaphors.

3 Our Approach

To better capture the distinctions between metaphorical and literal usages of the same word (target word), we approach the task in two directions. First, we model how topics in context change for both metaphorical and literal instances of a target word (Section 3.1). Second, we consider the situational context for why individuals choose to use metaphor (Section 3.2). We use multi-level modeling to combine these two types of features with the specific target word to model interactions between the features and a particular metaphor (Section 3.3).

3.1 Topic Transition

In writing, cohesion refers to the presence or absence of explicit cues in the text that allow the reader to make connections between ideas (Crossley and McNamara, 2010). For example, overlapping words and concepts between sentences indicate that the same ideas are being referred to across these sentences. Metaphorically used words tend to be semantically incohesive with the governing context. Therefore, determining semantic or topical cohesion is important for metaphor detection.

However, even if a text is literal and cohesive, not all words within the text are semantically related. In example (1), a human could easily determine that "pillows", "music", "flickering candles", and "a foot massage" share the theme of relaxation. But it is difficult to define their relatedness computationally – these terms are not synonyms, hypernyms, antonyms, or in any other well-defined lexical relation. Additionally, even if the whole sentence is correctly interpreted as ways of indulging oneself, it is still semantically contrasted with the surrounding sentences about medicine. In this example, the target word "candle" is used literally, but the contrast between the sentence containing the target word and its context makes it computationally difficult to determine that it is not metaphorical:

> (1) ... yet encouraged to hear you have a diagnosis and it's being treated. Since you have to give up your scented stuff you'll just have to figure out some very creative ways to indulge yourself. *Soft pillows, relaxing music, flickering candles, maybe a foot massage*. Let's hope your new pain relief strategy works and the Neulasta shot is not so bad . I never had Taxotere, but have read it can be much easier than AC for many people. ...

Example (2) also shows semantic inconsistency between the candidate metaphor "boat" and the surrounding sentences about medicine. However, in this example, "boat" is metaphorically used. Thus, it is difficult to determine whether a word is metaphorical or literal when there is semantic contrast because both example (1) and example (2) show semantic contrast.

> (2) When my brain mets were discovered last year, I had to see a neurosurgeon. He asked if I understood that my treatment was pallative care. *Boy, did it rock my boat to hear that phrase!* I agree with Fitz, pallative treatment is to help with pain and alleviate symptoms.....but definitely different than hospice care.

The primary difference between these two examples is in the nature of the semantic contrast. In example (1), the topic of the sentence containing "candle" is relaxation, while the topic of the previous and following sentences is medicine. The transition between medicine and relaxation tends to be more literal, whereas the transition between the topic in the sentence containing "boat" and the surrounding medical topic sentences tends to be more metaphorical.

We use these differences in the topic transition for metaphor detection. We consider topic transitions at the sentence level, rather than the word level, because people often represent an idea at or above the sentence level. Thus, topic is better-represented at the sentence level.

To model context at the sentence level, we first assign topics to each sentence using Sentence Latent Dirichlet Allocation (LDA) (Jo and Oh, 2011). Sentence LDA has two main advantages over standard LDA for our work. First, while standard LDA assumes that each word is assigned a topic derived from the topic distribution of a document, Sentence LDA makes the constraint that all words in the same sentence must be assigned the same topic. Due to this property, the generated topics are better aligned with the role or purpose of a sentence, compared to topics generated from LDA. Additionally, having each sentence assigned to one topic helps us avoid using heuristics for representing the topic of each sentence. [1]

Using Sentence LDA, we modeled four features to capture how the topic changes around the sentence where a target word resides. We refer to this sentence as the *target sentence*.

Target Sentence Topic (TargetTopic): We hypothesize that sentences containing a metaphor may prefer topics that are different from those of sentences where the same word is used literally. Hence, TargetTopic is a T-dimensional binary feature, where T is the number of topics, that indicates the topic assigned to the sentence containing the target word.

Topic Difference (TopicDiff): We hypothesize that a metaphorical sentence is more likely to be different from its neighboring sentences, in terms of topic, than a literal sentence. Therefore, TopicDiff is a two-dimensional binary feature that indicates whether the topic assigned to the target sentence is different from that of the previous and next sentences.

Topic Similarity (TopicSim): Under the same hypothesis as TopicDiff, TopicSim is a two-dimensional feature that represents the similarity between the topic of the target sentence and its previous and next sentences. Unlike TopicDiff, which is binary, TopicSim has continuous values between 0 and 1, as we use the cosine similarity between each topic's word distributions as topic similarity. Note that in Sentence LDA, all topics share the same vocabulary, but assign different probabilities to different words as in LDA although all tokens in a sentence are assigned to the same topic in Sentence LDA.

Topic Transition (TopicTrans): The topic of a metaphorical sentence may extend over multiple sentences, so a topic transition may occur a few sentences ahead or behind the target sentence. TopicTrans looks for the nearest sentences with a different topic before and after the current target sentence and encodes the topics of the different-topic sentences. Hence, TopicTrans is a $2T$-dimensional feature, where T is the number of topics, that indicates the topics of the nearest sentences that have a different topic from the target sentence.

Topic Transition Similarity (TopicTransSim): The topics before and after a transition, even in the extended case for TopicTrans, are still expected to be more different in metaphorical cases than in literal cases, as we assume for TopicSim. Therefore, TopicTransSim is a two-dimensional continuous feature that encodes the cosine similarity between the topic of the target sentence and the topics of the nearest sentences that have a different topic before and after the target sentence.

3.2 Emotion and Cognition

Metaphors are often used to explain or describe abstract ideas, such as difficult concepts or emotions (Meier and Robinson, 2005). (Fainsilber and Ortony, 1987) showed that descriptions of feelings contain more metaphorical language than descriptions of behavior.

In our domain, writers are searching for support through the emotionally tumultuous experience of breast cancer and often turn to metaphor to express this emotion. For example, the word "road" can be used as a metaphor to express the emotional experiences of waiting for or passing through steps in treatment. A similar phenomenon is that markers of cognition, such as "I think", can occur to introduce the abstract source of the metaphor. In example (3), one breast cancer patient in our data describes her speculation about her condition metaphorically, writing,

(3) i have such a long *road* i just wonder what to do with myself.

To encode these emotional and cognitive elements as features, we use Linguistic Inquiry Word Count (LIWC) (Tausczik and Pennebaker, 2010). LIWC is a tool that counts word use in certain

[1] We also tried standard LDA for assigning topics to sentences, by representing each sentence as a topic distribution over its words. However, this representation was not as informative as Sentence LDA in our task, so we leave out the LDA topics in further discussion.

psychologically relevant categories. Focusing on emotional and cognitive processes, we use the LIWC term lists for categories seen in Table 1.

LIWC category	Example Terms
affect	ache, like, sweet
positive emotion	passion, agree, giving
negative emotion	agony, annoy, miss
anxiety	embarrass, avoid
anger	assault, offend
sadness	despair, grim
cognitive mechanisms	if, could
insight	believe, aware
cause	make, pick
discrep	would, hope
tentativeness	anyone, suppose
certainty	never, true

Table 1: Selected LIWC categories.

We count the number of words that fall into each category within either an immediate or global context. For these LIWC features, we take the target sentence and its neighboring sentences as the immediate context and the entire post as the global context for a candidate metaphor instance. The counts for each category in either the immediate or global context are used as features encoded by what degree the immediate or global context expresses the emotional or cognitive category.

We expect words indicative of emotion and cognition to appear more frequently in metaphorical cases. Our preliminary statistical analysis on the development set revealed that this holds true within the target sentence and shows a tendency in the surrounding sentences.

3.3 Multi-Level Modeling

Our topical and emotion and cognition context features are general across target words. However, the specific features that are informative for metaphor identification may depend on the target word. To account for the specificity of target words, we use multi-level modeling (Daume III, 2007). The idea of multi-level modeling is to pair each of our features with every target word while keeping one set of features independent of the target words. There are then multiple copies of each topic transition and emotion/cognition feature, all paired with a different target word. Thus, if there are N target words, our feature space becomes $N + 1$ times larger.

4 Experiments

Our main experimental task is metaphor detection or disambiguation – given a post containing a candidate metaphor word, we aim to determine whether the word is used literally or metaphorically in context.

4.1 Data

We conducted experiments on a dataset of posts from a public breast cancer support group discussion forum, annotated by Jang et al. (2015). We chose to work on this dataset because it features metaphors occurring in naturalistic language.

In this dataset, posts are restricted to those containing one of seven candidate metaphors that appear either metaphorically or literally: "boat", "candle", "light", "ride", "road", "spice", and "train". We split the data randomly into a development set of 800 posts for preliminary analysis and a cross-validation set of 1,870 posts for classification as in (Jang et al., 2015).

4.2 Metrics

We report five evaluation metrics for every model: kappa, F1 score, precision, recall, and accuracy. Kappa, which corrects for agreement by chance, was calculated between predicted results and actual results. Because the dataset is skewed towards metaphorical instances, we rely on the first four measures over accuracy for our evaluation.

4.3 Baselines

We use the following two baselines: the feature set of (Jang et al., 2015) and a context unigram model.

Jang et al. (2015): We use the best configuration of features from Jang et al. (2015), the state-of-the-art model on our dataset, as a baseline. This feature set consists of all of their local context features (word category, semantic relatedness, concreteness), all of their global context features except lexical chaining (word category, global topic distribution), and context unigrams.

Context Unigram Model: All the words in a post, including the target word, are used as context features.

4.4 Settings

We ran Sentence LDA, setting the number of topics to 10, 20, 30, 50, and 100. α and β determine the sparsity of the topic distribution of each document and the word distribution of each topic,

Model	κ	F1	P-L	R-L	P-M	R-M	A
Unigram	.435	.714	.701	.434	.845	.943	.824
Unigram + AllTopic + AllLIWC***	.533	.765	.728	.550	.872	.937	.847
Unigram + MM AllTopic + MM AllLIWC***	.543	.770	.754	.546	.872	.946	.852
J	.575	.786	.758	.587	.882	.943	.859
J + AllTopic + AllLIWC*	.609	.804	.772	.626	.892	.943	.869
J + MM AllTopic**	.619	.809	.784	.630	.893	.947	.873
J + MM AllLIWC	.575	.787	.757	.589	.882	.942	.859
J + MM AllTopic + MM AllLIWC***	**.631**	**.815**	**.792**	**.642**	**.896**	**.948**	**.876**

Table 2: Performance on metaphor identification task. (**Models**) J: Jang et al. (2015), MM - Multilevel Modeling (**Metrics**) κ: Cohen's kappa, F1: average F1 score on M/L, P-L: precision on literals, R-L: recall on literals, P-M: precision on metaphors, R-M: recall on metaphors, A: accuracy, *: marginally statistically significant ($p < 0.1$), **: statistically significant ($p < 0.05$), ***: highly statistically significant ($p < 0.01$) improvement over corresponding baseline by Student's t-test.

respectively; the lower the sparser. Following convention, we set these parameters to 0.1 and 0.001, respectively, to enforce sparsity. We also removed the 37 most frequent words in the corpus, drawing the threshold at the point where content words and pronouns started to appear in the ranked list. The models with 10 topics performed the best on the development set, with performance degrading as the number of topics increased. We suspect that poorer performance on the models with more topics is due to feature sparsity.

We used the support vector machine (SVM) classifier provided in the `LightSIDE` toolkit (Mayfield and Rosé, 2010) with sequential minimal optimization (SMO) and a polynomial kernel of exponent 2. For each experiment, we performed 10-fold cross-validation. We also trained the baselines with the same SVM settings.

4.5 Results

The results of our classification experiment are shown in Table 2. We tested our topical and emotion and cognition features in combination with lexical features from our baselines: unigram and Jang et al. (2015).

Adding our topical and emotion/cognition features to the baselines improved performance in predicting metaphor detection. We see that our features combined with the unigram features improved over the Unigram baseline although they do not beat the Jang et al. (2015) baseline. However, when our features are combined with the features from Jang et al. (2015), we see large gains in performance. Additionally, our multi-level modeling significantly improved performance by taking into account the effects of specific metaphors. The topical features added to the baseline led to a significant improvement in accuracy, while emotion and cognition features only slightly improved the accuracy without statistical significance. However, the combination of these emotion and cognition features with topical features (in the last row of Table 2) leads to improvement. We performed a Student's t-test for calculating statistical significance.

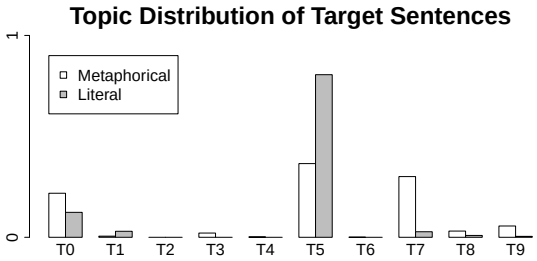

Figure 1: Proportions of topics assigned to target sentences, when target words were used metaphorically vs. literally. The proportions of metaphorical and literal cases are different with statistical significance of $p < 0.01$ by Pearson's chi-square test.

5 Discussion

Metaphorical instances tend to have personal topics. An author was more likely to use target words metaphorically when the target sentence relates more closely to their own experience of disease and treatment. Specifically, metaphors were relatively frequent when people shared their own disease experience (Topic 0, Topic 9) or sympa-

	Topic	Top Words	Example Sentences
0	Disease/ Treatment	get, chemo, if, they, as, out, can, like, now, she, feel, did, up, know, think, been, good, time, or, when	I'm scared of chemo and ct scans because it makes cancer come back and you become more resistance to treatment with drugs like these later.
1	Food	good, they, gt, can, like, eat, fat, or, if, some, one, as, them, get, up, fiber, think, more, what	*Martha's Way* Stuff a miniature marshmallow in the bottom of a sugar cone to prevent ice cream drips.
2	Emotions	love, great, laura, good, hope, like, debbie, amy, up, happy, too, everyone, day, glad, look, fun, mary, what, kelly, how	Too funny. / You're so cute! / ene23...the photo in the locket idea sounds great!
3	Time	chemo, week, go, last, then, next, weeks, taxol, good, done, treatment, first, start, one, more, rads, after, today, 'll, now	I am now 45, and just had my ONE year anniversary from finishing chemo last week!!
4	Greetings/ Thanks	thanks, hugs, hi, here, carrie, thank, welcome, love, us, glad, know, greg, good, everyone, thread, ladies, there, how, sorry, mags	Thank you so much for the story!! / Big Hugs!
5	People	she, he, they, out, get, up, her, when, like, one, as, from, there, our, time, did, if, can, go, what	She has three children and her twin sister has taken her and her 3 children in.
6	Support	good, hope, well, happy, everyone, doing, glad, luck, hear, better, take, jen, care, great, liz, birthday, hugs, lol, watson, feeling	YAY! / lol. / I wish you all good luck and peace.
7	Relation	what, know, she, as, can, her, cancer, if, there, has, think, been, how, like, our, who, when, they, would, us	She knows that she has BC but does not know that it has spread. / I just read your message and I wondered about you.
8	Religion	god, love, lord, us, prayers, our, bless, dear, her, lu, may, day, patti, thank, know, comfort, amen, xoxo, he, pray	Dear Lord, I come to you with a friend that is not doing well, Please bless her that her hands will reach for you threw the last part of her breast cancer fight.
9	Diagnosis	diagnosed, when, chemo, she, breast, years, stage, cancer, dx, now, found, nodes, no, after, lump, they, age, then, year, mastectomy	I was 64 when diagnosed wtth pure DCIS.....I had my ninght radiation treatment today. / I was diagnosed Nov 2007 at age 45.

Table 3: Topics learned by Sentence LDA.

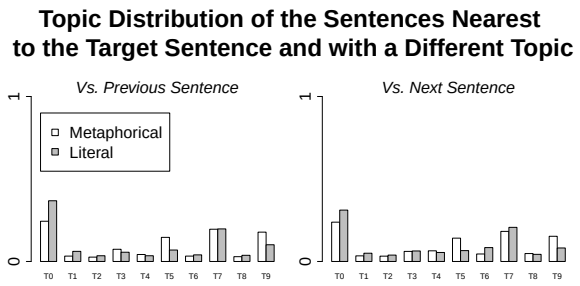

Figure 2: Proportions of the topics of the sentences that are nearest to the target sentence and have a different topic from the target sentence. The proportions of metaphorical and literal cases are different with statistical significance of $p < 0.01$ by Pearson's chi-square test.

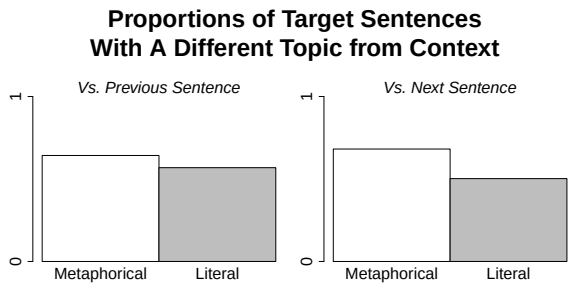

Figure 3: Proportions of target sentences whose topic is different from that of the previous/next sentence, when target words were used metaphorically vs. literally. The proportions of metaphorical and literal cases are different with statistical significance of $p < 0.01$ by Pearson's chi-square test.

thized with other people's experiences (Topic 7), but were more infrequent when they simply talked about other people in Topic 5 (Figure 1). According to our closer examination of sample sentences, Topic 0 had many personal stories about disease and treatment, and Topic 7 was about learning and relating to other people's experiences. Example metaphorical expressions include "There is *light* during chemo." (Topic 0) and "Hi Dianne - I am glad I found your post as I am sort of in the same *boat*." (Topic 7). Analysis of our LIWC features also supports the reflective nature of metaphors: "insight" and "discrepancy" words such as "wish", "seem", and "feel" occur more frequently around metaphorical uses of target terms.

The topics of the surrounding context (TopicTrans) were also informative for metaphor detection (Figure 2). However, the topics of the surrounding sentences followed an opposite pattern to the topics of the target sentence; talking

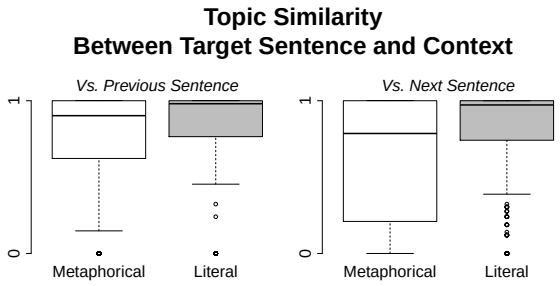

Figure 4: Cosine similarity between the topic of a target sentence and the topic of its previous/next sentence, when target words were used metaphorically vs. literally. The means of the metaphorical and literal cases are different with statistical significance of $p < 0.01$ by Welch's t-test.

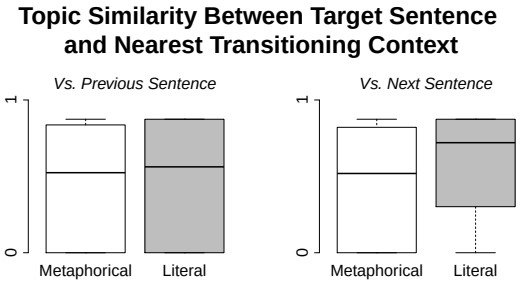

Figure 5: Cosine similarity of the topic of a target sentence and the topic of the sentences that are nearest to the target sentence and have a different topic from the target sentence. The means of metaphorical and literal cases are different with statistical significance only for the next sentence, with $p < 0.01$ by Welch's t-test.

about other people (Topic 5) in the context of a target sentence led to more metaphorical usage of target words. Similarly, writers used target words more literally before or after they shared their personal stories (Topic 0). This pattern could be because the topic of the target sentence differs from the topics of the surrounding sentences in these instances, which would mean that the target sentence is a topic that is more likely to be literal. Topic 9, however, does not follow the same pattern. One possible reason is that Topic 9 and Topic 0 tend to frequently co-occur and be metaphorical. Thus, if a target word comes after or before Topic 9 and it is Topic 0, then this word may more likely be metaphorical.

Topic transitions are effective indicators of metaphor. Metaphorical instances accompanied more drastic topic transitions than literal instances. This tendency, which matched our hypothesis, was shown in all our topic features. The immediately neighboring sentences of metaphorical instances were more likely to have a different topic from the target sentence than those of literal instances (Figure 3). Additionally, differences in topic between the target sentence and the neighboring sentences were greater for metaphorical instances (Figure 4). The nearest sentences with topics different from the target sentence (TopicTransSim) also showed this pattern (Figure 5). An interesting finding was that a topic transition after the target sentence was more indicative of metaphor than a transition before.

Emotion and cognitive words are discriminative depending on the metaphor. Emotion and cognition in the surrounding contexts, which were captured by the LIWC features, helped identify metaphors when combined with topical features. This result supports the claim in (Fainsilber and Ortony, 1987) that descriptions of feelings contain more metaphorical language than descriptions of behavior.

This effect, however, was limited to specific target words and emotions. For example, we saw a higher number of anxiety words in the immediate and global contexts of metaphors, but the trend was the opposite for anger words. This may be because our target words, "boat", "candle", "light", "ride", "road", "spice" and "train", relate more to anxiety in metaphors such as "bumpy road" and "rollercoaster ride", than to anger. On the other hand, cognitive words had more consistency, as words marking insight and discrepancy were seen significantly higher around metaphorical uses of the target words. These patterns, nevertheless, could be limited to our domain. It would be interesting to explore other patterns in different domains.

A multi-level model captures word-specific effects. Our features in context helped recognize metaphors in different ways for different target words, captured by the multi-level model. The paucity of general trends across metaphorical terms does not mean a limited applicability of our method, though, as our features do not suppose any specific trends. Rather, our method only assumes the existence of a correlation between metaphors and the theme of their context, and our multi-level model effectively identifies the interaction between metaphorical terms and their con-

texts as useful information.

For all the figures in this section, most target words have a similar pattern. See our supplemental material for graphs by target word.

6 Conclusion

We propose a new, effective method for metaphor detection using (1) sentence level topic transitions between target sentences and surrounding contexts and (2) emotion and cognition words. Both types of features showed significant improvement over the state-of-the-art. In particular, our system made significant gains in solving the problem of over-classification in metaphor detection.

We also find that personal topics are markers of metaphor, as well as certain patterns in topic transition. Additionally, language expressing emotion and cognition relates to metaphor, but in ways specific to particular candidate words. For our breast cancer forum dataset, we find more words related to anxiety around metaphors.

Our proposed features can be expanded to other domains. Though in other domains, the specific topic transition and emotion/cognition patterns would likely be different, these features would still be relevant to metaphor detection.

Abstract

Neural networks are among the state-of-the-art techniques for language modeling. Existing neural language models typically map discrete words to distributed, dense vector representations. After information processing of the preceding context words by hidden layers, an output layer estimates the probability of the next word. Such approaches are time- and memory-intensive because of the large numbers of parameters for word embeddings and the output layer. In this paper, we propose to compress neural language models by sparse word representations. In the experiments, the number of parameters in our model increases very slowly with the growth of the vocabulary size, which is almost imperceptible. Moreover, our approach not only reduces the parameter space to a large extent, but also improves the performance in terms of the perplexity measure.[1]

1 Introduction

Language models (LMs) play an important role in a variety of applications in natural language processing (NLP), including speech recognition and document recognition. In recent years, neural network-based LMs have achieved significant breakthroughs: they can model language more precisely than traditional n-gram statistics (Mikolov et al., 2011); it is even possible to generate new sentences from a neural LM, benefiting various downstream tasks like machine translation, summarization, and dialogue systems (Devlin et al., 2014; Rush et al., 2015; Sordoni et al., 2015; Mou et al., 2015b).

[1]Code released on https://github.com/chenych11/lm

Existing neural LMs typically map a discrete word to a distributed, real-valued vector representation (called *embedding*) and use a neural model to predict the probability of each word in a sentence. Such approaches necessitate a large number of parameters to represent the embeddings and the output layer's weights, which is unfavorable in many scenarios. First, with a wider application of neural networks in resource-restricted systems (Hinton et al., 2015), such approach is too memory-consuming and may fail to be deployed in mobile phones or embedded systems. Second, as each word is assigned with a dense vector—which is tuned by gradient-based methods—neural LMs are unlikely to learn meaningful representations for infrequent words. The reason is that infrequent words' gradient is only occasionally computed during training; thus their vector representations can hardly been tuned adequately.

In this paper, we propose a compressed neural language model where we can reduce the number of parameters to a large extent. To accomplish this, we first represent infrequent words' embeddings with frequent words' by sparse linear combinations. This is inspired by the observation that, in a dictionary, an unfamiliar word is typically defined by common words. We therefore propose an optimization objective to compute the sparse codes of infrequent words. The property of sparseness (only 4–8 values for each word) ensures the efficiency of our model.

Based on the pre-computed sparse codes, we design our compressed language model as follows. A dense embedding is assigned to each common word; an infrequent word, on the other hand, computes its vector representation by a sparse combination of common words' embeddings. We use the long short term memory (LSTM)-based recurrent neural network (RNN) as the hidden layer of

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 226–235,
Berlin, Germany, August 7-12, 2016.

our model. The weights of the output layer are also compressed in a same way as embeddings. Consequently, the number of trainable neural parameters is a constant regardless of the vocabulary size if we ignore the biases of words. Even considering sparse codes (which are very small), we find the memory consumption grows imperceptibly with respect to the vocabulary.

We evaluate our LM on the Wikipedia corpus containing up to 1.6 billion words. During training, we adopt noise-contrastive estimation (NCE) (Gutmann and Hyvärinen, 2012) to estimate the parameters of our neural LMs. However, different from Mnih and Teh (2012), we tailor the NCE method by adding a regression layer (called `ZRegressoion`) to predict the normalization factor, which stabilizes the training process. Experimental results show that, our compressed LM not only reduces the memory consumption, but also improves the performance in terms of the perplexity measure.

To sum up, the main contributions of this paper are three-fold. (1) We propose an approach to represent uncommon words' embeddings by a sparse linear combination of common ones'. (2) We propose a compressed neural language model based on the pre-computed sparse codes. The memory increases very slowly with the vocabulary size (4–8 values for each word). (3) We further introduce a `ZRegression` mechanism to stabilize the NCE algorithm, which is potentially applicable to other LMs in general.

2 Background

2.1 Standard Neural LMs

Language modeling aims to minimize the joint probability of a corpus (Jurafsky and Martin, 2014). Traditional n-gram models impose a Markov assumption that a word is only dependent on previous $n-1$ words and independent of its position. When estimating the parameters, researchers have proposed various smoothing techniques including back-off models to alleviate the problem of data sparsity.

Bengio et al. (2003) propose to use a feed-forward neural network (FFNN) to replace the multinomial parameter estimation in n-gram models. Recurrent neural networks (RNNs) can also be used for language modeling; they are especially capable of capturing long range dependencies in sentences (Mikolov et al., 2010; Sundermeyer et al., 2015).

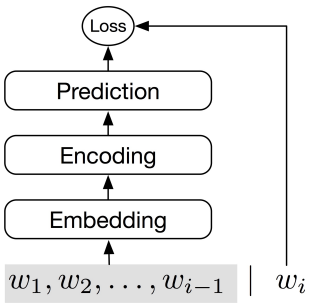

Figure 1: The architecture of a neural network-based language model.

In the above models, we can view that a neural LM is composed of three main parts, namely the `Embedding`, `Encoding`, and `Prediction` subnets, as shown in Figure 1.

The `Embedding` subnet maps a word to a dense vector, representing some abstract features of the word (Mikolov et al., 2013). Note that this subnet usually accepts a list of words (known as history or context words) and outputs a sequence of word embeddings.

The `Encoding` subnet encodes the history of a target word into a dense vector (known as *context* or *history* representation). We may either leverage FFNNs (Bengio et al., 2003) or RNNs (Mikolov et al., 2010) as the `Encoding` subnet, but RNNs typically yield a better performance (Sundermeyer et al., 2015).

The `Prediction` subnet outputs a distribution of target words as

$$p(w = w_i|h) = \frac{\exp(s(h, w_i))}{\sum_j \exp(s(h, w_j))}, \quad (1)$$

$$s(h, w_i) = \boldsymbol{W}_i^\top \boldsymbol{h} + b_i, \quad (2)$$

where $\boldsymbol{h}$ is the vector representation of context/history h, obtained by the `Encoding` subnet. $\boldsymbol{W} = (\boldsymbol{W}_1, \boldsymbol{W}_2, \ldots, \boldsymbol{W}_V) \in \mathbb{R}^{C \times V}$ is the *output weights* of `Prediction`; $\boldsymbol{b} = (b_1, b_2, \ldots, b_V) \in \mathbb{R}^C$ is the bias (the prior). $s(h, w_i)$ is a scoring function indicating the degree to which the context h matches a target word w_i. (V is the size of vocabulary $\mathcal{V}$; C is the dimension of context/history, given by the `Encoding` subnet.)

2.2 Complexity Concerns of Neural LMs

Neural network-based LMs can capture more precise semantics of natural language than n-gram models because the regularity of the `Embedding` subnet extracts meaningful semantics of a word

and the high capacity of `Encoding` subnet enables complicated information processing.

Despite these, neural LMs also suffer from several disadvantages mainly out of complexity concerns.

Time complexity. Training neural LMs is typically time-consuming especially when the vocabulary size is large. The normalization factor in Equation (1) contributes most to time complexity. Morin and Bengio (2005) propose hierarchical softmax by using a Bayesian network so that the probability is self-normalized. Sampling techniques—for example, importance sampling (Bengio and Senécal, 2003), noise-contrastive estimation (Gutmann and Hyvärinen, 2012), and target sampling (Jean et al., 2014)—are applied to avoid computation over the entire vocabulary. Infrequent normalization maximizes the unnormalized likelihood with a penalty term that favors normalized predictions (Andreas and Klein, 2014).

Memory complexity and model complexity. The number of parameters in the `Embedding` and `Prediction` subnets in neural LMs increases linearly with respect to the vocabulary size, which is large (Table 1). As said in Section 1, this is sometimes unfavorable in memory-restricted systems. Even with sufficient hardware resources, it is problematic because we are unlikely to fully tune these parameters. Chen et al. (2015) propose the differentiated softmax model by assigning fewer parameters to rare words than to frequent words. However, their approach only handles the output weights, i.e., $\boldsymbol{W}$ in Equation (2); the input embeddings remain uncompressed in their approach.

In this work, we mainly focus on memory and model complexity, i.e., we propose a novel method to compress the `Embedding` and `Prediction` subnets in neural language models.

2.3 Related Work

Existing work on model compression for neural networks. Buciluǎ et al. (2006) and Hinton et al. (2015) use a well-trained large network to guide the training of a small network for model compression. Jaderberg et al. (2014) compress neural models by matrix factorization, Gong et al. (2014) by quantization. In NLP, Mou et al. (2015a) learn an embedding subspace by supervised training. Our work resembles little, if any, to the above methods as we compress embeddings and output weights using sparse word representations. Existing model compression typically works with a compromise of performance. On the contrary, our model improves the perplexity measure after compression.

Sub-nets	RNN-LSTM	FFNN
`Embedding`	VE	VE
`Encoding`	$4(CE + C^2 + C)$	$nCE + C$
`Prediction`	$V(C + 1)$	$V(C + 1)$
TOTAL†	$\mathcal{O}((C + E)V)$	$\mathcal{O}((E + C)V)$

Table 1: Number of parameters in different neural network-based LMs. E: embedding dimension; C: context dimension; V: vocabulary size. †Note that $V \gg C$ (or E).

Sparse word representations. We leverage sparse codes of words to compress neural LMs. Faruqui et al. (2015) propose a sparse coding method to represent each word with a sparse vector. They solve an optimization problem to obtain the sparse vectors of words as well as a dictionary matrix simultaneously. By contrast, we do not estimate any dictionary matrix when learning sparse codes, which results in a simple and easy-to-optimize model.

3 Our Proposed Model

In this section, we describe our compressed language model in detail. Subsection 3.1 formalizes the sparse representation of words, serving as the premise of our model. On such a basis, we compress the `Embedding` and `Prediction` subnets in Subsections 3.2 and 3.3, respectively. Finally, Subsection 3.4 introduces NCE for parameter estimation where we further propose the `ZRegression` mechanism to stabilize our model.

3.1 Sparse Representations of Words

We split the vocabulary $\mathcal{V}$ into two disjoint subsets ($\mathcal{B}$ and $\mathcal{C}$). The first subset $\mathcal{B}$ is a base set, containing a fixed number of common words (8k in our experiments). $\mathcal{C} = \mathcal{V} \backslash \mathcal{B}$ is a set of uncommon words. We would like to use $\mathcal{B}$'s word embeddings to encode $\mathcal{C}$'s.

Our intuition is that oftentimes a word can be defined by a few other words, and that rare words should be defined by common ones. Therefore, it is reasonable to use a few common words' embeddings to represent that of a rare word. Following most work in the literature (Lee et al., 2006; Yang et al., 2011), we represent each uncommon word with a sparse, linear combination of com-

mon ones' embeddings. The sparse coefficients are called a *sparse code* for a given word.

We first train a word representation model like SkipGram (Mikolov et al., 2013) to obtain a set of embeddings for each word in the vocabulary, including both common words and rare words. Suppose $\boldsymbol{U} = (\boldsymbol{U}_1, \boldsymbol{U}_2, \ldots, \boldsymbol{U}_B) \in \mathbb{R}^{E \times B}$ is the (learned) embedding matrix of common words, i.e., $\boldsymbol{U}_i$ is the embedding of i-th word in $\mathcal{B}$. (Here, $B = |\mathcal{B}|$.)

Each word in $\mathcal{B}$ has a natural sparse code (denoted as $\boldsymbol{x}$): it is a one-hot vector with B elements, the i-th dimension being on for the i-th word in $\mathcal{B}$.

For a word $w \in \mathcal{C}$, we shall learn a sparse vector $\boldsymbol{x} = (x_1, x_2, \ldots, x_B)$ as the sparse code of the word. Provided that $\boldsymbol{x}$ has been learned (which will be introduced shortly), the embedding of w is

$$\hat{\boldsymbol{w}} = \sum_{j=1}^{B} x_j \boldsymbol{U}_j = \boldsymbol{U}\boldsymbol{x}, \tag{3}$$

To learn the sparse representation of a certain word w, we propose the following optimization objective

$$\min_{\boldsymbol{x}} \ \|\boldsymbol{U}\boldsymbol{x} - \boldsymbol{w}\|_2^2 + \alpha\|\boldsymbol{x}\|_1 + \beta|\boldsymbol{1}^\top \boldsymbol{x} - 1| + \gamma \boldsymbol{1}^\top \max\{\boldsymbol{0}, -\boldsymbol{x}\}, \tag{4}$$

where $\max$ denotes the component-wise maximum; $\boldsymbol{w}$ is the embedding for a rare word $w \in \mathcal{C}$.

The first term (called *fitting loss* afterwards) evaluates the closeness between a word's coded vector representation and its "true" representation $\boldsymbol{w}$, which is the general goal of sparse coding.

The second term is an ℓ_1 regularizer, which encourages a sparse solution. The last two regularization terms favor a solution that sums to 1 and that is nonnegative, respectively. The nonnegative regularizer is applied as in He et al. (2012) due to psychological interpretation concerns.

It is difficult to determine the hyperparameters α, β, and γ. Therefore we perform several tricks. First, we drop the last term in the problem (4), but clip each element in $\boldsymbol{x}$ so that all the sparse codes are nonnegative during each update of training.

Second, we re-parametrize α and β by balancing the fitting loss and regularization terms dynamically during training. Concretely, we solve the following optimization problem, which is slightly different but closely related to the conceptual objective (4):

$$\min_{\boldsymbol{x}} \ L(\boldsymbol{x}) + \alpha_t R_1(\boldsymbol{x}) + \beta_t R_2(\boldsymbol{x}), \tag{5}$$

where $L(\boldsymbol{x}) = \|\boldsymbol{U}\boldsymbol{x} - \boldsymbol{w}\|_2^2$, $R_1(\boldsymbol{x}) = \|\boldsymbol{x}\|_1$, and $R_2(\boldsymbol{x}) = |\boldsymbol{1}^\top \boldsymbol{x} - 1|$. α_t and β_t are adaptive parameters that are resolved during training time. Suppose $\boldsymbol{x}_t$ is the value we obtain after the update of the t-th step, we expect the importance of fitness and regularization remain unchanged during training. This is equivalent to

$$\frac{\alpha_t R_1(\boldsymbol{x}_t)}{L(\boldsymbol{x}_t)} = w_\alpha \equiv \text{const}, \tag{6}$$

$$\frac{\beta_t R_2(\boldsymbol{x}_t)}{L(\boldsymbol{x}_t)} = w_\beta \equiv \text{const}. \tag{7}$$

or

$$\alpha_t = \frac{L(\boldsymbol{x}_t)}{R_1(\boldsymbol{x}_t)} w_\alpha \text{ and } \beta_t = \frac{L(\boldsymbol{x}_t)}{R_2(\boldsymbol{x}_t)} w_\beta,$$

where w_α and w_β are the ratios between the regularization loss and the fitting loss. They are much easier to specify than α or β in the problem (4).

We have two remarks as follows.

- To learn the sparse codes, we first train the "true" embeddings by `word2vec`[2] for both common words and rare words. However, these true embeddings are slacked during our language modeling.
- As the codes are pre-computed and remain unchanged during language modeling, they are not tunable parameters of our neural model. Considering the learned sparse codes, we need only 4–8 values for each word on average, as the codes contain 0.05–0.1% nonzero values, which are almost negligible.

3.2 Parameter Compression for the `Embedding` Subnet

One main source of LM parameters is the `Embedding` subnet, which takes a list of words (history/context) as input, and outputs dense, low-dimensional vector representations of the words.

We leverage the sparse representation of words mentioned above to construct a compressed `Embedding` subnet, where the number of parameters is independent of the vocabulary size.

By solving the optimization problem (5) for each word, we obtain a non-negative sparse code $\boldsymbol{x} \in \mathbb{R}^B$ for each word, indicating the degree to which the word is related to common words in $\mathcal{B}$. Then the embedding of a word is given by $\hat{\boldsymbol{w}} = \boldsymbol{U}\boldsymbol{x}$.

[2] https://code.google.com/archive/p/word2vec

We would like to point out that the embedding of a word $\hat{\boldsymbol{w}}$ is not sparse because $\boldsymbol{U}$ is a dense matrix, which serves as a shared parameter of learning all words' vector representations.

3.3 Parameter Compression for the `Prediction` Subnet

Another main source of parameters is the `Prediction` subnet. As Table 1 shows, the output layer contains V target-word weight vectors and biases; the number increases with the vocabulary size. To compress this part of a neural LM, we propose a weight-sharing method that uses words' sparse representations again. Similar to the compression of word embeddings, we define a base set of weight vectors, and use them to represent the rest weights by sparse linear combinations.

Without loss of generality, we let $\boldsymbol{D} = \boldsymbol{W}_{:,1:B}$ be the output weights of B base target words, and $\boldsymbol{c} = \boldsymbol{b}_{1:B}$ be bias of the B target words.[3] The goal is to use $\boldsymbol{D}$ and $\boldsymbol{c}$ to represent $\boldsymbol{W}$ and $\boldsymbol{b}$. However, as the values of $\boldsymbol{W}$ and $\boldsymbol{b}$ are unknown before the training of LM, we cannot obtain their sparse codes in advance.

We claim that it is reasonable to share the same set of sparse codes to represent word vectors in `Embedding` and the output weights in the `Prediction` subnet. In a given corpus, an occurrence of a word is always companied by its context. The co-occurrence statistics about a word or corresponding context are the same. As both word embedding and context vectors capture these co-occurrence statistics (Levy and Goldberg, 2014), we can expect that context vectors share the same internal structure as embeddings. Moreover, for a fine-trained network, given any word w and its context h, the output layer's weight vector corresponding to w should specify a large inner-product score for the context h; thus these context vectors should approximate the weight vector of w. Therefore, word embeddings and the output weight vectors should share the same internal structures and it is plausible to use a same set of sparse representations for both words and target-word weight vectors. As we shall show in Section 4, our treatment of compressing the `Prediction` subnet does make sense and achieves high performance.

Formally, the i-th output weight vector is estimated by

$$\hat{\boldsymbol{W}}_i = \boldsymbol{D}\boldsymbol{x}_i, \tag{8}$$

[3] $\boldsymbol{W}_{:,1:B}$ is the first B columns of $\boldsymbol{W}$.

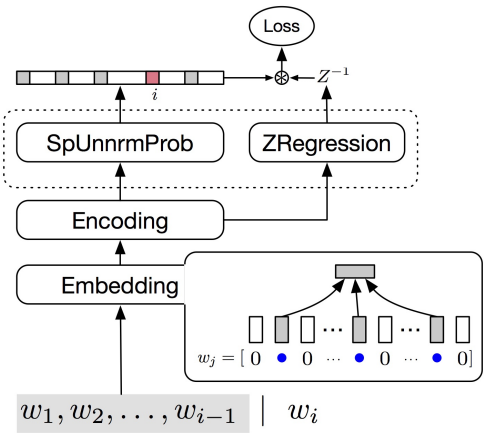

Figure 2: Compressing the output of neural LM. We apply NCE to estimate the parameters of the `Prediction` sub-network (dashed round rectangle). The SpUnnrmProb layer outputs a **sp**arse, **unnorm**alized **prob**ability of the next word. By "sparsity," we mean that, in NCE, the probability is computed for only the "true" next word (red) and a few generated negative samples.

The biases can also be compressed as

$$\hat{b}_i = \boldsymbol{c}\boldsymbol{x}_i. \tag{9}$$

where $\boldsymbol{x}_i$ is the sparse representation of the i-th word. (It is shared in the compression of weights and biases.)

In the above model, we have managed to compressed a language model whose number of parameters is irrelevant to the vocabulary size.

To better estimate a "prior" distribution of words, we may alternatively assign an independent bias to each word, i.e., $\boldsymbol{b}$ is not compressed. In this variant, the number of model parameters grows very slowly and is also negligible because each word needs only one extra parameter. Experimental results show that by not compressing the bias vector, we can even improve the performance while compressing LMs.

3.4 Noise-Contrastive Estimation with `ZRegression`

We adopt the noise-contrastive estimation (NCE) method to train our model. Compared with the maximum likelihood estimation of softmax, NCE reduces computational complexity to a large degree. We further propose the `ZRegression` mechanism to stablize training.

NCE generates a few negative samples for each positive data sample. During training, we only

need to compute the unnormalized probability of these positive and negative samples. Interested readers are referred to (Gutmann and Hyvärinen, 2012) for more information.

Formally, the estimated probability of the word w_i with history/context h is

$$P(w|h;\boldsymbol{\theta}) = \frac{1}{Z_h} P^0(w_i|h;\boldsymbol{\theta}) = \frac{1}{Z_h} \exp(s(w_i, h;\boldsymbol{\theta})), \quad (10)$$

where $\boldsymbol{\theta}$ is the parameters and Z_h is a context-dependent normalization factor. $P^0(w_i|h;\boldsymbol{\theta})$ is the unnormalized probability of the w (given by the SpUnnrmProb layer in Figure 2).

The NCE algorithm suggests to take Z_h as parameters to optimize along with $\boldsymbol{\theta}$, but it is intractable for context with variable lengths or large sizes in language modeling. Following Mnih and Teh (2012), we set $Z_h = 1$ for all h in the base model (without `ZRegression`).

The objective for each occurrence of context/history h is

$$J(\boldsymbol{\theta}|h) = \log \frac{P(w_i|h;\boldsymbol{\theta})}{P(w_i|h;\boldsymbol{\theta}) + kP_n(w_i)} + \sum_{j=1}^{k} \log \frac{kP_n(w_j)}{P(w_j|h;\boldsymbol{\theta}) + kP_n(w_j)},$$

where $P_n(w)$ is the probability of drawing a negative sample w; k is the number of negative samples that we draw for each positive sample.

The overall objective of NCE is

$$J(\boldsymbol{\theta}) = \mathbb{E}_h[J(\boldsymbol{\theta}|h)] \approx \frac{1}{M} \sum_{i=1}^{M} J(\boldsymbol{\theta}|h_i),$$

where h_i is an occurrence of the context and M is the total number of context occurrences.

Although setting Z_h to 1 generally works well in our experiment, we find that in certain scenarios, the model is unstable. Experiments show that when the true normalization factor is far away from 1, the cost function may vibrate. To comply with NCE in general, we therefore propose a `ZRegression` layer to predict the normalization constant Z_h dependent on h, instead of treating it as a constant.

The regression layer is computed by

$$Z_h^{-1} = \exp(\boldsymbol{W}_Z^\top \boldsymbol{h} + b_Z),$$

Partitions	Running words
Train (n-gram)	1.6 B
Train (neural LMs)	100 M
Dev	100 K
Test	5 M

Table 2: Statistics of our corpus.

where $\boldsymbol{W}_Z \in \mathbb{R}^C$ and $b_Z \in \mathbb{R}$ are weights and bias for `ZRegression`. Hence, the estimated probability by NCE with `ZRegression` is given by

$$P(w|h) = \exp(s(h, w)) \cdot \exp(\boldsymbol{W}_Z^\top \boldsymbol{h} + b_Z).$$

Note that the `ZRegression` layer does not guarantee normalized probabilities. During validation and testing, we explicitly normalize the probabilities by Equation (1).

4 Evaluation

In this part, we first describe our dataset in Subsection 4.1. We evaluate our learned sparse codes of rare words in Subsection 4.2 and the compressed language model in Subsection 4.3. Subsection 4.4 provides in-depth analysis of the `ZRegression` mechanism.

4.1 Dataset

We used the freely available Wikipedia[4] dump (2014) as our dataset. We extracted plain sentences from the dump and removed all markups. We further performed several steps of preprocessing such as text normalization, sentence splitting, and tokenization. Sentences were randomly shuffled, so that no information across sentences could be used, i.e., we did not consider cached language models. The resulting corpus contains about 1.6 billion running words.

The corpus was split into three parts for training, validation, and testing. As it is typically time-consuming to train neural networks, we sampled a subset of 100 million running words to train neural LMs, but the full training set was used to train the backoff n-gram models. We chose hyperparameters by the validation set and reported model performance on the test set. Table 2 presents some statistics of our dataset.

4.2 Qualitative Analysis of Sparse Codes

To obtain words' sparse codes, we chose 8k common words as the "dictionary," i.e., $B = 8000$.

[4] http://en.wikipedia.org

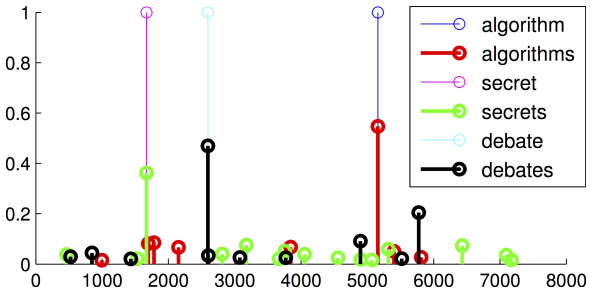

Figure 3: The sparse representations of selected words. The x-axis is the dictionary of 8k common words; the y-axis is the coefficient of sparse coding. Note that *algorithm*, *secret*, and *debate* are common words, each being coded by itself with a coefficient of 1.

We had 2k–42k uncommon words in different settings. We first pretrained word embeddings of both rare and common words, and obtained 200d vectors $\boldsymbol{U}$ and $\boldsymbol{w}$ in Equation (5). The dimension was specified in advance and not tuned. As there is no analytic solution to the objective, we optimized it by Adam (Kingma and Ba, 2014), which is a gradient-based method. To filter out small coefficients around zero, we simply set a value to 0 if it is less than $0.015 \cdot \max\{v \in \boldsymbol{x}\}$. w_α in Equation (6) was set to 1 because we deemed fitting loss and sparsity penalty are equally important. We set w_β in Equation (7) to 0.1, and this hyperparameter is insensitive.

Figure 3 plots the sparse codes of a few selected words. As we see, *algorithm*, *secret*, and *debate* are common words, and each is (sparsely) coded by itself with a coefficient of 1. We further notice that a rare word like *algorithms* has a sparse representation with only a few non-zero coefficient.

Moreover, the coefficient in the code of *algorithms*—corresponding to the base word *algorithm*—is large (~ 0.6), showing that the words *algorithm* and *algorithms* are similar. Such phenomena are also observed with *secret* and *debate*.

The qualitative analysis demonstrates that our approach can indeed learn a sparse code of a word, and that the codes are meaningful.

4.3 Quantitative Analysis of Compressed Language Models

We then used the pre-computed sparse codes to compress neural LMs, which provides quantitative analysis of the learned sparse representations of words. We take perplexity as the performance measurement of a language model, which is defined by

$$\text{PPL} = 2^{-\frac{1}{N}\sum_{i=1}^{N} \log_2 p(w_i|h_i)}$$

where N is the number of running words in the test corpus.

4.3.1 Settings

We leveraged LSTM-RNN as the `Encoding` subnet, which is a prevailing class of neural networks for language modeling (Sundermeyer et al., 2015; Karpathy et al., 2015). The hidden layer was 200d. We used the Adam algorithm to train our neural models. The learning rate was chosen by validation from $\{0.001, 0.002, 0.004, 0.006, 0.008\}$. Parameters were updated with a mini-batch size of 256 words. We trained neural LMs by NCE, where we generated 50 negative samples for each positive data sample in the corpus. All our model variants and baselines were trained with the same pre-defined hyperparameters or tuned over a same candidate set; thus our comparison is fair.

We list our compressed LMs and competing methods as follows.

- **KN3**. We adopted the modified Kneser-Ney smoothing technique to train a 3-gram LM; we used the SRILM toolkit (Stolcke and others, 2002) in out experiment.
- **LBL5**. A **L**og-**B**i**L**inear model introduced in Mnih and Hinton (2007). We used 5 preceding words as context.
- **LSTM-s**. A standard LSTM-RNN language model which is applied in Sundermeyer et al. (2015) and Karpathy et al. (2015). We implemented the LM ourselves based on Theano (Theano Development Team, 2016) and also used NCE for training.
- **LSTM-z**. An LSTM-RNN enhanced with the `ZRegression` mechanism described in Section 3.4.
- **LSTM-z,wb**. Based on LSTM-z, we compressed word embeddings in `Embedding` and the output weights and biases in `Prediction`.
- **LSTM-z,w**. In this variant, we did not compress the bias term in the output layer. For each word in $\mathcal{C}$, we assigned an independent bias parameter.

4.3.2 Performance

Tables 3 shows the perplexity of our compressed model and baselines. As we see, LSTM-based LMs significantly outperform the log-bilinear

Vocabulary	10k	22k	36k	50k

LSTM-z,wb	17.80	59.44	73.61	79.95

Table 4: Memory reduction (%) by our proposed methods in comparison with the uncompressed model LSTM-z. The memory of sparse codes are included.

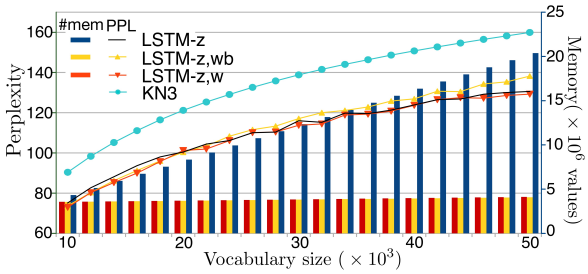

Figure 4: Fine-grained plot of performance (perplexity) and memory consumption (including sparse codes) versus the vocabulary size.

model as well as the backoff 3-gram LM, even if the 3-gram LM is trained on a much larger corpus with 1.6 billion words. The `ZRegression` mechanism improves the performance of LSTM to a large extent, which is unexpected. Subsection 4.4 will provide more in-depth analysis.

Regarding the compression method proposed in this paper, we notice that LSTM-z,wb and LSTM-z,w yield similar performance to LSTM-z. In particular, LSTM-z,w outperforms LSTM-z in all scenarios of different vocabulary sizes. Moreover, both LSTM-z,wb and LSTM-z,w can reduce the memory consumption by up to 80% (Table 4).

We further plot in Figure 4 the model performance (lines) and memory consumption (bars) in a fine-grained granularity of vocabulary sizes. We see such a tendency that compressed LMs (LSTM-z,wb and LSTM-z,w, yellow and red lines) are generally better than LSTM-z (black line) when we have a small vocabulary. However, LSTM-z,wb is slightly worse than LSTM-z if the vocabulary size is greater than, say, 20k. The LSTM-z,w remains comparable to LSTM-z as the vocabulary grows.

To explain this phenomenon, we may imagine that the compression using sparse codes has two effects: it loses information, but it also enables more accurate estimation of parameters especially for rare words. When the second factor dominates, we can reasonably expect a high performance of the compressed LM.

From the bars in Figure 4, we observe that traditional LMs have a parameter space growing linearly with the vocabulary size. But the number of parameters in our compressed models does not increase—or strictly speaking, increases at an extremely small rate—with vocabulary.

These experiments show that our method can largely reduce the parameter space with even performance improvement. The results also verify that the sparse codes induced by our model indeed capture meaningful semantics and are potentially useful for other downstream tasks.

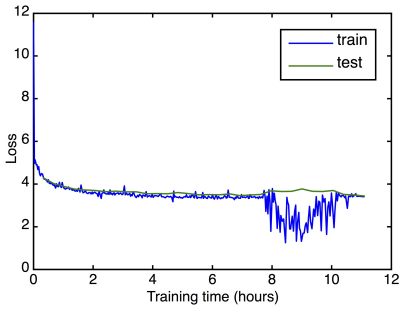
4.4 Effect of `ZRegression`

We next analyze the effect of `ZRegression` for NCE training. As shown in Figure 5a, the training process becomes unstable after processing 70% of the dataset: the training loss vibrates significantly, whereas the test loss increases.

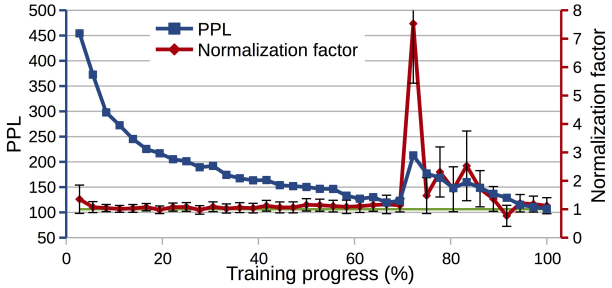
We find a strong correlation between unstableness and the Z_h factor in Equation (10), i.e., the sum of unnormalized probability (Figure 5b). Theoretical analysis shows that the Z_h factor tends to be self-normalized even though it is not forced to (Gutmann and Hyvärinen, 2012). However, problems would occur, should it fail.

In traditional methods, NCE jointly estimates normalization factor Z and model parameters (Gutmann and Hyvärinen, 2012). For language modeling, Z_h dependents on context h. Mnih and Teh (2012) propose to estimate a separate Z_h based on two history words (analogous to 3-gram), but their approach hardly scales to RNNs because of the exponential number of different combinations of history words.

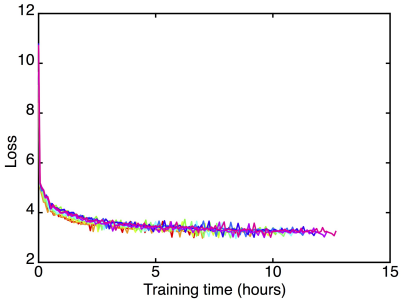
We propose the `ZRegression` mechanism in Section 3.4, which can estimate the Z_h factor well (Figure 5d) based on the history vector $\boldsymbol{h}$. In this way, we manage to stabilize the training process (Figure 5c) and improve the performance by



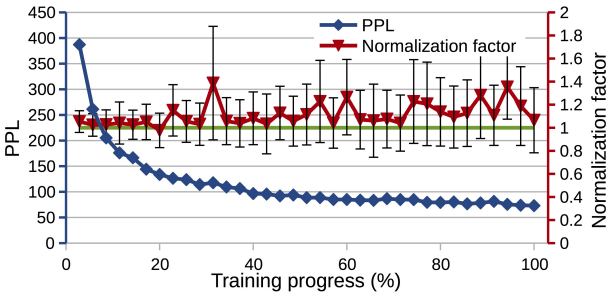
(a) Training/test loss vs. training time w/o `ZRegression`.



(b) The validation perplexity and normalization factor Z_h w/o `ZRegression`.



(c) Training loss vs. training time w/ `ZRegression` of different runs.



(d) The validation perplexity and normalization factor Z_h w/ `ZRegression`.

Figure 5: Analysis of `ZRegression`.

a large margin, as has shown in Table 3.

It should be mentioned that `ZRegression` is not specific to model compression and is generally applicable to other neural LMs trained by NCE.

5 Conclusion

In this paper, we proposed an approach to represent rare words by sparse linear combinations of common ones. Based on such combinations, we managed to compress an LSTM language model (LM), where memory does not increase with the vocabulary size except a bias and a sparse code for each word. Our experimental results also show that the compressed LM has yielded a better performance than the uncompressed base LM.

Intrinsic Subspace Evaluation of Word Embedding Representations

Yadollah Yaghoobzadeh and **Hinrich Schütze**

Abstract

We introduce a new methodology for intrinsic evaluation of word representations. Specifically, we identify four fundamental criteria based on the characteristics of natural language that pose difficulties to NLP systems; and develop tests that directly show whether or not representations contain *the subspaces necessary to satisfy these criteria*. Current intrinsic evaluations are mostly based on the overall similarity or *full-space similarity* of words and thus view vector representations as *points*. We show the limits of these point-based intrinsic evaluations. We apply our evaluation methodology to the comparison of a count vector model and several neural network models and demonstrate important properties of these models.

1 Introduction

Distributional word representations or *embeddings* are currently an active area of research in natural language processing (NLP). The motivation for embeddings is that knowledge about words is helpful in NLP. Representing words as vocabulary indexes may be a good approach if large training sets allow us to learn everything we need to know about a word to solve a particular task; but in most cases it helps to have a representation that contains distributional information and allows inferences like: "above" and "below" have similar syntactic behavior or "engine" and "motor" have similar meaning.

Several methods have been introduced to assess the quality of word embeddings. We distinguish two different types of evaluation in this paper: (i) *extrinsic evaluation* evaluates embeddings in an NLP application or task and (ii) *intrinsic evaluation* tests the quality of representations independent of a specific NLP task.

Each single word is a combination of a large number of morphological, lexical, syntactic, semantic, discourse and other features. Its embedding should accurately and consistently represent these features, and ideally a good evaluation method must clarify this and give a way to analyze the results. The goal of this paper is to build such an evaluation.

Extrinsic evaluation is a valid methodology, but it does not allow us to understand the properties of representations without further analysis; e.g., if an evaluation shows that embedding A works better than embedding B on a task, then that is not an analysis of the causes of the improvement. Therefore, extrinsic evaluations do not satisfy our goals.

Intrinsic evaluation analyzes the generic quality of embeddings. Currently, this evaluation mostly is done by testing overall distance/similarity of words in the embedding space, i.e., it is based on viewing word representations as points and then computing *full-space similarity*. The assumption is that the high dimensional space is smooth and similar words are close to each other. Several datasets have been developed for this purpose, mostly the result of human judgement; see (Baroni et al., 2014) for an overview. We refer to these evaluations as *point-based* and as *full-space* because they consider embeddings as points in the space – sub-similarities in subspaces are generally ignored.

Point-based intrinsic evaluation computes a score based on the full-space similarity of two words: a single number that generally does not say anything about the underlying reasons for a lower or higher value of full-space similarity. This makes it hard to interpret the results of point-based evaluation and may be the reason that contradictory results have been published; e.g., based on

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 236–246,
Berlin, Germany, August 7-12, 2016.

point-based evaluation, some papers have claimed that count-based representations perform as well as learning-based representations (Levy and Goldberg, 2014a). Others have claimed the opposite (e.g., Mikolov et al. (2013), Pennington et al. (2014), Baroni et al. (2014)).

Given the limits of current evaluations, we propose a new methodology for intrinsic evaluation of embeddings by identifying generic fundamental criteria for embedding models that are important for representing features of words accurately and consistently. We develop corpus-based tests using supervised classification that directly show whether the representations contain the information necessary to meet the criteria or not. The fine-grained corpus-based supervision makes the sub-similarities of words important by looking at the subspaces of word embeddings relevant to the criteria, and this enables us to give direct insights into properties of representation models.

2 Related Work

Baroni et al. (2014) evaluate embeddings on different intrinsic tests: similarity, analogy, synonym detection, categorization and selectional preference. Schnabel et al. (2015) introduce tasks with more fine-grained datasets. These tasks are unsupervised and generally based on cosine similarity; this means that only the overall direction of vectors is considered or, equivalently, that *words are modeled as points* in a space and only their full-space distance/closeness is considered. In contrast, we test embeddings in a classification setting and *different subspaces of embeddings are analyzed*. Tsvetkov et al. (2015) evaluate embeddings based on their correlations with WordNet-based linguistic embeddings. However, correlation does not directly evaluate how accurately and completely an application can extract a particular piece of information from an embedding.

Extrinsic evaluations are also common (cf. (Li and Jurafsky, 2015; Köhn, 2015; Lai et al., 2015)). Li and Jurafsky (2015) conclude that embedding evaluation must go beyond human-judgement tasks like similarity and analogy. They suggest to evaluate on NLP tasks. Köhn (2015) gives similar suggestions and also recommends the use of supervised methods for evaluation. Lai et al. (2015) evaluate embeddings in different tasks with different setups and show the contradictory results of embedding models on different tasks. Idiosyncrasies of different downstream tasks can affect extrinsic evaluations and result in contradictions.

3 Criteria for word representations

Each word is a combination of different properties. Depending on the language, these properties include lexical, syntactic, semantic, world knowledge and other features. We call these properties *facets*. The ultimate goal is to learn representations for words that accurately and consistently contain these facets. Take the facet gender (GEN) as an example. We call a representation 100% *accurate* for GEN if information it contains about GEN is always accurate; we call the representation 100% *consistent* for GEN if the representation of every word that has a GEN facet contains this information.

We now introduce four important criteria that a representation must satisfy to represent facets accurately and consistently. These criteria are applied across different problems that NLP applications face in the effective use of embeddings.

Nonconflation. A word embedding must keep the evidence from different local contexts separate – "do not conflate" – because each context can infer specific facets of the word. Embeddings for different word forms with the same stem, like plural and singular forms or different verb tenses, are examples vulnerable to conflation because they occur in similar contexts.

Robustness against sparseness. One aspect of natural language that poses great difficulty for statistical modeling is sparseness. Rare words are common in natural language and embedding models must learn useful representations based on a small number of contexts.

Robustness against ambiguity. Another central problem when processing words in NLP is lexical ambiguity (Cruse, 1986; Zhong and Ng, 2010). Polysemy and homonymy of words can make it difficult for a statistical approach to generalize and infer well. Embeddings should fully represent all senses of an ambiguous word. This criterion becomes more difficult to satisfy as distributions of senses become more skewed, but a robust model must be able to overcome this.

Accurate and consistent representation of multifacetedness. This criterion addresses settings with large numbers of facets. It is based on the following linguistic phenomenon, a phenomenon that occurs frequently crosslinguistically

(Comrie, 1989). (i) Words have a large number of facets, including phonetic, morphological, syntactic, semantic and topical properties. (ii) Each facet by itself constitutes a small part of the overall information that a representation should capture about a word.

4 Experimental setup and results

We now design experiments to directly evaluate embeddings on the four criteria. We proceed as follows. First, we design a probabilistic context free grammar (PCFG) that generates a corpus that is a manifestation of the underlying phenomenon. Then we train our embedding models on the corpus. The embeddings obtained are then evaluated in a classification setting, in which we apply a linear SVM (Fan et al., 2008) to classify embeddings. Finally, we compare the classification results for different embedding models and analyze and summarize them.

Selecting embedding models. Since this paper is about developing a new evaluation methodology, the choice of models is not important as long as the models can serve to show that the proposed methodology reveals interesting differences with respect to the criteria.

On the highest level, we can distinguish two types of distributional representations. *Count vectors* (Sahlgren, 2006; Baroni and Lenci, 2010; Turney and Pantel, 2010) live in a high-dimensional vector space in which each dimension roughly corresponds to a (weighted) count of cooccurrence in a large corpus. *Learned vectors* are learned from large corpora using machine learning methods: unsupervised methods such as LSI (e.g., Deerwester et al. (1990), Levy and Goldberg (2014b)) and supervised methods such as neural networks (e.g., Mikolov et al. (2013)) and regression (e.g., Pennington et al. (2014)). Because of the recent popularity of learning-based methods, we consider one count-based and five learning-based distributional representation models.

The learning-based models are: (i) vLBL (henceforth: LBL) (vectorized log-bilinear language model) (Mnih and Kavukcuoglu, 2013), (ii) SkipGram (henceforth: SKIP) (skipgram bag-of-word model), (iii) CBOW (continuous bag-of-word model (Mikolov et al., 2013), (iv) Structured SkipGram (henceforth SSKIP), (Ling et al., 2015) and CWindow (henceforth CWIN) (continuous window model) (Ling et al., 2015). These models learn word embeddings for input and target spaces using neural network models.

1	$P(aVb\|S)$	=	1/4	
2	$P(bVa\|S)$	=	1/4	
3	$P(aWa\|S)$	=	1/8	
4	$P(aWb\|S)$	=	1/8	
5	$P(bWa\|S)$	=	1/8	
6	$P(bWb\|S)$	=	1/8	
7	$P(v_i\|V)$	=	1/5	$0 \leq i \leq 4$
8	$P(w_i\|W)$	=	1/5	$0 \leq i \leq 4$

Figure 1: Global conflation grammar. Words v_i occur in a subset of the contexts of words w_i, but the global count vector signatures are the same.

For a given context, represented by the input space representations of the left and right neighbors $\vec{v}_{i-1}$ and $\vec{v}_{i+1}$, LBL, CBOW and CWIN predict the target space $\vec{v}_i$ by combining the contexts. LBL combines $\vec{v}_{i-1}$ and $\vec{v}_{i+1}$ linearly with position dependent weights and CBOW (resp. CWIN) combines them by adding (resp. concatenation). SKIP and SSKIP predict the context words v_{i-1} or v_{i+1} given the input space $\vec{v}_i$. For SSKIP, context words are in different spaces depending on their position to the input word. In summary, CBOW and SKIP are learning embeddings using bag-of-word (BoW) models, but the other three, CWIN, SSKIP and LBL, are using position dependent models. We use `word2vec`[1] for SKIP and CBOW, `wang2vec`[2] for SSKIP and CWIN, and Lai et al. (2015)'s implementation[3] for LBL.

The count-based model is position-sensitive PPMI, Levy and Goldberg (2014a)'s explicit vector space representation model.[4] For a vocabulary of size V, the representation $\vec{w}$ of w is a vector of size $4V$, consisting of four parts corresponding to the relative positions $r \in \{-2, -1, 1, 2\}$ with respect to occurrences of w in the corpus. The entry for dimension word v in the part of $\vec{w}$ corresponding to relative position r is the PPMI (positive pointwise mutual information) weight of w and v for that relative position. The four parts of the vector are length normalized. In this paper, we use only two relative positions: $r \in \{-1, 1\}$, so each $\vec{w}$ has two parts, corresponding to immediate left and right neighbors.

4.1 Nonconflation

Grammar. The PCFG grammar shown in Figure 1 generates v_i words that occur in two types of contexts: a-b (line 1) and b-a (line 2); and w_i words that also occur in these two contexts (lines 4 and 5), but in addition occur in a-a (line 3) and b-b (line 6) contexts. As a result, the set of contexts in which v_i and w_i occur is different, but if we simply count the number of occurrences in the contexts, then v_i and w_i cannot be distinguished.

Dataset. We generated a corpus of 100,000 sentences. Words that can occur in a-a and b-b contexts constitute the positive class, all other words the negative class. The words v_3, v_4, w_3, w_4 were assigned to the test set, all other words to the training set.

Results. We learn representations of words by our six models and train one SVM per model; it takes a word representation as input and outputs +1 (word can occur in a-a/b-b) or -1 (it cannot). The SVMs trained on PPMI and CBOW representations assigned all four test set words to the negative class; in particular, w_3 and w_4 were incorrectly classified. Thus, the accuracy of classification for these models (50%) was not better than random. The SVMs trained on LBL, SSKIP, SSKIP and CWIN representations assigned all four test set words to the correct class: v_3 and v_4 were assigned to the negative class and w_3 and w_4 were assigned to the positive class.

Discussion. The property of embedding models that is relevant here is that PPMI is an *aggregation model*, which means it calculates aggregate statistics for each word and then computes the final word embedding from these aggregate statistics. In contrast, all our learning-based models are *iterative models*: they iterate over the corpus and each local context of a word is used as a training instance for learning its embedding.

For iterative models, it is common to use composition of words in the context, as in LBL, CBOW and CWIN. Non-compositional iterative models like SKIP and SSKIP are also popular. Aggregation models can also use composite features from context words, but these features are too sparse to be useful. The reason that the model of Agirre et al. (2009) is rarely used is precisely its inability to deal with sparseness. All widely used distributional models employ individual word occurrences as basic features.

The bad PPMI results are explained by the fact

1	$P(AVB\|S)$	=	1/2	
2	$P(CWD\|S)$	=	1/2	
3	$P(a_i\|A)$	=	1/10	$0 \leq i \leq 9$
4	$P(b_i\|B)$	=	1/10	$0 \leq i \leq 9$
5	$P(c_i\|C)$	=	1/10	$0 \leq i \leq 9$
6	$P(d_i\|D)$	=	1/10	$0 \leq i \leq 9$
7	$P(v_i\|V)$	=	1/10	$0 \leq i \leq 9$
8	$P(w_i\|W)$	=	1/10	$0 \leq i \leq 9$
9	$L' =$	$L(S)$		
10		$\cup \{a_i u_i b_i \| 0 \leq i \leq 9\}$		
11		$\cup \{c_i x_i d_i \| 0 \leq i \leq 9\}$		

Figure 2: In language L', frequent v_i and rare u_i occur in a-b contexts; frequent w_i and rare x_i occur in c-d contexts. Word representations should encode possible contexts (a-b vs. c-d) for both frequent and rare words.

that it is an aggregation model: the PPMI model cannot distinguish two words with the same global statistics – as is the case for, say, v_3 and w_3. The bad result of CBOW is probably connected to its weak (addition) composition of context, although it is an iterative compositional model. Simple representation of context words with iterative updating (through backpropagation in each training instance), can influence the embeddings in a way that SKIP and SSKIP get good results, although they are non-compositional.

As an example of conflation occurring in the English Wikipedia, consider this simple example. We replace all single digits by "7" in tokenization. We learn PPMI embeddings for the tokens and see that among the one hundred nearest neighbors of "7" are the days of the week, e.g., "Friday". As an example of a conflated feature consider the word "falls" occurring immediately to the right of the target word. The weekdays as well as single digits often have the immediate right neighbor "falls" in contexts like "Friday falls on a public holiday" and "2 out of 3 falls match" – tokenized as "7 out of 7 falls match" – in World Wrestling Entertainment (WWE). The left contexts of "Friday" and "7" are different in these contexts, but the PPMI model does not record this information in a way that would make the link to "falls" clear.

4.2 Robustness against sparseness

Grammar. The grammar shown in Figure 2 generates frequent v_i and rare u_i in a-b contexts (lines 1 and 9); and frequent w_i and rare x_i in c-d contexts (lines 2 and 10). The language generated by the PCFG on lines 1–8 is merged on lines 9–11 with the ten contexts $a_0u_0b_0 \ldots a_9u_9b_9$ (line 9)

and the ten contexts $c_0x_0d_0 \ldots c_9x_9d_9$ (line 10); that is, each of the u_i and x_i occurs exactly once in the merged language L', thus modeling the phenomenon of sparseness.

Dataset. We generated a corpus of 100,000 sentences using the PCFG (lines 1–8) and added the 20 rare sentences (lines 9–11). We label all words that can occur in c-d contexts as positive and all other words as negative. The singleton words u_i and x_i were assigned to the test set, all other words to the training set.

Results. After learning embeddings with different models, the SVM trained on PPMI representations assigned all twenty test words to the negative class. This is the correct decision for the ten u_i (since they cannot occur in a c-d context), but the incorrect decision for the x_i (since they can occur in a c-d context). Thus, the accuracy of classification was 50% and not better than random. The SVMs trained on learning-based representations classified all twenty test words correctly.

Discussion. Representations of rare words in the PPMI model are sparse. The PPMI representations of the u_i and x_i only contain two nonzero entries, one entry for an a_i or c_i (left context) and one entry for a b_i or d_i (right context). Given this sparseness, it is not surprising that representations are not a good basis for generalization and PPMI accuracy is random.

In contrast, learning-based models learn that the a_i, b_i, c_i and d_i form four different distributional classes. The final embeddings of the a_i after learning is completed are all close to each other and the same is true for the other three classes. Once the similarity of two words in the same distributional class (say, the similarity of a_5 and a_7) has been learned, the contexts for the u_i (resp. x_i) look essentially the same to embedding models as the contexts of the v_i (resp. w_i). Thus, the embeddings learned for the u_i will be similar to those learned for the v_i. This explains why learning-based representations achieve perfect classification accuracy.

This sparseness experiment highlights an important difference between count vectors and learned vectors. Count vector models are less robust in the face of sparseness and noise because they base their representations on individual contexts; the overall corpus distribution is only weakly taken into account, by way of PPMI weighting. In contrast, learned vector models make much better use of the overall corpus distribution and they can leverage second-order effects for learning improved representations. In our example, the second order effect is that the model first learns representations for the a_i, b_i, c_i and d_i and then uses these as a basis for inferring the similarity of u_i to v_i and of x_i to w_i.

1	$P(AV_1B\|S)$	=10/20	
2	$P(CW_1D\|S)$	=9/20	
3	$P(CW_2D\|S)$	$=\beta\cdot$1/20	
4	$P(AW_2B\|S)$	$=(1-\beta)\cdot$1/20	
5	$P(a_i\|A)$	=1/10	$0 \leq i \leq 9$
6	$P(b_i\|B)$	=1/10	$0 \leq i \leq 9$
7	$P(c_i\|C)$	=1/10	$0 \leq i \leq 9$
8	$P(d_i\|D)$	=1/10	$0 \leq i \leq 9$
9	$P(v_i\|V_1)$	=1/50	$0 \leq i \leq 49$
10	$P(w_i\|W_1)$	=1/45	$5 \leq i \leq 49$
11	$P(w_i\|W_2)$	=1/5	$0 \leq i \leq 4$

Figure 3: Ambiguity grammar. v_i and $w_5 \ldots w_{49}$ occur in a-b and c-d contexts only, respectively. $w_0 \ldots w_4$ are ambiguous and occur in both contexts.

4.3 Robustness against ambiguity

Grammar. The grammar in Figure 3 generates two types of contexts that we interpret as two different meanings: a-b contexts (lines 1,4) and c-d contexts (lines 2, 3). v_i occur only in a-b contexts (line 1), $w_5 \ldots w_{49}$ occur only in c-d contexts (line 2); thus, they are unambiguous. $w_0 \ldots w_4$ are ambiguous and occur with probability β in c-d contexts (line 3) and with probability $(1-\beta)$ in a-b contexts (lines 3, 4). The parameter β controls the skewedness of the sense distribution; e.g., the two senses are equiprobable for $\beta = 0.5$ and the second sense (line 4) is three times as probable as the first sense (line 3) for $\beta = 0.25$.

Dataset. The grammar specified in Figure 3 was used to generate a training corpus of 100,000 sentences. Label criterion: A word is labeled positive if it can occur in a c-d context, as negative otherwise. The test set consists of the five ambiguous words $w_0 \ldots w_4$. All other words are assigned to the training set.

Linear SVMs were trained for the binary classification task on the train set. 50 trials of this experiment were run for each of eleven values of β: $\beta = 2^{-\alpha}$ where $\alpha \in \{1.0, 1.1, 1.2, \ldots, 2.0\}$. Thus, for the smallest value of α, $\alpha = 1.0$, the two senses have the same frequency; for the largest value of α, $\alpha = 2.0$, the dominant sense is three times as frequent as the less frequent sense.

Results. Figure 4 shows accuracy of the classi-

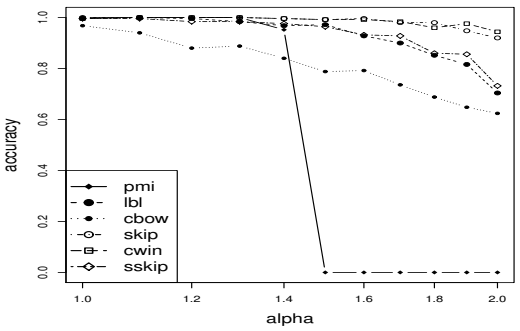

Figure 4: SVM classification results for the ambiguity dataset. X-axis: $\alpha = -\log_2 \beta$. Y-axis: classification accuracy:

fication on the test set: the proportion of correctly classified words out of a total of 250 (five words each in 50 trials).

All models perform well for balanced sense frequencies; e.g., for $\alpha = 1.0, \beta = 0.5$, the SVMs were all close to 100% accurate in predicting that the w_i can occur in a c-d context. PPMI accuracy falls steeply when α is increased from 1.4 to 1.5. It has a 100% error rate for $\alpha \geq 1.5$. Learning-based models perform better in the order CBOW (least robust), LBL, SSKIP, SKIP, CWIN (most robust). Even for $\alpha = 2.0$, CWIN and SKIP are still close to 100% accurate.

Discussion. The evaluation criterion we have used here is a classification task. The classifier attempts to answer a question that may occur in an application – can this word be used in this context? Thus, the evaluation criterion is: does the word representation contain a specific type of information that is needed for the application.

Another approach to ambiguity is to compute multiple representations for a word, one for each sense. We generally do not yet know what the sense of a word is when we want to use its word representation, so data-driven approaches like clustering have been used to create representations for different usage clusters of words that may capture some of its senses. For example, Reisinger and Mooney (2010) and Huang et al. (2012) cluster the contexts of each word and then learn a different representation for each cluster. The main motivation for this approach is the assumption that single-word distributional representations cannot represent all senses of a word well (Huang et al., 2012). However, Li and Jurafsky (2015) show that simply increasing the dimensionality of single-representation gets comparable results to using multiple-representation. Our results confirm that a single embedding can be robust against ambiguity, but also show the main challenge: skewness of sense distribution.

Figure 5: This grammar generates nouns ($x_i^{\text{n}\cdot}$) and adjectives ($x_i^{\text{a}\cdot}$) with masculine (x_i^{m}) and feminine (x_i^{f}) gender as well as paradigm features u_i. μ maps each U to one of $\{u_0 \ldots u_4\}$. μ is randomly initialized and then kept fixed.

4.4 Accurate and consistent representation of multifacetedness

Grammar. The grammar shown in Figure 5 models two syntactic categories, nouns and adjectives, whose left context is highly predictable: it is one of five left context words n_i (resp. a_i) for nouns, see lines 1, 3, 5 (resp. for adjectives, see lines 2, 4, 6). There are two grammatical genders: feminine (corresponding to the two symbols F_n and F_a) and masculine (corresponding to the two symbols M_n and M_a). The four combinations of syntactic category and gender are equally probable (lines 1–4). In addition to *gender*, nouns and adjectives are distinguished with respect to *morphological paradigm*. Line 7 generates one of five feminine nouns (x_i^{nf}) and the corresponding paradigm marker U_i^{nf}. A noun has two equally probable right contexts: a context indicating its gender (line 8) and a context indicating its paradigm (line 9). μ is a function that maps each U to one of five morphological paradigms $\{u_0 \ldots u_4\}$. μ is randomly initialized before a corpus is generated and kept fixed.

The function μ models the assignment of

paradigms to nouns and adjectives. Nouns and adjectives can have different (or the same) paradigms, but for a given noun or adjective the paradigm is fixed and does not change. Lines 7–9 generate gender and paradigm markers for feminine nouns, for which we use the symbols x_i^{nf}. Lines 10–18 cover the three other cases: masculine nouns (x_i^{nm}), feminine adjectives (x_i^{af}) and masculine adjectives (x_i^{am}).

Dataset. We perform 10 trials. In each trial, μ is initialized randomly and a corpus of 100,000 sentences is generated. The train set consists of the feminine nouns (x_i^{nf}, line 7) and the masculine nouns (x_i^{nm}, line 13). The test set consists of the feminine (x_i^{af}) and masculine (x_i^{am}) adjectives.

Results. Embeddings have been learned, SVMs are trained on the binary classification task feminine vs. masculine and evaluated on test. There was not a single error: accuracy of classifications is 100% for all embedding models.

Discussion. The facet gender is indicated directly by the distribution and easy to learn. For a noun or adjective x, we simply have to check whether f or m occurs to its right anywhere in the corpus. PPMI stores this information in two dimensions of the vectors and the SVM learns this fact perfectly. The encoding of "f or m occurs to the right" is less direct in the learning-based representation of x, but the experiment demonstrates that they also reliably encode it and the SVM reliably picks it up.

It would be possible to encode the facet in just one bit in a manually designed representation. While all representations are less compact than a one-bit representation – PPMI uses two real dimensions, learning-based models use an activation pattern over several dimensions – it is still true that most of the capacity of the embeddings is used for encoding facets other than gender: syntactic categories and paradigms. Note that there are five different instances each of feminine/masculine adjectives, feminine/masculine nouns and u_i words, but only two gender indicators: f and m. This is a typical scenario across languages: words are distinguished on a large number of morphological, grammatical, semantic and other dimensions and each of these dimensions corresponds to a small fraction of the overall knowledge we have about a given word.

Point-based tests do not directly evaluate specific facets of words. In similarity datasets, there is no individual test on facets – only full-space similarity is considered. There are test cases in analogy that hypothetically evaluate specific facets like gender of words, as in king-man+woman=queen. However, it does not consider the impact of other facets and assumes the only difference of "king" and "queen" is gender. A clear example that words usually differ on many facets, not just one, is the analogy: London:England $\sim$ Ankara:Turkey. *political-capital-of* applies to both, *cultural-capital-of* only to London:England since Istanbul is the cultural capital of Turkey.

To make our argument more clear, we designed an additional experiment that tries to evaluate gender in our dataset based on similarity and analogy methods. In the *similarity evaluation*, we search for the nearest neighbor of each word and accuracy is the proportion of nearest neighbors that have the same gender as the search word. In the *analogy evaluation*, we randomly select triples of the form $<x_i^{c_1 g_1}, x_j^{c_1 g_2}, x_k^{c_2 g_2}>$ where $(c_1, c_2) \in \{(\text{noun}, \text{adjective}), (\text{adjective}, \text{noun})\}$ and $(g_1, g_2) \in \{(\text{masculine}, \text{feminine}), (\text{feminine}, \text{masculine})\}$. We then compute $\vec{s} = \vec{x}_i^{c_1 g_1} - \vec{x}_j^{c_1 g_2} + \vec{x}_k^{c_2 g_2}$ and identify the word whose vector is closest to $\vec{s}$ where the three vectors $\vec{x}_i^{c_1 g_1}$, $\vec{x}_j^{c_1 g_2}$, $\vec{x}_k^{c_2 g_2}$ are excluded. If the nearest neighbor of $\vec{s}$ is of type $\vec{x}_l^{c_2 g_1}$, then the search is successful; e.g., for $\vec{s} = \vec{x}_i^{\text{nf}} - \vec{x}_j^{\text{nm}} + \vec{x}_k^{\text{am}}$, the search is successful if the nearest neighbor is feminine. We did this evaluation on the same test set for PPMI and LBL embedding models. Error rates were 29% for PPMI and 25% for LBL (similarity) and 16% for PPMI and 14% for LBL (analogy). This high error, compared to 0% error for SVM classification, indicates it is not possible to determine the presence of a low entropy facet accurately and consistently when full-space similarity and analogy are used as test criteria.

5 Analysis

In this section, we first summarize and analyze the lessons we learned through experiments in Section 4. After that, we show how these lessons are supported by a real natural-language corpus.

5.1 Learned lessons

(i) Two words with clearly different context distributions should receive different representations. Aggregation models fail to do so by calculating

	all entities		head entities		tail entities	
	MLP	1NN	MLP	1NN	MLP	1NN
PPMI	61.6	44.0	69.2	63.8	43.0	28.5
LBL	63.5	51.7	72.7	66.4	44.1	32.8
CBOW	63.0	53.5	71.7	69.4	39.1	29.9
CWIN	66.1	53.0	73.5	68.6	46.8	31.4
SKIP	64.5	**57.1**	69.9	**71.5**	**49.8**	**34.0**
SSKIP	**66.2**	52.8	**73.9**	68.5	45.5	31.4

Table 1: Entity typing results using embeddings learned with different models.

global statistics.

(ii) Embedding learning can have different effectiveness for sparse vs. non-sparse events. Thus, models of representations should be evaluated with respect to their ability to deal with sparseness; evaluation data sets should include rare as well as frequent words.

(iii) Our results in Section 4.3 suggest that single-representation approaches can indeed represent different senses of a word. We did a classification task that roughly corresponds to the question: does this word have a particular meaning? A representation can fail on similarity judgement computations because less frequent senses occupy a small part of the capacity of the representation and therefore have little impact on full-space similarity values. Such a failure does not necessarily mean that a particular sense is not present in the representation and it does not necessarily mean that single-representation approaches perform poor on real-world tasks. However, we saw that even though single-representations do well on balanced senses, they can pose a challenge for ambiguous words with skewed senses.

(iv) Lexical information is complex and multifaceted. In point-based tests, all dimensions are considered together and their ability to evaluate specific facets or properties of a word is limited. The full-space similarity of a word may be highest to a word that has a different value on a low-entropy facet. Any good or bad result on these tasks is not sufficient to conclude that the representation is weak. The valid criterion of quality is whether information about the facet is consistently and accurately stored.

5.2 Extrinsic evaluation: entity typing

To support the case for sub-space evaluation and also to introduce a new extrinsic task that uses the embeddings directly in supervised classification, we address a *fine-grained entity typing* task.

Learning taxonomic properties or types of words has been used as an evaluation method for word embeddings (Rubinstein et al., 2015). Since available word typing datasets are quite small (cf. Baroni et al. (2014), Rubinstein et al. (2015)), entity typing can be a promising alternative, which enables to do supervised classification instead of unsupervised clustering. Entities, like other words, have many properties and therefore belong to several semantic types, e.g., "Barack Obama" is a POLITICIAN, AUTHOR and AWARD_WINNER. We perform entity typing by learning types of knowledge base entities from their embeddings; this requires looking at subspaces because each entity can belong to multiple types.

We adopt the setup of Yaghoobzadeh and Schütze (2015) who present a dataset of Freebase entities;[5] there are 102 types (e.g., POLITICIAN FOOD, LOCATION-CEMETERY) and most entities have several. More specifically, we use a multilayer-perceptron (MLP) with one hidden layer to classify entity embeddings to 102 FIGER types. To show the limit of point-based evaluation, we also experimentally test an entity typing model based on *cosine similarity* of entity embeddings. To each test entity, we assign all types of the entity closest to it in the train set. We call this approach 1NN (kNN for $k = 1$).[6]

We take part of ClueWeb, which is annotated with Freebase entities using automatic annotation of FACC1[7] (Gabrilovich et al., 2013), as our corpus. We then replace all mentions of entities with their Freebase identifier and learn embeddings of words and entities in the same space. Our corpus has around 6 million sentences with at least one annotated entity. We calculate embeddings using our different models. Our hyperparameters: for learning-based models: dim=100, neg=10, iterations=20, window=1, sub=10^{-3}; for PPMI: SVD-dim=100, neg=1, window=1, cds=0.75, sub=10^{-3}, eig=0.5. See (Levy et al., 2015) for more information about the meaning of hyperparameters.

Table 1 gives results on test for all (about 60,000 entities), head (freq $>$ 100; about 12,200 entities) and tail (freq $<$ 5; about 10,000 entities). The MLP models consistently outperform 1NN on

[5] cistern.cis.lmu.de/figment

[6] We tried other values of k, but results were not better.

[7] lemurproject.org/clueweb12/FACC1

all and tail entities. This supports our hypothesis that only part of the information about types that is present in the vectors can be determined by similarity-based methods that use the overall direction of vectors, i.e., full-space similarity.

There is little correlation between results of MLP and 1NN in all and head entities, and the correlation between their results in tail entities is high.[8] For example, for all entities, using 1NN, SKIP is 4.3% (4.1%) better, and using MLP is 1.7% (1.6%) worse than SSKIP (CWIN). The good performance of SKIP on 1NN using cosine similarity can be related to its objective function, which maximizes the cosine similarity of cooccuring token embeddings.

The important question is not similarity, but whether the information about a specific type exists in the entity embeddings or not. Our results confirm our previous observation that a classification by looking at subspaces is needed to answer this question. In contrast, based on full-space similarity, one can infer little about the quality of embeddings. Based on our results, SSKIP and CWIN embeddings contain more accurate and consistent information because MLP classifier gives better results for them. However, if we considered 1NN for comparison, SKIP and CBOW would be superior.

6 Conclusion and future work

We have introduced a new way of evaluating distributional representation models. As an alternative to the common evaluation tasks, we proposed to identify generic criteria that are important for an embedding model to represent properties of words accurately and consistently. We suggested four criteria based on fundamental characteristics of natural language and designed tests that evaluate models on the criteria. We developed this evaluation methodology using PCFG-generated corpora and applied it on a case study to compare different models of learning distributional representations.

While we showed important differences of the embedding models, the goal was not to do a comprehensive comparison of them. We proposed an innovative way of doing intrinsic evaluation of embeddings. Our evaluation method gave direct insight about the quality of embeddings. Additionally, while most intrinsic evaluations consider word vectors as points, we used classifiers that identify different small subspaces of the full space. This is an important desideratum when designing evaluation methods because of the multifacetedness of natural language words: they have a large number of properties, each of which only occupies a small proportion of the full-space capacity of the embedding.

Based on this paper, there are serveral lines of investigation we plan to conduct in the future. (i) We will attempt to support our results on artificially generated corpora by conducting experiments on *real natural language data*. (ii) We will study the *coverage of our four criteria* in evaluating word representations. (iii) We modeled the four criteria using separate PCFGs, but they could also be modeled by one single unified PCFG. One question that arises is then to what extent the four criteria are orthogonal and to what extent interdependent. A single unified grammar may make it harder to interpret the results, but may give additional and more fine-grained insights as to how the performance of embedding models is influenced by different fundamental properties of natural language and their interactions.

Finally, we have made the simplifying assumption in this paper that the best conceptual framework for thinking about embeddings is that the embedding space can be *decomposed into subspaces*: either into completely orthogonal subspaces or – less radically – into partially "overlapping" subspaces. Furthermore, we have made the assumption that the smoothness and robustness properties that are the main reasons why embeddings are used in NLP can be reduced to *similarities in subspaces*. See Rothe et al. (2016) and Rothe and Schütze (2016) for work that makes similar assumptions.

The fundamental assumptions here are decomposability and linearity. The smoothness properties could be much more complicated. However even if this was the case, then much of the general framework of what we have presented in this paper would still apply; e.g., the criterion that a particular facet be fully and correctly represented is as important as before. But the validity of the assumption that embedding spaces can be decomposed into "linear" subspaces should be investigated in the future.

On the Role of Seed Lexicons in Learning Bilingual Word Embeddings

Ivan Vulić and **Anna Korhonen**

Abstract

A shared bilingual word embedding space (SBWES) is an indispensable resource in a variety of cross-language NLP and IR tasks. A common approach to the SBWES induction is to learn a mapping function between monolingual semantic spaces, where the mapping critically relies on a seed word lexicon used in the learning process. In this work, we analyze the importance and properties of seed lexicons for the SBWES induction across different dimensions (i.e., lexicon source, lexicon size, translation method, translation pair reliability). On the basis of our analysis, we propose a simple but effective hybrid bilingual word embedding (BWE) model. This model (HYBWE) learns the mapping between two monolingual embedding spaces using only highly reliable symmetric translation pairs from a seed document-level embedding space. We perform bilingual lexicon learning (BLL) with 3 language pairs and show that by carefully selecting reliable translation pairs our new HYBWE model outperforms benchmarking BWE learning models, all of which use more expensive bilingual signals. Effectively, we demonstrate that a SBWES may be induced by leveraging only a very weak bilingual signal (document alignments) along with monolingual data.

1 Introduction

Dense real-valued vector representations of words or word embeddings (WEs) have recently gained increasing popularity in natural language processing (NLP), serving as invaluable features in a broad range of NLP tasks, e.g., (Turian et al., 2010; Collobert et al., 2011; Chen and Manning, 2014). Several studies have showcased a direct link and comparable performance to "more traditional" distributional models (Turney and Pantel, 2010). Yet the widely used skip-gram model with negative sampling (SGNS) (Mikolov et al., 2013b) is considered as the state-of-the-art word representation model, due to its simplicity, fast training, as well as its solid and robust performance across a wide variety of semantic tasks (Baroni et al., 2014; Levy and Goldberg, 2014b; Levy et al., 2015).

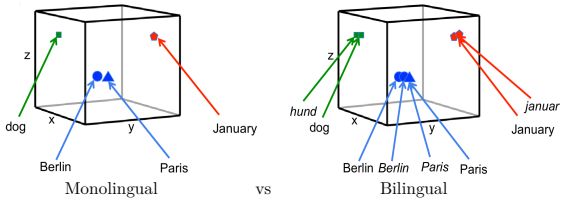

Figure 1: A toy example of a 3-dimensional monolingual vs shared bilingual word embedding space (further SBWES) from Gouws et al. (2015).

Research interest has recently extended to bilingual word embeddings (BWEs). BWE learning models focus on the induction of a *shared bilingual word embedding space* (SBWES) where words from both languages are represented in a uniform language-independent manner such that similar words (regardless of the actual language) have similar representations (see Fig. 1). A variety of BWE learning models have been proposed, differing in the essential requirement of a *bilingual signal* necessary to construct such a SBWES (discussed later in Sect. 2). SBWES may be used to support many tasks, e.g., computing cross-lingual/multilingual semantic word similarity (Faruqui and Dyer, 2014), learning bilingual word lexicons (Mikolov et al., 2013a; Gouws et al., 2015; Vulić et al., 2016), cross-lingual entity linking (Tsai and Roth, 2016),

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 247–257,
Berlin, Germany, August 7-12, 2016.

parsing (Guo et al., 2015; Johannsen et al., 2015), machine translation (Zou et al., 2013), or cross-lingual information retrieval (Vulić and Moens, 2015; Mitra et al., 2016).

BWE models should have two desirable properties: **(P1)** leverage (large) monolingual training sets tied together through a bilingual signal, **(P2)** use as inexpensive bilingual signal as possible in order to learn a SBWES in a scalable and widely applicable manner across languages and domains.

While we provide a classification of related work, that is, different BWE models according to these properties in Sect. 2.1, the focus of this work is on a popular class of models labeled *Post-Hoc Mapping with Seed Lexicons*. These models operate as follows (Mikolov et al., 2013a; Dinu et al., 2015; Lazaridou et al., 2015; Ammar et al., 2016): (1) two separate non-aligned monolingual embedding spaces are induced using any monolingual WE learning model (SGNS is the typical choice), (2) given a *seed lexicon* of word translation pairs as the bilingual signal for training, a mapping function is learned which ties the two monolingual spaces together into a SBWES.

All existing work on this class of models assumes that high-quality training seed lexicons are readily available. In reality, little is understood regarding what constitutes a high quality seed lexicon, even with "traditional" distributional models (Gaussier et al., 2004; Holmlund et al., 2005; Vulić and Moens, 2013). Therefore, in this work we ask *whether BWE learning could be improved by making more intelligent choices when deciding over seed lexicon entries*. In order to do this we delve deeper into the cross-lingual mapping problem by analyzing a spectrum of seed lexicons with respect to controllable parameters such as lexicon source, its size, translation method, and translation pair reliability.

The contributions of this paper are as follows:

(C1) We present a systematic study on the importance of seed lexicons for learning mapping functions between monolingual WE spaces.

(C2) Given the insights gained, we propose a simple yet effective hybrid BWE model HYBWE that removes the need for readily available seed lexicons, and satisfies properties P1 and P2. HYBWE relies on an inexpensive seed lexicon of highly reliable word translation pairs obtained by a document-level BWE model (Vulić and Moens, 2016) from document-aligned comparable data.

(C3) Using a careful pair selection process when constructing a seed lexicon, we show that in the BLL task HYBWE outperforms a BWE model of Mikolov et al. (2013a) which relies on readily available seed lexicons. HYBWE also outperforms state-of-the-art models of (Hermann and Blunsom, 2014b; Gouws et al., 2015) which require sentence-aligned parallel data.

2 Learning SBWES using Seed Lexicons

Given source and target language vocabularies V^S and V^T, all BWE models learn a representation of each word $w \in V^S \sqcup V^T$ in a SBWES as a real-valued vector: $\mathbf{w} = [f_1, \ldots, f_d]$, where $f_k \in \mathbb{R}$ denotes the value for the k-th cross-lingual feature for w within a d-dimensional SBWES. Semantic similarity $sim(w, v)$ between two words $w, v \in V^S \sqcup V^T$ is then computed by applying a similarity function (SF), e.g. cosine (*cos*) on their representations in the SBWES: $sim(w, v) = SF(\mathbf{w}, \mathbf{v}) = cos(\mathbf{w}, \mathbf{v})$.

2.1 Related Work: BWE Models and Bilingual Signals

BWE models may be clustered into four different types according to bilingual signals used in training, and properties P1 and P2 (see Sect. 1). Upadhyay et al. (2016) provide a similar overview of recent bilingual embedding learning architectures regarding different bilingual signals required for the embedding induction.

(Type 1) *Parallel-Only*: This group of BWE models relies on sentence-aligned and/or word-aligned parallel data as the only data source (Zou et al., 2013; Hermann and Blunsom, 2014a; Kočiský et al., 2014; Hermann and Blunsom, 2014b; Chandar et al., 2014). In addition to an expensive bilingual signal (colliding with P2), these models do not leverage larger monolingual datasets for training (not satisfying P1).

(Type 2) *Joint Bilingual Training*: These models jointly optimize two monolingual objectives, with the cross-lingual objective acting as a cross-lingual regularizer during training (Klementiev et al., 2012; Gouws et al., 2015; Soyer et al., 2015; Shi et al., 2015; Coulmance et al., 2015). The idea may be summarized by the simplified formulation (Luong et al., 2015): $\gamma(Mono_S + Mono_T) + \delta Bi$. The monolingual objectives $Mono_S$ and $Mono_T$ ensure that similar words in each language are assigned similar

embeddings and aim to capture the semantic structure of each language, whereas the cross-lingual objective Bi ensures that similar words across languages are assigned similar embeddings. It ties the two monolingual spaces together into a SBWES (thus satisfying P1). Parameters γ and δ govern the influence of the monolingual and bilingual components.[1] The main disadvantage of Type 2 models is the costly parallel data needed for the bilingual signal (thus colliding with P2).

(Type 3) *Pseudo-Bilingual Training*: This set of models requires *document alignments* as bilingual signal to induce a SBWES. Vulić and Moens (2016) create a collection of pseudo-bilingual documents by merging every pair of aligned documents in training data, in a way that preserves important local information: words that appeared next to other words within the same language and those that appeared in the same region of the document across different languages. This collection is then used to train word embeddings with monolingual SGNS from `word2vec`.

With pseudo-bilingual documents, the "context" of a word is redefined as a mixture of neighbouring words (in the original language) and words that appeared in the same region of the document (in the "foreign" language). The bilingual contexts for each word in each document steer the final model towards constructing a SBWES. The advantage over other BWE model types lies in exploiting weaker document-level bilingual signals (satisfying P2), but these models are unable to exploit monolingual corpora during training (unlike Type 2 or Type 4; thus colliding with P1).

(Type 4) *Post-Hoc Mapping with Seed Lexicons*: These models learn post-hoc mapping functions between monolingual WE spaces induced separately for two different languages (e.g., by SGNS). All Type 4 models (Mikolov et al., 2013a; Faruqui and Dyer, 2014; Dinu et al., 2015; Lazaridou et al., 2015) rely on readily available seed lexicons of highly frequent words obtained by e.g. *Google Translate* (GT) to learn the mapping (again colliding with P2), but they are able to satisfy P1.

[1]Type 1 models may be considered a special case of Type 2 models: Setting $\gamma = 0$ reduces Type 2 models to Type 1 models trained solely on parallel data, e.g., (Hermann and Blunsom, 2014b; Chandar et al., 2014). $\gamma = 1$ results in the models from (Klementiev et al., 2012; Gouws et al., 2015; Soyer et al., 2015; Coulmance et al., 2015).

2.2 Post-Hoc Mapping with Seed Lexicons: Methodology and Lexicons

Key Intuition One may infer that a type-*hybrid* procedure which would retain only highly reliable translation pairs obtained by a Type 3 model as a seed lexicon for Type 4 models effectively satisfies both requirements: (P1) unlike Type 1 and Type 3, it can learn from monolingual data and tie two monolingual spaces using the highly reliable translation pairs, (P2) unlike Type 1 and Type 2, it does not require parallel data; unlike Type 4, it does not require external lexicons and translation systems. The only bilingual signal required are document alignments. Therefore, our focus is on novel less expensive Type 4 models.

Overview The standard learning setup we use is as follows: First, two monolingual embedding spaces, $\mathbb{R}^{d_S}$ and $\mathbb{R}^{d_T}$, are induced separately in each of the two languages using a standard monolingual WE model such as CBOW or SGNS. d_S and d_T denote the dimensionality of monolingual WE spaces. The bilingual signal is a seed lexicon, i.e., a list of word translation pairs (x_i, y_i), where $x_i \in V^S$, $y_i \in V^T$, and $\mathbf{x_i} \in \mathbb{R}^{d_S}$, $\mathbf{y_i} \in \mathbb{R}^{d_T}$.

Learning Objectives Training is cast as a multivariate regression problem: it implies learning a function that maps the source language vectors from the training data to their corresponding target language vectors. A standard approach (Mikolov et al., 2013a; Dinu et al., 2015) is to assume a linear map $\mathbf{W} \in \mathbb{R}^{d_S \times d_T}$, where a L_2-regularized least-squares error objective (i.e., ridge regression) is used to learn the map $\mathbf{W}$. The map is learned by solving the following optimization problem (typically by stochastic gradient descent (SGD)):

$$\min_{\mathbf{W} \in \mathbb{R}^{d_S \times d_T}} ||\mathbf{XW} - \mathbf{Y}||_F^2 + \lambda ||\mathbf{W}||_F^2 \quad (1)$$

$\mathbf{X}$ and $\mathbf{Y}$ are matrices obtained through the respective concatenation of source language and target language vectors from training pairs. Once the linear map $\mathbf{W}$ is estimated, any previously unseen source language word vector $\mathbf{x_u}$ may be straightforwardly mapped into the target language embedding space $\mathbb{R}^{d_T}$ as $\mathbf{W x_u}$. After mapping all vectors $\mathbf{x}$, $x \in V^S$, the target embedding space $\mathbb{R}^{d_T}$ in fact serves as SBWES.[2]

[2]Another possible objective (found in the zero-shot learning literature) is a margin-based ranking loss (Weston et al., 2011; Lazaridou et al., 2015). We omit the results with this objective for brevity, and due to the fact that similar trends are observed as with (more standard) linear maps.

Seed Lexicon Source and Translation Method Prior work on post-hoc mapping with seed lexicons used a translation system (i.e., GT) to translate highly frequent English words to other languages such as Czech, Spanish (Mikolov et al., 2013a; Gouws et al., 2015) or Italian (Dinu et al., 2015; Lazaridou et al., 2015). This method presupposes the availability and high quality of such an external translation system. To simulate this setup, we take as a starting point the BNC word frequency list from Kilgarriff (1997) containing 6,318 most frequent English lemmas. The list is then translated to other languages via GT. We call the BNC-based lexicons obtained by employing Google Translate BNC+GT.

In this paper, we propose another option: first, we learn the "first" SBWES (i.e., SBWES-1) using another BWE model (see Sect. 2.1), and then translate the BNC list through SBWES-1 by retaining the nearest cross-lingual neighbor $y_i \in V^T$ for each x_i in the BNC list which is represented in SBWES-1. The pairs (x_i, y_i) constitute the seed lexicon needed for learning the mapping between monolingual spaces, that is, to induce the final SBWES-2.

Although in theory any BWE induction model may be used to induce SBWES-1, we rely on a document-level Type 3 BWE induction model from (Vulić and Moens, 2016), since it requires only document alignments as (weak) bilingual signal. The resulting hybrid BWE induction model (HYBWE) combines the output of a Type 3 model (SBWES-1) and a Type 4 model (SBWES-2). This seed lexicon and BWE learning variant is called BNC+HYB.

Our new hybrid model allows us to also use source language words occurring in SBWES-1 sorted by frequency as seed lexicon source, again leaning on the intuition that higher frequency phenomena are more reliably translated using statistical models. Their translations can also be found through SBWES-1 to obtain seed lexicon pairs (x_i, y_i). This variant is called HFQ+HYB.

Another possibility, recently introduced by Kiros et al. (2015) for vocabulary expansion in monolingual settings, relies on all words shared between two vocabularies to learn the mapping. In this work, we test the ability and limits of such orthographic evidence in cross-lingual settings: seed lexicon pairs are (x_i, x_i), where $x_i \in V^S$ and $x_i \in V^T$. This seed lexicon variant is called ORTHO.

Seed Lexicon Size While all prior reported only results with restricted seed lexicon sizes only (i.e., 1K, 2K and 5K lexicon pairs are used as standard), in this work we provide a full-fledged analysis of the influence of seed lexicon size on the SBWES performance in cross-lingual tasks. More extreme settings are also investigated, in the attempt to answer two important questions: (1) Can a Type 4 SBWES be induced in a limited setting with only a few hundred lexicon pairs available (e.g., 100-500)? (2) Can the Type 4 models profit from the inclusion of more seed lexicon pairs (e.g., more than 5K, even up to 40K-50K lexicon pairs)?

Translation Pair Reliability When building seed lexicons through SBWES-1 (i.e., BNC+HYB and HFQ+HYB methods), it is possible to control for the reliability of translation pairs to be included in the final lexicon, with the idea that the use of only highly reliable pairs can potentially lead to an improved SBWES-2. A simple yet effective reliability reliability feature for translation pairs is the *symmetry constraint* (Peirsman and Padó, 2010; Vulić and Moens, 2013) : two words $x_i \in V^S$ and $y_i \in V^S$ are used as seed lexicon pairs only if they are mutual nearest neighbours given their representations in SBWES-1. The two variants of seed lexicons with only symmetric pairs are BNC+HYB+SYM and HFREQ+HYB+SYM. We also test the variants without the symmetry constraint (i.e., BNC+HYB+ASYM and HFQ+HYB+ASYM).

Even more conservative reliability measures may be applied by exploiting the scores in the lists of translation candidates ranked by their similarity to the cue word x_i. We investigate a symmetry constraint with a *threshold*: two words $x_i \in V^S$ and $y_i \in V^S$ are included as seed lexicon pair (x_i, y_i) iff they are mutual nearest neighbours in SBWES-1 and it holds:

$$sim(x_i, y_i) - sim(x_i, z_i) > THR \quad (2)$$
$$sim(y_i, x_i) - sim(y_i, w_i) > THR \quad (3)$$

where $z_i \in V^T$ is the second best translation candidate for x_i, and $w_i \in V^S$ for y_i. THR is a parameter which specifies the margin between the two best translation candidates. The intuition is that highly unambiguous and monosemous translation pairs (which is reflected in higher score margins) are also highly reliable.[3]

[3]Other (more elaborate) reliability measures exist in the

3 Experimental Setup

Task: Bilingual Lexicon Learning (BLL) After the final SBWES is induced, given a list of n source language words $x_{u1}, \ldots, x_{un}$, the task is to find a target language word t for each x_u in the list using the SBWES. t is the target language word closest to the source language word x_u in the induced SBWES, also known as the *cross-lingual nearest neighbor*. The set of learned n (x_u, t) pairs is then run against a gold standard BLL test set. Following the standard practice (Mikolov et al., 2013a; Dinu et al., 2015), for all Type 4 models, all pairs containing any of the test words $x_{u1}, \ldots, x_{un}$ are removed from training seed lexicons.

Test Sets For each language pair, we evaluate on standard 1,000 ground truth one-to-one translation pairs built for three language pairs: Spanish (ES)-, Dutch (NL)-, Italian (IT)-English (EN) by Vulić and Moens (2013). The dataset is generally considered a benchmarking test set for BLL models that learn from non-parallel data, and is available online.[4] We have also experimented with two other benchmarking BLL test sets (Bergsma and Durme, 2011; Leviant and Reichart, 2015) observing a very similar relative performance of all the models in our comparison.

Evaluation Metrics We measure the BLL performance using the standard *Top 1* accuracy (Acc_1) metric (Gaussier et al., 2004; Mikolov et al., 2013a; Gouws et al., 2015).[5]

Baseline Models To induce SBWES-1, we resort to document-level embeddings of Vulić and Moens (2016) (Type 3). We also compare to results obtained directly by their model (BWESG) to measure the performance gains with HYBWE.

To compare with a representative Type 2 model, we opt for the BilBOWA model of Gouws et al. (2015) due to its solid performance and robustness in the BLL task when trained on general-domain corpora such as Wikipedia (Luong et al., 2015), its reduced complexity reflected in fast computations on massive datasets, as well as its public availability.[6] In short, BilBOWA combines the adapted SGNS for monolingual objectives together with a cross-lingual objective that minimizes the L_2-loss between the bag-of-word vectors of parallel sentences. BilBOWA uses the same training setup as HYBWE (monolingual datasets plus a bilingual signal), but relies on a stronger bilingual signal (sentence alignments as opposed to HYBWE's document alignments).

We also compare with a benchmarking Type 1 model from sentence-aligned parallel data called BiCVM (Hermann and Blunsom, 2014b). Finally, a SGNS-based BWE model with the BNC+GT seed lexicon is taken as a baseline Type 4 model (Mikolov et al., 2013a).[7]

Training Data and Setup We use standard training data and suggested settings to obtain BWEs for all models involved in comparison. We retain the 100K most frequent words in each language for all models. To induce monolingual WE spaces, two monolingual SGNS models were trained on the cleaned and tokenized Wikipedias from the Polyglot website (Al-Rfou et al., 2013) using SGD with a global learning rate of 0.025. For BilBOWA, as in the original work (Gouws et al., 2015), the bilingual signal for the cross-lingual regularization is provided by the first 500K sentences from Europarl.v7 (Tiedemann, 2012). We use SGD with a global rate of 0.15.[8] The window size is varied from 2 to 16 in steps of 2, and the best scoring model is always reported in all comparisons.

BWESG was trained on the cleaned and tokenized document-aligned Wikipedias available online[9], SGD on pseudo-bilingual documents with a global rate 0.025. For BiCVM, we use the tool released by its authors[10] and train on the whole Europarl.v7 for each language pair: we train an additive model, with hinge loss margin set to d (i.e., dimensionality) as in the original paper, batch size of 50, and noise parameter of 10. All BiCVM models are trained with 200 iterations.

For all models, we obtain BWEs with $d = 40, 64, 300, 500$, but we report only results with 300-dimensional BWEs as similar trends were observed with other d-s. Other parameters are: 15 epochs, 15 negatives, subsampling rate $1e-4$.

literature (Smith and Eisner, 2007; Tu and Honavar, 2012; Vulić and Moens, 2013), but we do not observe any significant gains when resorting to the more complex reliability estimates.

[4] http://people.cs.kuleuven.be/~ivan.vulic/

[5] Similar trends are observed within a more lenient setting with Acc_5 and Acc_{10} scores, but we omit these results for clarity and the fact that the actual BLL performance is best reflected in Acc_1 scores (i.e., best translation only).

4 Results and Discussion

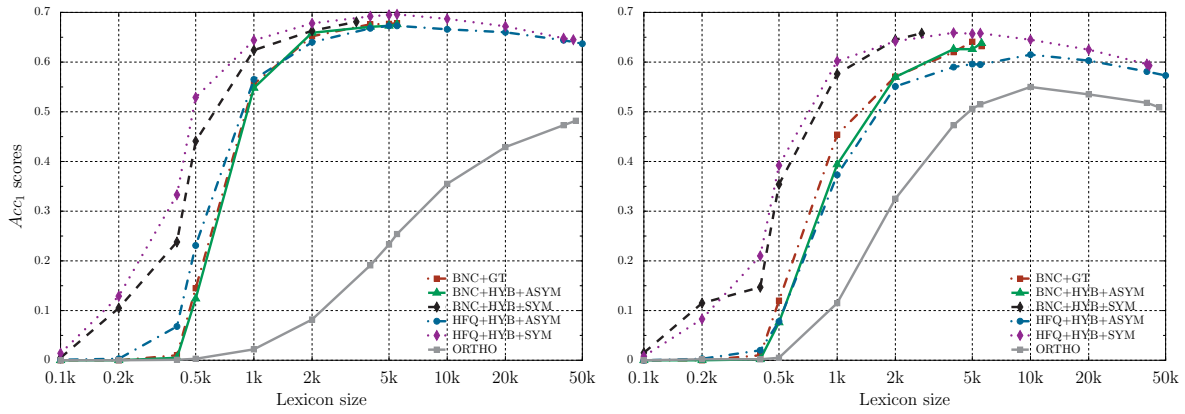
Exp. I: Standard BLL Setting First, we replicate the previous BLL setups with Type 4 models from (Mikolov et al., 2013a; Dinu et al., 2015) by relying on seed lexicons of exactly 5K word pairs (except for BNC+HYB+SYM which exhausts all possible pairs before the 5K limit) sorted by frequency of the source language word. Results with different lexicons for the three language pairs are summarized in Table 2, while Table 1 shows examples of nearest neighbour words for a Spanish word not present in any of the training lexicons.

Table 1 provides evidence for our first insight: Type 4 models do not necessarily require external lexicons (such as the BNC+GT model) to learn a semantically plausible SBWES (i.e., the lists of nearest neighbours are similar for all lexicons excluding ORTHO). Table 1 also suggests that the choice of seed lexicon pairs may strongly influence the properties of the resulting SBWES. Due to its design, ORTHO finds a mapping which naturally brings foreign words appearing in the English vocabulary closer in the induced SBWES.

This first batch of quantitative results already shows that Type 4 models with inexpensive automatically induced lexicons (i.e., HYBWE) are on a par with or even better than Type 4 models relying on external resources or translation systems. In addition, the best reported scores using the more constrained symmetric BNC/HFQ+HYB+SYM lexicon variants are higher than those for three baseline models (of Type 1, Type 2, and Type 3) that previously held highest scores on the BLL test sets (Vulić and Moens, 2016). These improvements over the baseline models and BNC+GT are statistically significant (using McNemar's statistical significance test, $p < 0.05$). Table 2 also suggests that a careful selection of reliable pairs can lead to peak performances even with a lower number of pairs, i.e., see the results of BNC+HYB+SYM.

Exp. II: Lexicon Size BLL results for ES-EN and NL-EN obtained by varying the seed lexicon sizes are displayed in Fig. 2(a) and 2(b). Results for IT-EN closely follow the patterns observed with ES-EN. BNC+HYB+SYM and HFQ+HYB+ASYM – the two models that do not blindly use all potential training pairs, but rely on sets of symmetric pairs (i.e., they include the simple measure of translation pair reliability) – display the best performance across all lexicon sizes. The finding confirms the intuition that a more intelligent pair selection strategy is essential for Type 4 BWE models. HFQ+HYB+SYM – a simple hybrid BWE model (HYBWE) combining a document-level Type 3 model with a Type 4 model and translation reliability detection – is the strongest BWE model overall (see also Table 2 again).

HYBWE-based models which do not perform any pair selection (i.e., BNC/HFQ+HYB+ASYM) closely follow the behaviour of the GT-based model. This demonstrates that an external lexicon or translation system may be safely replaced



(a) Spanish-English (b) Dutch-English

Figure 2: BLL results (Acc_1) across different seed lexicon sizes for all lexicons. x axes are in log scale.

by a document-level embedding model without any significant performance loss in the BLL task. The ORTHO-based model falls short of its competitors. However, we observe that even this model with the learning setting relying on the cheapest bilingual signal may lead to reasonable BLL scores, especially for the more related NL-EN pair.

The two models with the symmetry constraint display a particularly strong performance with settings relying on scarce resources (i.e., only a small portion of training pairs is available). For instance, HFQ+HYB+SYM scores 0.129 for ES-EN with only 200 training pairs (vs 0.002 with BNC+GT), and 0.529 with 500 pairs (vs 0.145 with BNC+GT). On the other hand, adding more pairs does not lead to an improved BLL performance. In fact, we observe a slow and steady decrease in performance with lexicons containing $10,000$ and more training pairs for all HYBWE variants. The phenomenon may be attributed to the fact that highly frequent words receive more accurate representations in SBWES-1, and adding less frequent and, consequently, less accurate training pairs to the SBWES-2 learning process brings in additional noise. In plain language, when it comes to seed lexicons Type 4 models prefer quality over quantity.

Exp. III: Translation Pair Reliability In the next experiment, we vary the threshold value THR (see sect. 2.2) in the HFQ+HYB+SYM variant with the following values in comparison: 0.0 (None), $0.01, 0.025, 0.05, 0.075, 0.1$. We investigate whether retaining only highly unambiguous pairs would lead to even better BLL performance. The results for all three language pairs are summarized in Fig. 3(a)-3(c). The results for all variant models again decrease when employing larger lexicons (due to the usage of less frequent word pairs in training). We observe that a slightly stricter selection criterion (i.e., THR $= 0.01, 0.025$) also leads to slightly improved peak BLL scores for ES-EN and IT-EN around the 5K region. The improvements, however, are not statistically significant. On the other hand, a too conservative pair selection criterion with higher threshold values significantly deteriorates the overall performance of HYBWE with HFQ+HYB+SYM. The conservative criteria discard plenty of potentially useful training pairs. Therefore, as one line of future research, we plan to investigate more sophisticated models for the selection of reliable seed lexicon pairs that will lead to a better trade-off between the lexicon size and reliability of the pairs.

Exp. IV: Another Task - Suggesting Word Translations in Context (SWTC) In the final experiment, we test whether the findings originating from the BLL task generalize to another cross-lingual semantic task: *suggesting word translations in context* (SWTC) recently proposed by Vulić and Moens (2014). Given an occurrence of a polysemous word $w \in V^S$, the SWTC task is to choose the correct translation in the target language of that particular occurrence of w from the given set $\mathcal{TC}(w) = \{t_1, \ldots, t_{tq}\}$, $\mathcal{TC}(w) \subseteq V^T$, of its tq possible translations/meanings. Whereas in the BLL task the candidate search is performed over the entire vocabulary V^T, the set $TC(w)$ typically comprises only a few pre-selected words/senses. One may refer to $\mathcal{TC}(w)$ as an inventory of translation candidates for w. The best scoring translation candidate in the ranked list is then the correct translation for that particular occurrence of w observing its local context $Con(w)$. SWTC is an extended

cross-lingual variant of the task proposed by Huang et al. (2012) which evaluates monolingual context-sensitive semantic similarity of words in sentential context, and it is also very related to cross-lingual lexical substitution (Mihalcea et al., 2010).

To isolate the performance of each BWE induction model from the details of the SWTC setup, we use the same approach with all models: we opt for the SWTC framework proven to yield excellent results with BWEs in the SWTC task (Vulić and Moens, 2016). In short, the context bag $Con(w) = \{cw_1, \ldots, cw_r\}$ is obtained by harvesting all r words that occur with w in the sentence. The vector representation of $Con(w)$ is the d-dimensional embedding computed by aggregating over all word embeddings for each $cw_j \in Con(w)$ using standard *addition* as the compositional operator (Mitchell and Lapata, 2008) which was proven a robust choice (Milajevs et al., 2014):

$$\mathbf{Con(w)} = \mathbf{cw}_1 + \mathbf{cw}_2 + \ldots + \mathbf{cw}_r \quad (4)$$

where $\mathbf{cw}_j$ is the embedding of the j-th context word, and $\mathbf{Con(w)}$ is the resulting embedding of the context bag $Con(w)$. Finally, for each $t_j \in \mathcal{TC}(w)$, the context-sensitive similarity with w is computed as: $sim(w, t_j, Con(w)) = cos(\mathbf{Con(w)}, \mathbf{t}_j)$, where $\mathbf{Con(w)}$ and $\mathbf{t}_j$ are representations of the (sentential) context bag and the candidate translation t_j in the same SBWES.[11]

The evaluation set consists of 360 sentences for 15 polysemous nouns (24 sentences for each noun) in each of the three languages: Spanish, Dutch, Italian, along with the single gold standard single word English translation given the sentential context.[12] Table 3 summarizes the results (Acc_1 scores) in the SWTC task. NO-CONTEXT refers to the context-insensitive majority baseline obtained by BNC+GT (i.e., it always chooses the most semantically similar translation candidate at the word type level). We also report the results of the best SWTC model from Vulić and Moens (2014).

The results largely support the claims established with the BLL evaluation. An exter-

[11] The same ranking of different models (with lower absolute scores) is observed when adapting the monolingual lexical substitution framework of Melamud et al. (2015) to the SWTC task as done by Vulić and Moens (2016).

[12] The SWTC evaluation set is available online at: http://aclweb.org/anthology/attachments/D/D14/D14-1040.Attachment.zip

nal seed lexicon of BNC+GT may be safely replaced by an automatically induced inexpensive seed lexicon (as in HYBWE with BNC+HYB+SYM/ASYM). The best performing models are again BNC+HYB+SYM and HFQ+HYB+SYM. The comparison of ASYM and SYM lexicon variants further suggests that filtering translation pairs using the symmetry constraint again leads to consistent improvements, but stricter selection criteria with higher thresholds do not lead to significant performance boosts, and may even hurt the performance (see the results for NL-EN). Various HYBWE variants significantly improve over baseline BWE models (Types 1-4), also outperforming previous best SWTC results.

5 Conclusions and Future Work

We presented a detailed analysis of the importance and properties of seed bilingual lexicons in learning bilingual word embeddings (BWEs) which are valuable for many cross-lingual/multilingual NLP tasks. On the basis of the analysis, we proposed a simple yet effective hybrid bilingual word embedding model called HYBWE. It learns the mapping between two monolingual embedding spaces using only highly reliable symmetric translation pairs from an inexpensive seed document-level embedding space. The results in the tasks of (1) bilingual lexicon learning and (2) suggesting word translations in context demonstrate that – due to its careful selection of reliable translation pairs for seed lexicons – HYBWE outperforms benchmarking BWE induction models, all of which use more expensive bilingual signals for training.

In future work, we plan to investigate other methods for seed pairs selection, settings with scarce resources (Agić et al., 2015; Zhang et al., 2016), other context types inspired by recent work in the monolingual settings (Levy and Goldberg, 2014a; Melamud et al., 2016), as well as model adaptations that can work with multi-word expressions. Encouraged by the excellent results, we also plan to test the portability of the approach to more language pairs, and other tasks and applications.

Abstract

We propose a brand new "Liberal" Event Extraction paradigm to extract events and discover event schemas from any input corpus simultaneously. We incorporate symbolic (e.g., Abstract Meaning Representation) and distributional semantics to detect and represent event structures and adopt a joint typing framework to simultaneously extract event types and argument roles and discover an event schema. Experiments on general and specific domains demonstrate that this framework can construct high-quality schemas with many event and argument role types, covering a high proportion of event types and argument roles in manually defined schemas. We show that extraction performance using discovered schemas is comparable to supervised models trained from a large amount of data labeled according to predefined event types. The extraction quality of new event types is also promising.

1 Introduction

Event extraction aims at identifying and typing trigger words and participants (arguments). It remains a challenging and costly task. The first question is what to extract? The TIPSTER (Onyshkevych et al., 1993), MUC (Grishman and Sundheim, 1996), CoNLL (Tjong et al., 2003; Pradhan et al., 2011), ACE [1] and TAC-KBP (Ji and Grishman, 2011) programs found that it was feasible to manually define an event schema based on the needs of potential users. An ACE event schema example is shown in Figure 1. This process is very expensive because consumers and expert linguists need to examine a lot of data before specifying the types of events and argument roles and writing detailed annotation guidelines for each type in the schema. Manually-defined event schemas often provide low coverage and fail to generalize to new domains. For example, none of the aforementioned programs include "*donation*" and "*evacuation*" in their schema in spite of their potential relevance to users.

In this paper we propose *Liberal Event Extraction*, a new paradigm to take humans out of the loop and enable systems to extract events in a more liberal fashion. It automatically discovers a complete event schema, customized for a specific input corpus. Figure 1 compares the ACE event extraction paradigm and our proposed Liberal event extraction paradigm.

We use the following examples to explain and motivate our approach, where event triggers are in bold and arguments are in italics and underlined:

E1. *Two Soldiers* were **killed** and *one* **injured** in the close-quarters **fighting** in *Kut*.

E2. *Bill Bennet*'s glam *gambling* **loss** changed my opinion.

E3. Gen. Vincent Brooks announced the **capture** of *Barzan Ibrahim Hasan al-Tikriti*, telling reporters he was an adviser to Saddam.

E4. This was the *Italian ship* that was **captured** by *Palestinian* terrorists back in 1985.

E5. *Ayman Sabawi Ibrahim* was **arrested** in *Tikrit* and was **sentenced** to life in *prison*.

We seek to cluster the event triggers and event arguments so that each cluster represents a type. We rely on distributional similarity for our clustering distance metric. The distributional hypothesis (Harris, 1954) states that words often occurring in similar contexts tend to have similar meanings. We formulate the following distributional

[1] http://www.itl.nist.gov/iad/mig/tests/ace/

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 258–268,
Berlin, Germany, August 7-12, 2016.

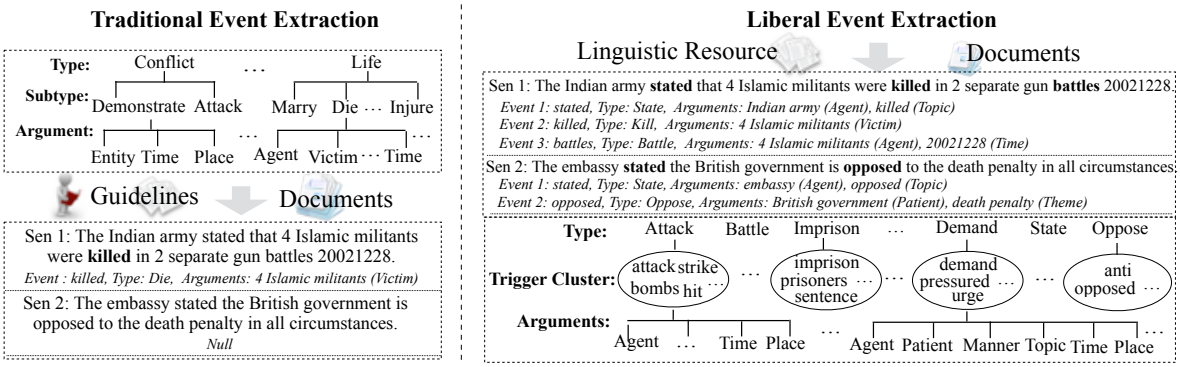

Figure 1: Comparison between ACE Event Extraction and Liberal Event Extraction.

hypotheses specifically for event extraction, and develop our approach accordingly.

Hypothesis 1: *Event triggers that occur in similar contexts and share the same sense tend to have similar types.*

Following the distributional hypothesis, when we simply learn general word embeddings from a large corpus for each word, we obtain similar words like those shown in Table 1. We can see similar words, such as those centered around "*injure*" and "*fight*", are converging to similar types. However, for words with multiple senses such as "*fire*" (shooting or employment termination), similar words may indicate multiple event types. Thus, we propose to apply Word Sense Disambiguation (WSD) and learn a distinct embedding for each sense (Section 2.3).

injure	Score	fight	Score	fire	Score
injures	0.602	fighting	0.792	fires	0.686
hurt	0.593	fights	0.762	aim	0.683
harm	0.592	battle	0.702	enemy	0.601
maim	0.571	fought	0.636	grenades	0.597
injuring	0.561	Fight	0.610	bombs	0.585
endanger	0.543	battles	0.590	blast	0.566
dislocate	0.529	Fighting	0.588	burning	0.562
kill	0.527	bout	0.570	smoke	0.558

Table 1: Top-8 Most Similar Words (in 3 Clusters)

Hypothesis 2: *Beyond the lexical semantics of a particular event trigger, its type is also dependent on its arguments and their roles, as well as other words contextually connected to the trigger.*

For example, in *E4*, the fact that the patient role is a vehicle ("*Italian ship*"), and not a person (as in *E3* and *E5*), suggests that the event trigger "*captured*" has type "*Transfer-Ownership*" as opposed to "*Arrest*". In *E2*, we know the "*loss*" event occurs in a *gambling* scenario, so we can determine its type as loss of money, not loss of life.

We therefore propose to enrich each trigger's representation by incorporating the distributional representations of various words in the trigger's context. Not all context words are relevant to event trigger type prediction, while those that are vary in their predictive value. We propose to use semantic relations, derived from a meaning representation for the text, to carefully select arguments and other words in an event trigger's context. These words are then incorporated into a "global" event structure for a trigger mention. We rely on semantic relations to (1) specify how the distributional semantics of relevant context words contribute to the overall event structure representation; (2) determine the order in which distributional semantics of relevant context words are incorporated into the event structure (Section 2.4).

2 Approach

2.1 Overview

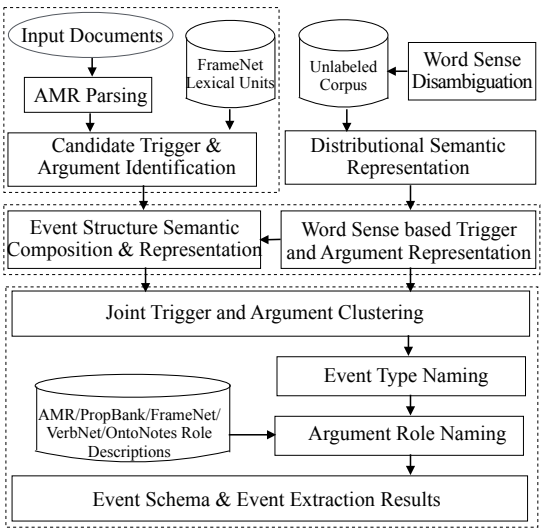

Figure 2: Liberal Event Extraction Overview.

Figure 2 illustrates the overall framework of

Liberal Event Extraction. Given a set of input documents, we first extract semantic relations, apply WSD and learn word sense embeddings. Next, we identify candidate triggers and arguments.

For each event trigger, we apply a series of compositional functions to generate that trigger's event structure representation. Each function is specific to a semantic relation, and operates over vectors in the embedding space. Argument representations are generated as a by-product.

Trigger and argument representations are then passed to a joint constraint clustering framework. Finally, we name each cluster of triggers, and name each trigger's arguments using mappings between the meaning representation and semantic role descriptions in FrameNet, VerbNet (Kipper et al., 2008) and Propbank (Palmer et al., 2005).

We compare settings in which semantic relations connecting triggers to context words are derived from three meaning representations: Abstract Meaning Representation (AMR) (Banarescu et al., 2013), Stanford Typed Dependencies (Marie-Catherine et al., 2006), and FrameNet (Baker and Sato, 2003). We derive semantic relations automatically for these three representations using CAMR (Wang et al., 2015a), Stanford's dependency parser (Manning, 2003), and SEMAFOR (Das et al., 2014), respectively.

2.2 Candidate Trigger and Argument Identification

Given a sentence, we consider all noun and verb concepts that are assigned an OntoNotes (Hovy et al., 2006) sense by WSD as candidate event triggers. Any remaining concepts that match both a verbal and a nominal lexical unit in the FrameNet corpus are considered candidate event triggers as well. This mainly helps to identify more nominal triggers like *"pickpocket"* and *"sin"*.[2]

For each candidate event trigger, we consider as candidate arguments all concepts for which one of a manually-selected set of semantic relations holds between it and the event trigger. For the setting in which AMR serves as our meaning representation, we selected a subset of all AMR relations that specify event arguments, as shown in Table 2. Note that some AMR relations generally do not specify event arguments, e.g. "mode", which can indicate sentence illocutionary force, or "snt" which is used to combine multiple sentences into one AMR graph.[3] When FrameNet is the meaning representation we allow all frame relations to identify arguments. For dependencies, we manually mapped dependency relations to AMR relations and use Table 2.

Categories	Relations
Core roles	ARG0, ARG1, ARG2, ARG3, ARG4
Non-core roles	mod, location, poss, manner, topic, medium, instrument, duration, prep-X
Temporal	year, duration, decade, weekday, time
Spatial	destination, path, location

Table 2: Event-Related AMR Relations.

In E1, for example, "*killed*", "*injured*" and "*fighting*" are identified as candidate triggers, and three concept sets are identified as candidate arguments using AMR relations: "{*Two Soldiers, very large missile*}", "{*one, Kut*}" and "{*Two Soldiers, Kut*}", as shown in Figure 3.

2.3 Trigger Sense and Argument Representation

Based on Hypothesis 1, we learn sense-based embeddings from a large data set, using the Continuous Skip-gram model (Mikolov et al., 2013). Specifically, we first apply WSD to link each word to its sense in WordNet using a state-of-the-art tool (Zhong and Ng, 2010), and map WordNet sense output to OntoNotes senses. [4] We map each trigger candidate to its OntoNotes sense and learn a distinct embedding for each sense. We use general lexical embeddings for arguments.

2.4 Event Structure Composition and Representation

Based on Hypothesis 2, we aim to exploit linguistic knowledge to incorporate inter-dependencies between event and argument role types into our event structure representation. Many meaning representations could provide such information to some degree. We illustrate our method for building event structures using semantic relations from meaning representations using AMR. In Section 3.4 we compare results using Stanford Typed Dependencies and FrameNet in place of AMR.

Let's take *E2* as an example. Based on AMR annotation and Table 2, we extract semantically re-

[2]For consistency, we use the same trigger identification procedure regardless of which meaning representation is used to derive semantic relations.

[4]WordNet-OntoNotes mapping from https://catalog.ldc.upenn.edu/LDC2011T03

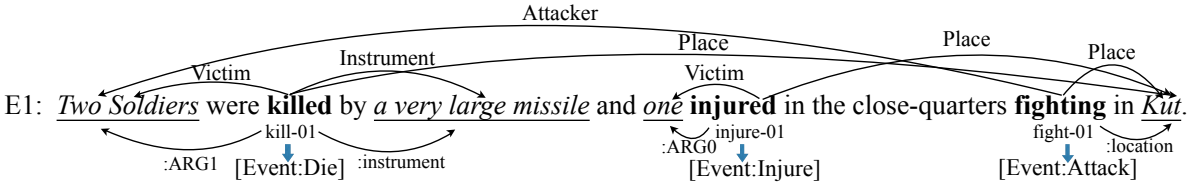

Figure 3: Event Trigger and Argument Annotations and AMR Parsing Results of *E1*.

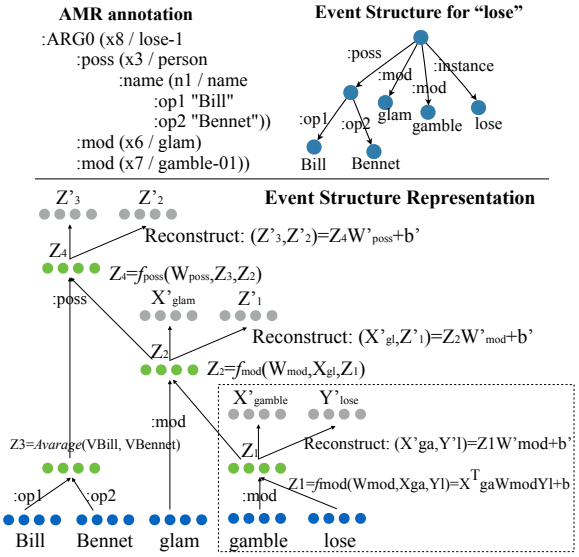

Figure 4: Partial AMR and Event Structure for *E2*.

lated words for the event trigger with sense "*lose-1*" and construct the event structure for the whole event, as shown in Figure 4.

We design a Tensor based Recursive Auto-Encoder (TRAE) (Socher et al., 2011) framework to utilize a tensor based composition function for each of a subset of the AMR semantic relations and compose the event structure representation based on multiple functional applications. This subset was manually selected by the authors as the set of relations that link a trigger to concepts that help to determine its type. Similarly, we selected a subset of dependency and FrameNet relations using the same criteria for experiments using those meaning representations.

Figure 4 shows an instance of a TRAE applied to an event structure to generate its representation. For each semantic relation type r, such as "*:mod*", we define the output of a tensor product Z via the following vectorized notation:

$$Z = f_{mod}(X, Y, W_r^{[1:d]}, b) = [X;Y]^T W_r^{[1:d]} [X;Y] + b$$

where $W_{mod} \in \mathbb{R}^{2d \cdot 2d \cdot d}$ is a 3-order tensor, and $X, Y \in \mathbb{R}^d$ are two input word vectors. $b \in \mathbb{R}^d$ is the bias term. $[X;Y]$ denotes the concatenation of two vectors X and Y. Each slice of the tensor acts as a coefficient matrix for one entry Z_i in Z:

$$Z_i = f_{mod}(X, Y, W_r^{[i]}, b) = [X;Y]^T W_r^{[i]} [X;Y] + b_i$$

We use the statistical mean to compose the words connected by ":op" relations (e.g. "*Bill*" and "*Bennet*" in Figure 4).

After composing the vectors of X and Y, we apply an element-wise sigmoid activation function to the composed vector and generate the hidden layer representations Z. One way to optimize Z is to try to reconstruct the vectors X and Y by generating X' and Y' from Z, and minimizing the reconstruction errors between the input $V_I = [X, Y]$ and output layers $V_O = [X', Y']$. The error is computed based on Euclidean distance function:

$$E(V_I, V_O) = \frac{1}{2} ||V_I - V_O||^2$$

For each pair of words X and Y, the reconstruction error back-propagates from its output layer to input layer through parameters $\Theta_r = (W_r', b_r', W_r, b_r)$. Let δ_O be the residual error of the output layer, and δ_H be the error of the hidden layer:

$$\delta_O = -(V_I - V_O) \cdot f'_{\text{sigmoid}}(V_H^O)$$

$$\delta_H = (\sum_{k=1}^{d} \delta_O^k \cdot (W_r'^k + (W_r'^k)^T) \cdot V_H^O) \cdot f'_{\text{sigmoid}}(V_H^I)$$

where V_H^I and V_H^O denote the input and output of the hidden layer, and $V_H^O = Z$. $W_r'^k$ is the k^{th} slice of tensor W_r'.

To minimize the reconstruction errors, we utilize gradient descent to iteratively update parameters Θ_r:

$$\frac{\partial E(\Theta_r)}{\partial W_r'^k} = \delta_O^k \cdot (V_H^O)^T \cdot V_H^O$$

$$\frac{\partial E(\Theta_r)}{\partial b_r'} = -(V_I - V_O) \cdot f'_{\text{sigmoid}}(V_H^O)$$

$$\frac{\partial E(\Theta_r)}{\partial W_r^k} = \delta_H^k \cdot (V_I)^T \cdot V_I$$

$$\frac{\partial E(\Theta_r)}{\partial b_r} = (\sum_{k=1}^{d} \delta_O^k \cdot (W_r'^k + (W_r'^k)^T) \cdot V_H^O) \cdot f'_{\text{sigmoid}}(V_H^I)$$

After computing the composition vector of Z_1 based on X and Y, for the next layer, it composes Z_1 and another new word vector such as

X_{gl}. For each type of relation r, we randomly sample 2,000 pairs to train optimized parameters Θ_r. For each event structure tree, we iteratively repeat the same steps for each layer. For multiple arguments at each layer, we compose them in the order of their distance to the trigger: the closest argument is composed first.

2.5 Joint Trigger and Argument Clustering

Based on the representation vectors generated above, we compute the similarity between each pair of triggers and arguments, and cluster them into types. Recall that a trigger's arguments are identified as in section 2.2. We observe that, for two triggers t_1 and t_2, if their arguments have the same type and role, then they are more likely to belong to the same type, and vice versa. Therefore we introduce a constraint function f, to enforce inter-dependent triggers and arguments to have coherent types:

$$f(\mathcal{P}_1, \mathcal{P}_2) = \log(1 + \frac{|\mathcal{L}_1 \cap \mathcal{L}_2|}{|\mathcal{L}_1 \cup \mathcal{L}_2|})$$

where $\mathcal{P}_1$ and $\mathcal{P}_2$ are triggers. Elements of $\mathcal{L}_i$ are pairs of the form $(r, \text{id}(a))$, where $\text{id}(a)$ is the cluster ID for argument a that stands in relation r to $\mathcal{P}_i$. For example, let $\mathcal{P}_1$ and $\mathcal{P}_2$ be triggers "*capture*" and "*arrested*" (c.f. Figure 5). If *Barzan Ibrahim Hasan al-Tikriti* and *Ayman Sabawi Ibrahim* share the same cluster ID, the pair $(arg1, \text{id(Barzan Ibrahim Hasan al-Tikriti)})$ will be a member of $\mathcal{L}_1 \cap \mathcal{L}_2$. This argument overlap is evidence that "*capture*" and "*arrested*" have the same type. We define f where $\mathcal{P}_i$ are arguments, and elements $\mathcal{L}_i$ are defined analogously to above.

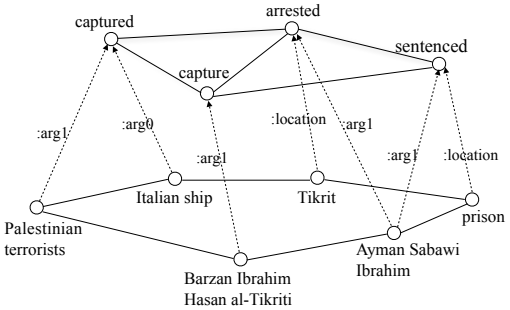

Figure 5: Joint Constraint Clustering for E3,4,5.

Given a trigger set T and their corresponding argument set A, we compute the similarity between two triggers t_1 and t_2 and two arguments a_1 and a_2 by:

$$sim(t_1, t_2) = \lambda \cdot sim_{\cos}(E_g^{t_1}, E_g^{t_2}) + (1-\lambda) \cdot \frac{\Sigma_{r \in R_{t_1} \cap R_{t_2}} sim_{\cos}(E_r^{t_1}, E_r^{t_2})}{|R_{t_1} \cap R_{t_2}|} + f(t_1, t_2)$$

$$sim(a_1, a_2) = sim_{\cos}(E_g^{a_1}, E_g^{a_2}) + f(a_1, a_2)$$

where E_g^t represents the trigger sense vector and E_g^a is the argument vector. R_t is the AMR relation set in the event structure of t, and E_r^t denotes the vector resulting from the last application of the compositional function corresponding to the semantic relation r for trigger t. λ is a regularization parameter that controls the trade-off between these two types of representations. In our experiment $\lambda = 0.6$.

We design a joint constraint clustering approach, which iteratively produces new clustering results based on the above constraints. To find a global optimum, which corresponds to an approximately optimal partition of the trigger set into K clusters $\mathcal{C}^T = \{\mathcal{C}_1^T, \mathcal{C}_2^T, ..., \mathcal{C}_K^T\}$, and a partition of the argument set into M clusters $\mathcal{C}^A = \{\mathcal{C}_1^A, \mathcal{C}_2^A, ..., \mathcal{C}_M^A\}$, we minimize the agreement across clusters and the disagreement within clusters:

$$\arg \min_{K_T, K_A, \lambda} O = (D_{\text{inter}}^T + D_{\text{intra}}^T) + (D_{\text{inter}}^A + D_{\text{intra}}^A)$$

$$D_{\text{inter}}^{\mathcal{P}} = \sum_{i \neq j = 1}^{K} \sum_{u \in \mathcal{C}_i^{\mathcal{P}}, v \in \mathcal{C}_j^{\mathcal{P}}} sim(\mathcal{P}_u, \mathcal{P}_v)$$

$$D_{\text{intra}}^{\mathcal{P}} = \sum_{i=1}^{K} \sum_{u,v \in \mathcal{C}_i^{\mathcal{P}}} (1 - sim(\mathcal{P}_u, \mathcal{P}_v))$$

We incorporate the Spectral Clustering algorithm (Luxburg, 2007) into joint constraint clustering process to get the final optimized clustering results. The detailed algorithm is summarized in Algorithm 1.

2.6 Event Type and Argument Role Naming

For each trigger cluster, we utilize the trigger which is nearest to the centroid of the cluster as the event type name. For a given event trigger, we assign a role name to each of its arguments (identified as in section 2.2). This process depends on which meaning representation was used to select the arguments.

For AMR, we first map the event trigger's OntoNotes sense to PropBank, VerbNet, and FrameNet. We assign each argument a role name as follows. We map AMR core roles (e.g. *":ARG0", "ARG1"*) to FrameNet if possible, otherwise to VerbNet if possible, and finally to PropBank roles if a mapping to VerbNet is not available.[5]. Nearly 5% of AMR core roles can

[5]OntoNotes 5.0 provides a mapping; https://catalog.ldc.upenn.edu/LDC2013T19

Algorithm 1 Joint Constraint Clustering Algorithm

Input: Trigger set T, argument set A, their lexical embedding E_g^T, E_g^A, event structure representation E_R^T, and the minimal (K_T^{min}, K_A^{min}) and maximal (K_T^{max}, K_A^{max}) number of clusters for triggers and arguments;
Output: The optimal clustering results: $\mathcal{C}^T$ and $\mathcal{C}^A$;

- $O_{min} = \infty, \mathcal{C}^T = \varnothing, \mathcal{C}^A = \varnothing$
- For $K_T = K_T^{min}$ to $K_T = K_T^{max}$, $K_A = K_A^{min}$ to $K_A = K_A^{max}$
  - Clustering with Spectral Clustering Algorithm:
  - $\mathcal{C}_{curr}^T = spectral(T, E_g^T, E_R^T, K_T)$
  - $\mathcal{C}_{curr}^A = spectral(A, E_g^A, K_A)$
  - $O_{curr} = O(\mathcal{C}_{curr}^T, \mathcal{C}_{curr}^A)$
  - if $O_{curr} < O_{min}$
    - $O_{min} = O_{curr}, \mathcal{C}^T = \mathcal{C}_{curr}^T, \mathcal{C}^A = \mathcal{C}_{curr}^A$
  - while iterate time ≤ 10
    - $\mathcal{C}_{curr}^T = spectral(T, E_g^T, E_R^T, K_T, \mathcal{C}_{curr}^A)$
    - $\mathcal{C}_{curr}^A = spectral(A, E_g^A, K_A, \mathcal{C}_{curr}^T)$
    - $O_{curr} = O(\mathcal{C}_{curr}^T, \mathcal{C}_{curr}^A)$
    - if $O_{curr} < O_{min}$
      - O_{min}=$O_{curr}, \mathcal{C}^T = \mathcal{C}_{curr}^T, \mathcal{C}^A = \mathcal{C}_{curr}^A$
- return $O_{min}, \mathcal{C}^T, \mathcal{C}^A$;

be mapped to FrameNet roles and 55% can be mapped to VerbNet roles, and the remaining can be mapped to PropBank. Table 3 shows some mapping examples. We map non-core roles from AMR to FrameNet, as shown in Table 4.

When Stanford Typed Dependencies are used for meaning representation we construct a manual mapping AMR relations and use the above procedure. When FrameNet is used for meaning representation we simply keep the FrameNet role name for argument role naming.

Concept	AMR Core Role	FrameNet Role	VerbNet Role	PropBank Description
fire.1	ARG0	Agent	Agent	Shooter
fire.1	ARG1	Projectile	Theme	Gun/projectile
extrude.1	ARG0		Agent	Extruder, agent
extrude.1	ARG1		Theme	Entity extruded
extrude.1	ARG2		Source	Extruded from
blood.1	ARG0			Agent
blood.1	ARG1			Theme, one bled

Table 3: Core Role Mapping Examples.

3 Evaluation

3.1 Data

We used the August 11, 2014 English Wikipedia dump to learn trigger sense and argument embeddings. For evaluation we choose a subset of ERE (Entity Relation Event) corpus (50 documents) which has perfect AMR annotations so we can compare the impact of perfect AMR and system generated AMR. To compare with state-of-the-art event extraction on Automatic Content Extraction (ACE2005) data, we follow the same evaluation setting in previous work (Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011) and use 40 newswire documents as our test set.

AMR None-Core Role	FrameNet Role
topic	Topic
instrument	Instrument
manner	Manner
poss	Possessor
prep-for, prep-to, prep-on-behalf	Purpose
time, decade, year, weekday, duration	Time
mod, cause, prep-as	Explanation
prep-by, medium, path	Means
location, destination, prep-in	Place

Table 4: None-Core Role Mapping.

3.2 Schema Discovery

Figure 6 shows some examples as part of the event schema discovered from the ERE data set. Each cluster denotes an event type, with a set of event mentions and sentences. Each event mention is also associated with some arguments and their roles. The event and argument role annotations for sample sentences may serve as an example-based corpus-customized "annotation guideline" for event extraction.

Table 5 compares the coverage of event schema discovered by our approach, using AMR as meaning representation, with the predefined ACE and ERE event schemas. Besides the types defined in ACE and ERE, this approach discovers many new event types such as **Build** and **Threaten** as displayed in Figure 6. Our approach can also discover new argument roles for a given event type. For example, for Attack events, besides five types of existing arguments (Attacker, Target, Instrument, Time, and Place) defined in ACE, we also discover a new type of argument **Purpose**. For example, in "*The Dutch government, facing strong public anti-war pressure, said it would not commit fighting forces to the war against Iraq but added it supported the military* ***campaign*** *to* ***disarm Saddam***.", "*disarm Saddam*" is identified as the **Purpose** for the **Attack** event triggered by "*campaign*". Note that while FrameNet specifies Purpose as an argument role for the Attack, such information specific to Attack is not part of AMR.

Event Type: Transport

S1: The court official stated that on 18 March 2008 Luong stated to judges that she was hired by an unidentified *man* to **ship** the *heroin* to *Australia* in exchange for 15000 U.S. dollars.
***Event**: ship,*
***Arguments**: man(Agent), Austrialia(Destination),heroin(Theme)*

S2: State media didn't identify the 2 convicts hanged in Zahedan but stated that *they* had been found guilty of **transporting** 5.25 kilograms of *heroin*.
***Event**: transporting, **Arguments**: they(Agent), heroin(Theme)*

Event Type: Die

S1: Police in the strict communist country discovered his methamphetamine manufacturing plant disguised as a soap factory and sentenced *him* to **death** in *1997*.
***Event**: death, **Arguments**: him(Theme), 1997(Time)*

S2: A newspaper report on January 1, 2008 that *Iran* **hanged** two convicted *drug traffickers* in the *south-eastern city of Zahedan*.
***Event**: hanged, **Arguments**: Iran(Agent), drug traffickers(Theme), southeastern city of Zahedan(Place)*

Event Type: Build

S1: The **construction** of the *facility* started in *790000*, but stopped after the 910000 Soviet collapse when Tajikistan slid into a 5 year civil war that undermined its economy.
***Event**:construction,*
***Arguments**: facility(Product), 790000(Time)*

S2: The closed *Soviet-era military facility* was **fou-nded** in *570000* and collects and analyzes all information gathered from Russia's military spy satellites.
***Event**: founded,*
***Arguments**: Soviet-era facility(Product), 570000(Time)*

Event Type: Threaten

S1: *Colombian Government* was **alarmed** because uranium is the primary basis for generating weapons of mass destruction.
***Event**:alarmed, **Arguments**:Columbian Government(Experiencer)*

S2: Cluster bomblets have been criticized by human rights groups because they kill indiscriminately and because unexploded *ordinance* poses a **threat** to *civilians* similar to that of land mines.
***Event**:threat,*
***Arguments**:ordinance(Cause), civilian(Experiencer)*

Figure 6: Example Output of the Event Schema.

Data	ACE			ERE				
	Human	*SystemAMR*	*Overlap*	*Human*	*PerfectAMR*	*Overlap*	*SystemAMR*	*Overlap*
# of Events	440	2,395	331	580	3,765	517	2,498	477
# of Event Types	33	134	N/A	26	137	N/A	120	N/A
# of Arguments	883	4,361	587	1,231	6,195	919	4,288	801

Table 5: Schema Coverage Comparison on ACE and ERE.

3.3 Event Extraction for All Types

To evaluate the performance of the whole event schema, we randomly sample 100 sentences from ERE data set and ask two linguistic experts to fully annotate the events and arguments. As a starting point, annotators were given output from our Schema Discovery using gold standard AMR. For each sentence, they saw event triggers and corresponding arguments. Their job was to correct this output by marking incorrectly identified events and arguments, and adding missing events and arguments. The inter-annotator agreement is 83% for triggers and 79% for arguments.

To evaluate trigger and argument identification, we automatically compare this gold standard with system output (see Table 6). To evaluate trigger and argument typing, annotators manually checked system output and assessed whether the type name was reasonable (see Table 6). Note that automatic comparison between system and gold standard output is not appropriate for typing; for a given cluster, there is no definitive "best" name.

We found that most event triggers not recovered by our system are multi-word expressions such as "*took office*" or adverbs such as "*previously*" and "*formerly*". For argument identification, our approach fails to identify some arguments that require world knowledge to extract. For example, in "*Anti-corruption judge **Saul Pena** stated Montesinos has admitted to the abuse of authority **charge***", "*Saul Pena*" is not identified as a **Adjudicator** argument of event "*charge*" because it has no direct semantic relations with the event trigger.

3.4 Impact of Semantic Information and Meaning Representations

Table 7 assesses the impact of various types of semantic information, and also compares the effectiveness of each type of meaning representation for the typing task only. We note that F-measure drops 14.4 points if only WSD based embeddings are not used. In addition, AMR relations specifying both core and non-core roles are informative for learning distinct compositional operators. To compare typing results across meaning representations, we use triggers identified by both the AMR and FrameNet parsers. Using Stanford Typed Dependencies, relations are likely too coarse-grained or lack sufficient semantic information. Thus, our approach cannot leverage the inter-dependency between event trigger type and argument role to achieve pure trigger clusters. Compared with dependency relations, the fine-grained AMR semantic relations such as *:location*, *:manner*, *:topic*, *:instrument* appear to be more informative to infer the argument roles. For example, in sentence "*Approximately 25 kilometers southwest of Sringar 2 militants were killed in a second gun battle.*", "*gun*" is identified as an **Instrument** for "*battle*" event based on the AMR relation :instrument. In contrast, dependency parsing identifies "*gun*" as a

Method	Trigger Identification (%)			Trigger Typing (%)			Arg Identification (%)			Arg Typing (%)		
	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1
Perfect AMR	87.0	98.7	92.5	70.0	79.5	74.5	94.0	83.7	88.6	72.4	64.4	68.2
System AMR	93.0	67.2	78.0	69.8	50.5	58.6	95.7	59.6	73.4	68.9	42.9	52.9

Table 6: Overall Performance of Liberal Event Extraction on ERE data for All Event Types.

Method	Trigger F_1 (%)			Arg F_1 (%)		
	P	R	F_1	P	R	F_1
Perfect AMR	70	79.5	74.5	72.4	64.4	68.2
w/o Structure Representation	52.8	59.4	55.9	52.1	48.0	50.0
w/o WSD based embeddings	62.8	57.4	60.1	61.9	50.3	55.5
w/o None-Core Roles	61.5	72.2	66.5	61.3	58.0	59.6
w/o Core Roles	57.3	49.7	53.2	63.6	49.5	55.7
System AMR	69.8	50.5	58.6	68.9	42.9	52.9
Replace AMR with Dependency Parsing	45.9	61.9	52.7	63.9	18.2	28.4
Replace AMR with FrameNet Parsing	43.1	57.1	49.2	78.1	7.1	13.0

Table 7: Impact of semantic information and representations on typing for ERE data.

compound modifier of "*battle*". Note that we used a static mapping to map dependency relations to AMR relations (see section 2.6), whereas ideally this mapping would be context-dependent. Creating a context-dependent mapping would constitute significant steps toward building an AMR parser.

Using FrameNet results in low recall for argument typing. SEMAFOR's output often does not identify all the arguments identified by our annotators. Many triggers are associated with zero or one argument, thus there is not enough data to learn the event structure representation. In addition, most of the arguments from identified by SEMAFOR are long phrases. Because no internal structure is assigned, we simply average all single token's vectors to represent the phrase. However, the high precision may be due to the fact that FrameNet relations are designed to specify semantic roles.

3.5 Event Extraction for ACE/ERE Types

We manually select the event triggers in the ACE and ERE evaluation sets discovered by our AMR-based approaches that are ACE/ERE events based on their annotation guidelines. If a trigger doesn't already have a gold standard ACE/ERE annotation we provide one. For each such event we use core roles and Instrument/Possessor/Time/Place relations to detect arguments. Each trigger and argument role type is assessed manually if an ACE/ERE annotation does not exist. We evaluate our approach for trigger and argument typing by comparing system output to manual annotation, considering synonymous labels to be equivalent (e.g., our approach's *kill* type ACE's *die*). We compare our approach with the following state-of-the-art supervised methods which are trained from 529 ACE documents or 336 ERE documents:

- DMCNN: A dynamic multi-pooling convolutional neural network based on distributed word representations (Chen et al., 2015).
- Joint: A structured perceptron model based on symbolic semantic features (Li et al., 2013).
- LSTM: A long short-term memory neural network (Hochreiter and Schmidhuber, 1997) based on distributed semantic features.

Table 8 shows the results. On ACE events, both DMCNN and Joint methods outperform our approach for trigger and argument extraction. However, when moving to ERE event schema, although re-trained based on ERE labeled data, their performance still degrades significantly. These previous methods heavily rely on the quality and quantity of the training data. When the training data is not adequate (the ERE training documents contain 1,068 events and 2,448 arguments, while ACE training documents contain more than 4,700 events and 9,700 arguments), the performance is low. In contrast, our approach is unsupervised and can automatically identify events, arguments and assign types/roles, and is not tied to one event schema.

3.6 Event Extraction for Biomedical Domain

To demonstrate the portability of our approach to a new domain, we conduct our experiment on 14 biomedical articles (755 sentences) with perfect AMR annotations (Garg et al., 2016). We utilize a word2vec model[6] trained from all paper abstracts from PubMed[7] and full-text documents from the PubMed Central Open Access subset. To evaluate the performance, we randomly sample 100 sentences and ask a biomedical scientist to assess the correctness of each event and argument role. Our approach achieves 83.1% precision on trigger labeling (619 events in total) and 78.4% precision on argument labeling (1,124 arguments in total).

Table 8: Performance on ERE and ACE events.

It demonstrates that our approach can be rapidly adapted to a new domain and discover domain-rich event schema. An example schema for an event type "*Dissociate*" is shown in Figure 7.

Event Type: Dissociate

S1: Ras acts as a molecular switch that is activated upon GTP loading and deactivated upon **hydrolysis** of GTP to GDP.

***Event**: hydrolysis **Arguments**:GTP (Patient), (GDP) (Result)*

S2: Activation requires **dissociation** of protein-bound GDP , an intrinsically slow process that is accelerated by guanine nucleotide exchange factors.

***Event**: dissociation **Arguments**: GDP (Patient)*

S3: His - ubiquitinated proteins were purified by Co2+ metal affinity chromatography in 8M urea **denaturing** conditions.

***Event**: denaturing **Arguments**: proteins(Patient)*

Figure 7: Example Output of the Discovered Biomedical Event Schema.

4 Related Work

Most of previous event extraction work focused on learning supervised models based on symbolic features (Ji and Grishman, 2008; Miwa et al., 2009; Liao and Grishman, 2010; Liu et al., 2010; Hong et al., 2011; McClosky et al., 2011; Sebastian and Andrew, 2011; Chen and Ng, 2012; Li et al., 2013) or distributional features through deep learning (Chen et al., 2015; Nguyen and Grishman, 2015). They usually rely on a predefined event schema and a large amount of training data. Compared with other paradigms such as Open Information Extraction (Etzioni et al., 2005; Banko et al., 2007; Banko et al., 2008; Etzioni et al., 2011; Ritter et al., 2012), Preemptive IE (Shinyama and Sekine, 2006), On-demand IE (Sekine, 2006) and semantic frame based event discovery (Kim et al., 2013), our approach can explicitly name each event type and argument role. Some recent work focused on universal schema discovery (Chambers and Jurafsky, 2011; Pantel et al., 2012; Yao et al., 2012; Yao et al., 2013; Chambers, 2013; Nguyen et al., 2015). However, the schemas discovered from these methods are rather static and they are not customized for any specific input corpus.

Our work is also related to efforts at composing word embeddings using syntactic structures (Hermann and Blunsom, 2013; Socher et al., 2013a; Socher et al., 2013b; Bowman et al., 2014; Zhao et al., 2015). Our trigger sense representation is similar to Word Sense Induction (Navigli, 2009; Bordag, 2006; Pinto et al., 2007; Brody and Lapata, 2009; Manandhar et al., 2010; Navigli and Lapata, 2010; Van de Cruys and Apidianaki, 2011; Wang et al., 2015b). Besides word sense, we exploit related concepts to enrich trigger representation.

5 Conclusions and Future Work

We proposed a novel Liberal event extraction framework which combines the merits of symbolic semantics and distributed semantics. Experiments on news and biomedical domain demonstrate that this framework can discover explicitly defined rich event schemas which cover not only most types in existing manually defined schemas, but also new event types and argument roles. The granularity of event types is also customized for specific input corpus. And it can produce high-quality event annotations simultaneously without using annotated training data. In the future, we will extend this framework to other Information Extraction tasks.

Abstract

Event extraction from texts aims to detect structured information such as what has happened, to whom, where and when. Event extraction and visualization are typically considered as two different tasks. In this paper, we propose a novel approach based on probabilistic modelling to jointly extract and visualize events from tweets where both tasks benefit from each other. We model each event as a joint distribution over named entities, a date, a location and event-related keywords. Moreover, both tweets and event instances are associated with coordinates in the visualization space. The manifold assumption that the intrinsic geometry of tweets is a low-rank, non-linear manifold within the high-dimensional space is incorporated into the learning framework using a regularization. Experimental results show that the proposed approach can effectively deal with both event extraction and visualization and performs remarkably better than both the state-of-the-art event extraction method and a pipeline approach for event extraction and visualization.

1 Introduction

Event extraction, one of the important and challenging tasks in information extraction, aims to detect structured information such as what has happened, to whom, where and when. The outputs of event extraction could be beneficial for downstream applications such as summarization and personalized news systems. Data visualization, an important exploratory data analysis task, provides a simple way to reveal the relationships among data (Nakaji and Yanai, 2012).

Although event extraction and visualization are two different tasks and typically studied separately in the literature, these two tasks are highly related. Documents which are close to each other in the low-dimensional visualization space are likely to describe the same event. Events in nearby locations in the visualization space are likely to share similar event elements. Therefore, jointly learning the two tasks could potentially bring benefits to each other. However, it is not straightforward to learn event extraction and visualization jointly since event extraction usually relies on semantic parsing results (McClosky et al., 2011) while visualization is accomplished by dimensionality reduction (Iwata et al., 2007; López-Rubio et al., 2002).

In this paper, we propose a novel probabilistic model, called Latent Event Extraction & Visualization (LEEV) model, for joint event extraction and visualization on Twitter. It is partly inspired by the Latent Event Model (LEM) (Zhou et al., 2015) where each tweet is assigned to one event instance and each event is modeled as a joint distribution over named entities, a date/time, a location and the event-related keywords. Going beyond LEM, we assume that each event is not only modeled as the joint distribution over event elements as in (Zhou et al., 2015), but also associate with coordinates in the visualization space. The Euclidean distance between a tweet and each events determines which event the tweet should be assigned to. Furthermore, the manifold assumption that the intrinsic geometry of tweets is a low-rank, non-linear manifold within the high-dimensional space, is incorporated in the learning framework using a regularization. Experimental results show that the proposed approach can effectively deal with both event extraction and visualization tasks and performs remarkably better than both the state-of-the-art event extraction method

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 269–278,
Berlin, Germany, August 7-12, 2016.

and a pipeline approach for event extraction and visualization.

2 Related Work

Our proposed work is related to two lines of research, event extraction and joint topic modeling and visualization.

2.1 Event Extraction

Research on event extraction of tweets can be categorized into domain-specific and open domain approaches. Domain-specific approaches usually have target events in mind and aim to extract events from a particular location or for emergency response during natural disasters. Anantharam et al. (2015) focused on extracting city events by solving a sequence labeling problem. Evaluation was carried out on a real-world dataset consisting of event reports and tweets collected over four months from San Francisco Bay Area. TSum4act (Nguyen et al., 2015) was designed for emergency response during disasters and was evaluated on a dataset containing 230,535 tweets.

Most of open domain approaches focused on extracting a summary of events discussed in social media. For example Benson et al. (2011) proposed a structured graphical model which simultaneously analyzed individual messages, clustered, and induced a canonical value for each event. Capdevila et al. (2015) proposed a model named Tweet-SCAN based on the hierarchical Dirichlet process to detect events from geo-located tweets. To extract more information, a system called SEEFT (Wang et al., 2015) used links in tweets and combined tweets and linked articles to identify events. Zhou et al. (2014; 2015) proposed an unsupervised Bayesian model called latent event model (LEM) for event extraction from Twitter by assuming that each tweet message is assigned to one event instance and each event is modeled as a joint distribution over named entities, a date/time, a location and the event-related keywords. Our proposed method is partly inspired by (Zhou et al., 2015). However, different from previous methods, our approach not only extracts the structured representation of events, but also learns the coordinates of events and tweets simultaneously.

2.2 Joint Topic Modeling and Visualization

Since our proposed approach can be considered as a variant of topic model, we also review the related work of joint topic modeling and visualization here.

Traditionally, topic modeling and visualization are considered as two disjoint tasks and can be combined for pipeline processing. For example, probabilistic latent semantic analysis (Hofmann, 1999) can be first performed followed by parametric embedding (Iwata et al., 2007). Another pipeline approach (Millar et al., 2009) is based on latent Dirichlet allocation followed by self-organizing maps (López-Rubio et al., 2002).

Jointly modeling topics and visualization is a new problem explored in very few works. The state-of-the-art is a joint approach proposed in (Iwata et al., 2008). In this model, both documents and topics are assumed to have latent coordinates in a visualization space. The topic proportions of a document are determined by the distances between the document and the topics in the visualization space, and each word is drawn from one of the topics according to the document's topic proportions. A visualization was obtained by fitting the model to a given set of documents using the EM algorithm. Following the same line, by considering the local consistency in terms of the intrinsic geometric structure of the document manifold, an unsupervised probabilistic model, called SEMAFORE, was proposed in (Le and Lauw, 2014a) by preserving the manifold in the lower dimensional space. In (Le and Lauw, 2014b), a semantic visualization model is learned by associating each document a coordinate in the visualization space, a multinomial distribution in the topic space, and a directional vector in a high-dimensional unit hypersphere in the word space.

Our work is partly inspired by (Le and Lauw, 2014a). However, our proposed approach differs from (Le and Lauw, 2014a) in that events, instead of topics, are modelled as the joint distribution over event elements. Both tweets and events are associate with coordinates in the visualization space.

3 Methodology

We follow the same pre-processing steps described in (Zhou et al., 2015) to filter out non-event-related tweets and extract dates, locations, and named entities by temporal resolution, part-of-speech (POS) tagging and named entity recognition. The pre-processed tweets are then fed into our proposed model for event extraction and visu-

Table 1: Definition of Notations.

Notation	Definition
e	event index, $e \in \{1..E\}$
$W = \{w_m\}$	tweets, $m \in \{1..M\}$
$Z = \{z_m\}$	event labels for tweets
N_{my}	number of named entities in w_m
N_{md}	number of dates in w_m
N_{ml}	number of locations in w_m
N_{mk}	number of keywords in w_m
θ_{ey}	probability of named entity y in event e
φ_{ed}	probability of date d in event e
ψ_{el}	probability of location l in event e
ω_{ek}	probability of keyword k in event e
$\beta, \gamma, \eta, \lambda$	Dirichlet hyperparameters
χ, δ	Normal hyperparameters
G	dimension of visualization space

alization. We describe our model in more details below.

3.1 Latent Event Extraction & Visualization (LEEV) Model

We propose an unsupervised latent variable model called the Latent Event Extraction & Visualization (LEEV) model which simultaneously extracts events from tweets and generates a visualization of the events. Table 1 lists notations used in this paper.

In LEEV, each tweet message w_m, $m \in \{1...M\}$ is associated with a latent coordinate x_m in the visualization space. Each event $e \in \{1...E\}$ is also associated with a coordinate ϕ_e. Assuming that each tweet message $w_m, m \in \{1...M\}$ is assigned to one event instance $z_m = e$ and e is modeled as a joint distribution over named entities y, the date d when e happened, the location l and the event-related keywords k, the generative process of the model is described as follows:

- For each event $e \in \{1..E\}$, draw multinomial distributions $\theta_e \sim$ Dirichlet(β), $\varphi_e \sim$ Dirichlet(γ), $\psi_e \sim$ Dirichlet(η), $\omega_e \sim$ Dirichlet(λ), draw event coordinate $\phi_e \sim$ Normal$(0, \chi^{-1}I)$;
- For each tweet $w_m, m \in \{1..M\}$
  - * Choose tweet coordinate: $x_m \sim$ Normal$(0, \delta^{-1}I)$;
  - * Choose an event $z_m = e \sim$ Multinomial$(\{P(e|x_m, \Phi)_{e=1}^{E}\})$;
  - * For each named entity in the tweet w_m, choose a named entity $y \sim$ Multinomial(θ_e);

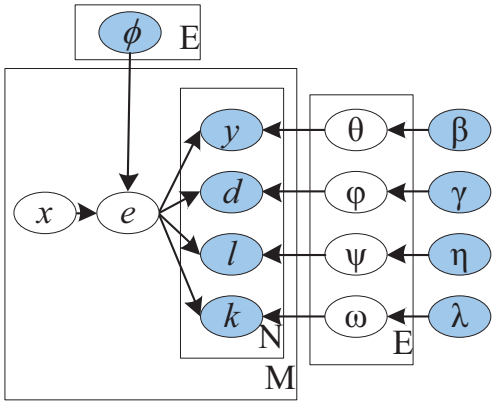

Figure 1: Latent Event Extraction & Visualization (LEEV) Model.

  - * For each date in the tweet w_m, choose a date $d \sim$ Multinomial(φ_e);
  - * For each location in the tweet w_m, choose a location $l \sim$ Multinomial(ψ_e);
  - * For other words in the tweet w_m, choose a word $k \sim$ Multinomial(ω_e).

Here, $\beta, \gamma, \eta, \lambda, \chi, \delta$ are priors, I is an identity matrix, and $P(e|x_m, \Phi)$ is the probability of the tweet w_m with coordinate x_m belonging to the event e. It is defined as,

$$P(e|x_m, \Phi) = \frac{\exp(-\frac{1}{2} \parallel x_m - \phi_e \parallel^2)}{\sum_{e'=1}^{E} \exp(-\frac{1}{2} \parallel x_m - \phi_{e'} \parallel^2)}. \quad (1)$$

It is calculated as the normalized Euclidean distance between a tweet w_m and an event e. Using this equation, when the Euclidean distance between a tweet w_m and and an event e is small, the probability that tweet w_m belongs to event e becomes large. The graphical model of LEEV is shown in Figure 1.

The parameters to be learned are $\Theta = \{\theta_e, \varphi_e, \psi_e, \omega_e\}_{e=1}^{E}$, tweets' coordinates $\mathcal{X} = \{x_m\}_{m=1}^{M}$ and events' coordinates $\Phi = \{\phi_e\}_{e=1}^{E}$, which are collectively denoted as $\mathcal{B} = \langle \Theta, \mathcal{X}, \Phi \rangle$. Let

$$H(w_m, e) = \prod_{n=1}^{N_{my}} P(y_n|\theta_e) \prod_{n=1}^{N_{md}} P(d_n|\varphi_e) \prod_{n=1}^{N_{ml}} P(l_n|\psi_e) \prod_{n=1}^{N_{mk}} P(k_n|\omega_e).$$

The log likelihood of $\mathcal{B}$ given tweets W is,

$$\mathcal{L}(\mathcal{B}|W) = \sum_{m=1}^{M} \log\Big\{\sum_{e=1}^{E} P(e|x_m, \Phi) \times H(w_m, e)\Big\} + \sum_{m=1}^{M} \log(P(x_m)) + \sum_{e=1}^{E} \log(P(\phi_e)) + \sum_{e=1}^{E} \{\log(P(\theta_e) * P(\varphi_e) * P(\psi_e) * P(\omega_e))\}. \quad (2)$$

For the events' coordinate ϕ_e and tweets' coordinate x_m, we use a Gaussian prior with a zero mean and a spherical covariance:

$$p(\phi_e) = (\frac{\chi}{2\pi})^{\frac{G}{2}} \exp(-\frac{\chi}{2} \parallel \phi_e \parallel^2)$$
$$p(x_m) = (\frac{\delta}{2\pi})^{\frac{G}{2}} \exp(-\frac{\delta}{2} \parallel x_m \parallel^2).$$

3.2 LEEV with Manifold Regularization

Recent studies suggest that the intrinsic geometry of textual data is a low-rank, non-linear manifold lying in the high dimensional space (Cai et al., 2008; Zhang et al., 2005). We therefore assume that when two tweets w_i and w_j are close in the intrinsic geometry of the manifold Υ, their low-rank representations should be close as well. To capture this assumption, we consider Laplacian Eigenmaps (LE) (Belkin and Niyogi, 2003) which has been commonly used in manifold learning algorithms (Le and Lauw, 2014a). It constructs a k-nearest neighbors graph to represent data residing on a low-dimensional manifold embedded in a higher-dimensional space. In this paper, we use LE to incorporate neighborhood information of tweets. We construct a manifold graph with edges connecting two data points w_i and w_j. Set the edge weight $v_{ij} = 1$ if w_j is one of the k-nearest neighbors of w_i; Otherwise $v_{ij} = 0$. That makes LEEV an special case when $\xi = 0$. We represent each tweet as a word-count vector, i.e., each element of a vector is weighted by its corresponding term frequency, and use cosine similarity metric to measure the distance between tweets when constructing the manifold graph. We also tried vectors with the TFIDF weighting strategy to represent tweets and found word-count vectors give better results.

We apply a regularization framework to incorporate a manifold structure into a learning model. The new regularized log-likelihood function L is

$$L(\mathcal{B}|W, \Upsilon) = L(\mathcal{B}|W) - \frac{\xi}{2}\mathcal{R}(\mathcal{B}|\Upsilon), \quad (3)$$

where ξ is the regularization parameter. The second component $\mathcal{R}$ is a regularization function, which consists of two parts:

$$\mathcal{R}(\mathcal{B}|\Upsilon) = \mathcal{R}_+(\mathcal{B}|\Upsilon) + \mathcal{R}_-(\mathcal{B}|\Upsilon), \quad (4)$$

$$\mathcal{R}_+(\mathcal{B}|\Upsilon) = \sum_{i,j=1;i\neq j}^{M} v_{ij} \cdot \mathcal{F}(w_i, w_j), \quad (5)$$

$$\mathcal{R}_-(\mathcal{B}|\Upsilon) = \sum_{i,j=1;i\neq j}^{M} \frac{1 - v_{ij}}{\mathcal{F}(w_i, w_j) + 1}, \quad (6)$$

where $\mathcal{F}$ is a distance function that operates on the low rank space. We define $\mathcal{F}$ as the squared Euclidean distance of coordinates in the visualization space. $\mathcal{F}(w_i, w_j)$is computed as follows:

$$\mathcal{F}(w_i, w_j) = \parallel x_i - x_j \parallel^2 . \quad (7)$$

Minimizing $\mathcal{R}_+$ leads to minimizing the distance between neighbors and minimizing $\mathcal{R}_-$ leads to maximizing the distance between non-neighbors. By enforcing manifold learning, we capture the spirit of keeping neighbors close and keeping none-neighbors apart.

3.3 Parameter Estimation

As in Equation 2, the presence of the sum over e prevents the logarithm form directly acting on the joint distribution. Assuming that the corresponding latent event z_m of each tweet w_m is known, $\{W, Z\}$ is called the complete data. Maximizing the log likelihood of the complete data, $\log P(W, Z|\mathcal{B})$, can be easily done. However, in practice we don't observe the latent variables Z and only have the incomplete data W. Therefore, the expectation maximization (EM) algorithm is employed to handle the incomplete data. EM involves an efficient iterative procedure to compute the Maximum Likelihood estimation of probabilistic models with unobserved latent variables involved.

The class posterior probability of the m^{th} tweet under the current parameter values $\hat{\mathcal{B}}$, $P(z_m = e|m, \hat{\mathcal{B}})$, is given as follows:

$$P(z_m = e|m, \hat{\mathcal{B}}) = \frac{P(z_m = e|\hat{x_m}, \hat{\Phi}, \hat{\mathcal{B}}) \times H(w_m, e)}{\sum_{e'=1}^{E} P(z_m = e'|\hat{x_m}, \hat{\Phi}, \hat{\mathcal{B}}) \times H(w_m, e')}, \quad (8)$$

which corresponds to the E-step in EM algorithm.

In M-step, model parameters $\mathcal{B}$ are updated by maximizing the regularized conditional expectation of the complete data log likelihood with priors defined as follows:

$$\begin{aligned}\mathcal{Q}(\mathcal{B}|\hat{\mathcal{B}}) &= \sum_{m=1}^{M}\sum_{e=1}^{E}\{P(z_m = e|m,\hat{\mathcal{B}}) \\ &\times \log[P(e|x_m,\Phi)\times H(w_m,e)]\} \\ &+ \sum_{m=1}^{M}\log(P(x_m)) + \sum_{e=1}^{E}\log(P(\phi_e)) \\ &+ \sum_{e=1}^{E}\{\log(P(\theta_e)*P(\varphi_e)*P(\psi_e)*P(\omega_e))\} \\ &- \frac{\xi}{2}\mathcal{R}(\mathcal{B}|\Upsilon),\end{aligned}$$

where $P(z_m = e|m,\hat{\mathcal{B}})$ is calculated in E-step.

By maximizing $\mathcal{Q}(\mathcal{B}|\hat{\mathcal{B}})$ w.r.t $\theta_{ey}, \varphi_{ed}, \psi_{el}, \omega_{ek}$, the next estimates are given as follows,

$$\theta_{ey} = \frac{\sum_{m=1}^{M}\sum_{n=1}^{N_{my}} I(y_{mn}=y)P(z_m=e|m,\hat{\mathcal{B}}) + \beta}{\sum_{y=1}^{Y}\sum_{m=1}^{M}\sum_{n=1}^{N_{my}} I(y_{mn}=y)P(z_m=e|m,\hat{\mathcal{B}}) + Y\beta},$$

$$\varphi_{ed} = \frac{\sum_{m=1}^{M}\sum_{n=1}^{N_{md}} I(d_{mn}=d)P(z_m=e|m,\hat{\mathcal{B}}) + \gamma}{\sum_{d=1}^{D}\sum_{m=1}^{M}\sum_{n=1}^{N_{md}} I(d_{mn}=d)P(z_m=e|m,\hat{\mathcal{B}}) + D\gamma},$$

$$\psi_{el} = \frac{\sum_{m=1}^{M}\sum_{n=1}^{N_{ml}} I(l_{mn}=l)P(z_m=e|m,\hat{\mathcal{B}}) + \eta}{\sum_{l=1}^{L}\sum_{m=1}^{M}\sum_{n=1}^{N_{ml}} I(l_{mn}=l)P(z_m=e|m,\hat{\mathcal{B}}) + L\eta},$$

$$\omega_{ek} = \frac{\sum_{m=1}^{M}\sum_{n=1}^{N_{mk}} I(k_{mn}=k)P(z_m=e|m,\hat{\mathcal{B}}) + \lambda}{\sum_{k=1}^{K}\sum_{m=1}^{M}\sum_{n=1}^{N_{mk}} I(k_{mn}=k)P(z_m=e|m,\hat{\mathcal{B}}) + K\eta},$$

where Y, D, L, K are the total numbers of distinct named entities, dates, locations, and words appeared in the whole Twitter corpus, respectively.

ϕ_e and x_m cannot be solved in a closed form, and are estimated by maximizing $\mathcal{Q}(\mathcal{B}|\hat{\mathcal{B}})$ using quasi-Newton method. The gradients of $\mathcal{Q}(\mathcal{B}|\hat{\mathcal{B}})$ w.r.t ϕ_e and x_m are as follows:

$$\begin{aligned}\frac{\partial\mathcal{Q}}{\partial\phi_e} &= \sum_{m=1}^{M} p(e|m,\hat{\mathcal{B}})(p(e|x_m,\Phi)-1)(\phi_e - x_m) \\ &- \chi\phi_e,\end{aligned}$$

$$\begin{aligned}\frac{\partial\mathcal{Q}}{\partial x_m} &= \sum_{e=1}^{E} p(e|m,\hat{\mathcal{B}})(p(e|x_m,\Phi)-1)(x_m - \phi_e) \\ &- \delta x_m - \frac{\xi}{2}\frac{\partial\mathcal{R}(\mathcal{B}|\Upsilon)}{\partial x_m},\end{aligned}$$

where the gradient of $\mathcal{R}(\mathcal{B}|\Upsilon)$ w.r.t. x_m is computed as follows:

$$\begin{aligned}\frac{\partial\mathcal{R}(\mathcal{B}|\Upsilon)}{\partial x_m} &= \sum_{j=1,j\neq m}^{M} 2\upsilon_{mj}(x_m - x_j) \\ &- \sum_{j=1,j\neq m}^{M} 2(x_m - x_j)\frac{1-\upsilon_{mj}}{(\mathcal{F}(x_m,x_j)+1)^2}.\end{aligned}$$

We set the parameter $\chi = 0.00005$, $\delta = 0.05$, $\beta = \gamma = \eta = \lambda = 0.1$ and run EM algorithm for 50 iterations. Finally we select an entity y, a date d, a location l and two keywords k with the highest probabilities to form a tuple $\langle y, d, l, k\rangle$ to represent each potential event.

3.4 Post-processing

In order to filter out spurious events, we calculate the correlation coefficient of each event element. Remove the event element if its correlation coefficient is less than a threshold C_e and remove the event if the sum of the correlation coefficients of all its four event elements is less than C_t.

For an event element A, its correlation coefficient is calculated below:

$$C_A = \log\frac{\sum_{B\in\Omega, B\neq A}\#(A,B)}{\#(A)}, \qquad (0)$$

where Ω is the set of the four event elements $\langle y, d, l, k\rangle$ and $\#(x)$ indicates the number of times x appeared in the whole corpus. We empirically set C_e to 0.4 and C_t to 4.

4 Experiments

In this section, we firstly describe the datasets used in our experiments and then present the experimental results.

4.1 Setup

We choose two datasets for model evaluation. The first one is the First Story Detection (FSD) dataset (Petrovic et al., 2013) (Dataset I) which contains 2,499 tweets published between 7th July and 12th September 2011. These tweets have been manually annotated with 27 events, covering a wide range of topics from accidents to science discoveries and from disasters to celebrity news. We filter out events mentioned in less than 15 tweets since events mentioned in very few tweets are less likely to be significant. The final dataset contains 2,453 tweets annotated with 20 events. This dataset has been previously used for evaluating event extraction models and the state-of-the-art results have been achieved using LEM (Zhou et al., 2015). We also create another dataset, called Dataset II, by manually annotating 1,000 tweets published in December 2010. A total of 20 events are annotated.

We compare our model with LEM (Zhou et al., 2015), which also extracts events as 4-tuples $\langle$

y,d,l,k $\rangle$. The main difference between LEM and our model is that LEM directly estimates the event distribution from the sampled latent event labels, while we derive the distribution from coordinates of tweets and events x_m, ϕ_e. We re-implemented the system described in (Zhou et al., 2015) and used the same evaluation metrics such as precision, recall and F-measure. Precision is defined as the proportion of the correctly identified events out of the system returned events. Recall is defined as the proportion of correctly identified true events. For calculating the precision of the 4-tuple $\langle y, d, l, k \rangle$, we use following criteria:

- Do the entity y, location l, date d and keyword k that we have extracted refer to the same event?
- If the extracted representation contains keywords, are they informative enough to tell us what happened?

As mentioned in Section 2, PE (Iwata et al., 2007) is a nonlinear visualization method which takes a set of class posterior vectors as input and embeds samples in a low-dimensional Euclidean space. By minimizing the sum of Kullback-Leibler divergences, PE tries to preserve the posterior structure in the embedding space. In order to evaluate the visualization results, we compare our proposed method with a pipeline approach, event extraction using LEM (Zhou et al., 2015) followed by event visualization using PE (Iwata et al., 2007), named as LEM+PE.

4.2 Event Extraction Results

Table 2 shows the event extraction results on the two datasets. LEEV+R is LEEV with manifold regularization incorporated, in which the model parameters are estimated by the EM algorithm described in Section 3.3. For LEEV and LEEV+R, the number of events, E, is set to 50 for both datasets. For LEEV+R, the number of neighborhood size k is set to 10 and the regularization parameter ξ is set to 1. For LEM, E is set to 25 for both datasets following the suggestion in (Zhou et al., 2015).

We ran our experiments on a server equipped with 3.40 GHz Intel Corel i7 CPU and 8 GB memory. The average running time of LEEV is 2328.1 seconds on Dataset I and 940.7 seconds on Dataset II for one iteration. The average running time of LEEV+R is 2612.7 seconds on Dataset I and 1296.4 seconds on Dataset II for one iteration.

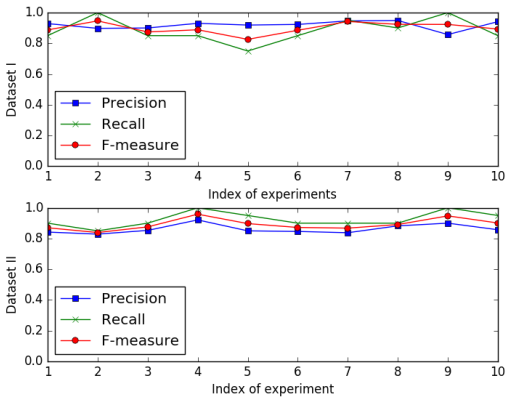

Figure 2: Experimental results of LEEV+R in 10 different runs.

Table 2: Comparison of the event extraction results on the two datasets.

Dataset I			
Method	Prec. (%)	Rec. (%)	F-measure (%)
LEM	84.00	76.19	80.35
LEEV	**92.10**	80.00	85.62
LEEV+R	91.91	**88.50**	**89.88**
Dataset II			
Method	Prec. (%)	Rec. (%)	F-measure (%)
LEM	80.00	90.00	84.70
LEEV	83.33	**95.00**	88.78
LEEV+R	**86.18**	92.50	**89.19**

It can be observed that both LEEV and LEEV+R outperforms the state-of-the-art results achieved by LEM on Dataset I. In particular, LEEV improves upon LEM by over 5% in F-measure and with regularization, LEEV-R further improves upon LEEV by over 4%. A similar trend is observed on Dataset II where both LEEV and LEEV+R outperforms LEM and the best performance is given by LEEV+R. This shows the effectiveness of using regularization in LEEV. We will further demonstrate its importance in visualization results. Overall, we see superior performance of LEEV+R over the other two models, with the F-measure of over 89% being achieved on both datasets.

As described in Section 3.1, the coordinates of tweets and events are randomly initialized. Therefore, we would like to see whether the performance of event extraction is influenced heavily by random initialization. We repeat the experiments

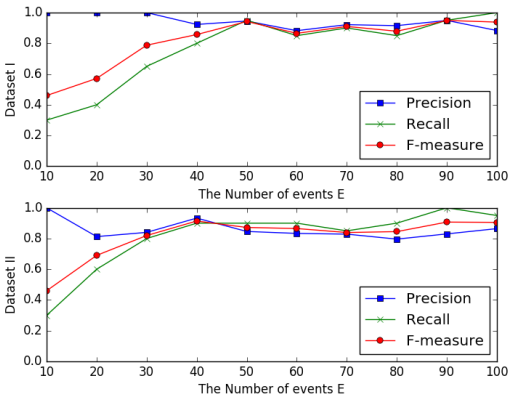

Figure 3: The performance of LEEV+R with different number of events E.

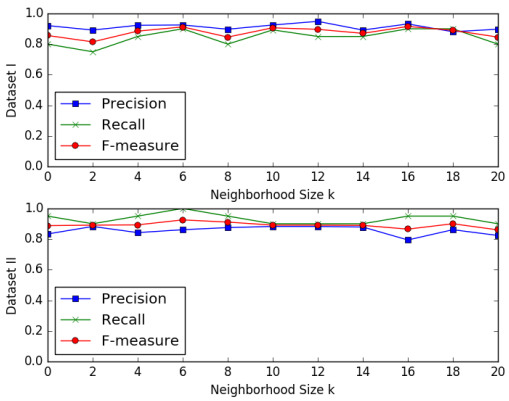

Figure 4: The performance of LEEV+R with different neighborhood size k.

on the two datasets for 10 times using LEEV+R. The experimental results are shown in Figure 2. It can be observed that the performance of LEEV+R is quite stable on both datasets. The standard deviation of F-measure on both Dataset I and I-I is 0.036, which shows that random initialization does not have significant impact on the final performance of the model.

4.3 Impact of Number of Events E

We need to pre-set the number of events E in the proposed approach. Figure 3 shows the performance of event extraction based on LEEV+R versus different values of E on the two datasets. It can be observed that the performance of the proposed approach improves with the increased value of E and when E goes beyond 50, we notice a more balanced precision/recall values and a relatively stable F-measure. This shows that the proposed approach is less sensitive to the number of events E so long as E is set to a relatively larger value.

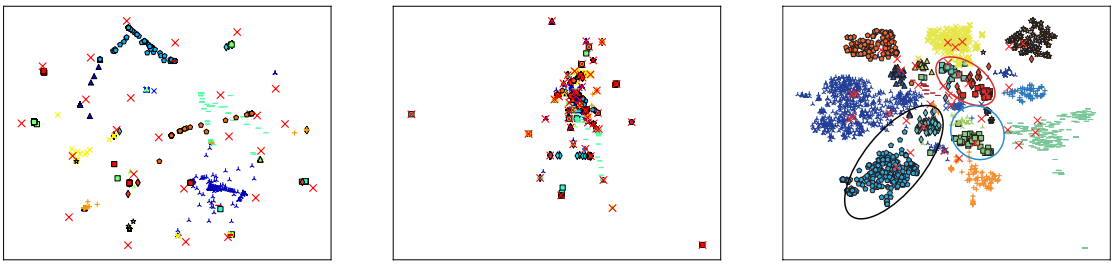
4.4 Impact of Neighborhood Size

As described in Section 3.2, the neighborhood information of tweets is incorporated into the learning framework. A manifold graph with edges connecting two tweets (or data points) w_i and w_j is constructed by setting the edge weight $v_{ij} = 1$ if w_j is among the k-nearest neighbors of w_i and $v_{ij} = 0$ otherwise. Therefore, it is crucial to see whether the performance of LEEV+R heavily depends on the setting of k. Figure 4 shows the performance of our proposed approach with different neighborhood size k. It can be observed that the performance of LEEV+R is quite stable and independent of the k value.

4.5 Visualization Results

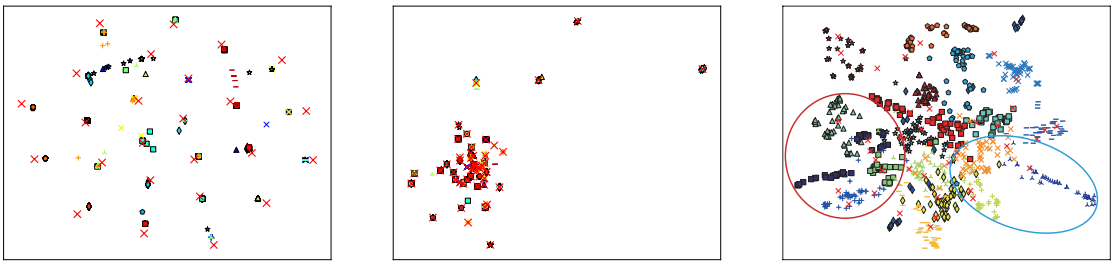
We show the visualization results produced by different approaches on the two datasets in Figure 5 and 6 respectively. We compare LEEV and LEEV+R with the pipeline approach LEM+PE. In the figures, each point represents a tweet and different shapes and colors represent the different events they are associated with. Each red cross represents an extracted event with coordinate ϕ_z.

For Dataset I, it can be observed from Figure 5(a) that the visualization result generated by LEM+PE is not informative. Tweets from different events are mixed together and events are evenly distributed across the whole visualization space. Thus, this visualization does not provide any sensible information about the relationships between tweets and events. The result generated by LEEV without manifold Regularization unit $\mathcal{R}$ seems better than that from LEM+PE, as shown in Figure 5(b). However, a large amount of tweets crowded together at the center, which makes it difficult to reveal the relations between tweets and events. The best visualization result is given by LEEV+R as shown in Figure 5(c) that different events are well separated and related events are located nearby. For example, the three events enclosed by a red circle represent "people died in terrorist attacks in Delhi, Oslo and Norway" respectively, while three events in the blue circle represent "riots in Ealing, Totteham and Croydon", respectively. And two events in the black circle represent "American credit rating" and "House



(a) LEM+PE (b) LEEV (c) LEEV+R

Figure 5: Visualization results on Dataset I.



(a) LEM+PE (b) LEEV (c) LEEV+R

Figure 6: Visualization results on Dataset II.

debt bill", respectively. It shows that LEEV+R with manifold learning incorporated significantly improved upon LEEV without regularization and gives better visualization results. The relationships of events are directly reflected in the distances between their coordinates in the visualization space.

Similar visualization results have been obtained on Dataset II. Figure 6(a) and 6(b) failed to convey the semantic relations between different events. LEEV+R in Figure 6(c) is good at separating tweets from different events. The events in the red circle are the government activities of the United States. The events in the blue circle are categorized as traffic accidents. They are " Transport chaos caused by heavy snow ", "Train to Paris crushed " and "Demonstrators attacked car carrying Prince Charles ". Compared to LEM+PE and LEEV, LEEV+R gives much more informative visualization results.

To further analyze the visualization results in more detail, the 4 representative events and their corresponding tweets in the red circle of Figure 6(c) are visualized in Figure 7. These four events are "Senate vote on repealing gay ban", "US state governor plan to visit North Korea", "Send letter to President Obama to stop tax cut deal" and "Congress passed the Child Nutrition Bill". Their corresponding tweets are denoted as green '△', blue '□', green '□' and blue '+' individually in Figure 7. It can be observed that these four events are all about government activities of the United States, and they are located close to each other in the low-dimensional visualization space. Moreover, the tweets describing the same event are located close to each other and center around their corresponding events, while the tweets describing different events are far away from each other.

5 Conclusions

In this paper, we have proposed an unsupervised Bayesian model, called Latent Event Extraction & Visualization (LEEV) model, to extract the structured representations of events from social media and simultaneously visualize them in a two-dimensional Euclidean space. The proposed approach has been evaluated on two datasets. Experimental results show that the proposed approach outperforms the previously reported best result on

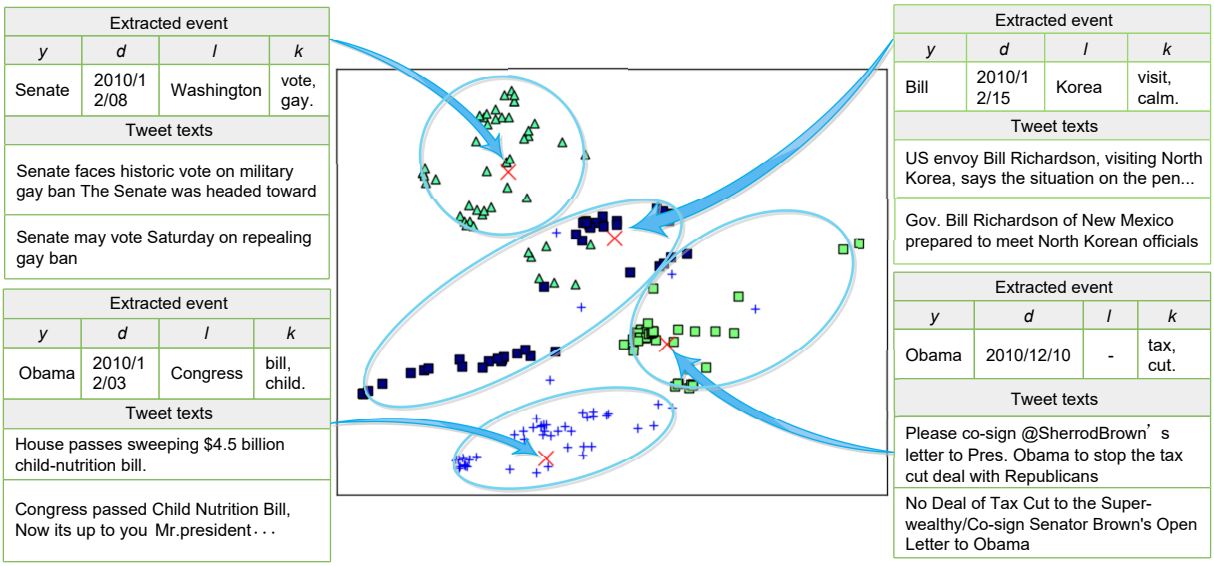


Figure 7: Four representative events and their corresponding tweets in the red circle of Figure 6(c).

Dataset I by nearly 10% in F-measure. Visualization results show that the proposed approach with manifold regularization can significantly improve the quality of event visualization. These results show that by jointly learning event extraction and visualization, our proposed approach is able to give better results on both tasks. In future work, we will investigate scalable and parallel model learning to explore the performance of our model for large-scale real-time event extraction and visualization.

Abstract

There is a small but growing body of research on statistical scripts, models of event sequences that allow probabilistic inference of implicit events from documents. These systems operate on structured verb-argument events produced by an NLP pipeline. We compare these systems with recent Recurrent Neural Net models that directly operate on raw tokens to predict sentences, finding the latter to be roughly comparable to the former in terms of predicting missing events in documents.

1 Introduction

Statistical scripts are probabilistic models of event sequences (Chambers and Jurafsky, 2008). A learned script model is capable of processing a document and inferring events that are probable but not explicitly stated. These models operate on automatically extracted structured events (for example, verbs with entity arguments), which are derived from standard NLP tools such as dependency parsers and coreference resolution engines.

Recent work has demonstrated that standard sequence models applied to such extracted event sequences, e.g. discriminative language models (Rudinger et al., 2015) and Long Short Term Memory (LSTM) recurrent neural nets (Pichotta and Mooney, 2016), are able to infer held-out events more accurately than previous approaches. These results call into question the extent to which statistical event inference systems require linguistic preprocessing and syntactic structure. In an attempt to shed light on this issue, we compare existing script models to LSTMs trained as *sentence-level language models* which try to predict the sequence of words in the next sentence from a learned representation of the previous sentences using no linguistic preprocessing.

Some prior statistical script learning systems are focused on knowledge induction. These systems are primarily designed to induce collections of co-occurring event types involving the same entities, and their ability to infer held-out events is not their primary intended purpose (Chambers and Jurafsky, 2008; Ferraro and Van Durme, 2016, *inter alia*). In the present work, we instead investigate the behavior of systems trained to directly optimize performance on the task of predicting subsequent events; in other words, we are investigating statistical models of events in discourse.

Much prior research on statistical script learning has also evaluated on inferring missing events from documents. However, the exact form that this task takes depends on the adopted definition of what constitutes an event: in previous work, events are defined in different ways, with differing degrees of structure. We consider simply using raw text, which requires no explicit syntactic annotation, as our mediating representation, and evaluate how raw text models compare to models of more structured events.

Kiros et al. (2015) introduced *skip-thought vector* models, in which an RNN is trained to encode a sentence within a document into a low-dimensional vector that supports predicting the neighboring sentences in the document. Though the objective function used to train networks maximizes performance on the task of predicting sentences from their neighbors, Kiros et al. (2015) do not evaluate directly on the ability of networks to predict text; they instead demonstrate that the intermediate low-dimensional vector embeddings are useful for other tasks. We directly evaluate the text predictions produced by such sentence-level RNN encoder-decoder models, and measure their utility for the task of predicting subsequent events.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 279–289,
Berlin, Germany, August 7-12, 2016.

We find that, on the task of predicting the text of held-out sentences, the systems we train to operate on the level of raw text generally outperform the systems we train to predict text mediated by automatically extracted event structures. On the other hand, if we run an NLP pipeline on the automatically generated text and extract structured events from these predictions, we achieve prediction performance roughly comparable to that of systems trained to predict events directly. The difference between word-level and event-level models on the task of event prediction is marginal, indicating that the task of predicting the next event, particularly in an encoder-decoder setup, may not necessarily need to be mediated by explicit event structures. To our knowledge, this is the first effort to evaluate sentence-level RNN language models directly on the task of predicting document text. Our results show that such models are useful for predicting missing information in text; and the fact that they require no linguistic preprocessing makes them more applicable to languages where quality parsing and co-reference tools are not available.

2 Background

2.1 Statistical Script Learning

Scripts, structured models of stereotypical sequences of events, date back to AI research from the 1970s, in particular the seminal work of Schank and Abelson (1977). In this conception, scripts are modeled as temporally ordered sequences of symbolic structured events. These models are nonprobabilistic and brittle, and pose serious problems for automated learning.

In recent years, there has been a growing body of research into statistical script learning systems, which enable statistical inference of implicit events from text. Chambers and Jurafsky (2008; 2009) describe a number of simple event co-occurrence based systems which infer (verb, dependency) pairs related to a particular discourse entity. For example, given the text:

> *Andrew Wiles won the 2016 Abel prize for proving Fermat's last theorem*,

such a system will ideally be able to infer novel facts like (*accept*, subject) or (*publish*, subject) for the entity *Andrew Wiles*, and facts like (*accept*, object) for the entity *Abel prize*. A number of other systems inferring the same types of pair events have been shown to provide superior performance in modeling events in documents (Jans et al., 2012; Rudinger et al., 2015).

Pichotta and Mooney (2014) give a co-occurrence based script system that models and infers more complex multi-argument events from text. For example, in the above example, their model would ideally be able to infer a single event like *accept*(*Wiles*, *prize*), as opposed to the two simpler pairs from which it is composed. They provide evidence that modeling and inferring more complex multi-argument events also yields superior performance on the task of inferring simpler (verb, dependency) pair events. These events are constructed using only coreference information; that is, the learned event co-occurrence models do not directly incorporate noun information.

More recently, Pichotta and Mooney (2016) presented an LSTM-based script inference model which models and infers multi-argument events, improving on previous systems on the task of inferring verbs with arguments. This system can incorporate both noun and coreference information about event arguments. We will use this multi-argument event formulation (formalized below) and compare LSTM models using this event formulation to LSTM models using raw text.

2.2 Recurrent Neural Networks

Recurrent Neural Networks (RNNs) are neural nets whose computation graphs have cycles. In particular, RNN sequence models are RNNs which map a sequence of inputs $x_1, \ldots, x_T$ to a sequence of outputs $y_1, \ldots, y_T$ via a learned latent vector whose value at timestep t is a function of its value at the previous timestep $t-1$.

The most basic RNN sequence models, so-called "vanilla RNNs" (Elman, 1990), are described by the following equations:

$$z_t = f(W_{i,z}x_t + W_{z,z}z_{t-1})$$
$$o_t = g(W_{z,o}z_t)$$

where x_t is the vector describing the input at time t; z_t is the vector giving the hidden state at time t; o_t is the vector giving the predicted output at time t; f and g are element-wise nonlinear functions (typically sigmoids, hyperbolic tangent, or rectified linear units); and $W_{i,z}$, $W_{z,z}$, and $W_{z,o}$ are learned matrices describing linear transformations. The recurrency in the computation graph arises from the fact that z_t is a function of z_{t-1}.

The more complex Long Short-Term Memory (LSTM) RNNs (Hochreiter and Schmidhuber,

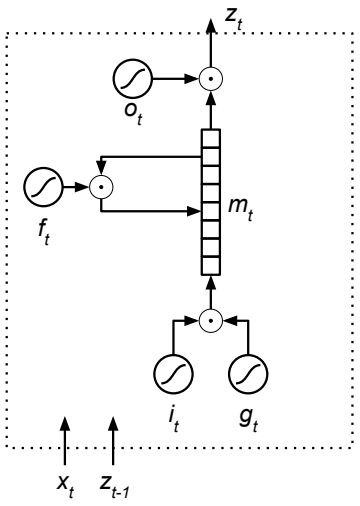

Figure 1: Long Short-Term Memory unit at timestep t. The four nonlinearity nodes (i_t, g_t, f_t, and o_t) all have, as inputs, x_t and z_{t-1}. Small circles with dots are elementwise vector multiplications.

1997) have been shown to perform well on a wide variety of NLP tasks (Sutskever et al., 2014; Hermann et al., 2015; Vinyals et al., 2015, *inter alia*). The LSTM we use is described by:

$$
\begin{aligned}
i_t &= \sigma\left(W_{x,i}x_t + W_{z,i}z_{t-1} + b_i\right) \\
f_t &= \sigma\left(W_{x,f}x_t + W_{z,f}z_{t-1} + b_f\right) \\
o_t &= \sigma\left(W_{x,o}x_t + W_{h,i}z_{t-1} + b_o\right) \\
g_t &= \tanh\left(W_{x,m}x_t + W_{z,m}z_{t-1} + b_g\right) \\
m_t &= f_t \circ m_{t-1} + i_t \circ g_t \\
z_t &= o_t \circ \tanh m_t.
\end{aligned}
$$

The model is depicted graphically in Figure 1. The memory vector m_t is a function of both its previous value m_{t-1} and the input x_t; the vector z_t is output both to any layers above the unit (which are trained to predict the output values y_t), and is additionally given as input to the LSTM unit at the next timestep $t+1$. The $W_{*,*}$ matrices and b_* vectors are learned model parameters, and $u \circ v$ signifies element-wise multiplication.

2.3 Sentence-Level RNN Language Models

RNN sequence models have recently been shown to be extremely effective for word-level and character-level language models (Mikolov et al., 2011; Jozefowicz et al., 2016). At each timestep, these models take a word or character as input, update a hidden state vector, and predict the next timestep's word or character. There is also a growing body of work on training RNN encoder-decoder models for NLP problems. These systems first encode the entire input into the network's hidden state vector and then, in a second step, decode the entire output from this vector (Sutskever et al., 2014; Vinyals et al., 2015; Serban et al., 2016).

Sentence-level RNN language models, for example the skip-thought vector system of Kiros et al. (2015), conceptually bridge these two approaches. Whereas standard language models are trained to predict the next token in the sequence of tokens, these systems are explicitly trained to predict the next *sentence* in the sequence of sentences. Kiros et al. (2015) train an encoder-decoder model to encode a sentence into a fixed-length vector and subsequently decode both the following and preceding sentence, using Gated Recurrent Units (Chung et al., 2014). In the present work, we train an LSTM model to predict a sentence's successor, which is essentially the forward component of the skip-thought system. Kiros et al. (2015) use the skip-thought system as a means of projecting sentences into low-dimensional vector embeddings, demonstrating the utility of these embeddings on a number of other tasks; in contrast, we will use our trained sentence-level RNN language model directly on the task its objective function optimizes: predicting a sentence's successor.

3 Methodology

3.1 Narrative Cloze Evaluation

The evaluation of inference-focused statistical script systems is not straightforward. Chambers and Jurafsky (2008) introduced the *Narrative Cloze* evaluation, in which a single event is held out from a document and systems are judged by the ability to infer this held-out event given the remaining events. This evaluation has been used by a number of published script systems (Chambers and Jurafsky, 2009; Jans et al., 2012; Pichotta and Mooney, 2014; Rudinger et al., 2015). This automated evaluation measures systems' ability to model and predict events as they co-occur in text.

The exact definition of the Narrative Cloze evaluation depends on the formulation of events used in a script system. For example, Chambers and Jurafsky (2008), Jans et al. (2012), and Rudinger et al. (2015) evaluate inference of held-out (verb, dependency) pairs from documents; Pichotta and Mooney (2014) evaluate inference of

verbs with coreference information about multiple arguments; and Pichotta and Mooney (2016) evaluate inference of verbs with noun information about multiple arguments. In order to gather human judgments of inference quality, the latter also learn an encoder-decoder LSTM network for transforming verbs and noun arguments into English text to present to annotators for evaluation.

We evaluate instead on the task of directly inferring sequences of words. That is, instead of defining the Narrative Cloze to be the evaluation of predictions of held-out events, we define the task to be the evaluation of predictions of held-out text; in this setup, predictions need not be mediated by noisy, automatically-extracted events. To evaluate inferred text against gold standard text, we argue that the BLEU metric (Papineni et al., 2002), commonly used to evaluate Statistical Machine Translation systems, is a natural evaluation metric. It is an n-gram-level analog to the event-level Narrative Cloze evaluation: whereas the Narrative Cloze evaluates a system on its ability to reconstruct events as they occur in documents, BLEU evaluates a system on how well it reconstructs the n-grams.

This evaluation takes some inspiration from the evaluation of neural encoder-decoder translation models (Sutskever et al., 2014; Bahdanau et al., 2015), which use similar architectures for the task of Machine Translation. That is, the task we present can be thought of as "translating" a sentence into its successor. While we do not claim that BLEU is necessarily the optimal way of evaluating text-level inferences, but we do claim that it is a natural ngram-level analog to the Narrative Cloze task on events.

If a model infers text, we may also evaluate it on the task of inferring events by automatically extracting structured events from its output text (in the same way as events are extracted from natural text). This allows us to compare directly to previous event-based models on the task they are optimized for, namely, predicting structured events.

3.2 Models

Statistical script systems take a sequence of events from a document and infer additional events that are statistically probable. Exactly what constitutes an *event* varies: it may be a (verb, dependency) pair inferred as relating to a particular discourse entity (Chambers and Jurafsky, 2008; Rudinger et al., 2015), a simplex verb (Chambers and Jurafsky, 2009; Orr et al., 2014), or a verb with multiple arguments (Pichotta and Mooney, 2014). In the present work, we adopt a representation of events as verbs with multiple arguments (Balasubramanian et al., 2013; Pichotta and Mooney, 2014; Modi and Titov, 2014). Formally, we define an event to be a variadic tuple (v, s, o, p^*), where v is a verb, s is a noun standing in subject relation to v, o is a noun standing as a direct object to v, and p^* denotes an arbitrary number of (*pobj*, *prep*) pairs, with *prep* a preposition and *pobj* a noun related to the verb v via the preposition *prep*.[1] Any argument except v may be *null*, indicating no noun fills that slot. For example, the text

Napoleon sent the letter to Josephine

would be represented by the event (*sent, Napoleon, letter, (Josephine, to)*). We represent arguments by their grammatical head words.

We evaluate on a number of different neural models which differ in their input and output. All models are LSTM-based encoder-decoder models. These models encode a sentence (either its events or text) into a learned hidden vector state and then, subsequently, decode that vector into its successor sentence (either its events or its text).

Our general system architecture is as follows. At each timestep t, the input token is represented as a learned 100-dimensional embedding vector (learned jointly with the other parameters of the model), such that predictively similar words should get similar embeddings. This embedding is fed as input to the LSTM unit (that is, it will be the vector x_t in Section 2.2, the input to the LSTM). The output of the LSTM unit (called z_t in Section 2.2) is then fed to a softmax layer via a learned linear transformation.

During the encoding phase the network is not trained to produce any output. During the decoding phase the output is a one-hot representation of the subsequent timestep's input token (that is, with a V-word vocabulary, the output will be a V-dimensional vector with one 1 and $V - 1$ zeros). In this way, the network is trained to consume an entire input sequence and, as a second step, iteratively output the subsequent timestep's

[1] This is essentially the event representation of Pichotta and Mooney (2016), but whereas they limited events to having a single prepositional phrase, we allow an arbitrary number, and we do not lemmatize words.

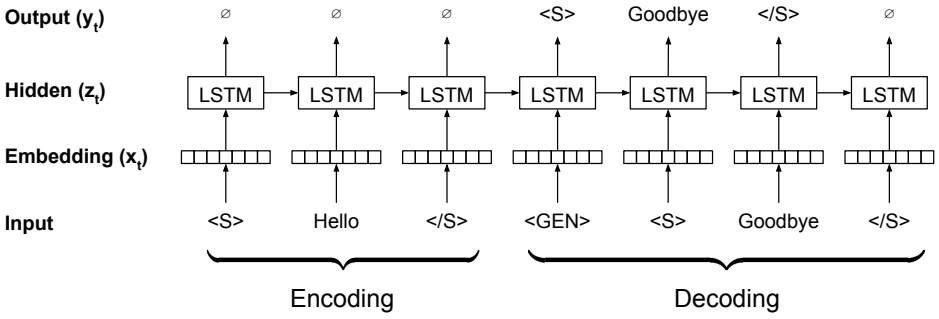

Figure 2: Encoder-Decoder setup predicting the text "Goodbye" from "Hello"

input, which allows the prediction of full output sequences. This setup is pictured diagrammatically in Figure 2, which gives an example of input and output sequence for a token-level encoder-decoder model, encoding the sentence "Hello ." and decoding the successor sentence "Goodbye ." Note that we add beginning-of-sequence and end-of-sequence pseudo-tokens to sentences. This formulation allows a system to be trained which can encode a sentence and then infer a successor sentence by iteratively outputting next-input predictions until the `</S>` end-of-sentence pseudo-token is predicted. We use different LSTMs for encoding and decoding, as the dynamics of the two stages need not be identical.

We notate the different systems as follows. Let s_1 be the input sentence and s_2 its successor sentence. Let t_1 denote the sequence of raw tokens in s_1, and t_2 the tokens of s_2. Further, let e_1 and e_2 be the sequence of structured events occurring in s_1 and s_2, respectively (described in more detail in Section 4.1), and let $e_2[0]$ denote the first event of e_2. The different systems we compare are named systematically as follows:

- The system $t_1 \rightarrow t_2$ is trained to encode a sentence's tokens and decode its successor's tokens.
- The system $e_1 \rightarrow e_2$ is trained to encode a sentence's events and decode its successor's events.
- The system $e_1 \rightarrow e_2 \rightarrow t_2$ is trained to encode a sentence's events, decode its successor's events, and then encode the latter and subsequently decode the successor's text.

We will not explicitly enumerate all systems, but other systems are defined analogously, with the schema $X \rightarrow Y$ describing a system which is trained to encode X and subsequently decode Y, and $X \rightarrow Y \rightarrow Z$ indicating a system which is trained to encode X, decode Y, and subsequently encode Y and decode Z. Note that in a system $X \rightarrow Y \rightarrow Z$, only X is provided as input.

We also present results for systems of the form $X \overset{a}{\rightarrow} Y$, which signifies that the system is trained to decode Y from X with the addition of an attention mechanism. We use the attention mechanism of Vinyals et al. (2015). In short, these models have additional parameters which can learn soft alignments between positions of encoded inputs and positions in decoded outputs. Attention mechanisms have recently been shown to be quite empirically valuable in many complex sequence prediction tasks. For more details on the model, see Vinyals et al. (2015).

Figure 3 gives a diagrammatic representation of the different system setups. Text systems infer successor text and, optionally, parse that text and extract events from it; event sequences infer successor events and, optionally, expand inferred events into text.

Note that the system $t_1 \rightarrow t_2$, in which both the encoding and decoding steps operate on raw text, is essentially a one-directional version of the skip-thought system of Kiros et al. (2015).[2] Further, the system $e_1 \rightarrow e_2 \rightarrow t_2$, which is trained to take a sentence's event sequence as input, predict its successor's events, and then predict its successor's words, is comparable to the event inference system of Pichotta and Mooney (2016). They use an LSTM sequence model of events in sequence

[2]The system of Kiros et al. (2015), in addition to being trained to predict the next sentence, also contains a backward-directional RNN trained to predict a sentence's predecessor; we condition only on previous text. Kiros et al. (2015) also use Gated Recurrent Units instead of LSTM.

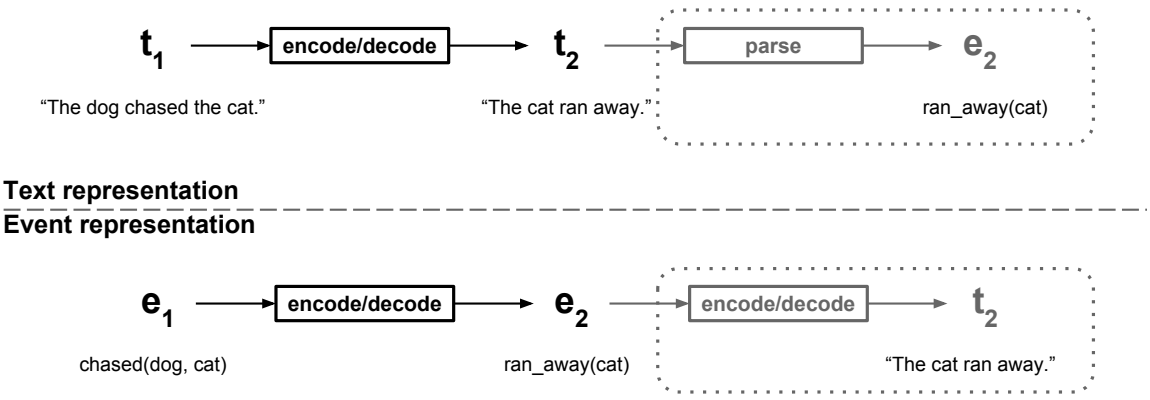

Figure 3: Different system setups for modeling the two-sentence sequence "The dog chased the cat." followed by "The cat ran away." The gray components inside dotted boxes are only present in some systems.

for event inference, and optionally transform inferred events to text using another LSTM; we, on the other hand, use an encoder/decoder setup to infer text directly.

4 Evaluation

4.1 Experimental Details

We train a number of LSTM encoder-decoder networks which vary in their input and output. Models are trained on English Language Wikipedia, with 1% of the documents held out as a validation set. Our test set consists of 10,000 unseen sentences (from articles in neither the training nor validation set). We train models with batch stochastic gradient descent with momentum, minimizing the cross-entropy error of output predictions. All models are implemented in TensorFlow (Abadi et al., 2015). We use a vocabulary of the 50,000 most frequent tokens, replacing all other tokens with an out-of-vocabulary pseudo-token. Learned word embeddings are 100-dimensional, and the latent LSTM vector is 500-dimensional. To extract events from text, we use the Stanford Dependency Parser (De Marneffe et al., 2006; Socher et al., 2013). We use the Moses toolkit (Koehn et al., 2007) to calculate BLEU.[3]

We evaluate the task of predicting held-out text with three metrics. The first metric is **BLEU**, which is standard BLEU (the geometric mean of modified 1-, 2-, 3-, and 4-gram precision against a gold standard, multiplied by a brevity penalty which penalizes short candidates). The second metric we present, **BLEU-BP,** is BLEU without the brevity penalty: in the task of predicting successor sentences, depending on predictions' end use, on-topic brevity is not necessarily undesirable. Evaluations are over top system inferences (that is, decoding is done by taking the argmax). Finally, we also present values for unigram precision (**1G P**), one of the components of BLEU.

We also evaluate on the task of predicting held-out verb-argument events, either directly or via inferred text. We use two evaluation metrics for this task. First, the **Accuracy** metric measures the percentage of a system's most confident guesses that are totally correct. That is, for each held-out event, a system makes its single most confident guess for that event, and we calculate the total percentage of such guesses which are totally correct. Some authors (e.g. Jans et al. (2012), Pichotta and Mooney (2016)) present results on the "Recall at k" metric, judging gold-standard recall against a list of top k event inferences; this metric is equivalent to "Recall at 1." This is quite a stringent metric, as an inference is only counted correct if the verb and all arguments are correct. To relax this requirement, we also present results on what we call the **Partial Credit** metric, which is the percentage of held-out event components identical to the respective components in a system's top inference.[4]

4.2 Experimental Evaluation

Table 1 gives the results of evaluating predicted successor sentence text against the gold standard using BLEU. The baseline system $t_1 \rightarrow t_1$ sim-

[3]Via the script `multi-bleu.pl`.

[4]This metric was used in Pichotta and Mooney (2014), but there it was called *Accuracy*. In the present work, we use "accuracy" only to mean Recall at 1.

System	BLEU	BLEU-BP	1G P
$t_1 \rightarrow t_1$	1.88	1.88	22.6
$e_1 \rightarrow e_2 \rightarrow t_2$	0.34	0.66	19.9
$e_1 \overset{a}{\rightarrow} e_2 \rightarrow t_2$	0.30	0.39	15.8
$t_1 \rightarrow t_2$	**5.20**	7.84	30.9
$t_1 \overset{a}{\rightarrow} t_2$	4.68	**8.09**	**32.2**

Table 1: Successor text predictions evaluated with BLEU.

System	Accuracy	Partial Credit
Most common	0.2	26.5
$e_1 \rightarrow e_2[0]$	**2.3**	26.7
$e_1 \overset{a}{\rightarrow} e_2[0]$	2.2	25.6
$t_1 \rightarrow t_2 \rightarrow e_2[0]$	2.0	**30.3**
$t_1 \overset{a}{\rightarrow} t_2 \rightarrow e_2[0]$	2.0	27.7

Table 2: Next event prediction accuracy (numbers are percentages: maximum value is 100).

ply reproduces the input sentence as its own successor.[5] Below this are systems which make predictions from event information, with systems which make predictions from raw text underneath. Transformations written $X \overset{a}{\rightarrow} Y$ are, recall, encoder-decoder LSTMs with attention.

Note, first, that the text-level models outperform other models on BLEU. In particular, the two-step model $e_1 \rightarrow e_2 \rightarrow t_2$ (and comparable model with attention) which first predicts successor events and then, as a separate step, expands these events into text, performs quite poorly. This is perhaps due to the fact that the translation from text to events is lossy, so reconstructing raw sentence tokens is not straightforward.

The BLEU-BP scores, which are BLEU without the brevity penalty, are noticeably higher in the text-level models than the raw BLEU scores. This is in part because these models seem to produce shorter sentences, as illustrated below in section 4.4.

The attention mechanism does not obviously benefit either text or event level prediction encoder-decoder models. This could be because there is not an obvious alignment structure between contiguous spans of raw text (or events) in natural documents.

These results provide evidence that, if the Narrative Cloze task is defined to evaluate prediction of held-out text from a document, then sentence-level RNN language models provide superior performance to RNN models operating at the event level. In other words, linguistic pre-processing does not obviously benefit encoder-decoder models trained to predict succeeding text.

Table 2 gives results on the task of predicting the next verb with its nominal arguments; that is, whereas Table 1 gave results on a text analog to the Narrative Cloze evaluation (BLEU), Table 2 gives results on the verb-with-arguments prediction version. In the $t_1 \rightarrow t_2 \rightarrow e_2[0]$ system (and the comparable system with attention), events are extracted from automatically generated text by parsing output text and applying the same event extractor to this parse used to extract events from raw text.[6] The row labeled **Most common** in Table 2 gives performance for the baseline system which always guesses the most common event in the training set.

The LSTM models trained to directly predict events are roughly comparable to systems which operate on raw text, performing slightly worse on accuracy and slightly better when taking partial credit into account. As with the previous comparisons with BLEU, the attention mechanism does not provide an obvious improvement when decoding inferences, perhaps, again, because the event inference problem lacks a clear alignment structure.

These systems infer their most probable guesses of $e_2[0]$, the first event in the succeeding sentence. In order for a system prediction to be counted as correct, it must have the correct strings for grammatical head words of all components of the correct event. Note also that we judge only against a system's single most confident prediction (as opposed to some prior work (Jans et al., 2012; Pichotta and Mooney, 2014) which takes the top k predictions—the numbers presented here are therefore noticeably lower). We do this mainly for computational reasons: namely, a beam search over a full sentence's text would be quite computationally expensive.

4.3 Adding Additional Context

The results given above are for systems which encode information about one sentence and decode

[5] "$t_1 \rightarrow t_1$" is minor abuse of notation, as the system is not an encoder/decoder but a simple identity function.

[6] This is also a minor abuse of notation, as the second transformation uses a statistical parser rather than an encoder/decoder.

information about its successor. This is within the spirit of the skip-gram system of Kiros et al. (2015), but we may wish to condition on more of the document. To investigate this, we perform an experiment varying the number of previous sentences input during the encoding step of $t_1 \rightarrow t_2$ text-level models without attention. We train three different models, which take either one, three, or five sentences as input, respectively, and are trained to output the successor sentence.

Num Prev Sents	BLEU	BLEU-BP	1G P
1	5.80	8.59	29.4
3	5.82	**9.35**	**31.2**
5	**6.83**	6.83	21.4

Table 3: Varying the amount of context in text-level models. "Num Prev Sents" is the number of previous sentences supplied during encoding.

Table 3 gives the results of running these models on 10,000 sentences from the validation set. As can be seen, in the training setup we investigate, more additional context sentences have a mixed effect, depending on the metric. This is perhaps due in part to the fact that we kept hyperparameters fixed between experiments, and a different hyperparameter regime would benefit predictions from longer input sequences. More investigation could prove fruitful.

4.4 Qualitative Analysis

Figure 4 gives some example automatic next-sentence text predictions, along with the input sentence and the gold-standard next sentence. Note that gold-standard successor sentences frequently introduce new details not obviously inferrable from previous text. Top system predictions, on the other hand, are frequently fairly short. This is likely due part to the fact that the cross-entropy loss does not directly penalize short sentences and part to the fact that many details in gold-standard successor text are inherently difficult to predict.

4.5 Discussion

The general low magnitude of the BLEU scores presented in Table 1, especially in comparison to the scores typically reported in Machine Translation results, indicates the difficulty of the task. In open-domain text, a sentence is typically not straightforwardly predictable from preceding text; if it were, it would likely not be stated.

On the task of verb-argument prediction in Table 2, the difference between $t_1 \rightarrow t_2$ and $e_1 \rightarrow e_2[0]$ is fairly marginal. This raises the general question of how much explicit syntactic analysis is required for the task of event inference, particularly in the encoder/decoder setup. These results provide evidence that a sentence-level RNN language model which operates on raw tokens can predict what comes next in a document as well or nearly as well as an event-mediated script model.

5 Future Work

There are a number of further extensions to this work. First, in this work (and, more generally, Neural Machine Translation research), though generated text is evaluated using BLEU, systems are optimized for per-token cross-entropy error, which is a different objective (Luong et al. (2016) give an example of a system which improves cross-entropy error but reduces BLEU score in the Neural Machine Translation context). Finding differentiable objective functions that more directly target more complex evaluation metrics like BLEU is an interesting future research direction.

Relatedly, though we argue that BLEU is a natural token-sequence-level analog to the verb-argument formulation of the Narrative Cloze task, it is not obviously the best metric for evaluating inferences of text, and comparing these automated metrics with human judgments is an important direction of future work. Pichotta and Mooney (2016) present results on crowdsourced human evaluation of script inferences that could be repeated for our RNN models.

Though we focus here on forward-direction models predicting successor sentences, bidirectional encoder-decoder models, which predict sentences from both previous and subsequent text, are another interesting future research direction.

6 Related Work

The use of scripts in AI dates back to the 1970s (Minsky, 1974; Schank and Abelson, 1977); in this conception, scripts were composed of complex events with no probabilistic semantics, which were difficult to learn automatically. In recent years, a growing body of research has investigated learning probabilistic co-occurrence models with simpler events. Chambers and Jurafsky (2008) propose a model of co-occurrence of (verb, dependency) pairs, which can be used to infer such

Input:	As of October 1 , 2008 , ⟨OOV⟩ changed its company name to Panasonic Corporation.
Gold:	⟨OOV⟩ products that were branded "National" in Japan are currently marketed under the "Panasonic" brand.
Predicted:	The company's name is now ⟨OOV⟩.
Input:	White died two days after Curly Bill shot him.
Gold:	Before dying, White testified that he thought the pistol had accidentally discharged and that he did not believe that Curly Bill shot him on purpose.
Predicted:	He was buried at ⟨OOV⟩ Cemetery.
Input:	The foundation stone was laid in 1867.
Gold:	The members of the predominantly Irish working class parish managed to save £700 towards construction, a large sum at the time.
Predicted:	The ⟨OOV⟩ was founded in the early 20th century.
Input:	Soldiers arrive to tell him that ⟨OOV⟩ has been seen in camp and they call for his capture and death.
Gold:	⟨OOV⟩ agrees .
Predicted:	⟨OOV⟩ is killed by the ⟨OOV⟩.

pairs from documents; Jans et al. (2012) give a superior model in the same general framework. Chambers and Jurafsky (2009) give a method of generalizing from single sequences of pair events to collections of such sequences. Rudinger et al. (2015) apply a discriminative language model to the (verb, dependency) sequence modeling task, raising the question of to what extent event inference can be performed with standard language models applied to event sequences. Pichotta and Mooney (2014) describe a method of learning a co-occurrence based model of verbs with multiple coreference-based entity arguments.

There is a body of related work focused on learning models of co-occurring events to automatically induce templates of complex events comprising multiple verbs and arguments, aimed ultimately at maximizing coherency of templates (Chambers, 2013; Cheung et al., 2013; Balasubramanian et al., 2013). Ferraro and Van Durme (2016) give a model integrating various levels of event information of increasing abstraction, evaluating both on coherence of induced templates and log-likelihood of predictions of held-out events. McIntyre and Lapata (2010) describe a system that learns a model of co-occurring events and uses this model to automatically generate stories via a Genetic Algorithm.

There have been a number of recent published neural models for various event- and discourse-related tasks. Pichotta and Mooney (2016) show that an LSTM event sequence model outperforms previous co-occurrence methods for predicting verbs with arguments. Granroth-Wilding and Clark (2016) describe a feedforward neural network which composes verbs and arguments into low-dimensional vectors, evaluating on a multiple-choice version of the Narrative Cloze task. Modi and Titov (2014) describe a feedforward network which is trained to predict event orderings. Kiros et al. (2015) give a method of embedding sentences in low-dimensional space such that embeddings are predictive of neighboring sentences. Li et al. (2014) and Ji and Eisenstein (2015), use RNNs for discourse parsing; Liu et al. (2016) use a Convolutional Neural Network for implicit discourse relation classification.

7 Conclusion

We have given what we believe to be the first systematic evaluation of sentence-level RNN language models on the task of predicting held-out document text. We have found that models operating on raw text perform roughly comparably to identical models operating on predicate-argument event structures when predicting the latter, and that text models provide superior predictions of raw text. This provides evidence that, for the task of held-out event prediction, encoder/decoder models mediated by automatically extracted events may not be learning appreciably more structure than systems trained on raw tokens alone.

A Supplemental Material

Our Wikipedia dump from which the training, development, and test sets are constructed is from Jan 2, 2014. We parse text using version 3.3.1 of the Stanford CoreNLP system. We use a vocab consisting of the 50,000 most common tokens, replacing all others with an Out-of-vocabulary pseudotoken. We train using batch stochastic gradient descent with momentum with a batch size of 10 sequences, using an initial learning rate of 0.1, damping the learning rate by 0.99 any time the previous hundred updates' average test error is greater than any of the average losses in the previous ten groups of hundred updates. Our momentum parameter is 0.95. Our embedding vectors are 100-dimensional, and our LSTM hidden state is 500-dimensional. We train all models for 300k batch updates (with the exception of the models compared in §4.3, all of which we train for 150k batch updates, as training is appreciably slower with longer input sequences). Training takes approximately 36 hours on an NVIDIA Titan Black GPU.

Two Discourse Driven Language Models for Semantics

Haoruo Peng and **Dan Roth**
University of Illinois, Urbana-Champaign
Urbana, IL, 61801
{hpeng7,danr}@illinois.edu

Abstract

Natural language understanding often requires deep semantic knowledge. Expanding on previous proposals, we suggest that some important aspects of semantic knowledge can be modeled as a language model if done at an appropriate level of abstraction. We develop two distinct models that capture semantic frame chains and discourse information while abstracting over the specific mentions of predicates and entities. For each model, we investigate four implementations: a "standard" N-gram language model and three discriminatively trained "neural" language models that generate embeddings for semantic frames. The quality of the semantic language models (SemLM) is evaluated both intrinsically, using perplexity and a narrative cloze test and extrinsically – we show that our SemLM helps improve performance on semantic natural language processing tasks such as co-reference resolution and discourse parsing.

1 Introduction

Natural language understanding often necessitates deep semantic knowledge. This knowledge needs to be captured at multiple levels, from words to phrases, to sentences, to larger units of discourse. At each level, capturing meaning frequently requires context sensitive abstraction and disambiguation, as shown in the following example (Winograd, 1972):

Ex.1 *[Kevin] was **robbed** by [Robert]. [He] was **arrested** by the police.*

Ex.2 *[Kevin] was **robbed** by [Robert]. [He] was **rescued** by the police.*

In both cases, one needs to resolve the pronoun "he" to either "Robert" or "Kevin". To make the correct decisions, one needs to know that the subject of "rob" is more likely than the object of "rob" to be the object of "arrest" while the object of "rob" is more likely to be the object of "rescue". Thus, beyond understanding individual predicates (e.g., at the semantic role labeling level), there is a need to place them and their arguments in a global context.

However, just modeling semantic frames is not sufficient; consider a variation of Ex.1:

Ex.3 *Kevin was **robbed** by Robert, but the police mistakenly **arrested** him.*

In this case, "him" should refer to "Kevin" as the discourse marker "but" reverses the meaning, illustrating that it is necessary to take discourse markers into account when modeling semantics.

In this paper we propose that these aspects of semantic knowledge can be modeled as a *Semantic Language Model* (SemLM). Just like the "standard" syntactic language models (LM), we define a basic vocabulary, a finite representation language, and a prediction task, which allows us to model the distribution over the occurrence of elements in the vocabulary as a function of their (well-defined) context. In difference from syntactic LMs, we represent natural language at a higher level of semantic abstraction, thus facilitating modeling deep semantic knowledge.

We propose two distinct discourse driven language models to capture semantics. In our first semantic language model, the *Frame-Chain SemLM*, we model all semantic frames and discourse markers in the text. Each document is viewed as a single chain of semantic frames and discourse markers. Moreover, while the vocabulary of discourse markers is rather small, the number of different surface form semantic frames that could appear in the text is very large. To achieve a better level of abstraction, we disambiguate semantic frames and map them to their PropBank/FrameNet represen-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 290–300,
Berlin, Germany, August 7-12, 2016.

tation. Thus, in Ex.3, the resulting frame chain is "rob.01 — but — arrest.01" ("01" indicates the predicate sense).

Our second semantic language model is called *Entity-Centered SemLM*. Here, we model a sequence of semantic frames and discourse markers involved in a specific co-reference chain. For each co-reference chain in a document, we first extract semantic frames corresponding to each co-referent mention, disambiguate them as before, and then determine the discourse markers between these frames. Thus, each unique frame contains both the disambiguated predicate and the argument label of the mention. In Ex.3, the resulting sequence is "rob.01#obj — but — arrest.01#obj" (here "obj" indicates the argument label for "Kevin" and "him" respectively). While these two models capture somewhat different semantic knowledge, we argue later in the paper that both models can be induced at high quality, and that they are suitable for different NLP tasks.

For both models of SemLM, we study four language model implementations: N-gram, skip-gram (Mikolov et al., 2013b), continuous bag-of-words (Mikolov et al., 2013a) and log-bilinear language model (Mnih and Hinton, 2007). Each model defines its own prediction task. In total, we produce eight different SemLMs. Except for N-gram model, others yield embeddings for semantic frames as they are neural language models.

In our empirical study, we evaluate both the quality of all SemLMs and their application to co-reference resolution and shallow discourse parsing tasks. Following the traditional evaluation standard of language models, we first use perplexity as our metric. We also follow the script learning literature (Chambers and Jurafsky, 2008b; Chambers and Jurafsky, 2009; Rudinger et al., 2015) and evaluate on the narrative cloze test, i.e. randomly removing a token from a sequence and test the system's ability to recover it. We conduct both evaluations on two test sets: a hold-out dataset from the New York Times Corpus and gold sequence data (for frame-chain SemLMs, we use PropBank (Kingsbury and Palmer, 2002); for entity-centered SemLMs, we use Ontonotes (Hovy et al., 2006)). By comparing the results on these test sets, we show that we do not incur noticeable degradation when building SemLMs using preprocessing tools. Moreover, we show that SemLMs improves the performance of co-reference resolution, as well as that of predicting the sense of discourse connectives for both explicit and implicit ones.

The main contributions of our work can be summarized as follows: 1) The design of two novel discourse driven Semantic Language models, building on text abstraction and neural embeddings; 2) The implementation of high quality SemLMs that are shown to improve state-of-the-art NLP systems.

2 Related Work

Our work is related to script learning. Early works (Schank and Abelson, 1977; Mooney and DeJong, 1985) tried to construct knowledge bases from documents to learn scripts. Recent work focused on utilizing statistical models to extract high-quality scripts from large amounts of data (Chambers and Jurafsky, 2008a; Bejan, 2008; Jans et al., 2012; Pichotta and Mooney, 2014; Granroth-Wilding et al., 2015; Pichotta and Mooney, 2016). Other works aimed at learning a collection of structured events (Chambers, 2013; Cheung et al., 2013; Cheung et al., 2013; Balasubramanian et al., 2013; Bamman and Smith, 2014; Nguyen et al., 2015), and several works have employed neural embeddings (Modi and Titov, 2014b; Modi and Titov, 2014a; Frermann et al., 2014; Titov and Khoddam, 2015).

In our work, the semantic sequences in the entity-centered SemLMs are similar to narrative schemas (Chambers and Jurafsky, 2009). However, we differ from them in the following aspects: 1) script learning does not generate a probabilistic model on semantic frames[1]; 2) script learning models semantic frame sequences incompletely as they do not consider discourse information; 3) works in script learning rarely show applications to real NLP tasks.

Some prior works have used scripts-related ideas to help improve NLP tasks (Irwin et al., 2011; Rahman and Ng, 2011; Peng et al., 2015b). However, since they use explicit script schemas either as features or constraints, these works suffer from data sparsity problems. In our work, the SemLM abstract vocabulary ensures a good coverage of frame semantics.

[1]Some works may utilize a certain probabilistic framework, but they mainly focus on generating high-quality frames by filtering.

Table 1: **Comparison of vocabularies between frame-chain (FC) and entity-centered (EC) SemLMs.** "F-Sen" stands for frames with predicate sense information while "F-Arg" stands for frames with argument role label information; "Conn" means discourse marker and "Per" means period. "Seq/Doc" represents the number of sequence per document.

	F-Sen	F-Arg	Conn	Per	Seq/Doc
FC	YES	NO	YES	YES	Single
EC	YES	YES	YES	NO	Multiple

3 Two Models for SemLM

In this section, we describe how we capture sequential semantic information consisted of semantic frames and discourse markers as semantic units (i.e. the vocabulary).

3.1 Semantic Frames and Discourse Markers

Semantic Frames A semantic frame is composed of a predicate and its corresponding argument participants. Here we require the predicate to be disambiguated to a specific sense, and we need a certain level of abstraction of arguments so that we can assign abstract labels. The design of PropBank frames (Kingsbury and Palmer, 2002) and FrameNet frames (Baker et al., 1998) perfectly fits our needs. They both have a limited set of frames (in the scale of thousands) and each frame can be uniquely represented by its predicate sense. These frames provide a good level of generalization as each frame can be instantiated into various surface forms in natural texts. We use these frames as part of our vocabulary for SemLMs. Formally, we use the notation f to represent a frame. Also, we denote fa $\triangleq$ f#Arg when referring to an argument role label (Arg) inside a frame (f).

Discourse Markers We use discourse markers (connectives) to model discourse relationships between frames. There is only a limited number of unique discourse markers, such as *and, but, however*, etc. We get the full list from the Penn Discourse Treebank (Prasad et al., 2008) and include them as part of our vocabulary for SemLMs. Formally, we use *dis* to denote the discourse marker. Note that discourse relationships can exist without an explicit discourse marker, which is also a challenge for discourse parsing. Since we cannot reliably identify implicit discourse relationships, we only consider explicit ones here. More importantly, discourse markers are associated with arguments (Wellner and Pustejovsky, 2007) in text (usually two sentences/clauses, sometimes one). We only add a discourse marker in the semantic sequence when its corresponding arguments contain semantic frames which belong to the same semantic sequence. We call them *frame-related discourse markers*. Details on generating semantic frames and discourse markers to form semantic sequences are discussed in Sec. 5.

3.2 Frame-Chain SemLM

For frame-chain SemLM, we model all semantic frames and discourse markers in a document. We form the semantic sequence by first including all semantic frames in the order they appear in the text: $[\mathrm{f}_1, \mathrm{f}_2, \mathrm{f}_3, \ldots]$. Then we add *frame-related discourse markers* into the sequence by placing them in their order of appearance. Thus we get a sequence like $[\mathrm{f}_1, \mathrm{dis}_1, \mathrm{f}_2, \mathrm{f}_3, \mathrm{dis}_2, \ldots]$. Note that discourse markers do not necessarily exist between all semantic frames. Additionally, we treat the *period* symbol as a special discourse marker, denoted by "o". As some sentences contain more than one semantic frame (situations like clauses), we get the final semantic sequence like this:

$$[\mathrm{f}_1, \mathrm{dis}_1, \mathrm{f}_2, \mathrm{o}, \mathrm{f}_3, \mathrm{o}, \mathrm{dis}_2, \ldots, \mathrm{o}]$$

3.3 Entity-Centered SemLM

We generate semantic sequences according to co-reference chains for entity-centered SemLM. From co-reference resolution, we can get a sequence like $[\mathrm{m}_1, \mathrm{m}_2, \mathrm{m}_3, \ldots]$, where mentions appear in the order they occur in the text. Each mention can be matched to an argument inside a semantic frame. Thus, we replace each mention with its argument label inside a semantic frame, and get $[\mathrm{fa}_1, \mathrm{fa}_2, \mathrm{fa}_3, \ldots]$. We then add discourse markers exactly in they way we do for frame-chain SemLM, and get the following sequence:

$$[\mathrm{fa}_1, \mathrm{dis}_1, \mathrm{fa}_2, \mathrm{fa}_3, \mathrm{dis}_2, \ldots]$$

The comparison of vocabularies between frame-chain and entity-centered SemLMs is summarized in Table 1.

4 Implementations of SemLM

In this work, we experiment with four language model implementations: N-gram (NG), Skip-Gram (SG), Continuous Bag-of-Words (CBOW) and Log-bilinear (LB) language model. For ease

of explanation, we assume that a semantic unit sequence is $s = [w_1, w_2, w_3, \ldots, w_k]$.

4.1 N-gram Model

For an n-gram model, we predict each token based on its $n-1$ previous tokens, i.e. we directly model the following conditional probability (in practice, we choose $n = 3$, Tri-gram (TRI)):

$$p(w_{t+2}|w_t, w_{t+1}).$$

Then, the probability of the sequence is

$$p(s) = p(w_1)p(w_2|w_1)\prod_{t=1}^{k-2} p(w_{t+2}|w_t, w_{t+1}).$$

To compute $p(w_2|w_1)$ and $p(w_1)$, we need to back off from Tri-gram to Bi-gram and Uni-gram.

4.2 Skip-Gram Model

The SG model was proposed in Mikolov et al. (2013b). It uses a token to predict its context, i.e. we model the following conditional probability:

$$p(c \in c(w_t)|w_t, \theta).$$

Here, $c(w_t)$ is the context for w_t and θ denotes the learned parameters which include neural network states and embeddings. Then the probability of the sequence is computed as

$$\prod_{t=1}^{k} \prod_{c \in c(w_t)} p(c|w_t, \theta).$$

4.3 Continuous Bag-of-Words Model

In contrast to skip-gram, CBOW (Mikolov et al., 2013a) uses context to predict each token, i.e. we model the following conditional probability:

$$p(w_t|c(w_t), \theta).$$

In this case, the probability of the sequence is

$$\prod_{t=1}^{k} p(w_t|c(w_t), \theta).$$

4.4 Log-bilinear Model

LB was introduced in Mnih and Hinton (2007). Similar to CBOW, it also uses context to predict each token. However, LB associates a token with three components instead of just one vector: a target vector v(w), a context vector v'(w) and a bias b(w). So, the conditional probability becomes:

$$p(w_t|c(w_t)) = \frac{\exp(v(w_t)^\intercal u(c(w_t)) + b(w_t))}{\sum_{w \in \mathcal{V}} \exp(v(w)^\intercal u(c(w_t)) + b(w))}.$$

Here, $\mathcal{V}$ denotes the vocabulary and we define $u(c(w_t)) = \sum_{c_i \in c(w_t)} q_i \odot v'(c_i)$. Note that $\odot$ represents element-wise multiplication and q_i is a vector that depends only on the position of a token in the context, which is a also a model parameter.

So, the overall sequence probability is

$$\prod_{t=1}^{k} p(w_t|c(w_t)).$$

5 Building SemLMs from Scratch

In this section, we explain how we build SemLMs from un-annotated plain text.

5.1 Dataset and Preprocessing

Dataset We use the New York Times Corpus[2] (from year 1987 to 2007) for training. It contains a bit more than 1.8M documents in total.

Preprocessing We pre-process all documents with semantic role labeling (Punyakanok et al., 2004) and part-of-speech tagger (Roth and Zelenko, 1998). We also implement the explicit discourse connective identification module in shallow discourse parsing (Song et al., 2015). Additionally, we utilize within document entity coreference (Peng et al., 2015a) to produce coreference chains. To obtain all annotations, we employ the Illinois NLP tools[3].

5.2 Semantic Unit Generation

FrameNet Mapping We first directly derive semantic frames from semantic role labeling annotations. As the Illinois SRL package is built upon PropBank frames, we do a mapping to FrameNet frames via VerbNet senses (Schuler, 2005), thus achieving a higher level of abstraction. The mapping file[4] defines deterministic mappings. However, the mapping is not complete and there are remaining PropBank frames. Thus, the generated vocabulary for SemLMs contains both PropBank and FrameNet frames. For example, "place" and

[2]https://catalog.ldc.upenn.edu/LDC2008T19

[3]http://cogcomp.cs.illinois.edu/page/software/

[4]http://verbs.colorado.edu/verb-index/fn/vn-fn.xml

"put" with the VerbNet sense id "9.1-2" are converted to the same FrameNet frame "Placing".

Augmenting to Verb Phrases We apply three heuristic modifications to augment semantic frames defined in Sec. 3.1: 1) if a preposition immediately follows a predicate, we append the preposition to the predicate e.g. "take over"; 2) if we encounter the semantic role label AM-PRD which indicates a secondary predicate, we also append this secondary predicate to the main predicate e.g. "be happy"; 3) if we see the semantic role label AM-NEG which indicates negation, we append "not" to the predicate e.g. "not like". These three augmentations can co-exist and they allow us to model more fine-grained semantic frames.

Verb Compounds We have observed that if two predicates appear very close to each other, e.g. "eat and drink", "decide to buy", they actually represent a unified semantic meaning. Thus, we construct compound verbs to connect them together. We apply the rule that if the gap between two predicates is less than two tokens, we treat them as a unified semantic frame defined by the conjunction of the two (augmented) semantic frames, e.g. "eat.01-drink.01" and "decide.01-buy.01".

Argument Labels for Co-referent Mentions To get the argument role label information for co-referent mentions, we need to match each mention to its corresponding semantic role labeling argument. If a mention head is inside an argument, we regard it as a match. We do not consider singleton mentions.

Vocabulary Construction After generating all semantic units for (augmented and compounded) semantic frames and discourse markers, we merge them together as a tentative vocabulary. In order to generate a sensible SemLM, we filter out rare tokens which appear less than 20 times in the data. We add the Unknown token (UNK) and End-of-Sequence token (EOS) to the eventual vocabulary.

Statistics on the eventual SemLM vocabularies and semantic sequences are shown in Table 2. We also compare frame-chain and entity-centered SemLMs to the usual syntactic language model setting. The statistics in Table 2 shows that they are comparable both in vocabulary size and in the total number of tokens for training. Moreover, entity-centered SemLMs have shorter sequences then frame-chain SemLMs. We also provide several examples of high-frequency augmented compound semantic frames in our generated SemLM vocabularies. All are very intuitive:

want.01-know.01, agree.01-pay.01, try.01-get.01, decline.02-comment.01, wait.01-see.01, make.02-feel.01, want.01(not)-give.08(up)

Table 2: **Statistics on SemLM vocabularies and sequences.** "F-s" stands for single frame while "F-c" stands for compound frame; "Conn" means discourse marker. "#seq" is the number of sequences, and "#token" is the total number of tokens (semantic units). We also compute the average token in a sequence i.e. "#t/s". We compare frame-chain (FC) and entity-centered (EC) SemLMs to the usual syntactic language model setting i.e. "LM".

	Vocabulary Size			Sequence Size		
	F-s	F-c	Conn	#seq	#token	#t/s
FC	14857	7269	44	1.2M	25.4M	21
EC	8758	2896	44	3.4M	18.6M	5
LM	∼20k			∼3M	∼38M	10-15

5.3 Language Model Training

NG We implement the N-gram model using the SRILM toolkit (Stolcke, 2002). We also employ the well-known KneserNey Smoothing (Kneser and Ney, 1995) technique.

SG & CBOW We utilize the word2vec package to implement both SG and CBOW. In practice, we set the context window size to be 10 for SG while set the number as 5 for CBOW (both are usual settings for syntactic language models). We generate 300-dimension embeddings for both models.

LB We use the OxLM toolkit (Paul et al., 2014) with Noise-Constrastive Estimation (Gutmann and Hyvarinen, 2010) for the LB model. We set the context window size to 5 and produce 150-dimension embeddings.

6 Evaluation

In this section, we first evaluate the quality of SemLMs through perplexity and a narrative cloze test. More importantly, we show that the proposed SemLMs can help improve the performance of co-reference resolution and shallow discourse parsing. This further proves that we successfully capture semantic sequence information which can potentially benefit a wide range of semantic related NLP tasks.

We have designed two models for SemLM: *frame-chain* (**FC**) and *entity-centered* (**EC**). By training on both types of sequences respectively, we implement four different language models:

TRI, SG, CBOW, LB. We focus the evaluation efforts on these eight SemLMs.

6.1 Quality Evaluation of SemLMs

Datasets We use three datasets. We first randomly sample 10% of the New York Times Corpus documents (roughly two years of data), denoted the *NYT Hold-out Data*. All our SemLMs are trained on the remaining NYT data and tested on this hold-out data. We generate semantic sequences for the training and test data using the methodology described in Sec. 5.

We use PropBank data with gold frame annotations as another test set. In this case, we only generate frame-chain SemLM sequences by applying semantic unit generation techniques on gold frames, as described in Sec 5.2. When we test on *Gold PropBank Data with Frame Chains*, we use frame-chain SemLMs trained from all NYT data.

Similarly, we use Ontonotes data (Hovy et al., 2006) with gold frame and co-reference annotations as the third test set, *Gold Ontonotes Data with Coref Chains*. We only generate entity-centered SemLMs by applying semantic unit generation techniques on gold frames and gold co-reference chains, as described in Sec 5.2.

Baselines We use Uni-gram (**UNI**) and Bi-gram (**BG**) as two language model baselines. In addition, we use the point-wise mutual information (PMI) for token prediction. Essentially, PMI scores each pair of tokens according to their co-occurrences. It predicts a token in the sequence by choosing the one with the highest total PMI with all other tokens in the sequence. We use the ordered PMI (**OP**) as our baseline, which is a variation of PMI by considering asymmetric counting (Jans et al., 2012).

6.1.1 Perplexity

As SemLMs are language models, it is natural to evaluate the perplexity, which is a measurement of how well a language model can predict sequences.

Results for SemLM perplexities are presented in Table 3. They are computed without considering end token (EOS). We apply tri-gram Kneser-Ney Smoothing to CBOW, SG and LB. LB consistently shows the lowest perplexities for both frame-chain and entity-centered SemLMs across all test sets. Similar to syntactic language models, perplexities are fast decreasing from UNI, BI to TRI. Also, CBOW and SG have very close perplexity results which indicate that their language modeling abilities are at the same level.

Table 3: **Perplexities for SemLMs.** UNI, BG, TRI, CBOW, SG, LB are different language model implementations while "FC" and "EC" stand for the two SemLM models studied, respectively. "FC-FM" and "EC-FM" indicate that we removed the "FrameNet Mapping" step (Sec. 5.2). LB consistently produces the lowest perplexities for both frame-chain and entity-centered SemLMs.

	Baselines		SemLMs			
	UNI	BG	TRI	CBOW	SG	LB
NYT Hold-out Data						
FC	952.1	178.3	119.2	115.4	114.1	**108.5**
EC	914.7	154.4	114.9	111.8	113.8	**109.7**
Gold PropBank Data with Frame Chains						
FC-FM	992.9	213.7	139.1	135.6	128.4	121.8
FC	970.0	191.2	132.7	126.4	123.5	**115.4**
Gold Ontonotes Data with Coref Chains						
EC-FM	956.4	187.7	121.1	115.6	117.2	113.7
EC	923.8	163.2	120.5	113.7	115.0	**109.3**

We can compare the results of our frame-chain SemLM on *NYT Hold-out Data* and *Gold PropBank Data with Frame Chains*, and our entity-centered SemLM on *NYT Hold-out Data* and *Gold Ontonotes Data with Coref Chains*. While we see differences in the results, the gap is narrow and the relative ranking of different SemLMs does not change. This indicates that the automatic SRL and Co-reference annotations added some noise but, more importantly, that the resulting SemLMs are robust to this noise as we still retain the language modeling ability for all methods.

Additionally, our ablation study removes the "FrameNet Mapping" step in Sec. 5.2 ("FC-FM" and "EC-FM" rows), resulting in only using PropBank frames in the vocabulary. The increase in perplexities shows that "FrameNet Mapping" does produce a higher level of abstraction, which is useful for language modeling.

6.1.2 Narrative Cloze Test

We follow the Narrative Cloze Test idea used in script learning (Chambers and Jurafsky, 2008b; Chambers and Jurafsky, 2009). As Rudinger et al. (2015) points out, the narrative cloze test can be regarded as a language modeling evaluation. In the narrative cloze test, we randomly choose and remove one token from each semantic sequence in the test set. We then use language models to predict the missing token and evaluate the correctness. For all SemLMs, we use the conditional probabilities defined in Sec. 4 to get token predictions. We also use ordered PMI as an additional baseline. The narrative cloze test is conducted on

Table 4: **Narrative cloze test results for SemLMs.** UNI, BG, TRI, CBOW, SG, LB are different language model implementations while "FC" and "EC" stand for our two SemLM models, respectively. "FC-FM" and "EC-FM" mean that we remove the FrameNet mappings. "w/o DIS" indicates the removal of discourse makers in SemLMs. "Rel-Impr" indicates the relative improvement of the best performing SemLM over the strongest baseline. We evaluate on two metrics: mean reciprocal rank (MRR)/recall at 30 (Recall@30). LB outperforms other methods for both frame-chain and entity-centered SemLMs.

	Baselines			SemLMs				Rel-Impr
	OP	UNI	BG	TRI	CBOW	SG	LB	
MRR								
NYT Hold-out Data								
FC	0.121	0.236	0.225	0.249	0.242	0.247	**0.276**	8.5%
EC	0.126	0.235	0.210	0.242	0.249	0.249	**0.261**	5.9%
EC w/o DIS	0.092	0.191	0.188	0.212	0.215	0.216	**0.227**	18.8%
Rudinger et al. (2015)*	0.083	0.186	0.181	—	—	—	**0.223**	19.9%
Gold PropBank Data with Frame Chains								
FC	0.106	0.215	0.212	0.232	0.228	0.229	**0.254**	18.1%
FC-FM	0.098	0.201	0.204	0.223	0.218	0.220	0.243	———
Gold Ontonotes Data with Coref Chains								
EC	0.122	0.228	0.213	0.239	0.247	0.246	**0.257**	12.7%
EC-FM	0.109	0.215	0.208	0.230	0.237	0.239	0.254	———
Recall@30								
NYT Hold-out Data								
FC	33.2	46.8	45.3	47.3	46.6	47.5	**55.4**	18.4%
EC	29.4	43.7	41.6	44.8	46.5	46.6	**52.0**	19.0%
Gold PropBank Data with Frame Chains								
FC	26.3	39.5	38.1	45.5	43.6	43.8	**53.9**	36.5%
FC-FM	24.4	37.3	37.3	42.8	41.9	42.1	48.2	———
Gold Ontonotes Data with Coref Chains								
EC	30.6	42.1	39.7	46.4	48.3	48.1	**51.5**	22.3%
EC-FM	26.6	39.9	37.6	45.4	46.7	46.2	49.8	———

the same test sets as the perplexity evaluation. We use mean reciprocal rank (MRR) and recall at 30 (Recall@30) to evaluate.

Results are provided in Table 4. Consistent with the results in the perplexity evaluation, LB outperforms other methods for both frame-chain and entity-centered SemLMs across all test sets. It is interesting to see that UNI performs better than BG in this prediction task. This finding is also reflected in the results reported in Rudinger et al. (2015). Though CBOW and SG have similar perplexity results, SG appears to be stronger in the narrative cloze test. With respect to the strongest baseline (UNI), LB achieves close to 20% relative improvement for Recall@30 metric on NYT hold-out data. On gold data, the frame-chain SemLMs get a relative improvement of 36.5% for Recall@30 while entity-centered SemLMs get 22.3%. For MRR metric, the relative improvement is around half that of the Recall@30 metric.

In the narrative cloze test, we also carry out an ablation study to remove the "FrameNet Mapping" step in Sec. 5.2 ("FC-FM" and "EC-FM" rows). The decrease in MRR and Recall@30 metrics further strengthens the argument that "FrameNet Mapping" is important for language modeling as it improves the generalization on frames.

We cannot directly compare with other related works (Rudinger et al., 2015; Pichotta and Mooney, 2016) because of the differences in data and evaluation metrics. Rudinger et al. (2015) also use the NYT portion of the Gigaword corpus, but with Concrete annotations; Pichotta and Mooney (2016) use the English Wikipedia as their data, and Stanford NLP tools for pre-processing while we use the Illinois NLP tools. Consequently, the eventual chain statistics are different, which leads to different test instances.[5] We counter this difficulty

[5]Rudinger et al. (2015) is similar to our entity-centered SemLM without discourse information. So, in Table 4, we

Table 5: **Co-reference resolution results with entity-centered SemLM features.** "EC" stands for the entity-centered SemLM. "TRI" is the tri-gram model while "LB" is the log-bilinear model. "p_c" means conditional probability features and "em" represents frame embedding features. "w/o DIS" indicates the ablation study by removing all discourse makers for SemLMs. We conduct the experiments by adding SemLM features into the base system. We outperform the state-of-art system (Wiseman et al., 2015), which reports the best results on CoNLL12 dataset. The improvement achieved by "EC_LB ($p_c + em$)" over the base system is statistically significant.

	ACE04	CoNLL12
Wiseman et al. (2015)	—	63.39
Base (Peng et al., 2015a)	71.20	63.03
Base+EC-TRI (p_c)	71.31	63.14
Base+EC-TRI w/o DIS	71.08	62.99
Base+EC-LB (p_c)	71.71	63.42
Base+EC-LB ($p_c + em$)	**71.79**	**63.46**
Base+EC-LB w/o DIS	71.12	63.00

by reporting results on "Gold PropBank Data" and "Gold Ontonotes Data". We hope that these two gold annotation datasets can become standard test sets. Rudinger et al. (2015) does share a common evaluation metric with us: MRR. If we ignore the data difference and make a rough comparison, we find that the absolute values of our results are better while Rudinger et al. (2015) have higher relative improvement ("Rel-Impr" in Table 4). This means that 1) the discourse information is very likely to help better model semantics 2) the discourse information may boost the baseline (UNI) more than it does for the LB model.

6.2 Evaluation of SemLM Applications

6.2.1 Co-reference Resolution

Co-reference resolution is the task of identifying mentions that refer to the same entity. To help improve its performance, we incorporate SemLM information as features into an existing co-reference resolution system. We choose the state-of-art Illinois Co-reference Resolution system (Peng et al., 2015a) as our base system. It employs a supervised joint mention detection and co-reference framework. We add additional features into the mention-pair feature set.

Given a pair of mentions (m_1, m_2) where m_1 appears before m_2, we first extract the corresponding semantic frame and the argument role label of each mention. We do this by following the procedures in Sec. 5. Thus, we can get a pair of semantic frames with argument information $(\text{fa}_1, \text{fa}_2)$. We may also get an additional discourse marker between these two frames, e.g. $(\text{fa}_1, \text{dis}, \text{fa}_2)$. Now, we add the following conditional probability as the feature from SemLMs:

$$p_c = p(\text{fa}_2|\text{fa}_1, \text{dis}).$$

We also add p_c^2, $\sqrt{p_c}$ and $1/p_c$ as features. To get the value of p_c, we follow the definitions in Sec. 4, and we only use the entity-centered SemLM here as its vocabulary covers frames with argument labels. For the neural language model implementations (CBOW, SG and LB), we also include frame embeddings as additional features.

We evaluate the effect of the added SemLM features on two co-reference benchmark datasets: ACE04 (NIST, 2004) and CoNLL12 (Pradhan et al., 2012). We use the standard split of 268 training documents, 68 development documents, and 106 testing documents for ACE04 data (Culotta et al., 2007; Bengtson and Roth, 2008). For CoNLL12 data, we follow the train and test document split from CoNLL-2012 Shared Task. We report CoNLL AVG for results (average of MUC, B^3, and $CEAF_e$ metrics), using the v7.0 scorer provided by the CoNLL-2012 Shared Task.

Co-reference resolution results with entity-centered SemLM features are shown in Table 5. Tri-grams with conditional probability features improve the performance by a small margin, while the log-bilinear model achieves a 0.4-0.5 F1 points improvement. By employing log-bilinear model embeddings, we further improve the numbers and we outperform the best reported results on the CoNLL12 dataset (Wiseman et al., 2015).

In addition, we carry out ablation studies to remove all discourse makers during the language modeling process. We re-train our models and study their effects on the generated features. Table 5 ("w/o DIS" rows) shows that without discourse information, the SemLM features would hurt the overall performance, thus proving the necessity of considering discourse for semantic language models.

6.2.2 Shallow Discourse Parsing

Shallow discourse parsing is the task of identifying explicit and implicit discourse connectives,

make a rough comparison between them.

Table 6: **Shallow discourse parsing results with frame-chain SemLM features.** "FC" stands for the frame-chain SemLM. "TRI" is the tri-gram model while "LB" is the log-bilinear model. "p_c", "em" are conditional probability and frame embedding features, resp. "w/o DIS" indicates the case where we remove all discourse makers for SemLMs. We do the experiments by adding SemLM features to the base system. The improvement achieved by "FC-LB ($p_c + em$)" over the baseline is statistically significant.

	CoNLL16 Test			CoNLL16 Blind		
	Explicit	Implicit	Overall	Explicit	Implicit	Overall
Base (Song et al., 2015)	89.8	35.6	60.4	75.8	31.9	52.3
Base + FC-TRI (q_c)	90.3	35.8	60.7	76.4	32.5	52.9
Base + FC-TRI w/o DIS	89.2	35.3	60.0	75.5	31.6	52.0
Base + FC-LB (q_c)	90.9	36.2	61.3	76.8	32.9	53.4
Base + FC-LB ($q_c + em$)	**91.1**	**36.3**	**61.4**	**77.3**	**33.2**	**53.8**
Base + FC-LB w/o DIS	90.1	35.7	60.6	76.9	33.0	53.5

determine their senses and their discourse arguments. In order to show that SemLM can help improve shallow discourse parsing, we evaluate on identifying the correct sense of discourse connectives (both explicit and implicit ones).

We choose Song et al. (2015), which uses a supervised pipeline approach, as our base system. The system extracts context features for potential discourse connectives and applies the discourse connective sense classifier. Consider an explicit connective "dis"; we extract the semantic frames that are closest to it (left and right), resulting in the sequence [f_1, dis, f_2] by following the procedures described in Sec. 5. We then add the following conditional probabilities as features. Compute

$$q_c = p(\mathrm{dis}|\mathrm{f}_1, \mathrm{f}_2).$$

and, similar to what we do for co-reference resolution, we add $q_c, q_c^2, \sqrt{q_c}, 1/q_c$ as conditional probability features, which can be computed following the definitions in Sec. 4. We also include frame embeddings as additional features. We only use frame-chain SemLMs here.

We evaluate on CoNLL16 (Xue et al., 2015) test and blind sets, following the train and development document split from the Shared Task, and report F1 using the official shared task scorer.

Table 6 shows the results for shallow discourse parsing with SemLM features. Tri-gram with conditional probability features improve the performance for both explicit and implicit connective sense classifiers. Log-bilinear model with conditional probability features achieves even better results, and frame embeddings further improve the numbers. SemLMs improve relatively more on explicit connectives than on implicit ones.

We also show an ablation study in the same setting as we did for co-reference, i.e. removing discourse information ("w/o DIS" rows). While our LB model can still exhibit improvement over the base system, its performance is lower than the proposed discourse driven version, which means that discourse information improves the expressiveness of semantic language models.

7 Conclusion

The paper builds two types of discourse driven semantic language models with four different language model implementations that make use of neural embeddings for semantic frames. We use perplexity and a narrative cloze test to prove that the proposed SemLMs have a good level of abstraction and are of high quality, and then apply them successfully to the two challenging tasks of co-reference resolution and shallow discourse parsing, exhibiting improvements over state-of-the-art systems. In future work, we plan to apply SemLMs to other semantic related NLP tasks e.g. machine translation and question answering.

Abstract

Domain adaptation is an important research topic in sentiment analysis area. Existing domain adaptation methods usually transfer sentiment knowledge from only one source domain to target domain. In this paper, we propose a new domain adaptation approach which can exploit sentiment knowledge from multiple source domains. We first extract both global and domain-specific sentiment knowledge from the data of multiple source domains using multi-task learning. Then we transfer them to target domain with the help of words' sentiment polarity relations extracted from the unlabeled target domain data. The similarities between target domain and different source domains are also incorporated into the adaptation process. Experimental results on benchmark dataset show the effectiveness of our approach in improving cross-domain sentiment classification performance.

1 Introduction

Sentiment classification is a hot research topic in natural language processing field, and has many applications in both academic and industrial areas (Pang and Lee, 2008; Liu, 2012; Wu et al., 2015; Wu and Huang, 2016). Sentiment classification is widely known as a domain-dependent task (Blitzer et al., 2007; Glorot et al., 2011). The sentiment classifier trained in one domain may not perform well in another domain. This is because sentiment expressions used in different domains are usually different. For example, "boring" and "lengthy" are frequently used to express negative sentiments in *Book* domain. However, they rarely appear in *Electronics* domain (Bollegala et al., 2011). Thus a sentiment classifier trained in *Electronics* domain cannot accurately predict their sentiments in *Book* domain. In addition, the same word may convey different sentiments in different domains. For example, in *Electronics* domain "easy" is usually used in positive reviews, e.g., "this digital camera is easy to use." However, it is frequently used as a negative word in *Movie* domain. For instance, "the ending of this movie is easy to guess." Thus, the sentiment classifier trained in one domain usually cannot be applied to another domain directly (Pang and Lee, 2008).

In order to tackle this problem, sentiment domain adaptation has been widely studied (Liu, 2012). For example, Blitzer et al. (2007) proposed to compute the correspondence among features from different domains using their associations with pivot features based on structural correspondence learning (*SCL*). Pan et al. (2010) proposed a spectral feature alignment (*SFA*) algorithm to align the domain-specific words from different domains in order to reduce the gap between source and target domains. However, all of these methods transfer sentiment information from only one source domain. When the source and target domains have significant difference in feature distributions, the adaptation performance will heavily decline. In some cases, the performance of sentiment domain adaptation is even worse than that without adaptation, which is usually known as *negative transfer* (Pan and Yang, 2010).

In this paper we propose a new domain adaptation approach for cross-domain sentiment classification. Our approach can exploit the sentiment information in multiple source domains to reduce the risk of negative transfer effectively. Our approach consists of two steps, i.e., *training* and

Berlin, Germany, August 7-12, 2016.

adaptation. At the *training* stage, we extract two kinds of sentiment models, i.e., the global model and the domain-specific models, from the data of multiple source domains using multi-task learning. The global sentiment model can capture the common sentiment knowledge shared by various domains, and has better generalization performance than the sentiment model trained in a single source domain. The domain-specific sentiment model can capture the specific sentiment knowledge in each source domain. At the *adaptation* stage, we transfer both kinds of sentiment knowledge to target domain with the help of the words' sentiment graph of target domain. The sentiment graph contains words' domain-specific sentiment polarity relations extracted from the syntactic parsing results of the unlabeled data in target domain. Since sentiment transfer between similar domains is more effective than dissimilar domains, we incorporate the similarities between target domain and different source domains into the adaptation process. In order to estimate the similarity between two domains, we propose a novel domain similarity measure based on their sentiment graphs. Extensive experiments were conducted on the benchmark Amazon product review dataset. The experimental results show that our approach can improve the performance of cross-domain sentiment classification effectively.

2 Related work

Sentiment classification is widely known as a domain-dependent task, since different expressions are used to express sentiments in different domains (Blitzer et al., 2007). The sentiment classifier trained in one domain may not perform well in another domain. Since there are massive domains, it is impractical to annotate enough data for each new domain. Thus, *domain adaptation*, or so called *cross-domain sentiment classification*, which transfers the sentiment knowledge from domains with sufficient labeled data (i.e., source domain) to a new domain with no or scarce labeled data (i.e., target domain), has been widely studied. Existing domain adaptation methods mainly transfer sentiment information from only one source domain. For example, Blitzer et al. (2007) proposed a domain adaptation method based on structural correspondence learning (*SCL*). In their method, a set of pivot features are first selected according to their associations with source domain labels. Then the correspondence among features from source and target domains is computed using their associations with pivot features. In order to reduce the gap between source and target domains, Pan et al. (2010) proposed a spectral feature alignment (*SFA*) algorithm to align the domain-specific sentiment words from different domains into clusters. He et al. (2011) proposed to extract polarity-bearing topics using joint sentiment-topic (*JST*) model to expand the feature representations of texts from both source and target domains. Li et al. (2009) proposed to transfer sentiment knowledge from source domain to target domain using nonnegative matrix factorization. A common shortcoming of above methods is that if the source and target domains have significantly different distributions of sentiment expressions, then the domain adaptation performance will heavily decline (Li et al., 2013).

Using multiple source domains in cross-domain sentiment classification has also been explored. Glorot et al. (2011) proposed a sentiment domain adaptation method based on a deep learning technique, i.e., Stacked Denoising Auto-encoders. The core idea of their method is to learn a high-level representation that can capture generic concepts using the unlabeled data from multiple domains. Yoshida et al. (2011) proposed a probabilistic generative model for cross-domain sentiment classification with multiple source and target domains. In their method, each word is assigned three attributes, i.e., the domain label, the domain dependence/independence label, and sentiment polarity. Bollegala et al. (2011) proposed to construct a sentiment sensitive thesaurus for cross-domain sentiment classification using data from multiple source domains. This thesaurus is used to expand the feature vectors for both training and classification. However, the similarities between target domain and different source domains are not considered in these methods. In addition, although unlabeled data is utilized in these methods, the useful word-level sentiment knowledge in the unlabeled target domain data is not exploited.

General-purpose multiple source domain adaptation methods have also been studied. For example, Mansour et al. (2009) proposed a distribution weighted hypothesis combination approach, and gave theoretical guarantees for it. However, this method is based on the assumption that target distribution is some mixture of source distri-

butions, which may not hold in sentiment domain adaptation scenario. Duan et al. (2009) proposed a Domain Adaptation Machine (*DAM*) method to learn a Least-Squares SVM classifier for target domain by leveraging the classifiers independently trained in multiple source domains. Chattopadhyay et al. (2011) explored to assign psuedo labels to unlabeled samples in the target domain using the classifiers from multiple source domains. Then target domain classifier is trained on these psuedo labeled samples. Compared with these general-purpose domain adaptation methods with multiple source domains, our approach is more suitable for sentiment domain adaptation because our approach exploits more sentiment-related characteristics and knowledge, such as the general sentiment knowledge shared by different domains and the word-level sentiment polarity relations, which is validated by experiments.

3 Sentiment Graph Extraction and Domain Similarity Measure

In this section we introduce two important components used in our sentiment domain adaptation approach, i.e., the words' sentiment graph and domain similarity.

3.1 Sentiment Graph Extraction

Compared with labeled data, unlabeled data is usually much easier and cheaper to collect on a large scale. Although unlabeled samples are not associated with sentiment labels, they can still provide a lot of useful sentiment information for domain adaptation. For example, if "great" and "quick" are frequently used to describe the same target in the same review of *Kitchen* domain, then they probably convey the same sentiment polarity in this domain. Since "great" is a general positive word in both *Book* and *Kitchen* domains, we can infer that "quick" is also a positive word in *Kitchen* domain when transferring from *Book* domain to *Kitchen* domain.

Motivated by above observations, in this paper we propose to extract sentiment polarity relations among words from massive unlabeled data for sentiment domain adaptation. Two kinds of polarity relations are explored, i.e., sentiment coherent relation and sentiment opposite relation. The former means that two words convey the same sentiment polarity while the latter indicates opposite sentiment polarities. These polarity relations are extracted from the syntactic parsing results according to manually selected rules. Two rules are used to extract sentiment coherent relations. The first one is that two words are connected by coordinating conjunctions such as "and" and "as well as". For example, a review in *Kitchen* domain may be "it is so high-quality and professional." Since "high-quality" and "professional" are connected by the coordinating conjunction "and", we infer that they probably convey the same sentiment polarity. The second rule is that two words are not directly connected but are used to describe the same target in the same sentence. For example, a review in *Electronics* domain may be "It is a beautiful, durable, easy-to-use camera." Since "beautiful", "durable", and "easy-to-use" are all used to describe the same camera in the same review, they tend to convey the same sentiment polarity. We also propose two rules for extracting sentiment opposite relations. The first rule is that two words are connected by adversative conjunctions such as "but" and "however". The second rule is that two words are connected by coordinating conjunctions but there is a negation symbol before one of them. For example, a review may be "The battery of this camera is small and not durable." We can infer that "small" and "durable" may convey opposite sentiments when they are used to describe camera battery. An illustrative example of extracting sentiment polarity relations from syntactic parsing results is shown in Fig. 1.

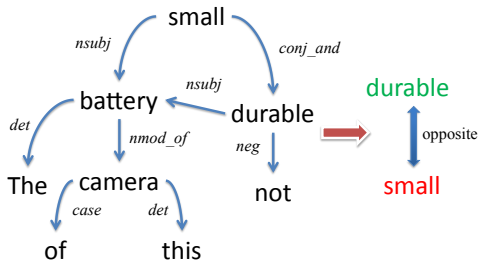

Figure 1: An illustrative example of extracting sentiment polarity relations from syntactic parsing results.

Based on the sentiment polarity relations among words extracted from the unlabeled data, we can build a words' sentiment graph for each domain. The nodes of the sentiment graph represent words and the edges stand for sentiment polarity relations. We denote $\mathbf{R} \in \mathbb{R}^{D \times D}$ as the words' sentiment graph of a specific domain. $R_{i,j}$ represents the sentiment polarity relation score between words i

and j. In this paper we define $R_{i,j}$ as $\frac{n^C_{i,j}-n^O_{i,j}}{n^C_{i,j}+n^O_{i,j}}$, where $n^C_{i,j}$ and $n^O_{i,j}$ represent the frequencies of words i and j sharing coherent and opposite sentiment polarity relations respectively in all the unlabeled samples. Thus, $R_{i,j} \in [-1, 1]$. If $R_{i,j} > 0$, then words i and j tend to convey the same sentiment polarity. Similarly, if $R_{i,j} < 0$, then these two words are more likely to convey opposite sentiments. The absolute value of $R_{i,j}$ represents the confidence of this sentiment polarity relation.

3.2 Domain Similarity

Different pairs of domains have different sentiment relatedness (Remus, 2012; Wu and Huang, 2015). Researchers have found that sentiment domain adaptation between similar domains, such as *Kitchen* and *Electronics*, is much more effective than that between dissimilar domains, such as *Kitchen* and *Book* (Blitzer et al., 2007; Pan et al., 2010). Thus, it is beneficial if we take the similarity between source and target domains into consideration when transferring sentiment knowledge.

In this paper we explore two methods to measure domain similarity. The first one is based on term distribution. The assumption behind this method is that similar domains usually share more common terms than dissimilar domains. For example, *Smart Phone* and *Digital Camera* domains share many common terms such as "screen", "battery", "light", and "durable", while the term distributions of *Digital Camera* and *Book* domains may have significant difference. Term distribution based domain similarity measures, such as $\mathcal{A}$-distance, have been explored in previous works (Blitzer et al., 2007). Inspired by (Remus, 2012), here we apply Jensen-Shannon divergence to measure domain similarity based on term distributions, which is more easy to compute than $\mathcal{A}$-distance. Denote $\mathbf{t}^m \in \mathbb{R}^{D\times 1}$ as the term distribution of domain m, where t^m_w is the probability of term w appearing in domain m. Then the similarity between domains m and n is formulated as:

$$\begin{aligned} TermSim(m,n) &= 1 - D_{JS}(\mathbf{t}^m, \mathbf{t}^n) \\ &= 1 - \frac{1}{2}(D_{KL}(\mathbf{t}^m, \bar{\mathbf{t}}) + D_{KL}(\mathbf{t}^n, \bar{\mathbf{t}})), \end{aligned} \tag{1}$$

where $\bar{\mathbf{t}} = \frac{1}{2}(\mathbf{t}^m + \mathbf{t}^n)$ is the average distribution, and $D_{KL}(\cdot,\cdot)$ is the Kullback-Leibler divergence:

$$D_{KL}(\mathbf{p}, \mathbf{q}) = \sum_{i=1}^{D} p_i \log_2 \left(\frac{p_i}{q_i}\right). \tag{2}$$

We can verify that $D_{JS}(\mathbf{t}^m, \mathbf{t}^n) \in [0, 1]$. Thus, the range of $TermSim(m, n)$ is also $[0, 1]$.

The term distribution based domain similarity can measure whether similar words are used in two domains. However, sharing similar terms does not necessarily mean that sentiment expressions are used similarly in these domains. For example, *CPU* and *Battery* are both related to electronics. The word "fast" is positive when used to describe *CPU*. However, it is frequently used as a negative word in *Battery* domain. For example, "this battery runs out fast." Thus, it is more useful to measure domain similarity based on sentiment word distributions. However, although we can infer the sentiment word distributions of source domains according to labeled samples, it is difficult to compute the sentiment word distribution of target domain, since the labeled data does not exist or is very scarce in target domain.

In order to tackle this problem, in this paper we propose to estimate the similarity between two domains based on their sentiment graphs. Similar domains usually share more common sentiment words and sentiment word pairs than dissimilar domains. In addition, the polarity relation scores of a pair of words in the sentiment graphs of similar domains are also more similar. In other words, they tend to be both positive or negative in these two domains. Motivated by above observations, the domain similarity based on sentiment graph is formulated as follows:

$$SentiSim(m,n) = \frac{\sum_{w=1}^{D}\sum_{v\neq w} |R^m_{w,v} + R^n_{w,v}| \cdot N^{m\cap n}_{w,v}}{\sum_{w=1}^{D}\sum_{v\neq w} (|R^m_{w,v}| \cdot N^m_{w,v} + |R^n_{w,v}| \cdot N^n_{w,v})}, \tag{3}$$

where $R^m_{w,v}$ is the sentiment polarity relation score between words w and v in domain m, and $N^m_{w,v}$ is its frequency in this domain. $N^{m\cap n}_{w,v} = \min\{N^m_{w,v}, N^n_{w,v}\}$. We can verify that $SentiSim(m, n) \in [0, 1]$. If two domains have more common sentiment word pairs and the polarity relation scores of these word pairs are more similar, then these two domains share higher domain similarity according to Eq. (3).

4 Sentiment Domain Adaptation with Multiple Sources

In this section we introduce our sentiment domain adaptation approach in detail. First we introduce several notations that will be used in following discussions. Assume there are M source domains.

Denote $\{\mathbf{X}^m \in \mathbb{R}^{N_m \times D}, \mathbf{y}^m \in \mathbb{R}^{N_m \times 1}\}$ as the labeled data in source domain m, where N_m is the number of labeled samples and D is the size of feature vector. $\mathbf{x}_i^m \in \mathbb{R}^{D \times 1}$ is the feature vector of the i_{th} sample in domain m, and its sentiment label is y_i^m. In this paper we focus on sentiment polarity classification, and $y_i^m \in \{+1, -1\}$. Denote $\mathbf{w} \in \mathbb{R}^{D \times 1}$ as the global sentiment model extracted from multiple source domains and $\mathbf{w}_m \in \mathbb{R}^{D \times 1}$ as the domain-specific sentiment model of source domain m. Denote $\mathbf{w}_t \in \mathbb{R}^{D \times 1}$ as the domain-specific sentiment model of target domain. Denote $f(\mathbf{x}, y, \mathbf{w})$ as the loss of classifying sample $\mathbf{x}$ into label y under linear classification model $\mathbf{w}$. Our approach is flexible to the selection of loss function f, which can be square loss, logistic loss, and hinge loss. Denote $\mathbf{R}^m \in \mathbb{R}^{D \times D}$ as the sentiment graph knowledge of domain m, and $S_{m,t} \in [0, 1]$ as the similarity between source domain m and target domain.

Our sentiment domain adaptation with multiple sources approach (*SDAMS*) consists of two steps, i.e., *training* and *adaptation*. At the *training* stage, the global and domain-specific sentiment knowledge are extracted from the data of multiple source domains. And at the *adaptation* stage, these two kinds of sentiment knowledge are transferred to target domain by incorporating the sentiment graph knowledge of target domain and the similarities between target and source domains.

4.1 Training

Given the labeled data and the sentiment graph knowledge of multiple source domains, at the *training* stage, our goal is to train a robust global sentiment model to capture the general sentiment knowledge shared by various domains and a domain-specific sentiment model for each source domain. The model of the *training* process is motivated by multi-task learning (Evgeniou and Pontil, 2004; Liu et al., 2009) and is formulated as:

$$\begin{aligned}\arg\min_{\mathbf{w},\mathbf{w}_m} \mathcal{L}(\mathbf{w}, \mathbf{w}_m) &= \sum_{m=1}^{M} \frac{1}{N_m} \sum_{i=1}^{N_m} f(\mathbf{x}_i^m, y_i^m, \mathbf{w} + \mathbf{w}_m) \\ &+ \alpha \sum_{m=1}^{M} \sum_{i=1}^{D} \sum_{j \neq i} R_{i,j}^m |(w_i + w_{m,i}) - (w_j + w_{m,j})| \\ &+ \lambda_1 \|\mathbf{w}\|_2^2 + \lambda_1 \sum_{m=1}^{M} \|\mathbf{w}_m\|_2^2 + \lambda_2 \|\mathbf{w}\|_1 + \lambda_2 \sum_{m=1}^{M} \|\mathbf{w}_m\|_1, \end{aligned} \tag{4}$$

where α, λ_1, and λ_2 are nonnegative regularization coefficients. The sentiment classification model of each source domain is decomposed into two components, i.e., a global one and a domain-specific one. The global sentiment model is shared by all source domains and is trained in these domains simultaneously. It is used to capture the general sentiment knowledge, such as the general sentiment words "great", "worst", "perfect" and so on. The domain-specific sentiment model is trained on the labeled data within one source domain and is used to capture the specific sentiment knowledge of this domain. For example, the domain-specific sentiment word "easy" is a positive word in *Electronics* domain but is used as a negative word in *Movie* domain.

In Eq. (4), the first term means minimizing the empirical classification loss on the labeled data of multiple source domains. In this way we incorporate the sentiment information in labeled samples into sentiment classifier learning. In the second term we incorporate the sentiment graph knowledge of each source domain. It is motivated by graph-guided fused Lasso (Chen et al., 2012). If two words have strong coherent (or opposite) sentiment polarity relations, then we constrain that their sentiment scores are more similar (or dissimilar) with each other in the final classification model. The L_1-norm regularization terms are motivated by Lasso (Tibshirani, 1996). It can set many minor sentiment scores in the models to exact zeros. Since not all the words convey sentiments, these terms can help conduct sentiment word selection. We also incorporate the L_2-norm regularization terms in order to improve model stability in high-dimensional problems, which is inspired by elastic net regularization (Zou and Hastie, 2003).

4.2 Adaptation

At the *adaptation* stage, we incorporate the global sentiment knowledge, the domain-specific sentiment knowledge of multiple source domains, the sentiment graph knowledge of target domain, and the domain similarities between target and source domains into a unified framework to learn an accurate sentiment classifier for target domain. The model of our *adaptation* framework is formulated as follows:

$$\begin{aligned}\arg\min_{\mathbf{w}_t} \mathcal{L}(\mathbf{w}_t) &= \sum_{m=1}^{M} S_{m,t} \|\mathbf{w}_m - \mathbf{w}_t\|_2^2 + \lambda_1 \|\mathbf{w}_t\|_2^2 \\ &+ \lambda_2 \|\mathbf{w}_t\|_1 + \beta \sum_{i=1}^{D} \sum_{j \neq i} R_{i,j}^t |(w_i + w_{t,i}) - (w_j + w_{t,j})|, \end{aligned} \tag{5}$$

where β, λ_1, and λ_2 are nonnegative regularization coefficients. The final sentiment classifier of the target domain is a linear combination of $\mathbf{w}$ and $\mathbf{w}_t$, i.e., $\mathbf{w}+\mathbf{w}_t$, where $\mathbf{w}$ is the global sentiment model extracted from multiple source domains at the *training* stage, and $\mathbf{w}_t$ is the domain-specific sentiment model of target domain learned at the *adaptation* stage. In the first term of Eq. (5), we transfer the knowledge in domain-specific sentiment models from multiple source domains to $\mathbf{w}_t$. Since the sentiment knowledge transfer between similar domains is more effective, the transfer of domain-specific sentiment knowledge is weighted by the similarities between target domain and different source domains. If target domain is more similar with source domain m than source domain n (i.e., $S_{m,t} > S_{n,t}$), then more domain-specific sentiment knowledge will be transferred to $\mathbf{w}_t$ from $\mathbf{w}_m$ than $\mathbf{w}_n$. Through the last term we incorporate the sentiment graph knowledge extracted from massive unlabeled data of target domain into the adaptation process. If two words share strong coherent (or opposite) sentiment polarity relations in the target domain, then we constrain that their sentiment scores in the sentiment classification model of target domain are more similar (or dissimilar). This term can help transfer the sentiment knowledge from source domains to target domain more effectively. For example, if we know that "great" is a positive word in the global sentiment model and there is a strong coherent polarity relation between "easy" and "great" in *Electronics* domain, then we can infer that "easy" is also a positive word in this domain.

5 Experiments

5.1 Dataset and Experimental Settings

The dataset used in our experiments is the famous Amazon product review dataset collected by Blitzer et al. (2007). It is widely used as a benchmark dataset for cross-domain sentiment classification. Four domains, i.e., *Book*, *DVD*, *Electronics* and *Kitchen*, are included in this dataset. Each domain contains 1,000 positive and 1,000 negative reviews. Besides, a large number of unlabeled reviews are provided. The detailed statistics of this dataset are shown in Table 1.

In our experiments, each domain was selected in turn as target domain, and remaining domains as source domains. In each experiment, we randomly selected N labeled samples from the source domains to train sentiment models at the *training* stage. These samples were balanced among different source domains. In order to perform fair comparisons with baseline methods, following (Bollegala et al., 2011), we limited the total number of training samples, i.e., N, to 1,600. The target domain sentiment classifier was tested on all the labeled samples of target domain. Following (Blitzer et al., 2007), unigrams and bigrams were used as features. The sentiment polarity relations of bigrams were extracted by expanding the polarity relations between unigrams using modifying relations. For example, from the review "this phone is very beautiful and not expensive," we extract not only sentiment polarity relation between "beautiful" and "expensive", but also polarity relation between "beautiful" and "not_expensive" (coherent sentiment), and that between "very_beautiful" and "expensive" (opposite sentiment), since "very" and "not" are used to modify "beautiful" and "expensive" respectively. Classification accuracy was selected as the evaluation metric. We manually set β in Eq. (5) to 0.01. The values of α, λ_1, and λ_2 in Eq. (4) were selected using cross validation. The optimization problems in Eq. (4) and Eq. (5) were solved using alternating direction method of multipliers (ADMM) (Boyd et al., 2011). Each experiment was repeated 10 times independently and average results were reported.

Table 1: The statistics of the dataset.

Domain	Book	DVD	Electronics	Kitchen
positive	1,000	1,000	1,000	1,000
negative	1,000	1,000	1,000	1,000
unlabeled	973,194	122,438	21,009	17,856

5.2 Comparison of Domain Similarity Measures

In this section, we conducted experiments to compare the effectiveness of the two kinds of domain similarity measures introduced in Section 3.2 in sentiment domain adaptation task. The experimental results are summarized in Fig. 2. The classification loss function used in our approach is hinge loss. The results of other loss functions show similar patterns.

From Fig. 2 we can see that the domain similarity measure based on sentiment graph performs consistently better than that based on term distribution in our approach. This result validates our

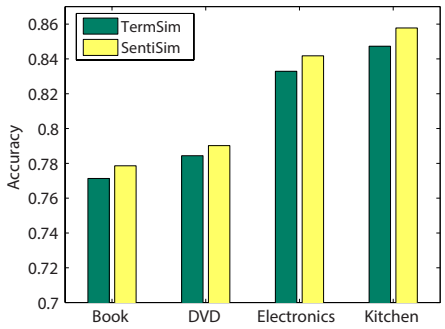

Figure 2: The performance of our approach with different kinds of domain similarity measure.

assumption in Section 3.2 that the sentiment graph based domain similarity can better model the sentiment relatedness between different domains than that based on term distribution in sentiment domain adaptation task. In all the following experiments, the sentiment graph based domain similarities were used in our approach.

5.3 Performance Evaluation

In this section we conducted experiments to evaluate the performance of our approach by comparing it with a series of baseline methods. The methods to be compared are: 1) *SCL*, domain adaptation based on structural correspondence learning (Blitzer et al., 2007); 2) *SFA*, domain adaptation based on spectral feature alignment (Pan et al., 2010); 3) *SCL-com* and *SFA-com*, adapting *SCL* and *SFA* to multiple source domain scenario by first training a cross-domain sentiment classifier in each source domain and then combining their classification results using majority voting; 4) *SST*, cross-domain sentiment classification by using multiple source domains to construct a sentiment sensitive thesaurus for feature expansion (Bollegala et al., 2011); 5) *IDDIWP*, multiple-domain sentiment analysis by identifying domain dependent/independent word polarity (Yoshida et al., 2011); 6) *DWHC*, *DAM* and *CP-MDA*, three general-purpose multiple source domain adaptation methods proposed in (Mansour et al., 2009), (Duan et al., 2009) and (Chattopadhyay et al., 2011) respectively; 7) *SDAMS-LS*, *SDAMS-SVM*, and *SDAMS-Log*, our proposed sentiment domain adaptation approaches with square loss, hinge loss, and logistic loss respectively; 8) *All-Training*, all the domains were involved in the training phase of our approach and there is no adaptation phase. This method is introduced to provide an upper bound for the performance of our approach. The experimental results of these methods are summarized in Table 2.

Table 2: The performance of different methods.

	Book	DVD	Electronics	Kitchen
SCL	0.7457	0.7630	0.7893	0.8207
SFA	0.7598	0.7848	0.7808	0.8210
SCL-com	0.7523	0.7675	0.7918	0.8247
SFA-com	0.7629	0.7869	0.7864	0.8258
SST	0.7632	0.7877	0.8363	0.8518
IDDIWP	0.7524	0.7732	0.8167	0.8383
DWHC	0.7611	0.7821	0.8312	0.8478
DAM	0.7563	0.7756	0.8284	0.8419
CP-MDA	0.7597	0.7792	0.8331	0.8465
SDAMS-LS	0.7795	0.7880	0.8398	0.8596
SDAMS-SVM	0.7786	0.7902	**0.8418**	0.8578
SDAMS-Log	**0.7829**	**0.7913**	0.8406	**0.8629**
All-Training	0.7983	0.8104	0.8463	0.8683

From Table 2 we can see that our approach achieves the best performance among all the methods compared here. *SCL* and *SFA* are famous cross-domain sentiment classification methods. In these methods, the sentiment knowledge is transferred from one source domain to target domain. According to Table 2, our approach performs significantly better than them. This result indicates that the sentiment knowledge extracted from one source domain may contain heavy domain-specific bias and may be inappropriate for the target domain. Our approach can tackle this problem by extracting the global sentiment model from multiple source domains. This global model can capture the general sentiment knowledge shared by various domains and has better generalization performance. It can reduce the risk of negative transfer effectively. Our approach also outperforms *SCL-com* and *SFA-com*. In *SCL-com* and *SFA-com*, the sentiment information in different source domains is combined at the classification stage, while in our approach it is combined at the learning stage. The superior performance of our approach compared with *SCL-com* and *SFA-com* shows that our approach is a more appropriate way to exploit the sentiment knowledge in different source domains. *SST* and *IDDIWP* also utilize data from multiple source domains as our approach. But our approach can still outperform them. This is because in these methods, the similarities between target domain and different source domains are not considered. Since different domains usually

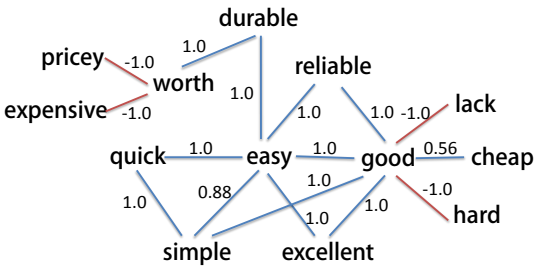

Figure 3: An illustrative example of the sentiment graph of *Electronics* domain. The value on the line represents the sentiment polarity relation score.

have different sentiment relatedness, our approach can exploit the sentiment information in multiple source domains more accurately by incorporating the similarities between target domain and each source domain into the *adaptation* process. Our approach also outperforms the state-of-the-art general-purpose multiple source domain adaptation methods, such as *DWHC*, *DAM*, and *CP-MDA*. This is because our approach can exploit more sentiment-related characteristics and knowledge for sentiment domain adaptation, such as the general sentiment knowledge shared by various domains, the sentiment graph based domain similarities, and the word-level sentiment polarity relations. Thus, our approach is more suitable for sentiment domain adaptation than these general-purpose multiple source domain adaptation methods. Another observation from Table 2 is that the performance of our approach is quite close to the upper bound, i.e., *All-Training*, especially in *Electronics* and *Kitchen* domains. This result validates the effectiveness of our approach in sentiment domain adaptation.

5.4 Case Study

In this section we conducted several case studies to further explore how our sentiment domain adaptation approach works. As an illustrative example, we selected *Electronics* domain as the target domain and remaining domains as source domains. The top sentiment words in the global and domain-specific sentiment models learned from the data of multiple source domains are shown in Table 3. A subgraph of the sentiment graph extracted from the unlabeled data of target domain (*Electronics*) is shown in Fig. 3. The top words in the final domain-specific sentiment model of target domain returned by our approach are shown in Table 3.

From Table 3 we have following observations. First, the global sentiment model extracted from multiple source domains can capture the general sentiment knowledge quite well. It contains many general sentiment words, such as "excellent", "great", "waste" and so on. These general sentiment words convey strong sentiment orientations. In addition, their sentiment polarities are consistent in different domains. Thus, the global sentiment model extracted from multiple source domains has good generalization ability and is more suitable for domain adaptation than the sentiment model trained in a single source domain, which may contain heavy domain-specific sentiment bias. Second, the domain-specific sentiment models can capture rich specific sentiment expressions in each source domain. For example, "easy" is a positive word in *Kitchen* domain while "return" is a negative word in this domain. Third, different domains have different domain-specific sentiment expressions. For example, "read" is frequently used as a positive word in *Book* domain, while it is a negative word in *DVD* domain. Thus, it is important to separate the global and the domain-specific sentiment knowledge. In addition, although different sentiment expressions are used in different domains, similar domains may share many common domain-specific sentiment expressions. For example, "easy" and "works" are positive words in both *Electronics* and *Kitchen* domains, and "return" and "broken" are both negative words in them. Thus, transferring the domain-specific sentiment models from similar source domains to target domain is helpful. From Fig. 3 we can see that the sentiment polarity relations in the sentiment graph extracted from massive unlabeled data are reasonable. Words with positive relation scores tend to convey similar sentiments, and words with negative relation scores usually convey opposite sentiments. In addition, this sentiment graph contains rich domain-specific sentiment information in target domain, which is useful to transfer the sentiment knowledge from multiple source domains to target domain. For example, "excellent", "easy", "simple", and "quick" share the same sentiment polarity in *Electronics* domain according to Fig. 3. We can infer that "easy" is positive in this domain using the sentiment of "excellent" in the global sentiment model and the sentiment relation between "easy" and "excellent". Then we can further infer the sentiments of the domain-specific sentiment words

Table 3: The top words in the global and domain-specific sentiment models.

Global	Positive	excellent, great, best, perfect, love, wonderful, the_best, loved, well, fantastic, enjoy, favorite
	Negative	bad, waste, boring, disappointed, worst, poor, disappointing, disappointment, terrible, poorly
Book	Positive	excellent, wonderful, easy, loved, enjoyable, life, fun, favorite, a_must, read, important, novel
	Negative	no, boring, disappointing, bad, instead, waste, little, writing, poorly, pages, unfortunately
DVD	Positive	enjoy, hope, loved, season, better_than, best, a_must, first, superman, classic, times, back
	Negative	worst, boring, bad, the_worst, terrible, waste, awful, book, horrible, dull, lame, read, hard
Kitchen	Positive	easy, great, perfect, love, works, easy_to, best, little, well, good, nice, long, durable, clean
	Negative	disappointed, back, poor, broken, too, return, off, returned, broke, waste, tried, times, doesn't
Electronics	Positive	excellent, great, perfect, best, love, easy_to, easy, little, the_best, works, good, nice, wonderful
	Negative	disappointed, poor, waste, too, bad, worst, back, broken, return, horrible, off, tried, poorly

"simple" and "quick" in target domain using the polarity of "easy" and their sentiment relations with it, even if they may be covered by no source domain.

6 Conclusion

This paper presents a sentiment domain adaptation approach which transfers the sentiment knowledge from multiple source domains to target domain. Our approach consists of two steps. First, we extract both global and domain-specific sentiment knowledge from the data of multiple source domains. Second, we transfer these two kinds of sentiment knowledge to target domain with the help of the words' sentiment graph. We proposed to build words' sentiment graph for target domain by extracting their sentiment polarity relations from massive unlabeled data. Besides, we proposed a novel domain similarity measure based on sentiment graphs, and incorporated the domain similarities between target and different source domains into the domain adaptation process. The experimental results on a benchmark dataset show that our approach can effectively improve the performance of cross-domain sentiment classification.

Connotation Frames: A Data-Driven Investigation

Hannah Rashkin **Sameer Singh** **Yejin Choi**
Computer Science & Engineering
University of Washington
{hrashkin, sameer, yejin}@cs.washington.edu

Abstract

Through a particular choice of a predicate (e.g., "x violated y"), a writer can subtly connote a range of implied sentiment and presupposed facts about the entities x and y: (1) *writer's perspective*: projecting x as an "antagonist" and y as a "victim", (2) *entities' perspective*: y probably dislikes x, (3) *effect*: something bad happened to y, (4) *value*: y is something valuable, and (5) *mental state*: y is distressed by the event.

We introduce *connotation frames* as a representation formalism to organize these rich dimensions of connotation using typed relations. First, we investigate the feasibility of obtaining connotative labels through crowdsourcing experiments. We then present models for predicting the connotation frames of verb predicates based on their distributional word representations and the interplay between different types of connotative relations. Empirical results confirm that connotation frames can be induced from various data sources that reflect how language is used in context. We conclude with analytical results that show the potential use of connotation frames for analyzing subtle biases in online news media.

1 Introduction

People commonly express their opinions through subtle and nuanced language (Thomas et al., 2006; Somasundaran and Wiebe, 2010). Often, through seemingly objective statements, the writer can influence the readers' judgments toward an event and their participants. Even by choosing a particular predicate, the writer can indicate rich connotative information about the entities that interact through the predicate. More specifically, through a simple statement such as "x violated y", the writer can convey:

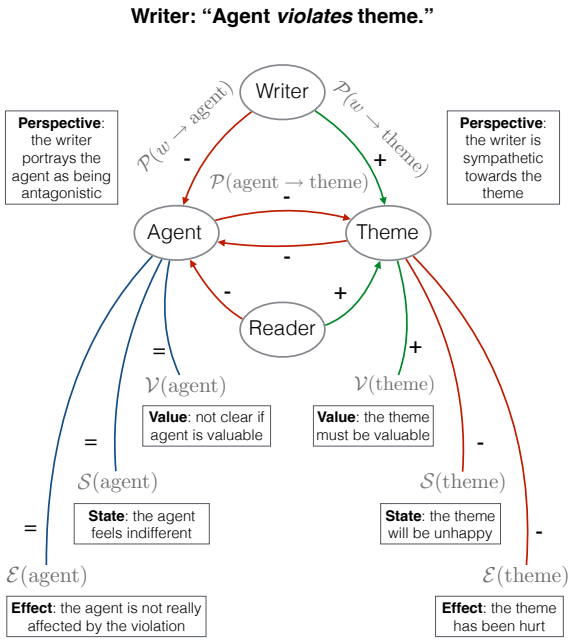

Figure 1: An example connotation frame of "violate" as a set of typed relations: perspective $\mathcal{P}(x \rightarrow y)$, effect $\mathcal{E}(x)$, value $\mathcal{V}(x)$, and mental state $\mathcal{S}(x)$.

(1) writer's perspective: the writer is projecting x as an "antagonist" and y as a "victim", eliciting negative perspective from readers toward x (i.e., blaming x) and positive perspective toward y (i.e., sympathetic or supportive toward y).

(2) entities' perspective: y most likely feels negatively toward x as a result of being violated.

(3) effect: something bad happened to y.

(4) value: y is something valuable, since it does not make sense to violate something worthless. In other words, the writer is presupposing a positive value of y as a fact.

(5) mental state: y is most likely unhappy about the outcome.[1]

[1]To be more precise, y is most likely in a negative state

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 311–321,
Berlin, Germany, August 7-12, 2016.

Verb	Subset of Typed Relations		Example Sentences	L/R
suffer	$\mathcal{P}(w \rightarrow \text{agent}) = +$ $\mathcal{P}(w \rightarrow \text{theme}) = -$ $\mathcal{P}(\text{agent} \rightarrow \text{theme}) = -$	$\mathcal{E}(\text{agent}) = -$ $\mathcal{V}(\text{agent}) = +$ $\mathcal{S}(\text{agent}) = -$	The story begins in Illinois in 1987, when *a 17-year-old girl* **suffered** *a botched abortion.*	R
guard	$\mathcal{P}(w \rightarrow \text{agent}) = +$ $\mathcal{P}(w \rightarrow \text{theme}) = +$ $\mathcal{P}(\text{agent} \rightarrow \text{theme}) = +$	$\mathcal{E}(\text{theme}) = +$ $\mathcal{V}(\text{theme}) = +$ $\mathcal{S}(\text{theme}) = +$	In August, *marshals* **guarded** *25 clinics* in 18 cities.	L
uphold	$\mathcal{P}(w \rightarrow \text{theme}) = +$ $\mathcal{P}(\text{agent} \rightarrow \text{theme}) = +$	$\mathcal{E}(\text{theme}) = +$ $\mathcal{V}(\text{theme}) = +$	A hearing is scheduled to make a decision on whether to **uphold** *the clinic's suspension.*	R

Table 1: Example typed relations (perspective $\mathcal{P}(x \rightarrow y)$, effect $\mathcal{E}(x)$, value $\mathcal{V}(x)$, and mental state $\mathcal{S}(x)$). Not all typed relations are shown due to space constraints. The example sentences demonstrate the usage of the predicates in left [L] or right [R] leaning news sources.

Even though the writer might not explicitly state any of the interpretation [1-5] above, the readers will be able interpret these intentions as a part of their comprehension. In this paper, we present an empirical study of how to represent and induce the connotative interpretations that can be drawn from a verb predicate, as illustrated above.

We introduce *connotation frames* as a representation framework to organize the rich dimensions of the implied sentiment and presupposed facts. Figure 1 shows an example of a connotation frame for the predicate *violate*. We define four different typed relations: $\mathcal{P}(x \rightarrow y)$ for perspective of x towards y, $\mathcal{E}(x)$ for effect on x, $\mathcal{V}(x)$ for value of x, and $\mathcal{S}(x)$ for mental state of x. These relationships can all be either positive (+), neutral (=), or negative (-).

Our work is the first study to investigate frames as a representation formalism for connotative meanings. This contrasts with previous computational studies and resource development for frame semantics, where the primary focus was almost exclusively on denotational meanings of language (Baker et al., 1998; Palmer et al., 2005). Our formalism draws inspirations from the earlier work of frame semantics, however, in that we investigate the connection between a word and the related world knowledge associated with the word (Fillmore, 1976), which is essential for the readers to interpret many layers of the implied sentiment and presupposed value judgments.

We also build upon the extensive amount of literature in sentiment analysis (Pang and Lee, 2008; Liu and Zhang, 2012), especially the recent emerging efforts on implied sentiment analysis (Feng et al., 2013; Greene and Resnik, 2009), entity-entity sentiment inference (Wiebe and Deng, 2014), opinion role induction (Wiegand and Ruppenhofer, 2015) and effect analysis (Choi and Wiebe, 2014). However, our work is the first to organize various aspects of the connotative information into coherent frames.

More concretely, our contributions are threefold: (1) a new formalism, model, and annotated dataset for studying connotation frames from large-scale natural language data and statistics, (2) new data-driven insights into the dynamics among different typed relations within each frame, and (3) an analytic study showing the potential use of connotation frames for analyzing subtle biases in journalism.

The rest of the paper is organized as follows: in §2, we provide the definitions and data-driven insights for connotation frames. In §3, we introduce models for inducing the connotation frames, followed by empirical results, annotation studies, and analysis on news media in §4. We discuss related work in §5 and conclude in §6.

2 Connotation Frame

Given a predicate v, we define a connotation frame $\mathcal{F}(v)$ as a collection of typed relations and their polarity assignments: (i) **perspective** $\mathcal{P}^v(a_i \rightarrow a_j)$: a directed sentiment from the entity a_i to the entity a_j, (ii) **value** $\mathcal{V}^v(a_i)$: whether a_i is presupposed to be valuable, (iii) **effect** $\mathcal{E}^v(a_i)$: whether the event denoted by the predicate v is good or bad for the entity a_i, and (iv) **mental state** $\mathcal{S}^v(a_i)$: the likely mental state of the entity a_i as a result of the event. We assume that each typed relation can have one of the three connotative polarities $\in \{+, -, =\}$, i.e., positive, negative, or neutral. Our goal in this paper is to focus on the general connotation of the predicate considered out of context. We leave contextual interpretation of connotation as future work.

Table 1 shows examples of connotation frame

assuming it is an entity that can have a mental state.

Verb	x's role	$\mathcal{P}(\mathbf{w} \rightarrow \cdot)$	Left-leaning Sources	Right-leaning Sources
accuse	agent	-	Putin, Progressives, Limbaugh, Gingrich	activist, U.S., protestor, Chavez
	theme	+	official, rival, administration, leader	Romney, Iran, Gingrich, regime
attack	agent	-	McCain, Trump, Limbaugh	**Obama**, campaign, Biden, Israel
	theme	+	Gingrich, **Obama**, policy	citizen, Zimmerman
criticize	agent	-	Ugandans, rival, Romney, Tyson	Britain, passage, **Obama**, Maddow
	theme	+	**Obama**, Allen, Cameron, Congress	Pelosi, Romey, GOP, Republicans

Table 2: Media Bias in Connotation Frames: Obama, for example, is portrayed as someone who *attacks* or *criticizes* others by the right-leaning sources, whereas the left-leaning sources portray Obama as the victim of harsh acts like "attack" and "criticize".

relations for the verbs *suffer*, *guard*, and *uphold*, along with example sentences. For instance, for the verb *suffer*, the writer is likely to have a positive perspective towards the agent (e.g., being supportive or sympathetic toward the "17-year-old girl" in the example shown on the right) and a negative perspective towards the theme (e.g., being negative towards 'botched abortion").

2.1 Data-driven Motivation

Since the meaning of language is ultimately contextual, the exact connotation will vary depending on the context of each utterance. Nonetheless, there still are common shifts or biases in the connotative polarities, as we found from two data-driven analyses.

First, we looked at words from the Subjectivity Lexicon (Wilson et al., 2005) that are used in the argument positions of a small selection of predicates in Google Syntactic N-grams (Goldberg and Orwant, 2013). For this analysis, we assumed that the word in the subject position is the agent while the object is the theme. We found 64% of the words in the agent position of *suffer* are positive, and 94% of the words in the theme position are negative, which is consistent with the polarities of the writer's perspective towards these arguments, as shown in Table 1. For *guard*, 57% of the subjects and 76% of the objects are positive, and in the case of *uphold*, 56% of the subjects and 72% of the objects are positive.

We also investigated how media bias can potentially be analyzed through connotation frames. From the Stream Corpus 2014 dataset (KBA, 2014), we selected all articles from news outlets with known political biases,[2] and compared how they use polarised words such as "accuse", "attack", and "criticize" differently in light of $\mathcal{P}(w \rightarrow agent)$ and $\mathcal{P}(w \rightarrow theme)$ relations of the connotation frames. Table 2 shows interesting contrasts. Obama, for example, is portrayed as someone who *attacks* or *criticizes* others according to the right-leaning sources, whereas the left-leaning sources portray Obama as the victim of harsh acts like "attack" or "criticize".[3] Furthermore, by knowing the perspective relationships $\mathcal{P}(w \rightarrow a_i)$ associated with a predicate, we can make predictions about how the left-leaning and right-leaning sources feel about specific people or issues. For example, because left-leaning sources frequently use McCain, Trump, and Limbaugh in the subject position of attack, we might predict that these sources have a negative sentiment towards these entities.

2.2 Dynamics between Typed Relations

Given a predicate, the polarity assignments of typed relations are interdependent. For example, if the writer feels positively towards the agent but negatively towards the theme, then it is likely that the agent and the theme do not feel positively towards each other. This insight is related to that of Wiebe and Deng (2014), but differs in that the polarities are predicate-specific and do not rely on knowledge of prior sentiment towards the arguments. This and other possible interdependencies are summarized in Table 3. These interdependencies serve as general guidelines of what properties we expect to depend on one another, especially in the case where the polarities are non-neutral. We will promote these internal consistencies in our factor graph model (§3) as soft constraints.

There also exist other interdependencies that we will use to simplify our task. First, the directed

[2]The articles come from 30 news sources indicated by others as exhibiting liberal or conservative leanings (Mitchell et al., 2014; Center for Media and Democracy, 2013; Center for Media and Democracy, 2012; HWC Library, 2011)

[3]That is, even if someone truly deserves criticism from Obama, left-learning sources would choose slightly different wordings to avoid a potentially harsh cast on Obama.

Perspective Triad: If A is positive towards B, and B is positive towards C, then we expect A is also positive towards C. Similar dynamics hold for the negative case. $\mathcal{P}_{w\rightarrow a_1} = \neg\left(\mathcal{P}_{w\rightarrow a_2} \oplus \mathcal{P}_{a_1\rightarrow a_2}\right)$
Perspective – Effect: If a predicate has a positive effect on the Subject, then we expect that the interaction between the Subject and Object was positive. Similar dynamics hold for the negative case and for other perspective relations. $\mathcal{E}_{a_1} = \mathcal{P}_{a_2\rightarrow a_1}$
Perspective – Value: If A is presupposed as valuable, then we expect that the writer also views A positively. Similar dynamics hold for the negative case. $\mathcal{V}_{a_1} = \mathcal{P}_{w\rightarrow a_1}$
Effect – Mental State: If the predicate has a positive effect on A, then we expect that A will gain a positive mental state. Similar dynamics hold for the negative case. $\mathcal{S}_{a_1} = \mathcal{E}_{a_1}$

Table 3: Potential Dynamics among Typed Relations: we propose models that parameterize these dynamics using log-linear models (frame-level model in §3).

sentiments between the agent and the theme are likely to be reciprocal, or at least do not directly conflict with + and − simultaneously. Therefore, we assume that $\mathcal{P}(a_1 \rightarrow a_2) = \mathcal{P}(a_2 \rightarrow a_1) = \mathcal{P}(a_1 \leftrightarrow a_2)$, and we only measure for these binary relationships going in one direction. In addition, we assume the *predicted*[4] perspective from the reader r to an argument $\mathcal{P}(r \rightarrow a)$ is likely to be the same as the *implied* perspective from the writer w to the same argument $\mathcal{P}(w \rightarrow a)$. So, we only try to learn the perspective of the writer. Lifting these assumptions will be future work.

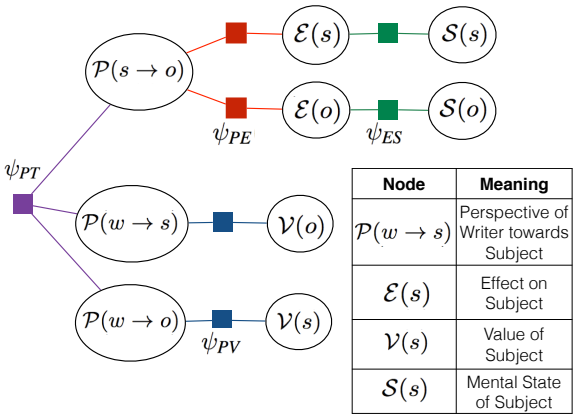
For simplicity, our model only explores the polarities involving the agent and the theme roles. We will assume that these roles are correlated to the subject and object positions, and henceforth refer to them as the "Subject" and "Object" of the event.

3 Modeling Connotation Frames

Our task is essentially that of lexicon induction (Akkaya et al., 2009; Feng et al., 2013) in that we want to induce the connotation frames of previously unseen verbs. For each predicate, we infer a connotation frame composed of 9 relationship aspects that represent: *perspective* $\{\mathcal{P}(w \rightarrow o), \mathcal{P}(w \rightarrow s), \mathcal{P}(s \rightarrow o)\}$, *effect* $\{\mathcal{E}(o), \mathcal{E}(s)\}$, *value* $\{\mathcal{V}(o), \mathcal{V}(s)\}$, and *mental state* $\{\mathcal{S}(o), \mathcal{S}(s)\}$ polarities.

We propose two models: an aspect-level model that makes the prediction for each typed relation independently based on the distributional representation of the context in which the predicate appears (§3.1), and a frame-level model that makes the prediction over the connotation frame collectively in consideration the dynamics between typed relations (§3.2).

[4]Surely different readers can and will form varying opinions after reading the same text. Here we concern with the most likely perspective of the general audience, as a result of reading the text.



Node	Meaning
$\mathcal{P}(w \rightarrow s)$	Perspective of Writer towards Subject
$\mathcal{E}(s)$	Effect on Subject
$\mathcal{V}(s)$	Value of Subject
$\mathcal{S}(s)$	Mental State of Subject

Figure 2: A factor graph for predicting the polarities of the typed relations that define a connotation frame for a given verb predicate. The factor graph also includes unary factors (ψ_{emb}), which we left out for brevity.

3.1 Aspect-Level

Our aspect-level model predicts labels for each of these typed relations separately. As input, we use the 300-dimensional dependency-based word embeddings from Levy and Goldberg (2014). For each aspect, there is a separate MaxEnt (maximum entropy) classifier used to predict the label of that aspect on a given word-embedding, which is treated as a 300 dimensional input vector to the classifier. The MaxEnt classifiers learn their weights using LBFGS on the training data examples with re-weighting of samples to maximize for the best average F1 score.

3.2 Frame-Level

Next we present a factor graph model (Figure 2) of the connotation frames that parameterize the dynamics between typed relations. Specifically, for each verb predicate,[5] the factor graph contains 9 nodes representing the different aspects of the connotation frame. All these variables take polarity values from the set $\{-, =, +\}$.

We define $\mathbf{Y}_i := \{\mathcal{P}_{wo}, \mathcal{P}_{ws}, \mathcal{P}_{so}, \mathcal{E}_o, \mathcal{E}_s, \mathcal{V}_o, \mathcal{V}_s, \mathcal{S}_o, \mathcal{S}_s\}$ as the set of relational aspects for the i^{th} verb. The factor graph for $\mathbf{Y}_i$, is illustrated in Figure 2, and we will describe the factor potentials in more detail in the rest of this section. The probability of an assignment of polarities to the nodes in $\mathbf{Y}_i$ is:

$$\begin{aligned} P(\mathbf{Y}_i) \propto\ & \psi_{\text{PV}}(\mathcal{P}_{ws}, \mathcal{V}_s)\ \psi_{\text{PV}}(\mathcal{P}_{wo}, \mathcal{V}_o) \\ & \psi_{\text{PE}}(\mathcal{P}_{so}, \mathcal{E}_s)\ \psi_{\text{PE}}(\mathcal{P}_{so}, \mathcal{E}_o) \\ & \psi_{\text{ES}}(\mathcal{E}_s, \mathcal{S}_s)\ \psi_{\text{ES}}(\mathcal{E}_o, \mathcal{S}_o) \\ & \psi_{\text{PT}}(\mathcal{P}_{wo}, \mathcal{P}_{ws}, \mathcal{P}_{so}) \prod_{y \in \mathbf{Y}_i} \psi_{emb}(y) \end{aligned}$$

Embedding Factors We include unary factors on all nodes to represent the results of the aspect-level classifier. Incorporating this knowledge as factors, as opposed to *fixing* the variables as observed, affords us the flexibility of representing noise in the labels as soft evidence. The potential function ψ_{emb} is a log-linear function of a feature vector f, which is a one-hot feature vector representing the polarity of a node (+,−,or =). For example, with the node representing the value of the object ($\mathcal{V}_o$):

$$\psi_{emb}(\mathcal{V}_o) = e^{w_{\mathcal{V}_o} \cdot f(\mathcal{V}_o)}$$

The potential ψ_{emb} is defined similarly for the other 8 remaining nodes. All weights were learned using stochastic gradient descent (SGD) over training data.

Interdependency Factors We include interdependency factors to promote the properties defined by the dynamics between relations (§2.2). The potentials for Perspective Triad, Perspective-Value, Perspective-Effect, and Effect-State Relationships (ψ_{PT}, ψ_{PV}, ψ_{PE}, ψ_{ES} respectively) are all defined using log-linear functions of one-hot feature vectors that encode the combination of polarities of the neighboring nodes. The potential for ψ_{PT} is therefore:

$$\psi_{PT}(\mathcal{P}_{wo}, \mathcal{P}_{ws}, \mathcal{P}_{so}) = e^{w_{PT} \cdot f(\mathcal{P}_{wo}, \mathcal{P}_{ws}, \mathcal{P}_{so})}$$

[5] We consider only verb predicates here.

And we define the potentials for ψ_{PV}, ψ_{PE}, and ψ_{ES} for subject nodes as:

$$\psi_{PV}(\mathcal{P}_{ws}, \mathcal{V}_s) = e^{w_{PV,s} \cdot f(\mathcal{P}_{ws}, \mathcal{V}_s)}$$

$$\psi_{PE}(\mathcal{P}_{so}, \mathcal{E}_s) = e^{w_{PE,s} \cdot f(\mathcal{P}_{so}, \mathcal{E}_s)}$$

$$\psi_{ES}(\mathcal{E}_s, \mathcal{S}_s) = e^{w_{ES,s} \cdot f(\mathcal{E}_s, \mathcal{S}_s)}$$

and we define the potentials for the object nodes similarly. As with the unary seed factors, weights were learned using SGD over training data.

Belief Propagation We use belief propagation to induce the connotation frames of previously unseen verbs. In the belief propagation algorithm, messages are iteratively passed between the nodes to their neighboring factors and vice versa. Each message μ, containing a scalar for each value $x \in \{-, 0, +\}$, is defined from each node v to a neighboring factor a as follows:

$$\mu_{v \to a}(x) \propto \prod_{a^* \in N(v)\ a} \mu_{a^* \to v}(x)$$

and from each factor a to a neighboring node v as:

$$\mu_{a \to v} \propto \sum_{x', x'_v = x} \psi(x') \prod_{v^* \in N(a)\ v} \mu_{v^* \to a}(x'_{v^*})$$

At the conclusion of message passing, the probability of a specific polarity associated with node v being equal to x is proportional to $\prod_{a \in N(v)} \mu_{a \to v}(x)$. Our factor graph does not contain any loops, so we are able to perform exact inference.

4 Experiments

We first describe crowd-sourced annotations (§4.1), then present the empirical results of predicting connotation frames (§4.2), and conclude with qualitative analysis of a large corpus (§4.3).

4.1 Data and Crowdsourcing

In order to understand how humans interpret connotation frames, we designed an Amazon Mechanical Turk (AMT) annotation study. We gathered a set of transitive verbs commonly used in the New York Times corpus (Sandhaus, 2008), selecting the 2400 verbs that are used more than 200 times in the corpus. Of these, AMT workers annotated the 1000 most frequently used verbs.

Annotation Design In a pilot annotation experiment, we found that annotators have difficulty thinking about subtle connotative polarities when shown predicates without any context. Therefore,

we designed the AMT task to provide a generic context as follows. We first split each verb predicate into 5 separate tasks that each gave workers a different generic sentence using the verb. To create generic sentences, we used Google Syntactic N-grams (Goldberg and Orwant, 2013) to come up with a frequently seen Subject-Verb-Object tuple which served as a simple three-word sentence with generic arguments. For each of the 5 sentences, we asked 3 annotators to answer questions like "How do you think the Subject feels about the event described in this sentence?" In total, each verb has 15 annotations aggregated over 5 different generic sentences containing the verb.

In order to help the annotators, some of the questions also allowed annotators to choose sentiment using additional classes for "positive or neutral" or "negative or neutral" for when they were less confident but still felt like a sentiment might exist. When taking inter-annotator agreement, we count "positive or neutral" as agreeing with either "positive" or "neutral" classes.

Annotator agreement Table 4 shows agreements and data statistics. The non-conflicting (NC) agreement only counts opposite polarities as disagreement.[6] From this study, we can see that non-expert annotators are able to see these sort of relationships based on their understanding of how language is used. From the NC agreement, we see that annotators do not frequently choose completely opposite polarities, indicating that even when they disagree, their disagreements are based on the degree of connotations rather than the polarity itself. The average Krippendorff alpha for all of the questions posed to the workers is 0.25, indicating stronger than random agreement. Considering the subtlety of the implicit sentiments that we are asking them to annotate, it is reasonable that some annotators will pick up on more nuances than others. Overall, the percent agreement is encouraging that the connotative relationships are visible to human annotators.

Aggregating Annotations We aggregated over crowdsourced labels (fifteen annotations per verb) to create a polarity label for each aspect of a verb.[7]

Final distributions of the aggregated labels are included in the right-hand columns of Table 4.

Aspect	% Agreement		Distribution	
	Strict	NC	% +	% -
$\mathcal{P}(w \rightarrow o)$	75.6	95.6	36.6	4.6
$\mathcal{P}(w \rightarrow s)$	76.1	95.5	47.1	7.9
$\mathcal{P}(s \rightarrow o)$	70.4	91.9	45.8	5.0
$\mathcal{E}(o)$	52.3	94.6	50.3	20.24
$\mathcal{E}(s)$	53.5	96.5	45.1	4.7
$\mathcal{V}(o)$	65.2	-	78.64	2.7
$\mathcal{V}(s)$	71.9	-	90.32	1.4
$\mathcal{S}(o)$	79.9	98.0	12.8	14.5
$\mathcal{S}(s)$	70.4	92.5	50.72	8.6

Table 4: Label Statistics: % Agreement refers to pairwise inter-annotator agreement. The strict agreement counts agreement over 3 classes ("positive or neutral" was counted as agreeing with either + or neutral), while non-conflicting (NC) agreement also allows agreements between neutral and -/+ (no direct conflicts). Distribution shows the final class distribution of -/+ labels created by averaging annotations.

Notably, the distributions are skewed toward positive and neutral labels. The most skewed connotation frame aspect is the value $\mathcal{V}(x)$ which tends to be positive, especially for the subject argument. This makes some intuitive sense since, as the subject actively causes the predicate event to occur, they most likely have some intrinsic potential to be valuable. An example of a verb where the subject was labelled as not valuable is "contaminate". In the most generic case, the writer is using contaminate to frame the subject as being worthless (and even harmful) with regards to the other event participants. For example, in the sentence "his touch contaminated the food," it is clear that the writer considers "his touch" to be of negative value in the context of how it impacts the rest of the event.

4.2 Connotation Frame Prediction

Using our crowdsourced labels, we randomly divided the annotated verbs into training, dev, and held-out test sets of equal size (300 verbs each). For evaluation we measured average accuracy and F1 score over the 9 different Connotation Frame relationship types for which we have annotations: $\mathcal{P}(w \rightarrow o)$, $\mathcal{P}(w \rightarrow s)$, $\mathcal{P}(s \rightarrow o)$, $\mathcal{V}(o)$, $\mathcal{V}(s)$, $\mathcal{E}(o)$, $\mathcal{E}(s)$, $\mathcal{S}(o)$, and $\mathcal{S}(s)$.

Baselines To show the non-trivial challenge of learning Connotation Frames, we include a simple majority-class baselines. The MAJORITY classifier assigns each of the 9 relationships the label of the majority of that relationship type found in the training data. Some of these relationships (in particular, the Value of subject/object) have skewed

[6] Annotators were asked yes/no questions related to Value, so this does not have a corresponding NC agreement score.

[7] We take the average to obtain scalar value between $[-1., 1.]$ for each aspect of a verb's connotation frame. For simplicity, we cutoff the ranges of negative, neutral and positive polarities as $[-1, -0.25)$, $[-0.25, 0.25]$ and $(0.25, 1]$, respectively.

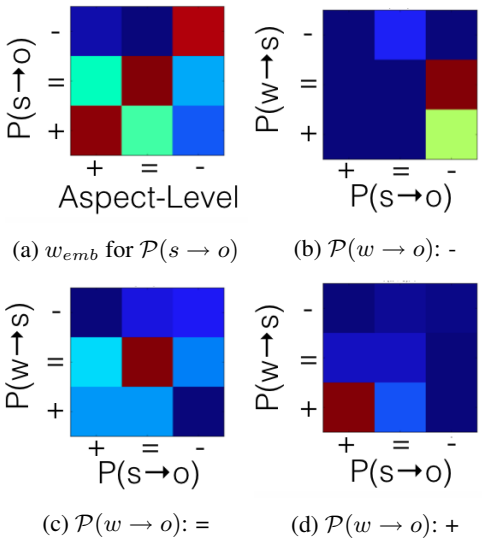
distributions, so we expect this classifier to achieve a much higher accuracy than random but a much lower overall F1 score.

Additionally, we add a GRAPH PROP baseline that is comparable to algorithms like graph propagation or label propagation which are often used for (sentiment) lexicon induction. We use a factor graph with nodes representing the polarity of each typed relation for each verb. Binary factors connect nodes representing a particular type of relation for two similar verbs (e.g. $\mathcal{P}(w \rightarrow o)$ for verbs *persuade* and *convince*). These binary factors have hand-tuned potentials that are proportional to the cosine similarity of the verbs' embeddings, encouraging similar verbs to have the same polarity for the various relational aspects. We use words in the training data as the seed set and use loopy belief propagation to propagate polarities from known nodes to the unknown relationships.

Finally, we use a 3-NEAREST NEIGHBOR baseline that labels relationships for a verb based on the predicate's 300-dimensional word embedding representation, using the same embeddings as in our aspect-level. 3-NEAREST NEIGHBOR labels each verb using the polarities of the three closest verbs found in the training set. The most similar verbs are determined using the cosine similarity between word embeddings.

Results As shown in Table 5, aspect-level and frame-level models consistently outperform all three baselines — MAJORITY, 3-NN, GRAPH PROP in the development set across the different types of relationships. In particular, the improved F1 scores show that these models are able to perform better across all three classes of labels even in the most skewed cases. The frame-level model also frequently improves the F1 scores of the labels from what they were in the aspect-level model. The summarized comparison of the classifiers' performance test set is shown in Table 6. As with the development set, aspect-level and frame-level are both able to outperform the baselines. Furthermore, the frame-level formulation is able to make improvement over the results of the aspect-level classification, indicating that the modelling of inter-dependencies between relationships did help correct some of the mistakes made.

One point of interest about the frame-level results is whether the learned weights over the consistency factors match our initial intuitions about interdependencies between relationships. The weights



(a) w_{emb} for $\mathcal{P}(s \rightarrow o)$ (b) $\mathcal{P}(w \rightarrow o)$: -

(c) $\mathcal{P}(w \rightarrow o)$: = (d) $\mathcal{P}(w \rightarrow o)$: +

Figure 3: Learned weights of embedding factor for the perspective of subject to object and the weights the perspective triad (PT) factor. Red is for weights that are more positive, whereas blue are more negative.

learned in our algorithm do tell us something interesting about the degree to which these interdependencies are actually found in our data.

We show the heat maps for some of the learned weights in Figure 3. In 3a, we show the weights of one of the embedding factors, and how the polarities are more strongly weighted when they match the relation-level output. In the rest of the figure, we show the weights for the other perspective relationships when $\mathcal{P}(w \rightarrow o)$ is negative (3b), neutral (3c), and positive (3d), respectively. Based on the expected interdependencies, when $\mathcal{P}(w \rightarrow o) : -$, the model should favor $\mathcal{P}(w \rightarrow s) \neq \mathcal{P}(s \rightarrow o)$ and when $\mathcal{P}(w \rightarrow o) : +$, the model should favor $\mathcal{P}(w \rightarrow s) = \mathcal{P}(s \rightarrow o)$. Our model does, in fact, learn a similar trend, with slightly higher weights along these two diagonals in the maps 3b and 3d. Interestingly, when $\mathcal{P}(w \rightarrow o)$ is neutral, weights slightly prefer for the other two perspectives to resemble one another, but with highest weights being when other perspectives are also neutral.

4.3 Analysis of a Large News Corpus

Using the connotation frame, we present measured implied sentiment in online journalism.

Data From the Stream Corpus (KBA, 2014), we select 70 million news articles. We extract subject-verb-object relations for this subset using the direct dependencies between noun phrases

Aspect	Algorithm	Acc.	Avg F_1

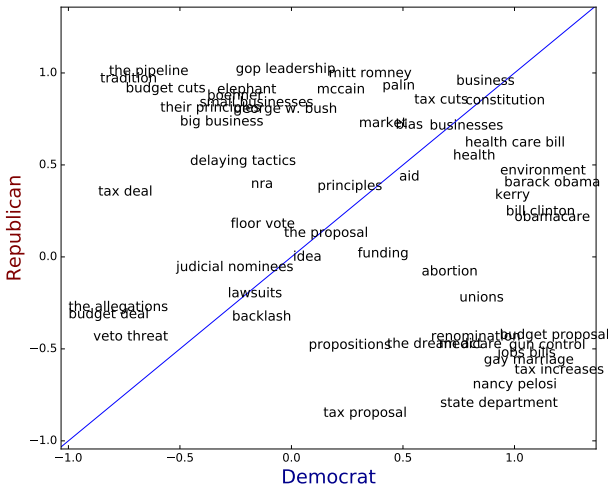

Figure 4: Average sentiment of Democrats and Republicans (as subjects) to selected nouns (as their objects), aggregated over a large corpus using the learned lexicon (§4.2). The line indicates identical sentiments, i.e. Republicans are more positive towards the nouns that are above the line.

and verbs as identified by the BBN Serif system, obtaining 1.2 billion unique tuples of the form *(url,subject,verb,object,count)*.We also extracted subject-verb-object tuples from news articles found in the Annotated English Gigaword Corpus (Napoles et al., 2012), which contains nearly 10 million articles. From the Gigaword corpus we extracted a further 120 million unique tuples.

Estimating Entity Polarities Using connotation frames, we can also measure entity-to-entity sentiment at a large scale. Figure 4, for example, presents the polarity of entities "Democrats" and "Republicans" towards a selected set of nouns, by computing the average estimated polarity (using our lexicon) over triples where one of these entities appears as part of the subject (e.g. "Democrats" or "Republican party"). Apart from nouns that both entities are positive ("business", "constitution") or negative ("the allegations","veto threat") towards, we can also see interesting examples in which Democrats feel more positively (below the line: "nancy pelosi", "unions", "gun control", etc.) and ones where Republicans are more positive ("the pipeline", "gop leaders", "budget cuts", etc.) Also, both entities are neutral towards "idea" and "the proposal", which probably owes to the fact that ideas or proposals can be good or bad for either entity depending on the context.

5 Related Work

Most prior work on sentiment lexicons focused on the overall polarity of words without taking into account their semantic arguments (Wilson et al., 2005; Baccianella et al., 2010; Wiebe et al., 2005; Velikovich et al., 2010; Kaji and Kitsuregawa, 2007; Kamps et al., 2004; Takamura et al., 2005; Adreevskaia and Bergler, 2006). Several recent studies began exploring more specific and nuanced aspects of sentiment such as connotation (Feng et al., 2013), good and bad effects (Choi and Wiebe, 2014), and evoked sentiment (Mohammad and Turney, 2010). Drawing inspirations from them, we present connotation frames as a unifying representation framework to encode the rich dimensions of implied sentiment, presupposed value judgements, and effect evaluation, and propose a factor graph formulation that captures the interplay among different types of connotation relations.

Goyal et al. (2010a; 2010b) investigated how characters (protagonists, villains, victims) in children's stories are affected by certain predicates, which is related to the effect relations studied in this work. While Klenner et al. (2014) similarly investigated the relation between the polarity of the verbs and arguments, our work introduces new perspective types and proposes a unified representation and inference model. Wiegand and Ruppenhofer (2015) also looked at perspective-based relationships induced by verb predicates with a focus on opinion roles. Building on this concept, our framework also incorporates information about the perspectives' polarities as well as information about other typed relations. There have been growing interests for modeling framing (Greene and Resnik, 2009; Hasan and Ng, 2013), biased language (Recasens et al., 2013) and ideology detection (Yano et al., 2010). All these tasks are relatively less studied, and we hope our connotation frame lexicon will be useful for them.

Sentiment inference rules have been explored by the recent work of Wiebe and Deng (2014) and Deng and Wiebe (2014). In contrast, we make a novel conceptual connection between inferred sentiments and frame semantics, organized as connotation frames, and present a unified model that integrates different aspects of the connotation frames. Finally, in a broader sense, what we study as connotation frames draws a connection to schema and script theory (Schank and Abelson, 1975). Unlike most prior work that focused on directly observable actions (Chambers and Jurafsky, 2009; Frermann et al., 2014; Bethard et al., 2008), we focus on implied sentiments that are framed by predicate verbs.

6 Conclusion

In this paper, we presented a novel system of connotative frames that define a set of implied sentiment and presupposed facts for a predicate. Our work also empirically explores different methods of inducing and modelling these connotation frames, incorporating the interplay between relations within frames. Our work suggests new research avenues on learning connotation frames, and their applications to deeper understanding of social and political discourse. All the learned connotation frames and annotations will be shared at `http://homes.cs.washington.edu/~hrashkin/connframe.html`.

Abstract

Sentiment classification aims to automatically predict sentiment polarity (e.g., positive or negative) of user generated sentiment data (e.g., reviews, blogs). Due to the mismatch among different domains, a sentiment classifier trained in one domain may not work well when directly applied to other domains. Thus, domain adaptation for sentiment classification algorithms are highly desirable to reduce the domain discrepancy and manual labeling costs. To address the above challenge, we propose a novel domain adaptation method, called Bi-Transferring Deep Neural Networks (BTDNNs). The proposed BTDNNs attempts to transfer the source domain examples to the target domain, and also transfer the target domain examples to the source domain. The linear transformation of BTDNNs ensures the feasibility of transferring between domains, and the distribution consistency between the transferred domain and the desirable domain is constrained with a linear data reconstruction manner. As a result, the transferred source domain is supervised and follows similar distribution as the target domain. Therefore, any supervised method can be used on the transferred source domain to train a classifier for sentiment classification in a target domain. We conduct experiments on a benchmark composed of reviews of 4 types of Amazon products. Experimental results show that our proposed approach significantly outperforms the several baseline methods, and achieves an accuracy which is competitive with the state-of-the-art method for domain adaptation.

1 Introduction

With the rise of social media (e.g., blogs and social networks etc.), more and more user generated sentiment data have been shared on the Web (Pang et al., 2002; Pang and Lee, 2008; Liu, 2012; Zhou et al., 2011). They exist in the form of user reviews on shopping or opinion sites, in posts of blogs/questions or customer feedbacks. This has created a surge of research in sentiment classification (or sentiment analysis), which aims to automatically determine the sentiment polarity (e.g., positive or negative) of user generated sentiment data (e.g., reviews, blogs, questions).

Machine learning algorithms have been proved promising and widely used for sentiment classification (Pang et al., 2002; Pang and Lee, 2008; Liu, 2012). However, the performance of these models relies on manually labeled training data. In many practical cases, we may have plentiful labeled data in the source domain, but very few or no labeled data in the target domain with a different data distribution. For example, we may have many labeled books reviews, but we are interested in detecting the polarity of electronics reviews. Reviews for different products might have different vocabularies, thus classifiers trained on one domain often fail to produce satisfactory results when transferring to another domain. This has motivated much research on cross-domain (domain adaptation) sentiment classification which transfers the knowledge from the source domain to the target domain (Thomas et al., 2006; Snyder and Barzilay, 2007; Blitzer et al., 2006; Blitzer et al., 2007; Daume III, 2007; Li and Zong, 2008; Li et al., 2009; Pan et al., 2010; Kumar et al., 2010; Glorot et al., 2011; Chen et al., 2011a; Chen et al., 2012; Li et al., 2012; Xia et al., 2013a; Li et al., 2013; Zhou et al., 2015a; Zhuang et al., 2015).

Depending on whether the labeled data are available for the target domain, cross-domain sen-

Berlin, Germany, August 7-12, 2016.

timent classification can be divided into two categories: supervised domain adaptation and unsupervised domain adaptation. In scenario of supervised domain adaptation, labeled data is available in the target domain but the number is usually too small to train a good sentiment classifier, while in unsupervised domain adaptation only unlabeled data is available in the target domain, which is more challenging. This work focuses on the unsupervised domain adaptation problem of which the essence is how to employ the unlabeled data of target domain to guide the model learning from the labeled source domain.

The fundamental challenge of cross-domain sentiment classification lies in that the source domain and the target domain have different data distribution. Recent work has investigated several techniques for alleviating the domain discrepancy: instance-weight adaptation (Huang et al., 2007; Jiang and Zhai, 2007; Li and Zong, 2008; Mansour et al., 2009; Dredze et al., 2010; Chen et al., 2011b; Chen et al., 2011a; Chen et al., 2012; Li et al., 2013; Xia et al., 2013a) and feature representation adaptation (Thomas et al., 2006; Snyder and Barzilay, 2007; Blitzer et al., 2006; Blitzer et al., 2007; Li et al., 2009; Pan et al., 2010; Zhou et al., 2015a; Zhuang et al., 2015). The first kind of methods assume that some training data in the source domain are very useful for the target domain and these data can be used to train models for the target domain after re-weighting. In contrast, feature representation approaches attempt to develop an adaptive feature representation that is effective in reducing the difference between domains.

Recently, some efforts have been initiated on learning robust feature representations with deep neural networks (DNNs) in the context of cross-domain sentiment classification (Glorot et al., 2011; Chen et al., 2012). Glorot et al. (2011) proposed to learn robust feature representations with stacked denoising auto-encoders (SDAs) (Vincent et al., 2008). Denoising auto-encoders are one-layer neural networks that are optimized to reconstruct input data from partial and random corruption. These denoisers can be stacked into deep learning architectures. The outputs of their intermediate layers are then used as input features for SVMs (Fan et al., 2008). Chen et al. (2012) proposed a marginalized SDA (mSDA) that addressed the two crucial limitations of SDAs: high

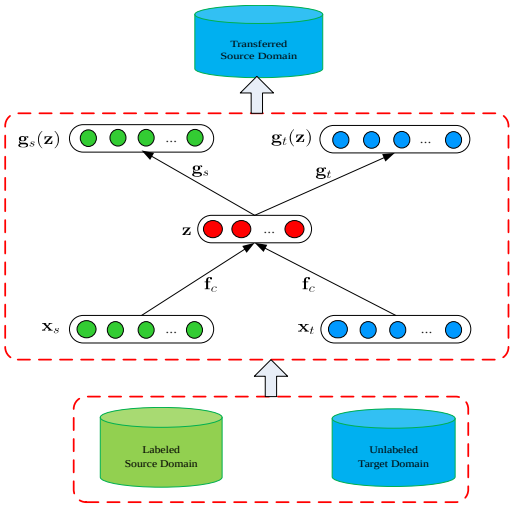

Figure 1: The framework of Bi-transferring Deep Neural Networks (BTDNNs). Through BTDNNs, a source domain example can be transferred to the target domain where it can be reconstructed by the target domain examples, and vice versa.

computational cost and lack of scalability to high-dimensional features. However, these methods learn the unified domain-invariable feature representations by combining the source domain data and that of the target domain data together, which cannot well characterize the domain-specific features as well as the commonality of domains.

To this end, we propose a Bi-Transferring Deep Neural Networks (BTDNNs) which can transfer the source domain examples to the target domain and also transfer the target domain examples to the source domain, as shown in Figure 1. In BTDNNs, the linear transformation makes the feasibility of transferring between domains, and the linear data reconstruction manner ensures the distribution consistency between the transferred domain and the desirable domain. Specifically, our BTDNNs has one common encoder $\mathbf{f}_c$, two decoders $\mathbf{g}_s$ and $\mathbf{g}_t$ which can map an example to the source domain and the target domain respectively. As a result, the source domain can be transferred to the target domain along with its sentiment label, and any supervised method can be used on the transferred source domain to train a classifier for sentiment classification in the target domain, as the transferred source domain data share the similar distribution as the target domain. Experimental results show that the proposed approach significantly outperforms several baselines, and achieves an accuracy which is competitive with the state-of-

the-art method for cross-domain sentiment classification.

The remainder of this paper is organized as follows. Section 2 introduces the related work. Section 3 describes our proposed bi-transferring deep neural networks (BTDNNs). Section 4 presents the experimental results. In Section 5, we conclude with ideas for future research.

2 Related Work

Domain adaptation aims to generalize a classifier that is trained on a source domain, for which typically plenty of training data is available, to a target domain, for which data is scarce. Cross-domain generalization is important in many real applications, the key challenge is that data in the source and the target domain are often distributed differently.

Recent work has investigated several techniques for alleviating the difference in the context of cross-domain sentiment classification task. Blitzer et al. (2007) proposed a structural correspondence learning (SCL) algorithm to train a cross-domain sentiment classifier. SCL is motivated by a multi-task learning algorithm, alternating structural optimization (ASO), proposed by Ando and Zhang (2005). Given labeled data from a source domain and unlabeled data from both source and target domains, SCL attempts to model the relationship between "pivot features" and "non-pivot features". Pan et al. (2010) proposed a spectral feature alignment (SFA) algorithm to align the domain-specific words from the source and target domains into meaningful clusters, with the help of domain-independent words as a bridge. In the way, the cluster can be used to reduce the gap between domain-specific words of two domains. Dredze et al. (2010) combined classifier weights using confidence-weighted learning, which represented the covariance of the weight vectors. Xia et al. (2013a) proposed an instance selection and instance weighting method for cross-domain sentiment classification. After that, Xia et al. (2013b) proposed a feature ensemble plus sample selection method to further improve the sentiment classification adaptation. Zhou et al. (Zhou et al., 2015b) proposed to bridge the domain gap with the help of topical correspondence. Li et al. (2009) proposed to transfer common lexical knowledge across domains via matrix factorization techniques. Zhou et al. (2015a) further improved the matrix factorization techniques via a regularization term on the pivots and domain-specific words, ensuring that the pivots capture only correspondence aspects and the domain-specific words capture only individual aspects. Li and Zong (2008) proposed the multi-label consensus training approach which combined several base classifiers trained with SCL. Chen et al. (2012) proposed a domain adaptation algorithm based on sample and feature selection. Li et al. (2013) proposed an active learning algorithm for cross-domain sentiment classification. Xiao and Guo (2013) investigated the online active domain adaptation problem in a novel but practical setting where the labels can be acquired with a lower cost in the source domain than in the target domain.

There has also been research in exploring careful structuring of features or prior knowledge for domain adaptation. Daumé III (2007) proposed a kernel-mapping function which maps both source and target domains data to a high-dimensional feature space so that data points from the same domain are twice as similar as those form different domains. Dai et al. (2008) proposed translated learning which used a language model to link the class labels to the features in the source domain, which in turn is translated to the features in the target domain. Xia et al. (2010) proposed a POS-based ensemble model for cross-domain sentiment classification. Xiao et al. (2013) proposed a supervised representation learning method to tackle domain adaptation by inducing predictive latent features based on supervised word clustering. He et al. (2011) employed a joint sentiment-topic model for cross-domain sentiment classification; Bollegala et al. (2011) used a sentiment sensitive thesaurus to perform cross-domain sentiment classification. Xiao and Guo (2015) proposed to learn distributed state representations for cross-domain sequence predictions.

Recently, some efforts have been initiated on learning robust feature representations with deep neural networks (DNNs) for cross-domain natural language processing. Glorot et al. (2011) and Chen et al. (2012) proposed to use deep learning for cross-domain sentiment classification. Most recently, Yang and Eisenstein (2014) proposed an unsupervised domain adaptation method with marginalized structured dropout. Furthermore, Yang and Eisenstein (2015) proposed to use feature embeddings with metadata domain attributes for multi-domain adaptation. In this paper,

our proposed approach BTDNNs tackles the domain discrepancy with a linear data construction manner, which can effectively model the domain-specific features as well as the commonality of domains. Deep learning techniques have also been proposed to heterogeneous transfer learning (Socher et al., 2013; Zhou et al., 2014; Kan et al., 2015; Long et al., 2015), where knowledge is transferred from one modality to another based on the correspondences at hand. Our proposed framework can be considered as a more general case, where the bias of the correspondences between the source and target domains is constrained with a linear data reconstruction manner.

Besides, other researchers also explore the DNNs for sentiment analysis (Socher et al., 2011; Tang et al., 2014; Tang et al., 2015; Zhai and Zhang, 2016; Chandar et al., 2014). However, all these methods focus on the sentiment analysis without considering the domain discrepancy. In this paper, we focus on domain adaptation for sentiment classification with a different model formulation and task definition.

3 Bi-Transferring Deep Neural Networks

3.1 Problem Definition

Given two domains X_s and X_t, where X_s and X_t are referred to a source domain and a target domain, respectively. Suppose we have a set of labeled sentiment examples as well as some unlabeled examples in the source domain X_s with size n_s, containing terms from a vocabulary $\mathcal{V}$ with size m. The examples in the source domain X_s can be represented as a term-document matrix $\mathbf{X}_s = \{\mathbf{x}_1^s, \cdots, \mathbf{x}_{n_s}^s\} \in \mathbb{R}^{m \times n_s}$, with their sentiment labels $\mathbf{y}_s = \{y_1^s, \cdots, \mathbf{y}_{n_s}^s\}$, where $\mathbf{x}_i^s \in \mathbb{R}^m$ is the feature representation of the i-th source domain example with a tf-idf weight of the corresponding term and $y_i^s \in \{+1, -1\}$ is its sentiment label.[1]

Similarly, suppose we have a set of unlabeled examples in the target domain X_t with size n_t, containing terms from a vocabulary $\mathcal{V}$ with size m. The examples in target domain X_t can also be represented as a term-document matrix $\mathbf{X}_t = \{\mathbf{x}_1^{(t)}, \cdots, \mathbf{x}_{n_t}^{(t)}\} \in \mathbb{R}^{m \times n_t}$, where each example denotes a tf-idf weight of the corresponding term. The task of cross-domain sentiment classification is to learn a robust classifier to predict the polarity of unseen examples from X_t. Note that we only consider one source domain and one target domain in this paper. However, our proposed algorithm is a general framework and can be easily adapted to multi-domain problems.

[1]We use upper case and lower case characters represent the matrices and vectors respectively throughout the paper.

3.2 Basic Auto-Encoder

An auto-encoder is an unsupervised neural network which is trained to reconstruct a given input vector from its latent representation (Bengio et al., 2007). It can be seen as a special neural network with three layers: the input layer, the latent layer, and the reconstruction layer. An auto-encoder contains two parts: encoder and decoder. The encoder, denoted as $\mathbf{f}$, attempts to map an input vector $\mathbf{x} \in \mathbb{R}^{m \times 1}$ to the latent representation $\mathbf{z} \in \mathbb{R}^{k \times 1}$, in which k is the number of neurons in the latent layer. Usually, $\mathbf{f}$ is a nonlinear function as follows:

$$\mathbf{z} = \mathbf{f}(\mathbf{x}) = s_e(\mathbf{W}\mathbf{x} + \mathbf{b}) \tag{1}$$

where s_e is the activation function of the encoder, whose input is called the activation function, which is usually non-linear, such as sigmoid function or tanh function is a linear transform parameter, and $\mathbf{b} \in \mathbb{R}^{k \times 1}$ is the basis.

The decoder, denoted as $\mathbf{g}$, tries to map the latent representation $\mathbf{z}$ back to a reconstruction:

$$\mathbf{g}(z) = s_d(\mathbf{W}'\mathbf{z} + \mathbf{b}') \tag{2}$$

Similarly, s_d is the activation function of the decoder with parameters $\{\mathbf{W}', \mathbf{b}'\}$.

The training objective is the determination of parameters $\{\mathbf{W}, \mathbf{b}\}$ and $\{\mathbf{W}', \mathbf{b}'\}$ that minimize the average reconstruction errors:

$$\mathcal{L} = \min_{\mathbf{W},\mathbf{b},\mathbf{W}',\mathbf{b}'} \sum_{i=1}^{N} \left\| \mathbf{x}_i - \mathbf{g}(\mathbf{f}(\mathbf{x}_i)) \right\|_2^2 \tag{3}$$

where $\mathbf{x}_i$ represents the i-th one of N training examples. Parameters $\{\mathbf{W}, \mathbf{b}\}$ and $\{\mathbf{W}', \mathbf{b}'\}$ can be optimized by stochastic or mini-batch gradient descent. By minimizing the reconstruction error, we require the latent features should be able to reconstruct the original input as much as possible.

3.3 Bi-Transferring Deep Neural Networks

The traditional auto-encoder in subsection 3.2 attempts to reconstruct the input itself, which is usually used for feature representation learning. Nevertheless, our proposed bi-transferring deep neural networks (BTDNNs) attempts to transfer

examples between domains to deal with the domain discrepancy, with the inspiration of DNNs in computer vision (Kan et al., 2015). Motivated by the successful application in computer vision (Kan et al., 2015), we construct the architecture of BTDNNs with one encoder $\mathbf{f}_e$, and two decoders, $\mathbf{g}_s$ and $\mathbf{g}_t$ shown in Figure 1, which can transform an input example to the source domain and the target domain respectively.[2]

Specifically, the encoder $\mathbf{f}_c$ tries to map an input example $\mathbf{x}$ into the latent feature representation $\mathbf{z}$, which is common to both the source and target domains as follows:

$$\mathbf{z} = \mathbf{f}_c(\mathbf{x}) = s_e(\mathbf{W}_c\mathbf{x} + \mathbf{b}_c) \tag{4}$$

The decoder $\mathbf{g}_s$ attempts to map the latent representation to the source domain, and the decoder $\mathbf{g}_t$ attempts to map the latent representation to the target domain as follows:

$$\mathbf{g}_s(\mathbf{x}) = s_d(\mathbf{W}_s\mathbf{z} + \mathbf{b}_s) \tag{5}$$

$$\mathbf{g}_t(\mathbf{x}) = s_d(\mathbf{W}_t\mathbf{z} + \mathbf{b}_t) \tag{6}$$

where $s_e(\cdot)$ and $s_d(\cdot)$ are the element-wise nonlinear activation function, e.g., sigmoid or tanh function, $\mathbf{W}_c$ and $\mathbf{b}_c$ are the parameters for encoder $\mathbf{f}_c$, $\mathbf{W}_s$ and $\mathbf{b}_s$ are the parameters for decoder $\mathbf{g}_s$, $\mathbf{W}_t$ and $\mathbf{b}_t$ are the parameters for decoder $\mathbf{g}_t$.

Following the literature (Kan et al., 2015), we attempt to map the source domain examples $\mathbf{X}_s$ to the source domain (e.g., $\mathbf{X}_s$ itself) with an encoder $\mathbf{f}_c$ and a decoder $\mathbf{g}_s$. Similarly, given an encoder $\mathbf{f}_c$ and a decoder $\mathbf{g}_t$, we aim to map the source domain examples $\mathbf{X}_s$ to the target domain. Although it is unknown what the mapped examples look like, they are expected to follow the similar distribution as the target domain. This kind of distribution consistency between two domains can be characterized from the perspective of a linear data reconstruction manner.

The two domains $\mathbf{X}_s$ and $\mathbf{X}_t$ can be generally reconstructed from each other, and their distances can be used to measure the domain discrepancy. Following the literature (He et al., 2012), BTDNNs attempt to represent a transferred source domain $\mathbf{g}_t(\mathbf{f}_c(\mathbf{x}_i^s))$ with a linear reconstruction function from the target domain:

$$\|\mathbf{g}_t(\mathbf{f}_c(\mathbf{x}_i^s)) - \mathbf{X}_t\beta_i^t)\|_2^2 \tag{7}$$

[2]In the implementation, we use the stacked denoising auto-encoders (SDA) (Vincent et al., 2008) to model the source and the target domain data.

where β_i^t is the coefficients for the reconstruction of transferred source domain examples. Equation (7) enforces that each example of transferred domain is consistent with that of target domain, which ensures that the transferred source domain follows the similar distribution as the target domain. The overall objective for the examples of source domain $\mathbf{X}_s$ can be formulated as below:

$$\min_{\mathbf{f}_c,\mathbf{g}_s,\mathbf{g}_t,\beta_i^s} \|\mathbf{X}_s - \mathbf{g}_s(\mathbf{f}_c(\mathbf{X}_s))\|_2^2 + \|\mathbf{g}_t(\mathbf{f}_c(\mathbf{X}_s)) - \mathbf{X}_t\mathbf{B}_t)\|_2^2$$
$$s.t.\ \|\beta_i^t\|_2^2 < \tau,\ \ \mathbf{B}_t = [\beta_1^t, \beta_2^t, \cdots, \beta_{n_s}^t]^T \in \mathbb{R}^{n_s \times n_t}$$

where $\mathbf{g}_s(\mathbf{f}_c(\mathbf{X}_s) = [\mathbf{g}_s(\mathbf{f}_c(\mathbf{x}_1^s)), \cdots, \mathbf{g}_s(\mathbf{f}_c(\mathbf{x}_{n_t}^s))]$ and $\mathbf{g}_t(\mathbf{f}_c(\mathbf{X}_s) = [\mathbf{g}_t(\mathbf{f}_c(\mathbf{x}_1^t)), \mathbf{g}_t(\mathbf{f}_c(\mathbf{x}_{n_s}^t))]$. The same simplifications are used hereinafter if without misunderstanding.

Similarly, for the examples of target domain $\mathbf{X}_t$, with encoder $\mathbf{f}_c$ and decoder $\mathbf{g}_t$ they should be mapped on the target domain. Also, with encoder $\mathbf{f}_c$ and decoder $\mathbf{g}_s$ they should be mapped to the source domain, where they can be reconstructed by the source domain examples from the point of view of a linear data reconstruction manner (He et al., 2012), so as to ensure a similar distribution between the source domain and the transferred target domain. The overall objective for the examples of target domain $\mathbf{X}_t$ can be written as:

$$\min_{\mathbf{f}_c,\mathbf{g}_s,\mathbf{g}_t,\beta_i^t} \|\mathbf{X}_t - \mathbf{g}_t(\mathbf{f}_c(\mathbf{X}_t))\|_2^2 + \|\mathbf{g}_s(\mathbf{f}_c(\mathbf{X}_t)) - \mathbf{X}_s\mathbf{B}_s)\|_2^2$$
$$s.t.\ \|\beta_j^s\|_2^2 < \tau,\ \ \mathbf{B}_s = [\beta_1^s, \beta_2^s, \cdots, \beta_{n_t}^s]^T \in \mathbb{R}^{n_t \times n_s}$$

Combining the above equations, the overall objective of BTDNNs can be formulated as follows:

$$\begin{aligned}\min_{\mathbf{f}_c,\mathbf{g}_s,\mathbf{g}_t,\mathbf{B}_s,\mathbf{B}_t} & \|\mathbf{X}_s - \mathbf{g}_s(\mathbf{f}_c(\mathbf{X}_s))\|_2^2 + \|\mathbf{g}_t(\mathbf{f}_c(\mathbf{X}_s)) - \mathbf{X}_t\mathbf{B}_t)\|_2^2 \\ & + \|\mathbf{X}_t - \mathbf{g}_t(\mathbf{f}_c(\mathbf{X}_t))\|_2^2 + \|\mathbf{g}_s(\mathbf{f}_c(\mathbf{X}_t)) - \mathbf{X}_s\mathbf{B}_s)\|_2^2 \\ & + \gamma\Big(\sum_{i=1}^{n_s}\|\beta_i^t\|_2^2 + \sum_{j=1}^{n_t}\|\beta_j^s\|_2^2\Big)\end{aligned} \tag{8}$$

where γ is a regularization parameter controlling the amount of shrinkage. With the optimization of equation (8), our proposed approach BTDNNs can map any input examples to the source and target domains respectively. Especially, the source domain examples $\mathbf{X}_s$ can transferred to the target domain along with their sentiment labels. The transferred source domain data $\mathbf{g}_t(\mathbf{f}_s(\mathbf{X}_s))$ share the similar distribution as the target domain, so any supervised method can be used to learn a classifier for sentiment classification in the target domain. In this paper, a linear support vector machine (SVM) (Fan et al., 2008) is employed for building sentiment classification models.

3.4 Learning Algorithm

Note that the optimization problem in equation (8) is not convex in variables $\{\mathbf{f}_c, \mathbf{g}_s, \mathbf{g}_t, \mathbf{B}_s, \mathbf{B}_t\}$ together. However, when considering one variable at a time, the cost function turns out to be convex. For example, given $\{\mathbf{g}_s, \mathbf{g}_t, \mathbf{B}_s, \mathbf{B}_t\}$, the cost function is a convex function w.r.t. $\mathbf{f}_c$. Therefore, although we cannot expect to get a global minimum of the above problem, we shall develop a simple and efficient optimization algorithm via alternative iterations.

3.4.1 Optimize $\{\mathbf{f}_c, \mathbf{g}_s, \mathbf{g}_t\}$ given $\{\mathbf{B}_s, \mathbf{B}_t\}$

When $\mathbf{B}_s$ and $\mathbf{B}_t$ are fixed, the objective function in equation (8) can be formulated as:

$$\min_{\mathbf{f}_c,\mathbf{g}_s,\mathbf{g}_t} \|\mathbf{X}_s - \mathbf{g}_s(\mathbf{f}_c(\mathbf{X}_s))\|_2^2 + \|\mathbf{g}_t(\mathbf{f}_c(\mathbf{X}_s)) - \bar{\mathbf{X}}_t)\|_2^2 + \|\mathbf{X}_t - \mathbf{g}_t(\mathbf{f}_c(\mathbf{X}_t))\|_2^2 + \|\mathbf{g}_s(\mathbf{f}_c(\mathbf{X}_t)) - \bar{\mathbf{X}}_s)\|_2^2 \quad (9)$$

where $\bar{\mathbf{X}}_s = \mathbf{X}_s\mathbf{B}_s$ and $\bar{\mathbf{X}}_t = \mathbf{X}_t\mathbf{B}_t$. Equation (9) can easily optimized by gradient descent as the basic auto-encoder (Bengio et al., 2007).

3.4.2 Optimize $\{\mathbf{B}_s, \mathbf{B}_t\}$ given $\{\mathbf{f}_c, \mathbf{g}_s, \mathbf{g}_t\}$

When $\{\mathbf{f}_c, \mathbf{g}_s, \mathbf{g}_t\}$ are fixed, the objective function in equation (8) can be written as:

$$\min_{\mathbf{B}_s,\mathbf{B}_t} \|\mathbf{G}_t - \mathbf{X}_t\mathbf{B}_t)\|_2^2 + \|\mathbf{G}_s - \mathbf{X}_s\mathbf{B}_s)\|_2^2 + \gamma\Big(\sum_{i=1}^{n_s}\|\beta_i^t\|_2^2 + \sum_{j=1}^{n_t}\|\beta_j^s\|_2^2\Big)$$

where $\mathbf{g}_s(\mathbf{f}_c(\mathbf{X}_t)) = \mathbf{G}_s = [\mathbf{g}_1^s, \cdots, \mathbf{g}_{n_t}^s]$ and $\mathbf{g}_t(\mathbf{f}_c(\mathbf{X}_s)) = \mathbf{G}_t = [\mathbf{g}_1^t, \cdots, \mathbf{g}_{n_s}^t]$. Since $\mathbf{G}_s$ and $\mathbf{G}_t$ are independent with each other, so they can be optimized independently. The optimization of $\mathbf{G}_s$ with other variables fixed is a least squares problem with ℓ_2-regularization. It can also be decomposed into n_t optimization problems, with each corresponding to one β_j^s and can be solved in parallel:

$$\min_{\beta_j^s} \|\mathbf{g}_j^s - \mathbf{X}_s\beta_j^s\|_2^2 + \gamma\|\beta_j^s\|_2^2 \quad (10)$$

for $j = 1, 2, \cdots, n_t$. It is a standard ℓ_2-regularized least squares problem and the solution is:

$$\beta_j^s = \left(\mathbf{X}_s^T\mathbf{X}_s + \gamma\mathbf{I}\right)^{-1}\mathbf{X}_s^T\mathbf{g}_j^s \quad (11)$$

where $\mathbf{I}$ is an identity matrix with all entries equal to 1.

Similarly, The optimization of $\mathbf{G}_t$ can also be decomposed into n_s ℓ_2-regularized least squares problems and the solution of each one is:

$$\beta_i^t = \left(\mathbf{X}_t^T\mathbf{X}_t + \gamma\mathbf{I}\right)^{-1}\mathbf{X}_t^T\mathbf{g}_i^t \quad (12)$$

for $i = 1, 2, \cdots, n_s$. We repeat the above equations until $\mathbf{f}_c$, $\mathbf{g}_s$, $\mathbf{g}_t$, $\mathbf{B}_s$ and $\mathbf{B}_t$ converge or a maximum number of iterations is exceeded.

3.5 Algorithm Complexity

In this section, we analyze the computational complexity of the learning algorithm described in equations (9), (11) and (12). Besides expressing the complexity of the algorithm using big O notation, we also count the number of arithmetic operations to provide more details about the run time. Computational complexity of learning matrix $\mathbf{G}_s$ is $O(m \times n_s \times k)$ per iteration. Similarly, for each iteration, learning matrices $\mathbf{G}_t$ takes $O(m \times n_t \times k)$. Learning matrices $\mathbf{B}_s$ and $\mathbf{B}_t$ takes $O(m^2 \times n_s)$ and $O(m^2 \times n_t)$ operations per iteration. In real applications, we have $k \ll m$. Therefore, the overall complexity of the algorithm, dominated by computation of matrices $\mathbf{B}_s$ and $\mathbf{B}_t$, is $O(m^2 \times n)$ where $n = \max(n_s, n_t)$.

4 Experiments

4.1 Data Set

Domain adaptation for sentiment classification has been widely studied in the NLP community. A large majority experiments are performed on the benchmark made of reviews of Amazon products gathered by Blitzer et al. (2006). This data set contains 4 different domains: Book (B), DVDs (D), Electronics (E) and Kitchen (K). For simplicity and comparability, we follow the convention of (Blitzer et al., 2006; Pan et al., 2010; Glorot et al., 2011; Xiao and Guo, 2013) and only consider the binary classification problem whether a review is positive (higher than 3 stars) or negative (3 stars or lower). There are 1000 positive and 1000 negative reviews for each domain, as well as approximately 4,000 unlabeled reviews (varying slightly between domains). The positive and negative reviews are also exactly balanced.

Following the literature (Pan et al., 2010), we can construct 12 cross-domain sentiment classification tasks: D → B, E → B, K → B, K → E, D → E, B → E, B → D, K → D, E → D, B → K, D → K, E → K, where the word before an arrow corresponds with the source domain and the word after an arrow corresponds with the target domain. To be fair to other algorithms that we compare to, we use the raw bag-of-words unigram/bigram features as their input and pre-process with tf-idf (Blitzer et al., 2006). Table 1 presents the statistics of the data set.

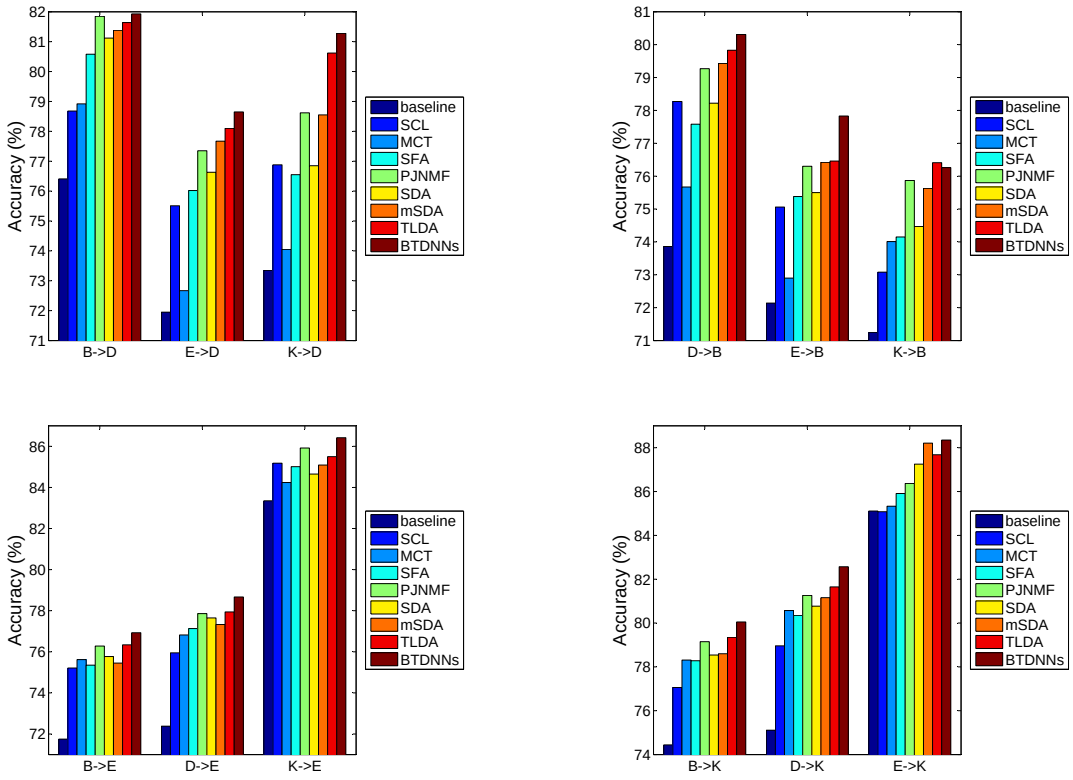

Figure 2: Average results for cross-domain sentiment classification on the Amazon product benchmark of 4 domains.

Domain	#Train	#Test	#Unlab.	% Neg.
Books	1600	400	4465	50%
DVDs	1600	400	5945	50%
Electronics	1600	400	5681	50%
Kitchen	1600	400	3586	50%

Table 1: Amazon review statistics. This table depicts the number of training, testing and unlabeled reviews for each domain, as well as the portion of negative training reviews of the data set.

4.2 Compared Methods

As a *baseline* method, we train a linear SVM (Fan et al., 2008) on the raw bag-of-words representation of the labeled *source* domain and test it on the *target* domain. In the original paper regarding the benchmark data set, Blitzer et al. (2006) adapted Structural Correspondence Learning (SCL) for sentiment analysis. Li and Zong (2008) proposed the Multi-label Consensus Training (MCT) approach which combined several base classifiers trained with SCL. Pan et al. (2010) first used a Spectral Feature Alignment (SFA) algorithm to align words from the source and target domains to help bridge the gap between them. Zhou et al. (2015a) proposed a method called PJNMF, which linked heterogeneous input features with pivots via joint non-negative matrix factorization.

Recently, some efforts have been initiated on learning robust feature representations with DNNs for cross-domain sentiment classification. Glorot et al. (2011) first employed stacked Denoising Auto-encoders (SDA) to extract meaningful representation for domain adaptation. Chen et al. (2012) proposed marginalized SDA (mSDA) that addressed the high computational cost and lack of scalability to high-dimensional features. Zhuang et al. (2015) proposed a state-of-the-art method called transfer learning with deep auto-encoders (TLDA).

For SCL, PJNMF, SDA, mSDA and TLDA, we use the source codes provided by the authors. For SFA and MCT, we re-implement them based on the original papers. The above methods serve as comparisons in our empirical evaluation. For fair comparison, all hyper-parameters are set by 5-fold cross validation on the training set from the source domain.[3] For our proposed BTDNNs, the number

[3]We keep the default value of some of the parameters in SCL and SFA, e.g., the number of stop-words removed and stemming parameters – as they were already tuned for this

of hidden neurons is set as 1000, the regularization parameter γ is tuned via 5-fold cross-validation.

For SDA, mSDA, TLDA and BTDNNs, we can construct the classifiers for the target domain in two ways. The first way is directly to use the stacking SVM on top of the output of the hidden layer. The second way is to apply the standard SVM to train a classifier for source domain in the embedding space. Then the classifiers is applied to predict sentiment labels for target domain data. For fair comparison with the shallow models, we choose the second way in this paper.

Figure 2 shows the accuracy of classification results for all methods and for all source-target domain pairs. We can check that all compared methods achieve the similar performance with the results reported in the original papers. From Figure 2, we can see that our proposed approach BTDNNs outperforms all other eight comparison methods in general. The `baseline` performs poorly on all the 12 tasks, while the other seven domain adaptation methods, SCL, MCT, SFA, PJNMF, SDA, mSDA and TLDA, consistently outperform the `baseline` method across all the 12 tasks, which demonstrates that the transferred knowledge from the source domain to the target domain is useful for sentiment classification. Nevertheless, the improvements achieved by these seven methods over the `baseline` are much smaller than the proposed approach BTDNNs.

Surprisingly, we note that the deep learning based methods (SDA, mSDA and TLDA) perform worse than our approach, the reason may be that SDA, mSDA and TLDA learn the unified domain-invariable feature representations by combining the source domain data and that of the target domain data together, which cannot well characterize the domain-specific features as well as the commonality of domains. On the contrary, our proposed BTDNNs ensures the feasibility of transferring between domains, and the distribution consistency between the transferred domain and the desirable domain is constrained with a linear data reconstruction manner.

We also conduct significance tests for our proposed approach BTDNNs and the state-of-the-art method (TLDA) using a McNemar paired test for labeling disagreements (Gillick and Cox, 1989). In general, the average result on the 12 source-target domain pairs indicates that the difference between BTDNNs and TLDA is mildly significant with $p < 0.08$. Furthermore, we also conduct the experiments on a much larger industrial-strength data set of 22 domains (Glorot et al., 2011). The preliminary results show that BTDNNs significantly outperforms TLDA ($p < 0.05$). Therefore, we will report our detailed results and discussions in our future work.

benchmark set by the authors.

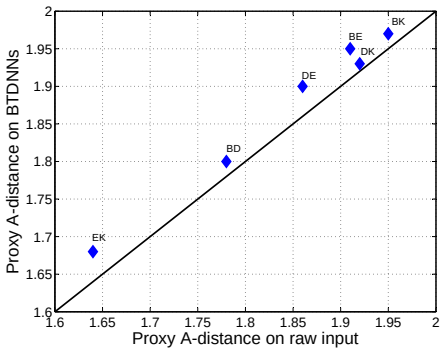

Figure 3: Proxy A-distance between domains of the Amazon benchmark for the 6 different pairs.

4.3 Domain Divergence

In this subsection, we look into how similar two domains are to each other. Ben-David et al. (2006) showed that the A-distance as a measure of how different between the two domains. They hypothesized that it should be difficult to discriminate between the source and target domains in order to have a good transfer between them. In practice, computing the exact A-distance is impossible and one has to compute a proxy. Similar to (Glorot et al., 2011), the proxy for the A-distance is then defined as $2(1 - 2\epsilon)$, where ϵ is the generalization error of a linear SVM classifier trained on the binary classification problem to distinguish inputs between the two domains.

Figure 3 presents the results for each pair of domains. Surprisingly, the distance is increased with the help of new feature representations, e.g., distinguishing between domains becomes easier with the BTDNNs features. We explain this effect through the fact that BTDNNs can ensure the feasibility of transferring between domains, and the distribution consistency between the transferred domain and the desirable domain is constrained with a linear data reconstruction manner, which can learn a generally better representations for the input data. This helps both tasks, distinguishing between domains and sentiment classification

(e.g., in the book domain BTDNNs might interpolate the feature "exciting" from "boring", both are not particularly relevant for sentiment classification but might help distinguish the review from the Electronic domain.).

5 Conclusions and Future Work

In this paper, we propose a novel Bi-Transferring Deep Neural Networks (BTDNNs) for cross-domain sentiment classification. The proposed BTDNNs attempts to transfer the source domain examples to the target domain, and also transfer the target domain examples to the source domain. The linear transformation of BTDNNs ensures the feasibility of transferring between domains, and the distribution consistency between the transferred domain and the desirable domain is constrained with a linear data reconstruction manner. Experimental results show that BTDNNs significantly outperforms the several baselines, and achieves an accuracy which is competitive with the state-of-the-art method for sentiment classification adaptation.

There are some ways in which this research could be continued. First, since deep learning may obtain better generalization on large-scale data sets (Bengio, 2009), a straightforward path of the future research is to apply the proposed BTDNNs for domain adaptation on a much larger industrial-strength data set of 22 domains (Glorot et al., 2011). Second, we will try to investigate the use of the proposed approach for other kinds of data set, such as 20 newsgroups and Reuters-21578 (Li et al., 2012; Zhuang et al., 2013).

Document-level Sentiment Inference with Social, Faction, and Discourse Context

Eunsol Choi **Hannah Rashkin** **Luke Zettlemoyer** **Yejin Choi**
Computer Science & Engineering

Abstract

We present a new approach for document-level sentiment inference, where the goal is to predict directed opinions (*who* feels positively or negatively towards *whom*) for all entities mentioned in a text. To encourage more complete and consistent predictions, we introduce an ILP that jointly models (1) sentence- and discourse-level sentiment cues, (2) factual evidence about entity factions, and (3) global constraints based on social science theories such as homophily, social balance, and reciprocity. Together, these cues allow for rich inference across groups of entities, including for example that CEOs and the companies they lead are likely to have similar sentiment towards others. We evaluate performance on new, densely labeled data that provides supervision for all pairs, complementing previous work that only labeled pairs mentioned in the same sentence. Experiments demonstrate that the global model outperforms sentence-level baselines, by providing more coherent predictions across sets of related entities.

1 Introduction

Documents often present a complex web of facts and opinions that hold among the entities they describe. Consider the international relations story in Figure 1. Representatives from three countries form factions and create a network of sentiment. While some opinions are relatively directly stated (e.g., Russia criticizes Belarus), many others must be inferred based on the factual ties among entities (e.g., Moscow, Gryzlov, and Russia probably share the same sentiment towards other entities) and known social context (e.g., Russia probably dislikes Saakhashvili since Russia criticized Belarus for supporting him). In this paper, we show that jointly reasoning about all of these factors can provide more complete and consistent document-level sentiment predictions.

Russia criticized *Belarus* for permitting *Georgian* President *Mikheil Saakhashvili* to appear on *Belorussian* television. "The appearance was an unfriendly step towards *Russia*," the speaker of *Russian* parliament *Boris Gryzlov* said. . . . *Saakhashvili* announced Thursday that *he* did not understand *Russia*'s claims. *Moscow* refused to have any business with *Georgia*'s president after the armed conflict in 2008 . . .

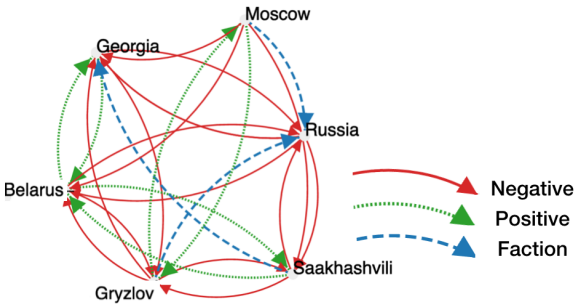

Figure 1: Example text excerpt paired with the document-level sentiment graph we aim to recover. The graph includes edges with direct textual support (e.g., from Russian to Belarus given the verb "criticized") as well as ones that must be inferred at the whole-document level (e.g., from Gryzlov to Saakhashvili given the web of relationships and opinions between them, Georgia, Russian, and Belarus).

More concretely, we present a global model for document-level entity-to-entity sentiment, i.e., *who* feels positively (or negatively) towards *whom*. Our goal is to make exhaustive predictions over all entity pairs, including those that require cross-sentence inference. We present a Integer Linear Programming (ILP) model that combines three complementary types of evidence: entity-pair sentiment classification, template-based faction extraction, and sentiment dynamics in social groups. Together, they allow for recovering more complete predictions of both the explicitly stated and im-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 333–343,
Berlin, Germany, August 7-12, 2016.

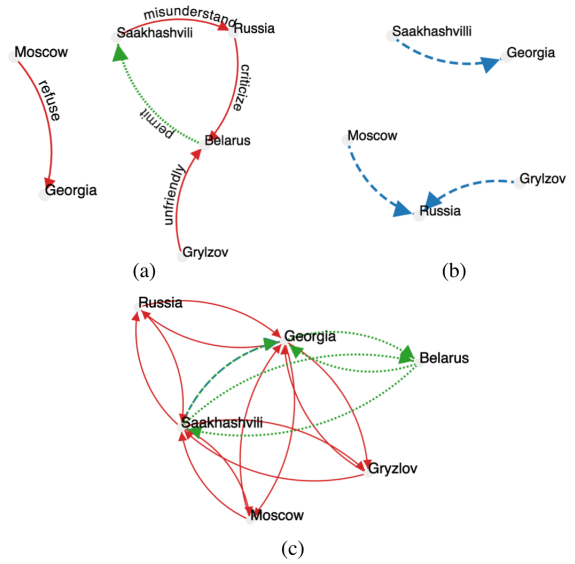

Figure 2: Entity subgraphs for the example in Figure 1: (a) shows explicitly stated sentiment, (b) shows faction relationships and (c) shows all edges for Georgia and its representative Saakhashvili. Through Saakhasvili's relationship with Belarus, Georgia forms an alliance with Belarus, providing evidence for an inferred negative stance towards Russia. Green dotted edges represent positive sentiment, red are negative, and blue dashed lines show faction relationship.

plicit sentiment, while preserving consistency.

The sentiment dynamics in social groups, motivated by social science theories, are encoded as soft ILP constraints. They include a notion of homophily, that entities in the same group tend to have similar opinions (Lazarsfeld and Merton, 1954). For example, Figure 2b shows directed faction edges, where one entity is likely to agree with the other's opinions. They also encode dyadic social constraints (i.e., the likely reciprocity of opinions (Gouldner, 1960)) and triadic social dynamics following social balance theory (Heider, 1946). For example, from Russia's criticism on Belarus and Belarus' positive attitude towards Saakhashvilli (in Figure 2a), we can infer that Russia is negative towards Saakhashvilli (in Figure 2c). When considered in aggregate, these constraints can greatly improve the consistency over the overall document-level predictions.

Our work stands in contrast to previous approaches in three aspects. First, we apply social dynamics motivated by social science theories to entity-entity sentiment analysis in unstructured text. In contrast, most previous studies focused on social media or dialogue data with overt social network structure when integrating social dynamics (Tan et al., 2011; Hu et al., 2013; West et al., 2014). Second, we aim to recover sentiment that can be inferred through partial evidence that spans multiple sentences. This complements prior efforts for accessing implied sentiment where the key evidence is, by and large, at the sentence level (Zhang and Liu, 2011; Yang and Cardie, 2013; Deng and Wiebe, 2015a). Finally, we present the first approach to model the relationship between factual and subjective relations.

We evaluate the approach on a newly gathered corpus with dense document-level sentiment labels in news articles.[1] This data includes comprehensively annotated sentiment between all entity pairs, including those that do not appear together in any single sentence. Experiments demonstrate that the global model significantly improves performance over a pairwise classifier and other strong baselines. We also perform a detailed ablation and error analysis, showing cases where the global constraints contribute and pointing towards important areas for future work.

2 A Document-level Sentiment Model

Given a news document d, and named entities e_1,...,e_n in d, where each entity e_i has mentions $m_{i1} \cdots m_{ik}$, the task is to decide directed sentiment between all pairs of entities. We predict the directed sentiment from e_i to e_j at the document level, i.e., sent($e_i \rightarrow e_j$) $\in$ {positive, unbiased, negative}, for all e_i, $e_j \in d$ where $i \neq j$, assuming that sentiment is consistent within the document.

We introduce a document-level ILP that includes base models and soft social constraints. ILP has been used successfully for a wide range of NLP tasks (Roth and Yih, 2004), perhaps because they easily support incorporating different types of global constraints. We use two base models: (1) a learned pairwise sentiment classifier (Sec 3.1) that combines sentence- and discourse-level features to make predictions for each entity pair and (2) a pattern-based faction extractor (Sec 3.2) that detects alliances among a subset of the entities.

The ILP is solved by maximizing:

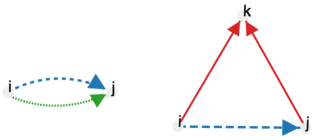
$$F = \psi_{social} + \psi_{fact} + \sum_{i=1}^{n}\sum_{j=1}^{n} \psi_{ij}$$

where F combines soft constraints (ψ_{social}, ψ_{fact} defined in detail in this section) with pairwise potentials ψ_{ij} defined as:

[1] All data will be made publicly available. You can browse it at `http://homes.cs.washington.edu/~eunsol/project_page/acl16`, and download it from the author's webpage.

Sentence	i	j
Canadian Prime Minister Harper. . .	Canada	Harper
. . . Reid, the Democratic leader. . .	Reid	Democratic
Goldman spokesman DuVally	Goldman	DuVally
. . . Djibouti, a key U.S. ally.	Djibouti	U.S.

(a) Detection examples



(b) Visual representation of common inference patterns.

Figure 3: An example sentiment inference from faction relationships. Pairs in factions are encouraged to share opinions, and to be positive towards other tied entities. On the right, sentiment edges can be both positive or both negative.

$$\psi_{ij} = \phi_{pos_{ij}} \cdot \texttt{pos}_{ij} + \phi_{neg_{ij}} \cdot \texttt{neg}_{ij} + \phi_{neu_{ij}} \cdot \texttt{neu}_{ij}$$

Each potential ψ_{ij} includes the sentiment classifier scores (ϕ_{pos}, ϕ_{neg}, ϕ_{neu}) with binary variables $\texttt{pos}_{ij}$, $\texttt{neu}_{ij}$ and $\texttt{neg}_{ij}$ where, for example, $\texttt{neg}_{ij}$=1 indicates that e_i is negative towards e_j. Decision variables $\texttt{pos}_{ij}$ and $\texttt{neu}_{ij}$ are defined analogously for positive and neutral opinion. Finally, we introduce a hard constraint:

$$\forall i, j \; \texttt{pos}_{ij} + \texttt{neg}_{ij} + \texttt{neu}_{ij} = 1$$

to ensure a single prediction is made per pair.

2.1 Inference with factions

Our first soft ILP constraint ψ_{fact} models that fact that entities in supportive social relations tend to share similar sentiment toward others (Lazarsfeld and Merton, 1954), and are often positive towards each other. For now, we assume access to a base extractor to provide such faction relations (Sec. 3.2 provides details of our pattern-based extractor). Figure 3a illustrates sample detections.

We introduce a binary variable $\texttt{tie}_{ij}$, where $\texttt{tie}_{ij}$=1 denotes an extracted faction relationship. These variables are tied to the variables regarding sentiment via the variables

$$\begin{aligned}
\texttt{tie_same}_{ijk} &= \texttt{tie}_{ij} \wedge \texttt{pos}_{ik} \wedge \texttt{pos}_{jk} \\
&\quad + \texttt{tie}_{ij} \wedge \texttt{neg}_{ik} \wedge \texttt{neg}_{jk} \\
\texttt{tie_diff}_{ijk} &= \texttt{tie}_{ij} \wedge \texttt{pos}_{ik} \wedge \texttt{neg}_{jk} \\
&\quad + \texttt{tie}_{ij} \wedge \texttt{neg}_{ik} \wedge \texttt{pos}_{jk} \\
\texttt{itself}_{ij} &= \texttt{tie}_{ij} \wedge \texttt{pos}_{ij} - \texttt{tie}_{ij} \wedge \texttt{neg}_{ij}
\end{aligned}$$

which are used in the following objective term:

$$\psi_{fact} = \sum_{i=1}^{n}\sum_{j=1}^{n}(\alpha_{itself} \cdot \texttt{itself}_{ij} + \sum_{k=1}^{n}(\alpha_{fact} \cdot (\texttt{tie\_same}_{ijk} - \texttt{tie\_diff}_{ijk})))$$

This formulation enables the model to predict implicit sentiment by jointly considering factual and sentiment relations among other entity pairs, essentially drawing a connection between sentiment analysis and information extraction. Figure 3 visualizes this inference pattern.

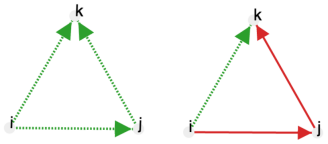


Figure 4: Balance Theory Constraints. When i is positive towards j, sharing same sentiment towards k define a balanced state. When i is negative towards j, differing opinions towards k define a balanced state.

2.2 Inference with sentiment relations

We also include constraints ψ_{social} in the objective that model social balance and reciprocity.

Balance theory constraints: Social balance theory (Heider, 1946) models the sentiment dynamics in an interpersonal network. In particular, in balanced states, entities on positive terms have similar opinions towards other entities and those on negative terms have opposing opinions. We introduce a set of variables to capture this insight: for example, the case where e_i is positive towards e_j is shown below (analogous when negative).

$$\begin{aligned}
\texttt{pos_same}_{ijk} &= \texttt{pos}_{ij} \wedge \texttt{pos}_{ik} \wedge \texttt{pos}_{jk} \\
&\quad + \texttt{pos}_{ij} \wedge \texttt{neg}_{ik} \wedge \texttt{neg}_{jk} \\
\texttt{pos_diff}_{ijk} &= \texttt{pos}_{ij} \wedge \texttt{neg}_{ik} \wedge \texttt{pos}_{ik} \\
&\quad + \texttt{pos}_{ij} \wedge \texttt{pos}_{ik} \wedge \texttt{neg}_{ik}
\end{aligned}$$

and add the term ψ_{bl} to ψ_{social}.

$$\psi_{bl} = \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{n}(\alpha_{bl} \cdot (\texttt{pos\_same}_{ijk} + \texttt{neg\_diff}_{ijk}) + \alpha_{bad_{bl}} \cdot (\texttt{pos\_diff}_{ijk} + \texttt{neg\_same}_{ijk}))$$

A visualization of these constraints is in Figure 4.

	Faction	Balance	Reciprocity
POS	57%	64%	73%
NEG	60%	61%	78%

Table 1: Percentage of labels where each constraint holds. For example, positive on reciprocity means when $pos(e_i, e_j)$ is true, 73% of times $pos(e_j, e_i)$ is also true.

Reciprocity constraint: Reciprocity of sentiment has been recognized as a key aspect of social stability (Johnston, 1916; Gouldner, 1960). To model reciprocity among the real world entities, we introduce variables:

$$\texttt{r\_same}_{ij} = \texttt{pos}_{ij} \wedge \texttt{pos}_{ji} + \texttt{neg}_{ij} \wedge \texttt{neg}_{ji}$$
$$\texttt{r\_diff}_{ij} = \texttt{pos}_{ij} \wedge \texttt{neg}_{ji} + \texttt{neg}_{ij} \wedge \texttt{pos}_{ji}$$
$$\psi_r = \sum_{i=1}^{n}\sum_{j=1}^{n} \alpha_r(\texttt{r\_same}_{ij}) + \alpha_{bad_r}(\texttt{r\_diff}_{ij})$$

and add the term ψ_r to the ψ_{social}.

2.3 Discussion

While many studies exist on homophily, social balance, and reciprocity, no prior work has reported quantitative analysis on the sentiment dynamics among the real world entities that appear in unstructured text. Thus we report the data statistics based on the development set in Table 1. We find that the global constraints hold commonly but are not universal, motivating the use of soft constraints (see Sec. 6).

3 Pairwise Base Models

The global model in Sec. 2 uses two base models, one for pairwise sentiment classification and the other for detecting faction relationships.

3.1 Sentiment Classifier

The entity-pair classifier considers a holder entity e_i, its mentions $m_{i1} \cdots m_{ip}$, a target entity e_j, its mentions $m_{j1} \cdots m_{jq}$, and document d. It predicts sent($e_i \rightarrow e_j$) $\in$ {positive, unbiased, negative}. The input is plain text and no gold labels are assumed; entity detection, dependency parse and co-reference resolution are automatic, and include common nouns and pronoun mentions (details in Sec. 4.1). We trained separate classifiers for pairs that co-occur in a sentence and those that do not, using a linear class-weighted SVM classifier with crowd-sourced data described in Sec. 4.2.

In what follows, we describe three different types of features we developed: dependency features, document features, and quotation features. Many of the features test the overall sentiment of a set of words (e.g., the complete document, a dependency path, or a quotation). In each case, we define the *sentiment label* for the text to be positive if it contains more words that appear in the positive sentiment lexicon than that appear in the negative one (and similarly for the negative label). We used MPQA sentiment lexicon (Wilson et al., 2005) for our study, which contains 2,718 positive and 4,912 negative lexicons.

Dependency Features We consider all dependency paths between the head word of e_i and e_j in each sentence, and aggregate over all co-occurring sentences. The features compute: (1) The sentiment label of the path containing `dobj` and `nsubj_rev`, up to length three if the path contains sentiment lexicon words (e.g., *Olympic* hero *Skah* accuses *Norway* over custody battle.) (2) The sentiment label of the path e_i $\uparrow$ `nsubj` $\downarrow$ `ccomp` $\downarrow$ `nsubj` $\downarrow e_j$, when it exists (e.g., *McCully* said any action against *Henry* is a matter entirely for TVNZ) (3) The sentiment label of path when the path does not contain any named entity (e.g., *Nobel* winner , *Shirin Ebadi*) (4) An indicator for the link `nmod:against`.

Document Features Previous work has shown that notions related to salience (e.g., proximity to sentiment words) can help to detect sentiment targets (Ben-Ami et al., 2014). In our data, we found that an entity's occurrence pattern is highly indicative of being involved in sentiment, for example the most frequently mentioned entity is 3.4 times more likely to be polarized and an entity in the headline is two times more likely to be polarized.

Pairwise features include the NER type of e_i and e_j and the percentage of sentences they co-occur in. We also use features indicating whether e_i and e_j (1) are mentioned in the headline and (2) appear only once in the document. When they are the two most frequent entities, we add the document sentiment label as a feature. For entity pairs that do not appear together in any sentence, we also include the rank of holder and target in terms of overall number of mentions in the document.

Quotation Features Quotations often involve subjective opinions towards prominent entities in news articles. Thus we include document-level

features encoding this intuition. For example, the sentence *"We're pleased to put this behind us," said Michael DuVally* implies positive sentiment from DuVally. We extract direct quotations using regular expressions. We include the sentiment label of the direct quotation from the speaker to the entities in it, excluding entities that appear less than three times in the document. We add the sentiment label of the quotation as a feature to (speaker, the most frequent entity) pair as well.

To extract indirect quotations, we follow studies (Bethard et al., 2004; Lu, 2010) and use a list of 20 verbs indicating speech events (e.g., say, speak, and announce) to detect direct quotations and their opinion holders. We then add the sentiment label of words connected to e_j via a dependency path of length up to two that also includes the subject of quotation verb to e_j (e.g. *Hassanal* said that cooperation between *Brunei* and *China* were fruitful). We also include an indicator feature for whether e_i is the subject of the quotation verb.

3.2 Faction Detector

We use a simple pattern-based detector that extracts a faction relationship between a pair of entities if the dependency path between them either:

1. contains only one link of modifier or compound label (`nmod`, `nmod : poss`, `amod`, `nn`, or `compound`).
2. or contains less than three links and has a possessive or appositive label (`poss` or `appos`).

Example extractions for this approach, which we adopted for its simplicity and the fact that it works reasonably well in practice, are shown in Figure 3a. On average we detect 1.7 ties per document on a small development set with roughly 30% recall and 60% precision. Improving performance and adding more relation types is an important area for future work.[2]

4 Data

We collected new datasets that densely label sentiment among entities in news articles, including: 208 documents, 2,226 sentences, and 15,185 entity pair labels. It complements existing datasets such as MPQA which provides rich annotations at the sentence-level (Deng and Wiebe, 2015b) and the recent KBP challenge which provides sparse annotations at the corpus-level (Ellis et al., 2014), by providing document-level annotations for all entity pairs (see Sec. 7 for discussion).

	KBP	MPQA	Crowdsourced
Document count	154	54	914
Avg. sentence count	10.0	12.7	14.8
Avg. entity count	7.9	10.6	8.8
Avg. mentions / entity	3.6	2.7	3.5

Table 2: Corpus Statistics

4.1 Document Preprocessing

All-pair annotation can be expensive, as there are N^2 pairs to annotate for each document with N entities. We determined that it would be more cost efficient to cover a large number of short documents than a small number of very long documents. We therefore selected articles with less than eleven entities from KBP and less than fifteen from MPQA and took the first 15 sentences for annotation. We used Stanford CoreNLP (Manning et al., 2014) for sentence splitting, part-of-speech tagging, named entity recognition, co-reference resolution and dependency parsing. We discarded entities of type date, duration, money, time and number and merged named entities using several heuristics, such as merging acronyms, merging named entity of person type with the same last name (e.g., Tiger Woods to Woods). We merged names listed as alias in when there is an exact match from Freebase. We included all mentions in a co-reference chain with the named entity, discarding chains with more than one entity. The corpus statistics are shown in Table 2.

4.2 Sentiment Data Collection

We annotated data using two methods: freelancers ($7.6 per article on average) covering all entity pairs and crowd-sourcing ($1.6 per article on average) covering a subset of entity pairs.

Evaluation Dataset We provide exhaustive annotations covering all pairs for the evaluation set. We hired freelancers from UpWork,[3] after examining performance on five documents. They labeled entity pairs with one of the following classes.

POS: positive towards the target.
NOTNEG: positive or unbiased towards the target.

[2] We experimented with using relations from an external knowledge base (Freebase), but KB sparsity and entity linking errors posed major challenges.

[3] `https://www.upwork.com`

Label	KBP	MPQA
POS	3.93	3.52
NOT NEG	5.73	8.06
UNBIASED	44.64	91.04
NOT POS	2.73	6.70
NEG	2.27	2.94

Table 3: Sentiment Label Statistics. Each count represents the average number per document.

UNB: unbiased towards the target
NOTPOS: negative or unbiased towards the target.
NEG: negative towards the target.

Here, we introduced the NOTPOS and NOTNEG classes to mark more subjective cases where we expect agreement might be lower. For example, one assigned NOTPOS to sentiment(Goldman, FINRA), *The FINRA said Goldman lacked adequate procedures to ...* and another assigned NOTNEG to sentiment(Macalintal, Arroyo) in the next example. *... Arroyo's election lawyer, Romulo Macalintal*. Arguments could be made for NEG or POS, respectively, but the decision is inherently subjective and requires careful reading.[4]

We also asked annotators to mark the label as inferred when not explicitly stated but implied from the context or world knowledge. Allowing for inferred labels and finer-grained labels encouraged annotators to capture implicit sentiment. For each judgement, we acquired two labels. Inter-annotator agreement, in Table 4, is high for the relaxed metrics, confirming our intuitions about the ambiguity of the NOTNEG and NOTPOS labels.

For experiments, we combine the fine grained labels as follows: POS or NEG is assigned when both marked it as such. When only one of the annotators marked it, we assigned the weaker sentiment (POS to NOTNEG, NEG to NOTPOS). NOTNEG and NOTPOS are assigned when either annotator marked it without 'Inferred' label. When the labels contradict in polarity or the labels are inferred weaker sentiment, UNB was assigned.

Crowdsourced Dataset We also randomly selected news articles from the Gigaword corpus,[5] and collected labels to train the base sentiment classifier (Sec. 3.1). We designed a pipelined approach, with three steps:

1. Document selection: Is there sentiment among entities in this document?
2. Entity selection: (1) Select all entities **holding** sentiment towards any other entities., and (2) Select all entities which are the **target** of sentiment by any other entity.
3. Sentiment label collection: Choose the sentiment A has towards B, from {Positive, No Sentiment, Negative}

We used CrowdFlower,[6] where annotators were randomly presented test questions for quality control. We collected labels from three annotators for each entity pair, and considered labels when at least two agreed. The resulting annotation contains total 2,995 labels on 914 documents, 682 positive, 836 negative and 474 without sentiment, which we discarded.

	Exact	Strict	Relaxed
Positive	0.35	0.54	0.67
Negative	0.50	0.64	0.74

Table 4: Inter-annotator Agreement. Cohen's kappa score: Exact counts only exact matches, Strict counts allows NOT NEG labels to match POS, and Relaxed allows NOT NEG to match POS or UNBIASED (analogously for negative).

	POS	NOT NEG	NOT POS	NEG
KBP	25%	29%	30%	28%
MPQA	35%	49%	46%	50%

Table 5: Percentage of entity pairs that do not co-occur in a sentence.

	POS	NOTNEG	NOTPOS	NEG
KBP	70%	94%	88%	58%
MPQA	68%	74%	83%	66%

Table 6: Percentage of labels marked as inferred.

4.3 Insights Into Data

This data supports the study of sentiment-laden entity pairs across sentence boundaries and inferred labels among entities, as we show here.

Sentiment Beyond Sentence Boundary Approximately 25% of polarized sentiment labels are between entities that do not co-occur[7] in a sentence (see Table 5). For example, in the article

[4] In the construction of MPQA3.0 dataset, entity-entity/event sentiment corpus, even with iterative expert annotation, 31% of disagreements are caused by negligence.

[5] LDC2014E13:TAC2014KBP English Corpus

[6] http://www.crowdflower.com

[7] This is an estimate due to co-reference resolution errors.

with headline 'Russia heat, smog trigger health problems',

> . . . "We never care to work with a future perspective in mind," *Alexei Skripkov* of the *Federal Medical and Biological Agency* said. "It's a big systemic mistake."

Skripkov never appears together with Russia in any sentence, but he manifests negative sentiment towards it. When a document revolves around a theme (in this example Russia), sentiment is often directed to it without being explicitly mentioned.

Inferred sentiment Annotators marked labels as inferred frequently, especially on less polarized sentiment (see Table 6). Various clues led to sentiment inference. For example, in the following document, we can read *Sam Lake*'s positive attitude towards *Paul Auster* from his 'citing' action:

> Ask most video-game designers about their inspirations . . . *Sam Lake* cites *Paul Auster*'s "*The Book of Illusions*"

Sentiment can also be inferred through reasoning over another entity.

> The *U.N.* imposed an embargo against *Eritrea* for helping insurgents opposed to the *Somali* government.

By considering relations with Eritrea, we can infer U.N. would be positive towards Somalia.

5 Experimental Setup

Data and Metrics We randomly split the densely labeled KBP document set, using half as a test data and half as a development data. One half of the development set was used to tune hyper parameters,[8] and the other for error analysis and ablations. After development, we ran on the test sets composed of KBP documents and MPQA documents. For MPQA we did not create a separate development set and reserved all of the relatively modest amount of data for a more reliable test set. For the pairwise classifier, we report development results using five-fold cross validation on the training data.

We report macro-averaged precision, recall, and F-measure for both sentiment labels.

Comparison Systems We compare performance to two simple baselines and two adaptations of existing sentiment classifiers. The baselines include our base pairwise classifier (Pair) and randomly assigning labels according to their empirical distribution (Random).

The first existing method adaptation (Sentence) uses the publicly released sentence-level RNN sentiment model from Socher et al (2013). For each entity pair, we collect sentiment labels from sentences they co-occur in and assign a positive label if a positive-labeled sentence exists, negative if there exists more than one sentence with a negative label and no positives.[9]

We also report a proxy for doing similar aggregation over a state-of-the-art entity-entity sentiment classifier. Here, because we added our new labels to the original KBP and MPQA3.0 annotations, we can simply predict the union of the original gold annotations using mention string overlap to align the entities (KM_Gold). This provides a reasonable upper bound on the performance of any extractor trained on this data.[10]

Implementation Details We use CPLEX4[11] to solve the ILP described in Sec. 2. For computational efficiency and to avoid erroneous propagation, soft constraints associated with reciprocity and balance theory are introduced only on pairs for which a high-precision classifier assigned polarity. For the pairwise classifier, we use a class-weighted linear SVM.[12] We include annotated pairs, and randomly sample negative examples from pairs without a label in the crowd-sourced training dataset. We made two versions of pairwise classifiers by tuning weight on polarized classes and negative sampling ratio by grid search. One is tuned for high precision to be used as a base classifier for ILP (ILP base), and the other is tuned for the best F1 (Pairwise).[13]

6 Results

Table 7 shows results on the evaluation datasets. The global model achieves the best F1 on both labels. All systems do significantly better than the random baseline but, overall, we see that entity-entity sentiment detection is challenging, requir-

[8] We used the following values (α_r, α_{bad_r}, α_{itself}, $\alpha_{faction}$, α_{bl}, $\alpha_{bad_{bl}}$) = (0.7, -0.8, 0.4, 0.5, 0.1, -0.5).

[9] Due to domain difference, the system predicted negative labels more (73% of sentences were classified as negative).

[10] We consider this gold evaluation a direct proxy for the recent work Deng and Wiebe (2015a), which is the most related recent entity-entity sentiment model trained on the gold data whose predictions we are evaluating against.

[11] http://tinyurl.com/joccfqy

[12] http://scikit-learn.org/

[13] We use 10 as the weights for the polarized classes. Pairwise and base classifier for MPQA sampled 4%, base classifier for KBP sampled 10% of unlabeled pairs.

ing identification of holders, targets, and sentiment jointly. While the numbers are not directly comparable, the best performing system for KBP 2014 sentiment task achieved F1 score of 25.7.

The first row (KM_Gold) shows the comparison against gold annotations from different datasets, highlighting the differences between the task definitions. Our annotations are much more dense, while KBP focuses on specific query entities and MPQA has a much broader focus with less emphasis on covering all entity pairs. The high precision suggests that all of the approaches agree when considering the same entity pairs.

The global model also improves performance over the pairwise classifier (Pairwise) for both datasets, but we see very different behavior due to the different sentiment label distributions (see Table 3). The KBP data has many fewer unbiased pairs and many mistakes are from choosing the wrong polarity. For the pairwise classifier 17% of all predictions were assigned the opposite polarity. After the global inference, it is reduced to 11%, contributing to the gain in overall precision. For MPQA the base classifier has a more challenging detection task, due to relatively large amount of the unbaised pairs. Here, the best base classifier misses many pairs and the global model helps to fill in some of these gaps in recall.

In both cases, the document-level model often propagates correct labels by detecting easier, explicit expressions. For example, given the sentence *Buphavanh said Laos creates favorable conditions for Vietnamese companies*, the base classifier detected positive sentiment from Buphavanh to Vietnam, but not between Vietnam and Laos. By detecting the fact that Buphavanh is the prime minister of Laos, it infers the extra sentiment pairs.

Sentiment expression detection error	21.0%
Missing world knowledge	19.3%
Named entity detection error	17.5%
Co-reference failure	14.8%
Propagation error	12.3%
Missing faction	7.0%

Table 10: Error Analysis on the development set.

We also did ablation studies to measure the contributions of different components. Table 8 shows ablations of each soft constraint. The faction constraint is the most helpful, improving both precision and recall for both labels. The reciprocity and social balance constraints tend to improve recall at the cost of precision. Table 9 shows ablations of the base classifier features. All features are helpful, with dependency features most helpful for positive labels, and quotation and document-level features more with negatives.

Error Analysis We manually analyzed errors on 20 articles from the development set (Table 10). Our system failed when there were sentiment words not in the lexicon, or negated sentiment words. Capturing subtle sentiment expressions beyond sentiment lexicon should improve the performance. Preprocessing, as a whole, was the largest source of error. It includes co-reference failure and named entity error. Co-reference mistakes happen as a result of not resolving pronouns, referring expressions, as well as named entities co-references (e.g., Financial Industry Regulatory Authority to FINRA), or erroneously merging them. Lengthy quotations or nested mentions triggered co-reference error, affecting mostly recall. Named entity errors includes incorrect named

entity detection (e.g., pro-Israel) and mention detection boundary errors. For example, we detected negative sentiment from Mexico to Pakistan from *Mexico condemns Pakistan series suicide bomb attacks.* While actual sentiment is positive. Finally, the ILP propagates sentiment labels erroneously at times. Our constraints often hold among entities of the same type, but are less predictive among entities of different types. For example, when a person supports a peace treaty, the treaty does not have sentiment towards him/her. For future work refining constraints based on entity type should help performance.

7 Related Work

Sentiment Inference Our sentiment inference task is related to the recent KBP sentiment task,[14] in that we aim to find opinion target and holder. While we study the complete document-level analysis over all entity pairs, the KBP task is formulated as query-focused retrieval of entity sentiment from a large pool of potentially relevant documents. Thus, their annotations focus only on query entities and relatively sparse compared to ours (see Sec. 6). Another recent dataset is MPQA 3.0 (Deng and Wiebe, 2015b), which captures various aspects of sentiment. Their sentiment pair annotations are only at the sentence-level and are therefore much sparser than we provide (see Sec. 6) for entity-entity relation analysis.

Several recent studies focused on various aspects of implied sentiment (Greene and Resnik, 2009; Mohammad and Turney, 2010; Zhang and Liu, 2011; Feng et al., 2013; Deng and Wiebe, 2014; Deng et al., 2014). Deng and Wiebe (2015a) in particular introduced sentiment implicature rules relevant for sentence-level entity-entity sentiment. Our work contributes to these recent efforts by presenting a new model and dataset for document-level sentiment inference over all entity pairs.

Document-level Analysis Stoyanov and Claire (2011) also studied document-level sentiment analysis based on fine-grained detection of directed sentiment. They aggregate sentence-level detections to make document-level predictions, while our we model global coherency among entities and can discover implied sentiment without direct sentence-level evidence. In the event extraction domain, previous research showed the effectiveness of jointly considering multiple sentences. Yang and Mitchell (2016) proposed joint extraction of entities and events with the document context, improving on the event extraction. Most work focuses on events, while we primarily study sentiment relations.

Social Network Analysis While many previous studies considered the effect of social dynamics for social media analysis, most relied on an explicitly available social network structure or considered dialogues and speech acts for which opinion holders are given (Tan et al., 2011; Hu et al., 2013; Li et al., 2014; West et al., 2014; Krishnan and Eisenstein, 2015). Compared to the recent work that focused on relationships among fictional characters in movie summaries and stories (Chaturvedi et al., 2016; Srivastava et al., 2016; Iyyer et al., 2016), we consider a broader types of named entities on news domains.

8 Conclusion

We presented an approach to interpreting sentiment among entities in news articles, with global constraints provided by social, faction and discourse context. Experiments demonstrated that the approach can infer implied sentiment and point toward potential directions for future work, including joint entity detection and incorporation of more varied types of factual relationships.

Abstract

Different from traditional active learning based on sentence-wise full annotation (FA), this paper proposes active learning with dependency-wise partial annotation (PA) as a finer-grained unit for dependency parsing. At each iteration, we select a few most uncertain words from an unlabeled data pool, manually annotate their syntactic heads, and add the partial trees into labeled data for parser retraining. Compared with sentence-wise FA, dependency-wise PA gives us more flexibility in task selection and avoids wasting time on annotating trivial tasks in a sentence. Our work makes the following contributions. First, we are the first to apply a probabilistic model to active learning for dependency parsing, which can 1) provide tree probabilities and dependency marginal probabilities as principled uncertainty metrics, and 2) directly learn parameters from PA based on a forest-based training objective. Second, we propose and compare several uncertainty metrics through simulation experiments on both Chinese and English. Finally, we conduct human annotation experiments to compare FA and PA on real annotation time and quality.

1 Introduction

During the past decade, supervised dependency parsing has gained extensive progress in boosting parsing performance on canonical texts, especially on texts from domains or genres similar to existing manually labeled treebanks (Koo and Collins, 2010; Zhang and Nivre, 2011). However, the upsurge of web data (e.g., tweets, blogs, and product comments) imposes great challenges to existing parsing techniques. Meanwhile, previous research on out-of-domain dependency parsing gains little success (Dredze et al., 2007; Petrov and McDonald, 2012). A more feasible way for open-domain parsing is to manually annotate a certain amount of texts from the target domain or genre. Recently, several small-scale treebanks on web texts have been built for study and evaluation (Foster et al., 2011; Petrov and McDonald, 2012; Kong et al., 2014; Wang et al., 2014).

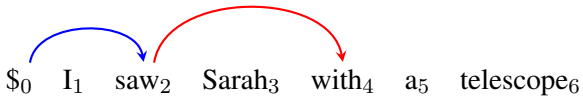

Figure 1: A partially annotated sentence, where only the heads of "*saw*" and "*with*" are decided.

Meanwhile, active learning (AL) aims to reduce annotation effort by choosing and manually annotating unlabeled instances that are most valuable for training statistical models (Olsson, 2009). Traditionally, AL utilizes full annotation (FA) for parsing (Tang et al., 2002; Hwa, 2004; Lynn et al., 2012), where a whole syntactic tree is annotated for a given sentence at a time. However, as commented by Mejer and Crammer (2012), the annotation process is complex, slow, and prone to mistakes when FA is required. Particularly, annotators waste a lot of effort on labeling trivial dependencies which can be well handled by current statistical models (Flannery and Mori, 2015).

Recently, researchers report promising results with AL based on partial annotation (PA) for dependency parsing (Sassano and Kurohashi, 2010; Mirroshandel and Nasr, 2011; Majidi and Crane, 2013; Flannery and Mori, 2015). They find

Berlin, Germany, August 7-12, 2016.

that smaller units rather than sentences provide more flexibility in choosing potentially informative structures to annotate.

Beyond previous work, this paper endeavors to more thoroughly study this issue, and has made substantial progress from the following perspectives.

(1) This is the first work that applies a state-of-the-art probabilistic parsing model to AL for dependency parsing. The CRF-based dependency parser on the one hand allows us to use probabilities of trees or marginal probabilities of single dependencies for uncertainty measurement, and on the other hand can directly learn parameters from partially annotated trees. Using probabilistic models may be ubiquitous in AL for relatively simpler tasks like classification and sequence labeling, but is definitely novel for dependency parsing which is dominated by linear models with perceptron-like training.

(2) Based on the CRF-based parser, we make systematic comparison among several uncertainty metrics for both FA and PA. Simulation experiments show that compared with using FA, AL with PA can greatly reduce annotation effort in terms of dependency number by 62.2% on Chinese and by 74.2% on English.

(3) We build a visualized annotation platform and conduct human annotation experiments to compare FA and PA on real annotation time and quality, where we obtain several interesting observations and conclusions.

All codes, along with the data from human annotation experiments, are released at `http://hlt.suda.edu.cn/~zhli` for future research study.

2 Probabilistic Dependency Parsing

Given an input sentence $\mathbf{x} = w_1...w_n$, the goal of dependency parsing is to build a directed dependency tree $\mathbf{d} = \{h \curvearrowright m : 0 \leq h \leq n, 1 \leq m \leq n\}$, where $|\mathbf{d}| = n$ and $h \curvearrowright m$ represents a dependency from a *head* word h to a *modifier* word m. Figure 1 depicts a partial tree containing two dependencies.[1]

In this work, we for the first time apply a probabilistic CRF-based parsing model to AL for dependency parsing. We adopt the second-order graph-based model of McDonald and Pereira (2006), which casts the problem as finding an optimal tree from a fully-connect directed graph and factors the score of a dependency tree into scores of pairs of sibling dependencies.

$$\begin{aligned} \mathbf{d}^* &= \arg\max_{\mathbf{d}\in\mathcal{Y}(\mathbf{x})} Score(\mathbf{x}, \mathbf{d}; \mathbf{w}) \\ Score(\mathbf{x}, \mathbf{d}; \mathbf{w}) &= \sum_{\substack{(h,s,m): h\curvearrowright s\in\mathbf{d}, \\ h\curvearrowright m\in\mathbf{d}}} \mathbf{w}\cdot\mathbf{f}(\mathbf{x}, h, s, m) \end{aligned} \tag{1}$$

where s and m are adjacent siblings both modifying h; $\mathbf{f}(\mathbf{x}, h, s, m)$ are the corresponding feature vector; $\mathbf{w}$ is the feature weight vector; $\mathcal{Y}(\mathbf{x})$ is the set of all legal trees for $\mathbf{x}$ according to the dependency grammar in hand; $\mathbf{d}^*$ is the 1-best parse tree which can be gained efficiently via a dynamic programming algorithm (Eisner, 2000). We use the state-of-the-art feature set listed in Bohnet (2010).

Under the log-linear CRF-based model, the probability of a dependency tree is:

$$p(\mathbf{d}|\mathbf{x}; \mathbf{w}) = \frac{e^{Score(\mathbf{x},\mathbf{d};\mathbf{w})}}{\sum_{\mathbf{d}'\in\mathcal{Y}(\mathbf{x})} e^{Score(\mathbf{x},\mathbf{d}';\mathbf{w})}} \tag{2}$$

Ma and Zhao (2015) give a very detailed and thorough introduction to CRFs for dependency parsing.

2.1 Learning from FA

Under the supervised learning scenario, a labeled training data $\mathcal{D} = \{(\mathbf{x}_i, \mathbf{d}_i)\}_{i=1}^N$ is provided to learn $\mathbf{w}$. The objective is to maximize the log likelihood of $\mathcal{D}$:

$$\mathcal{L}(\mathcal{D}; \mathbf{w}) = \sum_{i=1}^{N} \log p(\mathbf{d}_i|\mathbf{x}_i; \mathbf{w}) \tag{3}$$

which can be solved by standard gradient descent algorithms. In this work, we adopt stochastic gradient descent (SGD) with L2-norm regularization for all CRF-based parsing models.[2]

[1] In this work, we follow many previous works to focus on unlabeled dependency parsing (constructing the skeleton dependency structure). However, the proposed techniques explored in this paper can be easily extended to the case of labeled dependency parsing.

[2] We borrow the implementation of SGD in CRFsuite (`http://www.chokkan.org/software/crfsuite/`), and use 100 sentences for a batch.

2.2 Marginal Probability of Dependencies

Marcheggiani and Artières (2014) shows that marginal probabilities of local labels can be used as an effective uncertain metric for AL for sequence labeling problems. In the case of dependency parsing, the marginal probability of a dependency is the sum of probabilities of all legal trees that contain the dependency.

$$p(h \curvearrowright m|\mathbf{x};\mathbf{w}) = \sum_{\mathbf{d}\in\mathcal{Y}(\mathbf{x}):h\curvearrowright m\in\mathbf{d}} p(\mathbf{d}|\mathbf{x};\mathbf{w}) \quad (4)$$

Intuitively, marginal probability is a more principled metric for measuring reliability of a dependency since it considers all legal parses in the search space, compared to previous methods based on scores of local classifiers (Sassano and Kurohashi, 2010; Flannery and Mori, 2015) or votes of n-best parses (Mirroshandel and Nasr, 2011). Moreover, Li et al. (2014) find strong correlation between marginal probability and correctness of a dependency in cross-lingual syntax projection.

3 Active Learning for Dependency Parsing

This work adopts the standard pool-based AL framework (Lewis and Gale, 1994; McCallum and Nigam, 1998). Initially, we have a small set of labeled seed data $\mathcal{L}$, and a large-scale unlabeled data pool $\mathcal{U}$. Then the procedure works as follows.

(1) Train a new parser on the current $\mathcal{L}$.

(2) Parse all sentences in $\mathcal{U}$, and select a set of the most informative tasks $\mathcal{U}'$

(3) Manually annotate: $\mathcal{U}' \rightarrow \mathcal{L}'$

(4) Expand labeled data: $\mathcal{L} \cup \mathcal{L}' \rightarrow \mathcal{L}$

The above steps loop for many iterations until a predefined stopping criterion is met.

The key challenge for AL is how to measure the informativeness of structures in concern. Following previous work on AL for dependency parsing, we make a simplifying assumption that if the current model is most uncertain about an output (sub)structure, the structure is most informative in terms of boosting model performance.

3.1 Sentence-wise FA

Sentence-wise FA selects K most uncertain sentences in Step (2), and annotates their whole tree structures in Step (3). In the following, we describe several uncertainty metrics and investigate their practical effects through experiments. Given an unlabeled sentence $\mathbf{x} = w_1...w_n$, we use $\mathbf{d}^*$ to denote the 1-best parse tree produced by the current model as in Eq. (1). For brevity, we omit the feature weight vector $\mathbf{w}$ in the equations.

Normalized tree score. Following previous works that use scores of local classifiers for uncertainty measurement (Sassano and Kurohashi, 2010; Flannery and Mori, 2015), we use $Score(\mathbf{x}, \mathbf{d}^*)$ to measure the uncertainty of $\mathbf{x}$, assuming that the model is more uncertain about $\mathbf{x}$ if $\mathbf{d}^*$ gets a smaller score. However, we find that directly using $Score(\mathbf{x}, \mathbf{d}^*)$ always selects very short sentences due to the definition in Eq. (1). Thus we normalize the score with the sentence length n as follows.[3]

$$Confi(\mathbf{x}) = \frac{Score(\mathbf{x}, \mathbf{d}^*)}{n^{1.5}} \quad (5)$$

Normalized tree probability. The CRF-based parser allows us, for the first time in AL for dependency parsing, to directly use tree probabilities for uncertainty measurement. Unlike previous approximate methods based on k-best parses (Mirroshandel and Nasr, 2011), tree probabilities globally consider all parse trees in the search space, and thus are intuitively more consistent and proper for measuring the reliability of a tree. Our initial assumption is that the model is more uncertain about $\mathbf{x}$ if $\mathbf{d}^*$ gets a smaller probability. However, we find that directly using $p(\mathbf{d}^*|\mathbf{x})$ would select very long sentences because the solution space grows exponentially with sentence length. We find that the normalization strategy below works well.[4]

$$Confi(\mathbf{x}) = \sqrt[n]{p(\mathbf{d}^*|\mathbf{x})} \quad (6)$$

Averaged marginal probability. As discussed in Section 2.2, the marginal probability of a dependency directly reflects its reliability, and thus can be regarded as another global measurement besides tree probabilities.In fact, we find that the effect of sentence length is naturally handled with the following metric.[5]

$$Confi(\mathbf{x}) = \frac{\sum_{h\curvearrowright m\in\mathbf{d}^*} p(h \curvearrowright m|\mathbf{x})}{n} \quad (7)$$

[3]We have also tried replacing $n^{1.5}$ with n (still prefer short sentences) and n^2 (bias to long sentences).

[4]We have also tried $p(\mathbf{d}^*|\mathbf{x}) \times f(n)$, where $f(n) = \log n$ or $f(n) = \sqrt{n}$, but both work badly.

[5]We have also tried $\sqrt[n]{\prod_{h\curvearrowright m\in\mathbf{d}^*} p(h \curvearrowright m|\mathbf{x})}$, leading to slightly inferior results.

3.2 Single Dependency-wise PA

AL with single dependency-wise PA selects M most uncertain words from $\mathcal{U}$ in Step (2), and annotates the heads of the selected words in Step (3). After annotation, the newly annotated sentences with partial trees $\mathcal{L}'$ are added into $\mathcal{L}$. Different from the case of sentence-wise FA, $\mathcal{L}'$ are also put back to $\mathcal{U}$, so that new tasks can be further chosen from them.

Marcheggiani and Artières (2014) make systematic comparison among a dozen uncertainty metrics for AL with PA for several sequence labeling tasks. We borrow three effective metrics according to their results.

Marginal probability max. Suppose $h^0 = \arg\max_h p(h \curvearrowright i|\mathbf{x})$ is the most likely head for i. The intuition is that the lower $p(h^0 \curvearrowright i)$ is, the more uncertain the model is on deciding the head of the token i.

$$Confi(\mathbf{x}, i) = p(h^0 \curvearrowright i|\mathbf{x}) \quad (8)$$

Marginal probability gap. Suppose $h^1 = \arg\max_{h \neq h^0} p(h \curvearrowright i|\mathbf{x})$ is the second most likely head for i. The intuition is that the smaller the probability gap is, the more uncertain the model is about i.

$$Confi(\mathbf{x}, i) = p(h^0 \curvearrowright i|\mathbf{x}) - p(h^1 \curvearrowright i|\mathbf{x}) \quad (9)$$

Marginal probability entropy. This metric considers the entropy of all possible heads for i. The assumption is that the smaller the *negative* entropy is, the more uncertain the model is about i.

$$Confi(\mathbf{x}, i) = \sum_h p(h \curvearrowright i|\mathbf{x}) \log p(h \curvearrowright i|\mathbf{x}) \quad (10)$$

3.3 Batch Dependency-wise PA

In the framework of single dependency-wise PA, we assume that the selection and annotation of dependencies in the same sentence are strictly independent. In other words, annotators may be asked to annotate the head of one selected word after reading and understanding a whole (sometimes partial) sentence, and may be asked to annotate another selected word in the same sentence in next AL iteration. Obviously, frequently switching sentences incurs great waste of cognitive effort,

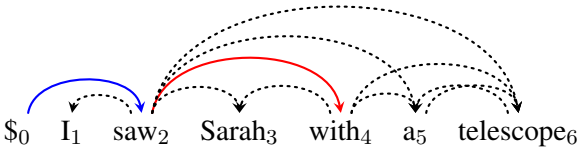

Figure 2: An example parse forest converted from the partial tree in Figure 1.

and annotating one dependency can certainly help decide another dependency in practice.

Inspired by the work of Flannery and Mori (2015), we propose AL with batch dependency-wise PA, which is a compromise between sentence-wise FA and single dependency-wise PA. In Step 2, AL with batch dependency-wise PA selects K most uncertain sentences from $\mathcal{U}$, and also determines $r\%$ most uncertain words from each sentence at the same time. In Step 3, annotators are asked to label the heads of the selected words in the selected sentences. We propose and experiment with the following three strategies based on experimental results of sentence-wise FA and single dependency-wise PA.

Averaged marginal probability & gap. First, select K sentences from $\mathcal{U}$ using averaged marginal probability. Second, select $r\%$ words using marginal probability gap for each selected sentence.

Marginal probability gap. First, for each sentence in $\mathcal{U}$, select $r\%$ most uncertain words according to marginal probability gap. Second, select K sentences from $\mathcal{U}$ using the averaged marginal probability gap of the selected $r\%$ words in a sentence as the uncertainty metric.

Averaged marginal probability. This strategy is the same with the above strategy, except it measures the uncertainty of a word i according to the marginal probability of the dependency pointing to i in $\mathbf{d}^*$, i.e., $p(j \curvearrowright i|\mathbf{x})$, where $j \curvearrowright i \in \mathbf{d}^*$.

3.4 Learning from PA

A major challenge for AL with PA is how to learn from partially labeled sentences, as depicted in Figure 1. Li et al. (2014) show that a probabilistic CRF-based parser can naturally and effectively learn from PA. The basic idea is converting a partial tree into a forest as shown in Figure 2,

and using the forest as the gold-standard reference during training, also known as *ambiguous labeling* (Riezler et al., 2002; Täckström et al., 2013).

For each remaining word without head, we add all dependencies linking to it as long as the new dependency does not violate the existing dependencies. We denote the resulting forest as $\mathcal{F}$j, whose probability is naturally the sum of probabilities of each tree $\mathbf{d}$ in $\mathcal{F}$.

$$\begin{aligned} p(\mathcal{F}|\mathbf{x};\mathbf{w}) &= \sum_{\mathbf{d}\in\mathcal{F}} p(\mathbf{d}|\mathbf{x};\mathbf{w}) \\ &= \frac{\sum_{\mathbf{d}\in\mathcal{F}} e^{Score(\mathbf{x},\mathbf{d};\mathbf{w})}}{\sum_{\mathbf{d}'\in\mathcal{Y}(\mathbf{x})} e^{Score(\mathbf{x},\mathbf{d}';\mathbf{w})}} \end{aligned} \tag{11}$$

Suppose the partially labeled training data is $\mathcal{D} = \{(\mathbf{x}_i, \mathcal{F}_i)\}_{i=1}^{N}$. Then its log likelihood is:

$$\mathcal{L}(\mathcal{D};\mathbf{w}) = \sum_{i=1}^{N} \log p(\mathcal{F}_i|\mathbf{x}_i;\mathbf{w}) \tag{12}$$

Täckström et al. (2013) show that the partial derivative of the $\mathcal{L}(\mathcal{D};\mathbf{w})$ with regard to $\mathbf{w}$ (a.k.a the gradient) in both Equation (3) and (12) can be efficiently solved with the classic Inside-Outside algorithm.[6]

4 Simulation Experiments

We use Chinese Penn Treebank 5.1 (*CTB*) for Chinese and Penn Treebank (*PTB*) for English. For both datasets, we follow the standard data split, and convert original bracketed structures into dependency structures using Penn2Malt with its default head-finding rules. To be more realistic, we use automatic part-of-speech (POS) tags produced by a state-of-the-art CRF-based tagger (94.1% on *CTB*-test, and 97.2% on *PTB*-test, n-fold jackknifing on training data), since POS tags encode much syntactic annotation. Because AL experiments need to train many parsing models, we throw out all training sentences longer than 50 to speed up our experiments. Table 1 shows the data statistics.

Following previous practice on AL with PA (Sassano and Kurohashi, 2010; Flannery and Mori, 2015), we adopt the following AL settings for both Chinese and English . The first 500 training sentences are used as the seed labeled data $\mathcal{L}$. In the case of FA, $K = 500$ new sentences are selected and annotated at each iteration. In the case of single dependency-wise PA, we select and annotate $M = 10,000$ dependencies, which roughly correspond to 500 sentences considering that the averaged sentence length is about 22.3 in *CTB*-train and 23.2 in *PTB*-train. In the case of batch dependency-wise PA, we set $K = 500$, and $r = 20\%$ for Chinese and $r = 10\%$ for English, considering that the parser trained on all data achieves about 80% and 90% accuracies.

		Train	Dev	Test
Chinese	#Sentences	14,304	803	1,910
	#Tokens	318,408	20,454	50,319
English	#Sentences	39,115	1,700	2,416
	#Tokens	908,154	40,117	56,684

Table 1: Data statistics.

We measure parsing performance using the standard unlabeled attachment score (UAS) *including punctuation marks*. Please note that we always treat punctuation marks as ordinary words when selecting annotation tasks and calculating UAS, in order to make fair comparison between FA and PA.[7]

4.1 FA vs. Single Dependency-wise PA

First, we make comparison on the performance of AL with FA and with single dependency-wise PA.

Results on Chinese are shown in Figure 3. Following previous work, we use the number of annotated dependencies (x-axis) as the annotation cost in order to fairly compare FA and PA. We use FA with random selection as a baseline. We also draw the accuracy of the CRF-based parser trained on all training data, which can be regarded as the upper bound.

For FA, the curve of the normalized tree score intertwines with that of random selection. Meanwhile, the performance of normalized tree probability is very close to that of averaged marginal probability, and both are clearly superior to the baseline with random selection.

For PA, the difference among the three uncertainty metrics is small. The marginal probability gap clearly outperforms the other two metrics before 50,000 annotated dependencies, and remains

[6]This work focuses on projective dependency parsing. Please refer to Koo et al. (2007), McDonald and Satta (2007), and Smith and Smith (2007) for building a probabilistic non-projective parser.

[7]Alternatively, we can exclude punctuation marks for task selection in AL with PA. Then, to be fair, we have to discard all dependencies pointing to punctuation marks in the case of FA. This makes the experiment setting more complicated.

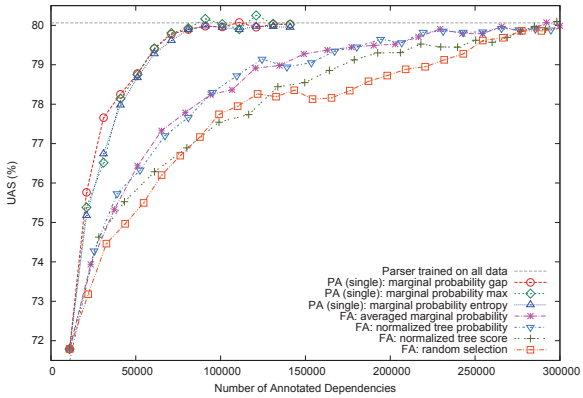

Figure 3: FA vs. PA on *CTB*-dev.

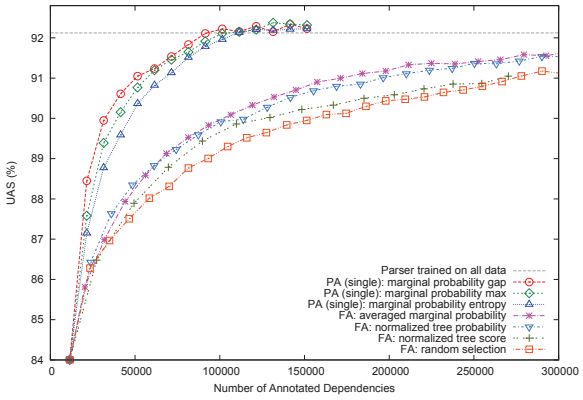

Figure 4: FA vs. PA on *PTB*-dev.

very competitive at all other points. The marginal probability max achieves best peak UAS, and even outperforms the parser trained on all data, which can be explained by small disturbance during complex model training. The marginal probability entropy, although being the most complex metric among the three, seems inferior all the time.

It is clear that using PA can greatly reduce annotation effort compared with using FA in terms of annotated dependencies.

Results on English are shown in Figure 4. The overall findings are similar to those in Figure 3, except that the distinction among different methods is more clear. For FA, normalized tree score is consistently better than the random baseline. Normalized tree probability always outperforms normalized tree score. Averaged marginal probability performs best, except being slightly inferior to normalized tree probability in earlier stages.

For PA, it is consistent that marginal probability gap is better than marginal probability max, and marginal probability entropy is the worst.

In summary, based on the results on the development data in Figure 3 and 4, the best AL method with PA only needs about $\frac{80{,}000}{318{,}408} = 25\%$ annotated dependencies on Chinese, and about $\frac{90{,}000}{908{,}154} = 10\%$ on English, to reach the same performance with parsers trained on all data. Moreover, the PA methods converges much faster than the FA ones, since for the same x-axis number, much more sentences (with partial trees) are used as training data for AL with PA than FA.

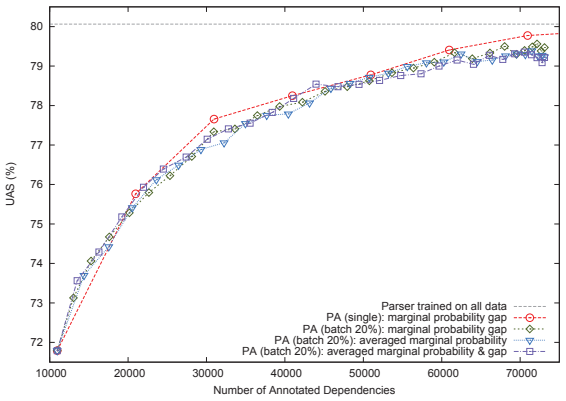

Figure 5: Single vs. batch dependency-wise PA on *CTB*-dev.

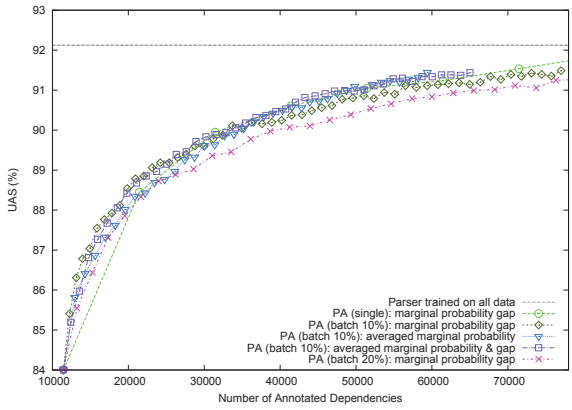

Figure 6: Single vs. batch dependency-wise PA on *PTB*-dev.

4.2 Single vs. Batch Dependency-wise PA

Then we make comparison on AL with single dependency-wise PA and with the more practical batch dependency-wise PA.

Results on Chinese are shown in Figure 5. We can see that the three strategies achieve very similar performance and are also very close to single dependency-wise PA. AL with batch dependency-wise PA even achieves higher accuracy before $20,000$ annotated dependencies, which should be caused by the smaller active learning steps (about

$2,000$ dependencies at each iteration, contrasting $10,000$ for single dependency-wise PA). When the training data runs out at about $7,300$ dependencies, AL with batch dependency-wise PA only lags behind with single dependency-wise PA by about 0.3%, which we suppose can be reduced if larger training data is available.

Results on English are shown in Figure 6, and are very similar to those on Chinese. One tiny difference is that the marginal probability gap is slightly worse that the other two metrics. The three uncertainty metrics have very similar accuracy curves, which are also very close to the curve of single dependency-wise PA. In addition, we also try $r = 20\%$ and find that results are inferior to $r = 10\%$, indicating that the extra 10% annotation tasks are less valuable and contributive.

4.3 Main Results on Test Data

Table 2 shows the results on test data. We compare our CRF-based parser with ZPar v6.0[8], a state-of-the-art transition-based dependency parser (Zhang and Nivre, 2011). We train ZPar with default parameter settings for 50 iterations, and choose the model that performs best on dev data. We can see that when trained on all data, our CRF-based parser outperforms ZPar on both Chinese and English.

To compare FA and PA, we report the number of annotated dependencies needed under each AL strategy to achieve an accuracy lower by about 1% than the parser trained on all data.[9]

FA (best) refers to FA with averaged marginal probability, and it needs $\frac{187,123-149,051}{187,123} = 20.3\%$ less annotated dependencies than FA with random selection on Chinese, and $\frac{395,199-197,907}{395,199} = 50.0\%$ less on English.

PA (single) with marginal probability gap needs $\frac{149,051-50,958}{149,051} = 65.8\%$ less annotated dependencies than FA (best) on Chinese, and $\frac{197,907-61,448}{197,907} = 69.0\%$ less on English.

PA (batch) with marginal probability gap needs slightly more annotation than PA (single) on Chinese but slightly less annotation on English, and can reduce the amount of annotated dependencies by $\frac{149,051-56,389}{149,051} = 62.2\%$ over FA (best) on Chinese and by $\frac{197,907-51,016}{197,907} = 74.2\%$ on English.

	Chinese		English	
	#Dep labeled	UAS	#Dep labeled	UAS
ZPar	318,408	77.97	908,154	91.45
This parser	318,408	78.36	908,154	91.66
FA (random)	187,123	77.43	395,199	90.67
FA (best)	149,051	77.32	197,907	90.66
PA (single)	50,958	77.22	61,448	90.72
PA (batch)	56,389	77.38	51,016	90.70

Table 2: Results on test data.

5 Human Annotation Experiments

So far, we measure annotation effort in terms of the number of annotated dependencies and assume that it takes the same amount of time to annotate different words, which is obviously unrealistic. To understand whether active learning based on PA can really reduce annotation time over based on FA in practice, we build a web browser based annotation system,[10] and conduct human annotation experiments on Chinese.

In this part, we use *CTB* 7.0 which is a newer and larger version and covers more genres, and adopt the newly proposed Stanford dependencies (de Marneffe and Manning, 2008; Chang et al., 2009) which are more understandable for annotators.[11] Since manual syntactic annotation is very difficult and time-consuming, we only keep sentences with length $[10, 20]$ in order to better measure annotation time by focusing on sentences of reasonable length, which leave us $12,912$ training sentences under the official data split. Then, we use a random half of training sentences to train a CRF-based parser, and select 20% most uncertain words with marginal probability gap for each sentence of the left half.

We employ 6 postgraduate students as our annotators who are at different levels of familiarity in syntactic annotation. Before annotation, the annotators are trained for about two hours by introducing the basic concepts, guidelines, and illustrating examples. Then, they are asked to practice on the annotation system for about another two hours. Finally, all annotators are required to

[8] http://people.sutd.edu.sg/~yue_zhang/doc/

[9] The gap 1% is chosen based on the curves on development data (Figure 3 and 4) with the following two considerations: 1) larger gap may lead to wrong impression that AL is weak; 2) smaller gap (e.g., 0.5%) cannot be reached for the worst AL method (FA: random).

[10] http://hlt-service.suda.edu.cn/syn-dep-batch. Please try.

[11] We use Stanford Parser 3.4 (2014-06-16) for constituent-to-dependency structure conversion.

	Time: Sec/Dep		Annotation accuracy	
	FA	PA	FA (on 20%)	PA (diff)
Annotator #1	**4.0**	**7.9**	**84.65** (**73.41**)	**75.28** (+1.87)
Annotator #2	7.5	16.0	78.90 (72.22)	62.18 (*-10.04*)
Annotator #3	*10.0*	*22.2*	69.75 (59.77)	56.91 (-2.86)
Annotator #4	5.1	8.7	66.75 (49.19)	61.77 (+**12.58**)
Annotator #5	7.0	17.3	65.47 (48.50)	48.39 (-0.11)
Annotator #6	7.0	10.6	*58.05* (*43.28*)	*48.37* (+5.09)
Overall	6.7	13.6	70.36 (57.28)	59.06 (+1.78)

Table 3: Statistics of human annotation.

formally annotate the same 100 sentences. The system is programed that each sentence has 3 FA submissions and 3 PA submissions. During formal annotation, the annotators are not allowed to discuss with each other or look up any guideline or documents, which may incur unnecessary inaccuracy in timing. Instead, the annotators can only decide the syntactic structures based on the basic knowledge of dependency grammar and one's understanding of the sentence structure. The annotation process lasts for about 5 hours. On average, each annotator completes 50 sentences with FA (763 dependencies) and 50 sentences with PA (178 dependencies).

Table 3 lists the results in descending order of an annotator's experience in syntactic annotation. The first two columns compare the time needed for annotating a dependency in seconds. On average, *annotating a dependency in PA takes about twice as much time as in FA*, which is reasonable considering the words to be annotated in PA may be more difficult for annotators while the annotation of some tasks in FA may be very trivial and easy. Combined with the results in Table 2, we may infer that to achieve 77.3% accuracy on *CTB*-test, AL with FA requires $149,051 \times 6.7 = 998,641.7$ seconds of annotation, whereas AL with batch dependency-wise PA needs $56,389 \times 13.6 = 766,890.4$ seconds. Thus, we may roughly say that *AL with PA can reduce annotation time over FA by* $\frac{998,641.7-766,890.4}{998,641.7} = 23.2\%$.

We also report annotation accuracy according to the gold-standard Stanford dependencies converted from bracketed structures.[12] Overall, the accuracy of FA is $70.36 - 59.06 = 11.30\%$ higher than that of PA, which should be due to the trivial tasks in FA. To be more fair, we compare the accuracies of FA and PA on the same 20% selected difficult words, and find that annotators exhibit different responses to the switch. Annotator #4 achieve 12.58% higher accuracy when under PA than under FA. The reason may be that under PA, annotators can be more focused and therefore perform better on the few selected tasks. In contrast, some annotators may perform better under FA. For example, annotation accuracy of annotator #2 increases by 10.04% when switching from PA to FA, which may be due to that FA allows annotators to spend more time on the same sentence and gain help from annotating easier tasks. Overall, we find that the accuracy of PA is $59.06 - 57.28 = 1.78\%$ higher than that of FA, indicating that *PA actually can improve annotation quality*.

[12] An anonymous reviewer commented that the direct comparison between an annotator's performance on PA and FA based on accuracy may be misleading since the FA and PA sentences for one annotator are mutually exclusive.

6 Related Work

Recently, AL with PA attracts much attention in sentence-wise natural language processing such as sequence labeling and parsing. For sequence labeling, Marcheggiani and Artières (2014) systematically compare a dozen uncertainty metrics in token-wise AL with PA (without comparison with FA), whereas Settles and Craven (2008) investigate different uncertainty metrics in AL with FA. Li et al. (2012) propose to only annotate the most uncertain word boundaries in a sentence for Chinese word segmentation and show promising results on both simulation and human annotation experiments. All above works are based on CRFs and make extensive use of sequence probabilities and token marginal probability.

In parsing community, Sassano and Kurohashi (2010) select bunsetsu (similar to phrases) pairs with smallest scores from a local classifier, and let annotators decide whether the pair composes a dependency. They convert partially annotated instances into local dependency/non-dependency classification instances to help a simple shift-reduce parser. Mirroshandel and Nasr (2011) select most uncertain words based on votes of n-best parsers, and convert partial trees into full trees by letting a baseline parser perform constrained decoding in order to preserve partial annotation. Under a different query-by-committee AL framework, Majidi and Crane (2013) select most uncertain words using a committee of diverse parsers, and convert partial trees into full trees by letting

the parsers of committee to decide the heads of remaining tokens. Based on a first-order (pointwise) Japanese parser, Flannery and Mori (2015) use scores of a local classifier for task selection, and treat PA as dependency/non-dependency instances (Flannery et al., 2011). Different from above works, this work adopts a state-of-the-art probabilistic dependency parser, uses more principled tree probabilities and dependency marginal probabilities for uncertainty measurement, and learns from PA based on a forest-based training objective which is more theoretically sound.

Most previous works on AL with PA only conduct simulation experiments. Flannery and Mori (2015) perform human annotation to measure true annotation time. A single annotator is employed to annotate for two hours alternating FA and PA (33% batch) every fifteen minutes. Beyond their initial expectation, they find that the annotation time per dependency is nearly the same for FA and PA (different from our findings) and gives a few interesting explanations.

Under a non-AL framework, Mejer and Crammer (2012) propose an interesting light feedback scheme for dependency parsing by letting annotators decide the better one from top-2 parse trees produced by the current parsing model.

Hwa (1999) pioneers the idea of using PA to reduce manual labeling effort for constituent grammar induction. She uses a variant Inside-Outside re-estimation algorithm (Pereira and Schabes, 1992) to induce a grammar from PA. Clark and Curran (2006) propose to train a Combinatorial Categorial Grammar parser using partially labeled data only containing predicate-argument dependencies. Tsuboi et al. (2008) extend CRF-based sequence labeling models to learn from incomplete annotations, which is the same with Marcheggiani and Artières (2014). Li et al. (2014) propose a CRF-based dependency parser that can learn from partial tree projected from source-language structures in the cross-lingual parsing scenario. Mielens et al. (2015) propose to impute missing dependencies based on Gibbs sampling in order to enable traditional parsers to learn from partial trees.

7 Conclusions

This paper for the first time applies a state-of-the-art probabilistic model to AL with PA for dependency parsing. It is shown that the CRF-based parser can on the one hand provide tree probabilities and dependency marginal probabilities as principled uncertainty metrics and on the other hand elegantly learn from partially annotated data. We have proposed and compared several uncertainty metrics through simulation experiments, and show that AL with PA can greatly reduce the amount of annotated dependencies by 62.2% on Chinese 74.2% on English. Finally, we conduct human annotation experiments on Chinese to compare PA and FA on real annotation time and quality. We find that annotating a dependency in PA takes about 2 times long as in FA. This suggests that AL with PA can reduce annotation time by 23.2% over with FA on Chinese. Moreover, the results also indicate that annotators tend to perform better under PA than FA.

For future work, we would like to advance this study in the following directions. The first idea is to combine uncertainty and representativeness for measuring informativeness of annotation targets in concern. Intuitively, it would be more profitable to annotate instances that are both difficult for the current model and representative in capturing common language phenomena. Second, we so far assume that the selected tasks are equally difficult and take the same amount of effort for human annotators. However, it is more reasonable that human are good at resolving some ambiguities but bad at others. Our plan is to study which syntactic structures are more suitable for human annotation, and balance informativeness of a candidate task and its suitability for human annotation. Finally, one anonymous reviewer comments that we may use automatically projected trees (Rasooli and Collins, 2015; Guo et al., 2015; Ma and Xia, 2014) as the initial seed labeled data, which is cheap and interesting.

Acknowledgments

The authors would like to thank the anonymous reviewers for the helpful comments. We also thank Junhui Li and Chunyu Kit for reading our paper and giving many good suggestions. Particularly, Zhenghua is very grateful to many of his students: Fangli Lu, Qiuyi Yan, and Yue Zhang build the annotation system; Jiayuan Chao, Wei Chen, Ziwei Fan, Die Hu, Qingrong Xia, and Yue Zhang participate in data annotation. Abstract

We present a novel dependency parsing method which enforces two structural properties on dependency trees: bounded block degree and well-nestedness. These properties are useful to better represent the set of admissible dependency structures in treebanks and connect dependency parsing to context-sensitive grammatical formalisms. We cast this problem as an Integer Linear Program that we solve with Lagrangian Relaxation from which we derive a heuristic and an exact method based on a Branch-and-Bound search. Experimentally, we see that these methods are efficient and competitive compared to a baseline unconstrained parser, while enforcing structural properties in all cases.

1 Introduction

We address the problem of enforcing two structural properties on dependency trees, namely bounded block degree and well-nestedness, without sacrificing algorithmic efficiency. Intuitively, bounded block degree constraints force each subtree to have a yield decomposable into a limited number of blocks of contiguous words, while well-nestedness asserts that every two distinct subtrees must not interleave: either the yield of one subtree is entirely inside some gap of the other or they are completely separated. These two types of constraints generalize the notion of projectivity: projective trees actually have a block degree bounded to one and are well-nested.

Our first motivation is the fact that most dependency trees in NLP treebanks are well-nested and have a low block degree which depends on the language and the linguistic representation, as shown in (Pitler et al., 2012). Unfortunately, although polynomial algorithms exist for this class of trees (Gómez-Rodríguez et al., 2009), they are not efficient enough to be of practical use in applications requiring syntactic structures. In addition, if either property is dropped, but not the other, then the underlying decision problem becomes harder. That is why practical parsing algorithms are either completely unconstrained (McDonald et al., 2005) or enforce strict projectivity (Koo and Collins, 2010). This work is, to the best of our knowledge, the first attempt to build a discriminative dependency parser that enforces well-nestedness and/or bounded block degree and to use it on treebank data.

We base our method on the following observation: a non-projective dependency parser, thus not requiring neither well-nestedness nor bounded block degree, returns dependency trees satisfying these constraints in the vast majority of sentences. This would tend to indicate that the heavy machinery involved to parse with these constraints is only needed in very few cases.

We consider arc-factored dependency parsing with well-nestedness and bounded block degree constraints. We formulate this problem as an Integer Linear Program (ILP) and apply Lagrangian Relaxation where the dualized constraints are those associated with bounded block degree and well-nestedness. The Lagrangian dual objective then reduces to a maximum spanning arborescence and can be solved very efficiently. This provides an efficient heuristic for our problem. An exact method can be derived by embedding this Lagrangian Relaxation in a Branch-and-Bound procedure to solve the problem with an optimality certificate. Despite the exponential worst-time complexity of the Branch-and-Bound procedure, it is tractable in practice. Our formulation can enforce both types of constraints or only one of them without changing the resolution method.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 355–366,
Berlin, Germany, August 7-12, 2016.

As stated in (Bodirsky et al., 2009), well-nested dependency trees with 2-bounded block degree are structurally equivalent to derivations in Lexicalized Tree Adjoining Grammars (LTAGs) (Joshi and Schabes, 1997).[1][2] While LTAGs can be parsed in polynomial time, developing an efficient parser for these grammars remains an open problem (Eisner and Satta, 2000) and we believe that this work could be a useful step in that direction.

Related work is reviewed in Section 2. We define arc-factored dependency parsing with block degree and well-nestedness constraints in Section 3. We derive an ILP formulation of this problem in Section 4 and then present our method based on Lagrangian Relaxation in Section 5 and Branch-and-Bound in Section 6. Section 7 contains experimental results on several languages.

2 Related Work

A dynamic programming algorithm has been proposed for parsing well-nested and k-bounded block degree dependency trees in (Gómez-Rodríguez et al., 2009; Gómez-Rodríguez et al., 2011). Unfortunately, it has a prohibitive $O(n^{3+2k})$ time complexity, equivalent to Lexicalized TAG parsing when $k = 2$. Variants of this algorithm have also been proposed for further restricted classes of dependency trees: 1-inherit ($O(n^6)$) (Pitler et al., 2012), head-split ($O(n^6)$) (Satta and Kuhlmann, 2014) and both 1-inherit and head-split ($O(n^5)$) (Satta and Kuhlmann, 2014). Although those restricted classes have good empirical coverage, they do not cover the exact search space of Lexicalized TAG derivation and their time complexity is still prohibitive. Spinal TAGs, described as a dependency parsing task in (Carreras et al., 2008), weaken even more the empirical coverage in practice, restricted to projective trees, but still remain hardly tractable with a complexity of $O(n^4)$. On the contrary, the present work does not restrict the search space.

Parsing mildly context-sensitive languages with dependencies has been explored in (Fernández-González and Martins, 2015) but the resulting parser cannot guarantee compliance with strict structural properties. On the other hand, the present method enforces the well-nestedness and bounded block degree of solutions.

The methods mentioned above all use the graph-based approach and rely on dynamic programming to achieve tractability. There is also a line of of work in transition-based parsing for various dependency classes. Systems have been proposed for projective dependency trees (Nivre, 2003), non-projective, or even unknown classes (Attardi, 2006). Pitler and McDonald (2015) propose a transition system for crossing interval trees, a more general class than well-nested trees with bounded block degree. In the case of spinal TAGs, we can mention the work of Ballesteros and Carreras (2015) and Shen and Joshi (2007). Transition-based algorithms offer low space and time complexity, typically linear in the length of sentences usually by relying on local predictors and beam strategies and thus do not provide any optimality guarantee on the produced structures. The present work follows the graph-based approach, but replaces dynamic programming with a greedy algorithm and Lagrangian Relaxation.

The use of Lagrangian Relaxation to elaborate sophisticated parsing models based on plain maximum spanning arborescence solutions originated in (Koo et al., 2010) where this method was used to parse with higher-order features. This technique has been explored to parse CCG dependencies in (Du et al., 2015) without a precise definition of the class of trees. We can also draw connections between our problem reduction procedure and the use of Lagrangian Relaxation to speed up dynamic programming and beam search with exact pruning in (Rush et al., 2013).

In this work we rely on Non-Delayed Relax-and-Cut for lazy constraint generation (Lucena, 2006). This can be linked to (Riedel, 2009) which uses a cutting plane algorithm to solve MAP inference in Markov Logic and (Riedel et al., 2012) which uses column and row generation for higher-order dependency parsing.

In NLP, the Branch-and-Bound framework (Land and Doig, 1960) has previously been used for dependency parsing with high order features in (Qian and Liu, 2013), and Das et al. (2012) combined Branch-and-Bound to Lagrangian Relaxation in order to retrieve integral solutions for shallow semantic parsing.

[1] It is possible to express a wider class of dependencies with LTAG if we allow dependencies direction to be different from the derivation tree (Kallmeyer and Kuhlmann, 2012).

[2] In order to be fully compatible with LTAGs, we must ensure that the root has only one child. For algorithmic issues see (Fischetti and Toth, 1992) or (Gabow and Tarjan, 1984).

3 Dependency Parsing

We model the dependency parsing problem using a graph-based approach. Given a sentence $s = \langle s_0, \dots, s_n \rangle$ where s_0 is a dummy root symbol, we consider the directed graph $D = (V, A)$ with $V = \{0, \dots n\}$ and $A \subseteq V \times V$. Vertex $i \in V$ corresponds to word s_i and arc $(i, j) \in A$ models a dependency from word s_i to word s_j. In the rest of the paper, we denote $V \setminus \{0\}$ by V^+.

An *arborescence* is a set of arcs T inducing a connected graph with no circuit such that every vertex has at most one entering arc. The set of vertices incident with any arc of T is denoted by $V[T]$. If $V[T] = V$, then T is a *spanning arborescence*. Among the vertices of $V[T]$, the one with no entering arc is called the *root* of T. A vertex t is *reachable* from a vertex s with respect to T if there exists a path from s to t using only arcs of T. The *yield* of a vertex $v \in V$ corresponds to the set of vertices reachable from v with respect to T.

It is well-known that there is a bijection between dependency trees for s and spanning arborescences with root 0 (McDonald et al., 2005). In what follows, the term dependency tree will refer to both the dependency tree of s and its associated spanning arborescence of D with root 0.

In the dependency parsing problem, one has to find a dependency tree with maximal score. Several scores can be associated with each dependency tree and different conditions can restrict the set of valid dependency trees.

In this paper, we consider an *arc-factored* model: each arc $(i, j) \in A$ is assigned a score w_{ij}; the score of a dependency tree is defined as the sum of the scores of the arcs it contains. This model can be computed in $O(n^2)$ with Chu–Liu-Edmonds' algorithm for Maximum Spanning Arborescence (MSA) (McDonald et al., 2005). Unfortunately, this algorithm forbids any modification of the score function, for example adding score contribution for combinations of arcs (i.e. grand-parent or sibling models). Moreover, adding score contribution for combinations of couple of arcs makes the problem NP-hard (McDonald and Pereira, 2006), although several methods have been developed to tackle this problem, for instance dual decomposition (Koo et al., 2010).

Likewise, restrictions on the tree structure such as the well-nestedness and bounded block degree conditions are not permitted in the MSA algorithm. We first give a precise definition of these structural properties, equivalent to (Bodirsky et al., 2009), before we present a method to take them into account. From now on, we suppose that instances are equipped with a positive integer k and we call *valid dependency trees* those satisfying the k-bounded block degree and well-nestedness conditions. A graph-theoretic definition of these two conditions can be given as follows.

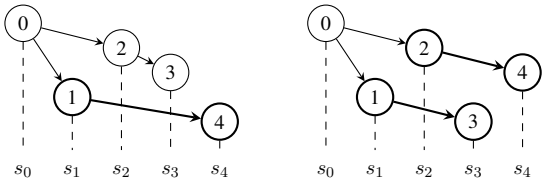

Figure 1: (Left) A 2-BBD arborescence: the block degree of vertex 1 is 2 (its yield is $\{1, 4\}$) whereas the block degree of all other vertices is 1. (Right) A not well-nested arborescence: the yields of vertices 1 and 2 interleave.

Block degree The *block degree* of a vertex set $W \subseteq V$ is the number of vertices of W without a predecessor[3] inside W. Given an arborescence T, the *block degree* of a vertex is the block degree of its yield and the *block degree* of T is the maximum block degree of its incident vertices. An arborescence satisfies the k-bounded block degree condition if its block degree is less than or equal to k. We then say it is *k-BBD* for short. Figure 1 (left) gives an example of a 2-BBD arborescence.

Well-nestedness Two disjoint subsets $I_1, I_2 \subset V^+$ *interleave* if there exist $i, j \in I_1$ and $k, l \in I_2$ such that $i < k < j < l$. An arborescence is *well-nested* if it is not incident to two vertices whose yields interleave. Figure 1 (right) shows an arborescence which is not well-nested.

4 ILP Formulation

In this section we formulate the dependency parsing problem described in Section 3 as an ILP. We start with some notation and two theorems characterizing k-BBD and well-nested dependency trees.

Given a subset $W \subseteq V$, the set of arcs entering W is denoted by $\delta^{\text{in}}(W)$ and the set of arcs leaving W is denoted by $\delta^{\text{out}}(W)$. The set $\delta(W) = \delta^{\text{in}}(W) \cup \delta^{\text{out}}(W)$ is called the *cut* of W. Given a positive integer l, let $\mathcal{W}^{\geq l}$ be the family of vertex subsets of V^+ with block degree greater than or equal to l. For instance, given any sentence with more than 6 words, $\{1, 3, 5, 6\} \in \mathcal{W}^{\geq 3}$,

[3]The predecessor of a vertex $v \in V$ is $v - 1$.

while $\{1,2,5,6\} \notin \mathcal{W}^{\geq 3}$. We also denote by $\mathcal{I}$ the family of couples of disjoint interleaving vertex subsets of V^+. For instance, $(\{1,4\},\{2,3,5\})$ belongs to $\mathcal{I}$. Finally, given a vector $x \in \mathbb{R}^A$ and a subset $B \subseteq A$, $x(B)$ corresponds to $\sum_{a\in B} x_a$.

Theorem 1. *A dependency tree T is not k-BBD iff there exists a vertex subset $W \in \mathcal{W}^{\geq k+1}$ whose cut $\delta(W)$ contains a unique arc of T.*

Proof. By definition of block degree, a dependency tree is not k-BBD iff it is incident with a vertex whose yield W belongs to $\mathcal{W}^{\geq k+1}$. It is equivalent to say that T contains a subarborescence T' such that $V[T']$ equals W. This holds iff W has one entering arc (since $0 \notin W$) and no leaving arc belonging to T. □

Theorem 2. *A dependency tree T is not well-nested iff there exists $(I_1, I_2) \in \mathcal{I}$ such that $\delta(I_1) \cap T$ and $\delta(I_2) \cap T$ are singletons.*

Proof. $\delta(I_1)$ and $\delta(I_2)$ both intersect T only once iff T contains two arborescences T_1 and T_2 such that $V[T_1] = I_1$ and $V[T_2] = I_2$. This means that T is incident with two vertices whose yields are I_1 and I_2, respectively. Result follows from the definition of $\mathcal{I}$ and well-nested arborescences. □

The dependency parsing problem can be formulated as follows. A dependency tree will be represented by its incidence vector. Hence, we use variables $z \in \mathbb{R}^A$ such that $z_a = 1$ if arc a belongs to the dependency tree and 0 otherwise.

$$\max_z \sum_{a\in A} w_a z_a \tag{1}$$

$$z(\delta^{\text{in}}(v)) = 1 \qquad \forall v \in V^+ \tag{2}$$

$$z(\delta^{\text{in}}(W)) \geq 1 \qquad \forall W \subseteq V^+ \tag{3}$$

$$z(\delta(W)) \geq 2 \qquad \forall\, W \in \mathcal{W}^{\geq k+1} \tag{4}$$

$$z(\delta(I_1)) + z(\delta(I_2)) \geq 3 \quad \forall (I_1, I_2) \in \mathcal{I} \tag{5}$$

$$z \in \{0,1\}^A \tag{6}$$

The objective function (1) maximizes the score of the dependency tree. Inequalities (2) ensure that all vertices but the root have one entering arc. Inequalities (3) force the set of arcs associated with z to induce a connected graph. Inequalities (2) and (3), together with $z \geq 0$, give a linear description of the convex hull of the incidence vectors of the spanning arborescences with root 0 — see *e.g.,* (Schrijver, 2003). Inequalities (4) ensure that the dependency tree is k-BBD and inequalities (5) impose well-nestedness. The validity of (4) and (5) follows from Theorems 1 and 2, respectively.

Remark that (3) could be replaced by a polynomial number of additional flow variables and constraints, see (Martins et al., 2009).[4]

5 Lagrangian Relaxation

Solving this ILP using an off-the-shelf solver is ineffective due to the huge number of constraints. We tackle this problem with Lagrangian Relaxation, which has become popular in the NLP community, see for instance (Rush and Collins, 2012). Note that contrary to most previous work on Lagrangian Relaxation for NLP, we do not use it to derive a decomposition method.

We note that optimizing objective (1) subject to constraints (2), (3) and (6) amounts to finding a MSA and can be solved combinatorially (McDonald et al., 2005). Thus, since formulation (1)–(6) is based only on arc variables, by relaxing constraints (4) and (5), one obtains a Lagrangian dual objective which is nothing but a MSA problem with reparameterized arc scores. Our Lagrangian approach relies on a subgradient descent where a MSA problem is solved at each iteration. We give more details in the rest of the section.

5.1 Dual Problem

Let Z be the set of the incidence vectors of dependency trees. Keeping tree shape constraints (2), (3) and (6) while dualizing k-bounded block degree constraints (4) and well-nestedness constraints (5), we build the following Lagrangian (Lemaréchal, 2001):

$$\begin{aligned} L(z,u) = &\sum_{a\in A} w_a z_a \\ &+ \sum_{W\in\mathcal{W}^{\geq k}} u_1^W \times (z(\delta(W)) - 2) \\ &+ \sum_{(I_1,I_2)\in\mathcal{I}} u_2^{I_1,I_2} \times (z(\delta(I_1)) + z(\delta(I_2)) - 3) \end{aligned} \tag{7}$$

[4] Based on this remark, we also developed a formulation of this problem with a polynomial number of variables and constraints. However it requires adding many more variables than (Martins et al., 2009). This leads to a formulation which is not tractable, see Section 7.2. Moreover, it cannot be tackled by our Lagrangian Relaxation approach.

with $z \in Z$ and $u = (u_1, u_2) \geq 0$ is a vector of Lagrangian multipliers. We refactor to:

$$L(z, u) = \sum_{a \in A} \theta_a z_a + c \tag{8}$$

where θ are modified scores and c a constant term.

The dual objective is $L^*(u) = \max_z L(z, u)$ with $z \in Z$. Note that computing $L^*(u)$ amounts to solving the MSA problem with modified scores θ and can be efficiently computed. The dual problem is $\min_{u \geq 0} L^*(u)$. L^* is a non-differentiable convex piece-wise linear function and one can find its minimum via subgradient descent. For any vector u, we use the following subgradient. Denote $Mz \leq b$ the set of constraints given by (4) and (5) and $z^* = \arg\max_z L(z, u)$. Let $g = b - Mz^*$ be a subgradient at u, see (Lemaréchal, 2001) for more details. From this subgradient, we compute the descent direction following (Camerini et al., 1975), which aggregates information during the iteration of the subgradient descent algorithm. Unfortunately, optimizing the dual is expensive with so many relaxed constraints. We handle this problem in the next subsection.

5.2 Efficient Optimization with Many Constraints

The *Non Delayed Relax-and-Cut* (NDRC) method (Lucena, 2005) tackles the problem of optimizing a Lagrangian dual problem with exponentially many relaxed constraints. In standard subgradient descent, at each iteration p of the descent, the Lagrangian update can be formulated as:

$$u^{p+1} = (u^p - s^p \times g^p)_+ \tag{9}$$

where $s^p > 0$ is the stepsize[5] and $()_+$ denotes the projection onto $\mathbb{R}^+$, which replaces each negative component by 0. If all Lagrangian multipliers are initialized to 0, the compononent corresponding to a constraint will not be changed until this constraint is violated for the first time. Indeed, by definition of g, we have $[g^p]_i \geq 0$ if constraint i is satisfied at iteration p: the projection on $\mathbb{R}^+$ ensure that $[u^{p+1}]_i$ stays at 0.[6] Thus we do not need to know constraints that have not been violated yet in order to correctly update the Lagrangian multipliers: this is the main intuition behind the NDRC method. However, s^p may depend on the full subgradient information. A common step size (Fisher, 1981) is:

$$s^p = \alpha^p \times \frac{L^*(u^p) - LB^p}{\|g^p\|^2} \tag{10}$$

with α^p a scalar and LB^p the best known lower bound. This is also the case with more recent approaches like AdaGrad (Duchi et al., 2011) and AdaDelta (Zeiler, 2012). As reported in (Beasley, 1993; Lucena, 2006), when dealing with many relaxed constraints, the $\|g^p\|^2$ term can result in each Lagrangian update being almost equal to 0. Therefore, a good practice is to modify the subgradient such that if $[g^p]_i > 0$ and $[u^p]_i = 0$, then we set $[g^p]_i = 0$: this has the same effect on the multipliers as the projection on $\mathbb{R}^+$ in (9), but it prevents the stepsize from becoming too small. Hence, instead of generating a full subgradient at each iteration, which is an expensive operation because we would need to consider all multipliers associated with constraints, we process only a subpart, namely the one associated with constraints that have been violated.

Following (Lucena, 2005), at each iteration p of the subgradient descent we define two sets: *Currently Violated Active Constraints* (CA^p) and *Previously Violated Active Constraints* (PA^p). CA^p and PA^p are not necessarily disjoint. The subgradient is computed only for constraints in $CA^p \cup PA^p$. At each iteration p, we update $PA^p = PA^{p-1} \cup CA^{p-1}$ and a *violation detection step*, similar to the separation step in a cutting plane algorithm, generates CA^p. Two strategies are possible for the detection: (1) adding to CA^p all the constraints violated by the current dual solution; (2) adding only a subset of them. The latter is justified by the fact that many constraints may overlap thus leading to exageration of modified scores on some arcs. We found that strategy (2) gives better convergence results.

Detection for violated block degree constraints (4) can be done with the algorithm described in (Möhl, 2006) in $O(n^2)$. If no violated block degree constraint is found, we search for violated well-nestedness constraints (5) using the $O(n^2)$ algorithm described in (Havelka, 2007).

5.3 Lagrangian Heuristic

We derive a heuristic from the Lagragian Relaxation. First, a dependency tree is computed with

[5] As stated above, instead of the subgradient we follow an improved descent direction which aggregates information of previous iterations. However, this does not change the proposal of this subsection.

[6] $[x]_i$ denotes the ith component of vector x.

the MSA algorithm. If it is valid, it then corresponds to the optimal solution. Otherwise, we proceed as follows. The computation of the step size in (10) in the subgradient descent needs a lower bound which can be given by the score of any valid dependency tree. In our experiments, we compute the best projective spanning arborescence (Eisner, 2000). Each iteration of the subgradient descent computes a spanning arborescence. Since violating (4) and (5) is penalized in the objective function, it tends to produce valid dependency trees. The heuristic returns the highest scoring one.

6 Branch and Bound

Solving the Lagrangian dual problem may not always give an optimal solution to the original problem because of the potential duality gap. Still, we always obtain an upper bound on the optimal solution and if a dual solution satisfies constraints (4) and (5), its score with the original weights provides a lower bound.[7]

Moreover, the subgradient descent algorithm theoretically converges but we have no guarantee that this will happen in a realistic number of iterations. Therefore, in order to retrieve an optimal solution in all cases, we embed the Lagrangian Relaxation of the problem within a Branch-and-Bound procedure (Land and Doig, 1960).

The search space is recursively split according to an arc variable, creating two subspaces, one where it is fixed to 1 and the other to 0 (branching step). The procedure returns a candidate solution when all arc variables are fixed and constraints are satisfied, and the optimal solution is the highest-scoring candidate solution.

For each subspace, we estimate an upper bound using the Lagrangian Relaxation (bounding step). The recursive exploration of a subspace stops (pruning step) if (1) we can prove that all candidate solutions it contains have a score lower than the best found so far, or (2) we detect an unsastifiable constraint.

The branching strategy is built upon Lagrangian multipliers: we branch on the variable z_a with highest value $\theta_a - w_a$. Intuitively, if the branching step sets $z_a = 1$, it indicates that we add a *hard* constraint on an arc which has been strongly promoted by Lagrangian Relaxation. This strategy, compared to other variants, gave the best parsing time on development data.

6.1 Problem Reduction

The efficiency of the Branch-and-Bound procedure crucially depends on the number of free variables. To prune the search space, we rely on problem reduction (Beasley, 1993), once again based on duality and Lagrangian Relaxation, which provides certificates on optimal variable settings.

We fix a variable to 1 (resp. 0), and compute an upper bound on the optimal score with this new constraint. If it is lower than the score of the best solution found so far without this constraint, we can guarantee that this variable cannot (resp. must) be in the optimal solution and safely set it to 0 (resp. 1).

Problem reduction is performed at each node of the Branch-and-Bound tree after computing the upper bound with subgradient descent.

6.2 Fixing Variables to 1

Since a node in V^+ must have exactly one parent, fixing $z_{ij} = 1$ for an arc $a = (i, j)$ greatly reduces the problem size, as it will also fix $z_{hj} = 0, \forall h \neq i$. Among all arc variables that can be set to 1, promising candidates are the arcs in a solution of the unconstrained MSA and the arcs obtained in a solution after the subgradient descent.

There are exactly n such arcs in each set of candidates, so we test fixation for less than $2n$ variables. In this case, we are ready to pay the price of a quadratic computation for each of these arcs.

Hence, for each candidate arc we obtain an upper bound by seeking the (unconstrained) MSA on the graph where this arc is removed. If this upper bound is lower than the score of the best solution found so far, we can safely say that this arc is in the optimal solution.

6.3 Fixing Variables to 0

We could apply the same strategy for fixing variables to 0. However, this reduction is less rewarding and there are many more variables set to 0 than 1 in a MSA solution. Instead, we solve an easier problem, at the expense of a looser upper bound.

For each arc a which is not in the MSA, we compute a maximum directed graph that contains this arc and where all nodes but the root have one parent. Remark that if this graph is connected then it corresponds to a dependency tree. Therefore, the score of this directed graph provides an upper bound on a solution containing arc a. If this upper

[7] Because relaxed constraints are inequalities, constraint satisfaction does not guarantee optimality (Beasley, 1993).

bound is lower than the score of the best solution found so far, we can fix the variable z_a to 0.

Note that this whole fixing procedure can be done in $O(n^2)$.

7 Experiments

We ran a series of experiments to test our method in the case of unlabelled dependency parsing. Our prototype has been developped in Python with some parts in Cython and C++. We use the MSA implementation available in the LEMON library.[8]

7.1 Datasets

We ran experiments on 5 different corpora:

English: Dependencies were extracted from the WSJ part of the Penn Treebank (PTB) with additional NP bracketings (Vadas and Curran, 2007) with the *LTH* converter[9] (default options). Sections 02-21 are used for training, 22 for development and 23 for testing. POS tags were predicted by the Stanford tagger[10] trained with 10-jackkniffing.[11]

German: We used dependencies from the SPMRL dataset (Seddah et al., 2014), with predicted POS tags and the official split. We removed sentences of length greater than 100 in the test set.

Dutch, Spanish and Portuguese: We used the Universal Dependency Treebank 1.2 (Van der Beek et al., 2002; McDonald et al., 2013; Afonso et al., 2002) with gold POS tags and the official split. We removed sentences of length greater than 100 in the test sets.

Those datasets contain different structure distributions as shown in Table 1. Fortunately, our method allows us to easily change the bounded degree constraint or toggle the well-nestedness one. For each language, we decided to use the most constrained combination of bounded block degree constraints and well-nestedness which covers over 99% of the data. Therefore, we chose to enforce 2-BBD and well-nestedness for English and Spanish, 3-BBD and well-nestedness for Dutch and Portuguese and 3-BBD only for German.

7.2 Decoding

In order to compare our methods with previous approaches, we tested five decoding strategies. (`MSA`) computes the best unconstrained dependency tree. (`Eisner`) computes the best projective tree. (`LR`) and (`B&B`) are the heuristic and the exact method presented in Sections 5.3 and 6 respectively.[12] Finally (`MSA/Eisner`) consists in running the MSA algorithm and, if the solution is invalid, returning the (`Eisner`) solution instead.

Our attempt to run the dynamic programming algorithm of (Gómez-Rodríguez et al., 2009) was unsuccessful. Even with heavy pruning we were not able to run it on sentences above 20 words. We also tried to use CPLEX on a compact ILP formulation based on multi-commodity flows (see footnote 4). Parsing time was also prohibitive: a total of 3473 seconds on English data without the well-nestedness constraint, 7298 for German.

We discuss the efficiency of our methods on data for English and German. Other languages give similar results. Optimality rate after the subgradient descent are reported in Figure 2. We see that Lagrangian Relaxation often returns optimal solutions but fails to give a certificate of their optimality. Table 2 shows parsing times. We see that (`LR`) and (`B&B`), while slower than (`MSA`), are fast in the majority of cases, below the third quartile. Inevitably, there are some rare cases where a large portion of the search space is explored, and thus their parsing time is high. Let us remark that these algorithms are run only when (`MSA`) returns an invalid structure, and so total time is very acceptable compared to the baseline.

Finally, we stress the importance of problem reduction as a pre-processing step in `B&B`: after subgradient descent is performed, it removes an average of 83.97% (resp. 76.59%) of arc variables in the English test set (resp. German test set).

7.3 Training

Feature weights are trained using the averaged structured perceptron (Collins, 2002) with 10 iterations where the best iteration is selected on the development set. We used the same feature set as in TurboParser (Martins et al., 2010), including features for lemma. For German, we additionally use morpho-syntactic features.

The decoding algorithm used at training time is the MSA. We experimented with Branch-and-Bound and Lagrangian Relaxation decoding dur-

Block degree 3	0.12	0.01	3.86	0.30	2.24	0.01	0.02	-	3.76	-
Block degree 4	-	-	0.19	<0.01	0.04	-	-	-	0.54	-
Block degree > 4	-	-	0.11	<0.01	-	-	-	-	0.14	-

Table 1: Distribution of dependency tree characteristics in datasets.

	English (96 sentences)			German (59 sentences)		
	MSA	LR	B&B	MSA	LR	B&B
Mean	0.02	0.26	0.53	0.04	0.51	0.71
Std.	0.01	0.20	0.86	0.02	0.41	1.39
Med.	0.02	0.21	0.27	0.03	0.47	0.47
3rd	0.03	0.34	0.53	0.05	0.71	0.80
Total	1.81	25.09	50.52	2.18	30.19	42.20

Table 2: Timings for strategies (see Section 7.2) on test for solutions which do not satisfy constraints after running MSA. We give (in seconds) average time, standard deviation, median time, time to parse up to the 3rd quartile and total time.

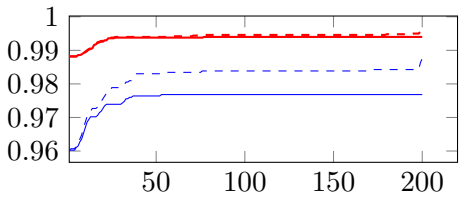

Figure 2: Optimality rate (y-axis) vs number of subgradient iterations (x-axis) for English (thin blue) and German (thick red). Solid line is the optimal rate with certificate, dashed is without.

ing training. It did not significantly improve accuracy and made training and decoding slower.

7.4 Parsing Results

Table 3 shows attachment score (UAS), percentage of valid dependency trees and relative time to (MSA) for different systems for our five decoding strategies. We can see (B&B) is on a par with (LR) on some corpora and more accurate on the others. The former takes more time, and the improvement is correlated with time difference for all corpora but the PTB. Dividing the five corpora in three cases, we can see that:

1. For English and Spanish, where projective dependency trees represent more than 90% of the data, (Eisner) outperforms (MSA). Our methods lie between the two. Here it is better to search for projective trees and (LR) and (B&B) are not interesting in terms of UAS. This is confirmed by the results of (MSA/Eisner).

2. For German and Dutch, where projective dependency trees represent less than 70% of the data, (MSA) outperforms (Eisner). For German, where well-nestedness is not required, our methods are as accurate as (MSA)[13], while for Dutch our methods seem to be useful, as (B&B) outperforms all systems. Moreover, our two methods guarantee validity.

3. For Portuguese, where projective dependency trees represent around 80% of the data, (MSA) is as accurate as (Eisner). In this case we see that, while our heuristic is below, the exact method is more accurate. This seems to be an edge case where neither unconstrained nor projective dependency trees seem to adequately capture the solution space. We also see that it is harder for our methods to give solutions (longer computation times, which tend to indicate that LR cannot guarantee optimality). Our methods are best fitted for this case.

In order to see how much well-nested and bounded block-degree structures are missed by a state-of-the-art parser, we compare our results with TurboParser.[14] We run the parser with three different feature sets: arc-factored, standard (second-order features), and full (third-order features). The results are shown in Table 4. Our model, by enforcing strict compliance to structural rules (100% valid dependency trees), is closer to the empirical distribution than TurboParser in arc-factored mode on all languages but German. Higher-order scoring functions manage to get more similar to the treebank data than our strict thresholds for all languages but Portuguese, at the expense of a significative computational burden.

[13] For German, we notice a small regression which we attribute to the representation of enumerations in the corpus: for enumerations of k elements, k-bounded block-degree subtrees must be generated.

[14] We used 2.1.0 and all defaults but the feature set.

Table 4: UAS, percentage of valid dependency trees (VDT) and relative time (RT) obtained by Turboparser for different score functions on test sets. For each language we give the percentage of valid dependency structures in the data, according to the constraints postulated in Section 7.1.

We interpret this fact as an indication that adding higher order features into our system would make the relaxation method converge more often and faster.

8 Conclusion

We presented a novel characterization of dependency trees complying with two structural rules: bounded block degree and well-nestedness from which we derived two methods for arc-factored dependency parsing. The first one is a heuristic which relies on Lagrangian Relaxation and the Chu-Liu-Edmonds efficient maximum spanning arborescence algorithm. The second one is an exact Branch-and-Bound procedure where bounds are provided by Lagrangian Relaxation. We showed experimentally that these methods give results comparable with state-of-the-art arc-factored parsers, while enforcing constraints in all cases.

In this paper we focused on arc-factor models, but our method could be extended to higher order models, following the dual decomposition method presented in (Koo et al., 2010) in which the maximum-weight spanning arborescence component would be replaced by our constrained model.

Our method opens new perspectives for LTAG parsing, in particular using decomposition techniques where dependencies and templates are predicted separately. Moreover, while well-nested dependencies with 2-bounded block degree can represent LTAG derivations, toggling the well-nestedness or setting the block degree bound allows to express the whole range of derivations in lexicalized LCFRS, whether well-nested or with a bounded fan-out. Our algorithm can exactly represent these settings with a comparable complexity.

Abstract

Continuous space word embeddings have received a great deal of attention in the natural language processing and machine learning communities for their ability to model term similarity and other relationships. We study the use of term relatedness in the context of query expansion for *ad hoc* information retrieval. We demonstrate that word embeddings such as word2vec and GloVe, when trained globally, underperform corpus and query specific embeddings for retrieval tasks. These results suggest that other tasks benefiting from global embeddings may also benefit from local embeddings.

1 Introduction

Continuous space embeddings such as word2vec (Mikolov et al., 2013b) or GloVe (Pennington et al., 2014a) project terms in a vocabulary to a dense, lower dimensional space. Recent results in the natural language processing community demonstrate the effectiveness of these methods for analogy and word similarity tasks. In general, these approaches provide global representations of words; each word has a fixed representation, regardless of any discourse context. While a global representation provides some advantages, language use can vary dramatically by topic. For example, ambiguous terms can easily be disambiguated given local information in immediately surrounding words (Harris, 1954; Yarowsky, 1993). The window-based training of word2vec style algorithms exploits this distributional property.

A global word embedding, even when trained using local windows, risks capturing only coarse representations of those topics dominant in the corpus. While a particular embedding may be appropriate for a specific word within a sentence-length context globally, it may be entirely inappropriate within a specific topic. Gale *et al.* refer to this as the 'one sense per discourse' property (Gale et al., 1992). Previous work by Yarowsky demonstrates that this property can be successfully combined with information from nearby terms for word sense disambiguation (Yarowsky, 1995). Our work extends this approach to word2vec-style training in the context word similarity.

For many tasks that require topic-specific linguistic analysis, we argue that topic-specific representations should outperform global representations. Indeed, it is difficult to imagine a natural language processing task that would *not* benefit from an understanding of the local topical structure. Our work focuses on a query expansion, an information retrieval task where we can study different lexical similarity methods with an extrinsic evaluation metric (i.e. retrieval metrics). Recent work has demonstrated that similarity based on global word embeddings can be used to outperform classic pseudo-relevance feedback techniques (Sordoni et al., 2014; al Masri et al., 2016).

We propose that embeddings be learned on topically-constrained corpora, instead of large topically-unconstrained corpora. In a retrieval scenario, this amounts to retraining an embedding on documents related to the topic of the query. We present local embeddings which capture the nuances of topic-specific language better than global embeddings. There is substantial evidence that global methods underperform local methods for information re-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 367–377,
Berlin, Germany, August 7-12, 2016.

trieval tasks such as query expansion (Xu and Croft, 1996), latent semantic analysis (Hull, 1994; Schütze et al., 1995; Singhal et al., 1997), cluster-based retrieval (Tombros and van Rijsbergen, 2001; Tombros et al., 2002; Willett, 1985), and term clustering (Attar and Fraenkel, 1977). We demonstrate that the same holds true when using word embeddings for text retrieval.

2 Motivation

For the purpose of motivating our approach, we will restrict ourselves to word2vec although other methods behave similarly (Levy and Goldberg, 2014). These algorithms involve discriminatively training a neural network to predict a word given small set of context words. More formally, given a target word w and observed context c, the instance loss is defined as,

$$\ell(w,c) = \log \sigma(\phi(w) \cdot \psi(c)) + \eta \cdot \mathbb{E}_{\overline{w} \sim \theta_C} \left[\log \sigma(-\phi(w) \cdot \psi(\overline{w}))\right]$$

where $\phi : \mathcal{V} \rightarrow \Re^k$ projects a term into a k-dimensional embedding space, $\psi : \mathcal{V}^m \rightarrow \Re^k$ projects a set of m terms into a k-dimensional embedding space, and $\overline{w}$ is a randomly sampled 'negative' context. The parameter η controls the sampling of random negative terms. These matrices are estimated over a set of contexts sampled from a large corpus and minimize the expected loss,

$$\mathcal{L}_c = \mathbb{E}_{w,c \sim p_c} \left[\ell(w,c)\right] \quad (1)$$

where p_c is the distribution of word-context pairs in the training corpus and can be estimated from corpus statistics.

While using corpus statistics may make sense absent any other information, oftentimes we know that our analysis will be topically constrained. For example, we might be analyzing the 'sports' documents in a collection. The language in this domain is more specialized and the distribution over word-context pairs is unlikely to be similar to $p_c(w,c)$. In fact, prior work in information retrieval suggests that documents on subtopics in a collection have very different unigram distributions compared to the whole corpus (Cronen-Townsend et al., 2002). Let $p_t(w,c)$ be the probability

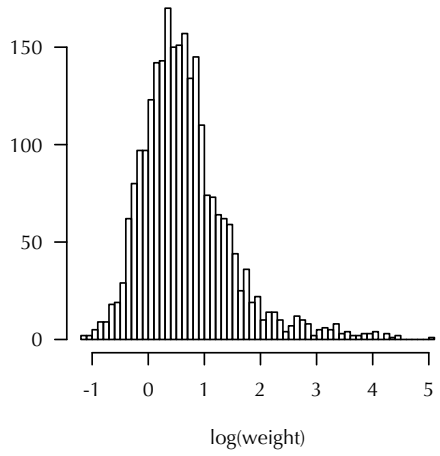

Figure 1: Importance weights for terms occurring in documents related to 'argentina pegging dollar' relative to frequency in gigaword.

of observing a word-context pair conditioned on the topic t. The expected loss under this distribution is (Shimodaira, 2000),

$$\mathcal{L}_t = \mathbb{E}_{w,c \sim p_c} \left[\frac{p_t(w,c)}{p_c(w,c)} \ell(w,c)\right] \quad (2)$$

In general, if our corpus consists of sufficiently diverse data (e.g. Wikipedia), the support of $p_t(w,c)$ is much smaller than and contained in that of $p_c(w,c)$. The loss, ℓ, of a context that occurs more frequently in the topic, will be amplified by the importance weight $\omega = \frac{p_t(w,c)}{p_c(w,c)}$. Because topics require specialized language, this is likely to occur; at the same time, these contexts are likely to be underemphasized in training a model according to Equation 1.

In order to quantify this, we took a topic from a TREC *ad hoc* retrieval collection (see Section 5 for details) and computed the importance weight for each term occurring in the set of on-topic documents. The histogram of weights ω is presented in Figure 1. While larger probabilities are expected since the size of a topic-constrained vocabulary is smaller, there are a non-trivial number of terms with much larger importance weights. If the loss, $\ell(w)$, of a word2vec embedding is worse for these words with low $p_c(w)$, then we expect these errors to be exacerbated for the topic.

Of course, these highly weighted terms may have a low value for $p_t(w)$ but a very high value relative to the corpus. We can adjust the

Figure 3: Terms similar to 'cut' for a word2vec model trained on a general news corpus and another trained only on documents related to 'gasoline tax'.

weights by considering the pointwise Kullback-Leibler divergence for each word w,

$$D_w(p_t \| p_c) = p_t(w) \log \frac{p_t(w)}{p_c(w)} \quad (3)$$

Words which have a much higher value of $p_t(w)$ than $p_c(w)$ *and* have a high absolute value of $p_t(w)$ will have high pointwise KL divergence. Figure 2 shows the divergences for the top 100 most frequent terms in $p_t(w)$. The higher ranked terms (i.e. good query expansion candidates) tend to have much higher probabilities than found in $p_c(w)$. If the loss on those words is large, this may result in poor embeddings for the most important words for the topic.

A dramatic change in distribution between the corpus and the topic has implications for performance precisely because of the objective used by word2vec (i.e. Equation 1). The training emphasizes word-context pairs occurring with high frequency in the corpus. We will demonstrate that, even with heuristic downsampling of frequent terms in word2vec, these techniques result in inferior performance for specific topics.

Thus far, we have sketched out why using the corpus distribution for a specific topic may result in undesirable outcomes. However, it is even unclear that $p_t(w|c) = p_c(w|c)$. In fact, we suspect that $p_t(w|c) \neq p_c(w|c)$ because of the 'one sense per discourse' claim (Gale et al., 1992). We can qualitatively observe the difference in $p_c(w|c)$ and $p_t(w|c)$ by training two word2vec models: the first on the large, generic Gigaword corpus and the second on a topically-constrained subset of the gigaword. We present the most similar terms to 'cut' using both a global embedding and a topic-specific embedding in Figure 3. In this case, the topic is 'gasoline tax'. As we can see, the 'tax cut' sense of 'cut' is emphasized in the topic-specific embedding.

3 Local Word Embeddings

The previous section described several reasons why a global embedding may result in over-general word embeddings. In order to perform topic-specific training, we need a set of topic-specific documents. In information retrieval scenarios users rarely provide the system with examples of topic-specific documents, instead providing a small set of keywords.

Fortunately, we can use information retrieval techniques to generate a query-specific set of topical documents. Specifically, we adopt a language modeling approach to do so (Croft and Lafferty, 2003). In this retrieval model, each document is represented as a maximum likelihood language model estimated from document term frequencies. Query language models are estimated similarly, using term frequency in the query. A document score then, is the Kullback-Leibler divergence between the query and document language

models,

$$D(p_q \| p_d) = \sum_{w \in \mathcal{V}} p_q(w) \log \frac{p_q(w)}{p_d(w)} \quad (4)$$

Documents whose language models are more similar to the query language model will have a *lower* KL divergence score. For consistency with prior work, we will refer to this as the query likelihood score of a document.

The scores in Equation 4 can be passed through a softmax function to derive a multinomial over the entire corpus (Lavrenko and Croft, 2001),

$$p(d) = \frac{\exp(-D(p_q \| p_d))}{\sum_{d'} \exp(-D(p_q \| p_{d'}))} \quad (5)$$

Recall in Section 2 that training a word2vec model weights word-context pairs according to the corpus frequency. Our query-based multinomial, $p(d)$, provides a weighting function capturing the documents relevant to this topic. Although an estimation of the topic-specific documents from a query will be imprecise (i.e. some nonrelevant documents will be scored highly), the language use tends to be consistent with that found in the known relevant documents.

We can train a local word embedding using an arbitrary optimization method by sampling documents from $p(d)$ instead of uniformly from the corpus. In this work, we use word2vec, although any method that operates on a sample of documents can be used.

4 Query Expansion with Word Embeddings

When using language models for retrieval, query expansion involves estimating an alternative to p_q. Specifically, when each expansion term is associated with a weight, we normalize these weights to derive the expansion language model, p_{q^+}. This language model is then interpolated with the original query model,

$$p_q^1(w) = \lambda p_q(w) + (1 - \lambda) p_{q^+}(w) \quad (6)$$

This interpolated language model can then be used with Equation 4 to rank documents (Abdul-Jaleel et al., 2004). We will refer to this as the expanded query score of a document.

Now we turn to using word embeddings for query expansion. Let $\mathbf{U}$ be an $|\mathcal{V}| \times k$ term embedding matrix. If $\mathbf{q}$ is a $|\mathcal{V}| \times 1$ column term vector for a query, then the expansion term weights are $\mathbf{U}\mathbf{U}^\top\mathbf{q}$. We then take the top k terms, normalize their weights, and compute $p_{q^+}(w)$.

We consider the following alternatives for $\mathbf{U}$. The first approach is to use a global model trained by sampling documents uniformly. The second approach, which we propose in this paper, is to use a local model trained by sampling documents from $p(d)$.

5 Methods

5.1 Data

To evaluate the different retrieval strategies described in Section 3, we use the following datasets. Two newswire datasets, trec12 and robust, consist of the newswire documents and associated queries from TREC *ad hoc* retrieval evaluations. The trec12 corpus consists of Tipster disks 1 and 2; and the robust corpus consists of Tipster disks 4 and 5. Our third dataset, web, consists of the ClueWeb 2009 Category B Web corpus. For the Web corpus, we only retain documents with a Waterloo spam rank above 70.[1] We present corpus statistics in Table 1.

We consider several publicly available global embeddings. We use four GloVe embeddings of different dimensionality trained on the union of Wikipedia and Gigaword documents.[2] We use one publicly available word2vec embedding trained on Google News documents.[3] We also trained a global embedding for trec12 and robust using the entire corpus. Instead of training a global embedding on the large web collection, we use a GloVe embedding trained on Common Crawl data.[4]

We train local embeddings with word2vec using one of three retrieval sources. First, we consider documents retrieved from the target corpus of the query (i.e. trec12, robust, or web). We also consider training a local embed-

Table 1: Corpora used for retrieval and local embedding training.

ding by performing a retrieval on large auxiliary corpora. We use the Gigaword corpus as a large auxiliary news corpus. We hypothesize that retrieving from a larger news corpus will provide substantially more local training data than a target retrieval. We also use a Wikipedia snapshot from December 2014. We hypothesize that retrieving from a large, high fidelity corpus will provide cleaner language than that found in lower fidelity target domains such as the web. Table 1 shows the relative magnitude of these auxiliary corpora compared to the target corpora.

All corpora in Table 1 were stopped using the SMART stopword list[5] and stemmed using the Krovetz algorithm (Krovetz, 1993). We used the Indri implementation for indexing and retrieval.[6]

5.2 Evaluation

We consider several standard retrieval evaluation metrics, including NDCG@10 and interpolated precision at standard recall points (Järvelin and Kekäläinen, 2002; van Rijsbergen, 1979). NDCG@10 provides insight into performance specifically at higher ranks. An interpolated precision recall graph describes system performance throughout the entire ranked list.

5.3 Training

All retrieval experiments were conducted by performing 10-fold cross-validation across queries. Specifically, we cross-validate the number of expansion terms, $k \in \{5, 10, 25, 50, 100, 250, 500\}$, and interpolation weight, $\lambda \in [0, 1]$. For local word2vec training, we cross-validate the learning rate $\alpha \in \{10^{-1}, 10^{-2}, 10^{-3}\}$.

[5] http://jmlr.csail.mit.edu/papers/volume5/lewis04a/a11-smart-stop-list/english.stop

[6] http://www.lemurproject.org/indri/

All word2vec training used the publicly available word2vec cbow implementation.[7] When training the local models, we sampled 1000 documents from $p(d)$ with replacement. To compensate for the much smaller corpus size, we ran word2vec training for 80 iterations. Local word2vec models use a fixed embedding dimension of 400 although other choices did not significantly affect our results. Unless otherwise noted, default parameter settings were used.

In our experiments, expanded queries rescore the top 1000 documents from an initial query likelihood retrieval. Previous results have demonstrated that this approach results in performance nearly identical with an expanded retrieval at a much lower cost (Diaz, 2015). Because publicly available embeddings may have tokenization inconsistent with our target corpora, we restricted the vocabulary of candidate expansion terms to those occurring in the initial retrieval. If a candidate term was not found in the vocabulary of the embedding matrix, we searched for the candidate in a stemmed version of the embedding vocabulary. In the event that the candidate term was still not found after this process, we removed it from consideration.

6 Results

We present results for retrieval experiments in Table 2. We find that embedding-based query expansion outperforms our query likelihood baseline across all conditions. When using the global embedding, the news corpora benefit from the various embeddings in different situations. Interestingly, for trec12, using an embedding trained on the target corpus significantly outperforms all other global embeddings, despite using substantially less data to estimate the model. While this performance may be due to the embedding having a tokenization consistent with the target corpus, it may also come from the fact that the corpus is more representative of the target documents than other embeddings which rely on online news or are mixed with non-news content. To some extent this supports our desire to move training closer to the target distribution.

Across all conditions, local embeddings sig-

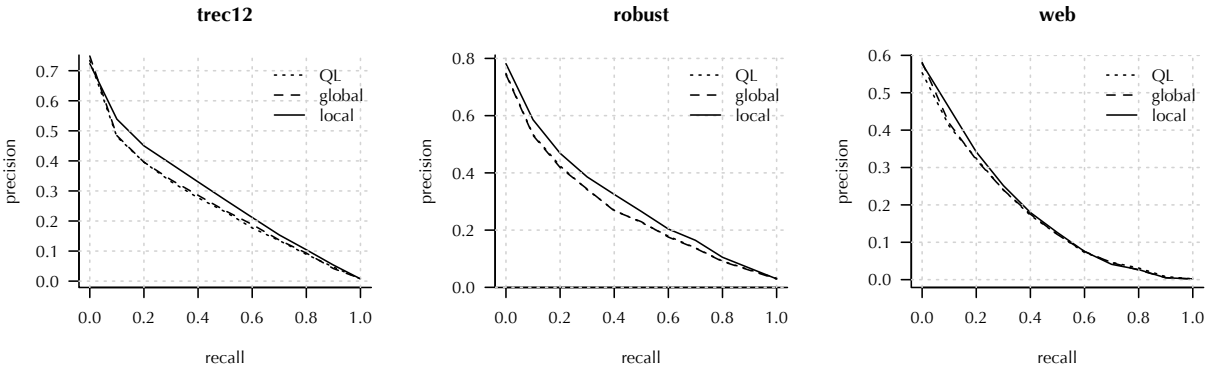

Figure 4: Interpolated precision-recall curves for query likelihood, the best global embedding, and the best local embedding from Table 2.

nificantly outperform global embeddings for query expansion. For our two news collections, estimating the local model using a retrieval from the larger Gigaword corpus led to substantial improvements. This effect is almost certainly due to the Gigaword corpus being similar in writing style to the target corpus but, at the same time, providing significantly more relevant content (Diaz and Metzler, 2006). As a result, the local embedding is trained using a larger variety of topical material than if it were to use a retrieval from the smaller target corpus. An embedding trained with a retrieval from Wikipedia tended to perform worse most likely because the language is dissimilar from news content. Our web collection, on the other hand, benefitted more from embeddings trained using retrievals from the general Wikipedia corpus. The Gigaword corpus was less useful here because news-style language is almost certainly not representative of general web documents.

Figure 4 presents interpolated precision-recall curves comparing the baseline, the best global query expansion method, and the best local query expansion method. Interestingly, although global methods achieve strong performance for NDCG@10, these improvements over the baseline are not reflected in our precision-recall curves. Local methods, on the other hand, almost always strictly dominate both the baseline and global expansion across all recall levels.

The results support the hypothesis that local embeddings provide better similarity measures than global embeddings for query expansion. In order to understand why, we first compare the performance differences between local and global embeddings. Figure 2 suggests that we should adopt a local embedding when the local unigram language model deviates from the corpus language model. To test this, we computed the KL divergence between the local unigram distribution, $\sum_d p(w|d)p(d)$, and the corpus unigram language model (Cronen-Townsend et al., 2002). We hypothesize that, when this value is high, the topic language is different from the corpus language and the

Table 3: Kendall's τ and Spearman's ρ between improvement in NDCG@10 and local KL divergence with the corpus language model. The improvement is measured for the best local embedding over the best global embedding.

global embedding will be inferior to the local embedding. We tested the rank correlation between this KL divergence and the relative performance of the local embedding with respect to the global embedding. These correlations are presented in Table 3. Unfortunately, we find that the correlation is low, although it is positive across collections.

We can also qualitatively analyze the differences in the behavior of the embeddings. If we have access to the set of documents labeled relevant to a query, then we can compute the frequency of terms in this set and consider those terms with high frequency (after stopping and stemming) to be good query expansion candidates. We can then visualize where these terms lie in the global and local embeddings. In Figure 5, we present a two-dimensional projection (van der Maaten and Hinton, 2008) of terms for the query 'ocean remote sensing', with those good candidates highlighted. Our projection includes the top 50 candidates by frequency and a sample of terms occurring in the query likelihood retrieval. We notice that, in the global embedding, the good candidates are spread out amongst poorer candidates. By contrast, the local embedding clusters the candidates in general but also situates them closely around the query. As a result, we suspect that the similar terms extracted from the local embedding are more likely to include these good candidates.

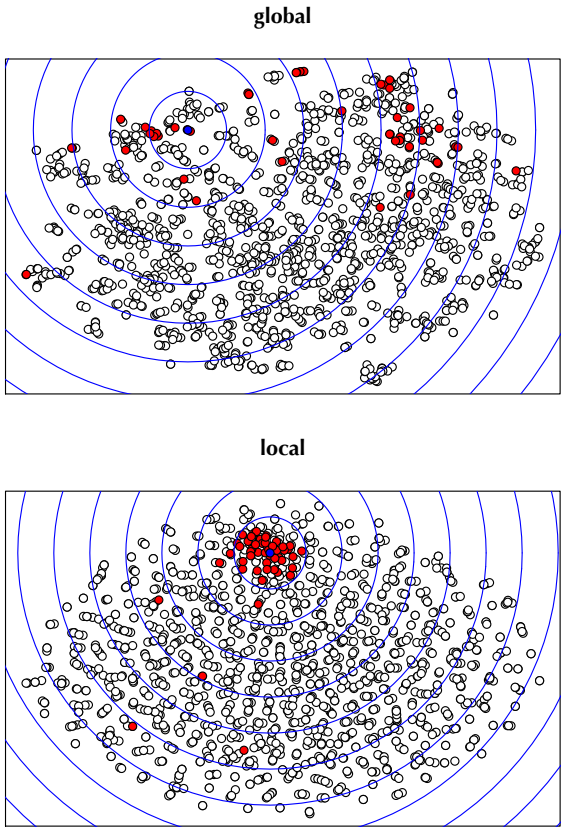

Figure 5: Global versus local embedding of highly relevant terms. Each point represents a candidate expansion term. Red points have high frequency in the relevant set of documents. White points have low or no frequency in the relevant set of documents. The blue point represents the query. Contours indicate distance from the query.

7 Discussion

The success of local embeddings on this task should alarm natural language processing researchers using global embeddings as a representational tool. For one, the approach of learning from vast amounts of data is only effective if the data is appropriate for the task at hand. And, when provided, much smaller high-quality data can provide much better performance. Beyond this, our results suggest that the approach of estimating global representations, while computationally convenient, may overlook insights possible at query time, or evaluation time in general. A similar local embedding approach can be adopted for any natural language processing task where topical locality is expected and can be estimated. Although we used a query to re-weight the corpus in our experiments, we could just as easily use alternative contextual information (e.g. a sentence, paragraph, or document) in other tasks.

Despite these strong results, we believe that

there are still some open questions in this work. First, although local embeddings provide effectiveness gains, they can be quite inefficient compared to global embeddings. We believe that there is opportunity to improve the efficiency by considering offline computation of local embeddings at a coarser level than queries but more specialized than the corpus. If the retrieval algorithm is able to select the appropriate embedding at query time, we can avoid training the local embedding. Second, although our supporting experiments (Table 3, Figure 5) add some insight into our intuition, the results are not strong enough to provide a solid explanation. Further theoretical and empirical analysis is necessary.

8 Related Work

Topical adaptation of models The shortcomings of learning a single global vector representation, especially for polysemic words, have been pointed out before (Reisinger and Mooney, 2010b). The problem can be addressed by training a global model with multiple vector embeddings per word (Reisinger and Mooney, 2010a; Huang et al., 2012) or topic-specific embeddings (Liu et al., 2015). The number of senses for each word may be fixed (Neelakantan et al., 2015), or determined using class labels (Trask et al., 2015). However, to the best of our knowledge, this is the first time that training topic-specific word embeddings has been explored.

Several methods exist in the language modeling community for topic-dependent adaptation of language models (Bellegarda, 2004). These can lead to performance improvements in tasks such as machine translation (Zhao et al., 2004) and speech recognition (Nanjo and Kawahara, 2004). Topic-specific data may be gathered in advance, by identifying corpus of topic-specific documents. It may also be gathered during the discourse, using multiple hypotheses from N-best lists as a source of topic-specific language. Then a topic-specific language model is trained (or the global model is adapted) online using the topic-specific training data. A topic-dependent model may be combined with the global model using linear interpolation (Iyer and Ostendorf, 1999) or other more sophisticated approaches (Federico, 1996; Kuhn and De Mori, 1990). Similarly to the adaptation work, we use topic-specific documents to train a topic-specific model. In our case the documents come from a first round of retrieval for the user's current query, and the word embedding model is trained based on sentences from the topic-specific document set. Unlike the past work, we do not focus on interpolating the local and global models, although this is a promising area for future work. In the current study we focus on a direct comparison between the local-only and global-only approach, for improving retrieval performance.

Word embeddings for IR Information Retrieval has a long history of learning representations of words that are low-dimensional dense vectors. These approaches can be broadly classified into two families based on whether they are learnt based on a *term-document* matrix or *term co-occurence* data. Using the *term-document* matrix for embedding leads to several well-studied approaches such as LSA (Deerwester et al., 1990), PLSA (Hofmann, 1999), and LDA (Blei et al., 2003; Wei and Croft, 2006). The performance of these models varies depending on the task, for example they are known to perform poorly for retrieval tasks unless combined with lexical features (Atreya and Elkan, 2011a). *Term-cooccurence* based embeddings, such as word2vec (Mikolov et al., 2013b; Mikolov et al., 2013a) and (Pennington et al., 2014b), have recently been remarkably popular for many natural language processing and logical reasoning tasks. However, there are relatively less known successful applications of these models in IR. Ganguly *et. al.* (Ganguly et al., 2015) used the word similarity in the word2vec embedding space as a way to estimate term transformation probabilities in a language modelling setting for retrieval. More recently, Nalisnick *et. al.* (Nalisnick et al., 2016) proposed to model document about-ness by computing the similarity between all pairs of query and document terms using dual embedding spaces. Both these approaches estimate the semantic relatedness between two terms as the cosine distance between them in the embedding space(s). We adopt a similar notion of term relatedness but focus on demon-

strating improved retrieval performance using locally trained embeddings.

Local latent semantic analysis Despite the mathematical appeal of latent semantic analysis, several experiments suggest that its empirical performance may be no better than that of ranking using standard term vectors (Deerwester et al., 1990; Dumais, 1995; Atreya and Elkan, 2011b). In order to address the coarseness of corpus-level latent semantic analysis, Hull proposed restricting analysis to the documents relevant to a query (Hull, 1994). This approach significantly improved over corpus-level analysis for routing tasks, a result that has been reproduced in consequent research (Schütze et al., 1995; Singhal et al., 1997). Our work can be seen as an extension of these results to more recent techniques such as word2vec.

9 Conclusion

We have demonstrated a simple and effective method for performing query expansion with word embeddings. Importantly, our results highlight the value of locally-training word embeddings in a query-specific manner. The strength of these results suggests that other research adopting global embedding vectors should consider local embeddings as a potentially superior representation. Instead of using a "Sriracha sauce of deep learning," as embedding techniques like word2vec have been called, we contend that the situation sometimes requires, say, that we make a béchamel or a mole verde or a sambal—or otherwise learn to cook.

Abstract

Community Question Answering (cQA) services like Yahoo! Answers[1], Baidu Zhidao[2], Quora[3], StackOverflow[4] *etc.* provide a platform for interaction with experts and help users to obtain precise and accurate answers to their questions. The time lag between the user posting a question and receiving its answer could be reduced by retrieving similar historic questions from the cQA archives. The main challenge in this task is the "lexico-syntactic" gap between the current and the previous questions. In this paper, we propose a novel approach called *"Siamese Convolutional Neural Network for cQA (SCQA)"* to find the semantic similarity between the current and the archived questions. SCQA consist of twin convolutional neural networks with shared parameters and a contrastive loss function joining them.

SCQA learns the similarity metric for question-question pairs by leveraging the question-answer pairs available in cQA forum archives. The model projects semantically similar question pairs nearer to each other and dissimilar question pairs farther away from each other in the semantic space. Experiments on large scale real-life "Yahoo! Answers" dataset reveals that SCQA outperforms current state-of-the-art approaches based on translation models, topic models and deep neural network based models which use non-shared parameters.

1 Introduction

The cQA forums have emerged as popular and effective means of information exchange on the Web. Users post queries in these forums and receive precise and compact answers in stead of a list of documents. Unlike in Web search, opinion based queries are also answered here by experts and users based on their personal experiences. The question and answers are also enhanced with rich metadata like categories, subcategories, user expert level, user votes to answers *etc.*

One of the serious concerns in cQA is *"question-starvation"* (Li and King, 2010) where a question does not get immediate answer from any user. When this happens, the question may take several hours and sometimes days to get satisfactory answers or may not get answered at all. This delay in response may be avoided by retrieving semantically related questions from the cQA archives. If a similar question is found in the database of previous questions, then the corresponding best answer can be provided without any delay. However, the major challenge associated with retrieval of similar questions is the *lexico-syntactic gap* between them. Two questions may mean the same thing but they may differ lexically and syntactically. For example the queries *"Why are yawns contagious?"* and *"Why do we yawn when we see somebody else yawning?"* convey the same meaning but differ drastically from each other in terms of words and syntax.

Several techniques have been proposed in the literature for similar question retrieval and they could be broadly classified as follows:

1. **Classic Term Weighting Based Approaches:** Classical IR based retrieval

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 378–387,
Berlin, Germany, August 7-12, 2016.

models like $BM25$ (Robertson et al., 1994) and Language modeling for Information Retrieval ($LMIR$) (Zhai and Lafferty, 2004) score the similarity based on the weights of the matching text terms between the questions.

2. **Translation Models:** Learning word or phrase level translation models from question-answer pairs in parallel corpora of same language (Jeon et al., 2005; Xue et al., 2008; Zhou et al., 2011). The similarity function between questions is then defined as the probability of translating a given question into another.

3. **Topic Models:** Learning topic models from question-answer pairs (Ji et al., 2012; Cai et al., 2011; Zhang et al., 2014). Here, the similarity between questions, is defined in the latent topic space discovered by the topic model.

4. **Deep Learning Based Approaches:** Deep Learning based models like (Zhou et al., 2016),(Qiu and Huang, 2015), (Das et al., 2016) use variants of neural network architectures to model question-question pair similarity.

Retrieving semantically similar questions can be thought of as a classification problem with large number of categories. Here, each category contains a set of related questions and the number of questions per category is small. It is possible that given a test question, we find that there are no questions semantically related to it in the archives, it will belong to a entirely new unseen category. Thus, only a subset of the categories is known during the time of training. The intuitive approach to solve this kind of problem would to learn a similarity metric between the question to be classified and the archive of previous questions. Siamese networks have shown promising results in such distance based learning methods (Bromley et al., 1993; Chopra et al., 2005). These networks possess the capability of learning the similarity metric from the available data, without requiring specific information about the categories.

In this paper, we propose a novel unified model called *Siamese Convolutional Neural Network for cQA*. $SCQA$ architecture contain deep convolutional neural networks as twin networks with a contrastive energy function at the top. These twin networks share the weights with each other (parameter sharing). The energy function used is suitable for discriminative training for Energy-Based models (LeCun and Huang, 2005). $SCQA$ learns the shared model parameters and the similarity metric by minimizing the energy function connecting the twin networks. Parameter sharing guarantees that question and its relevant answer are nearer to each other in the semantic space while the question and any answer irrelevant to it are far away from each other. For example, the representations of *"President of USA"* and *"Barack Obama"* should be nearer to each other than those of *"President of USA"* and *"Tom Cruise lives in USA"*. The learnt similarity metric is used to retrieve semantically similar questions from the archives given a new posted question.

Similar question pairs are required to train SCQA which is usually hard to obtain in large numbers. Hence, $SCQA$ overcomes this limitation by leveraging Question-Answer pairs (Q, A) from the cQA archives. This also has additional advantages such as:

- The knowledge and expertise of the answerers and askers usually differ in a cQA forum. The askers, who are novices or non-experts, usually use less technical terminology whereas the answerers, who are typically experts, are more likely to use terms which are technically appropriate in the given realm of knowledge. Due to this, a model which learns from Question-Answer (Q, A) training data has the advantage of learning mappings from non-technical and simple terms to technical terms used by experts such as $shortsight => myopia$ etc. This advantage will be lost if we learn from (Q, Q) pairs where both the questions are posed by non-experts only.

- Experts usually include additional topics that are correlated to the question topic which the original askers may not even be aware of. For example, for the question *"how can I overcome short sight?"*, an expert may give an answer containing the concepts *"laser surgery"*, *"contact lens"*, *"LASIK surgery"* etc. Due to this, the concept *short sight* gets associated with these expanded concepts as well. Since, the askers are non-experts, such

rich concept associations are hard to learn from (Q, Q) training archives even if they are available in large scale. Thus, leveraging (Q, A) training data leads to learning richer concept/term associations in SCQA.

In summary, the following are our main contributions in this paper:

- We propose a novel model $SCQA$ based on Siamese Convolutional Neural Network which use shared parameters to learn the similarity metric between question-answer pairs in a cQA dataset.
- In SCQA, we overcome the non-availability of training data in the form of question-question pairs by leveraging existing question-answer pairs from the cQA archives which also helps in improving the effectiveness of the model.
- We reduce the computational complexity by directly using character-level representations of question-answer pairs in stead of using sentence modeling based representations which also helps in handling spelling errors and out-of-vocabulary (OOV) words in documents.

The rest of the paper is organized as follows. Section 2 presents the previous approaches to conquer the problem. Section 3 describes the architecture of $SCQA$. Sections 4 and 5 explain the training and testing phase of $SCQA$ respectively. Section 6 introduces a variant of $SCQA$ by adding textual similarity to it. Section 7 describes the experimental set-up, details of the evaluation dataset and evaluation metrics. In Section 8, quantitative and qualitative results are presented. Finally, Section 9 concludes the paper.

2 Related Work

The classical retrieval models $BM25$ (Robertson et al., 1994), $LMIR$ (Zhai and Lafferty, 2004) do not help much to capture semantic relatedness because they mainly consider textual similarity between queries. Researchers have used translation based models to solve the problem of question retrieval. Jeon *et al.* (2005) leveraged the similarity between the archived answers to estimate the translation probabilities. Xue *et al.* (2008) enhanced the performance of word based translation model by combining query likelihood language model to it. Zhou *et al.* (2011) used phrase based translation model where they considered question answer pairs as parallel corpus. However, Zhang *et al.* (2014) stated that questions and answers cannot be considered parallel because they are heterogeneous in lexical level and in terms of user behaviors. To overcome these vulnerabilities topic modeling was introduced by (Ji et al., 2012; Cai et al., 2011; Zhang et al., 2014). The approach assumes that questions and answers share some common latent topics. These techniques match questions not only on a term level but also on a topic level.

Zhou *et al.* (2015) used a fisher kernel to model the fixed size representation of the variable length questions. The model enhances the embedding of the questions with the metadata "category" involved with them. Zhang *et al.* (2016) learnt representations of words and question categories simultaneously and incorporated the learnt representations into traditional language models.

Following the recent trends, deep learning is also employed to solve this problem. Qiu *et al.* (2015) introduced convolutional neural tensor network (CNTN), which combines sentence modeling and semantic matching. CNTN transforms the word tokens into vectors by a lookup layer, then encode the questions and answers to fixed-length vectors with convolutional and pooling layers, and finally model their interactions with a tensor layer. Das *et al.* (2016) used deep structured topic modeling that combined topic model and paired convolutional networks to retrieve related questions. Zhou *et al.* (2016) used a deep neural network (DNN) to map the question answer pairs to a common semantic space and calculated the relevance of each answer given the query using cosine similarity between their vectors in that semantic space. Finally they fed the learnt semantic vectors into a learning to rank (LTR) framework to learn the relative importance of each feature.

On a different line of research, several Textual-based Question Answering (QA) systems (Qanda[5], QANUS[6], QSQA[7] *etc.*) are developed that retrieve answers from the Web and other textual sources. Similarly, structured QA systems

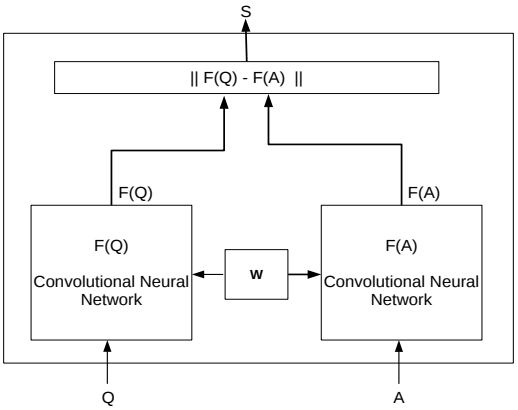

Figure 1: Architecture of Siamese network.

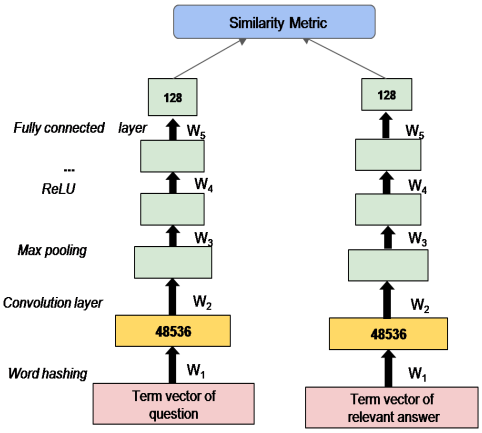

Figure 2: Architecture of SCQA. The network consists of repeating convolution, max pooling and ReLU layers and a fully connected layer. Also the weights W_1 to W_5 are shared between the sub-networks.

(Aqualog[8], NLBean[9] *etc.*) obtain answers from structured information sources with predefined ontologies. QALL-ME Framework (Ferrandez et al., 2011) is a reusable multilingual QA architecture built using structured data modeled by an ontology. The reusable architecture of the system may be utilized later to incorporate multilingual question retrieval in $SCQA$.

2.1 Siamese Neural Network

Siamese Neural Networks (shown in Figure 1) were introduced by Bromley *et al.* (1993) to solve the problem of signature verification. Later, Chopra *et al.* (2005) used the architecture with discriminative loss function for face verification. Recently these networks are used extensively to enhance the quality of visual search (Liu et al., 2008; Ding et al., 2008).

Let, $F(X)$ be the family of functions with set of parameters W. $F(X)$ is assumed to be differentiable with respect to W. Siamese network seeks a value of the parameter W such that the symmetric similarity metric is small if X_1 and X_2 belong to the same category, and large if they belong to different categories. The scalar energy function $S(Q, A)$ that measures the semantic relatedness between question answer pair (Q,A) can be defined as:

$$S(Q, A) = \|F(Q) - F(A)\| \quad (1)$$

In $SCQA$ question and relevant answer pairs are fed to train the network. The loss function is minimized so that $S(Q, A)$ is small if the answer A is relevant to the question Q and large otherwise.

[9] http://www.markwatson.com/opensource/

3 Architecture of SCQA

As shown in Figure 2, $SCQA$ consists of a pair of deep convolutional neural networks (CNN) with convolution, max pooling and rectified linear (ReLU) layers and a fully connected layer at the top. CNN gives a non linear projection of the question and answer term vectors in the semantic space. The semantic vectors yielded are connected to a layer that measures distance or similarity between them. The contrastive loss function combines the distance measure and the label. The gradient of the loss function with respect to the weights and biases shared by the sub-networks, is computed using back-propagation. Stochastic Gradient Descent method is used to update the parameters of the sub-networks.

3.1 Inputs to SCQA

The size of training data used is in millions, thus representing every word with one hot vector would be practically infeasible. Word hashing introduced by Mcnamee *et al.* (2004) involves letter n-gram to reduce the dimensionality of term vectors. For a word, say, "table" represented as (#table#) where # is used as delimiter, letter 3-grams would be #ta, tab, abl, ble, le#. Thus word hashing is character level representation of documents which takes care of OOV words and words with minor spelling errors. It represents a query using a lower dimensional vector with dimension equal to number of unique letter trigrams in the training dataset (48,536 in our case).

The input to the twin networks of $SCQA$ are word hashed term vectors of the question and

answer pair and a label. The label indicates whether the sample should be placed nearer or farther in the semantic space. For positive samples (which are expected to be nearer in the semantic space), twin networks are fed with word hashed vectors of question and relevant answers which are marked as "best-answer" or "most voted answers" in the cQA dataset of Yahoo! Answers (question-relevant answer pair). For negative samples (which are expected to be far away from each other in the semantic space), twin networks are fed with word hashed vectors of question and answer of any other random question from the dataset (question-irrelevant answer pair).

3.2 Convolution

Each question-answer pair is word hashed into (q_i-a_i) such that $q_i \in \mathbb{R}^{n_t}$ and $a_i \in \mathbb{R}^{n_t}$ where n_t is the total number of unique letter trigrams in the training data. Convolution layer is applied on the word hashed question answer vectors by convolving a filter with weights $\mathbf{c} \in \mathbb{R}^{hxw}$ where h is the filter height and w is the filter width. A filter consisting of a layer of weights is applied to a small patch of word hashed vector to get a single unit as output. The filter is slided across the length of vector such that the resulting connectivity looks like a series of overlapping receptive fields which output of width w.

3.3 Max Pooling

Max pooling performs a kind of non-linear down-sampling. It splits the filter outputs into small non-overlapping grids (larger grids result to greater the signal reduction), and take the maximum value in each grid as the value in the output of reduced size. Max pooling layer is applied on top of the output given by convolutional network to extract the crucial local features to form a fixed-length feature vector.

3.4 ReLU

Non-linear function Rectified linear unit (ReLU) is applied element-wise to the output of max pooling layer. ReLU is defined as $f(x) = max(0, x)$. ReLU is preferred because it simplifies backpropagation, makes learning faster and also avoids saturation.

3.5 Fully Connected layer

The terminal layer of the convolutional neural sub-networks is a fully connected layer. It converts the output of the last ReLU layer into a fixed-length semantic vector $\mathbf{s} \in \mathbb{R}^{n_s}$ of the input to the sub-network. We have empirically set the value of n_s to 128 in $SCQA$.

4 Training

We train $SCQA$ for a question while looking for semantic similarity with the answers relevant to it. $SCQA$ is different from the other deep learning counterparts due to its property of parameter sharing. Training the network with a shared set of parameters not only reduces number of parameters (thus, save lot of computations) but also ensures consistency of the representation of questions and answers in semantic space. The shared parameters of the network are learnt with the aim to minimize the semantic distance between the question and the relevant answers and maximize the semantic distance between the question and the irrelevant answers.

Given an input $\{q_i, a_i\}$ where q_i and a_i are the i^{th} question answer pair, and a label y_i with $y_i \in \{1,\text{-}1\}$, the loss function is defined as:

$$loss(q_i, a_i) = \begin{cases} 1 - \cos(q_i, a_i), & \text{if } y = 1; \\ \max(0, \cos(q_i, a_i) - m), & \text{if } y = -1; \end{cases}$$

where m is the margin which decides by how much distance dissimilar pairs should be moved away from each other. It generally varies between 0 to 1. The loss function is minimized such that question answer pairs with label 1 (question-relevant answer pair) are projected nearer to each other and that with label -1 (question-irrelevant answer pair) are projected far away from each other in the semantic space. The model is trained by minimizing the overall loss function in a batch. The objective is to minimize :

$$L(\Lambda) = \sum_{(q_i,a_i) \in C \cup C'} loss(q_i, a_i) \qquad (2)$$

where C contains batch of question-relevant answer pairs and C' contain batch of question-irrelevant answer pairs. The parameters shared by the convolutional sub-networks are updated using Stochastic Gradient escent (SGD).

5 Testing

While testing, we need to retrieve similar questions given a query. During testing we make pairs of all the questions with the query and feed them

to $SCQA$. The term vectors of the question pairs are word hashed and fed to the twin sub-networks. The trained shared weights of the $SCQA$ projects the question vector in the semantic space. The similarity between the pairs is calculated using the similarity metric learnt during the training. Thus $SCQA$ outputs a value of distance measure (score) for each pair of questions. The threshold is dynamically set to the average similarity score across questions and we output only those which have a similarity greater than the average similarity score.

6 Siamese Neural Network with Textual Similarity

$SCQA$ is trained using question-relevant answer pairs as positive samples and question-irrelevant answer pairs as negative samples. It poorly models the basic text similarity because in the (Q, A) training pairs, the answerers often do not repeat the question words while providing the answer. For example: for the question "Who is the President of the US?", the answerer would just provide "Barrack Obama". Due to this, although the model learns that $president\, the\, US \implies Barrack\, Obama$, the similarity for $president \implies president$ wouldn't be much and hence needs to be augmented through $BM25$ or some such similarity function.

Though $SCQA$ can strongly model semantic relations between documents, it needs boosting in the area of textual similarity. The sense of word based similarity is infused to $SCQA$ by using BM25 ranking algorithm. Lucene[10] is used to calculate the BM25 scores for question pairs. The score from similarity metric of $SCQA$ is combined with the BM25 score. A new similarity score is calculated by the weighted combination of the $SCQA$ and $BM25$ score as:

$$score = \alpha * SCQA_{score} + (1 - \alpha) * BM25_{score} \quad (3)$$

where α control the weights given to $SCQA$ and $BM25$ models. It range from 0 to 1. $SCQA$ with this improved similarity metric is called Siamese Convolutional Neural Network for cQA with Textual Similartity (*T-SCQA*). Figure 4 depicts the testing phase of *T-SCQA*. This model will give better performance in datasets with good mix of questions that are lexically and semantically similar. The value of α can be tuned according to the nature of dataset.

7 Experiments

We collected Yahoo! Answers dataset from Yahoo! Labs Webscope[11]. Each question in the dataset contains title, description, best answer, most voted answers and meta-data like categories, sub categories etc. For training dataset, we randomly selected 2 million data and extracted question-relevant answer pairs and question-irrelevant answer pairs from them to train $SCQA$. Similarly, our validation dataset contains 400,000 question answer pairs. The hyperparameters of the network are tuned on the validation dataset. The values of the hyperparameters for which we obtained the best results is shown in Table 1.

We used the annotated survey dataset of 1018 questions released by Zhang *et al.* (2014) as testset for all the models. On this gold data, we evaluated the performance of the models with three evaluation criteria: Mean Average Precision (MAP), Mean Reciprocal Rank (MRR) and Precision at K (P@K).

Each question and answer was pre-processed by lower-casing, stemming, stopword and special character removal.

7.1 Parameter Sharing

In order to find out whether parameter sharing helps in the present task we build two models named Deep Structured Neural Network for Community Question Answering($DSQA$) and Deep Structured Neural Network for Community Question Answering with Textual Similarity *T-DSQA*. $DSQA$ and *T-DSQA* have the same architecture as $SCQA$ and *T-SCQA* with the exception that in

the former models weights are not shared by the convolutional sub-networks. The weightage α for controlling corresponding scores of $SCQA$ and $BM25$ for the model *T-SCQA* was tuned on the validation set.

8 Results

We did a comparative study of the results of the previous methods with respect to $SCQA$ and *T-SCQA*. The baseline performance is shown by query likelihood language model (LM). For the translation based methods $translation(word)$, $translation+LM$ and $translation(phrase)$ we implemented the papers by Jeon *et al.* (2005), Xue *et al.* (2008), Zhou *et al.* (2011) respectively. The first paper deals with word based translation, the second enhanced the first by adding language model to it and the last paper implements phrase based translation method to bridge lexical gap. As seen from Table 2, the translation based methods outperforms the baseline significantly. The models are trained using GIZA++[12] tool with the question and best answer pair as the parallel corpus. For the topic based *Q-A topic model* and $Q\text{-}A\ topic\ model(s)$, we implemented the models $QATM\text{-}PR$ (Question-Answer Topic Model) Ji *et al.*(2012) and $TBLM_{SQATM-V}$ (Supervised Question-Answer Topic Model with user votes as supervision) Zhang *et al.* (2014) respectively. Again it is visible from the Table 2 that topic based approaches show slight improvement over translation based methods but they show significant improvement over baseline. The models $DSQA$ and *T-DSQA* were built using convolutional neural sub-networks joined by a distance measure at the top. There is no sharing of parameters involved between the sub-networks of these models. It is clear from the comparison of results between *T-DSQA* and *T-SCQA* that parameter sharing definitely helps in the task of similar question retrieval in cQA forums. *T-SCQA* outperforms all the previous approaches significantly.

8.1 Quantitative Analysis

$SCQA$ and *T-SCQA* learns the semantic relationship between the question and their best and most voted answers. It is observed that by varying the weights of $SCQA$ and $BM25$ scores, the value of MAP changes significantly (Figure 5). The weight is tuned in the validation dataset. We trained our model for several epochs and observed how the results varied with the epochs. We found that the evaluation metrics changed with increasing the number of epochs but became saturated after epoch 60. The comparison of evaluation metrics with epochs can be visualised in Figure 3.

The comparisons $SCQA$ and *T-SCQA* with the previously proposed models is shown in Table 2. For baseline we considered the traditional language model $LMIR$. The results in the table are consistent with the literature which says translation based models outperform the baseline methods and topic based approaches outperform the translational methods. Also, it is observed that deep learning based solution with parameter sharing is more helpful for this task than without parameter sharing. Note, that the results of previous models stated in Table 2 differ from the original

[12] http://www.statmt.org/moses/giza/GIZA++.html

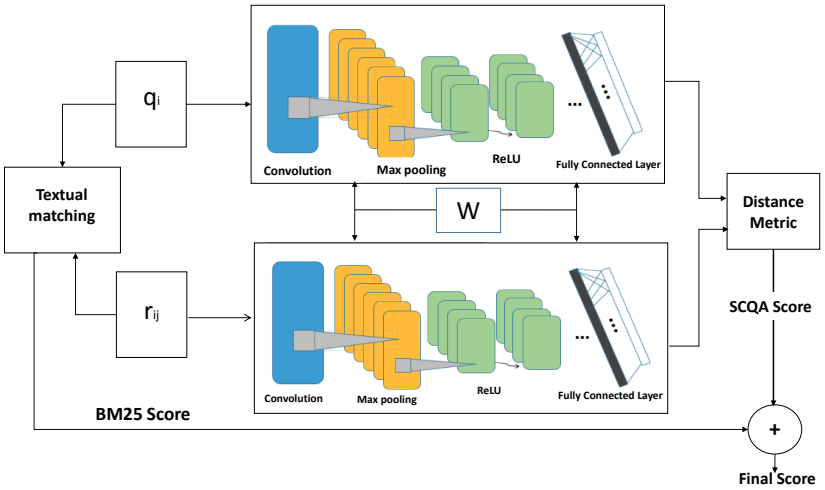

Figure 4: Testing phase of *T-SCQA*. Here the q_i is the i^{th} query and r_{ij} is the j^{th} question retrieved by q_i. The twin CNN networks share the parameters ($\mathbf{W}$) with each other. The connecting distance metric layer outputs the $SCQA$ score and the textual matching module outputs the $BM25$ score. The weighted combination of these scores give the final score. r_{ij} is stated similar to the query q_i if the final score of the pair exceeds an appropriate threshold.

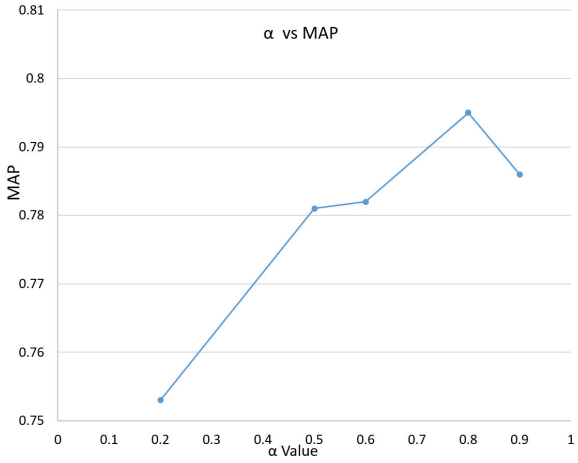

Figure 5: The variation of MAP with α.

papers since we tried to re-implement those models with our training data (to the best of our capability). Though we use the test data released by Zhang *et al.* (2014) we do not report their results in Table 2 due to the difference in training data used to train the models.

In the test dataset released by Zhang *et al.* (2014), there are fair amount of questions that possess similarity in the word level hence *T-SCQA* performed better than $SCQA$ for this dataset. *T-SCQA* gives the best performance in all evaluation measures. The results of *T-SCQA* in Table 2 uses the trained model at epoch 60 with the value of α as 0.8.

8.2 Qualitative Analysis

In Table 3 few examples are shown to depict how results of *T-SCQA* reflect strong semantic information when compared to other baseline methods. For Q1 we compare performance of *LMIR* and *T-SCQA*. *LMIR* outputs the question by considering word based similarity. It focuses on matching the words "how", "become", "naturally" *etc*, hence it outputs "How can I be naturally funny?" which is irrelevant to the query. On the other hand, $T-SCQA$ retrieves the questions that are semantically relevant to the query. For Q2 we compare the performance of *T-SCQA* with phrase based translation model (Zhou et al., 2011). The outputs of *translation(phrase)* model shows that the translation of "nursery" and "pre-school" to "day-care", "going to university" to "qualifications" are highly probable. The questions retrieved are semantically related, however asking craft ideas for pre-school kids for the event of mother's day is irrelevant in this context. The results of our model solely focuses on the qualifications, degrees and skills one needs to work in a nursery. For Q3 we compare the performance of *T-SCQA* with supervised topic model (Zhang et al., 2014). The questions retrieved by both the models revolve around the topic "effect of smoking on children". While the topic model retrieve questions which deal with smoking by mother and its effect on child, *T-SCQA* retrieve questions which deals not only with the affects of a mother smoking but also the effect of passive smoking on the child. For Q4 we com-

Query		Comment
Q1: How can I become naturally happy?		
$LMIR$	1.How can I be naturally happy? 2.How can I become naturally funny?	$LMIR$ performs word based matching using "how","become", "naturally" *etc.*
T-SCQA	1.Are some of us naturally born happy or do we learn how to become happy? 2.How can I become prettier and feel happier with myself?	
Q2: Do you need to go to university to work in a nursery or pre-school?		For *translation* (phrase) university->degree nursery->daycare are highly probable translations but craft ideas for daycare is irrelevant.
$translation$ $(phrase)$	1.What degree do you need to work in a nursery? 2. I work at a daycare with pre-school kids(3-5). Any ideas on crafts for mother's day?	
T-SCQA	1.Will my B.A hons in childhood studies put me in as an unqualified nursery nurse? 2.What skills are needed to work in a nursery, or learned from working in a nursery?	
Q3: Does smoking affect an unborn child?		Both models retrieve questions on topic "effect of smoking on children" but *T-SCQA* could retrieve based on passive smoking through father.
Q-A topic model(s)	1.How do smoking cigarettes and drinking affect an unborn child? 2.How badly will smoking affect an unborn child?	
T-SCQA	1.How does cigarette smoking and alcohol consumption by mothers affect unborn child? 2.Does smoking by a father affect the unborn child? If there is no passive smoking, then is it still harmful?	
Q4: How do I put a video on YouTube?		*T-DSQA* could not decipher "put". It relates "put" to download and transfer of videos while *T-SCQA* relates it to uploading videos.
T-DSQA	1.How can I download video from YouTube and put them on my Ipod? 2.I really want to put videos from YouTube to my Ipod..how?	
T-SCQA	1.How do I post a video on YouTube? 2.How can I make a channel on YouTube and upload videos on it? plz help me...	

Table 3: This table compares the qualitative performance of *T-SCQA* with *LMIR*, phrase based translation model *translation(phrase)*, supervised topic model *Q-A topic model(s)* and deep semantic model without parameter sharing *T-DSQA*. For queries Q1-4 *T-SCQA* show better performance than the previous models .

pare the performance of *T-SCQA* with *T-DSQA*. *T-DSQA* retrieves the questions that are related to downloading and transferring YouTube videos to other devices. Thus, *T-DSQA* cannot clearly clarify the meaning of "put" in Q4. However, the retrieved questions of *T-SCQA* are more aligned towards the ways to record videos and upload them in YouTube. The questions retrieved by *T-SCQA* are semantically more relevant to the query Q4.

9 Conclusions

In this paper, we proposed $SCQA$ for similar question retrieval which tries to bridge the lexico-syntactic gap between the question posed by the user and the archived questions. $SCQA$ employs twin convolutional neural networks with shared parameters to learn the semantic similarity between the question and answer pairs. Interpolating $BM25$ scores into the model *T-SCQA* results in improved matching performance for both textual and semantic matching. Experiments on large scale real-life "Yahoo! Answers" dataset revealed that T-SCQA outperforms current state-of-the-art approaches based on translation models, topic models and deep neural network based models which use non-shared parameters.

As part of future work, we would like to enhance SCQA with the meta-data information like categories, user votes, ratings, user reputation of the questions and answer pairs. Also, we would like to experiment with other deep neural architectures such as Recurrent Neural Networks, Long Short Term Memory Networks, *etc.* to form the sub-networks.

Abstract

In this work, we focus on the problem of news citation recommendation. The task aims to recommend news citations for both authors and readers to create and search news references. Due to the sparsity issue of news citations and the engineering difficulty in obtaining information on authors, we focus on content similarity-based methods instead of collaborative filtering-based approaches. In this paper, we explore word embedding (i.e., implicit semantics) and grounded entities (i.e., explicit semantics) to address the variety and ambiguity issues of language. We formulate the problem as a reranking task and integrate different similarity measures under the learning to rank framework. We evaluate our approach on a real-world dataset. The experimental results show the efficacy of our method.

1 Introduction

When an author writes an online news article, s/he often cites previously published news reports to elaborate a mentioned event or support his/her point of view. For the convenience of the readers, the editor usually associates the words with hyperlinks. Through the links the readers can directly access the referenced articles to know more details about the events. If there is no reference for a mentioned event, the readers may search the related news reports for further reading. Hence, it is valuable to have automatic news citation recommendations for authors and readers to create or search news references.

In this paper, we focus on the problem of *news citation recommendation*. As shown in Table 1, given a snippet of citing context (left), the task aims to retrieve a list of news articles (right) as references. This task differs from traditional recommendation tasks, e.g., citation recommendation for scientific papers, in that: (a) based on the statistics from our dataset, the number of references per news article is 4.56 on average, much less than the number of citations per academic paper (typically dozens); (b) the author-topic information is usually unavailable, since it is technically difficult to obtain author information from news articles. These differences make the collaborative filtering-based methods, which have been widely applied to paper citation recommendation, less available in our scenario. Therefore, in this paper we focus on content similarity-based methods to deal with the task of news citation recommendation.

Previous studies use string-based overlap (Xu et al., 2014), machine translation measures (Madnani et al., 2012), and dependency syntax (Wan et al., 2006; Wang et al., 2015) to model text similarity. More recent work focuses on neural network methods (Yin and Schütze, 2015; He et al., 2015; Hu et al., 2014; dos Santos et al., 2015; Lei et al., 2016). There are two major challenges rendering these approaches not suitable for this task: (i) the variety and (ii) the ambiguity of language. By variety, we mean that the same meaning may be expressed with different phrases. Taking the first row in Table 1 for example, *Vlaar* in the citing context refers to *Ron Vlaar*, a Dutch football player, who is referred to as *Dutch star* and *Netherlands international* in the cited article. By ambiguity, we mean that the same expression may have different meanings in different contexts. In the second example in Table 1, the mention *tiger* refers to *tiger the mammal*. By contrast, in "Detroit Tigers links: The Tigers are in trouble" for example, the word *Tiger* is the name of a team. In this paper, we explore both implicit and explicit semantics to ad-

Table 1: Two pair of news snippets. For readability concerns, we keep only the sentence associated with an anchor link in the citing part, and the **title** and lead paragraph of the cited part.

dress the above issues. Specifically, the implicit semantics can be obtained from the word embedding trained on large scale corpus, and the explicit semantics through linking entity mentions to the grounded entities in a knowledge base.

In this paper, we explore using both word embedding and grounded knowledge to model the relatedness between citing context and articles. We formulate the problem as a re-ranking task. We use learning to rank to integrate different similarity measures and evaluate the models on a real world dataset constructed from Bing News[1]. We further give quantitative analysis of the effects of word embedding and grounded entities in the task.

In summary, the main contributions of this paper are three-fold:

- We propose the task of *news citation recommendation* and construct a real-world dataset for this task.
- We utilize both word embedding based similarity measures and knowledge-based methods to tackle the problem. We formulate the problem as a re-ranking task and leverage learning to rank algorithm to integrate different similarity measures.
- We conduct extensive experiments on a large dataset. The results show the effectiveness of word embedding and grounded entities. We further quantitatively analyze how the implicit semantics from word embedding and explicit semantics from grounded knowledge benefit the task of interest.

2 Problem Formulation

In this section, we introduce the *news citation recommendation* problem and formulate it as a re-ranking task. We first introduce definitions that will be used through the rest of the paper:

Citing Context. *Citing context* is a sentence which contains an anchor text associated with a hyperlink. As shown in Table 1, the underlined words are associated with a hyperlink pointing to another news article, and the sentence (left) which contains the anchor is the citing context.

Cited Article. Given a piece of citing context, the article that the hyperlink links to is defined as its *cited article*. It is expected that a news article is well-structured, and its headline together with its lead paragraph gives a good brief description of the whole story (Kianmehr et al., 2009). In this paper, a news article can either be represented by its title and lead paragraph or by the passage as a whole. We conduct experiments under both of the two different settings.

Candidate Article Set. Considering efficiency, we follow the procedure adopted by many recommendation systems (Lei et al., 2016; Tan et al., 2015) and formulate the problem as a re-ranking task. In another word, given a citing context, we first use efficient retrieval methods with high recall to generate a list of articles as the *candidate article set*, and then run the system to get a re-ranked list.

News Citation Recommendation. Given a citing context, the task aims to construct an ordered list of news articles, top of which are most relevant to the context, and can serve as the cited articles.

3 Method

In this section, we first explain the similarity measures based on word embedding (implicit semantics) and grounded knowledge (explicit semantics) to deal with variety and ambiguity problems. Then we briefly introduce the baselines and the learning to rank framework.

3.1 Implicit Semantics for Variety

The distributed word representation by *word2vec* factors word distance and captures semantic similarities through vector arithmetic (Mikolov et al., 2013). In this work, we train a skip-gram model to bridge the vocabulary gap between context-article pairs. Previous work represents the documents with averaged vectors of words (Tang et al., 2014; Tan et al., 2015). However, this may lead to the loss of detailed information of the documents. In this paper, we adopt a different approach, explained below.

Word Mover's Distance (WMD). Kusner et al. (2015) combine distributed word representations with the earth mover's distance (EMD) (Rubner et al., 1998; Wan, 2007) to measure the distance between documents. They use the Euclidean distance between words' low dimensional representations as building blocks, and optimize a special case of the EMD to obtain the cumulative distance. More formally, let $X = \{(x_1, w_{x_1}), (x_2, w_{x_2}), \cdots, (x_m, w_{x_m})\}$ be the normalized bag-of-words representation for a citing context after removing stop-words, where word x_i appears w_{x_i} times (then normalized by the total count of words in X), $i = 1, 2, \cdots, m$. Similarly, we have the representation for a candidate article, $Y = \{(y_1, w_{y_1}), (y_2, w_{y_2}), \cdots, (y_n, w_{y_n})\}$. The WMD calculates the minimum cumulative cost by solving the linear programming problem below:

$$\min_{\mathbf{T}} \sum_{i=1}^{m} \sum_{j=1}^{n} \mathbf{T}_{ij} c_{ij}$$

$$s.t. \quad \sum_{j=1}^{n} \mathbf{T}_{ij} = w_{x_i}, \quad i = 1, 2, \cdots, m,$$

$$\sum_{i=1}^{m} \mathbf{T}_{ij} = w_{y_j}, \quad j = 1, 2, \cdots, n,$$

where $\mathbf{T} \in \mathbb{R}^{m \times n}$ is the transportation flow matrix, and c_{ij} indicates the distance between x_i and y_j. Here $c_{ij} = \|\mathbf{vector}(x_i) - \mathbf{vector}(y_j)\|$, where function $\mathbf{vector}(w)$ returns the word vector of w. Then the distance is normalized by the total flow:

$$WMD(X, Y) = \frac{\sum_{i=1}^{m} \sum_{j=1}^{n} \mathbf{T}_{ij} c_{ij}}{\sum_{i=1}^{m} \sum_{j=1}^{n} \mathbf{T}_{ij}}$$

3.2 Explicit Semantics for Ambiguity

News articles tend to be well written, and contain many named entity mentions. Making use of this property, we deal with the ambiguity problem by using grounded entities (explicit semantics). Given a context-article pair, we first recognize all named entity mentions on both sides and link them to knowledge bases (e.g., Wikipedia and Freebase), then use the following measures to model the similarity.

- **Entity Overlap.** Given a context–article pair, we consider two metrics, namely, $precision$ and $recall$, to measure their entity overlap. The $precision$ is defined as:

$$precision = \frac{entity\text{-}overlap(citing, cited)}{entity\text{-}count(citing)}$$

and $recall$ as:

$$recall = \frac{entity\text{-}overlap(citing, cited)}{entity\text{-}count(cited)}$$

- **Embedding Based Matching.** We build two separate information networks for Wikipedia entities using (a) the anchor links on Wikipedia pages and (b) the Freebase entity graph (Bollacker et al., 2008). Then we apply Large-scale Information Network Embedding (LINE) (Tang et al., 2015) system[2] to the networks to embed the entities into low-dimensional spaces. We then measure the similarity by the minimized cosine distance between entities' on the citing and the cited side:

$$minDIS_{citing} = \frac{1}{|citing|} \sum_{i=1}^{|citing|} \min_{y_j \in Y} (1 - cos(x_i, y_j)),$$

and vice versa:

$$minDIS_{cited} = \frac{1}{|citied|} \sum_{j=1}^{|cited|} \min_{x_i \in X} (1 - cos(x_i, y_j)),$$

where X refers to the citing context, and $x_i \in X$ are the grounded entities in the citing part. Similar with Y and y_j.

[2] https://github.com/tangjianpku/LINE

- **Wikipedia Evidence.** Given a context-article pair, we refer to world knowledge for supporting evidence. In particular, we first apply an entity linking system to detect the entity mentions on both sides and ground them into Wikipedia entries, each of which has its own description page. Second, we collect the descriptions for entities from the candidate article and extract as evidence those sentences containing entities from citing context. We refer to this evidence as *cited evidence*. For instance, the article in Table 8 contains grounded entity *Scottish National Party*. And in the description for it, there is a sentence containing the entity *Scotland* from the citing context: "The Scottish National Party (SNP) is a Scottish nationalist and social-democratic political party in *Scotland*." Thus we extract this sentence as cited evidence supporting this pair.
  We count the overlapping nouns between the citing context and the cited evidence to calculate $precision$ and $recall$,

$$precision = \frac{noun\text{-}overlap(context, cited\ evidence)}{noun\text{-}count(context)}$$

$$recall = \frac{noun\text{-}overlap(article, citing\ evidence)}{noun\text{-}count(article)}$$

3.3 Baselines

We design several baseline features for the two groups of features mentioned above:

- **TF-IDF Distance.** We use TF-IDF distance as a basic measure. The similarity is calculated with cosine distance based on TF-IDF vector representations for the text.
- **Ungrounded Mentions.** Note that entity overlap features also adapt to ungrounded mentions. The embedding-based matching features for ungrounded mentions are similar to those for grounded entities. The only difference is that here each mention is represented by the averaged vectors of all the words it contains. Wikipedia evidence is not feasible for ungrounded mentions.

Table 2 summarizes all the features we use. A cited article can either be represented by its headline+lead paragraph or as a whole. Therefore, we extract features under two different settings: (a) headlines and lead paragraphs only; (b) the full articles. Most of the features are extracted under both of the settings. However, feature 2 is much too computation-intensive and feature 7 needs POS-tagging as the preprocessing. Thus these two are only extracted under setting (a).

3.4 Learning to Rank Framework

Many different learning to rank algorithms have been proposed to deal with the ranking problem, including pointwise, pairwise, and listwise approaches (Xia et al., 2008). Listwise methods receive ranked lists as training samples, and directly optimize the metric of interest by minimizing the respective cost. And it has been reported that the listwise method usually achieves better performance compared to others (Qin et al., 2008; Cao et al., 2007). In this work, we use the linear model and apply coordinate ascent for parameter optimization.

4 Experiments

4.1 Data Collection

We collect one month's news articles from Bing News. The citing context set consists of all the sentences associated with anchor link(s). For each piece of citing context, its cited article is extracted through its hyperlink. If there are multiple links associated with the context, only the first one is considered. We pair each citing context and its cited article as a ground truth sample. We further label as ground truths those articles sharing the same title as the cited article. This is rather reasonable since a single passage may have multiple reprints by difference sources. On average, there are 2.20 ground truth cited articles for each citing context in the dataset.

In order to focus only on news events, we filter out those pairs whose hyperlinks are associated with three words or less (usually names for persons or places, and lead to definition pages). We also discard those samples whose citing contexts contain or are exactly the same as the titles of the cited articles. For example, "READ MORE: The stories you need to read, in one handy email" links to an article titled "The stories you need to read, in one handy email".

The dataset is preprocessed with Stanford CoreNLP toolkit (Manning et al., 2014), including sentence splitting, tokenizing for whole passages, and POS-tagging for titles and lead paragraphs. We use the JERL system by Luo et al. (2015) for entity detection and grounding. It recognizes entity mentions and links them to Wikipedia entries.

6	Ungrounded Mention Overlap	y	4	Precision and recall for ungrounded mentions.
7	Embedding-based Matching	y	4	Minimized matching distance with averaged vectors.
Total			33	

Table 2: A list of all features used in the experiments. The third column indicates whether the corresponding feature is extracted from the full articles. If not, it's extracted only from the headlines and lead paragraphs.

We use each mention's text span as an ungrounded mention, and its corresponding Wikipedia ID as a grounded entity. For instance, in Table 8, the detected text span *Westminster* is an ungrounded mention, and it's grounded to the entry *Parliament of the United Kindom*.

4.2 Selecting Candidates

Given a citing context, we construct its candidate article set with the top 200 articles retrieved by TF-IDF distance. In the experiments, approximately 92.61% of the ground truth cited articles appear in the candidate sets. We discard those that do not. We further randomly split the remaining 33318 pairs into training/validation/test sets with the proportion of 3:1:1.

For each training pair, we randomly sample 5 articles from its candidate article set (excluding ground truth) and pair them with the citing context as negative samples. According to Tan et al. (2015), the number of negative samples does not significantly affect the linear learning to rank model's performance. During validation and testing, all of the 200 candidates are taken into account.

4.3 Experimental Setup

In the experiments, we set the TF-IDF as the baseline, and incrementally add different groups of features to the system.

The word embedding is pretrained with skip-gram model (Mikolov et al., 2013) on Wikipedia corpus and then fine-tuned using the method proposed in Wieting et al. (2015) on PPDB (Ganitkevitch et al., 2013). The embedding fine-tuned with paraphrase pairs can better capture the semantic relatedness of different phrase. In the experiments, we observe a $1\% - 2\%$ improvement by the fine-tuned word representations compared to vanilla skip-gram vectors.

We use the linear model in RankLib[3] for the learning to rank implementation. Coordinate ascent is used for parameter optimization. The model is trained to directly optimize the evaluation metrics, Precision@1, Precision@5, NDCG@5 and MAP, respectively.

For NDCG@5 measure, we set a binary relevance score, i.e., the scores equal to 1 for ground truths, 0 for negative samples.

4.4 Experimental Results

Table 3 gives the performance of the baselines and the systems using different groups of features on test and validation sets. The results show that WMD brings a consistent improvement over its TF-IDF baseline, and so do grounded entities compared to ungrounded mentions.

Individually added to the TF-IDF baseline, WMD has the largest performance boost, followed by grounded entity features. Besides, the additional information from grounded entity knowledge helps the model outperform the ungrounded mentions, with a consistent margin of 1.0%-2.0% NDCG@5.

We further compare the performance of the models when using features from headlines+lead paragraphs only and those from full passages. As shown in Table 3, the former brings much better performance on each metric compared to the latter.

It's worth noting that there are ground truths mis-labeled as irrelevant in the dataset. A primary

8	+ Ungrounded+Grounded	**58.05**	**61.78**

Table 4: Experimental results in percentage on $\mathbf{S}$ and $\tilde{\mathbf{S}}$. $\mathbf{S}$ is a randomly constructed subset of the test set, and $\tilde{\mathbf{S}}$ is obtained by manually labeling samples in $\mathbf{S}$.

reason is that news sites sometimes individually publish different reports on a certain event. And the articles don't necessarily share the same title. To see how this affects the model, we randomly build a subset $\mathbf{S}$ of the test set and manually label the selected samples, which gives $\tilde{\mathbf{S}}$[4]. Table 4 compares the model's performance on $\mathbf{S}$ and $\tilde{\mathbf{S}}$ under Headline+Lead paragraph setting. There is a consistent improvement of NDCG@5 score on $\tilde{\mathbf{S}}$ compared to that on $\mathbf{S}$. Besides that, on manually labeled data, the model's performance across different feature settings is almost in accord with that on the full test set. These results show that there are indeed mis-labeled ground truths in the dataset, but they have little influence when comparing different groups of features.

[4]Manually labeling all of the dev and test samples would be too time consuming, and we leave it to future work.

5 Analysis

In this section, we give detailed win-loss analysis for the models trained with NDCG@5 metric under headlines+lead paragraphs setting. Specifically, given two systems with different feature configurations, we compare their performance on each test sample. The results are shown as a heatmap in Figure 1. X and Y axises indicate the identifiers for each feature group, following those in Table 3. For example, the data point at $(5, 1)$ indicates that the inclusion of WMD brings better ranking scores to TF-IDF on 18.4% of the test samples; and as a trade off, it lowers the scores on 11.4% of the samples. We also observe that grounded entities brings gain to 15.9% of the samples, and loss for 9.6% of them. On average, two different groups of features disagree on 26.4% of the test samples.

We further give several mis-predictions by the model using certain groups of features, and illustrate how they are corrected by the inclusion of others (or the other way round). By mis-prediction, we mean that no ground truth cited article appears in the top 5 predictions of the returned list.

5.1 Dealing with Variety

Table 5 shows a mis-prediction by TF-IDF, but corrected after including WMD.

TF-IDF distance favors the high-score match-

ing keywords *approval* and *rating* between the citing context and mis-predicted article. On the other hand, distributed word representations factor the distances between word pairs, which helps to capture their semantic closeness, e.g., (*Argentines*, *Argentina*, Cosince distance: 0.210), (*poll*, *election*, 0.020), and (*increasingly*, *growing*, 0.286). WMD helps to bridge the vocabulary gap between the citing context and the cited article.

On the other hand, though not often, the use of distributed representation can also create mistakes. Table 6 gives an example where the inclusion of the WMD feature changes a correct prediction by TF-IDF into a mistake. By analyzing the WMD's transportation flow matrix **T**, we find that the used word embedding relates *MP* to *minister*, and *publicly* to *government*. More curiously, persons' names are very similar in its semantic space: (*Davies*, *Stephen*, 0.602), and (*Davies*, *Harper*, 0.635). A possible reason could be that both of the two names are very common, and thus the cooccurrence-based representation learning method is not able to distinguish them. This also justifies our use of grounded entities as additional information: from the Wikipedia description for entity *Stephen Harper*, the system might be able to find out that he actually serves in Canadian government, not in the UK's nor in the Welsh.

5.2 Dealing with Ambiguity

Entity grounding helps by resolving the ambiguity e.g., alias, abbreviation, of the entity mentions.

As shown in Table 7, *tiger* refers to *the mammal* in the ground truth pair. However, the same word refers to *Detroit Tigers the team* in the mis-predicted article. This ambiguity is resolved when the mention is grounded to its Wikipedia entry. In another example shown in Table 8, ungrounded mention *SNP*, though detected, contributes little to supporting the ground truth pair. However, when it's grounded to the entry *Scottish National Party*, the system leverages world knowledge and relates it to the mention of *Scotland* in the citing context.

The inclusion of grounded entity information may also lead to mistakes, many of which are due to the limited performance of the entity recognition and disambiguation system. We'd like to discuss another kind of error here, shown in Table 9. In the citing context, *The Daily Telegraph* is a newspaper published in the UK. It has little to do with the involved event except for reporting it. However, the system favors a farmers' story which

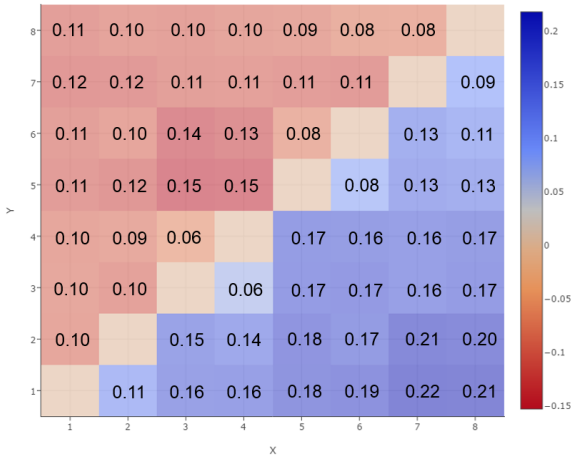

Figure 1: Heatmap for win-loss analysis results. Point (x, y) indicates how much feature x wins (loses if negative) against y.The X and Y axises indicate the identifiers for each feature group, following those in Table 3.

actually happened in the UK. We find that this contributes a lot to the system's errors when including grounded entities. We leave it to future work to figure out how to deal with this issue.

6 Related Work

This section reviews three lines of related work: (i) document recommendation, (ii) pharaphrase identification, (iii) question retrieval.

6.1 Document Recommendation

Existing literature mainly focuses on content-based methods and collaborative filtering (Adomavicius and Tuzhilin, 2005). There are studies trying to recommend documents based on citation contexts, either through identifying the motivations of the citations (Aya et al., 2005), or through the topical similarity (Ritchie, 2008; Ramachandran and Amir, 2007). On the other hand, Mcnee et al. (2002) leverage multiple information sources from authorship, paper-citation relations, and co-citations to recommend research papers.

Combining the context-based approaches and collaborative filtering, Torres et al. (2004) and Strohman et al. (2007) report better performance. Tang and Zhang (2009) use the Restricted Boltzmann Machine to model citations for placeholders, and Tan et al. (2015) integrate multiple features to recommend quotes for writings.

In the news domain, context-based approaches are presumably favorable due to the fact that the articles are relatively content-rich and citation-sparse. Previous studies manage to utilize information retrieval techniques to recommend news articles given a seed article (Yang et al., 2009; Bogers and van den Bosch, 2007).

Sides	–	Samples
citing	–	An earlier poll showed Argentines are also increasingly happy with her performance as President, putting her approval rating at almost 43%, up from 31% in September.
cited	Ground Truth	**Kirchner's Growing Popularity Could Skew Argentine Election** As Argentina gears up for a presidential election in October, the approval ratings of the current president, Cristina Kirchner, are improving and her rising reputation could affect the results of the election to replace her.
	Top-1 Prediction	**Bill Shorten's Approval Rating Falls in Wake of Royal Commission** The opposition leader gained approval from only 27% of the voters surveyed, while 52% disapproved.

6.2 Paraphrase Identification

Several hand-crafted features have proven helpful in modeling sentence/phrase similarity, e.g., string-based overlap (Xu et al., 2014), machine translation measures (Madnani et al., 2012), and dependency syntax (Wan et al., 2006; Wang et al., 2015). Using the combination and discriminative re-weighting of the mentioned features, Ji and Eisenstein (2013) manage to obtain more competitive results.

More recent work has switched the focus onto neural methods. Socher et al. (2011) recursively encode the representations of sentences by the compositions of words. Convolutional neural nets (LeCun et al., 1998; Collobert and Weston, 2008) are also exploited in the tasks of paraphrase identification and sentence matching (Yin and Schütze, 2015; He et al., 2015; Hu et al., 2014).

Story link detection (SLD) is a similar task which aims to classify whether two news stories discuss the same event. Farahat et al. (2003) leverage part of speech tagging technique as well as task-specific similarity measures to boost the system's performance. Shah et al. (2006) show that entity based document representation is a better choice compared to word-based representations in SLD. In our scenario, the query is typically a piece of context sentence instead of an entire article. Therefore, we find that document level methods yield sub-optimal performance when used to model the similarity of citing context and the articles. Besides, due to the fact that there might be multiple reports for a single event, we consider it reasonable to formulate our problem into a ranking task instead of classification.

6.3 Question Retrieval

The key problem in question retrieval lies in modeling questions' similarity. Machine translation techniques (Jeon et al., 2005) and topic models (Duan et al., 2008) have been utilized by previous works. An alternative is representation learning. Zhou et al. (2015) use category-based meta-data to learn word embeddings. dos Santos et al. (2015) and Lei et al. (2016) obtain superior performance over hand-crafted features with CNN.

News articles are more well-written than most documents in QA communities, which results in the feasibility of high-quality entity detection and grounding.

7 Discussions

In this paper, we propose a novel problem of *news citation recommendation*, which aims to recommend news citations for references based on a citing context. We develop a re-ranking system leveraging implicit and explicit semantics for content similarity. We construct a real-world dataset. The experimental results show the efficacy of our approach.

Grapheme-to-Phoneme Models for (Almost) Any Language

Aliya Deri and Kevin Knight
Information Sciences Institute
Department of Computer Science
University of Southern California
{aderi, knight}@isi.edu

Abstract

Grapheme-to-phoneme (g2p) models are rarely available in low-resource languages, as the creation of training and evaluation data is expensive and time-consuming. We use Wiktionary to obtain more than 650k word-pronunciation pairs in more than 500 languages. We then develop phoneme and language distance metrics based on phonological and linguistic knowledge; applying those, we adapt g2p models for high-resource languages to create models for related low-resource languages. We provide results for models for 229 adapted languages.

1 Introduction

Grapheme-to-phoneme (g2p) models convert words into pronunciations, and are ubiquitous in speech- and text-processing systems. Due to the diversity of scripts, phoneme inventories, phonotactic constraints, and spelling conventions among the world's languages, they are typically language-specific. Thus, while most statistical g2p learning methods are language-agnostic, they are trained on language-specific data—namely, a pronunciation dictionary consisting of word-pronunciation pairs, as in Table 1.

Building such a dictionary for a new language is both time-consuming and expensive, because it requires expertise in both the language and a notation system like the International Phonetic Alphabet, applied to thousands of word-pronunciation pairs. Unsurprisingly, resources have been allocated only to the most heavily-researched languages. GlobalPhone, one of the most extensive multilingual text and speech databases, has pronunciation dictionaries in only 20 languages (Schultz et al., 2013)[1].

[1]We have been unable to obtain this dataset.

lang	word	pronunciation
eng	anybody	ẹ n iː b ɒ d iː
pol	żołądka	ʐ�o w o n̪ t̪ k a
ben	শাক	ʂ ɔ k ʈ ɔ
heb	חלומות	ʁ a l o m o t

Table 1: Examples of English, Polish, Bengali, and Hebrew pronunciation dictionary entries, with pronunciations represented with the International Phonetic Alphabet (IPA).

word	eng	deu	nld
gift	g ɪ f t^{h}	g ɪ f t	ɣ ɪ f t
class	k^{h} l æ s	k l aː s	k l ɑ s
send	s ẹ n d	z ɛ n t	s ɛ n t

Table 2: Example pronunciations of English words using English, German, and Dutch g2p models.

For most of the world's more than 7,100 languages (Lewis et al., 2009), no data exists and the many technologies enabled by g2p models are inaccessible.

Intuitively, however, pronouncing an unknown language should not necessarily require large amounts of language-specific knowledge or data. A native German or Dutch speaker, with no knowledge of English, can approximate the pronunciations of an English word, albeit with slightly different phonemes. Table 2 demonstrates that German and Dutch g2p models can do the same.

Motivated by this, we create and evaluate g2p models for low-resource languages by adapting existing g2p models for high-resource languages using linguistic and phonological information. To facilitate our experiments, we create several notable data resources, including a multilingual pronunciation dictionary with entries for more than 500 languages.

The contributions of this work are:

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 399–408,
Berlin, Germany, August 7-12, 2016.

- Using data scraped from Wiktionary, we clean and normalize pronunciation dictionaries for 531 languages. To our knowledge, this is the most comprehensive multilingual pronunciation dictionary available.
- We synthesize several named entities corpora to create a multilingual corpus covering 384 languages.
- We develop a language-independent distance metric between IPA phonemes.
- We extend previous metrics for language-language distance with additional information and metrics.
- We create two sets of g2p models for "high resource" languages: 97 simple rule-based models extracted from Wikipedia's "IPA Help" pages, and 85 data-driven models built from Wiktionary data.
- We develop methods for adapting these g2p models to related languages, and describe results for 229 adapted models.
- We release all data and models.

2 Related Work

Because of the severe lack of multilingual pronunciation dictionaries and g2p models, different methods of rapid resource generation have been proposed.

Schultz (2009) reduces the amount of expertise needed to build a pronunciation dictionary, by providing a native speaker with an intuitive rule-generation user interface. Schlippe et al. (2010) crawl web resources like Wiktionary for word-pronunciation pairs. More recently, attempts have been made to automatically extract pronunciation dictionaries directly from audio data (Stahlberg et al., 2016). However, the requirement of a native speaker, web resources, or audio data specific to the language still blocks development, and the number of g2p resources remains very low. Our method avoids these issues by relying only on text data from high-resource languages.

Instead of generating language-specific resources, we are instead inspired by research on cross-lingual automatic speech recognition (ASR) by Vu and Schultz (2013) and Vu et al. (2014), who exploit linguistic and phonetic relationships in low-resource scenarios. Although these works focus on ASR instead of g2p models and rely on audio data, they demonstrate that speech technology is portable across related languages.

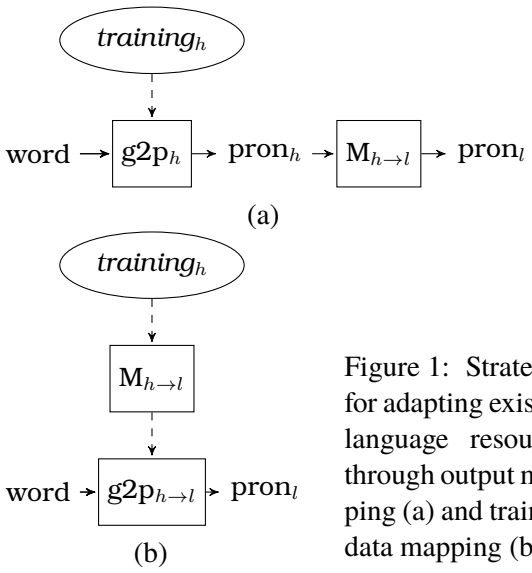

Figure 1: Strategies for adapting existing language resources through output mapping (a) and training data mapping (b).

3 Method

Given a low-resource language l without g2p rules or training data, we adapt resources (either an existing g2p model or a pronunciation dictionary) from a high-resource language h to create a g2p for l. We assume the existence of two modules: a phoneme-to-phoneme distance metric `phon2phon`, which allows us to map between the phonemes used by h to the phonemes used by l, and a closest language module `lang2lang`, which provides us with related language h.

Using these resources, we adapt resources from h to l in two different ways:

- Output mapping (Figure 1a): We use g2p$_h$ to pronounce word$_l$, then map the output to the phonemes used by l with `phon2phon`.
- Training data mapping (Figure 1b): We use `phon2phon` to map the pronunciations in h's pronunciation dictionary to the phonemes used by l, then train a g2p model using the adapted data.

The next sections describe how we collect data, create phoneme-to-phoneme and language-to-language distance metrics, and build high-resource g2p models.

4 Data

This section describes our data sources, which are summarized in Table 3.

4.1 Phoible

Phoible (Moran et al., 2014) is an online repository of cross-lingual phonological data. We use

<table>
<tr><td>Phoible</td><td>Wiki IPA Help tables</td><td colspan="2">Wiktionary</td></tr>
<tr><td>1674 languages
2155 lang. inventories
2182 phonemes
37 features</td><td rowspan="4">97 languages
24 scripts
1753 graph. segments
1534 phon. segments
3389 unique g-p rules</td><td colspan="2">531 languages
49 scripts
658k word-pron pairs</td></tr>
<tr><td>NE data</td><td>Wiktionary train</td><td>Wiktionary test</td></tr>
<tr><td>384 languages
36 scripts
9.9m NEs</td><td>85 languages
42 scripts
629k word-pron pairs</td><td>501 languages
45 scripts
26k word-pron pairs</td></tr>
</table>

Table 3: Summary of data resources obtained from Phoible, named entity resources, Wikipedia IPA Help tables, and Wiktionary. Note that, although our Wiktionary data technically covers over 500 languages, fewer than 100 include more than 250 entries (Wiktionary train).

two of its components: language phoneme inventories and phonetic features.

4.1.1 Phoneme inventories

A phoneme inventory is the set of phonemes used to pronounce a language, represented in IPA. Phoible provides 2156 phoneme inventories for 1674 languages. (Some languages have multiple inventories from different linguistic studies.)

4.1.2 Phoneme feature vectors

For each phoneme included in its phoneme inventories, Phoible provides information about 37 phonological features, such as whether the phoneme is nasal, consonantal, sonorant, or a tone. Each phoneme thus maps to a unique feature vector, with features expressed as `+`, `-`, or `0`.

4.2 Named Entity Resources

For our language-to-language distance metric, it is useful to have written text in many languages. The most easily accessible source of this data is multilingual named entity (NE) resources.

We synthesize 7 different NE corpora: Chinese-English names (Ji et al., 2009), Geonames (Vatant and Wick, 2006), JRC names (Steinberger et al., 2011), corpora from LDC[2], NEWS 2015 (Banchs et al., 2015), Wikipedia names (Irvine et al., 2010), and Wikipedia titles (Lin et al., 2011); to this, we also add multilingual Wikipedia titles for place names from an online English-language gazetteer (Everett-Heath, 2014). This yields a list of 9.9m named entities (8.9 not including English data) across 384 languages, which include the English translation, named entity type, and script information where possible.

4.3 Wikipedia IPA Help tables

To explain different languages' phonetic notations, Wikipedia users have created "IPA Help" pages,[3] which provide tables of simple grapheme examples of a language's phonemes. For example, on the English page, the phoneme z has the examples "**z**oo" and "ha**s**." We automatically scrape these tables for 97 languages to create simple grapheme-phoneme rules.

Using the `phon2phon` distance metric and mapping technique described in Section 5, we clean each table by mapping its IPA phonemes to the language's Phoible phoneme inventory, if it exists. If it does not exist, we map the phonemes to valid Phoible phonemes and create a phoneme inventory for that language.

4.4 Wiktionary pronunciation dictionaries

Ironically, to train data-driven g2p models for high-resource languages, and to evaluate our low-resource g2p models, we require pronunciation dictionaries for many languages. A common and successful technique for obtaining this data (Schlippe et al., 2010; Schlippe et al., 2012a; Yao and Kondrak, 2015) is scraping Wiktionary, an open-source multilingual dictionary maintained by Wikimedia. We extract unique word-pronunciation pairs from the English, German, Greek, Japanese, Korean, and Russian sites of Wiktionary. (Each Wiktionary site, while written in its respective language, contains word entries in multiple languages.)

[2]LDC2015E13, LDC2015E70, LDC2015E82, LDC2015E90, LDC2015E84, LDC2014E115, and LDC2015E91

[3]`https://en.wikipedia.org/wiki/Category:International_Phonetic_Alphabet_help`

Since Wiktionary data is very noisy, we apply length filtering as discussed by Schlippe et al. (2012b), as well as simple regular expression filters for HTML. We also map Wiktionary pronunciations to valid Phoible phonemes and language phoneme inventories, if they exist, as discussed in Section 5. This yields 658k word-pronunciation pairs for 531 languages. However, this data is not uniformly distributed across languages—German, English, and French account for 51% of the data.

We extract test and training data as follows: For each language with at least 1 word-pron pair with a valid word (at least 3 letters and alphabetic), we extract a test set of a maximum of 200 valid words. From the remaining data, for every language with 50 or more entries, we create a training set with the available data.

Ultimately, this yields a training set with 629k word-pronunciation pairs in 85 languages, and a test set with 26k pairs in 501 languages.

5 Phonetic Distance Metric

Automatically comparing pronunciations across languages is especially difficult in text form. Although two versions of the "sh" sound, "ʃ" and "ɕ," sound very similar to most people and very different from "m," to a machine all three characters seem equidistant.

Previous research (Özbal and Strapparava, 2012; Vu and Schultz, 2013; Vu et al., 2014) has addressed this issue by matching exact phonemes by character or manually selecting comparison features; however, we are interested in an automatic metric covering all possible IPA phoneme pairs.

We handle this problem by using Phoible's phoneme feature vectors to create `phon2phon`, a distance metric between IPA phonemes. In this section we also describe how we use this metric to clean open-source data and build phoneme-mapping models between languages.

5.1 `phon2phon`

As described in Section 4.1.2, each phoneme in Phoible maps to a unique feature vector; each feature value is `+`, `-`, or `0`, representing whether a feature is present, not present, or not applicable. (Tones, for example, can never be syllabic or stressed.)

We convert each feature vector into a bit representation by mapping each value to 3 bits. `+` to `110`, `-` to `101`, and `0` to `000`. This captures the idea that the features `+` and `-` are more similar than `0`.

lang	word	scraped	cleaned
ces	jód	ˈjoːd	j o d
pus	څلور	t͡saˈlor	t s a l o r
kan	ಭಾರತ	bhārata	b h a ɾ a ṭ a
hye	օդապարր	otʰaˈpɑɾ	o̤ t̤ʰ a p a l̤
ukr	тарган	tɑrˈɦɑn	t̪ a ɾ̪ h a n̪

Table 4: Examples of scraped and cleaned Wiktionary pronunciation data in Czech, Pashto, Kannada, Armenian, and Ukrainian.

Data: all phonemes P, scraped phoneme set S, language inventory T

initialize empty table M;
for p_s *in* S **do**
  if $p_s \notin P$ *and* ASCII$(p_s) \in P$ **then**
    $p_s = \text{ASCII}(p_s)$;
  end
  $p_p = \min_{\forall_{p_t \in T}} (\texttt{phon2phon}(p_s, p_t))$;
  add $p_s \rightarrow p_p$ to M;
end

Algorithm 1: A condensed version of our procedure for mapping scraped phoneme sets from Wikipedia and Wiktionary to Phoible language inventories. The full algorithm handles segmentation of the scraped pronunciation and heuristically promotes coverage of the Phoible inventory.

We then compute the normalized Hamming distance between every phoneme pair $p_{1,2}$ with feature vectors $f_{1,2}$ and feature vector length n as follows:

$$\texttt{phon2phon}(p_1, p_2) = \frac{\sum_{i=1}^{n} 1, \text{if} f_1^i \neq f_2^i}{n}$$

5.2 Data cleaning

We now combine `phon2phon` distances and Phoible phoneme inventories to map phonemes from scraped Wikipedia IPA help tables and Wiktionary pronunciation dictionaries to Phoible phonemes and inventories. We describe a condensed version of our procedure in Algorithm 1, and provide examples of cleaned Wiktionary output in Table 4.

5.3 Phoneme mapping models

Another application of `phon2phon` is to transform pronunciations in one language to another language's phoneme inventory. We can do this by

lang	avg	phon	script
English	German	Latin	French
Hindi	Gujarati	Bengali	Sanskrit
Vietnamese	Indonesian	Sindhi	Polish

Table 5: Closest languages with Wikipedia versions, based on `lang2lang` averaged metrics, phonetic inventory distance, and script distance.

creating a single-state weighted finite-state transducer (wFST) W for input language inventory I and output language inventory O:

$$\forall_{p_i \in I, p_o \in O} W.\text{add}(p_i, p_o, 1 - \texttt{phon2phon}(p_i, p_o))$$

W can then be used to map a pronunciation to a new language; this has the interesting effect of modeling accents by foreign-language speakers: *think* in English (pronounced "θ ɪ ŋ k^h") becomes "s̪ ɛ ŋ k" in German; the capital city *Dhaka* (pronounced in Bengali with a voiced aspirated "d̪ʱ") becomes the unaspirated "d æ k^h æ" in English.

6 Language Distance Metric

Since we are interested in mapping high-resource languages to low-resource related languages, an important subtask is finding the related languages of a given language.

The URIEL Typological Compendium (Littell et al., 2016) is an invaluable resource for this task. By using features from linguistic databases (including Phoible), URIEL provides 5 distance metrics between languages: genetic, geographic, composite (a weighted composite of genetic and geographic), syntactic, and phonetic. We extend URIEL by adding two additional metrics, providing averaged distances over all metrics, and adding additional information about resources. This creates `lang2lang`, a table which provides distances between and information about 2,790 languages.

6.1 Phoneme inventory distance

Although URIEL provides a distance metric between languages based on Phoible features, it only takes into account broad phonetic features, such as whether each language has voiced plosives. This can result in some non-intuitive results: based on this metric, there are almost 100 languages phonetically equivalent to the South Asian language Gujarati, among them Arawak and Chechen.

To provide a more fine-grained phonetic distance metric, we create a phoneme inventory distance metric using `phon2phon`. For each pair of language phoneme inventories $L_{1,2}$ in Phoible, we compute the following:

$$d(L_1, L_2) = \sum_{p_1 \in L_1} \min_{p_2 \in L_2} (\texttt{phon2phon}(p_1, p_2))$$

and normalize by dividing by $\sum_i d(L_1, L_i)$.

6.2 Script distance

Although Urdu is very similar to Hindi, its different alphabet and writing conventions would make it difficult to transfer an Urdu g2p model to Hindi. A better candidate language would be Nepali, which shares the Devanagari script, or even Bengali, which uses a similar South Asian script. A metric comparing the character sets used by two languages is very useful for capturing this relationship.

We first use our multilingual named entity data to extract character sets for the 232 languages with more than 500 NE pairs; then, we note that Unicode character names are similar for linguistically related scripts. This is most notable in South Asian scripts: for example, the Bengali ক, Gujarati ક, and Hindi क have Unicode names `BENGALI LETTER KA`, `GUJARATI LETTER KA`, and `DEVANAGARI LETTER KA`, respectively.

We remove script, accent, and form identifiers from the Unicode names of all characters in our character sets, to create a set of reduced character names used across languages. Then we create a binary feature vector f for every language, with each feature indicating the language's use of a reduced character (like `LETTER KA`). The distance between two languages $L_{1,2}$ can then be computed with a spatial cosine distance:

$$d(L_1, L_2) = 1 - \frac{f_1 \cdot f_2}{\|f_1\|_2 \, \|f_2\|_2}$$

6.3 Resource information

Each entry in our `lang2lang` distance table also includes the following features for the second language: the number of named entities, whether it is in Europarl (Koehn, 2005), whether it has its own Wikipedia, whether it is primarily written in the same script as the first language, whether it has an IPA Help page, whether it is in our Wiktionary test set, and whether it is in our Wiktionary training set.

Table 5 shows examples of the closest languages to English, Hindi, and Vietnamese, according to different lang2lang metrics.

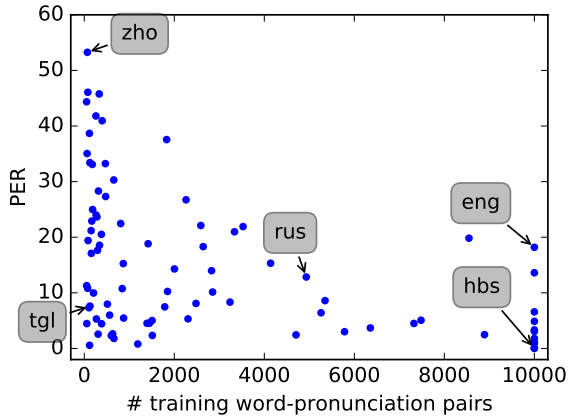

Figure 2: Training data size vs. PER for 85 models trained from Wiktionary. Labeled languages: English (eng), Serbo-Croatian (hbs), Russian (rus), Tagalog (tgl), and Chinese macrolanguage (zho).

7 Evaluation Metrics

The next two sections describe our high-resource and adapted g2p models. To evaluate these models, we compute the following metrics:

- % of words skipped: This shows the coverage of the g2p model. Some g2p models do not cover all character sequences. All other metrics are computed over non-skipped words.
- word error rate (WER): The percent of incorrect 1-best pronunciations.
- word error rate 100-best (WER 100): The percent of 100-best lists without the correct pronunciation.
- phoneme error rate (PER): The percent of errors per phoneme. A PER of 15.0 indicates that, on average, a linguist would have to edit 15 out of 100 phonemes of the output.

We then average these metrics across all languages (weighting each language equally).

8 High Resource g2p Models

We now build and evaluate g2p models for the "high-resource" languages for which we have either IPA Help tables or sufficient training data from Wiktionary. Table 6 shows our evaluation of these models on Wiktionary test data, and Table 7 shows results for individual languages.

8.1 IPA Help models

We first use the rules scraped from Wikipedia's IPA Help pages to build rule-based g2p models. We build a wFST for each language, with a path for each rule $g \rightarrow p$ and weight $w = 1/\text{count}(g)$. This method prefers rules with longer grapheme segments; for example, for the word *tin*, the output "ʃ n" is preferred over the correct "t^h ɪ n" because of the rule *ti*→ʃ. We build 97 IPA Help models, but have test data for only 91—some languages, like Mayan, do not have any Wiktionary entries.

As shown in Table 6, these rule-based models do not perform very well, suffering especially from a high percentage of skipped words. This is because IPA Help tables explain phonemes' relationships to graphemes, rather than vice versa. Thus, the English letter *x* is omitted, since its composite phonemes are better explained by other letters.

8.2 Wiktionary-trained models

We next build models for the 85 languages in our Wiktionary train data set, using the wFST-based Phonetisaurus (Novak et al., 2011) and MITLM (Hsu and Glass, 2008), as described by Novak et al (2012). We use a maximum of 10k pairs of training data, a 7-gram language model, and 50 iterations of EM.

These data-driven models outperform IPA Help models by a considerable amount, achieving a WER of 44.69 and PER of 15.06 averaged across all 85 languages. Restricting data to 2.5k or more training examples boosts results to a WER of 28.02 and PER of 7.20, but creates models for only 29 languages.

However, in some languages good results are obtained with very limited data; Figure 2 shows the varying quality across languages and data availability.

8.3 Unioned models

We also use our rule-based IPA Help tables to improve Wiktionary model performance. We accomplish this very simply, by prepending IPA help rules like the German *sch*→ʃ to the Wiktionary training data as word-pronunciation pairs, then running the Phonetisaurus pipeline.

Overall, the unioned g2p models outperform both the IPA help and Wiktionary models; however, as shown in Table 7, the effects vary across different languages. It is unclear what effect language characteristics, quality of IPA Help rules, and training data size have on unioned model improvement.

model	# langs	% skip	WER	WER 100	PER
ipa-help	91	21.49	78.13	59.18	35.36
wiktionary	85	4.78	44.69	23.15	15.06
unioned	85	3.98	44.17	21.97	14.70
ipa-help	56	22.95	82.61	61.57	35.51
wiktionary	56	3.52	40.28	20.30	13.06
unioned	56	2.31	39.49	18.51	12.52

Table 6: Results for high-resource models. The top portion of the table shows results for all models; the bottom shows results only for languages with both IPA Help and Wiktionary models.

lang	ben	tgl	tur	deu
# train	114	126	2.5k	10k
ipa-help	100.0	64.8	69.0	40.2
wikt	85.6	**34.2**	**39.0**	32.5
unioned	**66.2**	36.2	**39.0**	**24.5**

Table 7: WER scores for Bengali, Tagalog, Turkish, and German models. Unioned models with IPA Help rules tend to perform better than Wiktionary-only models, but not consistently.

9 Adapted g2p Models

Having created a set of high-resource models and our `phon2phon` and `lang2lang` metrics, we now explore different methods for adapting high-resource models and data for related low-resource languages. For comparable results, we restrict the set of high-resource languages to those covered by both our IPA Help and Wiktionary data.

9.1 No mapping

The simplest experiment is to run our g2p models on related low-resource languages, without adaptation. For each language l in our test set, we determine the top high-resource related languages $h_{1,2,...}$ according to the `lang2lang` averaged metric that have both IPA Help and Wiktionary data and the same script, not including the language itself. For IPA Help models, we choose the 3 most related languages $h_{1,2,3}$ and build a g2p model from their combined g-p rules. For Wiktionary and unioned models, we compile 5k words from the closest languages $h_{1,2,...}$ such that each h contributes no more than one third of the data (adding IPA Help rules for unioned models) and train a model from the combined data.

For each test word-pronunciation pair, we trivially map the word's letters to the characters used in $h_{1,2,...}$ by removing accents where necessary; we then use the high-resource g2p model to produce a pronunciation for the word. For example, our Czech IPA Help model uses a model built from g-p rules from Serbo-Croatian, Polish, and Slovenian; the Wiktionary and unioned models use data and rules from these languages and Latin as well.

This expands 56 g2p models (the languages covered by both IPA Help and Wiktionary models) to models for 211 languages. However, as shown in Table 8, results are very poor, with a very high WER of 92% using the unioned models and a PER of more than 50%. Interestingly, IPA Help models perform better than the unioned models, but this is primarily due to their high skip rate.

9.2 Output mapping

We next attempt to improve these results by creating a wFST that maps phonemes from the inventories of $h_{1,2...}$ to l (as described in Section 5.3). As shown in Figure 1a, by chaining this wFST to $h_{1,2...}$'s g2p model, we map the g2p model's output phonemes to the phonemes used by l. In each base model type, this process considerably improves accuracy over the no mapping approach; however, the IPA Help skip rate increases (Table 8).

9.3 Training data mapping

We now build g2p models for l by creating synthetic data for the Wiktionary and unioned models, as in Figure 1b. After compiling word-pronunciation pairs and IPA Help g-p rules from closest languages $h_{1,2,...}$, we then map the pronunciations to l and use the new pronunciations as training data. We again create unioned models by adding the related languages' IPA Help rules to the training data.

This method performs slightly worse in accuracy than output mapping, a WER of 87%, but has a much lower skip rate of 7%.

method	base model	# langs	% skip	WER	WER 100	PER
no mapping	ipa-help	211	12.46	**91.57**	**78.96**	**54.84**
	wikt	211	8.99	93.15	80.36	57.07
	unioned	211	**8.54**	92.38	79.26	57.21
output mapping	ipa-help	211	12.68	85.45	67.07	47.94
	wikt	211	15.00	86.48	66.20	46.84
	unioned	211	**11.72**	**84.82**	**63.63**	**46.25**
training data mapping	wikt	211	8.55	87.40	70.94	48.89
	unioned	211	**7.19**	**87.36**	**70.75**	**47.48**
rescripted	wikt	+10	15.94	**93.66**	81.76	**56.37**
	unioned	+10	**14.97**	94.45	**80.68**	57.35
final	wikt/unioned	229	6.77	88.04	69.80	48.01

Table 8: Results for adapted g2p models. Final adapted results (using the 85 languages covered by Wiktionary and unioned high-resource models, as well as rescripting) cover 229 languages.

lang	method	base model	rel langs	word	gold	hyp
eng	no mapping	ipa-help	deu, nld, swe	fuse	f j uː z	f ʏ s ɛ
arz	output mapping	unioned	fas, urd	بانجو	b æː n̪ g uː	b a n̪ d̪ ʃ uː
afr	training mapping	unioned	nld, lat, isl	dood	d ɔ t	d uː t
sah	training mapping	unioned	rus, bul, ukr	хатырык	k a t̪ ɯ r̪ ɯ k	k a t̪ i r̪ i k
kan	rescripted	unioned	hin, ben	ಡುಷ್ಟ	d̪ u ʂ ʈʰ a	d̪ uː ʂ ʈʰ
guj	rescripted	unioned	san, ben, hin	ક્રોએશિઆ	k ɾ o e ç ɪ a	k ɾ õː ə ʂ ɪ a

Table 9: Sample words, gold pronunciations, and hypothesis pronunciations for English, Egyptian Arabic, Afrikaans, Yakut, Kannada, and Gujarati.

9.4 Rescripting

Adaptation methods thus far have required that h and l share a script. However, this excludes languages with related scripts, like Hindi and Bengali.

We replicate our data mapping experiment, but now allow related languages $h_{1,2,...}$ with different scripts from l but a script distance of less than 0.2. We then build a simple "rescripting" table based on matching Unicode character names; we can then map not only h's pronunciations to l's phoneme set, but also h's word to l's script.

Although performance is relatively poor, rescripting adds 10 new languages, including Telugu, Gujarati, and Marwari.

9.5 Discussion

Table 8 shows evaluation metrics for all adaptation methods. We also show results using all 85 Wiktionary models (using unioned where IPA Help is available) and rescripting, which increases the total number of languages to 229. Table 9 provides examples of output with different languages.

In general, mapping combined with IPA Help rules in unioned models provides the best results. Training data mapping achieves similar scores as output mapping as well as a lower skip rate. Word skipping is problematic, but could be lowered by collecting g-p rules for the low-resource language.

Although the adapted g2p models make many individual phonetic errors, they nevertheless capture overall pronunciation conventions, without requiring language-specific data or rules. Specific points of failure include rules that do not exist in related languages (e.g., the silent "e" at the end of "fuse" and the conversion of "d̪ʃ" to "g" in Egyptian Arabic), mistakes in phoneme mapping, and overall "pronounceability" of the output.

9.6 Limitations

Although our adaptation strategies are flexible, several limitations prevent us from building a g2p model for any language. If there is not enough information about the language, our `lang2lang` table will not be able to provide related high-resource languages. Additionally, if the language's script is not closely related to another language's and thus cannot be rescripted (as with Thai and Armenian), we are not able to adapt related g2p data or models.

10 Conclusion

Using a large multilingual pronunciation dictionary from Wiktionary and rule tables from Wikipedia, we build high-resource g2p models and show that adding g-p rules as training data can improve g2p performance. We then leverage `lang2lang` distance metrics and `phon2phon` phoneme distances to adapt g2p resources for high-resource languages for 229 related low-resource languages. Our experiments show that adapting training data for low-resource languages outperforms adapting output. To our knowledge, these are the most broadly multilingual g2p experiments to date.

With this publication, we release a number of resources to the NLP community: a large multilingual Wiktionary pronunciation dictionary, scraped Wikipedia IPA Help tables, compiled named entity resources (including a multilingual gazetteer), and our `phon2phon` and `lang2lang` distance tables.[4]

Future directions for this work include further improving the number and quality of g2p models, as well as performing external evaluations of the models in speech- and text-processing tasks. We plan to use the presented data and methods for other areas of multilingual natural language processing.

Neural Word Segmentation Learning for Chinese

Deng Cai and **Hai Zhao***

thisisjcykcd@gmail.com, zhaohai@cs.sjtu.edu.cn

Abstract

Most previous approaches to Chinese word segmentation formalize this problem as a character-based sequence labeling task so that only contextual information within fixed sized local windows and simple interactions between adjacent tags can be captured. In this paper, we propose a novel neural framework which thoroughly eliminates context windows and can utilize complete segmentation history. Our model employs a gated combination neural network over characters to produce distributed representations of word candidates, which are then given to a long short-term memory (LSTM) language scoring model. Experiments on the benchmark datasets show that without the help of feature engineering as most existing approaches, our models achieve competitive or better performances with previous state-of-the-art methods.

1 Introduction

Most east Asian languages including Chinese are written without explicit word delimiters, therefore, word segmentation is a preliminary step for processing those languages. Since Xue (2003), most methods formalize the Chinese word segmentation (CWS) as a sequence labeling problem with character position tags, which can be handled with supervised learning methods such as Maximum Entropy (Berger et al., 1996; Low et al., 2005) and Conditional Random Fields (Lafferty et al., 2001; Peng et al., 2004; Zhao et al., 2006a). However, those methods heavily depend on the choice of handcrafted features.

Recently, neural models have been widely used for NLP tasks for their ability to minimize the effort in feature engineering. For the task of CWS, Zheng et al. (2013) adapted the general neural network architecture for sequence labeling proposed in (Collobert et al., 2011), and used character embeddings as input to a two-layer network. Pei et al. (2014) improved upon (Zheng et al., 2013) by explicitly modeling the interactions between local context and previous tag. Chen et al. (2015a) proposed a gated recursive neural network to model the feature combinations of context characters. Chen et al. (2015b) used an LSTM architecture to capture potential long-distance dependencies, which alleviates the limitation of the size of context window but introduced another window for hidden states.

Despite the differences, all these models are designed to solve CWS by assigning labels to the characters in the sequence one by one. At each time step of inference, these models compute the tag scores of character based on (i) context features within a fixed sized local window and (ii) tagging history of previous *one*.

Nevertheless, the tag-tag transition is insufficient to model the complicated influence from previous segmentation decisions, though it could sometimes be a crucial clue to later segmentation decisions. The fixed context window size, which is broadly adopted by these methods for feature engineering, also restricts the flexibility of modeling diverse distances. Moreover, word-level information, which is being the greater granularity unit as suggested in (Huang and Zhao, 2006), remains

unemployed.

To alleviate the drawbacks inside previous methods and release those inconvenient constrains such as the fixed sized context window, this paper makes a latest attempt to re-formalize CWS as a direct segmentation learning task. Our method does not make tagging decisions on individual characters, but directly evaluates the relative likelihood of different segmented sentences and then search for a segmentation with the highest score. To feature a segmented sentence, a series of distributed vector representations (Bengio et al., 2003) are generated to characterize the corresponding word candidates. Such a representation setting makes the decoding quite different from previous methods and indeed much more challenging, however, more discriminative features can be captured.

Though the vector building is word centered, our proposed scoring model covers all three processing levels from character, word until sentence. First, the distributed representation starts from character embedding, as in the context of word segmentation, the n-gram data sparsity issue makes it impractical to use word vectors immediately. Second, as the word candidate representation is derived from its characters, the inside character structure will also be encoded, thus it can be used to determine the word likelihood of its own. Third, to evaluate how a segmented sentence makes sense through word interacting, an LSTM (Hochreiter and Schmidhuber, 1997) is used to chain together word candidates incrementally and construct the representation of partially segmented sentence at each decoding step, so that the coherence between next word candidate and previous segmentation history can be depicted.

To our best knowledge, our proposed approach to CWS is the first attempt which explicitly models the entire contents of the segmenter's state, including the complete history of both segmentation decisions and input characters. The comparisons of feature windows used in different models are shown in Table 1. Compared to both sequence labeling schemes and word-based models in the past, our model thoroughly eliminates context windows and can capture the complete history of segmentation decisions, which offers more possibilities to effectively and accurately model segmentation context.

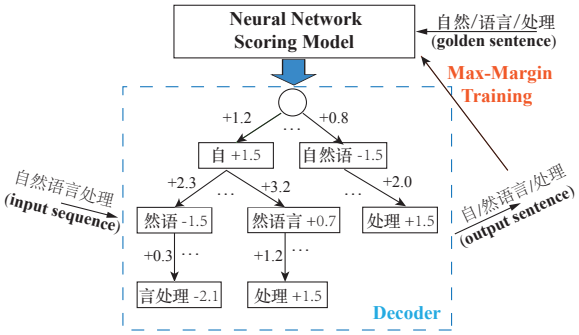

Figure 1: Our framework.

2 Overview

We formulate the CWS problem as finding a mapping from an input character sequence x to a word sequence y, and the output sentence y^* satisfies:

$$y^* = \arg\max_{y \in \text{GEN}(x)} \left(\sum_{i=1}^{n} \text{score}(y_i | y_1, \cdots, y_{i-1}) \right)$$

where n is the number of word candidates in y, and GEN(x) denotes the set of possible segmentations for an input sequence x. Unlike all previous works, our scoring function is sensitive to the complete contents of partially segmented sentence.

As shown in Figure 1, to solve CWS in this way, a neural network scoring model is designed to evaluate the likelihood of a segmented sentence. Based on the proposed model, a decoder is developed to find the segmented sentence with the highest score. Meanwhile, a max-margin method is utilized to perform the training by comparing

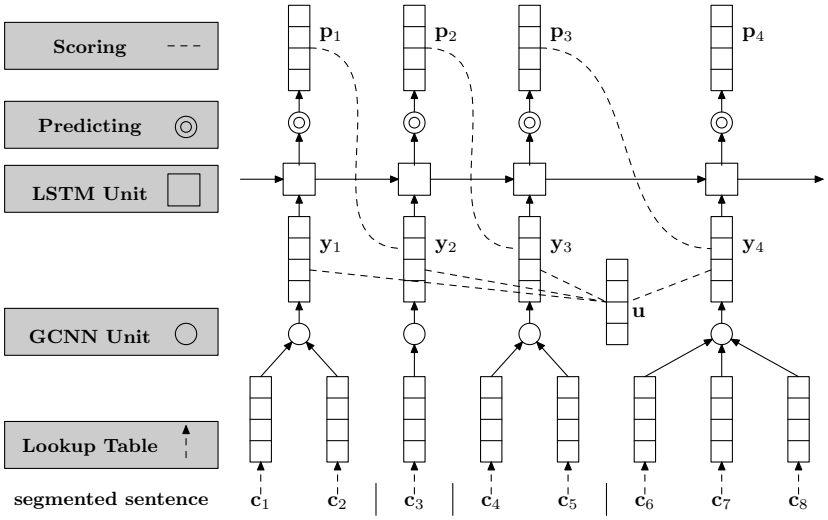

Figure 2: Architecture of our proposed neural network scoring model, where $\mathbf{c}_i$ denotes the i-th input character, $\mathbf{y}_j$ denotes the learned representation of the j-th word candidate, $\mathbf{p}_k$ denotes the prediction for the $(k+1)$-th word candidate and $\mathbf{u}$ is the trainable parameter vector for scoring the likelihood of individual word candidates.

the structured difference of decoder output and the golden segmentation. The following sections will introduce each of these components in detail.

3 Neural Network Scoring Model

The score for a segmented sentence is computed by first mapping it into a sequence of word candidate vectors, then the scoring model takes the vector sequence as input, scoring on each word candidate from two perspectives: (1) how likely the word candidate itself can be recognized as a legal word; (2) how reasonable the link is for the word candidate to follow previous segmentation history immediately. After that, the word candidate is appended to the segmentation history, updating the state of the scoring system for subsequent judgements. Figure 2 illustrates the entire scoring neural network.

3.1 Word Score

Character Embedding. While the scores are decided at the word-level, using word embedding (Bengio et al., 2003; Wang et al., 2016) immediately will lead to a remarkable issue that rare words and out-of-vocabulary words will be poorly estimated (Kim et al., 2015). In addition, the character-level information inside an n-gram can be helpful to judge whether it is a true word. Therefore, a lookup table of character embeddings is used as the bottom layer.

Formally, we have a character dictionary D of size $|D|$. Then each character $c \in D$ is represented as a real-valued vector (character embedding) $\mathbf{c} \in \mathbb{R}^d$, where d is the dimensionality of the vector space. The character embeddings are then stacked into an embedding matrix $\mathbf{M} \in \mathbb{R}^{d \times |D|}$. For a character $c \in D$, its character embedding $\mathbf{c} \in \mathbb{R}^d$ is retrieved by the embedding layer according to its index.

Gated Combination Neural Network. In order to obtain word representation through its characters, in the simplest strategy, character vectors are integrated into their word representation using a weight matrix $\mathbf{W}^{(L)}$ that is shared across all words with the same length L, followed by a non-linear function $g(\cdot)$. Specifically, $\mathbf{c}_i$ $(1 \leq i \leq L)$ are d-dimensional character vector representations respectively, the corresponding word vector $\mathbf{w}$ will be d-dimensional as well:

$$\mathbf{w} = g(\mathbf{W}^{(L)} \begin{bmatrix} \mathbf{c}_1 \\ \vdots \\ \mathbf{c}_L \end{bmatrix}) \quad (1)$$

where $\mathbf{W}^{(L)} \in \mathbb{R}^{d \times Ld}$ and g is a non-linear function as mentioned above.

Although the mechanism above seems to work well, it can not sufficiently model the complicated combination features in practice, yet.

Gated structure in neural network can be useful for hybrid feature extraction according to (Chen et al., 2015a; Chung et al., 2014; Cho et al., 2014),

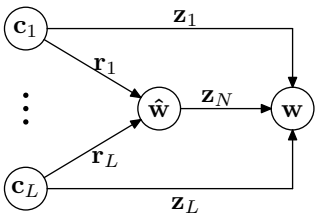

Figure 3: Gated combination neural network.

we therefore propose a gated combination neural network (GCNN) especially for character compositionality which contains two types of gates, namely *reset gate* and *update gate*. Intuitively, the reset gates decide which part of the character vectors should be mixed while the update gates decide what to preserve when combining the characters information. Concretely, for words with length L, the word vector $\mathbf{w} \in \mathbb{R}^d$ is computed as follows:

$$\mathbf{w} = \mathbf{z}_N \odot \hat{\mathbf{w}} + \sum_{i=1}^{L} \mathbf{z}_i \odot \mathbf{c}_i$$

where $\mathbf{z}_N, \mathbf{z}_i\ (1 \leq i \leq L)$ are update gates for new activation $\hat{\mathbf{w}}$ and governed characters respectively, and $\odot$ indicates element-wise multiplication.

The new activation $\hat{\mathbf{w}}$ is computed as:

$$\hat{\mathbf{w}} = \tanh(\mathbf{W}^{(L)} \begin{bmatrix} \mathbf{r}_1 \odot \mathbf{c}_1 \\ \vdots \\ \mathbf{r}_L \odot \mathbf{c}_L \end{bmatrix})$$

where $\mathbf{W}^{(L)} \in \mathbb{R}^{d \times Ld}$ and $\mathbf{r}_i \in \mathbb{R}^d\ (1 \leq i \leq L)$ are the reset gates for governed characters respectively, which can be formalized as:

$$\begin{bmatrix} \mathbf{r}_1 \\ \vdots \\ \mathbf{r}_L \end{bmatrix} = \sigma(\mathbf{R}^{(L)} \begin{bmatrix} \mathbf{c}_1 \\ \vdots \\ \mathbf{c}_L \end{bmatrix})$$

where $\mathbf{R}^{(L)} \in \mathbb{R}^{Ld \times Ld}$ is the coefficient matrix of reset gates and σ denotes the sigmoid function.

The update gates can be formalized as:

$$\begin{bmatrix} \mathbf{z}_N \\ \mathbf{z}_1 \\ \vdots \\ \mathbf{z}_L \end{bmatrix} = \exp(\mathbf{U}^{(L)} \begin{bmatrix} \hat{\mathbf{w}} \\ \mathbf{c}_1 \\ \vdots \\ \mathbf{c}_L \end{bmatrix}) \odot \begin{bmatrix} 1/\mathbf{Z} \\ 1/\mathbf{Z} \\ \vdots \\ 1/\mathbf{Z} \end{bmatrix}$$

where $\mathbf{U}^{(L)} \in \mathbb{R}^{(L+1)d \times (L+1)d}$ is the coefficient matrix of update gates, and $\mathbf{Z} \in \mathbb{R}^d$ is the normalization vector,

$$\mathbf{Z}_k = \sum_{i=1}^{L} [\exp(\mathbf{U}^{(L)} \begin{bmatrix} \hat{\mathbf{w}} \\ \mathbf{c}_1 \\ \vdots \\ \mathbf{c}_L \end{bmatrix})]_{d \times i + k}$$

where $0 \leq k < d$.

According to the normalization condition, the update gates are constrained by:

$$\mathbf{z}_N + \sum_{i=1}^{L} \mathbf{z}_i = \mathbf{1}$$

The gated mechanism is capable of capturing both character and character interaction characteristics to give an efficient word representation (See Section 6.3).

Word Score. Denote the learned vector representations for a segmented sentence y with $[\mathbf{y}_1, \mathbf{y}_2, \cdots, \mathbf{y}_n]$, where n is the number of word candidates in the sentence. *word score* will be computed by the dot products of vector $\mathbf{y}_i (1 \leq i \leq n)$ and a trainable parameter vector $\mathbf{u} \in \mathbb{R}^d$.

$$\text{Word\_Score}(\mathbf{y}_i) = \mathbf{u} \cdot \mathbf{y}_i \tag{2}$$

It indicates how likely a word candidate by itself is to be a true word.

3.2 Link Score

Inspired by the recurrent neural network language model (RNN-LM) (Mikolov et al., 2010; Sundermeyer et al., 2012), we utilize an LSTM system to capture the coherence in a segmented sentence.

Long Short-Term Memory Networks. The LSTM neural network (Hochreiter and Schmidhuber, 1997) is an extension of the recurrent neural network (RNN), which is an effective tool for sequence modeling tasks using its hidden states for history information preservation. At each time step t, an RNN takes the input $\mathbf{x}_t$ and updates its recurrent hidden state $\mathbf{h}_t$ by

$$\mathbf{h}_t = g(\mathbf{U}\mathbf{h}_{t-1} + \mathbf{W}\mathbf{x}_t + \mathbf{b})$$

where g is a non-linear function.

Although RNN is capable, in principle, to process arbitrary-length sequences, it can be difficult to train an RNN to learn long-range dependencies due to the vanishing gradients. LSTM addresses

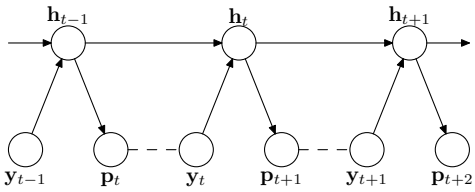

Figure 4: Link scores (dashed lines).

this problem by introducing a memory cell to preserve states over long periods of time, and controls the update of hidden state and memory cell by three types of gates, namely *input gate*, *forget gate* and *output gate*. Concretely, each step of LSTM takes input $\mathbf{x}_t, \mathbf{h}_{t-1}, \mathbf{c}_{t-1}$ and produces $\mathbf{h}_t, \mathbf{c}_t$ via the following calculations:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}^i\mathbf{x}_t + \mathbf{U}^i\mathbf{h}_{t-1} + \mathbf{b}^i) \\
\mathbf{f}_t &= \sigma(\mathbf{W}^f\mathbf{x}_t + \mathbf{U}^f\mathbf{h}_{t-1} + \mathbf{b}^f) \\
\mathbf{o}_t &= \sigma(\mathbf{W}^o\mathbf{x}_t + \mathbf{U}^o\mathbf{h}_{t-1} + \mathbf{b}^o) \\
\hat{\mathbf{c}}_t &= \tanh(\mathbf{W}^c\mathbf{x}_t + \mathbf{U}^c\mathbf{h}_{t-1} + \mathbf{b}^c) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \hat{\mathbf{c}}_t \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned}$$

where $\sigma, \odot$ are respectively the element-wise sigmoid function and multiplication, $\mathbf{i}_t, \mathbf{f}_t, \mathbf{o}_t, \mathbf{c}_t$ are respectively the input gate, forget gate, output gate and memory cell activation vector at time t, all of which have the same size as hidden state vector $\mathbf{h}_t \in \mathbb{R}^H$.

Link Score. LSTMs have been shown to outperform RNNs on many NLP tasks, notably language modeling (Sundermeyer et al., 2012).

In our model, LSTM is utilized to chain together word candidates in a left-to-right, incremental manner. At time step t, a prediction $\mathbf{p}_{t+1} \in \mathbb{R}^d$ about next word $\mathbf{y}_{t+1}$ is made based on the hidden state $\mathbf{h}_t$:

$$\mathbf{p}_{t+1} = \tanh(\mathbf{W}^p\mathbf{h}_t + \mathbf{b}^p)$$

link score for next word $\mathbf{y}_{t+1}$ is then computed as:

$$\text{Link\_Score}(\mathbf{y}_{t+1}) = \mathbf{p}_{t+1} \cdot \mathbf{y}_{t+1} \qquad (3)$$

Due to the structure of LSTM, the prediction vector $\mathbf{p}_{t+1}$ carries useful information detected from the entire segmentation history, including previous segmentation decisions. In this way, our model gains the ability of sequence-level discrimination rather than local optimization.

3.3 Sentence score

Sentence score for a segmented sentence y with n word candidates is computed by summing up word scores (2) and link scores (3) as follow:

$$s(y_{[1:n]}, \theta) = \sum_{t=1}^{n}(\mathbf{u} \cdot \mathbf{y}_t + \mathbf{p}_t \cdot \mathbf{y}_t) \qquad (4)$$

where θ is the parameter set used in our model.

4 Decoding

The total number of possible segmented sentences grows exponentially with the length of character sequence, which makes it impractical to compute the scores of every possible segmentation. In order to get exact inference, most sequence-labeling systems address this problem with a Viterbi search, which takes the advantage of their hypothesis that the tag interactions only exist within adjacent characters (Markov assumption). However, since our model is intended to capture complete history of segmentation decisions, such dynamic programming algorithms can not be adopted in this situation.

Algorithm 1 Beam Search.

Input: model parameters θ
beam size k
maximum word length w
input character sequence $c[1:n]$
Output: Approx. k best segmentations

$\pi[0] \leftarrow \{(score = 0, \mathbf{h} = \mathbf{h}_0, \mathbf{c} = \mathbf{c}_0)\}$
for $i = 1$ to n **do**
  ▷ Generate Candidate Word Vectors
  $X \leftarrow \emptyset$
  for $j = \max(1, i - w)$ to i **do**
    $\mathbf{w} =$ GCNN-Procedure$(c[j:i])$
    X.add$((index = j - 1, word = \mathbf{w}))$
  end for
  ▷ Join Segmentation
  $Y \leftarrow \{\ y$.append$(x) \mid y \in \pi[x.index]$ and $x \in X\}$
  ▷ Filter k-Max
  $\pi[i] \leftarrow k\text{-}\arg\max_{y \in Y} y.score$
end for
return $\pi[n]$

To make our model efficient in practical use, we propose a beam-search algorithm with dynamic programming motivations as shown in Algorithm 1. The main idea is that any segmentation of the

first i characters can be separated as two parts, the first part consists of characters with indexes from 0 to j that is denoted as y, the rest part is the word composed by $c[j+1:i]$. The influence from previous segmentation y can be represented as a triple ($y.score$, $y.\mathbf{h}$, $y.\mathbf{c}$), where $y.score$, $y.\mathbf{h}$, $y.\mathbf{c}$ indicate the current score, current hidden state vector and current memory cell vector respectively. Beam search ensures that the total time for segmenting a sentence of n characters is $w \times k \times n$, where w, k are maximum word length and beam size respectively.

5 Training

We use the max-margin criterion (Taskar et al., 2005) to train our model. As reported in (Kummerfeld et al., 2015), the margin methods generally outperform both likelihood and perception methods. For a given character sequence $x^{(i)}$, denote the correct segmented sentence for $x^{(i)}$ as $y^{(i)}$. We define a structured margin loss $\Delta(y^{(i)}, \hat{y})$ for predicting a segmented sentence $\hat{y}$:

$$\Delta(y^{(i)}, \hat{y}) = \sum_{t=1}^{m} \mu \mathbf{1}\{y^{(i),t} \neq \hat{y}^t\}$$

where m is the length of sequence $x^{(i)}$ and μ is the discount parameter. The calculation of margin loss could be regarded as to count the number of incorrectly segmented characters and then multiple it with a fixed discount parameter for smoothing. Therefore, the loss is proportional to the number of incorrectly segmented characters.

Given a set of training set Ω, the regularized objective function is the loss function $J(\theta)$ including an ℓ_2 norm term:

$$J(\theta) = \frac{1}{|\Omega|} \sum_{(x^{(i)}, y^{(i)}) \in \Omega} l_i(\theta) + \frac{\lambda}{2} ||\theta||_2^2$$

$$l_i(\theta) = \max_{\hat{y} \in \text{GEN}(x^{(i)})} (s(\hat{y}, \theta) + \Delta(y^{(i)}, \hat{y}) - s(y^{(i)}, \theta))$$

where the function $s(\cdot)$ is the sentence score defined in equation (4).

Due to the hinge loss, the objective function is not differentiable, we use a subgradient method (Ratliff et al., 2007) which computes a gradient-like direction. Following (Socher et al., 2013), we use the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatchs to minimize the objective.

Character embedding size	$d = 50$
Hidden unit number	$H = 50$
Initial learning rate	$\alpha = 0.2$
Margin loss discount	$\mu = 0.2$
Regularization	$\lambda = 10^{-6}$
Dropout rate on input layer	$p = 0.2$
Maximum word length	$w = 4$

Table 2: Hyper-parameter settings.

The update for the i-th parameter at time step t is as follows:

$$\theta_{t,i} = \theta_{t-1,i} - \frac{\alpha}{\sqrt{\sum_{\tau=1}^{t} g_{\tau,i}^2}} g_{t,i}$$

where α is the initial learning rate and $g_{\tau,i} \in \mathbb{R}^{|\theta_i|}$ is the subgradient at time step τ for parameter θ_i.

6 Experiments

6.1 Datasets

To evaluate the proposed segmenter, we use two popular datasets, PKU and MSR, from the second International Chinese Word Segmentation Bakeoff (Emerson, 2005). These datasets are commonly used by previous state-of-the-art models and neural network models.

Both datasets are preprocessed by replacing the continuous English characters and digits with a unique token. All experiments are conducted with standard Bakeoff scoring program[1] calculating precision, recall, and F_1-score.

6.2 Hyper-parameters

Hyper-parameters of neural network model significantly impact on its performance. To determine a set of suitable hyper-parameters, we divide the training data into two sets, the first 90% sentences as training set and the rest 10% sentences as development set. We choose the hyper-parameters as shown in Table 2.

We found that the character embedding size has a limited impact on the performance as long as it is large enough. The size 50 is chosen as a good trade-off between speed and performance. The number of hidden units is set to be the same as the character embedding. Maximum word length determines the number of parameters in GCNN part and the time consuming of beam search, since the words with a length $l > 4$ are relatively rare,

[1] http://www.sighan.org/bakeoff2003/score

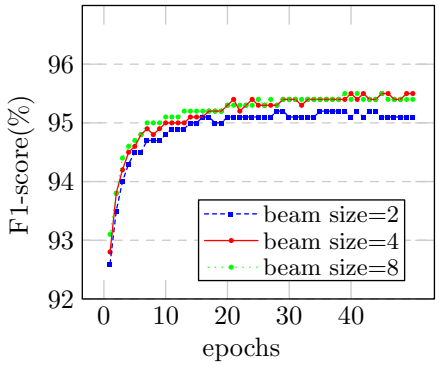

Figure 5: Performances of different beam sizes on PKU dataset.

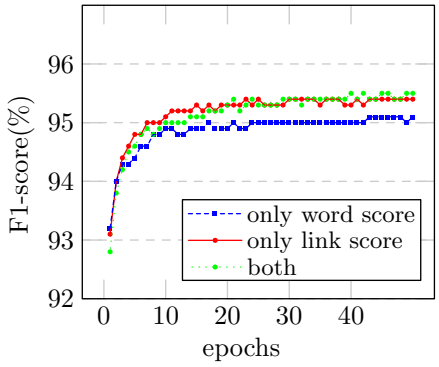

Figure 6: Performances of different score strategies on PKU dataset.

0.29% in PKU training data and 1.25% in MSR training data, we set the maximum word length to 4 in our experiments.[2]

Dropout is a popular technique for improving the performance of neural networks by reducing overfitting (Srivastava et al., 2014). We also drop the input layer of our model with dropout rate 20% to avoid overfitting.

6.3 Model Analysis

Beam Size. We first investigated the impact of beam size over segmentation performance. Figure 5 shows that a segmenter with beam size 4 is enough to get the best performance, which makes our model find a good balance between accuracy and efficiency.

GCNN. We then studied the role of GCNN in our model. To reveal the impact of GCNN, we re-implemented a simplified version of our model, which replaces the GCNN part with a single nonlinear layer as in equation (1). The results are listed in Table 3, which demonstrate that the performance is significantly boosted by exploiting the GCNN architecture (94.0% to 95.5% on F_1-score), while the best performance that the simplified version can achieve is 94.7%, but using a much larger character embedding size.

models	P	R	F
Single layer ($d = 50$)	94.3	93.7	94.0
GCNN ($d = 50$)	95.8	95.2	95.5
Single layer ($d = 100$)	94.9	94.4	94.7

This work	**95.7**	-	**96.4**	-

Table 4: Comparison of using different Chinese idiom dictionaries.[3]

Link Score & Word Score. We conducted several experiments to investigate the individual effect of link score and word score, since these two types of scores are intended to estimate the sentence likelihood from two different perspectives: the semantic coherence between words and the existence of individual words. The learning curves of models with different scoring strategies are shown in Figure 6.

The model with only word score can be regarded as the situation that the segmentation decisions are made only based on local window information. The comparisons show that such a model gives moderate performance. By contrast, the model with only link score gives a much better performance close to the joint model, which demonstrates that the complete segmentation history, which can not be effectively modeled in previous schemes, possesses huge appliance value for word segmentation.

6.4 Results

[2]This 4-character limitation is just for consistence for both datasets. We are aware that it is a too strict setting, especially which makes additional performance loss in a dataset with larger average word length, i.e., MSR.

[3]The dictionary used in (Chen et al., 2015a; Chen et al., 2015b) is neither publicly released nor specified the exact source until now. We have to re-run their code using our selected dictionary to make a fair comparison. Our dictionary has been submitted along with this submission.

Table 6: Comparison with previous state-of-the-art models. Results with * used external dictionary or corpus.

We first compare our model with the latest neural network methods as shown in Table 4. However, (Chen et al., 2015a; Chen et al., 2015b) used an extra preprocess to filter out Chinese idioms according to an external dictionary.[4] Table 4 lists the results (F_1-scores) with different dictionaries, which show that our models perform better when under the same settings.

Table 5 gives comparisons among previous neural network models. In the first block of Table 5, the character embedding matrix $\mathbf{M}$ is randomly initialized. The results show that our proposed novel model outperforms previous neural network methods.

Previous works have found that the performance can be improved by pre-training the character embeddings on large unlabeled data. Therefore, we use word2vec (Mikolov et al., 2013) toolkit[6] to pre-train the character embeddings on the Chinese Wikipedia corpus and use them for initialization. Table 5 also shows the results with additional pre-trained character embeddings. Again, our model achieves better performance than previous neural network models do.

Table 6 compares our models with previous state-of-the-art systems. Recent systems such as (Zhang et al., 2013), (Chen et al., 2015b) and (Chen et al., 2015a) rely on both extensive feature engineering and external corpora to boost performance. Such systems are not directly comparable with our models. In the closed-set setting, our models can achieve state-of-the-art performance

[4]In detail, when a dictionary is used, a preprocess is performed before training and test, which scans original text to find out Chinese idioms included in the dictionary and replace them with a unique token. This treatment does not strictly follow the convention of closed-set setting defined by SIGHAN Bakeoff, as no linguistic resources, either dictionary or corpus, other than the training corpus, should be adopted.

[5]To make comparisons fair, we re-run their code (https://github.com/dalstonChen) without their unspecified Chinese idiom dictionary.

Max. word length	F_1 score	Time (Days)
4	96.5	4
5	96.7	5
6	96.8	6

Table 7: Results on MSR dataset with different maximum decoding word length settings.

on PKU dataset but a competitive result on MSR dataset, which can attribute to too strict maximum word length setting for consistence as it is well known that MSR corpus has a much longer average word length (Zhao et al., 2010).

Table 7 demonstrates the results on MSR corpus with different maximum decoding word lengths, in which both F_1 scores and training time are given. The results show that the segmentation performance can indeed further be improved by allowing longer words during decoding, though longer training time are also needed. As 6-character words are allowed, F_1 score on MSR can be furthermore improved 0.3%.

For the running cost, we roughly report the current computation consuming on PKU dataset.[7] It takes about two days to finish 50 training epochs (for results in Figure 6 and the last row of Table 6) only with two cores of an Intel i7-5960X CPU. The requirement for RAM during training is less than 800MB. The trained model can be saved within 4MB on the hard disk.

7 Related Work

Neural Network Models. Most modern CWS methods followed (Xue, 2003) treated CWS as a sequence labeling problems (Zhao et al., 2006b). Recently, researchers have tended to explore neural network based approaches (Collobert et al., 2011) to reduce efforts of feature engineering (Zheng et al., 2013; Qi et al., 2014; Chen et al., 2015a; Chen et al., 2015b). They modeled CWS as tagging problem as well, scoring tags on individual characters. In those models, tag scores are decided by context information within local windows and the sentence-level score is obtained via *context-independently* tag transitions. Pei et al. (2014) introduced the tag embedding as input to capture the combinations of context and tag history. However, in previous works, only the tag of previous *one* character was taken into consideration though theoretically the complete history of actions taken by the segmenter should be considered.

Alternatives to Sequence Labeling. Besides sequence labeling schemes, Zhang and Clark (2007) proposed a word-based perceptron method. Zhang et al. (2012) used a linear-time incremental model which can also benefits from various kinds of features including word-based features. But both of them rely heavily on massive handcrafted features. Contemporary to this work, some neural models (Zhang et al., 2016a; Liu et al., 2016) also leverage word-level information. Specifically, Liu et al. (2016) use a semi-CRF taking segment-level embeddings as input and Zhang et al. (2016a) use a transition-based framework.

Another notable exception is (Ma and Hinrichs, 2015), which is also an embedding-based model, but models CWS as configuration-action matching. However, again, this method only uses the context information within limited sized windows.

Other Techniques. The proposed model might furthermore benefit from some techniques in recent state-of-the-art systems, such as semi-supervised learning (Zhao and Kit, 2008b; Zhao and Kit, 2008a; Sun and Xu, 2011; Zhao and Kit, 2011; Zeng et al., 2013; Zhang et al., 2013), incorporating global information (Zhao and Kit, 2007; Zhang et al., 2016b), and joint models (Qian and Liu, 2012; Li and Zhou, 2012).

8 Conclusion

This paper presents a novel neural framework for the task of Chinese word segmentation, which contains three main components: (1) a factory to produce word representation when given its governed characters; (2) a sentence-level likelihood evaluation system for segmented sentence; (3) an efficient and effective algorithm to find the best segmentation.

The proposed framework makes a latest attempt to formalize word segmentation as a direct structured learning procedure in terms of the recent distributed representation framework.

Though our system outputs results that are better than the latest neural network segmenters but comparable to all previous state-of-the-art systems, the framework remains a great of potential that can be further investigated and improved in the future.

Abstract

Character-based and word-based methods are two main types of statistical models for Chinese word segmentation, the former exploiting sequence labeling models over characters and the latter typically exploiting a transition-based model, with the advantages that word-level features can be easily utilized. Neural models have been exploited for character-based Chinese word segmentation, giving high accuracies by making use of external character embeddings, yet requiring less feature engineering. In this paper, we study a neural model for word-based Chinese word segmentation, by replacing the manually-designed discrete features with neural features in a word-based segmentation framework. Experimental results demonstrate that word features lead to comparable performances to the best systems in the literature, and a further combination of discrete and neural features gives top accuracies.

1 Introduction

Statistical word segmentation methods can be categorized character-based (Xue, 2003; Tseng et al., 2005) and word-based (Andrew, 2006; Zhang and Clark, 2007) approaches. The former casts word segmentation as a sequence labeling problem, using segmentation tags on characters to mark their relative positions inside words. The latter, in contrast, ranks candidate segmented outputs directly, extracting both character and full-word features.

An influential character-based word segmentation model (Peng et al., 2004; Tseng et al., 2005) uses B/I/E/S labels to mark a character as the beginning, internal (neither beginning nor end), end and only-character (both beginning and end) of a word, respectively, employing conditional random field (CRF) to model the correspondence between the input character sequence and output label sequence. For each character, features are extracted from a five-character context window and a two-label history window. Subsequent work explores different label sets (Zhao et al., 2006), feature sets (Shi and Wang, 2007) and semi-supervised learning (Sun and Xu, 2011), reporting state-of-the-art accuracies.

Figure 1: Word segmentation methods.

Recently, neural network models have been investigated for the character tagging approach. The main idea is to replace manual discrete features with automatic real-valued features, which are derived automatically from distributed character representations using neural networks. In particular, convolution neural network[1] (Zheng et al., 2013), tensor neural network (Pei et al., 2014), recursive neural network (Chen et al., 2015a) and long-short-term-memory (LSTM) (Chen et al., 2015b) have been used to derive neural feature representations from input word sequences, which are fed into a CRF inference layer.

In this paper, we investigate the effectiveness of word embedding features for neural network segmentation using transition-based models. Since it is challenging to integrate word features to the CRF inference framework of the existing

[1]The term in this paper is used to denote the neural network structure with convolutional layers, which is different from the typical convolution neural network that has a pooling layer upon convolutional layers (Krizhevsky et al., 2012).

character-based methods, we take inspiration from word-based discrete segmentation instead. In particular, we follow Zhang and Clark (2007), using the transition-based framework to decode a sentence from left-to-right incrementally, scoring partially segmented results using both character-level and word-level features. Beam-search is applied to reduce error propagation and large-margin training with early-update (Collins and Roark, 2004) is used for learning from inexact search.

We replace the discrete word and character features of Zhang and Clark (2007) with word and character embeddings, respectively, and change their linear model into a deep neural network. Following Zheng et al. (2013) and Chen et al. (2015b), we use convolution neural networks to achieve local feature combination and LSTM to learn global sentence-level features, respectively. The resulting model is a word-based neural segmenter that can leverage rich embedding features. Its correlation with existing work on Chinese segmentation is shown in Figure 1.

Results on standard benchmark datasets show the effectiveness of word embedding features for neural segmentation. Our method achieves state-of-the-art results without any preprocess based on external knowledge such as Chinese idioms of Chen et al. (2015a) and Chen et al. (2015b). We release our code under GPL for research reference.[2]

2 Baseline Discrete Model

We exploit the word-based segmentor of Zhang and Clark (2011) as the baseline system. It incrementally segments a sentence using a transition system, with a state holding a partially-segmented sentence in a buffer s and ordering the next incoming characters in a queue q. Given an input Chinese sentence, the buffer is initially empty and the queue contains all characters of the sentence, a sequence of transition actions are used to consume characters in the queue and build the output sentence in the buffer. The actions include:

- `Append` (APP), which removes the first character from the queue, and appends it to the last word in the buffer;
- `Separate` (SEP), which moves the first character of the queue onto the buffer as a new (sub) word.

Given the input sequence of characters "中国外企业务发展迅速" (The business of foreign company in China develops quickly), the correct output can be derived using action sequence "*SEP APP SEP APP SEP APP SEP APP SEP APP*", as shown in Figure 2.

Search. Based on the transition system, the decoder searches for an optimal action sequence for a given sentence. Denote an action sequence as $A = a_1 \cdots a_n$. We define the score of A as the total score of all actions in the sequence, which is computed by:

$$score(A) = \sum_{a \in A} score(a) = \sum_{a \in A} w \cdot f(s, q, a),$$

where w is the model parameters, f is a feature extraction function, s and q are the buffer and queue of a certain state before the action a is applied.

The feature templates are shown in Table 1, which are the same as Zhang and Clark (2011). These base features include three main source of information. First, characters in the front of the queue and the end of the buffer are used for scoring both *separate* and *append* actions (e.g. c_0). Second, words that are identified are used to guide *separate* actions (e.g. w_0). Third, relevant information of identified words, such as their lengths and first/last characters are utilized for additional features (e.g. $len(w_{-1})$).

We follow Zhang and Clark (2011) in using beam-search for decoding, shown in Algorith 1, where Θ is the set of model parameters. Initially the beam contains only the initial state. At each step, each state in the beam is extended by applying both *SEP* and *APP*, resulting in a set of new states, which are scored and ranked. The top *B* are

used as the beam states for the next step. The same process replaces until all input character are processed, and the highest-scored state in the beam is taken for output. Online leaning with max-margin is used, which is given in section 4.

3 Transition-Based Neural Model

We use a neural network model to replace the discrete linear model for scoring transition action sequences. For better comparison between discrete and neural features, the overall segmentation framework of the baseline is used, which includes the incremental segmentation process, the beam-search decoder and the training process integrated with beam-search (Zhang and Clark, 2011). In addition, the neural network scorer takes the similar feature sources as the baseline, which includes character information over the input, word information of the partially constructed output, and the history sequence of the actions that have been applied so far.

The overall architecture of the neural scorer is shown in Figure 3. Given a certain state

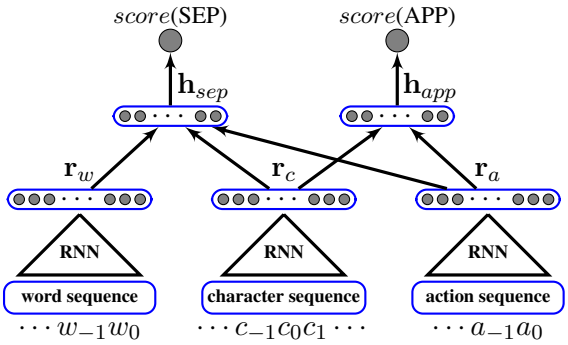

Figure 3: Scorer for the neural transition-based Chinese word segmentation model. We denote the last word in the buffer as w_0, the next incoming character as c_0 in the queue in consistent with Figure 2, and the last applied action as a_0.

configuration (s, q), we use three separate recurrent neural networks (RNN) to model the word sequence $\cdots w_{-1}w_0$, the character sequence $\cdots c_{-1}c_0c_1\cdots$, and the action sequence $\cdots a_{-1}a_0$, respectively, resulting in three dense real-valued vectors $\{\mathbf{r}_w, \mathbf{r}_c$ and $\mathbf{r}_a\}$, respectively. All the three feature vectors are used scoring the *SEP* action. For *APP*, on the other hand, we use only the character and action features $\mathbf{r}_c$ and $\mathbf{r}_a$ because the last word w_0 in the buffer is a partial word. Formally, given $\mathbf{r}_w, \mathbf{r}_c, \mathbf{r}_a$, the action scores are computed by:

$$score(\text{SEP}) = \mathbf{w}_{sep}\mathbf{h}_{sep}$$
$$score(\text{APP}) = \mathbf{w}_{app}\mathbf{h}_{app}$$

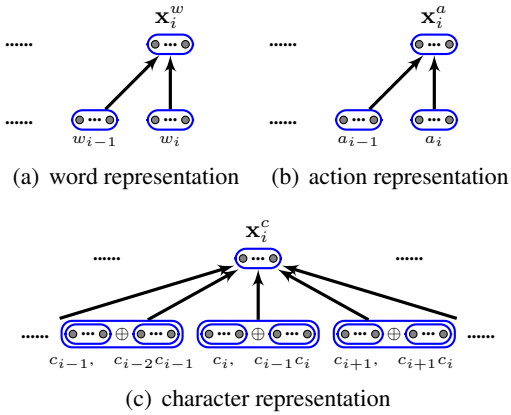
where

$$\mathbf{h}_{sep} = \tanh(W_{sep}[\mathbf{r}_w, \mathbf{r}_c, \mathbf{r}_a] + \mathbf{b}_{sep})$$
$$\mathbf{h}_{app} = \tanh(W_{app}[\mathbf{r}_c, \mathbf{r}_a] + \mathbf{b}_{app})$$

$W_{sep}, W_{app}, \mathbf{b}_{sep}, \mathbf{b}_{app}, \mathbf{w}_{sep}, \mathbf{w}_{app}$ are model parameters.

The neural networks take the embedding forms of words, characters and actions as input, for extracting $\mathbf{r}_w, \mathbf{r}_c$ and $\mathbf{r}_a$, respectively. We exploit the LSTM-RNN structure (Hochreiter and Schmidhuber, 1997), which can better capture non-local syntactic and semantic information from a sequential input, yet reducing gradient explosion or diminishing during training.

In general, given a sequence of input vectors $\mathbf{x}_0 \cdots \mathbf{x}_n$, the LSTM-RNN computes a sequence of hidden vectors $\mathbf{h}_0 \cdots \mathbf{h}_n$, respectively, with each $\mathbf{h}_i$ being determined by the input $\mathbf{x}_i$ and the previous hidden vector $\mathbf{h}_{i-1}$. A cell structure $\mathbf{ce}$ is



(a) word representation (b) action representation

(c) character representation

Figure 4: Input representations of LSTMS for $\mathbf{r}_a$ (actions) $\mathbf{r}_w$ (words) and $\mathbf{r}_c$ (characters).

used to carry long-term memory information over the history $\mathbf{h}_0 \cdots \mathbf{h}_i$ for calculating $\mathbf{h}_i$, and information flow is controlled by an input gate $\mathbf{ig}$, an output gate $\mathbf{og}$ and a forget gate $\mathbf{fg}$. Formally, the calculation of $\mathbf{h}_i$ using $\mathbf{h}_{i-1}$ and $\mathbf{x}_i$ is:

$$\begin{aligned}
\mathbf{ig}_i &= \sigma(W_{ig}\mathbf{x}_i + U_{ig}\mathbf{h}_{i-1} + V_{ig}\mathbf{ce}_{i-1} + \mathbf{b}_{ig}) \\
\mathbf{fg}_i &= \sigma(W_{fg}\mathbf{x}_i + U_{fg}\mathbf{h}_{i-1} + V_{fg}\mathbf{ce}_{i-1} + \mathbf{b}_{fg}) \\
\mathbf{ce}_i &= \mathbf{fg}_i \odot \mathbf{ce}_{i-1} + \\
&\qquad \mathbf{ig}_i \odot \tanh(W_{ce}\mathbf{x}_i + U_{ce}\mathbf{h}_{i-1} + \mathbf{b}_{ce}) \\
\mathbf{og}_i &= \sigma(W_{og}\mathbf{x}_i + U_{og}\mathbf{h}_{i-1} + V_{og}\mathbf{ce}_i + \mathbf{b}_{og}) \\
\mathbf{h}_i &= \mathbf{og}_i \odot \tanh(\mathbf{ce}_i),
\end{aligned}$$

where $U, V, W, \mathbf{b}$ are model parameters, and $\odot$ denotes Hadamard product.

When used to calculate $\mathbf{r}_w$, $\mathbf{r}_c$ and $\mathbf{r}_a$, the general LSTM structure above is given different input sequences $\mathbf{x}_0 \cdots \mathbf{x}_n$, according to the word, character and action sequences, respectively.

3.1 Input representation

Words. Given a word w, we use a looking-up matrix E_w to obtain its embedding $\mathbf{e}_w(w)$. The matrix can be obtained through pre-training on large size of auto segmented corpus. As shown in Figure 4(a), we use a convolutional neural layer upon a two-word window to obtain $\cdots \mathbf{x}_{-1}^w \mathbf{x}_0^w$ for the LSTM for $\mathbf{r}_w$, with the following formula:

$$\mathbf{x}_i^w = \tanh\left(W_w[\mathbf{e}_w(w_{i-1}), \mathbf{e}_w(w_i)] + \mathbf{b}_w\right)$$

Actions. We represent an action a with an embedding $\mathbf{e}_a(a)$ from a looking-up table E_a, and apply the similar convolutional neural network to obtain $\cdots \mathbf{x}_{-1}^a \mathbf{x}_0^a$ for $\mathbf{r}_a$, as shown in Figure 4(b). Given the input action sequence $\cdots a_{-1}a_0$, the $\mathbf{x}_i^a$ is computed by:

$$\mathbf{x}_i^a = \tanh\left(W_a[\mathbf{e}_a(a_{i-1}), \mathbf{e}_a(a_i)] + \mathbf{b}_a\right)$$

Characters. We make embeddings for both character unigrams and bigrams by looking-up matrixes E_c and E_{bc}, respectively, the latter being shown to be useful by Pei et al. (2014). For each character c_i, the unigram embedding $\mathbf{e}_c(c_i)$ and the bigram embedding $\mathbf{e}_{bc}(c_{i-1}c_i)$ are concatenated, before being given to a CNN with a convolution size of 5. For the character sequence $\cdots c_{-1}c_0c_1 \cdots$ of a given state (s, q), we compute its input vectors $\cdots \mathbf{x}_{-1}^c \mathbf{x}_0^c \mathbf{x}_1^c \cdots$ for the LSTM for $\mathbf{r}_c$ by:

$$\begin{aligned}
\mathbf{x}_i^c = \tanh\big(W_c[&\mathbf{e}_c(c_{i-2}) \oplus \mathbf{e}_{bc}(c_{i-3}c_{i-2}), \\
&\cdots, \mathbf{e}_c(c_i) \oplus \mathbf{e}_{bc}(c_{i-1}c_i), \cdots, \\
&\mathbf{e}_c(c_{i+2}) \oplus \mathbf{e}_{bc}(c_{i+1}c_{i+2})] + \mathbf{b}_c\big)
\end{aligned}$$

For all the above input representations, the looking-up tables E_w, E_a , E_c, E_{bc} and the weights W_w, W_a, W_c, $\mathbf{b}_w$, $\mathbf{b}_a$, $\mathbf{b}_c$ are model parameters. For calculating $\mathbf{r}_w$ and $\mathbf{r}_a$, we apply the LSTMs directly over the sequences $\cdots x_{-1}^w x_0^w$ and $\cdots x_{-1}^a x_0^a$ for words and actions, and use the outputs $\mathbf{h}_0^w$ and $\mathbf{h}_0^a$ for $\mathbf{r}_w$ and $\mathbf{r}_a$, respectively. For calculating $\mathbf{r}_c$, we further use a bi-directional extension of the original LSTM structure. In particular, the base LSTM is applied to the input character sequence both from left to right and from right to left, leading to two hidden node sequences $\cdots \mathbf{h}_{-1}^{cL}\mathbf{h}_0^{cL}\mathbf{h}_1^{cL} \cdots$ and $\cdots \mathbf{h}_{-1}^{cR}\mathbf{h}_0^{cR}\mathbf{h}_1^{cR} \cdots$, respectively. For the current character c_0, $\mathbf{h}_0^{cL}$ and $\mathbf{h}_0^{cR}$ are concatenated to form the final vector $\mathbf{r}_c$. This is feasible because the character sequence is input and static, and previous work has demonstrated better capability of bi-directional LSTM for modeling sequences (Yao and Zweig, 2015).

3.2 Integrating discrete features

Our model can be extended by integrating the baseline discrete features into the feature layer. In particular,

$$\begin{aligned}
score(\text{SEP}) &= \mathbf{w'}_{sep}(\mathbf{h}_{sep} \oplus f_{sep}) \\
score(\text{APP}) &= \mathbf{w'}_{app}(\mathbf{h}_{app} \oplus f_{app}),
\end{aligned}$$

where $\mathbf{f}_{sep}$ and $\mathbf{f}_{app}$ represent the baseline sparse vector for *SEP* and *APP* features, respectively, and $\oplus$ denotes the vector concatenation operation.

Algorithm 2 Max-margin training with early-update.

function TRAIN($c_1 \cdots c_n$, $a_1^g \cdots a_n^g$, Θ)
  agenda $\leftarrow$ { (ϕ, $c_1 \cdots c_n$, score=0.0) }
  for i **in** $1 \cdots n$
    beam $\leftarrow$ { }
    for *cand* **in** *agenda*
      new $\leftarrow$ SEP(*cand, c_i, Θ)*
      if $\{a_i^g \neq$ SEP$\}$ new.*score* += η
      ADDITEM*(*beam*,* new*)*
      new $\leftarrow$ APP*(*cand, c_i, Θ)
      if $\{a_i^g \neq$ APP$\}$ *new*.score += η
      ADDITEM(*beam*, *new*)
    agenda $\leftarrow$ TOP-B(*beam, B*)
    if $\{$ITEM$(a_1^g \cdots a_i^g) \notin$ agenda$\}$
      $\Theta = \Theta - f\big($BESTITEM(*agenda*)$\big)$
      $\Theta = \Theta + f\big($ITEM$((a_1^g \cdots a_i^g)\big)$
      return
  if $\{$ITEM$(a_1^g \cdots a_n^g) \neq$ BESTITEM(*agenda*)$\}$
    $\Theta = \Theta - f\big($BESTITEM(*agenda*)$\big)$
    $\Theta = \Theta + f\big($ITEM$((a_1^g \cdots a_n^g)\big)$

4 Training

To train model parameters for both the discrete and neural models, we exploit online learning with early-update as shown in Algorithm 2. A max-margin objective is exploited,[3] which is defined as:

$$L(\Theta) = \frac{1}{K}\sum_{k=1}^{K} l(A_k^g, \Theta) + \frac{\lambda}{2} \parallel \Theta \parallel^2$$

$$l(A_k^g, \Theta) = \max_{A} \big(score(A_k, \Theta) + \eta \cdot \delta(A_k, A_k^g)\big) - score(A_k^g, \Theta),$$

where Θ is the set of all parameters, $\{A_k^g\}_{n=1}^K$ are gold action sequences to segment the training corpus, A_k is the model output action sequence, λ is a regularization parameter and η is used to tune the loss margins.

For the discrete models, $f(\cdot)$ denotes the features extracted according to the feature templates in Table 1. For the neural models, $f(\cdot)$ denotes the corresponding $\mathbf{h}_{sep}$ and $\mathbf{h}_{app}$. Thus only the output layer is updated, and we further use back-propagation to learn the parameters of the other layers (LeCun et al., 2012). We use online AdaGrad (Duchi et al., 2011) to minimize the objective function for both the discrete and neural models. All the matrix and vector parameters are initialized by uniform sampling in $(-0.01, 0.01)$.

[3]Zhou et al. (2015) find that max-margin training did not yield reasonable results for neural transition-based parsing, which is different from our findings. One likely reason is that when the number of labels is small max-margin is effective.

5 Experiments

5.1 Experimental Settings

Data. We use three datasets for evaluation, namely CTB6, PKU and MSR. The CTB6 corpus is taken from Chinese Treebank 6.0, and the PKU and MSR corpora can be obtained from Bake-Off 2005 (Emerson, 2005). We follow Zhang et al. (2014), splitting the CTB6 corpus into training, development and testing sections. For the PKU and MSR corpora, only the training and test datasets are specified and we randomly split 10% of the training sections for development. Table 1 shows the overall statistics of the three datasets.

Embeddings. We use *word2vec*[4] to pre-train word, character and bi-character embeddings on Chinese Gigaword corpus (LDC2011T13). In order to train full word embeddings, the corpus is segmented automatically by our baseline model.

Hyper-parameters. The hyper-parameter values are tuned according to development performances. We list their final values in Table 3.

5.2 Development Results

To better understand the word-based neural models, we perform several development experiments. *All* the experiments in this section are conducted on the CTB6 development dataset.

(a) discrete (b) neural(-tune) (c) neural(+tune)

Figure 5: Accuracies against the training epoch using beam sizes 1, 2, 4, 8 and 16, respectively.

5.2.1 Embeddings and beam size

We study the influence of beam size on the baseline and neural models. Our neural model has two choices of using pre-trained word embeddings. We can either fine-tune or fix the embeddings during training. In case of fine-tuning, only words in the training data can be learned, while embeddings of out-of-vocabulary (OOV) words could not be used effectively.[5] In addition, following Dyer et al. (2015) we randomly set words with frequency 1 in the training data as the OOV words in order to learn the OOV embedding, while avoiding overfitting. If the pretrained word embeddings are not fine-tuned, we can utilize all word embeddings.

Figure 5 shows the development results, where the training curve of the discrete baseline is shown in Figure 5(a) and the curve of the neural model without and with fine tuning are shown in 5(b) and 5(c), respectively. The performance increases with a larger beam size in all settings. When the beam increases into 16, the gains levels out. The results of the discrete model and the neural model without fine-tuning are highly similar, showing the usefulness of beam-search.

On the other hand, with fine-tuning, the results are different. The model with beam size 1 gives better accuracies compared to the other models with the same beam size. However, as the beam size increases, the performance increases very little. The results are consistent with Dyer et al. (2015), who find that beam-search improves the results only slightly on dependency parsing. When a beam size of 16 is used, this model performs the worst compared with the discrete model and the neural model without fine-tuning. This is likely because the fine-tuning of embeddings leads to overfitting of in-vocabulary words, and underfitting over OOV words. Based on the observation, we exploit fixed word embeddings in our final models.

[5]We perform experiments using random initialized word embeddings as well when fine-tune is used, which is a fully supervised model. The performance is slightly lower.

Model	P	R	F

-action	95.00	95.31	95.17
+discrete features (combined)	96.38	96.22	96.30

Table 4: Feature experiments.

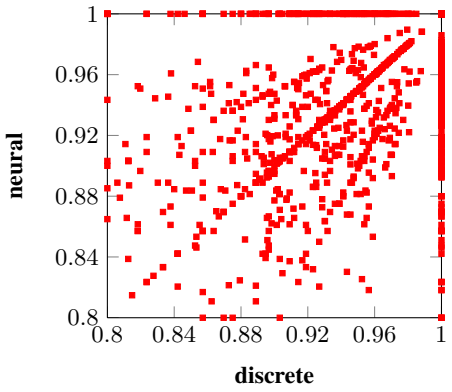

Figure 6: Sentence accuracy comparisons for the discrete and the neural models.

5.2.2 Feature ablation

We conduct feature ablation experiments to study the effects of the word, character unigram, character bigram and action features to the neural model. The results are shown in Table 4. Word features are particularly important to the model, without which the performance decreases by 4.5%. The effects of the character unigram, bigram and action features are relatively much weaker.[6] This demonstrates that in the word-based incremental search framework, words are the most crucial information to the neural model.

5.2.3 Integrating discrete features

Prior work has shown the effectiveness of integrating discrete and neural features for several NLP tasks (Turian et al., 2010; Wang and Manning,

[6]In all our experiments, we fix the character unigram and bigram embeddings, because fine-tuning of these embeddings results in little changes.

Table 5: Main results on CTB60 test dataset.

2013; Durrett and Klein, 2015; Zhang and Zhang, 2015). We investigate the usefulness of such integration to our word-based segmentor on the development dataset. We study it by two ways. First, we compare the error distributions between the discrete and the neural models. Intuitively, different error distributions are necessary for improvements by integration. We draw a scatter graph to show their differences, with the (x, y) values of each point denoting the F-measure scores of the two models with respect to sentences, respectively. As shown in Figure 6, the points are rather dispersive, showing the differences of the two models.

Further, we directly look at the results after integration of both discrete and neural features. As shown in Table 4, the integrated model improves the accuracies from 95.45% to 96.30%, demonstrating that the automatically-induced neural features contain highly complementary information to the manual discrete features.

5.3 Final Results

Table 6 shows the final results on CTB6 test dataset. For thorough comparison, we implement discrete, neural and combined character-based models as well.[7] In particular, the character-based discrete model is a CRF tagging model using character unigrams, bigrams, trigrams and tag transitions (Tseng et al., 2005), and the character-based neural model exploits a bi-directional LSTM layer to model character sequences[8] and a CRF layer for output (Chen et al., 2015b).[9] The combined model uses the same method for integrating discrete and neural features as our word-based model.

Table 6: Main results on PKU and MSR test datasets.

The word-based models achieve better performances than character-based models, since our model can exploit additional word information learnt from large auto-segmented corpus. We also compare the results with other models. Wang et al. (2011) is a semi-supervised model that exploits word statistics from auto-segmented raw corpus, which is similar with our combined model in using semi-supervised word information. We achieve slightly better accuracies. Zhang et al. (2014) is a joint segmentation, POS-tagging and dependency parsing model, which can exploit syntactic information.

To compare our models with other state-of-the-art models in the literature, we report the performance on the PKU and MSR datasets also.[10] Our combined model gives the best result on the MSR dataset, and the second best on PKU. The method of Zhang et al. (2013a) gives the best performance on PKU by co-training on large-scale data.

5.4 Error Analysis

To study the differences between word-based and character-based neural models, we conduct error analysis on the test dataset of CTB60. First,

[7] The code is released for research reference under GPL at https://github.com/SUTDNLP/NNSegmentation.

[8] We use a concatenation of character unigram and bigram embeddings at each position as the input to LSTM, because our experiments show that the character bigram embeddings are useful, without which character-based neural models are significantly lower than their discrete counterparts.

[9] Bi-directional LSTM is slightly better than a single left-right LSTM used in Chen et al. (2015b).

[10] The results of Chen et al. (2015a) and Chen et al. (2015b) are not listed, because they take a preprocessing step by replacing Chinese idioms with a uniform symbol in their test data.

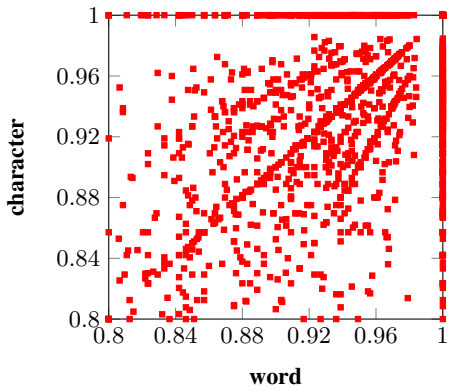

Figure 7: Sentence accuracy comparisons for word- and character-based neural models.

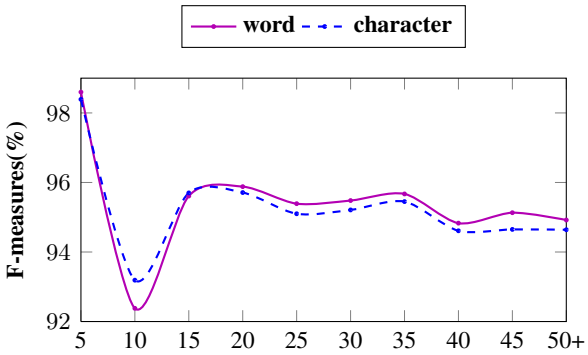

Figure 8: F-measure against character length.

we examine the error distribution on individual sentences. Figure 7 shows the F-measure values of each test sentence by word- and character-based neural models, respectively, where the x-axis value denotes the F-measure value of the word-based neural model, and the y-axis value denotes its performance of the character-based neural model. We can see that the majority scatter points are off the diagonal line, demonstrating strong differences between the two models. This results from the differences in feature sources.

Second, we study the F-measure distribution of the two neural models with respect to sentence lengths. We divide the test sentences into ten bins, with bin i denoting sentence lengths in $[5 * (i-1), 5 * i]$. Figure 8 shows the results. According to the figure, we observe that word-based neural model is relatively weaker for sentences with length in $[5, 10]$, while can better tackle long sentences.

Third, we compare the two neural models by their capabilities of modeling words with different lengths. Figure 9 shows the results. The performances are lower for words with lengths beyond 2, and the performance drops significantly for words with lengths over 3. Overall, the word-based neural model achieves comparable performances with the character-based model, but gives significantly better performances for long words, in particular when the word length is over 3. This demonstrates the advantage of word-level features.

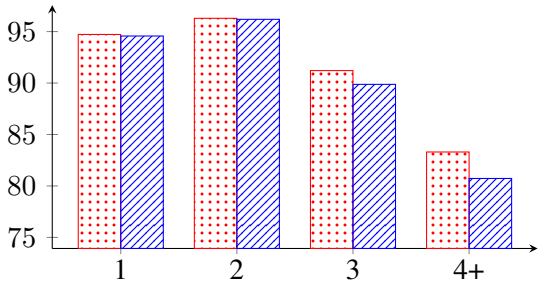

Figure 9: F-measure against word length, where the boxes with red dots denote the performances of word-based neural model, and the boxes with blue slant lines denote character-based neural model.

6 Related Work

Xue (2003) was the first to propose a character-tagging method to Chinese word segmentation, using a maximum entropy model to assign B/I/E/S tags to each character in the input sentence separately. Peng et al. (2004) showed that better results can be achieved by global learning using a CRF model. This method has been followed by most subsequent models in the literature (Tseng et al., 2005; Zhao, 2009; Sun et al., 2012). The most effective features have been character unigrams, bigrams and trigrams within a five-character window, and a bigram tag window. Special characters such as alphabets, numbers and date/time characters are also differentiated for extracting features.

Zheng et al. (2013) built a neural network segmentor, which essentially substitutes the manual discrete features of Peng et al. (2004), with dense real-valued features induced automatically from character embeddings, using a deep neural network structure (Collobert et al., 2011). A tag transition matrix is used for inference, which makes the model effectively. Most subsequent work on neural segmentation followed this method, improving the extraction of emission features by using more complex neural network structures.

Mansur et al. (2013) experimented with embeddings of richer features, and in particular charac-

ter bigrams. Pei et al. (2014) used a tensor neural network to achieve extensive feature combinations, capturing the interaction between characters and tags. Chen et al. (2015a) used a recursive network structure to the same end, extracting more combined features to model complicated character combinations in a five-character window. Chen et al. (2015b) used a LSTM model to capture long-range dependencies between characters in a sentence. Xu and Sun (2016) proposed a dependency-based gated recursive neural network to efficiently integrate local and long-distance features. The above methods are all character-based models, making no use of full word information. In contrast, we leverage both character embeddings and word embeddings for better accuracies.

For word-based segmentation, Andrew (2006) used a semi-CRF model to integrate word features, Zhang and Clark (2007) used a perceptron algorithm with inexact search, and Sun et al. (2009) used a discriminative latent variable model to make use of word features. Recently, there have been several neural-based models using word-level embedding features (Morita et al., 2015; Liu et al., 2016; Cai and Zhao, 2016), which are different from our work in the basic framework. For instance, Liu et al. (2016) follow Andrew (2006) using a semi-CRF for structured inference.

We followed the global learning and beam-search framework of Zhang and Clark (2011) in building a word-based neural segmentor. The main difference between our model and that of Zhang and Clark (2011) is that we use a neural network to induce feature combinations directly from character and word embeddings. In addition, the use of a bi-directional LSTM allows us to leverage non-local information from the word sequence, and look-ahead information from the incoming character sequence. The automatic neural features are complementary to the manual discrete features of Zhang and Clark (2011). We show that our model can accommodate the integration of both types of features. This is similar in spirit to the work of Sun (2010) and Wang et al. (2014), who integrated features of character-based and word-based segmentors.

Transition-based framework with beam search has been widely exploited in a number of other NLP tasks, including syntactic parsing (Zhang and Nivre, 2011; Zhu et al., 2013), information extraction (Li and Ji, 2014) and the work of joint models (Zhang et al., 2013b; Zhang et al., 2014). Recently, the effectiveness of neural features has been studied for this framework. In the natural language parsing community, it has achieved great success. Representative work includes Zhou et al. (2015), Weiss et al. (2015), Watanabe and Sumita (2015) and Andor et al. (2016). In this work, we apply the transition-based neural framework to Chinese segmentation, in order to exploit word-level neural features such as word embeddings.

7 Conclusion

We proposed a word-based neural model for Chinese segmentation, which exploits not only character embeddings as previous work does, but also word embeddings pre-trained from large scale corpus. The model achieved comparable performances compared with a discrete word-based baseline, and also the state-of-the-art character-based neural models in the literature. We further demonstrated that the model can utilize discrete features conveniently, resulting in a combined model that achieved top performances compared with previous work. Finally, we conducted several comparisons to study the differences between our word-based model with character-based neural models, showing that they have different error characteristics.

Abstract

Understanding unstructured text is a major goal within natural language processing. Comprehension tests pose questions based on short text passages to evaluate such understanding. In this work, we investigate machine comprehension on the challenging *MCTest* benchmark. Partly because of its limited size, prior work on *MCTest* has focused mainly on engineering better features. We tackle the dataset with a neural approach, harnessing simple neural networks arranged in a parallel hierarchy. The parallel hierarchy enables our model to compare the passage, question, and answer from a variety of trainable perspectives, as opposed to using a manually designed, rigid feature set. Perspectives range from the word level to sentence fragments to sequences of sentences; the networks operate only on word-embedding representations of text. When trained with a methodology designed to help cope with limited training data, our Parallel-Hierarchical model sets a new state of the art for *MCTest*, outperforming previous feature-engineered approaches slightly and previous neural approaches by a significant margin (over 15 percentage points).

1 Introduction

Humans learn in a variety of ways—by communication with each other and by study, the reading of text. Comprehension of unstructured text by machines, at a near-human level, is a major goal for natural language processing. It has garnered significant attention from the machine learning research community in recent years.

Machine comprehension (MC) is evaluated by posing a set of questions based on a text passage (akin to the reading tests we all took in school). Such tests are objectively gradable and can be used to assess a range of abilities, from basic understanding to causal reasoning to inference (Richardson et al., 2013). Given a text passage and a question about its content, a system is tested on its ability to determine the correct answer (Sachan et al., 2015). In this work, we focus on *MCTest*, a complex but data-limited comprehension benchmark, whose multiple-choice questions require not only extraction but also inference and limited reasoning (Richardson et al., 2013). Inference and reasoning are important human skills that apply broadly, beyond language.

We present a parallel-hierarchical approach to machine comprehension designed to work well in a data-limited setting. There are many use-cases in which comprehension over limited data would be handy: for example, user manuals, internal documentation, legal contracts, and so on. Moreover, work towards more efficient learning from any quantity of data is important in its own right, for bringing machines more in line with the way humans learn. Typically, artificial neural networks require numerous parameters to capture complex patterns, and the more parameters, the more training data is required to tune them. Likewise, deep models learn to extract their own features, but this is a data-intensive process. Our model learns to comprehend at a high level even when data is sparse.

The key to our model is that it compares the question and answer candidates to the text using several distinct *perspectives*. We refer to a question combined with one of its answer candidates as a *hypothesis* (to be detailed below). The *seman-*

*A. Trischler and Z. Ye contributed equally to this work.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 432–441,
Berlin, Germany, August 7-12, 2016.

tic perspective compares the hypothesis to sentences in the text viewed as single, self-contained thoughts; these are represented using a sum and transformation of word embedding vectors, similarly to Weston et al. (2014). The *word-by-word* perspective focuses on similarity matches between individual words from hypothesis and text, at various scales. As in the semantic perspective, we consider matches over complete sentences. We also use a sliding window acting on a subsentential scale (inspired by the work of Hill et al. (2015)), which implicitly considers the linear distance between matched words. Finally, this word-level sliding window operates on two different views of story sentences: the *sequential* view, where words appear in their natural order, and the *dependency* view, where words are reordered based on a linearization of the sentence's dependency graph. Words are represented throughout by embedding vectors (Bengio et al., 2000; Mikolov et al., 2013). These distinct perspectives naturally form a hierarchy that we depict in Figure 1. Language is hierarchical, so it makes sense that comprehension relies on hierarchical levels of understanding.

The perspectives of our model can be considered a type of feature. However, they are implemented by parametric differentiable functions. This is in contrast to most previous efforts on *MCTest*, whose numerous hand-engineered features cannot be trained. Our model, significantly, can be trained end-to-end with backpropagation. To facilitate learning with limited data, we also develop a unique training scheme. We initialize the model's neural networks to perform specific heuristic functions that yield decent (though not impressive) performance on the dataset. Thus, the training scheme gives the model a safe, reasonable baseline from which to start learning. We call this technique *training wheels*.

Computational models that comprehend (insofar as they perform well on MC datasets) have been developed contemporaneously in several research groups (Weston et al., 2014; Sukhbaatar et al., 2015; Hill et al., 2015; Hermann et al., 2015; Kumar et al., 2015). Models designed specifically for *MCTest* include those of Richardson et al. (2013), and more recently Sachan et al. (2015), Wang et al. (2015), and Yin et al. (2016). In experiments, our *Parallel-Hierarchical* model achieves state-of-the-art accuracy on *MCTest*, outperforming these existing methods.

Below we describe related work, the mathematical details of our model, and our experiments, then analyze our results.

2 The Problem

In this section, we borrow from Sachan et al. (2015), who laid out the MC problem nicely. Machine comprehension requires machines to answer questions based on unstructured text. This can be viewed as selecting the best answer from a set of candidates. In the multiple-choice case, candidate answers are predefined, but candidate answers may also be undefined yet restricted (*e.g.*, to *yes*, *no*, or any noun phrase in the text) (Sachan et al., 2015).

For each question q, let T be the unstructured text and $A = \{a_i\}$ the set of candidate answers to q. The machine comprehension task reduces to selecting the answer that has the highest evidence given T. As in Sachan et al. (2015), we combine an answer and a question into a *hypothesis*, $h_i = f(q, a_i)$. To facilitate comparisons of the text with the hypotheses, we also break down the passage into sentences t_j, $T = \{t_j\}$. In our setting, q, a_i, and t_j each represent a sequence of embedding vectors, one for each word and punctuation mark in the respective item.

3 Related Work

Machine comprehension is currently a hot topic within the machine learning community. In this section we will focus on the best-performing models applied specifically to *MCTest*, since it is somewhat unique among MC datasets (see Section 5). Generally, models can be divided into two categories: those that use fixed, engineered features, and neural models. The bulk of the work on *MCTest* falls into the former category.

Manually engineered features often require significant effort on the part of a designer, and/or various auxiliary tools to extract them, and they cannot be modified by training. On the other hand, neural models can be trained end-to-end and typically harness only a single feature: vector-representations of words. Word embeddings are fed into a complex and possibly deep neural network which processes and compares text to question and answer. Among deep models, mechanisms of attention and working memory are common, as in Weston et al. (2014) and Hermann et al. (2015).

3.1 Feature-engineering models

Sachan et al. (2015) treated *MCTest* as a structured prediction problem, searching for a latent *answer-entailing* structure connecting question, answer, and text. This structure corresponds to the best latent alignment of a hypothesis with appropriate snippets of the text. The process of (latently) selecting text snippets is related to the attention mechanisms typically used in deep networks designed for MC and machine translation (Bahdanau et al., 2014; Weston et al., 2014; Hill et al., 2015; Hermann et al., 2015). The model uses event and entity coreference links across sentences along with a host of other features. These include specifically trained word vectors for synonymy; antonymy and class-inclusion relations from external database sources; dependencies and semantic role labels. The model is trained using a latent structural SVM extended to a multitask setting, so that questions are first classified using a pretrained top-level classifier. This enables the system to use different processing strategies for different question categories. The model also combines question and answer into a well-formed statement using the rules of Cucerzan and Agichtein (2005).

Our model is simpler than that of Sachan et al. (2015) in terms of the features it takes in, the training procedure (stochastic gradient descent *vs.* alternating minimization), question classification (we use none), and question-answer combination (simple concatenation or mean *vs.* a set of rules).

Wang et al. (2015) augmented the baseline feature set from Richardson et al. (2013) with features for syntax, frame semantics, coreference chains, and word embeddings. They combined features using a linear latent-variable classifier trained to minimize a max-margin loss function. As in Sachan et al. (2015), questions and answers are combined using a set of manually written rules. The method of Wang et al. (2015) achieved the previous state of the art, but has significant complexity in terms of the feature set.

Space does not permit a full description of all models in this category, but we refer the reader to the contributions of Smith et al. (2015) and Narasimhan and Barzilay (2015) as well.

Despite its relative lack of features, the Parallel-Hierarchical model improves upon the feature-engineered state of the art for *MCTest* by a small amount (about 1% absolute) as detailed in Section 5.

3.2 Neural models

Neural models have, to date, performed relatively poorly on *MCTest*. This is because the dataset is sparse and complex.

Yin et al. (2016) investigated deep-learning approaches concurrently with the present work. They measured the performance of the Attentive Reader (Hermann et al., 2015) and the Neural Reasoner (Peng et al., 2015), both deep, end-to-end recurrent models with attention mechanisms, and also developed an attention-based convolutional network, the HABCNN. Their network operates on a hierarchy similar to our own, providing further evidence of the promise of hierarchical perspectives. Specifically, the HABCNN processes text at the sentence level and the *snippet* level, where the latter combines adjacent sentences (as we do through an n-gram input). Embedding vectors for the question and the answer candidates are combined and encoded by a convolutional network. This encoding modulates attention over sentence and snippet encodings, followed by max-pooling to determine the best matches between question, answer, and text. As in the present work, matching scores are given by cosine similarity. The HABCNN also makes use of a question classifier.

Despite the conceptual overlap between the HABCNN and our approach, the Parallel-Hierarchical model performs significantly better on *MCTest* (more than 15% absolute) as detailed in Section 5. Other neural models tested in Yin et al. (2016) fare even worse.

4 The Parallel-Hierarchical Model

Let us now define our machine comprehension model in full. We first describe each of the perspectives separately, then describe how they are combined. Below, we use subscripts to index elements of sequences, like word vectors, and superscripts to indicate whether elements come from the text, question, or answer. In particular, we use the subscripts k, m, n, p to index sequences from the text, question, answer, and hypothesis, respectively, and superscripts t, q, a, h. We depict the model schematically in Figure 1.

4.1 Semantic Perspective

The semantic perspective is similar to the Memory Networks approach for embedding inputs into memory space (Weston et al., 2014). Each sen-

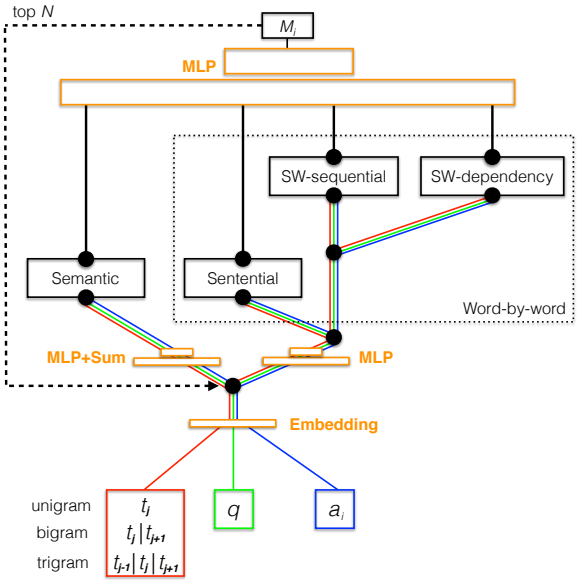

Figure 1: Schematic of the Parallel-Hierarchical model. SW stands for "sliding window." MLP represents a fully connected neural network.

tence of the text is a sequence of d-dimensional word vectors: $t_j = \{\mathbf{t}_k\}$, $\mathbf{t}_k \in \mathbb{R}^d$. The semantic vector $\mathbf{s}^t$ is computed by embedding the word vectors into a D-dimensional space using a two-layer network that implements weighted sum followed by an affine tranformation and a nonlinearity; *i.e.*,

$$\mathbf{s}^t = f\left(\mathbf{A}^t \sum_k \omega_k \mathbf{t}_k + \mathbf{b}_A^t\right). \quad (1)$$

The matrix $\mathbf{A}^t \in \mathbb{R}^{D\times d}$, the bias vector $\mathbf{b}_A^t \in \mathbb{R}^D$, and for f we use the *leaky ReLU* function. The scalar ω_k is a trainable weight associated with each word in the vocabulary. These scalar weights implement a kind of *exogenous* or bottom-up attention that depends only on the input stimulus (Mayer et al., 2004). They can, for example, learn to perform the function of stopword lists in a soft, trainable way, to nullify the contribution of unimportant filler words.

The semantic representation of a hypothesis is formed analogously, except that we concatenate the question word vectors $\mathbf{q}_m$ and answer word vectors $\mathbf{a}_n$ as a single sequence $\{\mathbf{h}_p\} = \{\mathbf{q}_m, \mathbf{a}_n\}$. For semantic vector $\mathbf{s}^h$ of the hypothesis, we use a unique transformation matrix $\mathbf{A}^h \in \mathbb{R}^{D\times d}$ and bias vector $\mathbf{b}_A^h \in \mathbb{R}^D$.

These transformations map a text sentence and a hypothesis into a common space where they can be compared. We compute the semantic match between text sentence and hypothesis using the cosine similarity,

$$M^{\text{sem}} = \cos(\mathbf{s}^t, \mathbf{s}^h). \quad (2)$$

4.2 Word-by-Word Perspective

The first step in building the word-by-word perspective is to transform word vectors from a text sentence, question, and answer through respective neural functions. For the text, $\tilde{\mathbf{t}}_k = f\left(\mathbf{B}^t\mathbf{t}_k + \mathbf{b}_B^t\right)$, where $\mathbf{B}^t \in \mathbb{R}^{D\times d}$, $\mathbf{b}_B^t \in \mathbb{R}^D$ and f is again the *leaky ReLU*. We transform the question and the answer to $\tilde{\mathbf{q}}_m$ and $\tilde{\mathbf{a}}_n$ analogously using distinct matrices and bias vectors. In contrast to the semantic perspective, we keep the question and answer candidates separate in the word-by-word perspective. This is because matches to answer words are inherently more important than matches to question words, and we want our model to learn to use this property.

4.2.1 Sentential

Inspired by the work of Wang and Jiang (2015) in paraphrase detection, we compute matches between hypotheses and text sentences at the word level. This computation uses the cosine similarity as before:

$$c_{km}^q = \cos(\tilde{\mathbf{t}}_k, \tilde{\mathbf{q}}_m), \quad (3)$$
$$c_{kn}^a = \cos(\tilde{\mathbf{t}}_k, \tilde{\mathbf{a}}_n). \quad (4)$$

The word-by-word match between a text sentence and question is determined by taking the maximum over k (finding the text word that best matches each question word) and then taking a weighted mean over m (finding the average match over the full question):

$$M^q = \frac{1}{Z}\sum_m \omega_m \max_k c_{km}^q. \quad (5)$$

Here, ω_m is the word weight for the question word and Z normalizes these weights to sum to one over the question. We define the match between a sentence and answer candidate, M^a, analogously. Finally, we combine the matches to question and answer according to

$$M^{\text{word}} = \alpha_1 M^q + \alpha_2 M^a + \alpha_3 M^q M^a. \quad (6)$$

Here, the α are trainable parameters that control the relative importance of the terms.

4.2.2 Sequential Sliding Window

The sequential sliding window is related to the original *MCTest* baseline by Richardson et al. (2013). Our sliding window decays from its focus word according to a Gaussian distribution, which we extend by assigning a trainable weight to each location in the window. This modification enables the window to use information about the distance between word matches; the original baseline (Richardson et al., 2013) used distance information through a predefined function.

The sliding window scans over the words of the text as one continuous sequence, without sentence breaks. Each window is treated like a sentence in the previous subsection, but we include a location-based weight $\lambda(k)$. This weight is based on a word's position in the window, which, given a window, depends on its global position k. The cosine similarity is adapted as

$$s^q_{km} = \lambda(k) \cos(\tilde{\mathbf{t}}_k, \tilde{\mathbf{q}}_m), \tag{7}$$

for the question and analogously for the answer. We initialize the location weights with a Gaussian and fine-tune them during training. The final matching score, denoted as M^{sws}, is computed as in (5) and (6) with s^q_{km} replacing c^q_{km}.

4.2.3 Dependency Sliding Window

The dependency sliding window operates identically to the linear sliding window, but on a different view of the text passage. The output of this component is M^{swd} and is formed analogously to M^{sws}.

The dependency perspective uses the Stanford Dependency Parser (Chen and Manning, 2014) as an auxiliary tool. Thus, the dependency graph can be considered a fixed feature. Moreover, linearization of the dependency graph, because it relies on an eigendecomposition, is not differentiable. However, we handle the linearization in data preprocessing so that the model sees only reordered word-vector inputs.

Specifically, we run the Stanford Dependency Parser on each text sentence to build a dependency graph. This graph has n_w vertices, one for each word in the sentence. From the dependency graph we form the Laplacian matrix $\mathbf{L} \in \mathbb{R}^{n_w \times n_w}$ and determine its eigenvectors. The second eigenvector $\mathbf{u}_2$ of the Laplacian is known as the *Fiedler* vector. It is the solution to the minimization

$$\underset{g}{\text{minimize}} \sum_{i,j=1}^{N} \eta_{ij} (g(v_i) - g(v_j))^2, \tag{8}$$

where v_i are the vertices of the graph and η_{ij} is the weight of the edge from vertex i to vertex j (Golub and Van Loan, 2012). The Fiedler vector maps a weighted graph onto a line such that connected nodes stay close, modulated by the connection weights.[1] This enables us to reorder the words of a sentence based on their proximity in the dependency graph. The reordering of the words is given by the ordered index set

$$I = \arg\text{sort}(\mathbf{u}_2). \tag{9}$$

To give an example of how this works, consider the following sentence from *MCTest* and its dependency-based reordering:

> *Jenny, Mrs. Mustard 's helper, called the police.*
> *the police, called Jenny helper, Mrs. 's Mustard.*

Sliding-window-based matching on the original sentence will answer the question *Who called the police?* with *Mrs. Mustard*. The dependency reordering enables the window to determine the correct answer, *Jenny*.

4.3 Combining Distributed Evidence

It is important in comprehension to synthesize information found throughout a document. *MCTest* was explicitly designed to ensure that it could not be solved by lexical techniques alone, but would instead require some form of inference or limited reasoning (Richardson et al., 2013). It therefore includes questions where the evidence for an answer spans several sentences.

To perform synthesis, our model also takes in n-grams of sentences, *i.e.*, sentence pairs and triples strung together. The model treats these exactly as it treats single sentences, applying all functions detailed above. A later pooling operation combines scores across all n-grams (including the single-sentence input). This is described in the next subsection.

[1] We experimented with assigning unique edge weights to unique relation types in the dependency graph. However, this had negligible effect. We hypothesize that this is because dependency graphs are trees, which do not have cycles.

With n-grams, the model can combine information distributed across contiguous sentences. In some cases, however, the required evidence is spread across distant sentences. To give our model some capacity to deal with this scenario, we take the top N sentences as scored by all the preceding functions, and then repeat the scoring computations, viewing these top N as a single sentence.

The reasoning behind these approaches can be explained well in a probabilistic setting. If we consider our similarity scores to model the likelihood of a text sentence given a hypothesis, $p(t_j \mid h_i)$, then the n-gram and top N approaches model a joint probability $p(t_{j_1}, t_{j_2}, \ldots, t_{j_k} \mid h_i)$. We cannot model the joint probability as a product of individual terms (score values) because distributed pieces of evidence are likely not independent.

4.4 Combining Perspectives

We use a multilayer perceptron (MLP) to combine M^{sem}, M^{word}, M^{swd}, and M^{sws}, as well as the scores for separate n-grams, as a final matching score M_i for each answer candidate. This MLP has multiple layers of staged input, because the distinct scores have different dimensionality: there is one M^{sem} and one M^{word} for each story sentence, and one M^{swd} and one M^{sws} for each application of the sliding window. The MLP's activation function is linear.

Our overall training objective is to minimize the ranking loss

$$\mathcal{L}(T, q, A) = \max(0, \mu + \max_i M_{i \neq i^*} - M_{i^*}), \tag{10}$$

where μ is a constant margin, i^* indexes the correct answer. We take the maximum over i so that we are ranking the correct answer over the best-ranked incorrect answer (of which there are three). This approach worked better than comparing the correct answer to the incorrect answers individually as in Wang et al. (2015).

Our implementation of the Parallel-Hierarchical model, built in *Theano* (Bergstra et al., 2010) using the *Keras* framework (Chollet, 2015), is available on `Github`.[2]

4.5 Training Wheels

Before training, we initialized the neural-network components of our model to perform sensible heuristic functions. Training did not converge on the small *MCTest* without this vital approach.

[2]https://github.com/Maluuba/mctest-model

Empirically, we found that we could achieve above 50% accuracy on *MCTest* using a simple sum of word vectors followed by a dot product between the story-sentence sum and the hypothesis sum. Therefore, we initialized the network for the semantic perspective to perform this sum, by initializing $\mathbf{A}^x$ as the *identity* matrix and $\mathbf{b}_A^x$ as the zero vector, $x \in \{t, h\}$. Recall that the activation function is a $ReLU$ so that positive outputs are unchanged.

We also found basic word-matching scores to be helpful, so we initialized the word-by-word networks likewise. The network for perspective-combination was initialized to perform a sum of individual scores, using a *zero* bias-vector and a weight matrix of *ones*, since we found that each perspective contributed positively to the overall result.

This *training wheels* approach is related to other techniques from the literature. For instance, Socher et al. (2013) proposed the identity-matrix initialization in the context of parsing, and Le et al. (2015) proposed it in the context of recurrent neural networks (to preserve the error signal through backpropagation). In residual networks (He et al., 2015), shortcut connections bypass certain layers in the network so that a simpler function can be trained in conjunction with the full model.

5 Experiments

5.1 The Dataset

MCTest is a collection of 660 elementary-level children's stories and associated questions, written by human subjects. The stories are fictional, ensuring that the answer must be found in the text itself, and carefully limited to what a young child can understand (Richardson et al., 2013).

The more challenging variant consists of 500 stories with four multiple-choice questions each. Despite the elementary level, stories and questions are more natural and more complex than those found in synthetic MC datasets like *bAbI* (Weston et al., 2014) and *CNN* (Hermann et al., 2015).

MCTest is challenging because it is both complicated and small. As per Hill et al. (2015), "it is very difficult to train statistical models only on *MCTest*." Its size limits the number of parameters that can be trained, and prevents learning any complex language modeling simultaneously with the capacity to answer questions.

5.2 Training and Model Details

In this section we describe important details of the training procedure and model setup. For a complete list of hyperparameter settings, our stopword list, and other minutiæ, we refer interested readers to our `Github` repository.

For word vectors we use Google's publicly available embeddings, trained with `word2vec` on the 100-billion-word *News corpus* (Mikolov et al., 2013). These vectors are kept fixed throughout training, since we found that training them was not helpful (likely because of *MCTest*'s size). The vectors are 300-dimensional ($d = 300$).

We do not use a stopword list for the text passage, instead relying on the trainable word weights to ascribe global importance ratings to words. These weights are initialized with the inverse document frequency (IDF) statistic computed over the *MCTest* corpus.[3] However, we do use a short stopword list for questions. This list nullifies query words such as {*who, what, when, where, how*}, along with conjugations of the verbs *to do* and *to be*.

Following earlier methods, we use a heuristic to improve performance on negation questions (Sachan et al., 2015; Wang et al., 2015). When a question contains the words *which* and *not*, we negate the hypothesis ranking scores so that the minimum becomes the maximum. This heuristic leads to an improvement around 6% on the validation set.

The most important technique for training the model was the *training wheels* approach. Without this, training was not effective at all (see the ablation study in Table 2). The identity initialization requires that the network weight matrices are square ($d = D$).

We found *dropout* (Srivastava et al., 2014) to be particularly effective at improving generalization from the training to the test set, and used 0.5 as the dropout probability. Dropout occurs after all neural-network transformations, if those transformations are allowed to change with training. Our best performing model held networks at the word-by-word level fixed.

For combining distributed evidence, we used up to trigrams over sentences and our best-performing model reiterated over the top two sentences ($N = 2$).

[3]We override the IDF initialization for words like *not*, which are frequent but highly informative.

We used the *Adam* optimizer with the standard settings (Kingma and Ba, 2014) and a learning rate of 0.003. To determine the best hyperparameters we performed a search over 150 settings based on validation-set accuracy. *MCTest*'s original validation set is too small for reliable hyperparameter tuning, so, following Wang et al. (2015), we merged the training and validation sets of *MCTest*-160 and *MCTest*-500, then split them randomly into a 250-story training set and a 200-story validation set. This repartition of the data did not affect overall performance *per se*; rather, the larger validation set made it easier to choose hyperparameters because validation results were more consistent.

5.3 Results

Table 1 presents the performance of feature-engineered and neural methods on the *MCTest* test set. Accuracy scores are divided among questions whose evidence lies in a single sentence (*single*) and across multiple sentences (*multi*), and among the two variants. Clearly, *MCTest*-160 is easier.

The first three rows represent feature-engineered methods. Richardson et al. (2013) + RTE is the best-performing variant of the original baseline published along with *MCTest*. It uses a lexical sliding window and distance-based measure, augmented with rules for recognizing textual entailment. We described the methods of Sachan et al. (2015) and Wang et al. (2015) in Section 3. On *MCTest*-500, the Parallel Hierarchical model significantly outperforms these methods on *single* questions ($> 2\%$) and slightly outperforms the latter two on *multi* questions ($\approx 0.3\%$) and overall ($\approx 1\%$). The method of Wang et al. (2015) achieves the best overall result on *MCTest*-160. We suspect this is because our neural method suffered from the relative lack of training data.

The last four rows in Table 1 are neural methods that we discussed in Section 3. Performance measures are taken from Yin et al. (2016). Here we see our model outperforming the alternatives by a large margin across the board ($> 15\%$). The Neural Reasoner and the Attentive Reader are large, deep models with hundreds of thousands of parameters, so it is unsurprising that they performed poorly on *MCTest*. The specifically-designed HABCNN fared better, its convolutional architecture cutting down on the parameter count. Because there are similarities between our model and the

Table 2: Ablation study on *MCTest*-500 (all).

HABCNN, we hypothesize that the performance difference is attributable to the greater simplicity of our model and our *training wheels* methodology.

6 Analysis and Discussion

We measure the contribution of each component of the model by ablating it. Results on the validation set are given in Table 2. Not surprisingly, the n-gram functionality is important, contributing almost 4% accuracy improvement. Without this, the model has almost no means for synthesizing distributed evidence. The top N function contributes similarly to the overall performance, suggesting that there is a nonnegligible number of *multi* questions that have their evidence distributed across noncontiguous sentences. Ablating the sentential component made a significant difference, reducing performance by about 5%. Simple word-by-word matching is obviously useful on *MCTest*. The sequential sliding window contributes about 1.3%, suggesting that word-distance measures are not overly important. Similarly, the dependency-based sliding window makes a very minor contribution. We found this surprising. It may be that linearization of the dependency graph removes too much of its information. The exogenous word weights make a significant contribution of over 3%. Allowing the embeddings to change with training reduced performance fairly significantly, almost 8%. As discussed, this is a case of having too many parameters for the available training data. Finally, we see that the training wheels methodology had enormous impact. Without heuristic-based initialization of the model's various weight matrices, accuracy goes down to about 35%, which is only ten points over random chance.

Analysis reveals that most of our system's test failures occur on questions about quantity (*e.g.*, *How many...?*) and temporal order (*e.g.*, *Who was invited last?*). Quantity questions make up 9.5% of our errors on the validation set, while order questions make up 10.3%. This weakness is not unexpected, since our architecture lacks any capacity for counting or tracking temporal order. Incorporating mechanisms for these forms of reasoning is a priority for future work (in contrast, the Memory Network model (Weston et al., 2014) is quite good at temporal reasoning).

The Parallel-Hierarchical model is simple. It does no complex language or sequence modeling. Its simplicity is a response to the limited data of *MCTest*. Nevertheless, the model achieves state-of-the-art results on the *multi* questions, which (putatively) require some limited reasoning. Our model is able to handle them reasonably well just by stringing important sentences together. Thus, the model imitates reasoning with a heuristic. This suggests that, to learn true reasoning abilities, *MCTest* is too simple a dataset—and it is almost certainly too small for this goal.

However, it may be that human language processing can be factored into separate processes of *comprehension* and *reasoning*. If so, the Parallel-Hierarchical model is a good start on the former. Indeed, if we train the method exclusively on *single* questions then its results become even more impressive: we can achieve a test accuracy of **79.1%** on *MCTest*-500. Note that this boost in performance comes from training on only about *half* the data. The 'single' questions can be con-

sidered a close analogue of the RTE task, at which our model becomes very adept even with less data.

Incorporating the various views of our model amounts to encoding prior knowledge about the problem structure. This is similar to the purpose of feature engineering, except that the views can be fully trained. Encoding problem structure into the structure of neural networks is not new: as another example, the convolutional architecture has led to large gains in vision tasks.

7 Conclusion

We have presented the novel Parallel-Hierarchical model for machine comprehension, and evaluated it on the small but complex *MCTest*. Our model achieves state-of-the-art results, outperforming several feature-engineered and neural approaches.

Working with our model has emphasized to us the following (not necessarily novel) concepts, which we record here to promote further empirical validation.

- Good comprehension of language is supported by hierarchical levels of understanding (*cf.* Hill et al. (2015)).
- Exogenous attention (the trainable word weights) may be broadly helpful for NLP.
- The *training wheels* approach, that is, initializing neural networks to perform sensible heuristics, appears helpful for small datasets.
- *Reasoning* over language is challenging, but easily simulated in some cases.

Abstract

Broad domain question answering is often difficult in the absence of structured knowledge bases, and can benefit from shallow lexical methods (broad coverage) and logical reasoning (high precision). We propose an approach for incorporating both of these signals in a unified framework based on natural logic. We extend the breadth of inferences afforded by natural logic to include relational entailment (e.g., *buy* → *own*) and meronymy (e.g., a person born in a city is born the city's country). Furthermore, we train an *evaluation function* – akin to gameplaying – to evaluate the expected truth of candidate premises on the fly. We evaluate our approach on answering multiple choice science questions, achieving strong results on the dataset.

1 Introduction

Question answering is an important task in NLP, and becomes both more important and more difficult when the answers are not supported by hand-curated knowledge bases. In these cases, viewing question answering as textual entailment over a very large premise set can offer a means of generalizing reliably to open domain questions.

A natural approach to textual entailment is to treat it as a logical entailment problem. However, this high-precision approach is not feasible in cases where a formal proof is difficult or impossible. For example, consider the following hypothesis (H) and its supporting premise (P) for the question *Which part of a plant produces the seeds?*:

P: *Ovaries are the female part of the flower, which produces eggs that are needed for making seeds.*

H: *A flower produces the seeds.*

This requires a relatively large amount of inference: the most natural atomic fact in the sentence is that ovaries produce eggs. These inferences are feasible in a limited domain, but become difficult the more open-domain reasoning they require. In contrast, even a simple lexical overlap classifier could correctly predict the entailment. In fact, such a bag-of-words entailment model has been shown to be surprisingly effective on the Recognizing Textual Entailment (RTE) challenges (MacCartney, 2009). On the other hand, such methods are also notorious for ignoring even trivial cases of nonentailment that are easy for natural logic, e.g., recognizing negation in the example below:

P: *Eating candy for dinner is an example of a poor health habit.*

H: *Eating candy is an example of a good health habit.*

We present an approach to leverage the benefits of both methods. Natural logic – a proof theory over the syntax of natural language – offers a framework for logical inference which is already familiar to lexical methods. As an inference system searches for a valid premise, the candidates it explores can be evaluated on their similarity to a premise by a conventional lexical classifier.

We therefore extend a natural logic inference engine in two key ways: first, we handle relational entailment and meronymy, increasing the total number of inferences that can be made. We further implement an *evaluation function* which quickly provides an estimate for how likely a candidate premise is to be supported by the knowledge base, without running the full search. This can then more easily match a known premise despite still not matching exactly.

We present the following contributions: (1) we extend the classes of inferences NaturalLI can perform on real-world sentences by incorporating relational entailment and meronymy, and by operat-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 442–452,
Berlin, Germany, August 7-12, 2016.

ing over dependency trees; (2) we augment NaturalLI with an evaluation function to provide an estimate of entailment for any query; and (3) we run our system over the Aristo science questions corpus, achieving the strong results.

2 Background

We briefly review natural logic and NaturalLI – the existing inference engine we use. Much of this paper will extend this system, with additional inferences (Section 3) and a soft lexical classifier (Section 4).

2.1 Natural Logic

Natural logic is a formal proof theory that aims to capture a subset of logical inferences by appealing directly to the structure of language, without needing either an abstract logical language (e.g., Markov Logic Networks; Richardson and Domingos (2006)) or denotations (e.g., semantic parsing; Liang and Potts (2015)). We use the logic introduced by the NatLog system (MacCartney and Manning, 2007; 2008; 2009), which was in turn based on earlier theoretical work on Monotonicity Calculus (van Benthem, 1986; Sánchez Valencia, 1991). We adopt the precise semantics of Icard and Moss (2014); we refer the reader to this paper for a more thorough introduction to the formalism.

At a high level, natural logic proofs operate by mutating spans of text to ensure that the mutated sentence follows from the original – each step is much like a syllogistic inference. Each mutation in the proof follows three steps:

1. An atomic lexical relation is induced by either inserting, deleting or mutating a span in the sentence. For example, in Figure 1, mutating *The* to *No* induces the $\curlywedge$ relation; mutating *cat* to *carnivore* induces the $\sqsubseteq$ relation. The relations $\equiv$ and $\sqsubseteq$ are variants of entailment; $\curlywedge$ and $\Downarrow$ are variants of negation.
2. This lexical relation between words is projected up to yield a relation between sentences, based on the *polarity* of the token. For instance, *The cat eats animals* $\sqsubseteq$ *some carnivores eat animals*. We explain this in more detail below.
3. These sentence level relations are *joined* together to produce a relation between a premise, and a hypothesis multiple mutations away. For example in Figure 1, if we join $\sqsubseteq$, $\equiv$, $\sqsubseteq$, and $\curlywedge$, we get negation ($\Downarrow$).

The notion of *projecting* a relation from a lexical item to a sentence is important to understand.[1] To illustrate, *cat* $\sqsubseteq$ *animal*, and *some cat meows* $\sqsubseteq$ *some animal meows* (recall, $\sqsubseteq$ denotes entailment), but *no cat barks* $\not\sqsubseteq$ *no animal barks*. Despite differing by the same lexical relation, the sentence-level relation is different in the two cases.

We appeal to two important concepts: *monotonicity* – a property of arguments to natural language operators; and *polarity* – a property of tokens. From the example above, *some* is monotone in its first argument (i.e., *cat* or *animal*), and *no* is antitone in its first argument. This means that the first argument to *some* is allowed to mutate up the specified hierarchy (e.g., hypernymy), whereas the first argument to *no* is allowed to mutate down.

Polarity is a property of tokens in a sentence determined by the operators acting on it. All lexical items have *upward* polarity by default; monotone operators – like *some*, *several*, or *a few* – preserve polarity. Antitone operators – like *no*, *not*, and *all* (in its first argument) – reverse polarity. For example, *mice* in ***no*** *cats eat mice* has downward polarity, whereas *mice* in ***no*** *cats do**n't*** *eat mice* has upward polarity (it is in the scope of two downward monotone operators).

As a final note, although we refer to the monotonicity calculus described above as *natural logic*, this formalism is only one of many possible natural logics. For example, McAllester and Givan (1992) introduce a syntax for first order logic which they call *Montagovian syntax*. This syntax has two key advantages over first order logic: first, the "quantifier-free" version of the syntax (roughly equivalent to the monotonicity calculus we use) is computationally efficient while still handling limited quantification. Second, the syntax more closely mirrors that of natural language.

2.2 NaturalLI

We build our extensions within the framework of NaturalLI, introduced by Angeli and Manning (2014). NaturalLI casts inference as a search problem: given a hypothesis and an arbitrarily large corpus of text, it searches through the space of lexical mutations (e.g., *cat* $\rightarrow$ *carnivore*), with associated costs, until a premise is found.

An example search using NaturalLI is given in Figure 1. The relations along the edges denote re-

[1] For clarity we describe a simplified semantics here; NaturalLI implements the semantics described in Icard and Moss (2014).

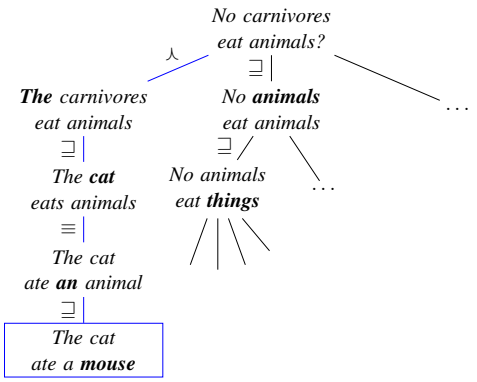

Figure 1: An illustration of NaturalLI searching for a candidate premise to support the hypothesis at the root of the tree. We are searching from a hypothesis *no carnivores eat animals*, and find a contradicting premise *the cat ate a mouse*. The edge labels denote Natural Logic inference steps.

lations between the associated sentences – i.e., the projected lexical relations from Section 2.2. Importantly, and in contrast with traditional entailment systems, NaturalLI searches over an arbitrarily large knowledge base of textual premises rather than a single premise/hypothesis pair.

3 Improving Inference in NaturalLI

We extend NaturalLI in three ways to improve its coverage. We adapt the search algorithm to operate over dependency trees rather than the surface forms (Section 3.1). We enrich the class of inferences warranted by natural logic beyond hypernymy and operator rewording to also encompass meronymy and relational entailment (Section 3.2). Lastly, we handle token insertions during search more elegantly (Section 3.3).

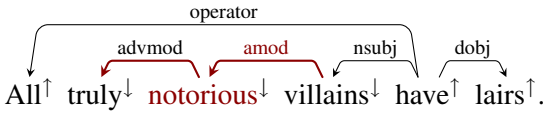
The general search algorithm in NaturalLI is parametrized as follows: First, an order is chosen to traverse the tokens in a sentence. For example, the original paper traverses tokens left-to-right. At each token, one of three operations can be performed: *deleting* a token (corresponding to inserting a word in the proof derivation), *mutating* a token, and *inserting* a token (corresponding to deleting a token in the proof derivation).

3.1 Natural logic over Dependency Trees

Operating over dependency trees rather than a token sequence requires reworking (1) the semantics of deleting a token during search, and (2) the order in which the sentence is traversed.

We recently defined a mapping from Stanford Dependency relations to the associated lexical relation deleting the dependent subtree would induce (Angeli et al., 2015). We adapt this mapping to yield the relation induced by *inserting* a given dependency edge, corresponding to our deletions in search; we also convert the mapping to use Universal Dependencies (de Marneffe et al., 2014). This now lends a natural deletion operation: at a given node, the subtree rooted at that node can be deleted to induce the associated natural logic relation.

For example, we can infer that *all truly notorious villains have lairs* from the premise *all villains have lairs* by observing that deleting an *amod* arc induces the relation $\sqsupseteq$, which in the downward polarity context of *villains*$^{\downarrow}$ projects to $\sqsubseteq$ (entailment):



An admittedly rare but interesting subtlety in the order we chose to traverse the tokens in the sentence is the effect mutating an operator has on the polarity of its arguments. For example, mutating *some* to *all* changes the polarity of its first argument. There are cases where we must mutate the argument to the operator before the operator itself, as well as cases where we must mutate the operator before its arguments. Consider, for instance:

P: *All felines have a tail*
H: *Some cats have a tail*

where we must first mutate *cat* to *feline*, versus:

P: *All cats have a tail*
H: *Some felines have a tail*

where we must first mutate *some* to *all*. Therefore, our traversal first visits each operator, then performs a breadth-first traversal of the tree, and then visits each operator a second time.

3.2 Meronymy and Relational Entailment

Although natural logic and the underlying monotonicity calculus has only been explored in the context of hypernymy, the underlying framework can be applied to any partial order.

Natural language operators can be defined as a mapping from denotations of objects to truth values. The domain of word denotations is then or-

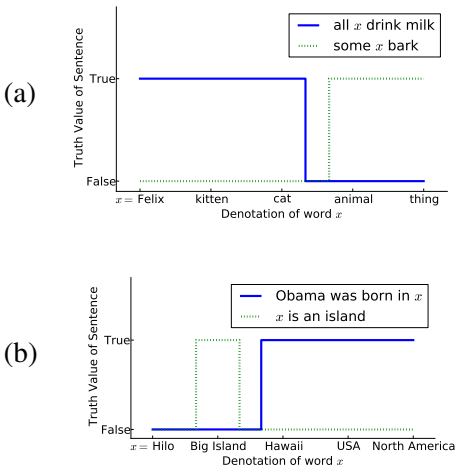


Figure 2: An illustration of monotonicity using different partial orders. (a) The monotonicity of *all* and *some* in their first arguments, over a domain of denotations. (b) An illustration of the *born in* monotone operator over the meronymy hierarchy, and the operator *is an island* as neither monotone or antitone.

dered by the subset operator, corresponding to ordering by hypernymy over the words.[2] However, hypernymy is not the only useful partial ordering over denotations. We include two additional orderings as motivating examples: relational entailment and meronymy.

Relational Entailment For two verbs v_1 and v_2, we define $v_1 \leq v_2$ if the first verb entails the second. In many cases, a verb v_1 may entail a verb v_2 even if v_2 is not a hypernym of v_1. For example, to *sell* something (hopefully) entails *own*ing that thing. Apart from context-specific cases (e.g., *orbit* entails *launch* only for man-made objects), these hold largely independent of context. Note that the usual operators apply to relational entailments – if *all cactus owners live in Arizona* then *all cactus sellers live in Arizona*.

This information was incorporated using data from VERBOCEAN (Chklovski and Pantel, 2004), adapting the confidence weights as transition costs. VERBOCEAN uses lexicosyntactic patterns to score pairs of verbs as candidate participants in a set of relations. We approximate the VERBOCEAN relations $\textit{stronger-than}(v_1, v_2)$ (e.g., to kill is stronger than to wound) and $\textit{happens-before}(v_2, v_1)$ (e.g., buying happens before owning) to indicate that v_1 entails v_2. These verb entailment transitions are incorporated using costs derived from the original weights from Chklovski and Pantel (2004).

Meronymy The most salient use-case for meronymy is with locations. For example, if Obama was born in Hawaii, then we know that Obama was born in America, because Hawaii is a meronym of (part of) America. Unlike relational entailment and hypernymy, meronymy is operated on by a distinct set of operators: if *Hawaii is an island*, we cannot necessarily entail that *America is an island*.

We semi-automatically collect a set of 81 operators (e.g., *born in*, *visited*) which then compose in the usual way with the conventional operators (e.g., *some*, *all*). These operators consist of dependency paths of length 2 that co-occurred in newswire text with a named entity of type *PERSON* and two different named entities of type *LOCATION*, such that one location was a meronym of the other. All other operators are considered non-monotone with respect to the meronym hierarchy.

Note that these are not the only two orders that can be incorporated into our framework; they just happen to be two which have lexical resources available and are likely to be useful in real-world entailment tasks.

3.3 Removing the Insertion Transition

Inserting words during search poses an inherent problem, as the space of possible words to insert at any position is on the order of the size of the vocabulary. In NaturalLI, this was solved by keeping a trie of possible insertions, and using that to prune this space. This is both computationally slow and adapts awkwardly to a search over dependency trees.

Therefore, this work instead opts to perform a bidirectional search: when constructing the knowledge base, we add not only the original sentence but also all entailments with subtrees deleted. For example, a premise of *some furry cats have tails* would yield two facts for the knowledge base: *some furry cats have tails* as well as *some cats have tails*. For this, we use the process described in Angeli et al. (2015) to generate short entailed sentences from a long utterance using natural logic. This then leaves the reverse search to only deal with mutations and inference insertions,

[2] Truth values are a trivial partial order corresponding to entailment: if $t_1 \leq t_2$ (i.e., $t_1 \sqsubseteq t_2$), and you know that t_1 is true, then t_2 must be true.

which are relatively easier.

The new challenge this introduces, of course, is the additional space required to store the new facts. To mitigate this, we hash every fact into a 64 bit integer, and store only the hashed value in the knowledge base. We construct this hash function such that it operates over a bag of edges in the dependency tree. This has two key properties: it allows us to be invariant to the word order of of the sentence, and more importantly it allows us to run our search directly over modifications to this hash function.

To elaborate, we notice that each of the two classes of operations our search is performing are done locally over a single dependency edge. When adding an edge, we can simply take the XOR of the hash saved in the parent state and the hash of the added edge. When mutating an edge, we XOR the hash of the parent state with the edge we are mutating, and again with the mutated edge. In this way, each search node need only carry an 8 byte hash, local information about the edge currently being considered (8 bytes), global information about the words deleted during search (5 bytes), a 3 byte backpointer to recover the inference path, and 8 bytes of operator metadata – 32 bytes in all, amounting to exactly half a cache line on our machines. This careful attention to data structures and memory layout turn out to have a large impact on runtime efficiency. More details are given in Angeli (2016).

4 An Evaluation Function for NaturalLI

There are many cases – particularly as the length of the premise and the hypothesis grow – where despite our improvements NaturalLI will fail to find any supporting premises; for example:

P: *Food serves mainly for growth, energy and body repair, maintenance and protection.*

H: *Animals get energy for growth and repair from food.*

In addition to requiring reasoning with multiple implicit premises (a concomitant weak point of natural logic), a correct interpretation of the sentence requires fairly nontrivial nonlocal reasoning: *Food serves mainly for* $x \rightarrow$ *Animals get* x *from food*.

Nonetheless, there enough lexical clues in the sentence that even a simple entailment classifier would get the example correct. We build such a classifier and adapt it as an evaluation function inside NaturalLI in case no premises are found during search.

4.1 A Standalone Entailment Classifier

Our entailment classifier is designed to be as domain independent as possible; therefore we define only 5 unlexicalized real-valued features, with an optional sixth feature encoding the score output by the Solr information extraction system (in turn built upon Lucene). In fact, this classifier is a stronger baseline than it may seem: evaluating the system on RTE-3 (Giampiccolo et al., 2007) yielded **63.75**% accuracy – 2 points above the median submission.

All five of the core features are based on an alignment of keyphrases between the premise and the hypothesis. A keyphrase is defined as a span of text which is either (1) a possibly empty sequence of adjectives and adverbs followed by a sequence of nouns, and optionally followed by either *of* or the possessive marker (*'s*), and another noun (e.g., *sneaky kitten* or *pail of water*); (2) a possibly empty sequence of adverbs followed by a verb (e.g., *quietly pounce*); or (3) a gerund followed by a noun (e.g., *flowing water*). The verb *to be* is never a keyphrase. We make a distinction between a *keyphrase* and a *keyword* – the latter is a single noun, adjective, or verb.

We then align keyphrases in the premise and hypothesis by applying a series of sieves. First, all exact matches are aligned to each other. Then, prefix or suffix matches are aligned, then if either keyphrase contains the other they are aligned as well. Last, we align a keyphrase in the premise p_i to a keyphrase in the hypothesis h_k if there is an alignment between p_{i-1} and h_{k-1} and between p_{i+1} and h_{k+1}. This forces any keyphrase pair which is "sandwiched" between aligned pairs to be aligned as well. An example alignment is given in Figure 3.

Features are extracted for the number of alignments, the numbers of alignments which do and do not match perfectly, and the number of keyphrases in the premise and hypothesis which were not aligned. A feature for the Solr score of the premise given the hypothesis is optionally included; we revisit this issue in the evaluation.

4.2 An Evaluation Function for Search

A version of the classifier constructed in Section 4.1, but over *keywords* rather than keyphrases can be incorporated directly into NaturalLI's search to give a score for each candidate premise

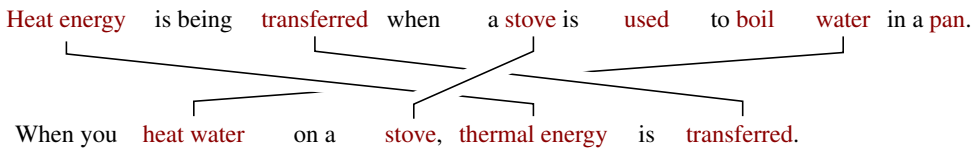

Figure 3: An illustration of an alignment between a premise and a hypothesis. Keyphrases can be multiple words (e.g., *heat energy*), and can be approximately matched (e.g., to *thermal energy*). In the premise, *used*, *boil* and *pan* are unaligned. Note that *heat water* is incorrectly tagged as a compound noun.

visited. This can be thought of as analogous to the evaluation function in game-playing search – even though an agent cannot play a game of Chess to completion, at some depth it can apply an evaluation function to its leaf states.

Using keywords rather than keyphrases is in general a hindrance to the fuzzy alignments the system can produce. Importantly though, this allows the feature values to be computed incrementally as the search progresses, based on the score of the parent state and the mutation or deletion being performed. For instance, if we are deleting a word which was previously aligned perfectly to the premise, we would subtract the weight for a perfect and imperfect alignment, and add the weight for an unaligned premise keyphrase. This has the same effect as applying the trained classifier to the new state, and uses the same weights learned for this classifier, but requires substantially less computation.

In addition to finding entailments from candidate premises, our system also allows us to encode a notion of likely negation. We can consider the following two statements naïvely sharing every keyword. Each token marked with its polarity:

P: *some*$^{\uparrow}$ *cats*$^{\uparrow}$ *have*$^{\uparrow}$ *tails*$^{\uparrow}$
H: *no*$^{\uparrow}$ *cats*$^{\downarrow}$ *have*$^{\downarrow}$ *tails*$^{\downarrow}$

However, we note that all of the keyword pairs are in opposite polarity contexts. We can therefore define a pair of keywords as *matching* in NaturalLI if the following two conditions hold: (1) their lemmatized surface forms match exactly, and (2) they have the same polarity in the sentence. The second constraint encodes a good approximation for negation. To illustrate, consider the polarity signatures of common operators:

Operators	**Subj. polarity**	**Obj. polarity**
Some, few, etc.	$\uparrow$	$\uparrow$
All, every, etc.	$\downarrow$	$\uparrow$
Not all, etc.	$\uparrow$	$\downarrow$
No, not, etc.	$\downarrow$	$\downarrow$
Most, many, etc.	–	$\uparrow$

We note that most contradictory operators (e.g., *some*/*no*; *all*/*not all*) induce the exact opposite polarity on their arguments. Otherwise, pairs of operators which share half their signature are usually compatible with each other (e.g., *some* and *all*).

This suggests a criterion for likely negation: If the highest classifier score is produced by a contradictory candidate premise, we have reason to believe that we may have found a contradiction. To illustrate with our example, NaturalLI would mutate *no cats have tails* to *the cats have tails*, at which point it has found a contradictory candidate premise which has perfect overlap with the premise *some cats have tails*. Even had we not found the exact premise, this suggests that the hypothesis is likely false.

5 Related Work

This work is similar in many ways to work on recognizing textual entailment – e.g., Schoenmackers et al. (2010), Berant et al. (2011), Lewis and Steedman (2013). In the RTE task, a single premise and a single hypothesis are given as input, and a system must return a judgment of either *entailment* or *nonentailment* (in later years, *nonentailment* is further split into contradiction and independence). These approaches often rely on alignment features, similar to ours, but do not generally scale to large premise sets (i.e., a comprehensive knowledge base). The discourse commitments in Hickl and Bensley (2007) can be thought of as similar to the additional entailed facts we add to the knowledge base (Section 3.3). In another line of work, Tian et al. (2014) approach the

RTE problem by parsing into Dependency Compositional Semantics (DCS) (Liang et al., 2011). This work particularly relevant in that it also incorporates an evaluation function (using distributional similarity) to augment their theorem prover – although in their case, this requires a translation back and forth between DCS and language. Beltagy et al. (To appear 2016) takes a similar approach, but encoding distributional information directly in entailment rules in a Markov Logic Network (Richardson and Domingos, 2006).

Many systems make use of structured knowledge bases for question answering. Semantic parsing methods (Zettlemoyer and Collins, 2005; Liang et al., 2011) use knowledge bases like Freebase to find support for a complex question. Knowledge base completion (e.g., Chen et al. (2013), Bordes et al. (2011), or Riedel et al. (2013)) can be thought of as entailment, predicting novel knowledge base entries from the original database. In contrast, this work runs inference over arbitrary text without needing a structured knowledge base. Open IE (Wu and Weld, 2010; Mausam et al., 2012) QA approaches – e.g., Fader et al. (2014) are closer to operating over plain text, but still requires structured extractions.

Of course, this work is not alone in attempting to incorporate strict logical reasoning into question answering systems. The COGEX system (Moldovan et al., 2003) incorporates a theorem prover into a QA system, boosting overall performance on the TREC QA task. Similarly, Watson (Ferrucci et al., 2010) incorporates logical reasoning components alongside shallower methods. This work follows a similar vein, but both the theorem prover and lexical classifier operate over text, without requiring either the premises or axioms to be in logical forms.

On the Aristo corpus we evaluate on, Hixon et al. (2015) proposes a dialog system to augment a knowledge graph used for answering the questions. This is in a sense an oracle measure, where a human is consulted while answering the question; although, they show that their additional extractions help answer questions other than the one the dialog was collected for.

6 Evaluation

We evaluate our entailment system on the Regents Science Exam portion of the Aristo dataset (Clark et al., 2013; Clark, 2015). The dataset consists of a collection of multiple-choice science questions from the New York Regents 4th Grade Science Exams (NYSED, 2014). Each multiple choice option is translated to a candidate hypotheses. A large corpus is given as a knowledge base; the task is to find support in this knowledge base for the hypothesis.

Our system is in many ways well-suited to the dataset. Although certainly many of the facts require complex reasoning (see Section 6.4), the majority can be answered from a single premise. Unlike FraCaS (Cooper et al., 1996) or the RTE challenges, however, the task does not have explicit premises to run inference from, but rather must infer the truth of the hypothesis from a large collection of supporting text.

6.1 Data Processing

We make use of two collections of unlabeled corpora for our experiments. The first of these is the Barron's study guide (BARRON'S), consisting of 1200 sentences. This is the corpus used by Hixon et al. (2015) for their conversational dialog engine Knowbot, and therefore constitutes a more fair comparison against their results. However, we also make use of the full SCITEXT corpus (Clark et al., 2014). This corpus consists of 1 316 278 supporting sentences, including the Barron's study guide alongside simple Wikipedia, dictionaries, and a science textbook.

Since we lose all document context when searching over the corpus with NaturalLI, we first pre-process the corpus to resolve high-precision cases of pronominal coreference, via a set of very simple high-precision sieves. This finds the most recent candidate antecedent (NP or named entity) which, in order of preference, matches either the pronoun's animacy, gender, and number. Filtering to remove duplicate sentences and sentences containing non-ASCII characters yields a total of 822 748 facts in the corpus.

These sentences were then indexed using Solr. The set of promising premises for the soft alignment in Section 4, as well as the Solr score feature in the lexical classifier (Section 4.1), were obtained by querying Solr using the default similarity metric and scoring function. On the query side, questions were converted to answers using the same methodology as Hixon et al. (2015). In cases where the question contained multiple sentences, only the last sentence was considered. As

discussed in Section 6.4, we do not attempt reasoning over multiple sentences, and the last sentence is likely the most informative sentence in a longer passage.

6.2 Training an Entailment Classifier

To train a soft entailment classifier, we needed a set of positive and negative entailment instances. These were collected on Mechanical Turk. In particular, for each true hypothesis in the training set and for each sentence in the Barron's study guide, we found the top 8 results from Solr and considered these to be candidate entailments. These were then shown to Turkers, who decided whether the premise entailed the hypothesis, the hypothesis entailed the premise, both, or neither. Note that each pair was shown to only one Turker, lowering the cost of data collection, but consequently resulting in a somewhat noisy dataset. The data was augmented with additional negatives, collected by taking the top 10 Solr results for each false hypothesis in the training set. This yielded a total of 21 306 examples.

The scores returned from NaturalLI incorporate negation in two ways: if NaturalLI finds a contradictory premise, the score is set to zero. If NaturalLI finds a soft negation (see Section 4.2), and did not find an explicit supporting premise, the score is discounted by 0.75 – a value tuned on the training set. For all systems, any premise which did not contain the candidate answer to the multiple choice query was discounted by a value tuned on the training set.

6.3 Experimental Results

We present results on the Aristo dataset in Table 1, alongside prior work and strong baselines. In all cases, NaturalLI is run with the evaluation function enabled; the limited size of the text corpus and the complexity of the questions would cause the basic NaturalLI system to perform poorly. The test set for this corpus consists of only 68 examples, and therefore both perceived large differences in model scores and the apparent best system should be interpreted cautiously. NaturalLI consistently achieves the best training accuracy, and is more stable between configurations on the test set. For instance, it may be consistently discarding lexically similar but actually contradictory premises that often confuse some subset of the baselines.

KNOWBOT is the dialog system presented in Hixon et al. (2015). We report numbers for two variants of the system: *held-out* is the system's performance when it is not allowed to use the dialog collected from humans for the example it is answering; *oracle* is the full system. Note that the *oracle* variant is a human-in-the-loop system.

System	Barron's		SCITEXT	
	Train	Test	Train	Test
KNOWBOT (held-out)	45	–	–	–
KNOWBOT (oracle)	57	–	–	–
Solr Only	49	42	62	58
Classifier	53	52	68	60
+ Solr	53	48	66	64
Evaluation Function	52	**54**	61	63
+ Solr	50	45	62	58
NaturalLI	52	51	65	61
+ Solr	**55**	49	73	61
+ Solr + Classifier	**55**	49	**74**	**67**

Table 1: Accuracy on the Aristo science questions dataset. All NaturalLI runs include the evaluation function. Results are reported using only the Barron's study guide or SCITEXT as the supporting KNOWBOT is the dialog system presented in Hixon et. al (2015). The held-out version uses additional facts from other question's dialogs; the oracle version made use of human input on the question it was answering. The test set did not exist at the time KNOWBOT was published.

We additionally present three baselines. The first simply uses Solr's IR confidence to rank entailment (*Solr Only* in Table 1). The max IR score of any premise given a hypothesis is taken as the score for that hypothesis. Furthermore, we report results for the entailment classifier defined in Section 4.1 (*Classifier*), optionally including the Solr score as a feature. We also report performance of the evaluation function in NaturalLI applied directly to the premise and hypothesis, without any inference (*Evaluation Function*).

Last, we evaluate NaturalLI with the improvements presented in this paper (*NaturalLI* in Table 1). We additionally tune weights on our training set for a simple model combination with (1) Solr (with weight 6:1 for NaturalLI) and (2) the standalone classifier (with weight 24:1 for NaturalLI). Empirically, both parameters were observed to be fairly robust.

To demonstrate the system's robustness on a larger dataset, we additionally evaluate on a test set of 250 additional science exam questions, with

System	Test Accuracy
Solr Only	46.8
Classifier	43.6
NaturalLI	46.4
+ Solr	**48.0**

Table 2: Results of our baselines and NaturalLI on a larger dataset of 250 examples. All NaturalLI runs include the evaluation function.

an associated 500 example training set (and 249 example development set). These are substantially more difficult as they contain a far larger number of questions that require an understanding of a more complex process. Nonetheless, the trend illustrated in Table 1 holds for this larger set, as shown in Table 2. Note that with a web-scale corpus, accuracy of an IR-based system can be pushed up to 51.4%; a PMI-based solver, in turn, achieves an accuracy of 54.8% – admittedly higher than our best system (Clark et al., 2016).[3] An interesting avenue of future work would be to run NaturalLI over such a large web-scale corpus, and to incorporate PMI-based statistics into the evaluation function.

6.4 Discussion

We analyze some common types of errors made by the system on the training set. The most common error can be attributed to the question requiring complex reasoning about multiple premises. 29 of 108 questions in the training set (26%) contain multiple premises. Some of these cases can be recovered from (e.g., *This happens because the smooth road has less friction.*), while others are trivially out of scope for our method (e.g., *The volume of water most likely decreased.*). Although there is usually still some signal for which answer is most likely to be correct, these questions are fundamentally out-of-scope for the approach.

Another class of errors which deserves mention are cases where a system produces the same score for multiple answers. This occurs fairly frequently in the standalone classifier (7% of examples in training; 4% loss from random guesses), and especially often in NaturalLI (11%; 6% loss from random guesses). This offers some insight into why incorporating other models – even with low weight – can offer significant boosts in the performance of NaturalLI. Both this and the previous class could be further mitigated by having a notion of a *process*, as in Berant et al. (2014).

Other questions are simply not supported by any single sentence in the corpus. For example, *A human offspring can inherit blue eyes* has no support in the corpus that does not require significant multi-step inferences.

A remaining chunk of errors are simply classification errors. For example, *Water freezing is an example of a gas changing to a solid* is marked as the best hypothesis, supported incorrectly by *An ice cube is an example of matter that changes from a solid to a liquid to a gas*, which after mutating *water* to *ice cube* matches every keyword in the hypothesis.

7 Conclusion

We have improved NaturalLI to be more robust for question answering by running the inference over dependency trees, pre-computing deletions, and incorporating a soft evaluation function for predicting likely entailments when formal support could not be found. Lastly, we show that relational entailment and meronymy can be elegantly incorporated into natural logic. These features allow us to perform large-scale broad domain question answering, achieving strong results on the Aristo science exams corpus.

Acknowledgments

We thank the anonymous reviewers for their thoughtful comments. We gratefully acknowledge the support of the Allen Institute for Artificial Intelligence, and in particular Peter Clark and Oren Etzioni for valuable discussions, as well as for access to the Aristo corpora and associated preprocessing. Easy Questions First?
A Case Study on Curriculum Learning for Question Answering

Mrinmaya Sachan **Eric P. Xing**
School of Computer Science
Carnegie Mellon University
{mrinmays, epxing}@cs.cmu.edu

Abstract

Cognitive science researchers have emphasized the importance of ordering a complex task into a sequence of easy to hard problems. Such an ordering provides an easier path to learning and increases the speed of acquisition of the task compared to conventional learning. Recent works in machine learning have explored a curriculum learning approach called self-paced learning which orders data samples on the easiness scale so that easy samples can be introduced to the learning algorithm first and harder samples can be introduced successively. We introduce a number of heuristics that improve upon self-paced learning. Then, we argue that incorporating easy, yet, a diverse set of samples can further improve learning. We compare these curriculum learning proposals in the context of four non-convex models for QA and show that they lead to real improvements in each of them.

1 Introduction

A key challenge in building an intelligent agent is in modeling the incrementality and the cumulative nature of human learning (Skinner, 1958; Peterson, 2004; Krueger and Dayan, 2009). Children typically learn grade by grade, progressing from simple concepts to more complex ones. Given a complex set of concepts, it is often the case that some concepts are easier than others. Some concepts can even be prerequisite to learning other concepts. Hence, evolving a useful curriculum where easy concepts are presented first and more complex concepts are gradually introduced can be beneficial for learning.

We explore methods for learning a curriculum in the context of non-convex models for question answering. Curriculum learning (CL) (Bengio et al., 2009) and self-paced learning (SPL) (Kumar et al., 2010) have been recently introduced in machine learning literature. However, their usefulness in the context of NLP tasks such as QA has not been studied so far. The main challenge in learning a curriculum is that it requires the identification of easy and hard concepts in the given training dataset. However, in real-world applications, such a ranking of training samples is difficult to obtain. Furthermore, a human judgement of 'easiness' of a task might not correlate with what is easy for the algorithm in the feature and hypothesis space employed for the given application. SPL combines the selection of the curriculum and the learning task in a single objective. The easiness of a question in self-paced learning is defined by its local loss. We propose and study other heuristics that define a measure of easiness and learn the curriculum by selecting samples using this measure. These heuristics are similar to those used in active learning, but with one key difference. In curriculum learning, all the training examples and labels are already known, which is not the case in active learning. Our experiments show that these heuristics work well in practice.

While the strategy of learning from easy questions first and then gradually handling harder questions is supported by many cognitive scientists, others (Cantor, 1946) argue that it is also important to expose the learning to diverse (even if sometimes harder) examples. We argue that the right curriculum should not only be arranged in the increasing order of difficulty but also introduce the learner to sufficient number of diverse examples that are sufficiently dissimilar from what has already been introduced to the learning process. We showed that the above heuristics when coupled with diversity lead to significant improvements.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 453–463,
Berlin, Germany, August 7-12, 2016.

We provide empirical evaluation on four QA models: (a) an alignment-based approach (Sachan et al., 2015) for machine comprehension – a reading comprehension task (Richardson et al., 2013) with a set of questions and associated texts, (b) an alignment-based approach (Sachan et al., 2016) for a multiple-choice elementary science test (Clark and Etzioni, 2016), (c) *QANTA* (Iyyer et al., 2014) – a recursive neural network for answering quiz bowl questions, and (d) memory networks (Weston et al., 2014) – a recurrent neural network with a long-term memory component for answering 20 pre-defined tasks for machine comprehension. We show value in our approaches for curriculum learning on all these settings.
Our paper has the following contributions:

1. In our knowledge, this is the first application of curriculum learning to the task of QA and one of the first in NLP. We hope to make the NLP and ML communities aware of the benefits of CL for non-convex optimization.
2. We perform an in-depth analysis of SPL, and propose heuristics which offer significant improvements over SPL; the state-of-the-art in curriculum learning.
3. We stress on diversity of questions in the curriculum during learning and propose a method that learns a curriculum while capturing diversity to gain more improvements.

2 Problem Setting for QA

For each question $q_i \in Q$, let $A_i = \{a_{i1}, \ldots, a_{im}\}$ be the set of candidate answers to the question. Let a_i^* be the correct answer. The candidate answers may be pre-defined, as in multiple-choice QA, or may be undefined but easy to extract with a high degree of confidence (e.g., by using a pre-existing system). We want to learn a function $f : (q, \mathcal{K}) \rightarrow a$ that, given a question q_i and background knowledge $\mathcal{K}$ (texts/resources required to answer the question), outputs an answer $\hat{a}_i \in A_i$. We consider a scoring function $S_{\mathbf{w}}(q, a; \mathcal{K})$ (with model parameters $\mathbf{w}$) and a prediction rule $f_{\mathbf{w}}(q_i) = \hat{a}_i = \underset{a_{ij} \in A_i}{\arg\max}\, S_{\mathbf{w}}(q_i, a_{ij}; \mathcal{K})$. Let $\Delta(\hat{a}_i, a_i^*)$ be the cost of giving a wrong answer. We consider the empirical risk minimization (ERM) framework given a loss function L and a regularizer Ω:

$$\min_{\mathbf{w}} \sum_{q_i \in Q} L_{\mathbf{w}}(a_i^*, f_{\mathbf{w}}(q_i); \mathcal{K}) + \Omega(\mathbf{w}) \qquad (1)$$

3 QA Models

The field of QA is quite rich. Solutions proposed have ranged from various IR based approaches that treat this as a problem of retrieval from existing knowledge bases or perform inference using a large corpus of unstructured texts by learning a similarity between the question and a set of candidate answers (Yih et al., 2013). A comprehensive review of QA is out of scope of this paper. So we point the interested readers to Jurafsky and Martin (2000), chapter 28 for a more comprehensive review. In this paper, we will explore curriculum learning in the context of non-convex models for QA. The models will be (1) latent structural SVM (Yu and Joachims, 2009) based solutions for standardized question-answering tests and (2) deep learning models (Iyyer et al., 2014; Weston et al., 2014) for QA.

Recently, researchers have proposed standardized tests as 'drivers for progress in AI' (Clark and Etzioni, 2016). Some example standardized tests are reading comprehensions (Richardson et al., 2013), algebra word problems (Kushman et al., 2014), geometry problems (Seo et al., 2014), entrance exams (Fujita et al., 2014; Arai and Matsuzaki, 2014), etc. These tests are usually in the form of question-answers and focus on elementary learning. The idea of learning the curriculum could be especially useful in the context of standardized tests. Standardized tests (Clark and Etzioni, 2016) are implicitly incremental in nature, covering various levels of difficulty. Thus they are rich sources of data for building systems that learn incrementally. These datasets can also help us understand the *shaping* hypothesis as we can use them to verify if easier questions are indeed getting picked by our incremental learning algorithm before harder questions.

On the other hand, deep learning models (LeCun et al., 2015) have recently shown good performance in many standard NLP and vision tasks, including QA. These models usually learn representations of data and the QA model jointly. The models use a cascade of many layers of nonlinear processing units, leading to a highly non-convex model and a large parameter space. This renders these models susceptible to local-minima. Hence, the idea of learning the curricula is also very useful in the context of deep-learning models, as the technique of processing questions in the increasing order of difficulty often leads to better minima

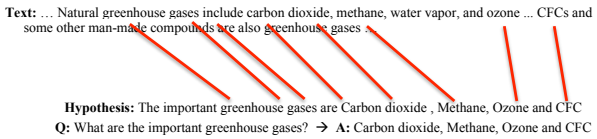

Figure 1: Alignment structure for an example question from the science QA dataset. The question and answer candidate are combined to generate a hypothesis sentence. Then alignments (shown by red lines) are found between the hypothesis and the appropriate snippet in the texts.

(as shown in our results).

3.1 Alignment Based Models

Alignment based models for QA (Yih et al., 2013; Sachan et al., 2015; Sachan et al., 2016) cast QA as a textual entailment problem by converting each question-answer candidate pair (q_i, a_{ij}) into a hypothesis statement h_{ij}. For example, the question "What are the important greenhouse gases?" and answer candidate "Carbon dioxide, Methane, Ozone and CFC" in Figure 1 can be combined to achieve a hypothesis "The important greenhouse gases are Carbon dioxide , Methane, Ozone and CFC.". A set of question matching/rewriting rules are used to achieve this transformation. These rules match the question into one of a large set of pre-defined templates and apply a unique transformation to the question and answer candidate to achieve the hypothesis statement. For each question q_i, the QA task thereby reduces to picking the hypothesis $\hat{h}_i$ that has the highest likelihood among the set of hypotheses $\mathbf{h}_i = \{h_{i1}, \ldots, h_{im}\}$ generated for that question of being entailed by a body of relevant texts. The body of relevant texts can vary for each instance of the QA task. For example, it could be just the passage in a reading comprehension task, or a set of science textbooks in the science QA task. Let $h_i^* \in \mathbf{h}_i$ be the correct hypothesis. The model considers the quality of word alignment from a hypothesis h_{ij} (formed by combining question-answer candidates (q_i, a_{ij})) to snippets in the textbooks as a proxy for the evidence. The alignment depends on: (a) snippet from the relevant texts chosen to be aligned to the hypothesis and (b) word alignment from the hypothesis to the snippet. The snippet from the texts to be aligned to the hypothesis is determined by picking a subset of sentences in the texts. Then each hypothesis word is aligned to a unique word in the snippet. See Figure 1 for an illustration. The choice of snippets composed with the word alignment is latent. Let $\mathbf{z}_{ij}$ represent the latent structure for the question-answer candidate pair $(q_i, a_{i,j})$. A natural solution is to treat QA as a problem of ranking the hypothesis set $\mathbf{h}_i$ such that the correct hypothesis is at the top of this ranking. Hence, a scoring function $S_{\mathbf{w}}(h, \mathbf{z})$ is learnt such that the score given to the correct hypothesis h_i^* and the corresponding latent structure $\mathbf{z}_i^*$ is higher than the score given to any other hypothesis and its corresponding latent structure. In fact, in a max-margin fashion, the model learns the scoring function such that $S_{\mathbf{w}}(h_i^*, \mathbf{z}_i^*) > S_{\mathbf{w}}(h_{ij}, \mathbf{z}_{ij}) + \Delta(h_i^*, h_{ij}) - \xi_i$ for all $h_j \in \mathbf{h} \setminus h^*$ for some slack ξ_i. This can be formulated as the following optimization problem:

$$\min_{||\mathbf{w}||} \quad \frac{1}{2}||\mathbf{w}||_2^2 + C\sum_i \xi_i$$
$$s.t. \quad S_{\mathbf{w}}(h_i^*, \mathbf{z}_i^*) \geq \max_{\mathbf{z}_{ij}} S_{\mathbf{w}}(h_{ij}, \mathbf{z}_{ij}) + \Delta(h_i^*, h_{ij}) - \xi_i$$

It is intuitive to use 0-1 cost, i.e. $\Delta(h_i^*, h_{ij}) = \mathbb{1}(h_i^* \neq h_{ij})$ If the scoring function is convex then this objective is in concave-convex form and can be minimized by the concave-convex programming procedure (CCCP) (Yuille and Rangarajan, 2003). The scoring function is assumed to be linear: $S_{\mathbf{w}}(h, \mathbf{z}) = \mathbf{w}^T\psi(h, \mathbf{z})$. Here, $\psi(h, \mathbf{z})$ is a task-dependent feature map (see Sachan et al. (2015) and Sachan et al. (2016) for details).

3.2 Deep Learning Models

We briefly review two neural network models for QA – Iyyer et al. (2014) and Weston et al. (2014).

QANTA: QANTA (Iyyer et al., 2014) answers quiz bowl questions using a dependency tree structured recursive neural network. It combines predictions across sentences to produce a question answering neural network with trans-sentential averaging. The model is optimized using AdaGrad (Duchi et al., 2011). In quiz bowl, questions typically consist of four to six sentences and are associated with factoid answers. Every sentence in the question is guaranteed to contain clues that uniquely identify its answer, even without the context of previous sentences[1]. Recently, QANTA had beaten the well-known Jeopardy! star Ken Jennings at an exhibition quiz bowl contest.

Memory Networks: Memory networks (Weston et al., 2014) are essentially recurrent neural networks with a long-term memory component. The memory can be read and written to, and can be used for prediction. The memory can be seen as

[1]Refer to Figure 1 in (Iyyer et al., 2014) for an example

acting like a dynamic knowledge base. The model is trained using a margin ranking loss and stochastic gradient descent. It was evaluated on a set of synthetic QA tasks. For each task, a set of statements were generated by a simulation of 4 characters, 3 objects and 5 rooms using an automated grammar with characters moving around, picking up and dropping objects are given, followed by a question whose answer is typically a single word[2].

4 Curriculum Learning

Studies in cognitive science (Skinner, 1958; Peterson, 2004; Krueger and Dayan, 2009) have shown that humans learn much better when the training examples are not randomly presented but organized in increasing order of difficulty. The idea of *shaping*, which consists of training a machine learning algorithm with a curriculum was first introduced by (Elman, 1993) in the context of grammatical structure learning using a recurrent connectionist network. This idea also lent support for the much debated Newport's "less is more" hypothesis (Goldowsky and Newport, 1993; Newport, 1990) that child language acquisition is aided, rather than hindered, by limited cognitive resources. Curriculum learning (Bengio et al., 2009) is a recent idea in machine learning, where a curriculum is designed by ranking samples based on manually curated difficulty measures. These measurements are usually not known in real-world scenarios, and are hard to elicit from humans.

4.1 Self-paced Learning

Self-paced learning (SPL) (Kumar et al., 2010; Jiang et al., 2014a; Jiang et al., 2015) reformulates curriculum learning as an optimization problem by jointly modeling the curriculum and the task at hand. Let $\mathbf{v} \in [0,1]^{|Q|}$ be the weight vector that models the weight of the sample questions in the curriculum. The SPL model includes a weighted loss term on all samples and an additional self-paced regularizer imposed on sample weights $\mathbf{v}$. SPL formulation for the ERM framework described in eq 1 can be rewritten as:

$$\min_{\mathbf{w},\mathbf{v}\in[0,1]^{|Q|}} \sum_{q_i \in Q} v_i L_{\mathbf{w}}(a_i^*, f_{\mathbf{w}}(q_i); \mathcal{K}) + g(v_i, \lambda) + \Omega(\mathbf{w})$$

[2]Refer to Table 1 in (Weston et al., 2015) for examples

The problem usually has closed-form solution with respect to $\mathbf{v}$ (described later; lets call the solution $\mathbf{v}^*(\lambda; L)$ for now). $g(\mathbf{v}, \lambda)$ is usually called the self-paced regularizer with the "age" or "pace" parameter λ. g is convex with respect to $\mathbf{v} \in [0,1]^{|Q|}$. Furthermore, $\mathbf{v}(\lambda; L)$ is monotonically decreasing with respect to L, and $\lim_{L\to 0} \mathbf{v}^*(\lambda; L) = 1$ and $\lim_{L\to\infty} \mathbf{v}^*(\lambda; L) = 0$. This means that the model inclines to select easy samples (with smaller losses) in favor of complex samples (with larger losses). Finally, $v^*(\lambda; L)$ is monotonically increasing with respect to λ, and $\lim_{\lambda\to 0} \mathbf{v}^*(\lambda; L) = 0$ and $\lim_{\lambda\to\infty} \mathbf{v}^*(\lambda; L) \leq 1$. This means that when the model "ages" (i.e. the age parameter λ gets larger), it tends to incorporate more, probably complex samples to train a 'mature' model.

Four popular self-paced regularizers in the literature (Kumar et al., 2010; Jiang et al., 2014a; Zhao et al., 2015) are *hard*, *soft logarithmic*, *soft linear* and *mixture*. These SP-regularizers, summarized with corresponding closed form solutions for $\mathbf{v}$ are shown in Table 1. Hard weighting is usually less appropriate as it cannot discriminate the importance of samples. However, soft weighting assigns real-valued weights and reflects the latent importance of samples in training. The soft linear regularizer linearly weighs samples with respect to their losses and the soft logarithmic penalizes the weight logarithmically. Mixture weighting combines both hard and soft weighting schemes. We can solve the model in the SPL regime by iteratively updating $\mathbf{v}$ (closed form solution for $\mathbf{v}$ is shown in Table 1) and $\mathbf{w}$ (by CCCP, AdaGrad or SGD), and gradually increasing the age parameter λ to let harder and harder problems in.

Since its inception, variations of SPL such as self-paced re-ranking (Jiang et al., 2014a), self-paced learning with diversity (Jiang et al., 2014b), self-paced multiple-instance learning (Zhang et al., 2015) and self-paced curriculum learning (Jiang et al., 2015) have been proposed. The techniques have been shown to be useful in some computer vision tasks (Lee and Grauman, 2011; Kumar et al., 2011; Tang et al., 2012; Supancic and Ramanan, 2013; Jiang et al., 2014a). SPL is different from active learning (Settles, 1995) in the sense that the training examples (and labels) are already provided and the solution only orders the examples to achieve a better solution. On the other hand, active learning tries to interactively query

Regularizer	$g(\mathbf{v};\lambda)$	$v^*(\lambda;L)$
Hard	$-\lambda\mathbf{v}$	$\begin{cases} 1, \textit{if } L \leq \lambda \\ 0, \textit{o/w} \end{cases}$
Soft Linear	$\lambda(\frac{1}{2}\mathbf{v}^2 - \mathbf{v})$	$\begin{cases} -\frac{L}{\lambda} + 1, \textit{if } L \leq \lambda \\ 0, \textit{otherwise} \end{cases}$
Soft Logarithmic	$\sum_{q_i \in Q} \left((1-\lambda)v_i - \frac{(1-\lambda)^{v_i}}{log(1-\lambda)} \right)$	$\begin{cases} \frac{log(L+1-\lambda)}{log(1-\lambda)}, \textit{if } L \leq \lambda \\ 0, \textit{o/w} \end{cases}$
Mixed	$\frac{\gamma^2}{\mathbf{v}+\frac{\gamma}{\lambda}}$	$\begin{cases} 1, \textit{if } L \leq \left(\frac{\lambda\gamma}{\lambda+\gamma}\right)^2 \\ 0, \textit{if } L \geq \lambda^2 \\ \gamma\left(\frac{1}{\sqrt{L}} - \frac{1}{\lambda}\right), \textit{o/w} \end{cases}$

Table 1: Various SP-regularizers for SPL.

the user (or another information source) to achieve a better model with few queries. Curriculum learning is also related to teaching dimension (Khan et al., 2011) which studies the strategies that humans follow as they teach a target concept to a robot by assuming a teaching goal of minimizing the learner's expected generalization error at each iteration. One can also think of curriculum learning as an approach for achieving a better local optimum in non-convex problems.

5 Improved Curriculum Learning Heuristics

SPL selects questions based on the local loss term of the question. This is not the only way to define 'easiness' of the question. Hence, we suggest some other heuristics for selecting the order of questions to be presented to our learning algorithm. The heuristics select the next question $q_i \in Q \setminus Q_0$ given the current model ($\mathcal{M}$) and the set of questions already presented for learning (Q_0). We assume access to a minimization oracle (CCCP/AdaGrad/SGD) for the QA models. We explore the following heuristics:

1) Greedy Optimal (GO): The simplest and greedy optimal heuristic (Schohn and Cohn, 2000) would be to pick a question $q_i \in Q \setminus Q_0$ which has the minimum expected effect on the model. The expected effect on adding q_i can be written as:
$\sum_{a_{ij} \in A_i} p(a_i^* = a_{ij}) \sum_{q_j \in Q_0 \cup q_i} \mathbb{E}\left[L_{\mathbf{w}}(a_j^*, f_{\mathbf{w}}(q_j); \mathcal{K})\right]$.
$p(a_i^* = a_{ij})$ can be estimated by normalizing $S_{\mathbf{w}}(q, a; \mathcal{K})$. $\sum_{q_j \in Q_0 \cup q_i} \mathbb{E}\left[L_{\mathbf{w}}(a_j^*, f_{\mathbf{w}}(q_j); \mathcal{K})\right]$ can be estimated by retraining the model on $Q_0 \cup q_i$.

2) Change in Objective (CiO): Choose the question $q_i \in Q \setminus Q_0$ that causes the smallest increase in the objective. If there are multiple questions with the smallest increase in objective, pick one of them randomly.

3) Mini-max ($\mathbf{M^2}$): Chooses question $q_i \in Q \setminus Q_0$ that minimizes the regularized expected risk when including the question with the answer candidate a_{ij} that yields the maximum error.

$$\hat{q}_i = \arg\min_{q_i \in Q \setminus Q_0} \max_{a_{ij} \in A_i} L_{\mathbf{w}}(a_{ij}, f_{\mathbf{w}}(q_i); \mathcal{K})$$

4) Expected Change in Objective (ECiO): In this greedy heuristic, we pick a question $q_i \in Q \setminus Q_0$ which has the minimum expected effect on the model. The expected effect can be written as $\sum_{a_{ij} \in A_i} p(a_i^* = a_{ij}) \times \mathbb{E}\left[L_{\mathbf{w}}(a_i^*, f_{\mathbf{w}}(q_i); \mathcal{K})\right]$. Here, $p(a_i^* = a_{ij})$ can be achieved by normalizing $S_{\mathbf{w}}(q, a; \mathcal{K})$ and $\mathbb{E}\left[L_{\mathbf{w}}(a_i^*, f_{\mathbf{w}}(q_i); \mathcal{K})\right]$ can be estimated by running inference for q_i.

4) Change in Objective-Expected Change in Objective (CiO - ECiO): We pick a question $q_i \in Q \setminus Q_0$ which has the minimum value of the difference between the change in objective and the expected change in objective. Intuitively, the difference represents how much the model is surprised to see this new question.

5) Correctly Answered (CA): Pick a question $q_i \in Q \setminus Q_0$ which is answered by the model $\mathcal{M}$ with the minimum cost $\Delta(\hat{a}_i, a_i^*)$. If there are multiple questions with minimum cost, pick one of them randomly.

6) Farthest from Decision Boundary (FfDB): This heuristic applies for latent structural SVMs only. Here, we choose the question $q_i \in Q \setminus Q_0$ whose predicted answer $\hat{a}_i$ is farthest from the decision boundary: $\max_{\mathbf{z}^*} w^T \phi(q_i, a^*, \mathbf{z}^*, \mathcal{K}) = \max_{\hat{\mathbf{z}}} w^T \phi(q, \hat{a}, \hat{\mathbf{z}}, \mathcal{K}) + \Delta(\hat{a}, a^*)$.

5.1 Timing Considerations:

A key consideration in applying the above heuristics is efficiency as the QA models considered (latent structural SVM and deep learning) are compu-

tationally expensive. Among our selection strategies, *GO* and *CiO* require updating the model, M^2, *ECiO*, *CA* and *FfDB* require performing inference on the candiate questions, while *CiO* - *ECiO* requires both retraining as well as inference. Consequently, M^2, *ECiO*, *CA* and *FfDB* are most efficient. We can also gain considerable speed-up by picking questions in batches. This results in significant speed-up with small loss in accuracy. We will discuss the batch question selection setup in more detail in our experiments.

5.2 Smarter Selection Strategies:

We further describe some improvements to the above selection strategies:

1) Ensemble Strategy: In this strategy, we combine all of the above heuristics into an ensemble. The ensemble computes the ratio of the score of the suggested question pick and the average score over remaining $Q \setminus Q_0$ questions for all the heuristics and picks the question with the highest ratio. As we will see in our results, this ensemble works well in practice.

2) Importance-Weighting (IW): Importance weighting is a common technique in active learning literature (Tong and Koller, 2002; Beygelzimer et al., 2009; Beygelzimer et al., 2010), which mitigates the problem that if we query questions actively instead of selecting them uniformly at random, the training (and test) question sets are no longer independent and identically distributed (i.i.d.). In other words, the training set will have a sample selection bias that can impair prediction performance. To mitigate this, we propose to sample questions from a biased sample distribution $\widetilde{D}$. To achieve $\widetilde{D}$, we introduce the weighted loss $\widetilde{L}_{\mathbf{w}}(a, f_{\mathbf{w}}(q); \mathcal{K}) = \widetilde{w}(q,a) \times L_{\mathbf{w}}(a, f_{\mathbf{w}}(q); \mathcal{K})$ where $\widetilde{w}(q,a)$ is the weighting function $\widetilde{w}(q,a) = \frac{p_D(q,a)}{p_{\widetilde{D}}(q,a)}$ which represents how likely it is to observe (q,a) under D compared to $\widetilde{D}$. In this setting, we can show that the generalization error under $\widetilde{D}$ is the same as that under D:

$$
\begin{aligned}
&\mathbb{E}_{(q,a)\sim\widetilde{D}}\left[\widetilde{L}_{\mathbf{w}}(a, f_{\mathbf{w}}(q); \mathcal{K})\right] \\
&= \int_{(q,a)} p_{\widetilde{D}}(q,a) \frac{p_D(q,a)}{p_{\widetilde{D}}(q,a)} L_{\mathbf{w}}(a, f_{\mathbf{w}}(q); \mathcal{K}) d(q,a) \\
&= \int_{(q,a)} p_D(q,a) L_{\mathbf{w}}(a, f_{\mathbf{w}}(q); \mathcal{K}) d(q,a) \\
&= \mathbb{E}_{(q,a)\sim D}\left[L_{\mathbf{w}}(a, f_{\mathbf{w}}(q); \mathcal{K})\right]
\end{aligned}
$$

Thus, given appropriate weights $\widetilde{w}(q,a)$, we modify our loss-function in order to compute an unbiased estimator of the generalization error. Each question-answer is assigned with a non-negative weight. For latent structural SVMs, one can minimize the weighted loss by simply multiplying the corresponding regularization parameter C_i with a corresponding term. In neural networks, this is simply achieved by multiplying the gradients with the corresponding weights. The weights can be set by an appropriate heuristic, e.g. proportional to distance from the decision boundary.

5.3 Incorporating Diversity with Explore and Exploit (E&E):

The strategy of learning from easy questions first and then gradually handling harder questions is intuitive as it helps the learning process. Yet, it has one key deficiency. Under curriculum learning, by focusing on easy questions first, our learning algorithm is usually not exposed to a diverse set of questions. This is particularly a problem for deep-learning approaches that learn representations during the process of learning. Hence, when a harder question arrives, it is usually hard for the learner to adjust to this new question as the current representation may not be appropriate for the new level of difficulty. This motivates our E&E strategy.

The explore and exploit strategy ensures that while we still select easy questions first, we also want to make our selection as diverse as possible. We define a measure for diversity as the angle between the hyperplanes that the question samples induce in feature space: $\angle(\phi(q_i, a_i^*, \mathbf{z}_i^*, \mathcal{K}), \phi(q_{i'}, a_{i'}^*, \mathbf{z}_{i'}^*, \mathcal{K})) = \textit{Cosine}^{-1}\left(\frac{|\phi(q_i,a_i^*,\mathbf{z}_i^*,\mathcal{K})\phi(q_{i'},a_{i'}^*,\mathbf{z}_{i'}^*,\mathcal{K})|}{||\phi(q_i,a_i^*,\mathbf{z}_i^*,\mathcal{K})||||\phi(q_{i'},a_{i'}^*,\mathbf{z}_{i'}^*,\mathcal{K})||}\right)$. The *E&E* solution picks the question which optimizes a convex combination of the curriculum learning objective and the sum of angles between the candidate question pick and questions in Q_0. The convex combination is tuned on the development set.

6 Experiments

6.1 Datasets

As described, we study curriculum learning on four different tasks. The first task is question answering for reading comprehensions. We use MCTest-500 dataset (Richardson et al., 2013), a freely available set of 500 stories (300 train, 50 dev and 150 test) and associated questions to evaluate our model. Each story in MCTest has four

		Machine Comprehension	Science QA	QANTA	Memory Networks

Table 2: Accuracy on the test set obtained on the four experiments, comparing results when no curriculum (NC) was learnt, when we use self-paced learning (SPL) with four variations of SP-regularizers, the six heuristics and four improvements proposed by us. Each cell reports the mean±se (standard error) accuracy over 10 repetitions of each experimental configuration.

multiple-choice questions, each with four answer choices. Each question has exactly one correct answer. The second task is science question answering. We use a mix of 855 third, fourth and fifth grade science questions derived from a variety of regional and state science exams[3] for training and evaluating our model. We used publicly available science textbooks available through $ck12.org$ and Simple English Wikipedia[4] as texts required to answer the questions. The model retrieves a section from the textbook or a Wikipedia page (using a lucene index on the sections and Wikipedia pages) by querying for the hypothesis h_{ij} and then aligning the hypothesis to snippets in the document. For QANTA (Iyyer et al., 2014), we use questions from quiz bowl tournaments for training as in Iyyer et al. (2014). The dataset contains 20,407 questions with 2347 answers. For each answer in the dataset, its corresponding Wikipedia page is also provided. Finally, for memory networks (Weston et al., 2014), we use the synthetic QA tasks defined in Weston et al. (2015) (version 1.1 of the dataset). There are 20 different types of tasks that probe different forms of reasoning and deduction. Each task consists of a set of statements, followed by a question whose answer is typically a single word or a set of words. We report mean accuracy across these 20 tasks.

6.2 Results

We implemented and compared the six selection heuristics (§5) with the suggested improvements (§5.2) and self-paced learning (§4) with the explore and exploit extension for both alignment based models (§3.1) and two deep learning models (§3.2). We use accuracy (proportion of test questions correctly answered) as our evaluation metric. In all our experiments, we begin with zero training data (random initialization). For alignment based models, we select 1 percent of training set questions after every epoch (an epoch is defined as a single pass through the current training set by the optimization oracle) and add them to the training set based on the selection strategy. For deep learning models, we discovered that the learning was a lot slower so we added 0.1 percent of new training set questions after every epoch. Hyper parameters of the alignment based models and the deep learning models were fixed to the corresponding values proposed in their corresponding papers (pre-tuned for the optimization oracle on a held-out development set). All the results reported in this paper are averaged over 10 runs of each experiment.

Table 5.3 reports test accuracies obtained on all the QA tasks, comparing the aforementioned proposals against corresponding models when curriculum learning is not used. We can observe from

[3] http://aristo-public-data.s3.amazonaws.com/AI2-Elementary-NDMC-Feb2016.zip

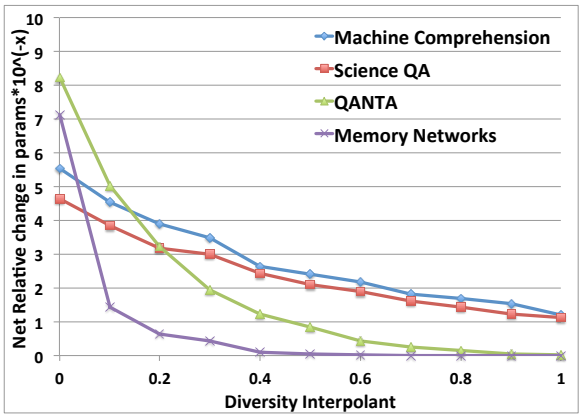

Figure 2: Relative change in parameters*10^{-x} where $x = 2$ for machine comprehension and science QA, 4 for QANTA and memory networks when CL is used.

these results that variants of SPL (and *E&E*) as well as the heuristics (and improvements) lead to improvements in the final test accuracy for both alignment-based models and QANTA.

The surprising ineffectiveness of the heuristics and SPL for memory networks essentially boils down to the abrupt restructure of memory the model has to do for curriculum learning. We provide support for this argument in Figure 2 which plots the net relative change in all the parameters $\mathbf{W}$ until convergence $\left(\frac{1}{\textit{No. of parameters}} \sum_{e:epoch=1}^{\infty} \frac{||\mathbf{W}_{e+1}-\mathbf{W}_e||_1}{||\mathbf{W}_e||_1}\right)$ for each of the four tasks on the model *Ensemble+E&E* against the linear interpolant used to tune the explore and exploit combination. As the interpolant grows from 0 to 1, more and more diverse questions get selected. We can observe that the change in parameters decreases as more diverse questions are selected for all the four tasks. Furthermore, once we bring in diversity (change the interpolant from 0 to 0.1), the relative change in parameters drops sharply for both neural network approaches. The drop is sharpest for memory networks. Easier examples usually require less memory than hard examples. Memory networks have no incentive to utilize only a fraction of its state for easy examples. They simply use the entire memory capacity. This implies that harder examples appearing later require a restructuring of all memory patterns. The network needs to change its memory representation every time in order to free space and accommodate the harder example. This process of memory pattern restructuring is difficult to achieve, so it could be the reason for the relatively poor performance of naive curriculum learning and SPL strategies. However, as we can see from the previous results, the explore and exploit strategy of mixing in some harder examples avoids the problem of having to abruptly restructure memory patterns. The extra samples of all difficulties prevent the network from utilizing all the memory on the easy examples, thus eliminating the need to restructure memory patterns.

From Table 5.3 , we can observe that the choice of the SP-regularizer is important. The soft regularizers perform better than the hard regularizer. The mixed regularizer (with mixture weighting) performs even better. We can also observe that all the heuristics work as well as SPL, despite being a lot simpler. The heuristics arranged in increasing order of performance are: *CA*, M^2, *ECiO*, *GO*, *CiO*, *FfDB* and *CiO-ECiO*,. The differences between the heuristics are larger for alignment-based models and smaller for deep learning models. The *ECiO* heuristic has very similar performance to SPL with hard SP-regularizer. This is understandable as SPL also selects 'easy' questions based on their expected objective value. The *Ensemble* is a significant improvement over the individual heuristics. Importance weighting (*IW*) and the explore and exploit strategies (*E&E*) provide further improvements. *E&E* is crucial to making curriculum learning work for deep learning approaches as described before. Motivated by the success of *E&E*, we also extended it to SPL[5] by tuning a convex combination as before. *E&E* provides improvements across all the experiments for all the SPL experiments. While, the strategy is more important for memory networks, it leads to improvements on all the tasks.

In order to understand the curriculum learning process and to test the hypothesis that the procedure indeed selects easy questions first, successively moving on to harder questions, we plot the number of questions of grade 3, 4 and 5 picked by *SPL*, *Ensemble* and *Ensemble+E&E* against the epoch number in Figure 3. We can observe that all the three methods pick more questions from grade 3 initially, successively moving on to more and more grade 4 questions and finally more grade 5 questions. Both *Ensemble* and *Ensemble+E&E* are more aggressive at learning this curriculum than *SPL*. *Ensemble* becomes too aggressive so

[5]This is different from Jiang et al. (2014c) which encourages diversity in samples across groups. On the other hand, we encourage diversity in feature space.

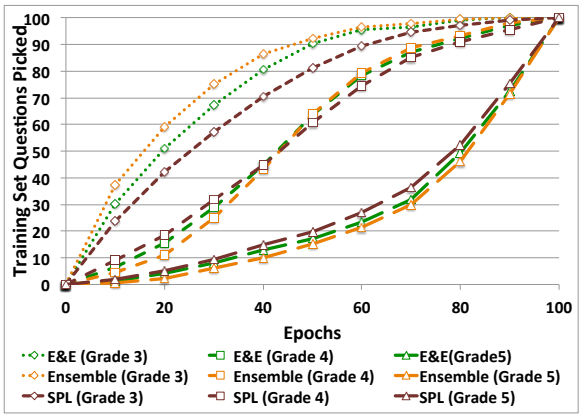

Figure 3: Number of grade 3, 4 and 5 questions picked vs Epoch for various CL approaches for Science QA.

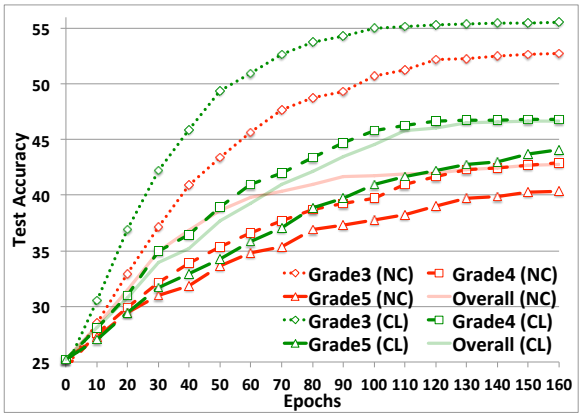

Figure 4: Test split accuracy on grade 3, 4 and 5 questions picked vs Epoch for Science QA when CL is used/not used.

E&E, initially increases the number of grade 4 and grade 5 questions received by the learner, thereby incorporating diversity in learning.

In order to further the claim that curriculum learning follows the principal of learning simpler concepts first and then learning successively harder and harder concepts, we plot the test accuracy on grade 3, 4 and 5 questions with curriculum learning (CL) – i.e. *Ensemble+E&E* and without curriculum learning (NC) against the epoch number in Figure 4. Here, we can see that the test accuracy increases for questions in all three grade levels. With curriculum learning, the accuracy on grade 3 questions rises sharply in the beginning. This rise is sharper than the case when curriculum learning is not used. Grade 3 test accuracy for curriculum learning then saturates (saturates earlier compared to the case when curriculum learning is not used). The improvements due to curriculum learning for grade 4 questions mainly occur in epochs 30-140. The final epochs of curriculum learning see greater gain in test accuracy for grade 5 questions over the case when curriculum learning is not used. All these experiments together support the intuition of curriculum learning. The models indeed pick and learn from easier questions first and successively learn from harder and harder questions. We also tried variants of our models where we used curriculum learning on grade 3 questions, followed by grade 4 and grade 5 questions. However, this did not lead to significant improvements. Perhaps, this is because questions that are easy for humans may not always correspond to what is easy for our algorithms. Characterizing what is easy for algorithms and how it relates to what is easy for humans is an interesting question for future research.

7 Conclusion

Curriculum learning is inspired by the way humans acquire knowledge and skills: by mastering simple concepts first, and progressing through information with increasing difficulty to grasp more complex topics. We studied self-paced learning, an approach for curriculum learning that expresses the difficulty of a data sample in terms of the value of the objective function and builds the curriculum via a joint optimization framework. We proposed a number of heuristics, an ensemble, and several improvements for selecting the curriculum that improves upon self-paced learning. We stressed on another important aspect of human learning – diversity, that requires that the right curriculum should not only arrange the data samples in increasing order of difficulty but should also introduce the learner to a small number of samples that are sufficiently dissimilar to the samples that have already been introduced to the learning process. We showed that our heuristics when coupled with diversity lead to significant improvements in a number of question answering tasks. The approach is quite general and we hope that this paper will encourage more NLP researchers to explore curriculum learning in their own works.

Acknowledgments

We thank the anonymous reviewers, along with Emmanouil A. Platanios and Snigdha Chaturvedi for their valuable comments and suggestions that helped improve the quality of this paper. This work was supported by the following research grants: NSF IIS1218282, NSF IIS1447676 and AFOSR FA95501010247.
