Originally proposed as an alternative statistical relational learning method, the *knowledge base embedding* approach has gained a significant amount of attention, due to its simple prediction time computation and strong empirical performance (Nickel et al., 2011; Chang et al., 2014). In this framework, entities and relations in a knowledge base are represented in a continuous space, such as vectors and matrices. Whether two entities have a previously unknown relationship can be predicted by simple functions of their corresponding vectors or matrices. Early work in this direction focuses on exploring various kinds of learning objectives and frameworks, but the model is learned solely from known *direct* relationships between two entities (e.g., `father(barack, sasha)`) (Nickel et al., 2011; Socher et al., 2013; Bordes et al., 2013; Chang et al., 2014; Yang et al., 2015). In contrast, using *multi-step* relation paths (e.g., `husband(barack, `*`michelle`*`) ∧ mother(`*`michelle`*`, sasha)`) to train KB embeddings has been proposed very recently (Guu et al., 2015; Garcia-Duran et al., 2015; Lin et al., 2015; Neelakantan et al., 2015).

While using relation paths improves model performance, it also poses a critical technical challenge. As the number of possible relation paths between pairs of entities grows exponentially with path length, the training complexity increases sharply. Consequently, existing methods need

*This research was conducted during the author's internship at Microsoft Research.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1434–1444,
Berlin, Germany, August 7-12, 2016.

to make approximations by sampling or pruning. The problem is worsened when the input is augmented with unlabeled text, which has been shown to improve performance (Lao et al., 2012; Gardner et al., 2013; Riedel et al., 2013; Gardner et al., 2014; Toutanova and Chen, 2015). Moreover, none of the prior methods distinguish relation paths that differ in the intermediate nodes they pass through (e.g., `michelle` in our example); all represent paths as a sequence of relation types.

In this work, we aim to develop a KB completion model that can incorporate relation paths efficiently. We start from analyzing the procedures in existing approaches, focusing on their time and space complexity. Based on the observation that compositional representations of relation paths are in fact decomposable, we propose a novel dynamic programming method that enables efficient modeling of *all* possible relation paths, while also representing *both* relation types and nodes on the paths.

We evaluated our approach on two datasets. The first is from the domain of gene regulatory networks. Apart from its obvious significance in biomedicine, it offers an excellent testbed for learning joint embedding of KBs and text, as it features existing knowledge bases such as NCI-PID and an even larger body of text that grows rapidly (over one million new articles per year). By modeling intermediate nodes on relation paths, we improve the model by 3 points in mean average precision compared to previous work, while also providing a more efficient algorithm. The second dataset is based on a network derived from WordNet and previously used in work on knowledge base completion. On that dataset we demonstrate the ability of the model to effectively handle longer relation paths composed of a larger set of knowledge base relation types, with smaller positive impact of modeling intermediate nodes.

2 Preliminaries

In this section, we first give a brief overview of the knowledge base and text representation used in this work. We then describe the task of knowledge base completion more formally and introduce our basic model setting and training objective.

Knowledge Base A knowledge base (KB) is represented as a collection of subject-predicate-object triples (s, r, t), where s and t are the subject and object entities from a set $\mathcal{E}$, and r is the predicate from a set $\mathcal{R}$ that denotes a relationship between s and t. For example, in a KB of movie facts, we may find a triple (`Han_Solo`, `character`, `Star_Wars`), indicating that "*Han Solo is a character in the Star Wars movie.*"

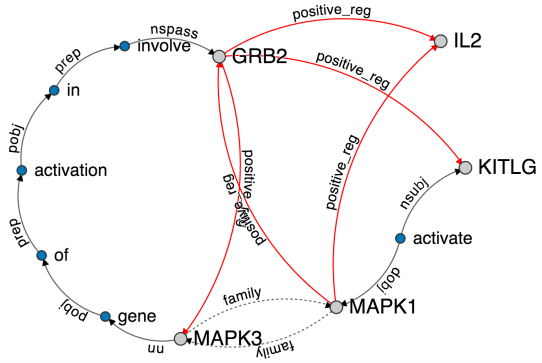

Figure 1: A snapshot depicting the knowledge graph of a gene regulatory network, augmented with gene family and dependency path relations.

Let $(s, \pi, t) = (s, r_1, e_1, r_2, e_2 \ldots, e_{n-1}, r_n, t)$ be a path in $\mathcal{G}$ with s/t as the start/end entities, $r_1, \ldots, r_n$ as the relation edges and $e_1, \ldots, e_{n-1}$ as the intermediate entities.

In the domain of gene regulations, entities are genes and directed edges represent regulations. At the abstract level, there are two key relations, positive_reg and negative_reg, which signify that the subject gene increases or decreases the activity of the object gene, respectively. Figure 1 shows a snapshot of a gene regulatory network. Genes such as `GRB2` and `MAPK3` are denoted by the light grey nodes. Regulations such as positive_reg are denoted by long edges pointing from subject to object. In addition, some genes stem from a common evolutionary origin and share similar functions. They form a "gene family", such as the `MAPK` family that includes `MAPK1` and `MAPK3`.

To jointly embed text, we use sentences containing co-occurring gene pairs, such as "*GRB2 was involved in the activation of gene MAPK3...*", and augment the above knowledge graph with dependency paths between the gene mentions, following the general approach of Riedel et al. (2013).

Task and Scoring Models The KB completion task is to predict the existence of links (s, r, t) that are not seen in the training knowledge base. More specifically, we focus on ranking object and subject entities for given queries $(s, r, *)$ and $(*, r, t)$.

The basic KB embedding models learn latent vector/matrix representations for entities and relations, and score each possible triple using learned parameters θ and a scoring function $f(s, r, t|\theta)$.

Below, we describe two basic model variations which we build on in the rest of the paper.

BILINEAR The BILINEAR model learns a square matrix $W_r \in \mathbb{R}^{d\times d}$ for each relation $r \in \mathcal{R}$ and a vector $x_e \in \mathbb{R}^d$ for each entity $e \in \mathcal{E}$. The scoring function of a relation triple (s, r, t) is defined as:

$$f(s, r, t|\theta) = x_s^\top W_r x_t. \quad (1)$$

For a knowledge graph $\mathcal{G}$ with $|\mathcal{E}| = N_e$ and $|\mathcal{R}| = N_r$, the parameter size of the BILINEAR model is $\mathrm{O}(d^2)$. The large number of parameters make it prone to overfitting, which motivates its diagonal approximation, BILINEAR-DIAG.

BILINEAR-DIAG The BILINEAR-DIAG model restricts the relation representations to the class of diagonal matrices. [1] In this case, the parameter size is reduced to $\mathrm{O}(d)$. Although we present model variants in terms of the BILINEAR representation, all experiments in this work are based on the BILINEAR-DIAG special case.

All models are trained using the same loss function, which maximizes the probability of correct subject/object fillers of a given set of triples with relations or relation paths. The probability is defined by a log-linear model normalized over a set of negative samples: $P(t|s, \pi; \theta) = \frac{e^{f(s,\pi,t|\theta)}}{\sum_{t'\in Neg(s,\pi,*)\cup\{t\}} e^{f(s,\pi,t'|\theta)}}$. The probability of subject entities is defined analogously.

Define the loss for a given training triple $L(s, \pi, t|\theta) = -\log P(t|s, \pi; \theta) - \log P(s|t, \pi; \theta)$. The overall loss function is the sum of losses over all triples, with an L_2 regularization term.

$$L(\theta) = \sum_i L(s_i, \pi_i, t_i; \theta) + \lambda\|\theta\|^2 \quad (2)$$

3 Relation-path-aware Models

We first review two existing methods using vector space relation paths modeling for KB completion in §3.1. We then introduce our new algorithm that can efficiently take into account all relation paths between two nodes as features and simultaneously model intermediate nodes on relation paths in §3.2. We present a detailed theoretical comparison of the efficiency of these three types of methods in §3.3.

3.1 Prior Approaches

The two approaches we consider here are: using relation paths to generate new auxiliary triples for training (Guu et al., 2015) and using relation paths as features for scoring (Lin et al., 2015).

Both approaches take into account embeddings of relation paths between entities, and both of them used vector space compositions to combine the embeddings of individual relation links r_i into an embedding of the path π. The intermediate nodes e_i are neglected. The natural composition function of a BILINEAR model is matrix multiplication (Guu et al., 2015). For this model, the embedding of a length-n path $\Phi_\pi \in \mathbb{R}^{d\times d}$ is defined as the matrix product of the sequence of relation matrices for the relations in π.

$$\Phi_\pi = W_{r_1} \dots W_{r_n}. \quad (3)$$

For the BILINEAR-DIAG model, all the matrices are diagonal and the computation reduces to coordinate-wise product of vectors in $\mathbb{R}^d$.

3.1.1 Relation Paths as a Compositional Regularizer

In Guu et al. (2015), information from relation paths was used to generate additional auxiliary terms in training, which serve to provide a compositional regularizer for the learned node and relation embeddings. A more limited version of the same method was simultaneously proposed in Garcia-Duran et al. (2015).

The method works as follows: starting from each node in the knowledge base, it samples m random walks of length 2 to a maximum length L, resulting in a list of samples $\{[s_i, \pi_i, t_i]\}$. s_i and t_i are the start and end nodes of the random walk, respectively, and π_i consists of a sequence of intermediate edges and nodes. Each of these samples is used to define a new triple used in the training loss function (eq. 2).

The score of each triple under a BILINEAR composition model is defined as $f(s_i, \pi_i, t_i|\theta) = x_{s_i}^t \Phi_{\pi_i} x_{t_i}$, where Φ_{π_i} is the product of matrices for relation link types in the path (eq. 3).

3.1.2 PRUNED-PATHS: Relation Paths as Compositional Features

Instead of using relation paths to augment the set of training triples, Lin et al. (2015) proposed to

[1] The downside of this approximation is that it enforces symmetry in every relation, i.e., $f(s, r, t) = (x_s \circ x_t)^\top w_r = (x_t \circ x_s)^\top w_r = f(t, r, s)$. However, empirically it has been shown to outperform the Bilinear model when the number of training examples is small (Yang et al., 2015).

use paths (s, π, t) to define the scoring function $f(s, r, t|\theta, \Pi_{s,t})$. Here $\Pi_{s,t}$ denotes the sum of the embeddings of a set of paths π between the two nodes in the graph, weighted by path-constrained random walk probabilities. Their implementation built on the TransE (Bordes et al., 2013) embedding model; in comparison, we formulate a similar model using the BILINEAR model.

We refer to such an approach as the PRUNED-PATHS model, for it discards paths with weights below a certain threshold. We define the model under a BILINEAR composition as follows: Let $\{\pi_1, \pi_2, \ldots, \pi_K\}$ denote a fixed set of path types that can be used as a source of features for the model. We abuse notation slightly to refer to a sequence of types of relation links $r_1, r_2, \ldots, r_n$ in a path in $\mathcal{G}$ as π. We denote by $P(t|s, \pi)$ the path-constrained random walk probability of reaching node t starting from node s and following sequences of relation types as specified in π. We define the weighted path representation $F(s, t)$ for a node pair as the weighted sum of the representations of paths π in the set $\{\pi_1, \pi_2, \ldots, \pi_K\}$ that have non-zero path-constrained random walk probabilities. The representation is defined as: $F(s, t) = \sum_\pi w_{|\pi|} P(t|s, \pi)\Phi(\pi)$, where $\Phi(\pi)$ is the path relation type representation from (eq. 3). The weights $w_{|\pi|}$ provide a shared parameter for paths of each length, so that the model may learn to trust the contribution of paths of different lengths differentially. The dependence on θ and the set of paths $\Pi_{s,t}$ between the two nodes in the graph was dropped for simplicity. Figure 2 illustrates the weighted path representation between nodes GRB2 and MAPK3 from Figure 1. [2]

Using the above definition, the score of a candidate triple $f(s, r, t|\theta, \Pi_{s,t})$ is defined as:

$$f(s, r, t) = x_s^\top W_r x_t + \text{vec}(F(s, t))^\top \text{vec}(W_r) \quad (4)$$

The first term of the scoring function is the same as that of the BILINEAR model, and the second term takes into account the similarity of the weighted path representations for (s, t) and the predicted relation r. Here we use element-wise product of the two matrices as the similarity metric. Training and scoring under this model requires explicit constructions of paths, and computing and storing the

[2]Unlike this illustration, the representations of dependency paths are not decomposed into representations of individual edges in our implementation.

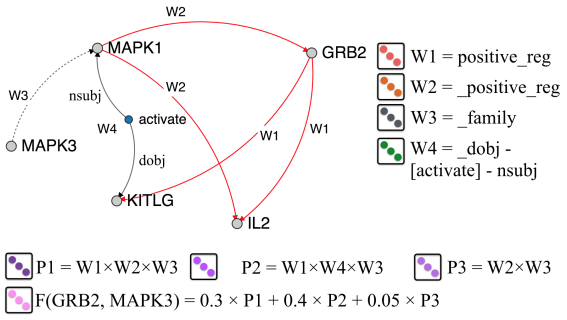

Figure 2: An illustration of the weighted sum of path representations for paths connecting GRB2 and MAPK3 from Figure 1.The prefix "_" of a relation type indicates an inverse relation. The path-constrained random walk probabilities for $P1$, $P2$ and $P3$ are 0.3, 0.4 and 0.05 respectively, and 0.0 for the rest. The path length weights are omitted.

random walk probabilities $P(t|s, \pi)$, which makes it expensive to scale. In the next section, we introduce an algorithm that can efficiently take into account all paths connecting two nodes, and naturally extend it to model the impact of intermediate nodes on the informativeness of the paths.

3.2 ALL-PATHS: A Novel Representation and Algorithm

We now introduce a novel algorithm for efficiently computing and learning the scoring function from (eq. 4), while summing over the set of all paths π up to a certain length L, and additionally modeling the impact of intermediate nodes on the representations $\Phi(\pi)$ of paths. Depending on the characteristics of the knowledge graph and the dimensionality of the learned embedding representations, this method in addition to being more exact, can be faster and take less memory than a method that explicitly generates and prunes full relation paths.

We first define a new representation function for paths of the form $(s, \pi, t) = (s, r_1, e_1, r_2, e_2 \ldots, e_{n-1}, r_n, t)$, which has as a special case the relation-type based function used in prior work, but can additionally model the impact of intermediate nodes e_j on the path representation.

We introduce new parameters w_{e_i} which can impact the representations of paths passing through nodes e_i. w_{e_i} is a scalar weight in our implementation, but vectors of dimensionality d could also be implemented using the same general approach. The embedding of the sample path π under a BILINEAR model is defined as: $\Phi_\pi = W_{r_1} \tanh(w_{e_1}) \cdots W_{r_n} \tanh(w_{e_n})$.

Here the weight of each node is first transformed into the range $[-1, 1]$ using a non-linear $\tanh$ function. To derive our exact algorithm, we

use quantities $F_l(s,t)$ denoting the weighted sum of path representations for all paths of length l between nodes s and t. The weighted sum of path representations $F(s,t)$ can be written as:

$$\sum_{l=1...L} w_l F_l(s,t), \tag{5}$$

where $F_l(s,t) = \sum_{\pi \in \mathcal{P}_l(s,t)} p(s|t,\pi)\Phi_\pi$ and $P_l(s,t)$ denotes all paths of length l between s,t.

Computing $F(s,t)$ in the naive way by enumerating all possible (s,t) paths is impractical since the number of possible paths can be very large, especially in graphs containing text. Therefore prior work selected a subset of paths through sampling and pruning (Neelakantan et al., 2015; Lin et al., 2015). However, the properties of the BILINEAR composition function for path representation enable us to incrementally build the sums of all path representations exactly, using dynamic programming. Algorithm 1 shows how to compute the necessary quantities $F_l(s,t)$ for all entity pairs in $\mathcal{G}$. [3]

Algorithm 1 Compute the sum of path representations (up to length L) for every entity pair (s,t).

Input : $\mathcal{G} = (\mathcal{E}, \mathcal{R})$, $\{W_r | r \in \mathcal{R}\}$, list of all entity pairs $EP = \{(s,t)\}$.
Output : $F_L(s,t)$ for every $(s,t) \in EP$.
Initialize:
for $(s,t) \in EP$ **do**
  if $\mathcal{R}(s,t) \neq \emptyset$ **then**
    $F_1(s,t) \leftarrow \sum_{r \in \mathcal{R}(s,t)} \tanh(w_t) p(t|s,r) W_{r(s,t)}$
  else
    $F_1(s,t) \leftarrow \mathbf{0}$
  end
end
for $l = 2, \ldots, L$ **do**
  for $(s,t) \in EP$ **do**
    $F_l(s,t) \leftarrow \mathbf{0}$
    for $e \in \nu(s)$ **do**
      $F_l(s,t) \leftarrow F_l(s,t) + F_1(s,e) F_{l-1}(e,t)$
    end
  end
end

The key to this solution is that the representations of the longer paths are composed of those of the shorter paths and that the random walk probabilities of relation paths are products of transition probabilities over individual relation edges. The sub-components of paths frequently overlap. For example, all paths π depicted in Figure 2 share the same tail edge family. The algorithms from prior work perform a sum over product representations of paths, but it is more efficient to regroup these into a product of sums. This regrouping allows taking into account exponentially many possible paths without explicitly enumerating them and individually computing their path-constrained random walk probabilities.

After all quantities $F_l(s,t)$ are computed, their weighted sum $F(s,t)$ can be computed using $O(dL)$ operations for each entity pair. These can directly be used to compute the scores of all positive and negative triples for training, using (eq. 4). As we can see, no explicit enumeration or storage of multi-step relation paths between pairs of nodes is needed. To compute gradients of the loss function with respect to individual model parameters, we use a similar algorithm to compute the error for each intermediate edge (e_i, r', e_j) for each group of length l paths between s and t. The algorithm is a variant of forward-backward, corresponding to the forward Algorithm 1.

Notice that directly adding node representations for the paths in the PRUNED-PATHS approach would be infeasible since it would lead to an exposition in the possible path types and therefore the memory and running time requirements of the model. Thus the use of an adaptation of our dynamic programming algorithm to the task of summing over node sequences for a given path type would become necessary to augment the parametric family of the PRUNED-PATHS approach with node representations.

3.3 Efficiency Analysis

We perform a worst-case analysis of the time and memory required for training and evaluation for each of the introduced methods. For the models taking into account relation paths, we assume that all paths up to a certain length L will be modeled[4]. For the basic model text is not taken into account in training, since modeling text and KB relations uniformly in this model did not help performance as seen in the Experiments section. We only take text into account as a source of relation path features or auxiliary path facts.

Notation Let N_e denote the number of nodes in the knowledge graph, E_{kb} the number of knowl-

[3] We further speed up the computation by pre-computing, for each node s, the set of notes t reachable via paths of length l. Then we iterate over non-zero entries only, instead of all pairs in the loops.

[4] If only a subset of paths is used, the complexity of the methods other than ALL-PATHS will be reduced. However, in order to compare the methods in a similar setting, we analyze performance in the case of modeling all multi-step paths.

edge graph links/triples, E_{txt} the number of textual links/triples, a the average number of outgoing links for a node in the graph given the outgoing relation type, N_r the number of distinct relations in the graph, η the number of negative triples for each training triple, and d the dimensionality of entity embeddings and (diagional) matrix representations of relations.

BILINEAR-DIAG In this basic model, the training time is $\mathrm{O}\big(2d(\eta+1)E_{kb}\big)$ and memory is $\mathrm{O}\big(dN_e + dN_r\big)$. The memory required is for storing embeddings of entities and relations, and the time is for scoring $2(\eta+1)$ triples for every fact in the training KB.

Guu et al. (2015) This method generates training path triples $\{(x, \pi, y)\}$ for all entity pairs connected by paths π up to length L. The number of such triples[5] is $\mathcal{T} = E_{kb} + E_{txt} + \sum_{l=2\ldots L} {N_r}^l \times N_e \times a^l$. The memory required is the memory to store all triples and the set of relation paths, which is $\mathrm{O}\big(\mathcal{T} + \sum_{l=2\ldots L} l{N_r}^l\big)$. The time required includes the time to compute the scores and gradients for all triples and their negative examples (for subject and object position), as well as to compute the compositional path representations of all path types. The time to compute compositional path representations is $\mathrm{O}\big(d\sum_{l=2\ldots L} l{N_r}^l\big)$ and the time spent per triple is $2d(\eta+1)$ as in the basic model. Therefore the overall time per iteration is $\mathrm{O}\big(2d(\eta+1)\mathcal{T}\big)$+$\mathrm{O}\big(d\sum_{l=2\ldots L} l{N_r}^l\big)$. The test time and memory requirements of this method are the same as these of BILINEAR-DIAG, which is a substantial advantage over other methods, if evaluation-time efficiency is important.

PRUNED-PATHS This method computes and stores the values of the random walk probabilities for all pairs of nodes and relation paths, for which these probabilities are non-zero. This can be done in time $\mathrm{O}\big(\mathcal{T}\big)$ where Triples is the same quantity used in the analysis of Guu et al. (2015). The memory requirements of this method are the same as these of (Guu et al., 2015), up to a constant to store random-walk probabilities for paths.

The time requirements are different, however. At training time, we compute scores and update gradients for triples corresponding to direct knowledge base edges, whose number is E_{kb}. For each considered triple, however, we need to compute the sum of representations of path features that are active for the triple. We estimate the average number of active paths per node pair as $\frac{\mathcal{T}}{{N_e}^2}$. Therefore the overall time for this method per training iteration is $\mathrm{O}\big(2d(\eta+1)E_{kb}\frac{\mathcal{T}}{{N_e}^2}\big)$+$\mathrm{O}\big(d\sum_{l=2\ldots L} l{N_r}^l\big)$.

We should note that whether this method or the one of Guu et al. (2015) will be faster in training depends on whether the average number of paths per node pair multiplied by E_{kb} is bigger or smaller than the total number of triples $\mathcal{T}$. Unlike the method of Guu et al. (2015), the evaluation-time memory requirements of this approach are the same as its training memory requirements, or they could be reduced slightly to match the evaluation-time memory requirements of ALL-PATHS, if these are lower as determined by the specific problem instance.

ALL-PATHS This method does not explicitly construct or store fully constructed paths (s, π, t). Instead, memory and time is determined by the dynamic program in Algorithm 1, as well as the forward-backward algorithm for computation of gradients. The memory required to store path representation sums $F_l(s,t)$ is $\mathrm{O}\big(dL{N_e}^2\big)$ in the worst case. Denote $E = E_{kb} + E_{txt}$. The time to compute these sums is $\mathrm{O}\big(dE(1+\sum_{l=2\ldots L}(l-1)N_e)\big)$. After this computation, the time to compute the scores of training positive and negative triples is $\mathrm{O}\big(d2(\eta+1)E_{kb}L\big)$. The time to increment gradients using each triple considered in training is $\mathrm{O}\big(dEL^2\big)$. The evaluation time memory is reduced relative to training time memory by a factor of L and the evaluation time per triple can also be reduced by a factor of L using precomputation.

Based on this analysis, we computed training time and memory estimates for our NCI+Txt knowledge base. Given the values of the quantities from our knowledge graph and $d = 50$, $\eta = 50$, and maximum path length of 5, the estimated memory for (Guu et al., 2015) and PRUNED-PATHS is 4.0×10^{18} and for ALL-PATHS the memory is 1.9×10^9. The time estimates are 2.4×10^{21}, 2.6×10^{25}, and 7.3×10^{15} for (Guu et al., 2015), PRUNED-PATHS, and ALL-PATHS, respectively.

[5]The computation uses the fact that the number of path type sequences of length l is N_r^l. We use a, the average branching factor of nodes given relation types, to derive the estimated number of triples of a given relation type for a path of length l.

4 Experiments

Our experiments are designed to study three research questions: (*i*) What is the impact of using path representations as a source of compositional regularization as in (Guu et al., 2015) versus using them as features for scoring as in PRUNED-PATHS and ALL-PATHS? (*ii*) What is the impact of using textual mentions for KB completion in different models? (*iii*) Does modeling intermediate path nodes improve the accuracy of KB completion?

Datasets We used two datasets for evaluation: NCI-PID and WordNet.

For the first set of experiments, we used the Pathway Interaction Database (NCI-PID) (Schaefer et al., 2009) as our knowledge base, which was created by editors from the Nature Publishing Groups, in collaboration with the National Cancer Institute. It contains a collection of high-quality gene regulatory networks (also referred to as *pathways*). The original networks are in the form of hypergraphs, where nodes could be complex gene products (e.g., "protein complex" with multiple proteins bound together) and regulations could have multiple inputs and outputs. Following the convention of most network modeling approaches, we simplified the hypergraphs into binary regulations between genes (e.g., GRB2 positive_reg MAPK3), which yields a graph with 2774 genes and 14323 triples. The triples are then split into train, dev, and test sets, of size 10224, 1315, 2784, respectively. We identified genes belonging to the same family via the common letter prefix in their names, which adds 1936 triples to training.

As a second dataset, we used a WordNet KB with the same train, dev, and test splits as Guu et al. (2015). There are 38,696 entities and 11 types of knowledge base relations. The KB includes 112,581 triples for training, 2,606 triples for validation, and 10,544 triples for testing. WordNet does not contain textual relations and is used for a more direct comparison with recent works.

Textual Relations We used PubMed abstracts for text for NCI-PID. We used the gene mentions identified by Literome (Poon et al., 2014), and considered sentences with co-occurring gene pairs from NCI-PID. We defined textual relations using the fully lexicalized dependency paths between two gene mentions, as proposed in Riedel et al. (2013). Additionally, we define trigger-mapped dependency paths, where only important "trigger" words are lexicalized and the rest of the words are replaced with a wild-card character X. A set of 333 words often associated with regulation events in Literome (e.g. *induce*, *inhibit*, *reduce*, *suppress*) were used as trigger words. To avoid introducing too much noise, we only included textual relations that occur at least 5 times between mentions of two genes that have a KB relation. This resulted in 3,827 distinct textual relations and 1,244,186 mentions.[6] The number of textual relations is much larger than that of KB relations, and it helped induce much larger connectivity among genes (390,338 pairs of genes are directly connected in text versus 12,100 pairs in KB).

Systems ALL-PATHS denotes our compositional learning approach that sums over all paths using

[6]Modeling such a large number of textual relations introduces sparsity, which necessitates models such as (Toutanova et al., 2015; Verga et al., 2015) to derive composed representations of text. We leave integration with such methods for future work.

dynamic programming; ALL-PATHS+NODES additionally models nodes in the paths. PRUNED-PATHS denotes the traditional approach that learns from sampled paths detailed in §3.1.2; paths with occurrence less than a cutoff are pruned ($c = 1$ in Table 1 means that all sampled paths are used). The most relevant prior approach is Guu et al. (2015). We ran experiments using both their publicly available code and our re-implementation. We also included the BILINEAR-DIAG baseline.

Implementation Details We used batch training with RProp (Riedmiller and Braun, 1993). The L_2 penalty λ was set to 0.1 for all models, and the entity vectors x_e were normalized to unit vectors. For each positive example we sample 500 negative examples. For our implementation of (Guu et al., 2015), we run 5 random walks of each length starting from each node and we found that adding a weight β to the multi-step path triples improves the results. After preliminary experimentation, we fixed β to 0.1. Models using KB and textual relations were initialized from models using KB relations only[7]. Model training was stopped when the development set MAP did not improve for 40 iterations; the parameters with the best MAP on the development set were selected as output. Finally, we used only paths of length up to 3 for NCI-PID and up to length 5 for WordNet.[8]

Evaluation metrics We evaluate our models on their ability to predict the subjects/objects of knowledge base triples in the test set. Since the relationships in the gene regulation network are frequently not one-to-one, we use the mean average precision (MAP) measure instead of the mean reciprocal rank often used in knowledge base completion works in other domains. In addition to MAP, we use Hits@10, which is the percentage of correct arguments ranked among the top 10 predictions[9]. We compute measures for ranking both the object entities $(s, r, *)$ and the subject entities$(*, r, t)$. We report evaluation metrics computed on the union of the two query set.

NCI-PID Results Table 1 summarizes the knowledge base (KB) completion results on the NCI-PID test. The rows compare our compositional learning approach ALL-PATHS+NODES with prior approaches. The comparison of the two columns demonstrates the impact when text is jointly embedded with KB. Our compositional learning approach significantly outperforms all other approaches in both evaluation metrics (MAP and HITS@10). Moreover, jointly embedding text and KB led to substantial improvement, compared to embedding KB only.[10] Finally, modeling nodes in the paths offers significant gains (ALL-PATHS+NODE gains 3 points in MAP over ALL-PATHS), with statistical significance ($p < .001$) according to a McNemar test.

Evaluating the effect of path pruning on the traditional approach (PRUNED-PATHS) is quite illuminating. As the number of KB relations is relatively small in this domain, when only KB is embedded, most paths occur frequently. So there is little difference between the heaviest pruned version (c=1000) and the lightest (c=1). When textual relations are included, the cutoff matters more, although the difference was small as many rarer textual relations were already filtered beforehand. In either case, the accuracy difference between ALL-PATHS and PRUNED-PATHS is small, and ALL-PATHS mainly gains in efficiency. However, when nodes are modeled, the compositional learning approach gains in accuracy as well, especially when text is jointly embedded.

Comparison among the baselines also offers valuable insights. The implementation of Guu et al. (2015) with default parameters performed significantly worse than our re-implementation. Also, our re-implementation achieves only a slight gain over the BILINEAR-DIAG baseline, whereas the original implementation obtains substantial improvement over its own version of BILINEAR-DIAG. These results underscore the importance of hyper-parameters and optimization, and invite future systematic research on the impact of such modeling choices.[11]

[7] In addition, models using path training were initialized from models trained on direct relation links only.

[8] Using paths up to length 4 on NCI-PID did not perform better.

[9] As a common practice in KB completion evaluation, for both MAP and Hits@10, we filtered out the other correct answers when ranking a particular triple to eliminate ranking penalization induced by other correct predictions.

[10] Text did not help for the models in the first four rows in the Table, possibly because in these approaches text and KB information are equally weighted in the loss function and the more numerous textual triples dominate the KB ones.

[11] The differences between our two implementations are: max-margin loss versus softmax loss and stochastic gradient training versus batch training.

Model	MAP	HITS@10
BILINEAR-DIAG (Guu et al., 2015)	N/A	12.9
BILINEAR-DIAG	8.0	12.2
+Guu et al. (2015)	N/A	14.4
PRUNED-PATHS $l = 3$ c=10	9.5	14.8
PRUNED-PATHS $l = 3$ c=1	9.5	14.9
PRUNED-PATHS $l = 5$ c=10	8.9	14.4
ALL-PATHS $l = 3$	9.4	14.7
ALL-PATHS+NODES l=3	9.4	15.2
ALL-PATHS $l = 5$	9.6	16.6
ALL-PATHS+NODES l=5	**9.8**	**16.7**

Table 2: KB completion results on the WordNet test set: comparison of our compositional learning approach (ALL-PATHS) with baseline systems. The maximum length of paths is denoted by l. Sampled paths occurring less than c times were pruned in PRUNED-PATHS.

WordNet Results Table 2 presents a comparative evaluation on the WordNet dataset. This dataset has a larger number of knowledge base relation types compared to NCI-PID, and longer relation paths in this KB are expected to be beneficial. Guu et al. (2015) evaluated their compositional regularization approach on this dataset and we can directly compare to their results. The first two rows in the Table show the baseline BILINEAR-DIAG model results according to the results reported in (Guu et al., 2015) and our implementation. The MAP results were not reported in Guu et al. (2015); hence the NA value for MAP in row one.[12] On this dataset, our implementation of the baseline model does not have substantially different results than Guu et al. (2015) and we use their reported results for the baseline and compositionally trained model.

Compositional training improved performance in Hits@10 from 12.9 to 14.4 in Guu et al. (2015), and we find that using PRUNED-PATHS as features gives similar, but a bit higher performance gains.

The PRUNED-PATHS method is evaluated using count cutoffs of 1 and 10, and maximum path lengths of 3 and 5. As can be seen, lower count cutoff performed better for paths up to length 3, but we could not run the method with path lengths up to 5 and count cutoff of 1, due to excessive memory requirements (more than 248GB). When using count cutoff of 10, paths up to length 5 performed worse than paths up to length 3. This performance degradation could be avoided with a staged training regiment where models with shorter paths are first trained and used to initialize models using longer paths.

The performance of the ALL-PATHS method can be seen for maximum paths up to lengths 3 and 5, and with or without using features on intermediate path nodes.[13] As shown in Table 2, longer paths were useful, and features on intermediate nodes were also beneficial. We tested the significance of the differences between several pairs of models and found that nodes led to significant improvement ($p < .002$) for paths of length up to 3, but not for the setting with longer paths. All models using path features are significantly better than the baseline BILINEAR-DIAG model.

To summarize both sets of experiments, the ALL-PATHS approach allows us to efficiently include information from long KB relation paths as in WordNet, or paths including both text and KB relations as in NCI-PID. Our dynamic programming algorithm considers relation paths efficiently, and is also straightforwardly generalizable to include modeling of intermediate path nodes, which would not be directly possible for the PRUNED-PATHS approach. Using intermediate nodes was beneficial on both datasets, and especially when paths could include textual relations as in the NCI-PID dataset.

5 Conclusions

In this work, we propose the first approach to efficiently incorporate all relation paths of bounded length in a knowledge base, while modeling both relations and intermediate nodes in the compositional path representations. Experimental results on two datasets show that it outperforms prior approaches by modeling intermediate path nodes. In the future, we would like to study the impact of relation paths for additional basic KB embedding models and knowledge domains.

Acknowledgments

The authors would like to thank the anonymous reviewers and meta-reviewer for suggestions on making the paper stronger, as well as Kenton Lee and Aria Haghighi for their helpful comments on the draft.

[12] We ran the trained model distributed by Guu et al. (2015) and obtained a much lower Hits@10 value of 6.4 and MAP of of 3.5. Due to the discrepancy, we report the original results from the authors' paper which lack MAP values instead.

[13] To handle the larger scale of the WordNet dataset in terms of the number of nodes in the knowledge base, we enforced a maximum limit (of 100) on the degree of a node that can be an intermediate node in a multi-step relation path.

Abstract

We enrich a curated resource of commonsense knowledge by formulating the problem as one of knowledge base completion (KBC). Most work in KBC focuses on knowledge bases like Freebase that relate entities drawn from a fixed set. However, the tuples in ConceptNet (Speer and Havasi, 2012) define relations between an unbounded set of *phrases*. We develop neural network models for scoring tuples on arbitrary phrases and evaluate them by their ability to distinguish true held-out tuples from false ones. We find strong performance from a bilinear model using a simple additive architecture to model phrases. We manually evaluate our trained model's ability to assign quality scores to novel tuples, finding that it can propose tuples at the same quality level as medium-confidence tuples from ConceptNet.

1 Introduction

Many ambiguities in natural language processing (NLP) can be resolved by using knowledge of various forms. Our focus is on the type of knowledge that is often referred to as "commonsense" or "background" knowledge. This knowledge is rarely expressed explicitly in textual corpora (Gordon and Van Durme, 2013). Some researchers have developed techniques for inferring this knowledge from patterns in raw text (Gordon, 2014; Angeli and Manning, 2014), while others have developed curated resources of commonsense knowledge via manual annotation (Lenat and Guha, 1989; Speer and Havasi, 2012) or games with a purpose (von Ahn et al., 2006).

Curated resources typically have high precision but suffer from a lack of coverage. For certain resources, researchers have developed methods to automatically increase coverage by inferring missing entries. These methods are commonly categorized under the heading of knowledge base completion (KBC). KBC is widely-studied for knowledge bases like Freebase (Bollacker et al., 2008) which contain large sets of entities and relations among them (Mintz et al., 2009; Nickel et al., 2011; Riedel et al., 2013; West et al., 2014), including recent work using neural networks (Socher et al., 2013; Yang et al., 2014).

Table 1: ConceptNet tuples with left term "soak in hotspring"; final column is confidence score.

We improve the coverage of commonsense resources by formulating the problem as one of knowledge base completion. We focus on a particular curated commonsense resource called ConceptNet (Speer and Havasi, 2012). ConceptNet contains tuples consisting of a left term, a relation, and a right term. The relations come from a fixed set. While terms in Freebase tuples are entities, ConceptNet terms can be arbitrary *phrases*. Some examples are shown in Table 1. An NLP application may wish to query ConceptNet for information about soaking in a hotspring, but may use different words from those contained in the ConceptNet tuples. Our goal is to do on-the-fly knowledge base completion so that queries can be answered robustly without requiring the precise linguistic forms contained in ConceptNet.

To do this, we develop neural network models to embed terms and provide scores to arbi-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1445–1455,
Berlin, Germany, August 7-12, 2016.

trary tuples. We train them on ConceptNet tuples and evaluate them by their ability to distinguish true and false held-out tuples. We consider several functional architectures, comparing two composition functions for embedding terms and two functions for converting term embeddings into tuple scores. We find that all architectures are able to outperform several baselines and reach similar performance on classifying held-out tuples.

We also experiment with several training objectives for KBC, finding that a simple cross entropy objective with randomly-generated negative examples performs best while also being fastest. We manually evaluate our trained model's ability to assign quality scores to novel tuples, finding that it can propose tuples at the same quality level as medium-confidence tuples from ConceptNet. We release all of our resources, including our ConceptNet KBC task data, large sets of randomly-generated tuples scored with our model, training code, and pretrained models with code for calculating the confidence of novel tuples.[1]

2 Related Work

Our methods are similar to past work on KBC (Mintz et al., 2009; Nickel et al., 2011; Lao et al., 2011; Nickel et al., 2012; Riedel et al., 2013; Gardner et al., 2014; West et al., 2014), particularly methods based on distributed representations and neural networks (Socher et al., 2013; Bordes et al., 2013; Bordes et al., 2014a; Bordes et al., 2014b; Yang et al., 2014; Neelakantan et al., 2015; Gu et al., 2015; Toutanova et al., 2015). Most prior work predicts new relational links between terms drawn from a *fixed* set. In a notable exception, Neelakantan and Chang (2015) add new entities to KBs using external resources along with properties of the KB itself. Relatedly, Yao et al. (2013) induce an unbounded set of entity categories and associate them with entities in KBs.

Several researchers have developed techniques for discovering commonsense knowledge from text (Gordon et al., 2010; Gordon and Schubert, 2012; Gordon, 2014; Angeli and Manning, 2014). Open information extraction systems like REVERB (Fader et al., 2011) and NELL (Carlson et al., 2010) find tuples with arbitrary terms and relations from raw text. In contrast, we start with a set of commonsense facts to use for training, though our methods could be applied to the output of these or other extraction systems.

Our goals are similar to those of the AnalogySpace method (Speer et al., 2008), which uses matrix factorization to improve coverage of ConceptNet. However, AnalogySpace can only return a confidence score for a pair of terms drawn from the training set. Our models can assign scores to tuples that contain novel terms (as long as they consist of words in our vocabulary).

Though we use ConceptNet, similar techniques can be applied to other curated resources like WordNet (Miller, 1995) and FrameNet (Baker et al., 1998). For WordNet, tuples can contain lexical entries that are linked via synset relations (e.g., "hypernym"). WordNet contains many multiword entries (e.g., "cold sweat"), which can be modeled compositionally by our term models; alternatively, entire glosses could be used as terms. To expand frame relationships in FrameNet, tuples can draw relations from the frame relation types (e.g., "is causative of") and terms can be frame lexical units or their definitions.

Several researchers have used commonsense knowledge to improve language technologies, including sentiment analysis (Cambria et al., 2012; Agarwal et al., 2015), semantic similarity (Caro et al., 2015), and speech recognition (Lieberman et al., 2005). Our hope is that our models can enable many other NLP applications to benefit from commonsense knowledge.

Our work is most similar to that of Angeli and Manning (2013). They also developed methods to assess the plausibility of new facts based on a training set of facts, considering commonsense data from ConceptNet in one of their settings. Like us, they can handle an unbounded set of terms by using (simple) composition functions for novel terms, which is rare among work in KBC. One key difference is that their best method requires iterating over the KB at test time, which can be computationally expensive with large KBs. Our models do not require iterating over the training set. We compare to several baselines inspired by their work, and we additionally evaluate our model's ability to score novel tuples derived from both ConceptNet and Wikipedia.

3 Models

Our goal is to represent commonsense knowledge such that it can be used for NLP tasks. We as-

[1] Available at `http://ttic.uchicago.edu/~kgimpel/commonsense.html`.

sume this knowledge is given in the form of tuples $\langle t_1, R, t_2 \rangle$, where t_1 is the **left term**, t_2 is the **right term**, and R is a (directed) **relation** that exists between the terms. Examples are shown in Table 1.[2]

Given a set of tuples, our goal is to develop a parametric model that can provide a confidence score for new, unseen tuples. That is, we want to design and train models that define a function $\text{score}(t_1, R, t_2)$ that provides a quality score for an arbitrary tuple $\langle t_1, R, t_2 \rangle$. These models will be evaluated by their ability to distinguish true held-out tuples from false ones.

We describe two model families for scoring tuples. We assume that we have embeddings for words and define models that use these word embeddings to score tuples. So our models are limited to tuples in which terms consist of words in the word embedding vocabulary, though future work could consider character-based architectures for open-vocabulary modeling (Huang et al., 2013; Ling et al., 2015).

3.1 Bilinear Models

We first consider bilinear models, since they have been found useful for KBC in past work (Nickel et al., 2011; Jenatton et al., 2012; García-Durán et al., 2014; Yang et al., 2014). A bilinear model has the following form for a tuple $\langle t_1, R, t_2 \rangle$:

$$v_1^\top M_R \, v_2$$

where $v_1 \in \mathbb{R}^r$ is the (column) vector representing t_1, $v_2 \in \mathbb{R}^r$ is the vector for t_2, and $M_R \in \mathbb{R}^{r \times r}$ is the parameter matrix for relation R.

To convert terms t_1 and t_2 into term vectors v_1 and v_2, we consider two possibilities: word averaging and a bidirectional long short-term memory (LSTM) recurrent neural network (Hochreiter and Schmidhuber, 1997). This provides us with two models: **Bilinear AVG** and **Bilinear LSTM**.

One downside of this architecture is that as the length of the term vectors grows, the size of the relation matrices grows quadratically. This can slow down training while requiring more data to learn the large numbers of parameters in the matrices. To address this, we include an additional nonlinear transformation of each term:

$$u_i = a(W^{(B)} v_i + b^{(B)})$$

where a is a nonlinear activation function (tuned among ReLU, $\tanh$, and logistic sigmoid) and where we have introduced additional parameters $W^{(B)}$ and $b^{(B)}$. This gives us the following model:

$$\text{score}_{\text{bilinear}}(t_1, R, t_2) = u_1^\top M_R \, u_2$$

When using the LSTM, we tune the decision about how to produce the final term vectors to pass to the bilinear model, including possibly using the final vectors from each direction and the output of max or average pooling. We use the same LSTM parameters for each term.

3.2 Deep Neural Network Models

Our second family of models is based on deep neural networks (DNNs). While bilinear models have been shown to work well for KBC, their functional form makes restrictions about how terms can interact. DNNs make no such restrictions.

As above, we define two models, one based on using word averaging for the term model (**DNN AVG**) and one based on LSTMs (**DNN LSTM**). For the DNN AVG model, we obtain the term vectors v_1 and v_2 by averaging word vectors in the respective terms. We then concatenate v_1, v_2, and a relation vector v_R to form the input of the DNN, denoted v_{in}. The DNN uses a single hidden layer:

$$\begin{aligned} u &= a(W^{(D1)} v_{in} + b^{(D1)}) \\ \text{score}_{\text{DNN}}(t_1, R, t_2) &= W^{(D2)} u + b^{(D2)} \end{aligned} \quad (1)$$

where a is again a (tuned) nonlinear activation function. The size of the hidden vector u is tuned, but the output dimensionality (the numbers of rows in $W^{(D2)}$ and $b^{(D2)}$) is fixed to 1. We do not use a nonlinear activation for the final layer since our goal is to output a scalar score.

For the DNN LSTM model, we first create a single vector for the two terms using an LSTM. That is, we concatenate t_1, a delimiter token, and t_2 to create a single word sequence. We use a bidirectional LSTM to convert this word sequence to a vector, again possibly using pooling (the decision is tuned; details below). We concatenate the output of this bidirectional LSTM with the relation vector v_r to create the DNN input vector v_{in}, then use Eq. 1 to obtain a score. We found this to work better than separately using an LSTM on each term. We can not try this for the Bilinear LSTM model since its functional form separates the two term vectors.

[2] These examples are from the Open Mind Common Sense (OMCS) part of ConceptNet version 5 (Speer and Havasi, 2012). In our experiments below, we only use OMCS tuples.

The relation vectors v_R are learned in addition to the DNN parameters $W^{(D1)}$, $W^{(D2)}$, $b^{(D1)}$, $b^{(D2)}$, and the LSTM parameters (in the case of the DNN LSTM model). Also, word embedding parameters are updated in all settings.

4 Training

Given a tuple training set T, we train our models using two different loss functions: hinge loss and a binary cross entropy function. Both rely on ways of generating negative examples (Section 4.3). Both also use regularization (Section 4.4).

4.1 Hinge Loss

Given a training tuple $\tau = \langle t_1, R, t_2 \rangle$, the hinge loss seeks to make the score of τ larger than the score of negative examples by a margin of at least γ. This corresponds to minimizing the following loss, summed over all examples $\tau \in T$:

$$\begin{aligned}&\text{loss}_{\text{hinge}}(\tau) = \\ &\quad \max\{0, \gamma - \text{score}(\tau) + \text{score}(\tau_{neg(t_1)})\} \\ &\quad + \max\{0, \gamma - \text{score}(\tau) + \text{score}(\tau_{neg(R)})\} \\ &\quad + \max\{0, \gamma - \text{score}(\tau) + \text{score}(\tau_{neg(t_2)})\}\end{aligned}$$

where $\tau_{neg(t_1)}$ is the negative example obtained by replacing t_1 in τ with some other t_1, and $\tau_{neg(R)}$ and $\tau_{neg(t_2)}$ are defined analogously for the relation and right term. We describe how we generate these negative examples in Section 4.3 below.

4.2 Binary Cross Entropy

Though we only have true tuples in our training set, we can create a binary classification problem by assigning a label of 1 to training tuples and a label of 0 to negative examples. Then we can minimize cross entropy (CE) as is common when using neural networks for classification. To generate negative examples, we consider the methods described in Section 4.3 below. We also need to convert our models' scores into probabilities, which we do by using a logistic sigmoid σ on score. We denote the label as ℓ, where the label is 1 if the tuple is from the training set and 0 if it is a negative example. Then the loss is defined:

$$\begin{aligned}&\text{loss}_{\text{CE}}(\tau, \ell) = \\ &-\ell \log \sigma(\text{score}(\tau)) - (1-\ell) \log(1 - \sigma(\text{score}(\tau)))\end{aligned}$$

When using this loss, we generate three negative examples for each positive example (one for swapping each component of the tuple, as in the hinge loss). For a mini-batch of size β, there are β positive examples and 3β negative examples used for training. The loss is summed over these 4β examples yielded by each mini-batch.

4.3 Negative Examples

For the loss functions above, we need ways of automatically generating negative examples. For efficiency, we consider using the current mini-batch only, as our models are trained using optimization on mini-batches. We consider the following three strategies to construct negative examples. Each strategy constructs three negative examples for each positive example τ: one by replacing t_1, one by replacing R, and one by replacing t_2.

Random sampling. We create the three negative examples for τ by replacing each component with its counterpart in a randomly-chosen tuple in the same mini-batch.

Max sampling. We create the three negative examples for τ by replacing each component with its counterpart in some other tuple in the mini-batch, choosing the substitution to maximize the score of the resulting negative example. For example, when swapping out t_1 in $\tau = \langle t_1, R, t_2 \rangle$, we choose the substitution t_1' as follows:

$$t_1' = \underset{t:\langle t, R', t_2' \rangle \in \mu \setminus \tau}{\text{argmax}} \text{score}(t, R, t_2)$$

where μ is the current mini-batch of tuples. We perform the analogous procedure for R and t_2.

Mix sampling. This is a mixture of the above, using random sampling 50% of the time and max sampling the remaining 50% of the time.

4.4 Regularization

We use L_2 regularization. For the DNN models, we add the penalty term $\lambda \|\theta\|^2$ to the losses, where λ is the regularization coefficient and θ contains all other parameters. However, for the bilinear models we regularize the relation matrices M_R toward the identity matrix instead of all zeroes, adding the following to the loss:

$$\lambda_1 \|\theta\|^2 + \lambda_2 \sum_R \|M_R - I_r\|_2^2$$

where I_r is the $r \times r$ identity matrix, the summation is performed over all relations R, and θ represents all other parameters.

5 Experimental Setup

We now evaluate our tuple models. We measure whether our models can distinguish true and false tuples by training a model on a large set of tuples and testing on a held-out set.

5.1 Task Design

The tuples are obtained from the Open Mind Common Sense (OMCS) entries in the ConceptNet 5 dataset (Speer and Havasi, 2012). They are sorted by a confidence score. The most confident 1200 tuples were reserved for creating our test set (TEST). The next most confident 600 tuples (i.e., those numbered 1201–1800) were used to build a development set (DEV1) and the next most confident 600 (those numbered 1801–2400) were used to build a second development set (DEV2).

For each set S ($S \in \{\text{DEV1}, \text{DEV2}, \text{TEST}\}$), for each tuple $\tau \in S$, we created a negative example and added it to S. So each set doubled in size. To create a negative example from $\tau \in S$, we randomly swapped one of the components of τ with another tuple $\tau' \in S$. One third of the time we swapped t_1 in τ for t_1 in τ', one third of the time we swapped their R's, and the remaining third of the time we swapped their t_2's. Thus, distinguishing positive and negative examples in this task is similar to the objectives optimized during training.

Each of DEV1 and DEV2 has 1200 tuples (600 positive examples and 600 negative examples), while TEST has 2400 tuples (1200 positive and 1200 negative). For training data, we selected 100,000 tuples from the remaining tuples (numbered 2401 and beyond).

The task is to separate the true and false tuples in our test set. That is, the labels are 1 for true tuples and 0 for false tuples. Given a model for scoring tuples, we select a threshold by maximizing accuracy on DEV1 and report accuracies on DEV2. This is akin to learning the bias feature weight (using DEV1) of a linear classifier that uses our model's score as its only feature. We tuned several choices—including word embeddings, hyperparameter values, and training objectives—on DEV2 and report final performance on TEST. One annotator (a native English speaker) attempted the same classification task on a sample of 100 tuples from DEV2 and achieved an accuracy of 95%. We release these datasets to the community so that others can work on this same task.

5.2 Word Embeddings

Our tuple models rely on initial word embeddings. To help our models better capture the commonsense knowledge in ConceptNet, we generated word embedding training data using the OMCS sentences underlying our training tuples (we excluded the top 2400 tuples which were used for creating DEV1, DEV2, and TEST). We created training data by merging the information in the tuples and their OMCS sentences. Our goal was to combine the grammatical context of the OMCS sentences with the words in the actual terms, so as to ensure that we learn embeddings for the words in the terms. We also insert the relations into the OMCS sentences so that we can learn embeddings for the relations themselves.

We describe the procedure by example and also release our generated data for ease of replication. The tuple ⟨soak in a hotspring, CAUSES, get pruny skin⟩ was automatically extracted/normalized (by the ConceptNet developers) from the OMCS sentence "The effect of [soaking in a hotspring] is [getting pruny skin]" where brackets surround terms. We replace the bracketed portions with their corresponding terms and insert the relation between them: "The effect of soak in a hotspring CAUSES get pruny skin". We do this for all training tuples.[3]

We used the `word2vec` (Mikolov et al., 2013) toolkit to train skip-gram word embeddings on this data. We trained for 20 iterations, using a dimensionality of 200 and a window size of 5. We refer to these as "CN-trained" embeddings for the remainder of this paper. Similar approaches have been used to learn embeddings for particular downstream tasks, e.g., dependency parsing (Bansal et al., 2014). We use our CN-trained embeddings within baseline methods and also provide the initial word embeddings of our models. For all of our models, we update the initial word embeddings during learning.

In the baseline methods described below, we compare our CN-trained embeddings to pretrained word embeddings. We use the GloVe (Pennington et al., 2014) embeddings trained on 840 billion tokens of Common Crawl web text and the PARAGRAM-SimLex embeddings of Wieting et al. (2015), which were tuned to have strong performance on the SimLex-999 task (Hill et al., 2015).

[3]For reversed relations, indicated by an asterisk in the OMCS sentences, we swap t_1 and t_2 in the tuple.

5.3 Baselines

We consider three baselines inspired by those of Angeli and Manning (2013):

- **Similar Fact Count (Count)**: For each tuple $\tau = \langle t_1, R, t_2 \rangle$ in the evaluation set, we count the number of similar tuples in the training set. A training tuple $\tau' = \langle t_1', R', t_2' \rangle$ is considered "similar" to τ if $R = R'$, one of the terms matches exactly, and the other term has the same head word. That is, $(R = R') \wedge (t_1 = t_1') \wedge (head(t_2) = head(t_2'))$, or $(R = R') \wedge (t_2 = t_2') \wedge (head(t_1) = head(t_1'))$. The head word for a term was obtained by running the Stanford Parser (Klein and Manning, 2003) on the term. This baseline does not use word embeddings.
- **Argument Similarity (ArgSim)**: This baseline computes the cosine similarity of the vectors for t_1 and t_2, ignoring the relation. Vectors for t_1 and t_2 are obtained by word averaging.
- **Max Similarity (MaxSim)**: For tuple τ in an evaluation set, this baseline outputs the maximum similarity between τ and any tuple in the training set. The similarity is computed by concatenating the vectors for t_1, R, and t_2, then computing cosine similarity. As in ArgSim, we obtain vectors for terms by averaging their words. We only consider R when using our CN-trained embeddings since they contain embeddings for the relations. When using GloVe and PARAGRAM embeddings for this baseline, we simply use the two term vectors (still constructed via averaging the words in each term).

We chose these baselines because they can all handle unbounded term sets but differ in their other requirements. ArgSim and MaxSim use word embeddings while Count does not. Count and MaxSim require iterating over the training set during inference while ArgSim does not.

For each baseline, we tuned a threshold on DEV1 to maximize classification accuracy then tested on DEV2 and TEST.

5.4 Training and Tuning

We used AdaGrad (Duchi et al., 2011) for optimization, training for 20 epochs through the training tuples. We separately tuned hyperparameters for each model and training objective. We tuned the following hyperparameters: the relation matrix size r for the bilinear models (also the length of the transformed term vectors, denoted u_1 and u_2 above), the activation a, the hidden layer size g for the DNN models, the relation vector length d for the DNN models, the LSTM hidden vector size h for models with LSTMs, the mini-batch size β, the regularization parameters λ, λ_1, and λ_2, and the AdaGrad learning rate α.

All tuning used early stopping: periodically during training, we used the current model to find the optimal threshold on DEV1 and evaluated on DEV2. Due to computational limitations, we were unable to perform thorough grid searches for all hyperparameters. We combined limited grid searches with greedy hyperparameter tuning based on regions of values that were the most promising.

For the Bilinear LSTM and DNN LSTM, we did hyperparameter tuning by training on the full training set of 100,000 tuples for 20 epochs, computing DEV2 accuracy once per epoch. For the averaging models, we tuned by training on a subset of 1000 tuples with $\beta = 200$ for 20 epochs; the averaging models showed more stable results and did not require the full training set for tuning. Below are the tuned hyperparameter values:

- **Bilinear AVG**: for CE: $r = 150$, $a = \tanh$, $\beta = 200$, $\alpha = 0.01$, $\lambda_1 = \lambda_2 = 0.001$. Hinge loss: same values as above except $\alpha = 0.005$.
- **Bilinear LSTM**: for CE: $r = 50$, $a =$ ReLU, $h = 200$, $\beta = 800$, $\alpha = 0.02$, and $\lambda_1 = \lambda_2 = 0.00001$. To obtain vectors from the term bidirectional LSTMs, we used max pooling. For hinge loss: $r = 50$, $a = \tanh$, $h = 200$, $\beta = 400$, $\alpha = 0.007$, $\lambda_1 = 0.00001$, and $\lambda_2 = 0.01$. To obtain vectors from the term bidirectional LSTMs, we used the concatenation of average pooling and final hidden vectors in each direction. For each sampling method and loss function, α was tuned by grid search with the others fixed to the above values.
- **DNN AVG**: for both losses: $a =$ ReLU, $d = 200$, $g = 1000$, $\beta = 600$, $\alpha = 0.01$, $\lambda = 0.001$.
- **DNN LSTM**: for both losses: $a =$ ReLU, $d = 200$, bidirectional LSTM hidden layer size $h = 200$, hidden layer dimension $g = 800$, $\beta = 400$, $\alpha = 0.005$, and $\lambda = 0.00005$. To get vectors from the term LSTMs, we used max pooling.

6 Results

Word Embedding Comparison. We first evaluate the quality of our word embeddings trained on the ConceptNet training tuples. Table 2 compares

	GloVe	PARAGRAM	CN-trained
ArgSim	68	69	**73**
MaxSim	73	70	**82**

Table 2: Accuracies (%) on DEV2 of two baselines using three different sets of word embeddings. Our ConceptNet-trained embeddings outperform GloVe and PARAGRAM embeddings.

	DNN AVG		DNN LSTM	
	CE	hinge	CE	hinge
random	124	230	710	783
mix	20755	21045	25928	26380
max	39338	41867	49583	49427

Table 4: Loss function runtime comparison (seconds per epoch) of the DNN models.

accuracies on DEV2 for the two baselines that use embeddings: ArgSim and MaxSim. We find that pretrained GloVe and PARAGRAM embeddings perform comparably, but both are outperformed by our ConceptNet-trained embeddings. We use the latter for the remaining experiments in this paper.

Training Comparison. Table 3 shows the results of our models with the two loss functions and three sampling strategies. We find that the binary cross entropy loss with random sampling performs best across models. We note that our conclusion differs from some prior work that found max or mix sampling to be better than random (Wieting et al., 2016). We suspect that this difference may stem from characteristics of the ConceptNet training data. It may often be the case that the max-scoring negative example in the mini-batch is actually a true fact, due to the generic nature of the facts expressed.

Table 4 shows a runtime comparison of the losses and sampling strategies.[4] We find random sampling to be orders of magnitude faster than the others while also performing the best.

Final Results. Our final results are shown in Table 5. We show the DEV2 and TEST accuracies for our baselines and for the best configuration (tuned on DEV2) for each model. All models outperform all baselines handily. Our models perform similarly, with the Bilinear models and the DNN AVG model all exceeding 90% on both DEV2 and TEST.

We note that the AVG models performed strongly compared to those that used LSTMs for

[4]These experiments were performed using 2 threads on a 3.40-GHz Intel Core i7-3770 CPU with 8 cores.

	DEV2	TEST
Count	75.4	79.0
ArgSim	72.9	74.2
MaxSim	81.9	83.5
Bilinear AVG	90.3	91.7
Bilinear LSTM	90.8	90.7
DNN AVG	91.3	92.0
DNN LSTM	88.1	89.2
Bilinear AVG + data	91.8	92.5
human	∼95.0	—

Table 5: Accuracies (%) of baselines and final model configurations on DEV2 and TEST. "+ data" uses enlarged training set of size 300,000, and then doubles this training set by including tuples with conjugated forms; see text for details. Human performance on DEV2 was estimated from a sample of size 100.

modeling terms. We suggest two reasons for this. The first is that most terms are short, with an average term length of 2.3 words in our training tuples. An LSTM may not be needed to capture long-distance properties. The second reason may be due to hyperparameter tuning. Recall that we used a greedy search for optimal hyperparameter values; we found that models with LSTMs take more time per epoch, more epochs to converge, and exhibit more hyperparameter sensitivity compared to models based on averaging. This may have contributed to inferior hyperparameter values for the LSTM models.

We also trained the Bilinear AVG model on a larger training set (row labeled "Bilinear AVG + data"). We note that the ConceptNet tuples typically contain unconjugated forms; we sought to use both conjugated and unconjugated words. We began with a larger training set of 300,000 tuples from ConceptNet, then augmented them to include conjugated word forms as in the following example. For the tuple ⟨soak in a hotspring, CAUSES, get pruny skin⟩ obtained from the OMCS sentence "The effect of [soaking in a hotspring] is [getting pruny skin]", we generated an additional tuple ⟨soaking in a hotspring, CAUSES, getting pruny skin⟩. We thus created twice as many training tuples. The results with this larger training set improved from 91.7 to 92.5 on the test set. We release this final model to the research community.

We note that the strongest baseline, MaxSim, is a nonparametric model that requires iterating over all training tuples to provide a score to new tuples. This is a serious bottleneck for use in NLP applications that may need to issue large numbers of

	Bilinear AVG		Bilinear LSTM		DNN AVG		DNN LSTM	
	CE	hinge	CE	hinge	CE	hinge	CE	hinge
random	**90**	84	**91**	83	**91**	87	**88**	57
mix	**90**	83	90	87	90	78	82	63
max	86	75	65	66	61	52	56	52

Table 3: Accuracies (%) on DEV2 of models trained with two loss functions (cross entropy (CE) and hinge) and three sampling strategies (random, mix, and max). The best accuracy for each model is shown in bold. Cross entropy with random sampling is best across models and is also fastest (see Table 4).

queries. Our models are parametric models that can compress a large training set into a fixed number of parameters. This makes them extremely fast for answering queries, particularly the AVG models, enabling use in downstream NLP applications.

7 Generating and Scoring Novel Tuples

We now measure our model's ability to score novel tuples generated automatically from ConceptNet and Wikipedia. We first describe simple procedures to generate candidate tuples from these two datasets. We then score the tuples using our MaxSim baseline and the trained Bilinear AVG model.[5] We evaluate the highly-scoring tuples using a small-scale manual evaluation.

The DNN AVG and Bilinear AVG models reached the highest TEST accuracies in our evaluation, though in preliminary experiments we found that the Bilinear AVG model appeared to perform better when scoring the novel tuples described below. We suspect this is because the DNN function class has more flexibility than the bilinear one. When scoring novel tuples, many of which may be highly noisy, it appears that the constrained structure of the Bilinear AVG model makes it more robust to the noise.

7.1 Generating Tuples From ConceptNet

In order to get new tuples, we automatically modify existing ConceptNet tuples. We take an existing tuple and randomly change one of the three fields (t_1, t_2, or R), ensuring that the result is not a tuple existing in ConceptNet. We then score these tuples using MaxSim and the Bilinear AVG model and analyze the results.

7.2 Generating Tuples from Wikipedia

We also propose a simple method to extract candidate tuples from raw text. We first run the Stanford part-of-speech (POS) tagger (Toutanova et al., 2003) on the terms in our ConceptNet training tuples. We enumerate the 50 most frequent term pair tag sequences for each relation. We do limited manual filtering of the frequent tag sequences, namely removing the sequences "DT NN NN" and "DT JJ NN" for the ISA relation. We do this in order to reduce noise in the extracted tuples. To focus on finding nontrivial tuples, for each relation we retain the top 15 POS tag sequences in which t_1 or t_2 has at least two words.

We then run the tagger on sentences from English Wikipedia. We extract word sequence pairs corresponding to the relation POS tag sequence pairs, requiring that there be a gap of at least one word between the two terms. We then remove word sequence pairs in which one term is solely one of the following words: be, the, always, there, has, due, however. We also remove tuples containing words that are not in the vocabulary of our ConceptNet-trained embeddings. We require that one term does not include the other term. We create tuples consisting of the two terms and all possible relations that occur with the POS sequences of those two terms. Finally, we remove tuples that exactly match our ConceptNet training tuples.

We use our trained Bilinear AVG model to score these tuples. We extract term pairs that occur within the same sentence because we hope that these will have higher precision than if we were to pair together arbitrary pairs. Some example tuples for $t_1 =$ *bus* are shown in Table 6.

t_1, R, t_2	score
bus, ISA, *public transportation*	0.95
bus, ISA, *public transit*	0.90
bus, ISA, *mass transit*	0.79
bus, ATLOCATION, *downtown area*	0.98
bus, ATLOCATION, *subway station*	0.98
bus, ATLOCATION, *city center*	0.94
bus, CAPABLEOF, *low cost*	0.72
bus, CAPABLEOF, *local service*	0.65
bus, CAPABLEOF, *train service*	0.63

Table 6: Top Wikipedia tuples for 3 relations with $t_1 =$ *bus*, scored by Bilinear AVG model.

[5] For the results in this section, we used the Bilinear AVG model that achieved 91.7 on TEST rather than the one augmented with additional data.

7.3 Manual Analysis of Novel Tuples

To evaluate our models on newly generated tuples, we rank them using different models and manually score the high-ranking tuples for quality. We first randomly sampled 3000 tuples from each set of novel tuples. We do so due to the time requirements of the MaxSim baseline, which requires iterating through the entire training set for each candidate tuple. We score these sampled tuples using MaxSim and the Bilinear AVG model and rank them by their scores. The top 100 tuples under each ranking were given to an annotator who is a native English speaker. The annotator assigned a quality score to each tuple, using the same 0-4 annotation scheme as Speer et al. (2010): 0 ("Doesn't make sense"), 1 ("Not true"), 2 ("Opinion/Don't know"), 3 ("Sometimes true"), and 4 ("Generally true"). We report the average quality score across each set of 100 tuples.

The results are shown in Table 7. To calibrate the scores, we also gave two samples of ConceptNet (CN) tuples to the annotator: a sample of 100 high-confidence tuples (first row) and a sample of 100 medium-confidence tuples (second row). We find the high-confidence tuples to be of high quality, recording an average of 3.68, though the medium-confidence tuples drop to 3.14.

The next two rows show the quality scores of the MaxSim baseline and the Bilinear AVG model. The latter outperforms the baseline and matches the quality of the medium-confidence ConceptNet tuples. Since our novel tuples are not contained in ConceptNet, this result suggests that our model can be used to add medium-confidence tuples to ConceptNet.

The novel Wikipedia tuples (top 100 tuples ranked by Bilinear AVG model) had a lower quality score (2.78), but this is to be expected due to the difference in domain. Since Wikipedia contains a wide variety of text, we found the novel tuples to be noisier than those from ConceptNet. Still, we are encouraged that on average the tuples are judged to be close to "sometimes true."

7.4 Text Analysis with Commonsense Tuples

We note that our method of tuple extraction and scoring could be used as an aid in applications that require sentence understanding. Two example sentences are shown in Table 8, along with the top tuples extracted and scored using our method. The tuples capture general knowledge about phrases contained in the sentence, rather than necessarily indicating what the sentence means. This procedure could provide relevant commonsense knowledge for a downstream application that seeks to understand the sentence. We leave further investigation of this idea to future work.

tuples	quality
high-confidence CN tuples	3.68
medium-confidence CN tuples	3.14
novel CN tuples, ranked by MaxSim	2.74
novel CN tuples, ranked by Bilinear AVG	3.20
novel Wiki tuples, ranked by Bilinear AVG	2.78

Table 7: Average quality scores from manual evaluation of novel tuples. Each row corresponds to a different set of tuples. See text for details.

murder, CAPABLEOF, *death*	0.51

Table 8: Top ranked tuples extracted from two example sentences and scored by Bilinear AVG model. $*$ = contained in ConceptNet.

8 Conclusion

We proposed methods to augment curated commonsense resources using techniques from knowledge base completion. By scoring novel tuples, we showed how we can increase the applicability of the knowledge contained in ConceptNet. In future work, we will explore how to use our model to improve downstream NLP tasks, and consider applying our methods to other knowledge bases. We have released all of our resources—code, data, and trained models—to the research community.[6]

Simpler Context-Dependent Logical Forms via Model Projections

Abstract

We consider the task of learning a context-dependent mapping from utterances to denotations. With only denotations at training time, we must search over a combinatorially large space of logical forms, which is even larger with context-dependent utterances. To cope with this challenge, we perform successive projections of the full model onto simpler models that operate over equivalence classes of logical forms. Though less expressive, we find that these simpler models are much faster and can be surprisingly effective. Moreover, they can be used to bootstrap the full model. Finally, we collected three new context-dependent semantic parsing datasets, and develop a new left-to-right parser.

1 Introduction

Suppose we are only told that a piece of text (a command) in some context (state of the world) has some denotation (the effect of the command)—see Figure 1 for an example. How can we build a system to learn from examples like these with no initial knowledge about what any of the words mean?

We start with the classic paradigm of training semantic parsers that map utterances to logical forms, which are executed to produce the denotation (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Zettlemoyer and Collins, 2009; Kwiatkowski et al., 2010). More recent work learns directly from denotations (Clarke et al., 2010; Liang, 2013; Berant et al., 2013; Artzi and Zettlemoyer, 2013), but in this setting, a constant struggle is to contain the exponential explosion of possible logical forms. With no initial lexicon and longer context-dependent texts, our situation is exacerbated.

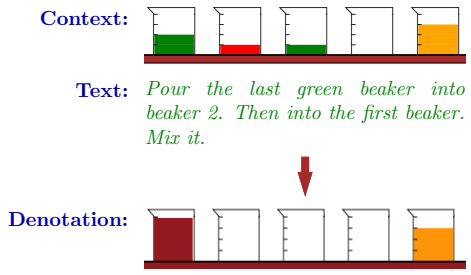

Figure 1: Our task is to learn to map a piece of text in some context to a denotation. An example from the ALCHEMY dataset is shown. In this paper, we ask: what intermediate logical form is suitable for modeling this mapping?

In this paper, we propose *projecting* a full semantic parsing model onto simpler models over equivalence classes of logical form derivations. As illustrated in Figure 2, we consider the following sequence of models:

- **Model A**: our full model that derives logical forms (e.g., in Figure 1, the last utterance maps to `mix(args[1][1])`) compositionally from the text so that spans of the utterance (e.g., "*it*") align to parts of the logical form (e.g., `args[1][1]`, which retrieves an argument from a previous logical form). This is based on standard semantic parsing (e.g., Zettlemoyer and Collins (2005)).
- **Model B**: collapse all derivations with the same logical form; we map utterances to full logical forms, but without an alignment between the utterance and logical forms. This "floating" approach was used in Pasupat and Liang (2015) and Wang et al. (2015).
- **Model C**: further collapse all logical forms whose top-level arguments have the same denotation. In other words, we map utterances

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1456–1465,
Berlin, Germany, August 7-12, 2016.

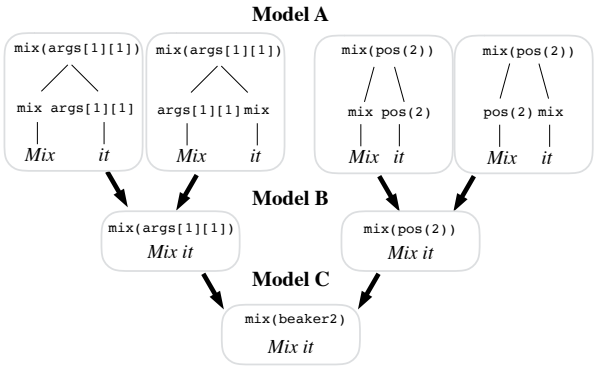

Figure 2: Derivations generated for the last utterance in Figure 1. All derivations above execute to `mix(beaker2)`. Model A generates anchored logical forms (derivations) where words are aligned to predicates, which leads to multiple derivations with the same logical form. Model B discards these alignments, and Model C collapses the arguments of the logical forms to denotations.

to flat logical forms (e.g., `mix(beaker2)`), where the arguments of the top-level predicate are objects in the world. This model is in the spirit of Yao et al. (2014) and Bordes et al. (2014), who directly predicted concrete paths in a knowledge graph for question answering.

Model A excels at credit assignment: the latent derivation explains how parts of the logical form are triggered by parts of the utterance. The price is an unmanageably large search space, given that we do not have a seed lexicon. At the other end, Model C only considers a small set of logical forms, but the mapping from text to the correct logical form is more complex and harder to model.

We collected three new context-dependent semantic parsing datasets using Amazon Mechanical Turk: ALCHEMY (Figure 1), SCENE (Figure 3), and TANGRAMS (Figure 4). Along the way, we develop a new parser which processes utterances left-to-right but can construct logical forms without an explicit alignment.

Our empirical findings are as follows: First, Model C is surprisingly effective, mostly surpassing the other two given bounded computational resources (a fixed beam size). Second, on a synthetic dataset, with infinite beam, Model A outperforms the other two models. Third, we can bootstrap up to Model A from the projected models with finite beam.

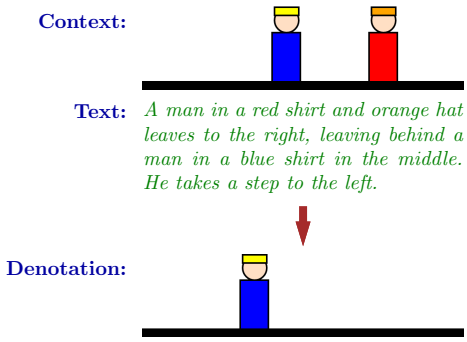

Figure 3: SCENE dataset: Each person has a shirt of some color and a hat of some color. They enter, leave, move around on a stage, and trade hats.

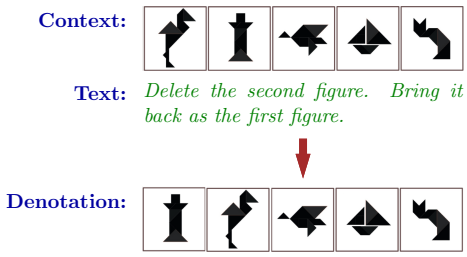

Figure 4: TANGRAMS dataset: One can add figures, remove figures, and swap the position of figures. All the figures slide to the left.

2 Task

In this section, we formalize the task and describe the new datasets we created for the task.

2.1 Setup

First, we will define the context-dependent semantic parsing task. Define w_0 as the initial world state, which consists of a set of entities (beakers in ALCHEMY) and properties (location, color(s), and amount filled). The text $\mathbf{x}$ is a sequence of utterances $x_1, \ldots, x_L$. For each utterance x_i (e.g., "*mix*"), we have a latent logical form z_i (e.g., `mix(args[1][2])`). Define the context $c_i = (w_0, z_{1:i-1})$ to include the initial world state w_0 and the history of past logical forms $z_{1:i-1}$. Each logical form z_i is executed on the context c_i to produce the next state: $w_i = \text{Exec}(c_i, z_i)$ for each $i = 1, \ldots, L$. Overloading notation, we write $w_L = \text{Exec}(w_0, \mathbf{z})$, where $\mathbf{z} = (z_1, \ldots, z_L)$.

The learning problem is: given a set of training examples $\{(w_0, \mathbf{x}, w_L)\}$, learn a mapping from the text $\mathbf{x}$ to logical forms $\mathbf{z} = (z_1, \ldots, z_L)$ that produces the correct final state ($w_L = \text{Exec}(w_0, \mathbf{z})$).

Dataset	# examples	# train	# test	words/example	utterances
SCENE	4402	3363	1039	56.2	"*then one more*", "*he moves back*"
ALCHEMY	4560	3661	899	39.9	"*mix*", "*throw the rest out*"
TANGRAMS	4989	4189	800	27.2	"*undo*", "*replace it*", "*take it away*"

Table 1: We collected three datasets. The number of examples, train/test split, number of tokens per example, along with interesting phenomena are shown for each dataset.

2.2 Datasets

We created three new context-dependent datasets, ALCHEMY, SCENE, and TANGRAMS (see Table 1 for a summary), which aim to capture a diverse set of context-dependent linguistic phenomena such as ellipsis (e.g., "*mix*" in ALCHEMY), anaphora on entities (e.g., "*he*" in SCENE), and anaphora on actions (e.g., "*repeat step 3*", "*bring it back*" in TANGRAMS).

For each dataset, we have a set of properties and actions. In ALCHEMY, properties are `color`, and `amount`; actions are `pour`, `drain`, and `mix`. In SCENE, properties are `hat-color` and `shirt-color`; actions are `enter`, `leave`, `move`, and `trade-hats`. In TANGRAMS, there is one property (`shape`), and actions are `add`, `remove`, and `swap`. In addition, we include the position property (`pos`) in each dataset. Each example has $L = 5$ utterances, each denoting some transformation of the world state.

Our datasets are unique in that they are grounded to a world state and have rich linguistic context-dependence. In the context-dependent ATIS dataset (Dahl et al., 1994) used by Zettlemoyer and Collins (2009), logical forms of utterances depend on previous logical forms, though there is no world state and the linguistic phenomena is limited to nominal references. In the map navigation dataset (Chen and Mooney, 2011), used by Artzi and Zettlemoyer (2013), utterances only reference the current world state. Vlachos and Clark (2014) released a corpus of annotated dialogues, which has interesting linguistic context-dependence, but there is no world state.

Data collection. Our strategy was to automatically generate sequences of world states and ask Amazon Mechanical Turk (AMT) workers to describe the successive transformations. Specifically, we started with a random world state w_0. For each $i = 1, \ldots, L$, we sample a valid action and argument (e.g., `pour(beaker1, beaker2)`). To encourage context-dependent descriptions, we upweight recently used actions and arguments (e.g., the next action is more like to be `drain(beaker2)` rather than `drain(beaker5)`). Next, we presented an AMT worker with states $w_0, \ldots, w_L$ and asked the worker to write a description in between each pair of successive states.

In initial experiments, we found it rather non-trivial to obtain interesting linguistic context-dependence in these micro-domains: often a context-independent utterance such as "*beaker 2*" is just clearer and not much longer than a possibly ambiguous "*it*". We modified the domains to encourage more context. For example, in SCENE, we removed any visual indication of absolute position and allowed people to only move next to other people. This way, workers would say "*to the left of the man in the red hat*" rather than "*to position 2*".

3 Model

We now describe Model A, our full context-dependent semantic parsing model. First, let $\mathcal{Z}$ denote the set of candidate logical forms (e.g., `pour(color(green),color(red))`). Each logical form consists of a top-level action with arguments, which are either primitive values (`green`, `3`, etc.), or composed via selection and superlative operations. See Table 2 for a full description. One notable feature of the logical forms is the context dependency: for example, given some context $(w_0, z_{1:4})$, the predicate `actions[2]` refers to the action of z_2 and `args[2][1]` refers to first argument of z_2.[1]

We use the term *anchored logical forms* (a.k.a. derivations) to refer to logical forms augmented with alignments between sub-logical forms of z_i and spans of the utterance x_i. In the example above, `color(green)` might align with "*green beaker*" from Figure 1; see Figure 2 for another example.

[1]These special predicates play the role of references in Zettlemoyer and Collins (2009). They perform context-independent parsing and resolve references, whereas we resolve them jointly while parsing.

Property[p] Value[v]	$\Rightarrow$ Set[$p(v)$]	all entities whose property p is v
Set[s] Property[p]	$\Rightarrow$ Value[argmin/argmax(s, p)]	element in s with smallest/largest p
Set[s] Int[i]	$\Rightarrow$ Value[$s[i]$]	i-th element of s
Action[a] Value[v_1] Value[v_2]	$\Rightarrow$ Root[$a(v_1, v_2)$]	top-level action applied to arguments v_1, v_2

Table 2: Grammar that defines the space of candidate logical forms. Values include numbers, colors, as well as special tokens `args`$[i][j]$ (for all $i \in \{1, \ldots, L\}$ and $j \in \{1, 2\}$) that refer to the j-th argument used in the i-th logical form. Actions include the fixed domain-specific set plus special tokens `actions`$[i]$ (for all $i \in \{1, \ldots, L\}$), which refers to the i-th action in the context.

	Derivation condition	Example
(F1)	z_i contains predicate r	(z_i contains predicate `pour`, "*pour*")
(F2)	property p of $z_i.b_j$ is y	(`color` of arg 1 is `green`, "*green*")
(F3)	action $z_i.a$ is a and property p of $z_i.y_j$ is y	(action is `pour` and `pos` of arg 2 is `2`, "*pour, 2*")
(F4)	properties p of $z_i.v_1$ is y and p' of $z_i.v_2$ is y'	(`color` of arg 1 is `green` and `pos` of arg 2 is `2`, "*first green, 2*")
(F5)	arg $z_i.v_j$ is one of z_{i-1}'s args	(arg reused, "*it*")
(F6)	action $z_i.a = z_{i-1}.a$	(action reused, "*pour*")
(F7)	properties p of $z_i.y_j$ is y and p' of $z_{i-1}.y_k$ is y'	(`pos` of arg 1 is `2` and `pos` of prev. arg 2 is `2`, "*then*")
(F8)	$t_1 < s_2$	spans don't overlap

Table 3: Features $\phi(x_i, c_i, z_i)$ for Model A: The left hand side describes conditions under which the system fires indicator features, and right hand side shows sample features for each condition. For each derivation condition (F1)–(F7), we conjoin the condition with the span of the utterance that the referenced actions and arguments align to. For condition (F8), we just fire the indicator by itself.

Log-linear model. We place a conditional distribution over anchored logical forms $z_i \in \mathcal{Z}$ given an utterance x_i and context $c_i = (w_0, z_{1:i-1})$, which consists of the initial world state w_0 and the history of past logical forms $z_{1:i-1}$. We use a standard log-linear model:

$$p_\theta(z_i \mid x_i, c_i) \propto \exp(\phi(x_i, c_i, z_i) \cdot \theta), \quad (1)$$

where ϕ is the feature mapping and θ is the parameter vector (to be learned). Chaining these distributions together, we get a distribution over a sequence of logical forms $\mathbf{z} = (z_1, \ldots, z_L)$ given the whole text $\mathbf{x}$:

$$p_\theta(\mathbf{z} \mid \mathbf{x}, w_0) = \prod_{i=1}^{L} p_\theta(z_i \mid x_i, (w_0, z_{1:i-1})). \quad (2)$$

Features. Our feature mapping ϕ consists of two types of indicators:

1. For each derivation, we fire features based on the structure of the logical form/spans.

2. For each span s (e.g., "*green beaker*") aligned to a sub-logical form z (e.g., `color(green)`), we fire features on unigrams, bigrams, and trigrams inside s conjoined with various conditions of z.

The exact features given in Table 3, references the first two utterances of Figure 1 and the associated logical forms below:

$x_1 =$ "*Pour the last green beaker into beaker 2.*"

$z_1 =$ `pour(argmin(color(green),pos),pos(2))`

$x_2 =$ "*Then into the first beaker.*"

$z_2 =$ `actions[1](args[1][2],pos(3))`.

We describe the notation we use for Table 3, restricting our discussion to actions that have two or fewer arguments. Our featurization scheme, however, generalizes to an arbitrary number of arguments. Given a logical form z_i, let $z_i.a$ be its action and $(z_i.b_1, z_i.b_2)$ be its arguments (e.g., `color(green)`). The first and second arguments are anchored over spans $[s_1, t_1]$ and $[s_2, t_2]$, respectively. Each argument $z_i.b_j$ has a corresponding value $z_i.v_j$ (e.g., `beaker1`), obtained by executing $z_i.b_j$ on the context c_i. Finally, let $j, k \in \{1, 2\}$ be indices of the arguments. For example, we would label the constituent parts of z_1 (defined above) as follows:

- $z_1.a =$ `pour`
- $z_1.b_1 =$ `argmin(color(green),pos)`
- $z_1.v_1 =$ `beaker3`
- $z_1.b_2 =$ `pos(2)`
- $z_1.v_2 =$ `beaker2`

4 Left-to-right parsing

We describe a new parser suitable for learning from denotations in the context-dependent setting. Like a shift-reduce parser, we proceed left to right, but each *shift* operation advances an entire utterance rather than one word. We then sit on the utterance for a while, performing a sequence of *build* operations, which either combine two logical forms on the stack (like the reduce operation) or generate fresh logical forms, similar to what is done in the floating parser of Pasupat and Liang (2015).

Our parser has two desirable properties: First, proceeding left-to-right allows us to build and score logical forms z_i that depend on the world state w_{i-1}, which is a function of the previous logical forms. Note that w_{i-1} is a random variable in our setting, whereas it is fixed in Zettlemoyer and Collins (2009). Second, the *build* operation allows us the flexibility to handle ellipsis (e.g., "*Mix.*") and anaphora on full logical forms (e.g., "*Do it again.*"), where there's not a clear alignment between the words and the predicates generated.

The parser transitions through a sequence of hypotheses. Each hypothesis is $h = (i, b, \sigma)$, where i is the index of the current utterance, where b is the number of predicates constructed on utterance x_i, and σ is a stack (list) of logical forms. The stack includes both the previous logical forms $z_{1:i-1}$ and fragments of logical forms built on the current utterance. When processing a particular hypothesis, the parser can choose to perform either the shift or build operation:

Shift: The parser moves to the next utterance by incrementing the utterance index i and resetting b, which transitions a hypothesis from (i, b, σ) to $(i + 1, 0, \sigma)$.

Build: The parser creates a new logical form by combining zero or more logical forms on the stack. There are four types of build operations:

1. Create a predicate out of thin air (e.g., `args[1][1]` in Figure 5). This is useful when the utterance does not explicitly reference the arguments or action. For example, in Figure 5, we are able to generate the logical form `args[1][1]` in the presence of ellipsis.

2. Create a predicate anchored to some span of the utterance (e.g., `actions[1]` anchored to "*Repeat*"). This allows us to do credit assignment and capture which part of the utterance explains which part of the logical form.

3. Pop z from the stack σ and push z' onto σ, where z' is created by applying a rule in Table 2 to z.

4. Pop z, z' from the stack σ and push z'' onto σ, where z'' is created by applying a rule in Table 2 to z, z' (e.g., `actions[1](args[1][1])` by the top-level root rule).

The build step stops once a maximum number of predicates B have been constructed or when the top-level rule is applied.

We have so far described the search space over logical forms. In practice, we keep a beam of the K hypotheses with the highest score under the current log-linear model.

5 Model Projections

Model A is ambitious, as it tries to learn from scratch how each word aligns to part of the logical form. For example, when Model A parses "*Mix it*", one derivation will correctly align "*Mix*" to `mix`, but others will align "*Mix*" to `args[1][1]`, "*Mix*" to `pos(2)`, and so on (Figure 2).

As we do not assume a seed lexicon that could map "*Mix*" to `mix`, the set of anchored logical forms is exponentially large. For example, parsing just the first sentence of Figure 1 would generate 1,216,140 intermediate anchored logical forms.

How can we reduce the search space? The key is that the space of logical forms is *much smaller* than the space of anchored logical forms. Even though both grow exponentially, dealing directly with logical forms allows us to generate `pour` without the combinatorial choice over alignments. We thus define Model B over the space of these logical forms. Figure 2 shows that the two anchored logical forms, which are treated differently in Model A are collapsed in Model B. This dramatically reduces the search space; parsing the first sentence of Figure 1 generates 7,047 intermediate logical forms.

We can go further and notice that many compositional logical forms reduce to the same flat logical form if we evaluate all the arguments. For example, in Figure 2, `mix(args[1][1])` and `mix(pos(2))` are equivalent to `mix(beaker2)`. We define Model C to be the

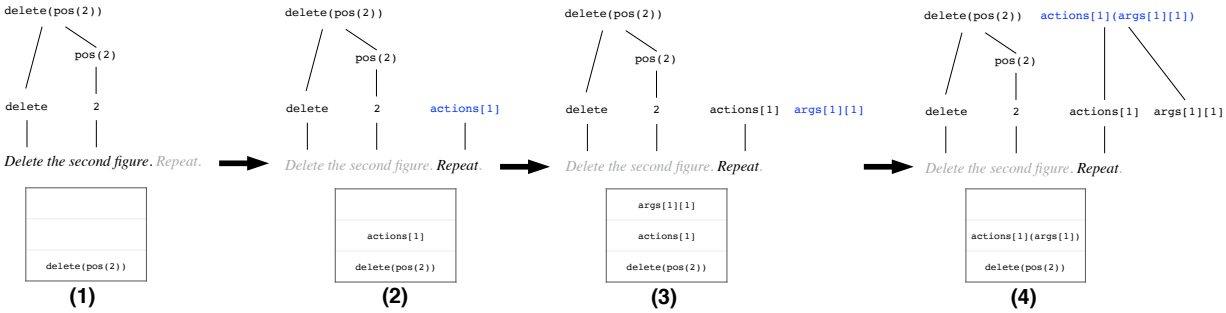

Figure 5: Suppose we have already constructed `delete(pos(2))` for "*Delete the second figure.*" Continuing, we shift the utterance "*Repeat*". Then, we build `action[1]` aligned to the word "*Repeat.*" followed by `args[1][1]`, which is unaligned. Finally, we combine the two logical forms.

space of these flat logical forms which consist of a top-level action plus primitive arguments. Using Model C, parsing the first sentence of Figure 1 generates only 349 intermediate logical forms.

Note that in the context-dependent setting, the number of flat logical forms (Model C) still increases exponentially with the number of utterances, but it is an overwhelming improvement over Model A. Furthermore, unlike other forms of relaxation, we are still generating logical forms that can express any denotation as before. The gains from Model B to Model C hinge on the fact that in our world, the number of denotations is much smaller than the number of logical forms.

Projecting the features. While we have defined the space over logical forms for Models B and C, we still need to define a distribution over these spaces to to complete the picture. To do this, we propose projecting the features of the log-linear model (1). Define $\Pi_{\text{A}\to\text{B}}$ to be a map from a anchored logical form z^{A} (e.g., `mix(pos(2))` aligned to "*mix*") to an unanchored one z^{B} (e.g., `mix(pos(2))`), and define $\Pi_{\text{B}\to\text{C}}$ to be a map from z^{B} to the flat logical form z^{C} (e.g., `mix(beaker2)`).

We construct a log-linear model for Model B by constructing features $\phi(z^{\text{B}})$ (omitting the dependence on x_i, c_i for convenience) based on the Model A features $\phi(z^{\text{A}})$. Specifically, $\phi(z^{\text{B}})$ is the component-wise maximum of $\phi(z^{\text{A}})$ over all z^{A} that project down to z^{B}; $\phi(z^{\text{C}})$ is defined similarly:

$$\phi(z^{\text{B}}) \stackrel{\text{def}}{=} \max\{\phi(z^{\text{A}}) : \Pi_{\text{A}\to\text{B}}(z^{\text{A}}) = z^{\text{B}}\}, \quad (3)$$

$$\phi(z^{\text{C}}) \stackrel{\text{def}}{=} \max\{\phi(z^{\text{B}}) : \Pi_{\text{B}\to\text{C}}(z^{\text{B}}) = z^{\text{C}}\}. \quad (4)$$

Concretely, Model B's features include indicator features over LF conditions in Table 3 conjoined with every n-gram of the entire utterance, as there is no alignment. This is similar to the model of Pasupat and Liang (2015). Note that most of the derivation conditions (F2)–(F7) already depend on properties of the denotations of the arguments, so in Model C, we can directly reason over the space of flat logical forms z^{C} (e.g., `mix(beaker2)`) rather than explicitly computing the max over more complex logical forms z^{B} (e.g., `mix(color(red))`).

Expressivity. In going from Model A to Model C, we gain in computational efficiency, but we lose in modeling expressivity. For example, for "*second green beaker*" in Figure 1, instead of predicting `color(green)[2]`, we would have to predict `beaker3`, which is not easily explained by the words "*second green beaker*" using the simple features in Table 3.

At the same time, we found that simple features can actually *simulate* some logical forms. For example, `color(green)` can be explained by the feature that looks at the `color` property of `beaker3`. Nailing `color(green)[2]`, however, is not easy. Surprisingly, Model C can use a conjunction of features to express superlatives (e.g., `argmax(color(red),pos)`) by using one feature that places more mass on selecting objects that are red and another feature that places more mass on objects that have a greater position value.

6 Experiments

Our experiments aim to explore the computation-expressivity tradeoff in going from Model A to Model B to Model C. We would expect that under the computational constraint of a finite beam size, Model A will be hurt the most, but with an

Dataset	Model	3-acc	3-ora	5-acc	5-ora
ALCHEMY	B	0.189	0.258	0.037	0.055
	C	**0.568**	**0.925**	**0.523**	**0.809**
SCENE	B	0.068	0.118	0.017	0.031
	C	**0.232**	**0.431**	**0.147**	**0.253**
TANGRAMS	B	**0.649**	**0.910**	**0.276**	0.513
	C	0.567	0.899	0.272	**0.698**

Table 4: Test set accuracy and oracle accuracy for examples containing $L = 3$ and $L = 5$ utterances. Model C surpasses Model B in both accuracy and oracle on ALCHEMY and SCENE, whereas Model B does better in TANGRAMS.

infinite beam, Model A should perform better.

We evaluate all models on *accuracy*, the fraction of examples that a model predicts correctly. A predicted logical form z is deemed to be correct for an example $(w_0, \mathbf{x}, w_L)$ if the predicted logical form $\mathbf{z}$ executes to the correct final world state w_L. We also measure the *oracle accuracy*, which is the fraction of examples where at least one $\mathbf{z}$ on the beam executes to w_L. All experiments train for 6 iterations using AdaGrad (Duchi et al., 2010) and L_1 regularization with a coefficient of 0.001.

6.1 Real data experiments

Setup. We use a beam size of 500 within each utterance, and prune to the top 5 between utterances. For the first two iterations, Models B and C train on only the first utterance of each example ($L = 1$). In the remaining iterations, the models train on two utterance examples. We then evaluate on examples with $L = 1, \ldots, 5$, which tests our models ability to extrapolate to longer texts.

Accuracy with finite beam. We compare models B and C on the three real datasets for both $L = 3$ and $L = 5$ utterances (Model A was too expensive to use). Table 4 shows that on 5 utterance examples, the flatter Model C achieves an average accuracy of 20% higher than the more compositional Model B. Similarly, the average oracle accuracy is 39% higher. This suggests that (i) the correct logical form often falls off the beam for Model B due to a larger search space, and (ii) the expressivity of Model C is sufficient in many cases.

On the other hand, Model B outperforms Model C on the TANGRAMS dataset. This happens for two reasons. The TANGRAMS dataset has the smallest search space, since all of the utterances refer to objects using position only. Additionally, many utterances reference logical forms that Model C is unable to express, such as "*repeat the first step*", or "*add it back*".

Figure 6 shows how the models perform as the number of utterances per example varies. When the search space is small (fewer number of utterances), Model B outperforms or is competitive with Model C. However, as the search space increases (tighter computational constraints), Model C does increasingly better.

Overall, both models perform worse as L increases, since to predict the final world state w_L correctly, a model essentially needs to predict an entire sequence of logical forms $z_1, \ldots, z_L$, and errors cascade. Furthermore, for larger L, the utterances tend to have richer context-dependence.

6.2 Artificial data experiments

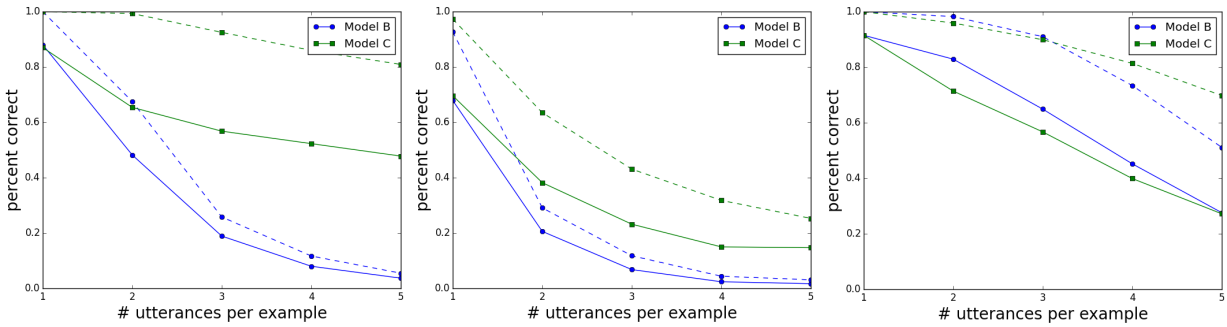
Setup. Due to the large search space, running model A on real data is impractical. In order feasibly evaluate Model A, we constructed an artificial dataset. The worlds are created using the procedure described in Section 2.2. We use a simple template to generate utterances (e.g., "*drain 1 from the 2 green beaker*").

To reduce the search space for Model A, we only allow actions (e.g., `drain`) to align to verbs and property values (e.g., `green`) to align to adjectives. Using these linguistic constraints provides a slightly optimistic assessment of Model A's performance.

We train on a dataset of 500 training examples and evaluate on 500 test examples. We repeat this procedure for varying beam sizes, from 40 to 260. The model only uses features (F1) through (F3).

Accuracy under infinite beam. Since Model A is more expressive, we would expect it to be more powerful when we have no computational constraints. Figure 7 shows that this is indeed the case: When the beam size is greater than 250, all models attain an oracle of 1, and Model A outperforms Model B, which performs similarly to Model C. This is because the alignments provide a powerful signal for constructing the logical forms. Without alignments, Models B and C learn noisier features, and accuracy suffers accordingly.

Bootstrapping. Model A performs the best with unconstrained computation, and Model C performs the best with constrained computation. Is there some way to bridge the two? Even though



(a) ALCHEMY (b) SCENE (c) TANGRAMS

Figure 6: Test results on our three datasets as we vary the number of utterances. The solid lines are the accuracy, and the dashed line are the oracles: With finite beam, Model C significantly outperforms Model B on ALCHEMY and SCENE, but is slightly worse on TANGRAMS.

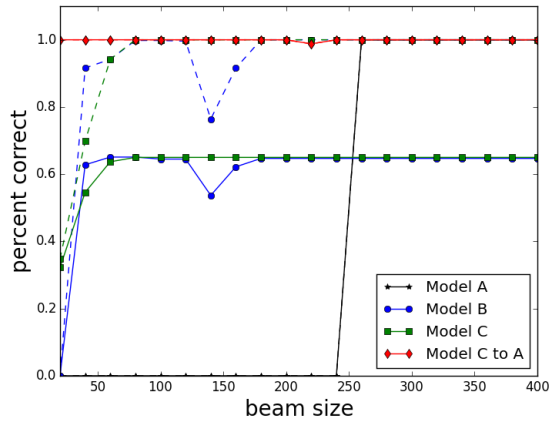


Figure 7: Test results on our artificial dataset with varying beam sizes. The solid lines are the accuracies, and the dashed line are the oracle accuracies. Model A is unable to learn anything with beam size < 240. However, for beam sizes larger than 240, Model A attains 100% accuracy. Model C does better than Models A and B when the beam size is small < 40, but otherwise performs comparably to Model B. Bootstrapping Model A using Model C parameters outperforms all of the other models and attains 100% even with smaller beams.

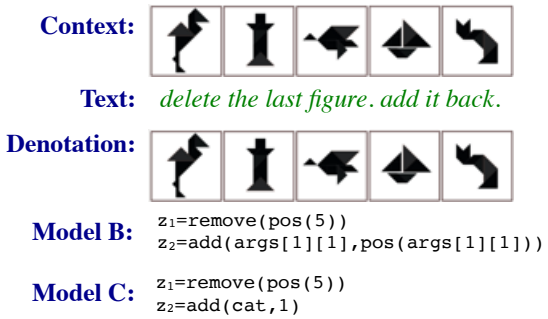

Figure 8: Predicted logical forms for this text: The logical form `add` takes a figure and position as input. Model B predicts the correct logical form. Model C does not understand that "*back*" refers to position 5, and adds the cat figure to position 1.

model	beam	action	argument	context	noise
B	0.47	0.03	0.17	0.23	0.04
C	0.15	0.03	0.25	0.5	0.07

Table 5: Percentage of errors for Model B and C: Model B suffers predominantly from computation constraints, while Model C suffers predominantly from a lack of expressivity.

Model C has limited expressivity, it can still learn to associate words like "*green*" with their corresponding predicate `green`. These should be useful for Model A too.

To operationalize this, we first train Model C and use the parameters to initialize model A. Then we train Model A. Figure 7 shows that although Model A and C predict different logical forms, the initialization allows Model C to A to perform well in constrained beam settings. This bootstrapping works here because Model C is a *projection* of Model A, and thus they share the same features.

6.3 Error Analysis

We randomly sampled 20 incorrect predictions on 3 utterance examples from each of the three real datasets for Model B and Model C. We categorized each prediction error into one of the following categories: (i) logical forms falling off the beam; (ii) choosing the wrong action (e.g., mapping "*drain*" to `pour`); (iii) choosing the wrong

argument due to misunderstanding the description (e.g., mapping "*third beaker*" to `pos(1)`); (iv) choosing the wrong action or argument due to misunderstanding of context (see Figure 8); (v) noise in the dataset. Table 5 shows the fraction of each error category.

7 Related Work and Discussion

Context-dependent semantic parsing. Utterances can depend on either linguistic context or world state context. Zettlemoyer and Collins (2009) developed a model that handles references to previous logical forms; Artzi and Zettlemoyer (2013) developed a model that handles references to the current world state. Our system considers both types of context, handling linguistic phenomena such as ellipsis and anaphora that reference both previous world states and logical forms.

Logical form generation. Traditional semantic parsers generate logical forms by aligning each part of the logical form to the utterance (Zelle and Mooney, 1996; Wong and Mooney, 2007; Zettlemoyer and Collins, 2007; Kwiatkowski et al., 2011). In general, such systems rely on a lexicon, which can be hand-engineered, extracted (Cai and Yates, 2013; Berant et al., 2013), or automatically learned from annotated logical forms (Kwiatkowski et al., 2010; Chen, 2012).

Recent work on learning from denotations has moved away from anchored logical forms. Pasupat and Liang (2014) and Wang et al. (2015) proposed generating logical forms without alignments, similar to our Model B. Yao et al. (2014) and Bordes et al. (2014) have explored predicting paths in a knowledge graph directly, which is similar to the flat logical forms of Model C.

Relaxation and bootstrapping. The idea of first training a simpler model in order to work up to a more complex one has been explored other contexts. In the unsupervised learning of generative models, bootstrapping can help escape local optima and provide helpful regularization (Och and Ney, 2003; Liang et al., 2009). When it is difficult to even find one logical form that reaches the denotation, one can use the relaxation technique of Steinhardt and Liang (2015).

Recall that projecting from Model A to C creates a more computationally tractable model at the cost of expressivity. However, this is because Model C used a linear model. One might imagine that a non-linear model would be able to recuperate some of the loss of expressivity. Indeed, Neelakantan et al. (2016) use recurrent neural networks attempt to perform logical operations. One could go one step further and bypass logical forms altogether, performing all the logical reasoning in a continuous space (Bowman et al., 2014; Weston et al., 2015; Guu et al., 2015; Reed and de Freitas, 2016). This certainly avoids the combinatorial explosion of logical forms in Model A, but could also present additional optimization challenges. It would be worth exploring this avenue to completely understand the computation-expressivity tradeoff.

Reproducibility

Our code, data, and experiments are available on CodaLab at `https://worksheets.codalab.org/worksheets/0xad3fc9f52f514e849b282a105b1e3f02/`.

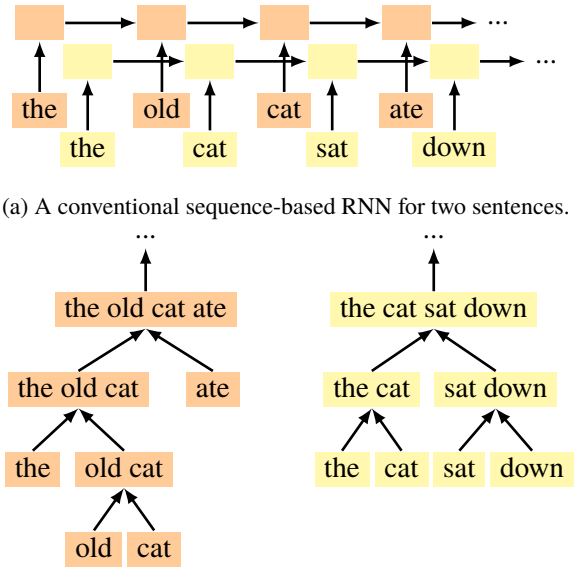
Abstract

Tree-structured neural networks exploit valuable syntactic parse information as they interpret the meanings of sentences. However, they suffer from two key technical problems that make them slow and unwieldy for large-scale NLP tasks: they usually operate on parsed sentences and they do not directly support batched computation. We address these issues by introducing the Stack-augmented Parser-Interpreter Neural Network (SPINN), which combines parsing and interpretation within a single tree-sequence hybrid model by integrating tree-structured sentence interpretation into the linear sequential structure of a shift-reduce parser. Our model supports batched computation for a speedup of up to 25× over other tree-structured models, and its integrated parser can operate on unparsed data with little loss in accuracy. We evaluate it on the Stanford NLI entailment task and show that it significantly outperforms other sentence-encoding models.

1 Introduction

A wide range of current models in NLP are built around a neural network component that produces vector representations of sentence meaning (e.g., Sutskever et al., 2014; Tai et al., 2015). This component, the sentence encoder, is generally formulated as a learned parametric function from a sequence of word vectors to a sentence vector, and this function can take a range of different forms. Common sentence encoders include sequence-based recurrent neural network models (RNNs, see Figure 1a) with Long Short-Term Memory (LSTM, Hochreiter and Schmidhuber, 1997), which accumulate information over the sentence sequentially; convolutional neural networks (Kalchbrenner et al., 2014; Zhang et al., 2015), which accumulate information using filters over short local sequences of words or characters; and tree-structured recursive neural networks (TreeRNNs, Goller and Küchler, 1996; Socher et al., 2011a, see Figure 1b), which propagate information up a binary parse tree.



(a) A conventional sequence-based RNN for two sentences.

(b) A conventional TreeRNN for two sentences.

Figure 1: An illustration of two standard designs for sentence encoders. The TreeRNN, unlike the sequence-based RNN, requires a substantially different connection structure for each sentence, making batched computation impractical.

Of these, the TreeRNN appears to be the principled choice, since meaning in natural language sentences is known to be constructed recursively according to a tree structure (Dowty, 2007, i.a.). TreeRNNs have shown promise (Tai et al., 2015; Li et al., 2015; Bowman et al., 2015b), but have

Figure 2: Two views of the Stack-augmented Parser-Interpreter Neural Network (SPINN).

largely been overlooked in favor of sequence-based RNNs because of their incompatibility with batched computation and their reliance on external parsers. Batched computation—performing synchronized computation across many examples at once—yields order-of-magnitude improvements in model run time, and is crucial in enabling neural networks to be trained efficiently on large datasets. Because TreeRNNs use a different model structure for each sentence, as in Figure 1, efficient batching is impossible in standard implementations. Partly to address efficiency problems, standard TreeRNN models commonly only operate on sentences that have already been processed by a syntactic parser, which slows and complicates the use of these models at test time for most applications.

This paper introduces a new model to address both these issues: the Stack-augmented Parser-Interpreter Neural Network, or SPINN, shown in Figure 2. SPINN executes the computations of a tree-structured model in a linearized sequence, and can incorporate a neural network parser that produces the required parse structure on the fly. This design improves upon the TreeRNN architecture in three ways: At test time, it can simultaneously parse and interpret unparsed sentences, removing the dependence on an external parser at nearly no additional computational cost. Secondly, it supports batched computation for both parsed and unparsed sentences, yielding dramatic speedups over standard TreeRNNs. Finally, it supports a novel tree-sequence hybrid architecture for handling local linear context in sentence interpretation. This model is a basically plausible model of human sentence processing and yields substantial accuracy gains over pure sequence- or tree-based models.

We evaluate SPINN on the Stanford Natural Language Inference entailment task (SNLI, Bowman et al., 2015a), and find that it significantly outperforms other sentence-encoding-based models, even with a relatively simple and underpowered implementation of the built-in parser. We also find that SPINN yields speed increases of up to 25× over a standard TreeRNN implementation.

2 Related work

There is a fairly long history of work on building neural network-based parsers that use the core operations and data structures from transition-based parsing, of which shift-reduce parsing is a variant (Henderson, 2004; Emami and Jelinek, 2005; Titov and Henderson, 2010; Chen and Manning, 2014; Buys and Blunsom, 2015; Dyer et al., 2015; Kiperwasser and Goldberg, 2016). In addition, there has been recent work proposing models designed primarily for generative language modeling tasks that use this architecture as well (Zhang et al., 2016; Dyer et al., 2016). To our knowledge, SPINN is the first model to use this architecture for the purpose of sentence interpretation, rather than parsing

or generation.

Socher et al. (2011a,b) present versions of the TreeRNN model which are capable of operating over unparsed inputs. However, these methods require an expensive search process at test time. Our model presents a much faster alternative approach.

3 Our model: SPINN

3.1 Background: Shift-reduce parsing

SPINN is inspired by shift-reduce parsing (Aho and Ullman, 1972), which builds a tree structure over a sequence (e.g., a natural language sentence) by a single left-to-right scan over its tokens. The formalism is widely used in natural language parsing (e.g., Shieber, 1983; Nivre, 2003).

A shift-reduce parser accepts a sequence of input tokens $\mathbf{x} = (x_0, \ldots, x_{N-1})$ and consumes transitions $\mathbf{a} = (a_0, \ldots, a_{T-1})$, where each $a_t \in \{\text{SHIFT}, \text{REDUCE}\}$ specifies one step of the parsing process. In general a parser may also generate these transitions on the fly as it reads the tokens. It proceeds left-to-right through a transition sequence, combining the input tokens $\mathbf{x}$ incrementally into a tree structure. For any binary-branching tree structure over N words, this requires $T = 2N - 1$ transitions through a total of $T + 1$ states.

The parser uses two auxiliary data structures: a stack S of partially completed subtrees and a buffer B of tokens yet to be parsed. The parser is initialized with the stack empty and the buffer containing the tokens $\mathbf{x}$ of the sentence in order. Let $\langle S, B\rangle = \langle \emptyset, \mathbf{x}\rangle$ denote this starting state. It next proceeds through the transition sequence, where each transition a_t selects one of the two following operations. Below, the | symbol denotes the *cons* (concatenation) operator. We arbitrarily choose to always *cons* on the left in the notation below.

SHIFT: $\langle S, x \mid B\rangle \rightarrow \langle x \mid S, B\rangle$. This operation pops an element from the buffer and pushes it on to the top of the stack.

REDUCE: $\langle x \mid y \mid S, B\rangle \rightarrow \langle (x, y) \mid S, B\rangle$. This operation pops the top two elements from the stack, merges them, and pushes the result back on to the stack.

3.2 Composition and representation

SPINN is based on a shift-reduce parser, but it is designed to produce a vector representation of a sentence as its output, rather than a tree as in standard shift-reduce parsing. It modifies the shift-reduce formalism by using fixed length vectors to represent each entry in the stack and the buffer. Correspondingly, its REDUCE operation combines two vector representations from the stack into another vector using a neural network function.

The composition function When a REDUCE operation is performed, the vector representations of two tree nodes are popped off of the stack and fed into a *composition function*, which is a neural network function that produces a representation for a new tree node that is the parent of the two popped nodes. This new node is pushed on to the stack.

The TreeLSTM composition function (Tai et al., 2015) generalizes the LSTM neural network layer to tree- rather than sequence-based inputs, and it shares with the LSTM the idea of representing intermediate states as a pair of an active state representation $\vec{h}$ and a memory representation $\vec{c}$. Our version is formulated as:

$$\text{(1)} \quad \begin{bmatrix} \vec{i} \\ \vec{f}_l \\ \vec{f}_r \\ \vec{o} \\ \vec{g} \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} \left(W_{\text{comp}} \begin{bmatrix} \vec{h}_s^1 \\ \vec{h}_s^2 \\ \vec{e} \end{bmatrix} + \vec{b}_{\text{comp}} \right)$$

$$\text{(2)} \quad \vec{c} = \vec{f}_l \odot \vec{c}_s^2 + \vec{f}_r \odot \vec{c}_s^1 + \vec{i} \odot \vec{g}$$

$$\text{(3)} \quad \vec{h} = \vec{o} \odot \vec{c}$$

where σ is the sigmoid activation function, $\odot$ is the elementwise product, the pairs $\langle \vec{h}_s^1, \vec{c}_s^1 \rangle$ and $\langle \vec{h}_s^2, \vec{c}_s^2 \rangle$ are the two input tree nodes popped off the stack, and $\vec{e}$ is an optional vector-valued input argument which is either empty or comes from an external source like the tracking LSTM (see Section 3.3). The result of this function, the pair $\langle \vec{h}, \vec{c} \rangle$, is placed back on the stack. Each vector-valued variable listed is of dimension D except $\vec{e}$, of the independent dimension D_{tracking}.

The stack and buffer The stack and the buffer are arrays of N elements each (for sentences of up to N words), with the two D-dimensional vectors $\vec{h}$ and $\vec{c}$ in each element.

Word representations We use word representations based on the 300D vectors provided with GloVe (Pennington et al., 2014). We do not update these representations during training. Instead, we use a learned linear transformation to map each input word vector $\vec{x}_{\text{GloVe}}$ into a vector pair $\langle \vec{h}, \vec{c} \rangle$ that is stored in the buffer:

$$\text{(4)} \quad \begin{bmatrix} \vec{h} \\ \vec{c} \end{bmatrix} = W_{\text{wd}} \vec{x}_{\text{GloVe}} + \vec{b}_{\text{wd}}$$

3.3 The tracking LSTM

In addition to the stack, buffer, and composition function, our full model includes an additional component: the tracking LSTM. This is a simple sequence-based LSTM RNN that operates in tandem with the model, taking inputs from the buffer and stack at each step. It is meant to maintain a low-resolution summary of the portion of the sentence that has been processed so far, which is used for two purposes: it supplies feature representations to the transition classifier, which allows the model to stand alone as a parser, and it additionally supplies a secondary input $\vec{e}$ to the composition function—see (1)—allowing context information to enter the construction of sentence meaning and forming what is effectively a tree-sequence hybrid model.

The tracking LSTM's inputs (yellow in Figure 2) are the top element of the buffer $\vec{h}_b^1$ (which would be moved in a SHIFT operation) and the top two elements of the stack $\vec{h}_s^1$ and $\vec{h}_s^2$ (which would be composed in a REDUCE operation).

Why a tree-sequence hybrid? Lexical ambiguity is ubiquitous in natural language. Most words have multiple senses or meanings, and it is generally necessary to use the context in which a word occurs to determine which of its senses or meanings is meant in a given sentence. Even though TreeRNNs are more effective at composing meanings in principle, this ambiguity can give simpler sequence-based sentence-encoding models an advantage: when a sequence-based model first processes a word, it has direct access to a state vector that summarizes the left context of that word, which acts as a cue for disambiguation. In contrast, when a standard tree-structured model first processes a word, it only has access to the constituent that the word is merging with, which is often just a single additional word. Feeding a context representation from the tracking LSTM into the composition function is a simple and efficient way to mitigate this disadvantage of tree-structured models. Using left linear context to disambiguate is also a plausible model of human interpretation.

It would be straightforward to augment SPINN to support the use of some amount of right-side context as well, but this would add complexity to the model that we think is largely unnecessary: humans are very effective at understanding the beginnings of sentences before having seen or heard the ends, suggesting that it is possible to get by without the unavailable right-side context.

3.4 Parsing: Predicting transitions

For SPINN to operate on unparsed inputs, it needs to produce its own transition sequence **a** rather than relying on an external parser to supply it as part of the input. To do this, the model predicts a_t at each step using a simple two-way softmax classifier whose input is the state of the tracking LSTM:

$$\vec{p}_{\text{a}} = \text{softmax}(W_{\text{trans}}\vec{h}_{\text{tracking}} + \vec{b}_{\text{trans}}) \quad (5)$$

The above model is nearly the simplest viable implementation of a transition decision function. In contrast, the decision functions in state-of-the-art transition-based parsers tend to use significantly richer feature sets as inputs, including features containing information about several upcoming words on the buffer. The value $\vec{h}_{\text{tracking}}$ is a function of only the very top of the buffer and the top two stack elements at each timestep.

At test time, the model uses whichever transition (i.e., SHIFT or REDUCE) is assigned a higher (unnormalized) probability. The prediction function is trained to mimic the decisions of an external parser. These decisions are used as inputs to the model during training. For SNLI, we use the binary Stanford PCFG Parser parses that are included with the corpus. We did not find scheduled sampling (Bengio et al., 2015)—having the model use its own transition decisions sometimes at training time—to help.

3.5 Implementation issues

Representing the stack efficiently A naïve implementation of SPINN needs to handle a size $O(N)$ stack at each timestep, any element of which may be involved in later computations. A naïve backpropagation implementation would then require storing each of the $O(N)$ stacks for a backward pass, leading to a per-example space requirement of $O(NTD)$ floats. This requirement is prohibitively large for significant batch sizes or sentence lengths N. Such a naïve implementation would also require copying a largely unchanged stack at each timestep, since each SHIFT or REDUCE operation writes only one new representation to the top of the stack.

We propose a space-efficient stack representation inspired by the zipper technique (Huet, 1997) that we call *thin stack*. For each input sentence, we

Algorithm 1 The thin stack algorithm

```
function STEP(bufferTop, a, t, S, Q)
    if a = SHIFT then
        S[t] := bufferTop
    else if a = REDUCE then
        right := S[Q.pop()]
        left := S[Q.pop()]
        S[t] := COMPOSE(left, right)
    Q.push(t)
```

represent the stack with a single $T \times D$ matrix S. Each row $S[t]$ (for $0 < t \leq T$) represents the top of the actual stack at timestep t. At each timestep we can SHIFT a new element onto the stack, or REDUCE the top two elements of the stack into a single element. To shift an element from the buffer to the top of the stack at timestep t, we simply write it into the location $S[t]$. In order to perform the REDUCE operation, we need to retrieve the top two elements of the actual stack. We maintain a queue Q of pointers into S which contains the row indices of S which are still present in the actual stack. The top two elements of the stack can be found by using the final two pointers in the queue Q. These retrieved elements are used to perform the REDUCE operation, which modifies Q to mark that some rows of S have now been replaced in the actual stack. Algorithm 1 describes the full mechanics of a stack feedforward in this compressed representation. It operates on the single $T \times D$ matrix S and a backpointer queue Q. Table 1 shows an example run.

This stack representation requires substantially less space. It stores each element involved in the feedforward computation exactly once, meaning that this representation can still support efficient backpropagation. Furthermore, all of the updates to S and Q can be performed batched and in-place on a GPU, yielding substantial speed gains over both a more naïve SPINN implementation and a standard TreeRNN implementation. We describe speed results in Section 3.7.

Preparing the data At training time, SPINN requires both a transition sequence **a** and a token sequence **x** as its inputs for each sentence. The token sequence is simply the words in the sentence in order. **a** can be obtained from any constituency parse for the sentence by first converting that parse into an unlabeled binary parse, then linearizing it (with the usual in-order traversal), then taking each word token as a SHIFT transition and each ')' as a REDUCE transition, as here:

Unlabeled binary parse: ((the cat) (sat down))
x: *the*, *cat*, *sat*, *down*
a: SHIFT, SHIFT, REDUCE, SHIFT, SHIFT, REDUCE, REDUCE

t	$S[t]$	Q_t	a_t
0		—	SHIFT
1	*Spot*	1	SHIFT
2	*sat*	1 2	SHIFT
3	*down*	1 2 3	REDUCE
4	(*sat down*)	1 4	REDUCE
5	(*Spot* (*sat down*))	5	

Table 1: The thin-stack algorithm operating on the input sequence **x** = (*Spot*, *sat*, *down*) and the transition sequence shown in the rightmost column. $S[t]$ shows the top of the stack at each step t. The last two elements of Q (underlined) specify which rows t would be involved in a REDUCE operation at the next step.

Handling variable sentence lengths For any sentence model to be trained with batched computation, it is necessary to pad or crop sentences to a fixed length. We fix this length at $N = 25$ words, longer than about 98% of sentences in SNLI. Transition sequences **a** are cropped at the left or padded at the left with SHIFTS. Token sequences **x** are then cropped or padded with empty tokens at the left to match the number of SHIFTS added or removed from **a**, and can then be padded with empty tokens at the right to meet the desired length N.

3.6 TreeRNN-equivalence

Without the addition of the tracking LSTM, SPINN (in particular the SPINN-PI-NT variant, for *parsed input, no tracking*) is precisely equivalent to a conventional tree-structured neural network model in the function that it computes, and therefore it also has the same learning dynamics. In both, the representation of each sentence consists of the representations of the words combined recursively using a TreeRNN composition function (in our case, the TreeLSTM function). SPINN, however, is dramatically faster, and supports both integrated parsing and a novel approach to context through the tracking LSTM.

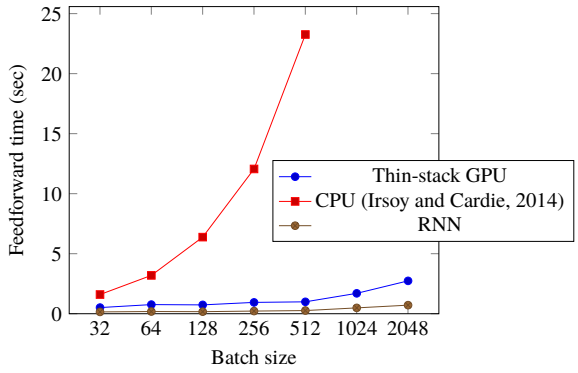

Figure 3: Feedforward speed comparison.

3.7 Inference speed

In this section, we compare the test-time speed of our SPINN-PI-NT with an equivalent TreeRNN implemented in the conventional fashion and with a standard RNN sequence model. While the full models evaluated below are implemented and trained using Theano (Theano Development Team, 2016), which is reasonably efficient but not perfect for our model, we wish to compare well-optimized implementations of all three models. To do this, we reimplement the feedforward[1] of SPINN-PI-NT and an LSTM RNN baseline in C++/CUDA, and compare that implementation with a CPU-based C++/Eigen TreeRNN implementation from Irsoy and Cardie (2014), which we modified to perform exactly the same computations as SPINN-PI-NT.[2] TreeRNNs like this can only operate on a single example at a time and are thus poorly suited for GPU computation.

Each model is restricted to run on sentences of 30 tokens or fewer. We fix the model dimension D and the word embedding dimension at 300. We run the CPU performance test on a 2.20 GHz 16-core Intel Xeon E5-2660 processor with hyperthreading enabled. We test our thin-stack implementation and the RNN model on an NVIDIA Titan X GPU.

Figure 3 compares the sentence encoding speed of the three models on random input data. We observe a substantial difference in runtime between the CPU and thin-stack implementations that increases with batch size. With a large but practical batch size of 512, the largest on which we tested the TreeRNN, our model is about 25× faster than the standard CPU implementation, and about 4× slower than the RNN baseline.

Though this experiment only covers SPINN-PI-NT, the results should be similar for the full SPINN model: most of the computation involved in running SPINN is involved in populating the buffer, applying the composition function, and manipulating the buffer and the stack, with the low-dimensional tracking and parsing components adding only a small additional load.

4 NLI Experiments

We evaluate SPINN on the task of natural language inference (NLI, a.k.a. recognizing textual entailment, or RTE; Dagan et al., 2006). NLI is a sentence pair classification task, in which a model reads two sentences (a premise and a hypothesis), and outputs a judgment of *entailment*, *contradiction*, or *neutral*, reflecting the relationship between the meanings of the two sentences. Below is an example sentence pair and judgment from the SNLI corpus which we use in our experiments:

Premise: Girl in a red coat, blue head wrap and jeans is making a snow angel.

Hypothesis: A girl outside plays in the snow.

Label: entailment

SNLI is a corpus of 570k human-labeled pairs of scene descriptions like this one. We use the standard train–test split and ignore unlabeled examples, which leaves about 549k examples for training, 9,842 for development, and 9,824 for testing. SNLI labels are roughly balanced, with the most frequent label, *entailment*, making up 34.2% of the test set.

Although NLI is framed as a simple three-way classification task, it is nonetheless an effective way of evaluating the ability of a model to extract broadly informative representations of sentence meaning. In order for a model to perform reliably well on NLI, it must be able to represent and reason with the core phenomena of natural language semantics, including quantification, coreference, scope, and several types of ambiguity.

4.1 Applying SPINN to SNLI

Creating a sentence-pair classifier To classify an SNLI sentence pair, we run two copies of SPINN with shared parameters: one on the premise sentence and another on the hypothesis sentence. We then use their outputs (the $\vec{h}$ states at the top of each

[1] We chose to reimplement and evaluate only the feedforward/inference pass, as inference speed is the relevant performance metric for most practical applications.

[2] The original code for Irsoy & Cardie's model is available at `https://github.com/oir/deep-recursive`. Our optimized C++/CUDA models and the Theano source code for the full SPINN are available at `https://github.com/stanfordnlp/spinn`.

Param.	Range	Strategy	RNN	SP.-PI-NT	SP.-PI	SP.
Initial LR	2×10^{-4}–2×10^{-2}	LOG	5×10^{-3}	3×10^{-4}	7×10^{-3}	2×10^{-3}
L2 regularization λ	8×10^{-7}–3×10^{-5}	LOG	4×10^{-6}	3×10^{-6}	2×10^{-5}	3×10^{-5}
Transition cost α	0.5–4.0	LIN	—	—	—	3.9
Embedding transformation dropout	80–95%	LIN	—	83%	92%	86%
Classifier MLP dropout	80–95%	LIN	94%	94%	93%	94%
Tracking LSTM size D_{tracking}	24–128	LOG	—	—	61	79
Classifier MLP layers	1–3	LIN	2	2	2	1

Table 2: Hyperparameter ranges and values. *Range* shows the hyperparameter ranges explored during random search. *Strategy* indicates whether sampling from the range was uniform, or log-uniform. Dropout parameters are expressed as keep rates rather than drop rates.

stack at time $t = T$) to construct a feature vector $\vec{x}_{\text{classifier}}$ for the pair. This feature vector consists of the concatenation of these two sentence vectors, their difference, and their elementwise product (following Mou et al., 2016):

$$\vec{x}_{\text{classifier}} = \begin{bmatrix} \vec{h}_{\text{premise}} \\ \vec{h}_{\text{hypothesis}} \\ \vec{h}_{\text{premise}} - \vec{h}_{\text{hypothesis}} \\ \vec{h}_{\text{premise}} \odot \vec{h}_{\text{hypothesis}} \end{bmatrix} \quad (6)$$

This feature vector is then passed to a series of 1024D ReLU neural network layers (i.e., an MLP; the number of layers is tuned as a hyperparameter), then passed into a linear transformation, and then finally passed to a softmax layer, which yields a distribution over the three labels.

The objective function Our objective combines a cross-entropy objective $\mathcal{L}_{\text{s}}$ for the SNLI classification task, cross-entropy objectives $\mathcal{L}_{\text{p}}^t$ and $\mathcal{L}_{\text{h}}^t$ for the parsing decision for each of the two sentences at each step t, and an L2 regularization term on the trained parameters. The terms are weighted using the tuned hyperparameters α and λ:

$$\mathcal{L}_{\text{m}} = \mathcal{L}_{\text{s}} + \alpha \sum_{t=0}^{T-1} (\mathcal{L}_{\text{p}}^t + \mathcal{L}_{\text{h}}^t) + \lambda \|\theta\|_2^2 \quad (7)$$

Initialization, optimization, and tuning We initialize the model parameters using the nonparametric strategy of He et al. (2015), with the exception of the softmax classifier parameters, which we initialize using random uniform samples from $[-0.005, 0.005]$.

We use minibatch SGD with the RMSProp optimizer (Tieleman and Hinton, 2012) and a tuned starting learning rate that decays by a factor of 0.75 every 10k steps. We apply both dropout (Srivastava et al., 2014) and batch normalization (Ioffe and Szegedy, 2015) to the output of the word embedding projection layer and to the feature vectors that serve as the inputs and outputs to the MLP that precedes the final entailment classifier.

We train each model for 250k steps in each run, using a batch size of 32. We track each model's performance on the development set during training and save parameters when this performance reaches a new peak. We use early stopping, evaluating on the test set using the parameters that perform best on the development set.

We use random search to tune the hyperparameters of each model, setting the ranges for search for each hyperparameter heuristically (and validating the reasonableness of the ranges on the development set), and then launching eight copies of each experiment each with newly sampled hyperparameters from those ranges. Table 2 shows the hyperparameters used in the best run of each model.

4.2 Models evaluated

We evaluate four models. The four all use the sentence-pair classifier architecture described in Section 4.1, and differ only in the function computing the sentence encodings. First, a single-layer LSTM RNN (similar to that of Bowman et al., 2015a) serves as a baseline encoder. Next, the minimal SPINN-PI-NT model (equivalent to a TreeLSTM) introduces the SPINN model design. SPINN-PI adds the tracking LSTM to that design. Finally, the full SPINN adds the integrated parser.

We compare our models against several baselines, including the strongest published non-neural network-based result from Bowman et al. (2015a) and previous neural network models built around several types of sentence encoders.

Model	Params.	Trans. acc. (%)	Train acc. (%)	Test acc. (%)
Previous non-NN results				
Lexicalized classifier (Bowman et al., 2015a)	—	—	99.7	78.2
Previous sentence encoder-based NN results				
100D LSTM encoders (Bowman et al., 2015a)	221k	—	84.8	77.6
1024D pretrained GRU encoders (Vendrov et al., 2016)	15m	—	98.8	81.4
300D Tree-based CNN encoders (Mou et al., 2016)	3.5m	—	83.4	82.1
Our results				
300D LSTM RNN encoders	3.0m	—	83.9	80.6
300D SPINN-PI-NT (*parsed input, no tracking*) encoders	3.4m	—	84.4	80.9
300D SPINN-PI (*parsed input*) encoders	3.7m	—	89.2	**83.2**
300D SPINN (unparsed input) encoders	2.7m	92.4	87.2	82.6

Table 3: Results on SNLI 3-way inference classification. Params. is the approximate number of trained parameters (excluding word embeddings for all models). Trans. acc. is the model's accuracy in predicting parsing transitions at test time. Train and test are SNLI classification accuracy.

4.3 Results

Table 3 shows our results on SNLI. For the full SPINN, we also report a measure of agreement between this model's parses and the parses included with SNLI, calculated as classification accuracy over transitions averaged across timesteps.

We find that the bare SPINN-PI-NT model performs little better than the RNN baseline, but that SPINN-PI with the added tracking LSTM performs well. The success of SPINN-PI, which is the hybrid tree-sequence model, suggests that the tree- and sequence-based encoding methods are at least partially complementary, with the sequence model presumably providing useful local word disambiguation. The full SPINN model with its relatively weak internal parser performs slightly less well, but nonetheless robustly exceeds the performance of the RNN baseline.

Both SPINN-PI and the full SPINN significantly outperform all previous sentence-encoding models. Most notably, these models outperform the tree-based CNN of Mou et al. (2016), which also uses tree-structured composition for local feature extraction, but uses simpler pooling techniques to build sentence features in the interest of efficiency. Our results show that a model that uses tree-structured composition fully (SPINN) outperforms one which uses it only partially (tree-based CNN), which in turn outperforms one which does not use it at all (RNN).

The full SPINN performed moderately well at reproducing the Stanford Parser's parses of the SNLI data at a transition-by-transition level, with 92.4% accuracy at test time.[3] However, its transition prediction errors are fairly evenly distributed across sentences, and most sentences were assigned partially invalid transition sequences that either left a few words out of the final representation or incorporated a few padding tokens into the final representation.

4.4 Discussion

The use of tree structure improves the performance of sentence-encoding models for SNLI. We suspect that this improvement is largely due to the more efficient learning of accurate generalizations overall, and not to any particular few phenomena. However, some patterns are identifiable in the results.

While all four models under study have trouble with negation, the tree-structured SPINN models do quite substantially better on these pairs. This is likely due to the fact that parse trees make the scope of any instance of negation (the portion of the sentence's content that is negated) relatively easy to identify and separate from the rest of the sentence. For test set sentence pairs like the one below where negation (*not* or *n't*) does not appear in the premise but does appear in the hypothesis, the RNN shows 67% accuracy, while all three tree-structured models exceed 73%. Only the RNN got the below example wrong:

Premise: The rhythmic gymnast completes her floor exercise at the competition.

Hypothesis: The gymnast cannot finish her exercise.

Label: contradiction

Note that the presence of negation in the hypothesis is correlated with a label of *contradiction* in SNLI, but not as strongly as one might intuit—only 45% of these examples in the test set are labeled as

[3]Note that this is scoring the model against automatic parses, not a human-judged gold standard.

contradictions.

In addition, it seems that tree-structured models, and especially the tree-sequence hybrid models, are more effective than RNNs at extracting informative representations of long sentences. The RNN model falls off in test accuracy more quickly with increasing sentence length than SPINN-PI-NT, which in turn falls of substantially faster than the two hybrid models, repeating a pattern seen more dramatically on artificial data in Bowman et al. (2015b). On pairs with premises of 20 or more words, the RNN's 76.7% accuracy, while SPINN-PI reaches 80.2%. All three SPINN models labeled the following example correctly, while the RNN did not:

Premise: A man wearing glasses and a ragged costume is playing a Jaguar electric guitar and singing with the accompaniment of a drummer.

Hypothesis: A man with glasses and a disheveled outfit is playing a guitar and singing along with a drummer.

Label: entailment

We suspect that the hybrid nature of the full SPINN model is also responsible for its surprising ability to perform better than an RNN baseline even when its internal parser is relatively ineffective at producing correct full-sentence parses. It may act somewhat like the tree-based CNN, only with access to larger trees: using tree structure to build up local phrase meanings, and then using the tracking LSTM, at least in part, to combine those meanings.

Finally, as is likely inevitable for models evaluated on SNLI, all four models under study did several percent worse on test examples whose ground truth label is *neutral* than on examples of the other two classes. *Entailment–neutral* and *neutral–contradiction* confusions appear to be much harder to avoid than *entailment–contradiction* confusions, where relatively superficial cues might be more readily useful.

5 Conclusions and future work

We introduce a model architecture (SPINN-PI-NT) that is equivalent to a TreeLSTM, but an order of magnitude faster at test time. We expand that architecture into a tree-sequence hybrid model (SPINN-PI), and show that this yields significant gains on the SNLI entailment task. Finally, we show that it is possible to exploit the strengths of this model without the need for an external parser by integrating a fast parser into the model (as in the full SPINN), and that the lack of external parse information yields little loss in accuracy.

Because this paper aims to introduce a general purpose model for sentence encoding, we do not pursue the use of soft attention (Bahdanau et al., 2015; Rocktäschel et al., 2016), despite its demonstrated effectiveness on the SNLI task.[4] However, we expect that it should be possible to productively combine our model with soft attention to reach state-of-the-art performance.

Our tracking LSTM uses only simple, quick-to-compute features drawn from the head of the buffer and the head of the stack. It is plausible that giving the tracking LSTM access to more information from the buffer and stack at each step would allow it to better represent the context at each tree node, yielding both better parsing and better sentence encoding. One promising way to pursue this goal would be to encode the full contents of the stack and buffer at each time step following the method used by Dyer et al. (2015).

For a more ambitious goal, we expect that it should be possible to implement a variant of SPINN on top of a modified stack data structure with differentiable PUSH and POP operations (as in Grefenstette et al., 2015; Joulin and Mikolov, 2015). This would make it possible for the model to learn to parse using guidance from the semantic representation objective, which currently is blocked from influencing the key parsing parameters by our use of hard SHIFT/REDUCE decisions. This change would allow the model to learn to produce parses that are, in aggregate, better suited to supporting semantic interpretation than those supplied in the training data.

Acknowledgments

We acknowledge financial support from a Google Faculty Research Award, the Stanford Data Science Initiative, and the National Science Foundation under grant nos. BCS 1456077 and IIS 1514268. Some of the Tesla K40s used for this research were donated by the NVIDIA Corporation. We also thank Kelvin Guu, Noah Goodman, and many others in the Stanford NLP group for helpful comments.

[4] Attention-based models like Rocktäschel et al. (2016), Wang and Jiang (2016), and the unpublished Cheng et al. (2016) have shown accuracies as high as 86.3% on SNLI, but are more narrowly engineered to suit the task and do not yield sentence encodings.

Investigating Language Universal and Specific Properties in Word Embeddings

Abstract

Recently, many NLP tasks have benefited from distributed word representation. However, it remains unknown whether embedding models are really immune to the typological diversity of languages, despite the language-independent architecture. Here we investigate three representative models on a large set of language samples by mapping dense embedding to sparse linguistic property space. Experiment results reveal the language universal and specific properties encoded in various word representation. Additionally, strong evidence supports the utility of word form, especially for inflectional languages.

1 Introduction

Word representation is a core issue in natural language processing. Context-based word representation, which is inspired by Harris (1954), has achieved huge successes in many NLP applications. Despite its popularity, character-based approach also comes out as an equal competitor (Santos and Zadrozny, 2014; Kim et al., 2016; Ling et al., 2015b; Ling et al., 2015a; Faruqui et al., 2016; Ballesteros et al., 2015) . Moreover, questions arise when we consider what these models could capture from linguistic cues under the perspective of cross-language typological diversity, as is argued by Bender (2009).

Despite previous efforts in empirically interpreting word embedding and exploring the intrinsic/extrinsic factors in learning process (Andreas and Klein, 2014; Lai et al., 2015; Köhn, 2015; Melamud et al., 2016), it remains unknown whether embedding models are really immune to the structural variance of languages.

Current research has gaps for understanding model behaviours towards language typological diversity as well as the utility of context and form for different languages. Thus, we select three representative types of models and design a series of experiments to reveal the universals and specifics of various word representations on decoding linguistic properties. Our work contributes to shedding new insights into the following topics:

a) How do typological differences of language structure influence a word embedding model? Does a model behave similarly towards phylogenetically-related languages?

b) Is word form a more efficient predictor of a certain grammatical function than word context for specific languages?

c) How do the neurons of a model respond to linguistic features? Can we explain the utility of context and form by analyzing neuron activation pattern?

2 Experiment Design

To study the proposed questions above, we design four series of experiments to comprehensively compare context-based and character-based word representations on different languages, covering syntactic, morphological and semantic properties. The basic paradigm is to decode interpretable linguistic features from a target collection of word representations. We hypothesize that there exists a linear/nonlinear map between a word representation x and a high-level sparse feature vector y if the word vector implicitly encode sufficient information[1]. Figure1 visualizes how a

*Corresponding author.

[1]Our experiment results show that nonlinear mapping model significantly works better than linear map for all languages. Only nonlinear mapping accuracies are mentioned in the following sections due to the space limit.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1478–1488,
Berlin, Germany, August 7-12, 2016.

word embedding is mapped to different linguistic attribute vectors. For example, the Czech word *dětem* means children in English. Its grammatical gender is female. It is in the plural form and should be used in dative case. These are all important properties of a word. The word embedding of *dětem* is mapped to different sparse representation of these lexical properties respectively.

Listed in Table1 is the outline of the experiments.

ID	Attribute	Category
I	Part-of-Speech	Syntax
II	Dependency Relation	
III	Gender / Number / Case Animacy / Definite / Person Tense / Aspect / Mood / Voice PronType / VerbForm	Morphology
IV	Sentiment Score	Semantics

Table 1: Outline of Experiment Design.

For linear map, we train a matrix Θ that maps word embedding $\mathbf{x}$ to a sparse feature vector $\mathbf{y}$ with the least L_2 error. For nonlinear map, we train a neural network (MLP) with 4 hidden layers via back propagation. Their dimensions are 50, 80, 80, and 50 in order. For each linguistic feature of each language, a mapping model is trained on the randomly-selected 90% of the words with the target feature and tested over the remaining 10%. Details about the construction of the linguistic feature vectors will be mentioned in the specific section of a certain experiment.

For syntactic and morphological features, we construct the corresponding feature vectors of a word from the Universal Dependencies Treebank (Joakim Nivre and Zhu, 2015) and the Chinese Treebank (CTB 7.0) (Xue et al., 2010). For a certain word w with a certain linguistic attribute a (e.g. POS), w may be annotated with one or different labels (e.g. NOUN, VERB, etc) from the possible label set of a in the whole treebank. We calculate the normalized label frequency distribution $\vec{\mathbf{y}}_w^a$ from the manual annotation of the corpus as the representation of the linguistic attribute a for the word w in each language.

For word sentiment feature, we use the manually annotated data collected by Dodds et al. (2015). The data contains emotion scores for a list of words in several languages. In our experiment, the original score scale in Dodds et al. (2015) is transformed into the interval $[0, 1]$.

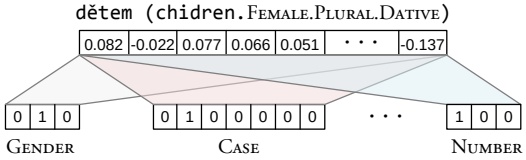

Figure 1: Visualizing experiment paradigm. The dense representation of a Czech word *dětem* is mapped to different sparse representation of the lexical properties respectively.

3 Embedding Model Description

Faced with three questions proposed before, we select the following models from various candidates, as they are popular, representative and based on either word context or purely word form.

Type I C&W Model (referred as CW in short), which aims to estimate the joint probability of a word sequence (Collobert et al., 2011). In this paper, C&W word vectors are all from the released version of the polyglot multilingual embeddings (Al-Rfou et al., 2013) trained on Wikipedia.

Type II Skip-gram[2] (referred as SG in short), which aims to predict the context words based on the target word. We use word2vec (Mikolov et al., 2013) to train SG on multilingual Wikipediea provided by (Al-Rfou et al., 2013).

Type III Character-based LSTM autoencoder (referred as AE in short), which takes the character sequence of a word as the input and reconstruct the input character sequence. It takes the advantage of pure word form instead of the context. The hidden layer vector of the model is used as a representation of the word. In this way, we are able to quantify the utility of pure word form by evaluating the representation generated from the character-based LSTM autoencoder on different decoding tasks. We trained one-hidden layer AE with the words covered in CW for each language independently.

To ensure a fair comparison, all the word vectors have the same dimension 64. CW and SG are trained with a common 5-word window size.

4 Results

4.1 Part-of-Speech

In experiment I, we decode Part-of-Speech, the most basic syntactic feature, from word embed-

[2]SG results for some languages are missed due to the lack of the corpus data or special preprocessing.

Table 2: Model comparison on decoding POS, along with WALS word-order features. Type I: VS+VO+Pre+NR. II: SV+VO+Pre+RN. III: SV+OV+Pre+NR. IV: SV+OV+Post+RN/Co. V: SV+OV+Post+NR. VI: SV+ND+Pre+NR. VII: SV+VO+Pre+NR. VIII: ND+VO+Pre+NR.

ding. To construct the POS vector for each word, we calculate the normalized POS-tag frequency distribution from the manual annotation of the Universal Dependencies (Version 1.2) (De Marneffe et al., 2014) and Chinese Treebank (CTB 7.0) (Xue et al., 2010) for each language.

We evaluate the predicted results by judging whether the most probable POS tag of a word predicted by the model equals to the most probable correct POS tag of the word. Formally, for a set of words W in a language, the correct tag of the i^{th} word W_i is $y^a_{W_i}$ and the predicted tag is $\hat{y}^a_{W_i}$. The accuracy is computed as:

$$acc = \frac{1}{|W|}\sum_{i}^{|W|}\Delta(\hat{y}^a_{W_i}, y^a_{W_i}) \quad (1)$$

$$\Delta(\hat{y}^a_{W_i}, y^a_{W_i}) = \begin{cases} 1 & \hat{y}^a_{W_i} = y^a_{W_i} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

It is obvious that context-based representation (CW and SG) performs better than character-based representation (AE). We, however, notice that AE peforms nearly as well as the context-based embedding on Russian, Czech and Indonesian.

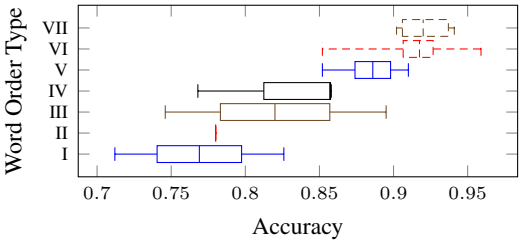

Figure 2: Interaction between CW performances on decoding POS tag and WALS word order features.

It turns out that these languages employ affix markers to indicate the POS category of a word. For example, in Indonesian, co-occurrence of the prefix *'me-'* and the suffix *'-kan'* in the word form means that this word is a verb.

Besides, we explore the relationship between CW performances on decoding POS tags and the word order typology of different languages, since CW is sensitive to word order. We classify the languages into 8 types, based on the basic word order features (Order of Subject and Verb; Order of Object and Verb; Order of Noun and Adposition; Order of Noun and Relative clause) from the World Atlas of Language Structures (Dryer and Haspelmath, 2013). Figure 2 shows that CW performs similar in this experiment for languages of the same word order type, indicating an implicit interaction between typological diversity and model performance.

4.2 Dependency Relation

In this section, we will get into the details of Experiment II: decoding dependency relation from word representation. Dependency relation refers to how a word is syntactically related to other words in a sentence. It is the label annotated on the arc of the dependency tree.

We compute the normalized frequency distribution of dependency relations for each word in the Universal Dependency Treebank and Chinese Treebank (CTB 7.0) (Xue et al., 2010). The distribution of dependency relations is the probabilistic distribution of different arc types, such as subject, object, nmod, etc. Evaluation is similar to that in Section 4.1.

We can see from Figure 3 that the overall performance is worse than that in Experiment I, as dependency analysis is more difficult than POS induction. CW achieves the best performance. It

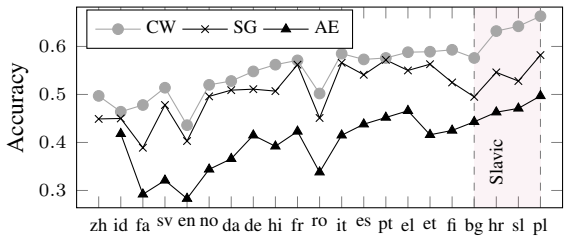

Figure 3: Comparison of models on decoding DEPENDENCY RELATION.

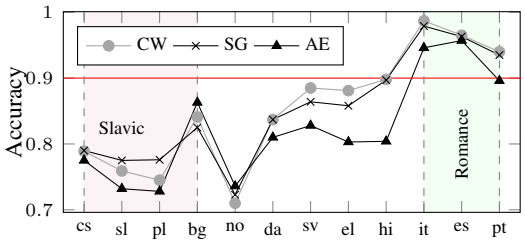

Figure 4: Comparison of models on decoding GENDER.

is also interesting to see that all the embeddings work slightly better on Slavic languages.

4.3 Morphological Features

Experiment III aims to decode morphological information from various word representation. Evaluation is similar to that in Section 4.1. Morphological information refers to the explicit marker of the grammatical functions. We consider 12 morphological features, as is shown in Table 1. They can be split into 5 nominal features (GENDER, NUMBER, CASE, ANIMACY, DEFINITENESS) and 7 verbal features (PERSON, TENSE, ASPECT, MOOD, VOICE, PRONOUNTYPE, VERBFORM).

Gender is a very special feature for western languages. It is partially based on semantics, such as biological sex. In most of the languages with gender features, there are agreements between the noun and the determiners. This could be a good indicator for context-based model. On the other hand, gender is also expressed as an inflectional feature via declension or umlaut, especially for adjectives and verbs. Therefore, we can see from Figure 4 that the AE also achieves some good results without using context information.

From a typological perspective, we found that all the embeddings work well on decoding word gender of Romance languages (Italian, Spanish and Portuguese) but worst on Slavic languages (e.g. Czech, Slovenian). This is probably

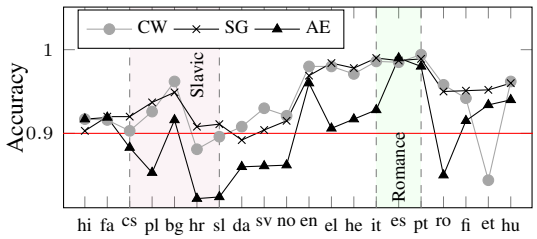

Figure 5: Model comparison on decoding NUMBER.

	Language	$\|V\|$	C&W	SG	AE	# Case

	Latin	4773	0.674	–	0.636	7

Table 3: Model comparison on decoding CASE.

because that Romance languages employ regular rules to judge the gender of a word. However, Slavic languages have other nonlinear fusional morphological features that are not easy to tackle.

Number refers to the linguistic abstraction of objects' quantities. It is an inflectional feature of noun and other parts of speech (adjective, verb) that have agreement with noun. The basic value can be singular, dual or plural. We can see from Figure 5 that SG, CW and AE all perform well. AE performs almost as well as CW and SG on English, Spanish and Portuguese.

Case is one of the most significant features. Gender and number are indexical morphemes, which means that there is a phrase in the sentence that necessarily agrees with the target item. Case, on the contrary, is a relational morpheme, according to (Croft, 2002). Case reflects the semantic role of a noun, relative to the pivot verb. All the languages studied in this paper, more or less, employ word inflection to explicitly express the specific case role. The model performances are listed in Table 3.

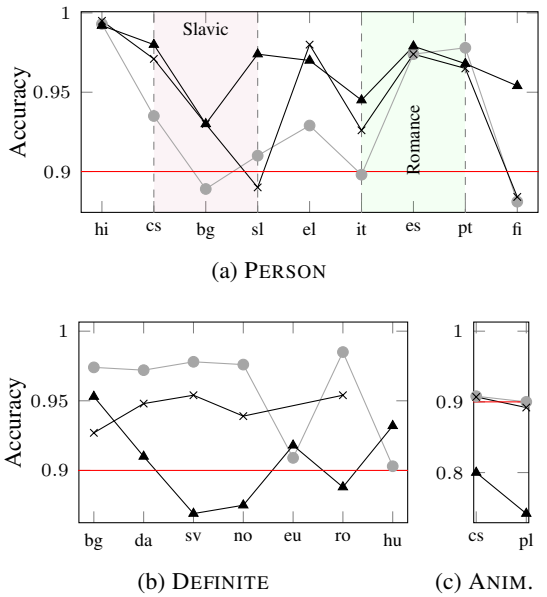
We notice some important inter-language differences. Swedish has only two cases, nominal and genitive. The form of genitive case is very simple. Adding an *s* to the coda of a noun will change it to genitive case. Thus, we can see that character-based encoding performs well

on Swedish. Since genitive case usually means possession, we also notice that context-based distributed representation also performs well in decoding case information from Swedish words.

By classifying these languages into different morphological types in Table 3, we find that word vectors of highly inflected fusional languages (e.g. Czech) performs worse than agglutinative languages (e.g. Finnish). This is typically reflected in AE, as agglutinative languages simply concatenate the case marker with the nominative form of a noun. The morphological transformation of agglutinative languages is linear and simple. Besides, the case system of the analytic languages has been largely simplified due to historical change. Therefore, all the embeddings perform well on analytic languages. This evidence supports that morphological complexity is positively correlated with the quality of word embedding.

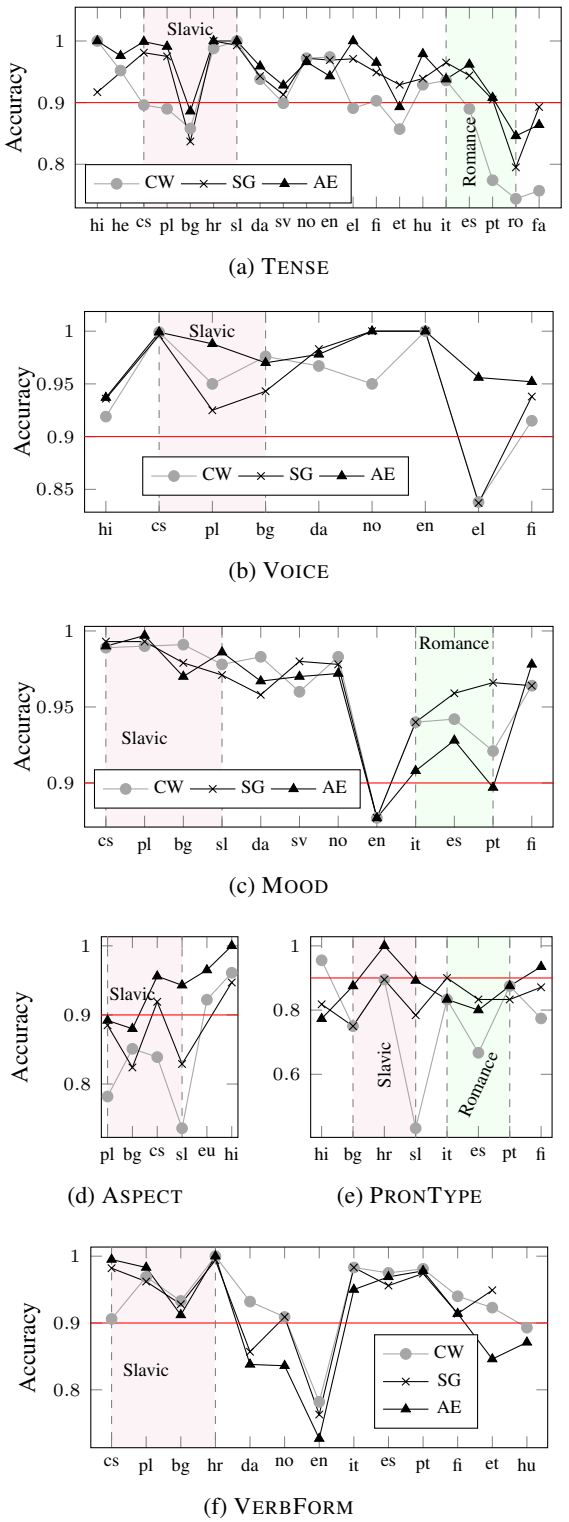
Besides, for fusional languages, using distributed representation and context information would largely increase the performance. This, in turn, indicates that cases are a special semantic relations distributed in the words around the target noun. Although a case is not explicitly agreed with other components in an utterance, the word category might serve as a good indicator, such as preposition and verb.

Animacy is a special nominal feature in a few languages, which is used to discriminate alive and animate objects from inanimate nouns. Generally, it is based on the lexical semantic feature. As is shown in Figure 6, it is easier to decode animacy from the context-based representations than character-based representation.



(a) PERSON (b) DEFINITE (c) ANIM.

Figure 6: Model comparison on decoding PERSON, DEFINITENESS and ANIMACY.



(a) TENSE (b) VOICE (c) MOOD (d) ASPECT (e) PRONTYPE (f) VERBFORM

Figure 7: Model comparison on TENSE, VOICE, MOOD, ASPECT, PRONTYPE and VERBFORM

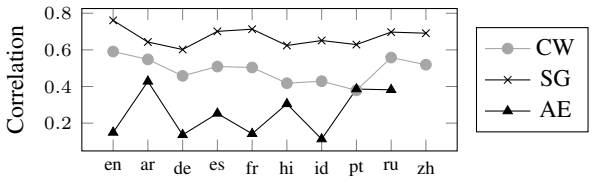


Figure 8: Model comparison on EMOTION.

From Figure 6, 7, we can see that all the three models give quite perfect performance on decoding person, definiteness, tense, voice, mood, aspect, pronoun type and verb form.

Overall, character-based representation is most effective for Slavic languages on decoding verbal morphological features but not nominal features. The result is vice versa for Romance languages, which is not as morphologically complex as Slavic. It is worth noticing that models behave differently on Bulgarian, an analytic language, although Bulgarian belongs to Slavic language from the phylogenetic perspective. We think that this is because many morphological features in Bulgarian have been simplified or weakened.

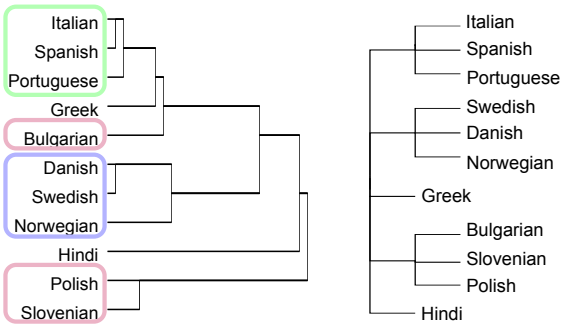
4.4 Emotion Score

In Experiment IV, we use the manually annotated data collected by Dodds et al. (2015). The data contains emotion scores for a list of words in several languages. In our experiment, the original score scale is transformed into the interval $[0, 1]$. A nonlinear map is trained to regress the representation of a word (CW, SG, AE) to its emotion score.

To evaluate the predicted results, we measure the Spearman correlation between the gold scores and predicted scores. The result in Figure 8 reveals a significantly strong correlation between the predicted emotion scores of SG and the real emotion scores. CW comes the second. For AE, it is hard to decode emotion just from the word form.

5 Contrastive Analysis

As we have mentioned before, Type I C&W model utilizes ordered context information to train the distributed word representation. Type II skip-gram model utilizes unordered context information. Type III character-based LSTM autoencoder model utilizes the grapheme information to represent a word. Towards the key questions that we raised at the very beginning of the paper, we propose our contrastive analysis based on the experiment results.



(a) Hierarchical tree based on model performances

(b) WALS Genus Tree

Figure 9: Comparison of the tree based on model performances and the WALS dendrogram manually constructed by linguists.

5.1 Typology vs. Phylogeny

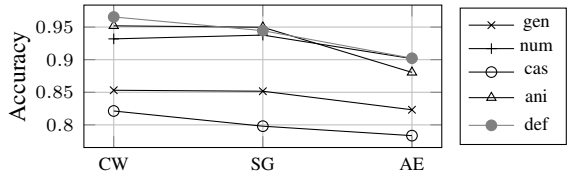
Experiment results have shown that word embedding models are influenced by the syntactic and morphological diversity more or less. Here we display how typological similarity and phylogenetic relation is revealed from the observed model performance variation. We hierarchically cluster languages according to the model performance on decoding syntactic and morphological features. The dendrogram of the languages in Figure 9 vividly shows that most of the phylogenetic-related languages are clustered together.

However, there is some interesting exceptions. Bulgarian does not form a primary cluster with other Slavic languages (e.g. Slovenian). We think that this is because Bulgarian is typologically dissimilar to Slavic language family. Therefore, Figure 9 reflects that language typology explains the model variation better than language phylogeny.

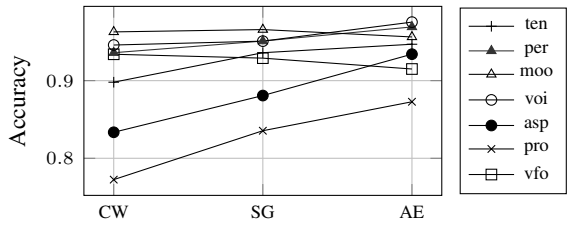
5.2 Form vs. Context

Here we discuss the effectiveness of word form and different types of word context.

Regarding the correlation between context type and language function, previous results show that SG performs worse than CW on decoding POS and dependency relation while SG performs better than CW on decoding emotion score. Since CW keeps word order of the context, this comparison suggests that word order information is vital to syntactic information, but it might also be a kind of noise for the word vectors to encode semantic information.



(a) Nominal features



(b) Verbal features

Table 5: Comparison of morpho-phonological knowledge transfer on different language pairs. The reconstruction accuracy is correlated with the overlapping proportion of grapheme patterns between source language and target language.

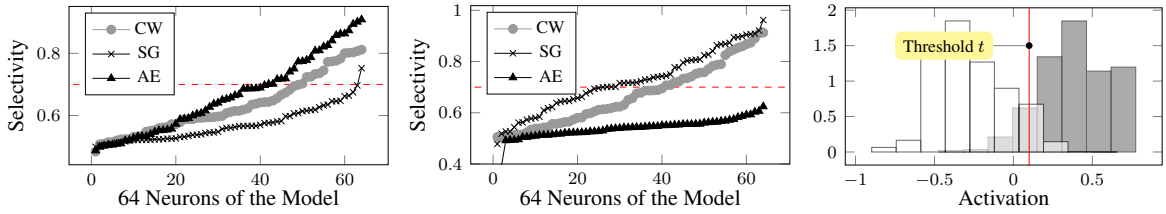
Regarding the correlation between form and language function, previous results on POS, dependency relation and emotion scores show the effectiveness of the word context. However, for morphological features, results in Table 10 indicate that context-based word representation works slightly better than character-based representation. Specifically, character-based embedding (AE) does outperform context-based embedding (CW, SG) on decoding verbal morphological features, even though AE does not access any context information. In other words, word form could be an explicit and discriminative cue for the model to decode the morphological feature of a word.

To prove that word form could provides informative and explicit cues for grammatical functions, we train another shuffled character-based word representation, which means that the autoencoder inputs shuffled letters and outputs the shuffled letters again. We use the hidden layer of the shuffled autoencoder as the representation for each word. The result in Table 4 shows that now the character-based model cannot perform as well as the original character-based autoencoder representation does, which again proves that the order of the word form is necessary for learning the grammatical function of a word.

Since many languages share similar phonographic writing systems, we naturally want to know whether the grapheme-phoneme knowledge from one language can be transferred to another language. We train an autoencoder purely on Finnish and directly test the trained model on memorizing raw English words, letter-shuffled English words and random letter sequences. Results in Table 5 indicate that the character autoencoder can successfully reconstruct raw English words instead of the letter-shuffled English words or random letter sequences. However, if we train an autoencoder purely on Arabic and then directly test the trained model on memorizing Urdu (ud) words or Persian (fa) words, the reconstruction accuracy is quite low, although Arabic, Persian and Urdu use the same Arabic writing system.

To explain the behaviour of AE, we calculate the correlation between the bigram character frequency in the words of the training language (e.g. Finnish) and the bigram character frequency in the words of the testing language (e.g. English). Table 5 reveals that phonological knowledge can be transferred if two languages share similar bigram and trigram character frequency distribution. For example, Finnish and English are both Indo-European language. Their writing system stores similar phonological structure. Arabic is a Semitic language. Persian is an Indo-European language. Their writing system stores different phonological structures respectively. This again proves that character-based LSTM autoencoder does 'memorize' the grapheme or phoneme clusters of a words. Morpho-phonological knowledge can be transferred among typologically-related languages.

Additionally, we are surprised to find that using the English word representations encoded



(a) me-- kan (b) Country names (c) Single neuron

Figure 11: Visualising the Neuron activation pattern for different word embedding models

by AE model trained on Finnish can increase the accuracy of English AE embedding in Experiment I (up to 0.7076), compared with the original accuracy 0.6587. This is probably due to the shared knowledge about the morphemes in the word form.

5.3 Neuronal Activation Pattern

Le (2011) found out that it is empirically possible to learn a 'Grandmother neuron'-like face detector from unlabelled data. In their experiment on unlabeled data, one neuron learns to activate specifically towards the pictures with cat faces instead of other pictures. Based on this finding, we hypothesize that there should exist selective neuron activation towards a linguistic feature trigger. The feature trigger can be a special consonant cluster, a specific suffix or the syntactic category of a word.

To quantitatively show the collective neuron behaviours and the individual neuron response towards different linguistic trigger, we compute the maximum probability that a neuron discriminates the words with trigger f from the words without trigger f. We defined this probability as the Degree of Selectivity p. For a given neuron $\mathbf{n}$ in a given model $\mathbf{M}$ towards linguistic trigger f, we try to find a threshold t that maximizes $p_{f,t}$,

$$c_{f,t} = \frac{N^+_{f,t}}{N_f}, c_{\neg f,t} = \frac{N^+_{\neg f,t}}{N_{\neg f}},$$

$$Selectivity = p_{f,t} = \frac{2 \times c_{f,t} \times c_{\neg f,t}}{c_{f,t} + c_{\neg f,t}}$$

where $N^+_{f,t}$ is the number of correctly discriminated words with linguistic feature f based on the threshold t. N_f is the real number of words with linguistic feature f. $N^+_{\neg f,t}$ is the number of correctly discriminated words without linguistic feature f based on the threshold t. $N_{\neg f}$ means the real number of words without linguistic feature f. $c_{f,t}$ / $c_{\neg f,t}$ is the accuracy for the neuron $\mathbf{n}$ of model $\mathbf{M}$ to detect the existence / nonexistence of the linguistic feature f. $p_{f,t}$ is the F-score of $c_{f,t}$ and $c_{\neg f,t}$, indicating the degree to which a certain neuron discriminates the words with/without a certain trigger f at a certain threshold t.

After calculating the selectivity of 64 neurons in an embedding model towards a linguistic trigger f, we sort the neurons according to the value of selectivity and draw the curve in Figure 11 for each model. The x-axis is the rank of the model neurons based on their selectivity towards a certain linguistic trigger. The y-axis is the selectivity of the corresponding neuron. The curve can tell us how many neurons selectively respond to trigger f to a certain degree. For example, we can see from Figure 11 that the max selectivity of the AE neurons reaches nearly 0.9. This means that one neuron of the AE model is especially sensitive to the prefix *'Me-'* and affix *'-an'*. It can detect the words with the prefix *'Me-'* and the affix *'-an'* just from its activation pattern.

It is also interesting to see from Figure 11 that neurons of AE respond more selectively to morphological triggers than those of the word-based model. For example, almost 30% of the AE neurons fall in the selectivity level [0.7, 1] towards the verb marker, namely prefix *'Me-'* and affix *'-an'*, in Indonesian. Context-based model also shows some selectivity towards this morphological triggers. For SG model, the max selectivity of the model neurons is only just above 0.7.

On the contrary, the context-based distributed models showed strong selective activation towards country names in Indonesian. However, the selectivity of all the AE neurons is below 0.7 towards these semantically-related words.

Similar patterns are found also in other languages. We conclude that the character-based model captures much morphological information

/ syntactic marker than semantic information. The popular word-based model captures both semantic information and syntactic information, although the latter is not displayed as explicitly as the former.

6 Related works

There have been a lot of research on interpreting or relating word embedding with linguistic features. Yogatama et al. (2014) projects word embedding into a sparse vector. They found some linguistically interpretable dimensions. Faruqui and Dyer (2015) use linguistic features to build word vector. Their results show that these representation of word meaning can also achieve good performance in the analogy and similarity tasks. These work can be regarded as the foreshadowing of our experiment paradigm that mapping dense vector to a sparse linguistic property space.

Besides, a lot of study focus on empirical comparison of different word embedding model. Melamud et al. (2016) investigates the influence of context type and vector dimension on word embedding. Their main finding is that concatenating two different types of embeddings can still improve performance even if the utility of dimensionality has run out. Andreas and Klein (2014) assess the potential syntactic information encoded in word embeddings by directly apply word embeddings to parser and they concluded that embeddings add redundant information to what the conventional parser has already extracted. Tsvetkov et al. (2015) propose a method to evaluate word embeddings through the alignment of distributional vectors and linguistic word vectors. However, the method still lacks a direct and comprehensive investigation of the utility of form, context and language typological diversity. This is exactly our novelty and contribution.

It is worth noticing that Köhn (2015) evaluates multilingual word embedding and compares skip-gram, language model and other competitive embedding models. They show that dependency-based skip-gram embedding is effective, even at low dimension. Although Köhn (2015) work involves different languages, they focus on the similarity among multilingual embeddings with only 7 languages. Our work, however, not only provides a comprehensive investigation with massive language samples (30 for Experiment I) and nonlinear mapping models, but also reveal the utility of pure word form and novelly point out the cross-language differences in word representation, which have been overlooked by huge amount of monolingual/bilingual research on well-studied languages.

7 Conclusion

In this paper, we quantify the utility of word form and the effect of language typological diversity in learning word representations. Cross-language perspective and novel analysis of neuron behaviours provide us with new evidence about the typological universal and specific revealed in word embedding. We summarize from our experiments on a massive set of languages that:

- Language typological diversity, especially the specific word order type and morphological complexity, does influence how linguistic information is encoded in word embedding.
- It is plausible (and sometimes even better) to decode grammatical function just from the word form, for certain inflectional languages.
- Quantification of neuron activation pattern reveals different characteristics of the context-based model and the character-based counterpart.

Therefore, we think that it is necessary to maximize both the utility of word form and the advantage of the context for a better word representation. It would also be a promising direction to incorporate the factor of language typological diversity when designing advanced word representation model for languages other than English.

Diachronic Word Embeddings Reveal Statistical Laws of Semantic Change

William L. Hamilton, Jure Leskovec, Dan Jurafsky
Department of Computer Science, Stanford University, Stanford CA, 94305
wleif,jure,jurafsky@stanford.edu

Abstract

Understanding how words change their meanings over time is key to models of language and cultural evolution, but historical data on meaning is scarce, making theories hard to develop and test. Word embeddings show promise as a diachronic tool, but have not been carefully evaluated. We develop a robust methodology for quantifying semantic change by evaluating word embeddings (PPMI, SVD, word2vec) against known historical changes. We then use this methodology to reveal statistical laws of semantic evolution. Using six historical corpora spanning four languages and two centuries, we propose two quantitative laws of semantic change: (i) the *law of conformity*—the rate of semantic change scales with an inverse power-law of word frequency; (ii) the *law of innovation*—independent of frequency, words that are more polysemous have higher rates of semantic change.

1 Introduction

Shifts in word meaning exhibit systematic regularities (Bréal, 1897; Ullmann, 1962). The rate of semantic change, for example, is higher in some words than others (Blank, 1999) — compare the stable semantic history of *cat* (from Proto-Germanic *kattuz*, "cat") to the varied meanings of English *cast*: "to mould", "a collection of actors', "a hardened bandage", etc. (all from Old Norse *kasta*, "to throw", Simpson et al., 1989).

Various hypotheses have been offered about such regularities in semantic change, such as an increasing subjectification of meaning, or the grammaticalization of inferences (e.g., Geeraerts, 1997; Blank, 1999; Traugott and Dasher, 2001).

But many core questions about semantic change remain unanswered. One is the role of *frequency*. Frequency plays a key role in other linguistic changes, associated sometimes with faster change—sound changes like lenition occur in more frequent words—and sometimes with slower change—high frequency words are more resistant to morphological regularization (Bybee, 2007; Pagel et al., 2007; Lieberman et al., 2007). What is the role of word frequency in meaning change?

Another unanswered question is the relationship between semantic change and *polysemy*. Words gain senses over time as they semantically drift (Bréal, 1897; Wilkins, 1993; Hopper and Traugott, 2003), and polysemous words[1] occur in more diverse contexts, affecting lexical access speed (Adelman et al., 2006) and rates of L2 learning (Crossley et al., 2010). But we don't know whether the diverse contextual use of polysemous words makes them more or less likely to undergo change (Geeraerts, 1997; Winter et al., 2014; Xu et al., 2015). Furthermore, polysemy is strongly correlated with frequency—high frequency words have more senses (Zipf, 1945; İlgen and Karaoglan, 2007)—so understanding how polysemy relates to semantic change requires controling for word frequency.

Answering these questions requires new methods that can go beyond the case-studies of a few words (often followed over widely different time-periods) that are our most common diachronic data (Bréal, 1897; Ullmann, 1962; Blank, 1999; Hopper and Traugott, 2003; Traugott and Dasher, 2001). One promising avenue is the use of distributional semantics, in which words are embedded in vector spaces according to their co-occurrence relationships (Bullinaria and Levy, 2007; Turney and Pantel, 2010), and the embeddings of words

[1] We use 'polysemy' here to refer to related senses as well as rarer cases of accidental homonymy.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1489–1501,
Berlin, Germany, August 7-12, 2016.

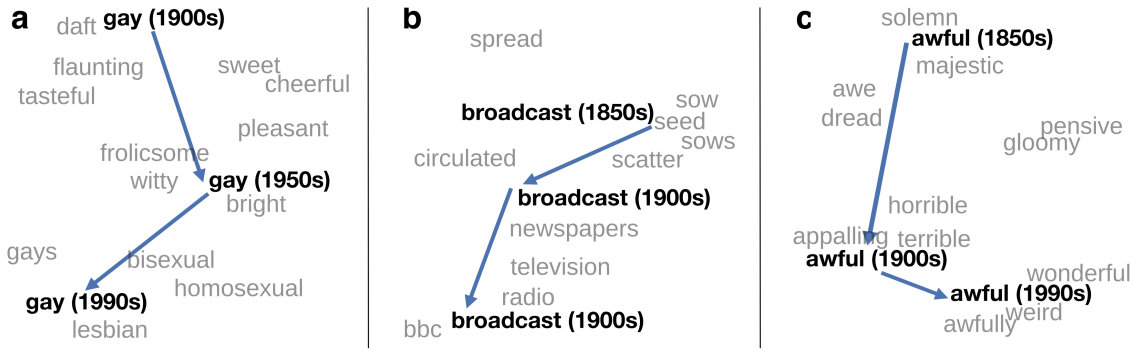

Figure 1: Two-dimensional visualization of semantic change in English using SGNS vectors.[2] **a**, The word *gay* shifted from meaning "cheerful" or "frolicsome" to referring to homosexuality. **b**, In the early 20th century *broadcast* referred to "casting out seeds"; with the rise of television and radio its meaning shifted to "transmitting signals". **c**, *Awful* underwent a process of pejoration, as it shifted from meaning "full of awe" to meaning "terrible or appalling" (Simpson et al., 1989).

are then compared across time-periods. This new direction has been effectively demonstrated in a number of case-studies (Sagi et al., 2011; Wijaya and Yeniterzi, 2011; Gulordava and Baroni, 2011; Jatowt and Duh, 2014) and used to perform large-scale linguistic change-point detection (Kulkarni et al., 2014) as well as to test a few specific hypotheses, such as whether English synonyms tend to change meaning in similar ways (Xu and Kemp, 2015). However, these works employ widely different embedding approaches and test their approaches only on English.

In this work, we develop a robust methodology for quantifying semantic change using embeddings by comparing state-of-the-art approaches (PPMI, SVD, word2vec) on novel benchmarks.

We then apply this methodology in a large-scale cross-linguistic analysis using 6 corpora spanning 200 years and 4 languages (English, German, French, and Chinese). Based on this analysis, we propose two statistical laws relating frequency and polysemy to semantic change:

- **The law of conformity:** Rates of semantic change scale with a negative power of word frequency.
- **The law of innovation:** After controlling for frequency, polysemous words have significantly higher rates of semantic change.

2 Diachronic embedding methods

The following sections outline how we construct diachronic (historical) word embeddings, by first constructing embeddings in each time-period and then aligning them over time, and the metrics that we use to quantify semantic change. All of the learned embeddings and the code we used to analyze them are made publicly available.[3]

2.1 Embedding algorithms

We use three methods to construct word embeddings within each time-period: PPMI, SVD, and SGNS (i.e., word2vec).[4] These distributional methods represent each word w_i by a vector $\mathbf{w}_i$ that captures information about its co-occurrence statistics. These methods operationalize the 'distributional hypothesis' that word semantics are implicit in co-occurrence relationships (Harris, 1954; Firth, 1957). The semantic similarity/distance between two words is approximated by the cosine similarity/distance between their vectors (Turney and Pantel, 2010).

2.1.1 PPMI

In the PPMI representations, the vector embedding for word $w_i \in \mathcal{V}$ contains the positive point-wise mutual information (PPMI) values between w_i and a large set of pre-specified 'context' words. The word vectors correspond to the rows of the matrix $\mathbf{M}^{\text{PPMI}} \in \mathbb{R}^{|\mathcal{V}| \times |\mathcal{V}_C|}$ with entries given by

$$\mathbf{M}^{\text{PPMI}}_{i,j} = \max\left\{\log\left(\frac{\hat{p}(w_i, c_j)}{\hat{p}(w)\hat{p}(c_j)}\right) - \alpha, 0\right\}, \quad (1)$$

where $c_j \in \mathcal{V}_C$ is a context word and $\alpha > 0$ is a negative prior, which provides a smoothing bias (Levy et al., 2015). The $\hat{p}$ correspond to the smoothed empirical probabilities of word

[2] Appendix B details the visualization method.

[3] http://nlp.stanford.edu/projects/histwords

[4] Synchronic applications of these three methods are reviewed in detail in Levy et al. (2015).

Name	Language	Description	Tokens	Years	POS Source
ENGALL	English	Google books (all genres)	8.5×10^{11}	1800-1999	(Davies, 2010)
ENGFIC	English	Fiction from Google books	7.5×10^{10}	1800-1999	(Davies, 2010)
COHA	English	Genre-balanced sample	4.1×10^{8}	1810-2009	(Davies, 2010)
FREALL	French	Google books (all genres)	1.9×10^{11}	1800-1999	(Sagot et al., 2006)
GERALL	German	Google books (all genres)	4.3×10^{10}	1800-1999	(Schneider and Volk, 1998)
CHIALL	Chinese	Google books (all genres)	6.0×10^{10}	1950-1999	(Xue et al., 2005)

Table 1: Six large historical datasets from various languages and sources are used.

(co-)occurrences within fixed-size sliding windows of text. Clipping the PPMI values above zero ensures they remain finite and has been shown to dramatically improve results (Bullinaria and Levy, 2007; Levy et al., 2015); intuitively, this clipping ensures that the representations emphasize positive word-word correlations over negative ones.

2.1.2 SVD

SVD embeddings correspond to low-dimensional approximations of the PPMI embeddings learned via singular value decomposition (Levy et al., 2015). The vector embedding for word w_i is given by

$$\mathbf{w}_i^{\text{SVD}} = (\mathbf{U}\mathbf{\Sigma}^{\gamma})_i\,, \tag{2}$$

where $\mathbf{M}^{\text{PPMI}} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^{\top}$ is the truncated singular value decomposition of $\mathbf{M}^{\text{PPMI}}$ and $\gamma \in [0, 1]$ is an eigenvalue weighting parameter. Setting $\gamma < 1$ has been shown to dramatically improve embedding qualities (Turney and Pantel, 2010; Bullinaria and Levy, 2012). This SVD approach can be viewed as a generalization of Latent Semantic Analysis (Landauer and Dumais, 1997), where the term-document matrix is replaced with $\mathbf{M}^{\text{PPMI}}$. Compared to PPMI, SVD representations can be more robust, as the dimensionality reduction acts as a form of regularization.

2.1.3 Skip-gram with negative sampling

SGNS 'neural' embeddings are optimized to predict co-occurrence relationships using an approximate objective known as 'skip-gram with negative sampling' (Mikolov et al., 2013). In SGNS, each word w_i is represented by two dense, low-dimensional vectors: a word vector ($\mathbf{w}_i^{\text{SGNS}}$) and context vector ($\mathbf{c}_i^{\text{SGNS}}$). These embeddings are optimized via stochastic gradient descent so that

$$\hat{p}(c_i|w_i) \propto \exp(\mathbf{w}_i^{\text{SGNS}} \cdot \mathbf{c}_j^{\text{SGNS}}), \tag{3}$$

where $p(c_i|w_i)$ is the empirical probability of seeing context word c_i within a fixed-length window of text, given that this window contains w_i. The SGNS optimization avoids computing the normalizing constant in (3) by randomly drawing 'negative' context words, c_n, for each target word and ensuring that $\exp(\mathbf{w}_i^{\text{SGNS}} \cdot \mathbf{c}_n^{\text{SGNS}})$ is small for these examples.

SGNS has the benefit of allowing incremental initialization during learning, where the embeddings for time t are initialized with the embeddings from time $t - \Delta$ (Kim et al., 2014). We employ this trick here, though we found that it had a negligible impact on our results.

2.2 Datasets, pre-processing, and hyperparameters

We trained models on the 6 datasets described in Table 1, taken from Google N-Grams (Lin et al., 2012) and the COHA corpus (Davies, 2010). The Google N-Gram datasets are extremely large (comprising $\approx$6% of all books ever published), but they also contain many corpus artifacts due, e.g., to shifting sampling biases over time (Pechenick et al., 2015). In contrast, the COHA corpus was carefully selected to be genre-balanced and representative of American English over the last 200 years, though as a result it is two orders of magnitude smaller. The COHA corpus also contains pre-extracted word lemmas, which we used to validate that our results hold at both the lemma and raw token levels. All the datasets were aggregated to the granularity of decades.[5]

We follow the recommendations of Levy et al. (2015) in setting the hyperparameters for the embedding methods, though preliminary experiments were used to tune key settings. For all methods, we used symmetric context windows of size 4 (on each side). For SGNS and SVD, we use embeddings of size 300. See Appendix A for further implementation and pre-processing details.

[5]The 2000s decade of the Google data was discarded due to shifts in the sampling methodology (Michel et al., 2011).

2.3 Aligning historical embeddings

In order to compare word vectors from different time-periods we must ensure that the vectors are aligned to the same coordinate axes. Explicit PPMI vectors are naturally aligned, as each column simply corresponds to a context word. Low-dimensional embeddings will not be naturally aligned due to the non-unique nature of the SVD and the stochastic nature of SGNS. In particular, both these methods may result in arbitrary orthogonal transformations, which do not affect pairwise cosine-similarities within-years but will preclude comparison of the same word across time. Previous work circumvented this problem by either avoiding low-dimensional embeddings (e.g., Gulordava and Baroni, 2011; Jatowt and Duh, 2014) or by performing heuristic local alignments per word (Kulkarni et al., 2014).

We use orthogonal Procrustes to align the learned low-dimensional embeddings. Defining $\mathbf{W}^{(t)} \in \mathbb{R}^{d \times |\mathcal{V}|}$ as the matrix of word embeddings learned at year t, we align across time-periods while preserving cosine similarities by optimizing:

$$\mathbf{R}^{(t)} = \arg \min_{\mathbf{Q}^\top \mathbf{Q} = \mathbf{I}} \|\mathbf{W}^{(t)}\mathbf{Q} - \mathbf{W}^{(t+1)}\|_F, \quad (4)$$

with $\mathbf{R}^{(t)} \in \mathbb{R}^{d \times d}$. The solution corresponds to the best rotational alignment and can be obtained efficiently using an application of SVD (Schönemann, 1966).

2.4 Time-series from historical embeddings

Diachronic word embeddings can be used in two ways to quantify semantic change: (i) we can measure changes in pair-wise word similarities over time, or (ii) we can measure how an individual word's embedding shifts over time.

Pair-wise similarity time-series Measuring how the cosine-similarity between pairs of words changes over time allows us to test hypotheses about specific linguistic or cultural shifts in a controlled manner. We quantify shifts by computing the similarity time-series

$$s^{(t)}(w_i, w_j) = \text{cos-sim}(\mathbf{w}_i^{(t)}, \mathbf{w}_j^{(t)}) \quad (5)$$

between two words w_i and w_j over a time-period $(t, ..., t + \Delta)$. We then measure the Spearman correlation (ρ) of this series against time, which allows us to assess the magnitude and significance of pairwise similarity shifts; since the Spearman correlation is non-parametric, this measure essentially detects whether the similarity series increased/decreased over time in a significant manner, regardless of the 'shape' of this curve.[6]

Measuring semantic displacement After aligning the embeddings for individual time-periods, we can use the aligned word vectors to compute the semantic displacement that a word has undergone during a certain time-period. In particular, we can directly compute the cosine-distance between a word's representation for different time-periods, i.e. cos-dist$(\mathbf{w}_t, \mathbf{w}_{t+\Delta})$, as a measure of semantic change. We can also use this measure to quantify 'rates' of semantic change for different words by looking at the displacement between consecutive time-points.

3 Comparison of different approaches

We compare the different distributional approaches on a set of benchmarks designed to test their scientific utility. We evaluate both their *synchronic* accuracy (i.e., ability to capture word similarity within individual time-periods) and their *diachronic* validity (i.e., ability to quantify semantic changes over time).

3.1 Synchronic Accuracy

We evaluated the synchronic (within-time-period) accuracy of the methods using a standard modern benchmark and the 1990s portion of the ENGALL data. On Bruni et al. (2012)'s MEN similarity task of matching human judgments of word similarities, SVD performed best ($\rho = 0.739$), followed by PPMI ($\rho = 0.687$) and SGNS ($\rho = 0.649$). These results echo the findings of Levy et al. (2015), who found SVD to perform best on similarity tasks while SGNS performed best on analogy tasks (which are not the focus of this work).

3.2 Diachronic Validity

We evaluate the diachronic validity of the methods on two historical semantic tasks: detecting known shifts and discovering shifts from data. For both these tasks, we performed detailed evaluations on a small set of examples (28 known shifts and the top-10 "discovered" shifts by each method). Using these reasonably-sized evaluation sets allowed the authors to evaluate each case rigorously using existing literature and historical corpora.

[6] Other metrics or change-point detection approaches, e.g. mean shifts (Kulkarni et al., 2014) could also be used.

Word	Moving towards	Moving away	Shift start	Source
gay	homosexual, lesbian	happy, showy	ca 1920	(Kulkarni et al., 2014)
fatal	illness, lethal	fate, inevitable	<1800	(Jatowt and Duh, 2014)
awful	disgusting, mess	impressive, majestic	<1800	(Simpson et al., 1989)
nice	pleasant, lovely	refined, dainty	ca 1900	(Wijaya and Yeniterzi, 2011)
broadcast	transmit, radio	scatter, seed	ca 1920	(Jeffers and Lehiste, 1979)
monitor	display, screen	—	ca 1930	(Simpson et al., 1989)
record	tape, album	—	ca 1920	(Kulkarni et al., 2014)
guy	fellow, man	—	ca 1850	(Wijaya and Yeniterzi, 2011)
call	phone, message	—	ca 1890	(Simpson et al., 1989)

Table 2: Set of attested historical shifts used to evaluate the methods. The examples are taken from previous works on semantic change and from the Oxford English Dictionary (OED), e.g. using 'obsolete' tags. The shift start points were estimated using attestation dates in the OED. The first six examples are words that shifted dramatically in meaning while the remaining four are words that acquired new meanings (while potentially also keeping their old ones).

Method	Corpus	% Correct	%Sig.
PPMI	ENGALL	96.9	84.4
	COHA	100.0	88.0
SVD	ENGALL	100.0	90.6
	COHA	100.0	96.0
SGNS	ENGALL	100.0	93.8
	COHA	100.0	72.0

Table 3: Performance on detection task, i.e. ability to capture the attested shifts from Table 2. SGNS and SVD capture the correct directionality of the shifts in all cases (%Correct), e.g., *gay* becomes more similar to *homosexual*, but there are differences in whether the methods deem the shifts to be statistically significant at the $p < 0.05$ level (%Sig).

Detecting known shifts. First, we tested whether the methods capture known historical shifts in meaning. The goal in this task is for the methods to correctly capture whether pairs of words moved closer or further apart in semantic space during a pre-determined time-period. We use a set of independently attested shifts as an evaluation set (Table 2). For comparison, we evaluated the methods on both the large (but messy) ENGALL data and the smaller (but clean) COHA data. On this task, all the methods performed almost perfectly in terms of capturing the correct directionality of the shifts (i.e., the pairwise similarity series have the correct sign on their Spearman correlation with time), but there were some differences in whether the methods deemed the shifts statistically significant at the $p < 0.05$ level.[7] Overall, SGNS performed the best on the full English data, but its performance dropped significantly on the smaller COHA dataset, where SVD performed best. PPMI was noticeably worse than the other two approaches (Table 3).

Discovering shifts from data. We tested whether the methods discover reasonable shifts by examining the top-10 words that changed the most from the 1900s to the 1990s according to the semantic displacement metric introduced in Section 2.4 (limiting our analysis to words with relative frequencies above 10^{-5} in both decades). We used the ENGFIC data as the most-changed list for ENGALL was dominated by scientific terms due to changes in the corpus sample.

Table 4 shows the top-10 words discovered by each method. These shifts were judged by the authors as being either clearly genuine, borderline, or clearly corpus artifacts. SGNS performed by far the best on this task, with 70% of its top-10 list corresponding to genuine semantic shifts, followed by 40% for SVD, and 10% for PPMI. However, a large portion of the discovered words for PPMI (and less so SVD) correspond to borderline cases, e.g. *know*, that have not necessarily shifted significantly in meaning but that occur in different contexts due to global genre/discourse shifts. The poor quality of the nearest neighbors generated by the PPMI algorithm—which are skewed by PPMI's sensitivity to rare events—also made it difficult to assess the quality of its discovered shifts. SVD was the most sensitive to corpus artifacts (e.g., co-occurrences due to cover pages and advertisements), but it still captured a number of genuine semantic shifts.

We opted for this small evaluation set and relied on detailed expert judgments to minimize ambiguity; each potential shift was analyzed in detail by consulting consulting existing literature (especially the OED; Simpson et al., 1989) and all disagreements were discussed.

Table 5 details representative example shifts in English, French, and German. Chinese lacks sufficient historical data for this task, as only years 1950-1999 are usable; however, we do still see

[7] All subsequent significance tests are at $p < 0.05$.

Method	Top-10 words that changed from 1900s to 1990s
PPMI	know, got, would, decided, think, stop, remember, **started**, must, wanted
SVD	harry, **headed**, **calls**, **gay**, wherever, male, **actually**, special, cover, naturally
SGNS	**wanting**, **gay**, **check**, **starting**, **major**, **actually**, touching, harry, **headed**, romance

Table 4: Top-10 English words with the highest semantic displacement values between the 1900s and 1990s. Bolded entries correspond to real semantic shifts, as deemed by examining the literature and their nearest neighbors; for example, *headed* shifted from primarily referring to the "top of a body/entity" to referring to "a direction of travel." Underlined entries are borderline cases that are largely due to global genre/discourse shifts; for example, *male* has not changed in meaning, but its usage in discussions of "gender equality" is relatively new. Finally, unmarked entries are clear corpus artifacts; for example, *special*, *cover*, and *romance* are artifacts from the covers of fiction books occasionally including advertisements etc.

Word	Language	Nearest-neighbors in 1900s	Nearest-neighbors in 1990s
wanting	English	lacking, deficient, lacked, lack, needed	wanted, something, wishing, anything, anybody
asile	French	refuge, asiles, hospice, vieillards, infirmerie	demandeurs, refuge, hospice, visas, admission
widerstand	German	scheiterte, volt, stromstärke, leisten, brechen	opposition, verfolgung, nationalsozialistische, nationalsozialismus, kollaboration

Table 5: Example words that changed dramatically in meaning in three languages, discovered using SGNS embeddings. The examples were selected from the top-10 most-changed lists between 1900s and 1990s as in Table 4. In English, *wanting* underwent subjectification and shifted from meaning "lacking" to referring to subjective "desire", as in "the education system is wanting" (1900s) vs. "I've been wanting to tell you" (1990s). In French *asile* ("asylum") shifted from primarily referring to "hospitals, or infirmaries" to also referring to "asylum seekers, or refugees". Finally, in German *Widerstand* ("resistance") gained a formal meaning as referring to the local German resistance to Nazism during World War II.

some significant changes for Chinese in this short time-period, such as 病毒 ("virus") moving closer to 电脑 ("computer", $\rho = 0.89$).

3.3 Methodological recommendations

PPMI is clearly worse than the other two methods; it performs poorly on all the benchmark tasks, is extremely sensitive to rare events, and is prone to false discoveries from global genre shifts. Between SVD and SGNS the results are somewhat equivocal, as both perform best on two out of the four tasks (synchronic accuracy, ENGALL detection, COHA detection, discovery). Overall, SVD performs best on the synchronic accuracy task and has higher average accuracy on the 'detection' task, while SGNS performs best on the 'discovery' task. These results suggest that both these methods are reasonable choices for studies of semantic change but that they each have their own tradeoffs: SVD is more sensitive, as it performs well on detection tasks even when using a small dataset, but this sensitivity also results in false discoveries due to corpus artifacts. In contrast, SGNS is robust to corpus artifacts in the discovery task, but it is not sensitive enough to perform well on the detection task with a small dataset. Qualitatively, we found SGNS to be most useful for discovering new shifts and visualizing changes (e.g., Figure 1), while SVD was most effective for detecting subtle shifts in usage.

4 Statistical laws of semantic change

We now show how diachronic embeddings can be used in a large-scale cross-linguistic analysis to reveal statistical laws that relate frequency and polysemy to semantic change. In particular, we analyze how a word's rate of semantic change,

$$\Delta^{(t)}(w_i) = \text{cos-dist}(\mathbf{w}_i^{(t)}, \mathbf{w}_i^{(t+1)}) \qquad (6)$$

depends on its frequency, $f^{(t)}(w_i)$ and a measure of its polysemy, $d^{(t)}(w_i)$ (defined in Section 4.4).

4.1 Setup

We present results using SVD embeddings (though analogous results were found to hold with SGNS). Using all four languages and all four conditions for English (ENGALL, ENGFIC, and COHA with and without lemmatization), we performed regression analysis on rates of semantic change, $\Delta^{(t)}(w_i)$; thus, we examined one data-point per word for each pair of consecutive decades and analyzed how a word's frequency and polysemy at time t correlate with its degree of semantic displacement over the next decade. To ensure the robustness of our results, we analyzed only the top-10000 non–stop words by aver-

Top-10 most polysemous	yet, always, even, little, called, also, sometimes, great, still, quite
Top-10 least polysemous	photocopying, retrieval, thirties, mom, sweater, forties, seventeenth, fifteenth, holster, postage

Table 6: The top-10 most and least polysemous words in the ENGFIC data. Words like *yet*, *even*, and *still* are used in many diverse ways and are highly polysemous. In contrast, words like *photocopying*, *postage*, and *holster* tend to be used in very specific well-clustered contexts, corresponding to a single sense; for example, *mail* and *letter* are both very likely to occur in the context of *postage* and are also likely to co-occur with each other, independent of *postage*.

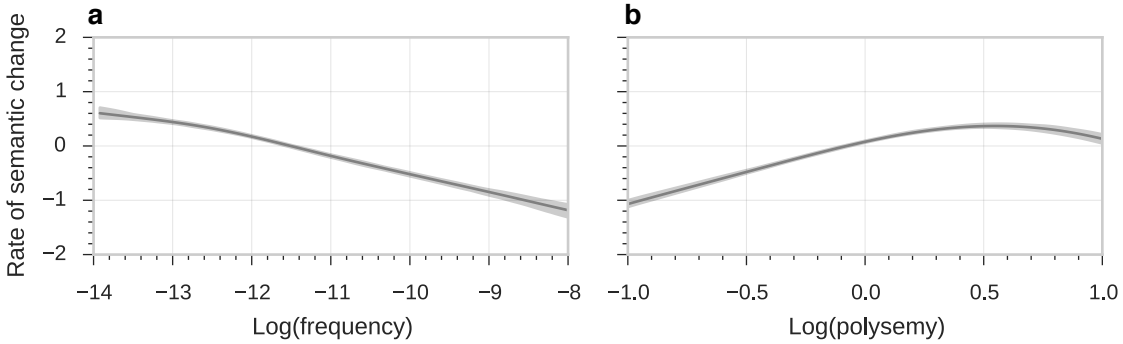

Figure 2: Higher frequency words have lower rates of change (**a**), while polysemous words have higher rates of change (**b**). The negative curvature for polysemy—which is significant only at high $d(w_i)$—varies across datasets and was not present with SGNS, so it is not as robust as the clear linear trend that was seen with all methods and across all datasets. The trendlines show 95% CIs from bootstrapped kernel regressions on the ENGALL data (Li and Racine, 2007).

age historical frequency (lower-frequency words tend to lack sufficient co-occurrence data across years) and we discarded proper nouns (changes in proper noun usage are primarily driven by non-linguistic factors, e.g. historical events, Traugott and Dasher, 2001). We also log-transformed the semantic displacement scores and normalized the scores to have zero mean and unit variance; we denote these normalized scores by $\tilde{\Delta}^{(t)}(w_i)$.

We performed our analysis using a linear mixed model with random intercepts per word and fixed effects per decade; i.e., we fit β_f, β_d, and β_t s.t.

$$\tilde{\Delta}^{(t)}(w_i) = \beta_f \log\left(f^{(t)}(w_i)\right) + \beta_d \log\left(d^{(t)}(w_i)\right) + \beta_t + z_{w_i} + \epsilon_{w_i}^{(t)} \;\; \forall w_i \in \mathcal{V}, t \in \{t_0, ..., t_n\}, \quad (7)$$

where $z_{w_i} \sim \mathcal{N}(0, \sigma_{w_i})$ is the random intercept for word w_i and $\epsilon_{w_i}^{(t)} \in \mathcal{N}(0, \sigma)$ is an error term. β_f, β_d and β_t correspond to the fixed effects for frequency, polysemy and the decade t, respectively[8]. Intuitively, this model estimates the effects of frequency and polysemy on semantic change, while controlling for temporal trends and correcting for the fact that measurements on same word will be correlated across time. We fit (7) using the standard restricted maximum likelihood algorithm (McCulloch and Neuhaus, 2001; Appendix C).

[8]Note that time is treated as a categorical variable, as each decade has its own fixed effect.

4.2 Overview of results

We find that, across languages, rates of semantic change obey a scaling relation of the form

$$\Delta(w_i) \propto f(w_i)^{\beta_f} \times d(w_i)^{\beta_d}, \quad (8)$$

with $\beta_f < 0$ and $\beta_d > 0$. This finding implies that frequent words change at slower rates while polysemous words change faster, and that both these relations scale as power laws.

4.3 Law of conformity: Frequently used words change at slower rates

Using the model in equation (7), we found that the logarithm of a word's frequency, $\log(f(w_i))$, has a significant and substantial negative effect on rates of semantic change in all settings (Figures 2a and 3a). Given the use of log-transforms in pre-processing the data this implies rates of semantic change are proportional to a negative power (β_f) of frequency, i.e.

$$\Delta(w_i) \propto f(w_i)^{\beta_f}, \quad (9)$$

with $\beta_f \in [-1.26, -0.27]$ across languages/datasets. The relatively large range of values for β_f is due to the fact that the COHA datasets are outliers due to their substantially smaller sample sizes (Figure 3; the range is $\beta_f \in [-0.66, -0.27]$ with COHA excluded).

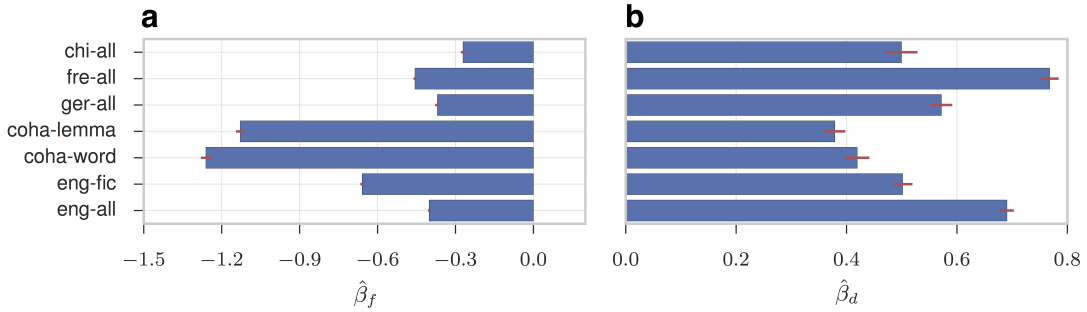

Figure 3: **a**, The estimated linear effect of log-frequency ($\hat{\beta}_f$) is significantly negative across all languages. The effect is significantly stronger in the COHA data, but this is likely due to its small sample size ($\sim$100$\times$ smaller than the other datasets); the small sample size introduces random variance that may artificially inflate the effect of frequency. From the COHA data, we also see that the result holds regardless of whether lemmatization is used. **b**, Analogous trends hold for the linear effect of the polysemy score ($\hat{\beta}_d$), which is strong and significantly positive across all conditions. Again, we see that the smaller COHA datasets are mild outliers.[9] 95% CIs are shown.

4.4 Law of innovation: Polysemous words change at faster rates

There is a common hypothesis in the linguistic literature that "words become semantically extended by being used in diverse contexts" (Winter et al., 2014), an idea that dates back to the writings of Bréal (1897). We tested this notion by examining the relationship between polysemy and semantic change in our data.

Quantifying polysemy

Measuring word polysemy is a difficult and fraught task, as even "ground truth" dictionaries differ in the number of senses they assign to words (Simpson et al., 1989; Fellbaum, 1998). We circumvent this issue by measuring a word's *contextual diversity* as a proxy for its polysemousness. The intuition behind our measure is that words that occur in many distinct, unrelated contexts will tend to be highly polysemous. This view of polysemy also fits with previous work on semantic change, which emphasizes the role of contextual diversity (Bréal, 1897; Winter et al., 2014).

We measure a word's contextual diversity, and thus polysemy, by examining its neighborhood in an empirical co-occurrence network. We construct empirical co-occurrence networks using the PPMI measure defined in Section 2. In these networks words are connected to each other if they co-occur more than one would expect by chance (after smoothing). The polysemy of a word is then measured as its local clustering coefficient within this network (Watts and Strogatz, 1998):

$$d(w_i) = -\frac{\sum_{c_i,c_j \in N_{\text{PPMI}}(w_i)} \mathbb{I}\left\{\text{PPMI}(c_i, c_j) > 0\right\}}{|N_{\text{PPMI}}(w_i)|(|N_{\text{PPMI}}(w_i)| - 1)}, \tag{10}$$

where $N_{\text{PPMI}}(w_i) = \{w_j : \text{PPMI}(w_i, w_j) > 0\}$. This measure counts the proportion of w_i's neighbors that are also neighbors of each other. According to this measure, a word will have a high clustering coefficient (and thus a low polysemy score) if the words that it co-occurs with also tend to co-occur with each other. Polysemous words that are contextually diverse will have low clustering coefficients, since they appear in disjointed or unrelated contexts.

Variants of this measure are often used in word-sense discrimination and correlate with, e.g., number of senses in WordNet (Dorow and Widdows, 2003; Ferret, 2004). However, we found that it was slightly biased towards rating contextually diverse discourse function words (e.g., *also*) as highly polysemous, which needs to be taken into account when interpreting our results. We opted to use this measure, despite this bias, because it has the strong benefit of being clearly interpretable: it simply measures the extent to which a word appears in diverse textual contexts. Table 6 gives examples of the least and most polysemous words in the ENGFIC data, according to this score.

As expected, this measure has significant intrinsic positive correlation with frequency. Across datasets, we found Pearson correlations in the range $0.45 < r < 0.8$ (all $p < 0.05$), confirming frequent words tend to be used in a greater diversity of contexts. As a consequence of this high correlation, we interpret the effect of this measure only after controlling for frequency (this control is naturally captured in equation (7)).

[9] The COHA data is $\sim$100$\times$ smaller, which has a global effect on the construction of the co-occurrence network (e.g., lower average degree) used to compute polysemy scores.

Polysemy and semantic change

After fitting the model in equation (7), we found that the logarithm of the polysemy score exhibits a strong positive effect on rates of semantic change, throughout all four languages (Figure 3b). As with frequency, the relation takes the form of a power law

$$\Delta(w_i) \propto d(w_i)^{\beta_d}, \tag{11}$$

with a language/corpus dependent scaling constant in $\beta_d \in [0.37, 0.77]$. Note that this relationship is a complete reversal from what one would expect according to $d(w_i)$'s positive correlation with frequency; i.e., since frequency and polysemy are highly positively correlated, one would expect them to have similar effects on semantic change, but we found that the effect of polysemy completely reversed after controlling for frequency. Figure 2b shows the relationship of polysemy with rates of semantic change in the ENGALL data after regressing out effect of frequency (using the method of Graham, 2003).

5 Discussion

We show how distributional methods can reveal statistical laws of semantic change and offer a robust methodology for future work in this area.

Our work builds upon a wealth of previous research on quantitative approaches to semantic change, including prior work with distributional methods (Sagi et al., 2011; Wijaya and Yeniterzi, 2011; Gulordava and Baroni, 2011; Jatowt and Duh, 2014; Kulkarni et al., 2014; Xu and Kemp, 2015), as well as recent work on detecting the emergence of novel word senses (Lau et al., 2012; Mitra et al., 2014; Cook et al., 2014; Mitra et al., 2015; Frermann and Lapata, 2016). We extend these lines of work by rigorously comparing different approaches to quantifying semantic change and by using these methods to propose new statistical laws of semantic change.

The two statistical laws we propose have strong implications for future work in historical semantics. The *law of conformity*—frequent words change more slowly—clarifies frequency's role in semantic change. Future studies of semantic change must account for frequency's conforming effect: when examining the interaction between some linguistic process and semantic change, the *law of conformity* should serve as a null model in which the interaction is driven primarily by underlying frequency effects.

The *law of innovation*—polysemous words change more quickly—quantifies the central role polysemy plays in semantic change, an issue that has concerned linguists for more than 100 years (Bréal, 1897). Previous works argued that semantic change leads to polysemy (Wilkins, 1993; Hopper and Traugott, 2003). However, our results show that polysemous words change faster, which suggests that polysemy may actually lead to semantic change.

Overall, these two factors—frequency and polysemy—explain between 48% and 88% of the variance[10] in rates of semantic change (across conditions). This remarkable degree of explanatory power indicates that frequency and polysemy are perhaps the two most crucial linguistic factors that explain rates of semantic change over time.

These empirical statistical laws also lend themselves to various causal mechanisms. The *law of conformity* might be a consequence of learning: perhaps people are more likely to use rare words mistakenly in novel ways, a mechanism formalizable by Bayesian models of word learning and corresponding to the biological notion of genetic drift (Reali and Griffiths, 2010). Or perhaps a sociocultural conformity bias makes people less likely to accept novel innovations of common words, a mechanism analogous to the biological process of purifying selection (Boyd and Richerson, 1988; Pagel et al., 2007). Moreover, such mechanisms may also be partially responsible for the *law of innovation*. Highly polysemous words tend to have more rare senses (Kilgarriff, 2004), and rare senses may be unstable by the *law of conformity*. While our results cannot confirm such causal links, they nonetheless highlight a new role for frequency and polysemy in language change and the importance of distributional models in historical research.

A Hyperparameter and pre-processing details

For all datasets, words were lowercased and stripped of punctuation. For the Google datasets we built models using the top-100000 words by their average frequency over the entire historical time-periods, and we used the top-50000 for COHA. During model learning we also discarded all words within a year that occurred below a certain threshold (500 for the Google data, 100 for the COHA data).

For all methods, we used the hyperparameters recommended in Levy et al. (2015). For the context word distributions in all methods, we used context distribution smoothing with a smoothing parameter of 0.75. Note that for SGNS this corresponds to smoothing the unigram negative sampling distribution. For both, SGNS and PPMI, we set the negative sample prior $\alpha = \log(5)$, while we set this value to $\alpha = 0$ for SVD, as this improved results. When using SGNS on the Google data, we also subsampled, with words being random removed with probability $p_r(w_i) = 1 - \sqrt{\frac{10^{-5}}{f(w_i)}}$, as recommended by Levy et al. (2015) and Mikolov et al. (2013). Furthermore, to improve the computational efficiency of SGNS (which works with text streams and not co-occurrence counts), we downsampled the larger years in the Google N-Gram data to have at most 10^9 tokens. No such subsampling was performed on the COHA data.

For all methods, we defined the context set to simply be the same vocabulary as the target words, as is standard in most word vector applications (Levy et al., 2015). However, we found that the PPMI method benefited substantially from larger contexts (similar results were found in Bullinaria and Levy, 2007), so we did not remove any low-frequency words per year from the context for that method. The other embedding approaches did not appear to benefit from the inclusion of these low-frequency terms, so they were dropped for computational efficiency.

For SGNS, we used the implementation provided in Levy et al. (2015). The implementations for PPMI and SVD are released with the code package associated with this work.

B Visualization algorithm

To visualize semantic change for a word w_i in two dimensions we employed the following procedure, which relies on the t-SNE embedding method (Van der Maaten and Hinton, 2008) as a subroutine:

1. Find the union of the word w_i's k nearest neighbors over all necessary time-points.

2. Compute the t-SNE embedding of these words on the most recent (i.e., the modern) time-point.

3. For each of the previous time-points, hold all embeddings fixed, except for the target word's (i.e., the embedding for w_i), and optimize a new t-SNE embedding only for the target word. We found that initializing the embedding for the target word to be the centroid of its k'-nearest neighbors in a time-point was highly effective.

Thus, in this procedure the background words are always shown in their "modern" positions, which makes sense given that these are the current meanings of these words. This approximation is necessary, since in reality all words are moving.

C Regression analysis details

In addition to the pre-processing mentioned in the main text, we also normalized the contextual diversity scores $d(w_i)$ within years by subtracting the yearly median. This was necessary because there was substantial changes in the median contextual diversity scores over years due to changes in corpus sample sizes etc. Data points corresponding to words that occurred less than 500 times during a time-period were also discarded, as

these points lack sufficient data to robustly estimate change rates (this threshold only came into effect on the COHA data, however). We removed stop words and proper nouns by (i) removing all stop-words from the available lists in Python's NLTK package (Bird et al., 2009) and (ii) restricting our analysis to words with part-of-speech (POS) tags corresponding to four main linguistic categories (common nouns, verbs, adverbs, and adjectives), using the POS sources in Table 1.

When analyzing the effects of frequency and contextual diversity, the model contained fixed effects for these features and for time along with random effects for word identity. We opted not to control for POS tags in the presented results, as contextual diversity is co-linear with these tags (e.g., adverbs are more contextual diverse than nouns), and the goal was to demonstrate the main effect of contextual diversity across all word types. That said, the effect of contextual diversity remained strong and significantly positive in all datasets even after controlling for POS tags.

To fit the linear mixed models, we used the Python `statsmodels` package with restricted maximum likelihood estimation (REML) (Seabold and Perktold, 2010). All mentioned significance scores were computed according to Wald's z-tests, though these results agreed with Bonferroni corrected likelihood ratio tests on the `eng-all` data.

The visualizations in Figure 2 were computed on the `eng-all` data and correspond to bootstrapped locally-linear kernel regressions with bandwidths selected via the AIC Hurvitch criteria (Li and Racine, 2007).

Beyond Plain Spatial Knowledge: Determining Where Entities Are and Are Not Located, and For How Long

Alakananda Vempala and **Eduardo Blanco**
Human Intelligence and Language Technologies Lab
University of North Texas
Denton, TX, 76203
AlakanandaVempala@my.unt.edu, eduardo.blanco@unt.edu

Abstract

This paper complements semantic role representations with spatial knowledge beyond indicating plain locations. Namely, we extract where entities are (and are not) located, and for how long (seconds, hours, days, etc.). Crowdsourced annotations show that this additional knowledge is intuitive to humans and can be annotated by non-experts. Experimental results show that the task can be automated.

1 Introduction

Extracting meaning from text is crucial for true text understanding and an important component of several natural language processing systems. Among many others, previous efforts have focused on extracting causal relations (Bethard and Martin, 2008), semantic relations between nominals (Hendrickx et al., 2010), spatial relations (Kordjamshidi et al., 2011) and temporal relations (Pustejovsky et al., 2003; Chambers et al., 2014).

In terms of corpora development and automated approaches, semantic roles are one of the most studied semantic representations (Toutanova et al., 2005; Màrquez et al., 2008). They have been proven useful for, among others, coreference resolution (Ponzetto and Strube, 2006) and question answering (Shen and Lapata, 2007). While semantic roles provide a useful semantic layer, they capture a portion of the meaning encoded in all but the simplest statements. Consider the sentence in Figure 1 and the semantic roles of *drove* (solid arrows). In addition to these roles, humans intuitively understand that (dashed arrow) (1) *John* was not located in *Berlin* before or during *drove*, (2) he was located in *Berlin* after *drove* for a short period of time (presumably, until he was done picking up the package, i.e., for a few minutes to an hour), and then left *Berlin* and thus (3) was not located there anymore. Some of this additional spatial knowledge is inherent to the motion verb *drive*: people cannot drive to the location where they are currently located, and they will be located at the destination of driving after *driving* takes place. But determining for how long the agent of *drive* remains at the destination depends on the arguments of *drive*: from *[John]*$_{\text{AGENT}}$ *[drove]*$_{v}$ *[home]*$_{\text{DESTINATION}}$ *[after an exhausting work day]*$_{\text{TIME}}$, it is reasonable to believe that *John* will be located at *home* overnight.

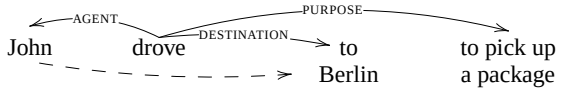

Figure 1: Semantic roles (solid arrows) and additional spatial knowledge (dashed arrow).

This paper manipulates semantic roles in order to extract temporally-anchored spatial knowledge. We extract where entities are and are *not* located, and temporally anchor this information. Temporal anchors indicate for how long something is (or is not) located somewhere, e.g., for 5 minutes before (or after) an event. We target additional spatial knowledge not only between arguments of motion verbs as exemplified above, but also between intra-sentential arguments of any verb. The main contributions are: (1) crowdsourced annotations on top of OntoNotes[1] indicating where something is and is not located (polarity), and for how long (temporal anchors); (2) detailed annotation analysis using coarse- and fine-grained labels (yes / no vs. seconds, minutes, years, etc.); and (3) experiments detailing results with several feature combinations, and using gold-standard and predicted linguistic information.

Berlin, Germany, August 7-12, 2016.

2 Definitions and Background

We use R(x, y) to denote a semantic relationship R between x and y. R(x, y) can be read "x has R y", e.g., AGENT(*drove*, *John*) can be read "*drove* has AGENT *John*." By definition, semantic roles are semantic relationships between predicates and their arguments—for all semantic roles R(x, y), x is a predicate and y is an argument of x. Generally speaking, semantic roles capture who did what to whom, how, when and where.

We use the term *additional spatial knowledge* to refer to spatial knowledge not captured with semantic roles, i.e., spatial meaning between x and y where (1) x is not a predicate or (2) x is a predicate and y is not an argument of x. As we shall see, we go beyond extracting "x has LOCATION y" with plain LOCATION(x, y) relations. We extract where entities are and are not located, and for how long they are located (and not located) somewhere.

2.1 Semantic Roles in OntoNotes

OntoNotes (Hovy et al., 2006) is large corpus (≈64K sentences) that includes verbal semantic role annotations, i.e., the first argument x of any role R(x, y) is a verb.[2] OntoNotes semantic roles follow PropBank framesets (Palmer et al., 2005). It uses a set of numbered arguments (ARG_0–ARG_5) whose meanings are verb-dependent, e.g., ARG_2 is used for "*employer*" with verb *work.01* and "*expected terminus of sleep*" with verb *sleep.01*. Additionally, it uses argument modifiers which share a common meaning across verbs (ARGM-LOC, ARGM-TMP, ARGM-PRP, ARGM-CAU, etc.). For a detailed description of OntoNotes semantic roles, we refer the reader to the LDC catalog[3] and PropBank (Palmer et al., 2005). To improve readability, we often rename numbered arguments, e.g., AGENT instead of ARG_0 in Figure 1.

3 Related Work

Approaches to extract PropBank-style semantic roles have been studied for years (Carreras and Màrquez, 2005), state-of-the-art tools sobtain F-measures of 83.5 (Lewis et al., 2015). In this paper, we complement semantic role representations with temporally-anchored spatial knowledge.

Extracting additional meaning on top of popular corpora is by no means a new problem. Gerber and Chai (2010) augmented NomBank (Meyers et al., 2004) annotations with additional numbered arguments appearing in the same or previous sentences, and Laparra and Rigau (2013) presented an improved algorithm for the same task. The SemEval-2010 Task 10 (Ruppenhofer et al., 2009) targeted cross-sentence missing arguments in FrameNet (Baker et al., 1998) and PropBank (Palmer et al., 2005). Silberer and Frank (2012) casted the SemEval task as an anaphora resolution task. We have previously proposed an unsupervised framework to compose semantic relations out of previously extracted relations (Blanco and Moldovan, 2011), and a supervised approach to infer additional argument modifiers (ARGM) for verbs in PropBank (Blanco and Moldovan, 2014). Unlike the current work, these previous efforts (1) improve the semantic representation of verbal and nominal predicates, or (2) infer relations between arguments of the same predicate.

More recently, we showed that spatial relations can be inferred from PropBank-style semantic roles (Blanco and Vempala, 2015; Vempala and Blanco, 2016). In this paper, we expand on this idea as follows. First, we not only extract whether "x has LOCATION y" before, during or after an event, but also specify for how long before and after (seconds, minutes, hours, days, weeks, months, years, etc.). Second, we release crowdsourced annotations for 1,732 potential additional spatial relations. Third, we experiment with both gold and predicted linguistic information.

Spatial semantics has received considerable attention in the last decade.

The task of spatial role labeling (Kordjamshidi et al., 2011; Kolomiyets et al., 2013) aims at representing spatial information with so-called spatial roles, e.g., trajector, landmark, spatial and motion indicators, etc. Unlike us, spatial role labeling does not aim at extracting where entities are *not* located or temporally-anchored spatial information. But doing so is intuitive to humans, as the examples and crowdsourced annotations in this paper show. Spatial knowledge is intuitively associated with motion events, e.g., *drive*, *go*, *fly*, *walk*, *run*. Hwang and Palmer (2015) presented a classifier to detect caused motion constructions triggered by non-motion verbs, e.g., *The crowd laughed the clown off the stage* (i.e., the crowd made the clown leave the stage). Our work does not target motion verbs or motion constructions,

[2] We use the CoNLL 2011 Shared Task release (Pradhan et al., 2011), `http://conll.cemantix.org/2011/`

[3] `https://catalog.ldc.upenn.edu/LDC2013T19`

as the examples in Table 3 show, non-motion constructions triggered by non-motion verbs also allow us to infer temporally-anchored spatial meaning, e.g., *played*, *honored*, *taught*, *fighting*.

4 Corpus Creation and Analysis

Our goal is to complement semantic role representations with additional spatial knowledge. Specifically, our goal is to infer temporally-anchored spatial knowledge between *x* and *y*, where semantic roles ARG$_i$(x_{verb}, *x*) and ARGM-LOC(y_{verb}, *y*) exists in the same sentence. In order to achieve this goal, we follow a two-step methodology. First, we automatically generate potential additional spatial knowledge by combining selected semantic roles. Second, we crowdsource annotations, including polarity and temporal anchors, to validate or discard the potential additional knowledge.

4.1 Generating Potential Spatial Knowledge

We generate potential additional relations LOCATION(*x*, *y*) by combining all ARG$_i$(x_{verb}, *x*) and ARGM-LOC(y_{verb}, *y*) semantic roles within a sentence (x_{verb} and y_{verb} need not be the same). Then, we enforce the following restrictions:

1. *x* and *y* must not overlap;
2. the head of *x* must be a named entity *person*, *org*, *work_of_art*, *fac*, *norp*, *product* or *event*;
3. the head of *y* must be a noun subsumed by *physical_entity.n.01* in WordNet, or a named entity *fac*, *gpe*, *loc*, or *org*;[4] and
4. the heads of *x* and *y* must be different than the heads of all previously generated pairs.

These restrictions were designed after manual analysis of randomly selected combinations of ARG$_i$ and ARGM-LOC semantic roles with two goals in mind: to (1) reduce the annotation effort and (2) generate the least amount of invalid potential additional spatial knowledge without arbitrarily discarding any predicates (e.g., focus only on motion verbs). Additional relations not satisfying restriction 1 are nonsensical, and restriction 4 simply discards potential additional relations that have already been generated. Restrictions 2 and 3 are designed to improve the likelihood that the potential additional spatial knowledge will not be discarded when crowdsourcing annotations, e.g., locations whose head is an adverb such as *here* and *there* (11% of all ARGM-LOC roles) do not yield valid additional spatial knowledge.

OntoNotes annotates 9,612 ARGM-LOC semantic roles, and the number of potential LOCATION relations generated is 1,732. Thus, our methodology aims at adding 18% of additional spatial relations on top of OntoNotes semantic roles. If we consider each temporal anchor as a different spatial relation, we aim at adding 54% additional spatial relations. As we shall see, over 69% of the additional potential relations are valid (Section 4.3).

4.2 Crowdsourcing Spatial Knowledge

Once potential spatial knowledge is generated, it must be validated or discarded. We are interested in additional spatial knowledge as intuitively understood by humans, so we avoid lengthy annotation guidelines and ask simple questions to non-experts via Amazon Mechanical Turk.

After in-house pilot annotations, it became clear that asking "Is *x* located in/at *y*" for each potential LOCATION(*x*, *y*) and forcing annotators to answer *yes* or *no* is suboptimal. For example, consider again Figure 1 and question "Is *John* located in *Berlin*?". An unabridged natural answer would be "not before or during *drove*, but certainly after *drove* for a few minutes until he was done *picking up the package*." In other words, it is intuitive to consider polarity (whether *x* is or is not located at *y*) and temporal anchors (for how long?).

We designed the interface in Figure 2 to gather annotations including polarity and temporal anchors, and accounting for granularity levels. Answers map to the following coarse-grained labels:

- Before and after: `yes`, `no`, `unk` and `inv`.
- During: `yes` (first 2 options), `no`, `unk` and `inv`.

Label `unk` stands for *unknown* and `inv` for *invalid*. Furthermore, `yes` maps to these fine-grained labels indicating specific periods of time:

- Before and after: an integer and a unit of time (`secs`, `mins`, `hours`, `days`, `weeks`, `months` or `years`)[5], or `inf` for infinity.
- During: `entire` or `some`.

[4] For a description and examples of these named entity types, refer to (Weischedel and Brunstein, 2005).

[5] The interface restricts the range of valid integers, e.g., numbers selectable with `secs` range from 1 to 59.

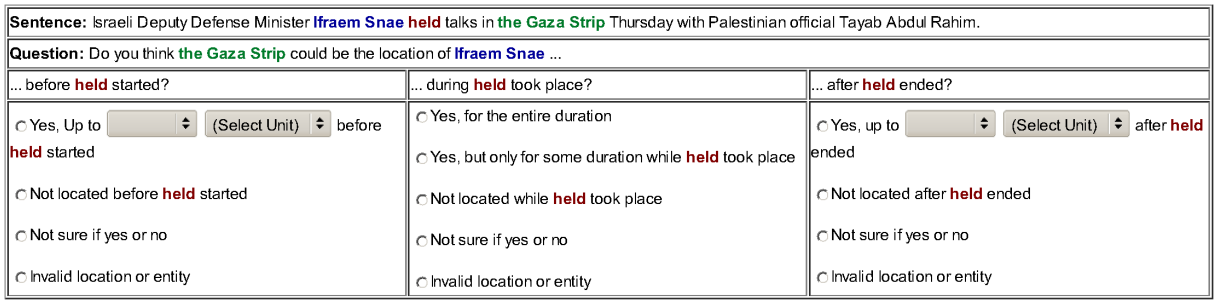

Figure 2: Amazon Mechanical Turk interface to collect temporally-anchored spatial annotations. Annotators were also provided with a description and examples of all answers (not shown).

	secs	mins	hours	days	weeks	months	years	inf	entire	some
Before	0.20	7.55	11.33	7.36	3.78	8.15	46.72	14.91	n/a	n/a
During	n/a	n/a	n/a	n/a	n/a	n/a	n/a	n/a	97.77	2.23
After	0.50	6.48	11.29	6.48	3.34	6.29	29.47	36.15	n/a	n/a

Table 1: Percentage of fine-grained labels for instances annotated with coarse-grained label `yes`.

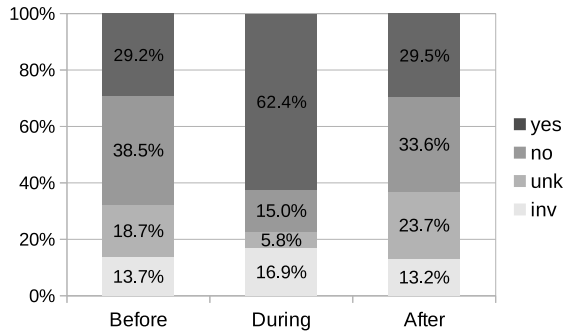

Figure 3: Percentage of coarse-grained labels per temporal anchor. Total number of annotations is $1{,}732 \times 3 = 5{,}196$.

We created one Human Intelligence Task (HIT) per potential LOCATION(x, y), and recruited annotators with previous approval rate $\geq 95\%$ and 5,000 or more previous approved HITs. A total of 74 annotators participated in the task, on average, they annotated 163.24 HITs (maximum: 1,547, minimum: 1). We rejected submissions that took unusually short time compared to other submissions, and those from annotators who always chose the same label. Overall, we only rejected 1.2% of submissions. We collected 7 annotations per HIT and paid $0.05 per HIT.

4.3 Annotation Analysis

Figure 3 shows the percentage of coarse-grained labels per temporal anchor. Labels `yes` and `no` combined account for 67.7% of labels (before), 77.4% (during) and 63.1% (after). Note that both `yes` and `no` yield valid additional spatial knowledge: whether x is (or is not) located at y. Annotators could not commit to `yes` or `no` in 16.1% of questions on average (`unk`), with a much smaller percentage for during temporal anchor (5.8%; before: 18.7%, after: 23.7%). This is not surprising, as arguments of some verbs, e.g., AGENT of *play*, must be located at the location of the event during the event, but not necessarily before or after. Finally, `inv` only accounts for 14.6% of labels (before: 13.7%, during: 16.9%, after: 13.2%), thus most potential additional knowledge automatically generated (Section 4.1) can be understood.

Percentages of fine-grained labels per temporal span, i.e., refinements of `yes` coarse-grained labels, are shown in Table 1. The vast majority of times (97.77%) annotators believe an entity is at a location during an event, the entity is there for the entire duration of the event (`entire`). Annotators barely used label `secs` (before: 0.20% and after: 0.50%), but percentages range between 3.34% and 46.72% for other units of time (uniform distribution would be $1/8 = 12.5\%$). Labels `years` and `inf`, which indicate that an entity is located somewhere for years or indefinitely before (or after) an event, are the most common fine-grained labels for *before* and *after* (14.91–46.72%).

4.3.1 Annotation Quality

Table 2 presents agreement measures. Pearson correlations are the weighted averages between each annotator and the majority label and are calculated following this mapping: (coarse labels): `yes`: 1, `unk`/`inv`: 0, `no`: -1; (fine labels): before/after: `secs`: 1, `mins`: $1 + 1/7$, `hours`:

	Coarse-grained labels						Fine-grained labels					
	Pearson	% instances s.t. a annotators agree					Pearson	% instances s.t. a annotators agree				
		$a=7$	$a\geq 6$	$a\geq 5$	$a\geq 4$	$a\geq 3$		$a=7$	$a\geq 6$	$a\geq 5$	$a\geq 4$	$a\geq 3$
Before	0.73	0.9	8.0	30.0	65.8	97.2	0.67	0.8	6.0	21.6	49.3	85.2
During	0.81	8.9	39.9	59.1	81.4	98.3	0.79	2.1	19.5	45.8	71.8	94.1
After	0.66	0.7	6.0	27.0	62.9	96.6	0.62	0.5	4.6	19.8	49.9	87.1
All	0.67	3.5	18.0	38.8	70.0	97.4	0.64	1.1	10.0	29.0	57.0	88.8

Table 2: Weighed Pearson correlations between annotators and the majority label, and percentage of instances for which at least 7, 6, 5, 4 and 3 annotators (out of 7) agree.

Statement	Before		During		After	
	C	F	C	F	C	F
Statement 1: [...] [Hsia]$_{\text{ARG}_0,\,v_1,v_2}$ [stopped]$_{v_1}$ off [in Milan]$_{\text{ARGM-LOC},v_1}$ [to [visit]$_{v_2}$ [Hsiao Chin]$_{\text{ARG}_1,v_2}$]$_{\text{ARGM-PRP},v_1}$.						
x: *Hsia*, *y*: *Milan*, y_{verb}: *stopped*	yes	mins	yes	entire	yes	hours
x: *Hsiao Chin*, *y*: *Milan*, y_{verb}: *stopped*	yes	years	yes	entire	yes	years
Statement 2: [President Clinton]$_{\text{ARG}_0,v_1}$ [played]$_{v_1}$ [a supporting role]$_{\text{ARG}_1,v_1}$ [today]$_{\text{ARGM-TMP},v_1}$ [in [New York City where]$_{\text{ARGM-LOC},v_2}$ [the first lady, Senator Clinton]$_{\text{ARG}_1,v_2}$, was [honored]$_{v_2}$ [at Madison Square Garden]$_{\text{ARGM-LOC},v_2}$]$_{\text{ARGM-LOC},v_1}$.						
x: *(President) Clinton*, *y*: *New York City*, y_{verb}: *played*	yes	hours	yes	entire	yes	hours
x: *(President) Clinton*, *y*: *Madison Square Garden*, y_{verb}: *honored*	yes	mins	yes	entire	yes	mins
x: *(Senator) Clinton*, *y*: *New York City*, y_{verb}: *played*	yes	hours	yes	entire	yes	hours
x: *(Senator) Clinton*, *y*: *Madison Square Garden*, y_{verb}: *honored*	yes	mins	yes	entire	yes	mins
Statement 3: [Before [joining]$_{v_2}$ [Maidenform]$_{\text{ARG}_1,v_2}$ [in 1972]$_{\text{ARGM-TMP},\,v_2}$]$_{\text{ARGM-TMP},\,v_1}$, [[Mr. Brawer, who]$_{\text{ARG}_0,v_3}$ [holds]$_{v_3}$ [a doctoral degree in English]$_{\text{ARG}_1,v_3}$]$_{\text{ARG}_0,\,v_1,v_2}$, [taught]$_{v_1}$ [at the University of Wisconsin]$_{\text{ARGM-LOC},\,v_1}$.						
x: *Maidenform*, *y*: *University of Wisconsin* , y_{verb}: *taught*	no	n/a	no	n/a	no	n/a
x: *Mr. Brawer*, *y*: *University of Wisconsin*, y_{verb}: *taught*	no	n/a	yes	entire	no	n/a
Statement 4: [...] [George Koskotas, self-confessed embezzler]$_{\text{ARG}_0,\,v_1}$, [now]$_{\text{ARGM-TMP},v_1}$ [residing]$_{v_1}$ [in [a jail cell in Salem, Mass., from where]$_{\text{ARGM-LOC},\,v_2}$ [he]$_{\text{ARG}_0,\,v_2}$ is [fighting]$_{v_2}$ [extradition proceedings]$_{\text{ARG}_1,v_2}$]$_{\text{ARG}_1,v_1}$.						
x: George Koskotas, *y*: *a jail cell in Salem, Mass.*, y_{verb}: *fighting*	yes	months	yes	entire	unk	n/a

Table 3: Annotation examples. For each statement, we indicate semantic roles with square brackets, all potential additional spatial knowledge (is *x* located at *y*?), and annotations with respect to y_{verb} (coarse- (C) and fine-grained (F) labels per temporal anchor: before, during and after).

$1 + 2/7$, `days`: $1 + 3/7$, `weeks`: $1 + 4/7$, `months`: $1 + 5/7$, `years`: $1 + 6/7$, `inf`: 2; during: `some`: 1 `entire`:2. Calculating the weighted average of individual Pearson correlations allows us to take into account the number of questions answered by each annotator.

Correlations range between 0.66 and 0.81 with coarse-grained labels, and are slightly lower with fine-grained labels (0.67 vs. 0.73, 0.79 vs. 0.81, and 0.62 vs. 0.66). Questions for *during* temporal anchor are easier to answer with both kinds of labels (coarse: 0.81, fine: 0.79).

Table 2 also shows how many annotators (out of 7) chose the same label (exact match). At least 4 annotators agreed with coarse-grained labels in most instances (70%), and at least 3 annotators agreed virtually always (97.4%). Percentages are lower with fine-grained labels: 57.0% and 88.8%.

4.4 Annotation Examples

Table 3 presents several annotation examples. We include all potential additional spatial knowledge (Section 4.1) and annotations per temporal anchor.

Two additional LOCATION(*x*, *y*) can be inferred from Statement (1): whether *Hsia* and *Hisao Chin* are located in *Milan* before, during and after *stopped.* Annotators understood that *Hsia* was in *Milan* temporarily: for a few minutes before *stopped*, during the full duration of *stopped* and for a few hours after *stopped.* In other words, *Hsia* was elsewhere, then went to *Milan* and left after visiting with *Hsiao* for a few hours. Regarding *Hsiao*, annotators interpreted that *Milan* is her permanent location: for years before and after *Hsia stopped* to visit her. While somehow ambiguous, these annotations are reasonably intuitive.

Statement (2) has 2 ARGM-LOC roles and 4 potential additional relations. Annotations for *during* are straightforward: both *President Clinton* and *Senator Clinton* were located in *New York City* during *played* and at *Madison Square Garden* during *honored.* Annotations for *before* and *after* are more challenging: both Clintons where located in *New York City* for hours (not days) before and after *played*, but at *Madison Square Garden* for a few minutes (not hours) before and after *honored.*

Feature		Description
basic	1–4	x_{verb}, y_{verb} and their part-of-speech tags
lexical	5–12	first and last words of *x* and *y*, and their part-of-speech tags
	13	whether *x* occurs before or after *y*
heads	14–17	heads of *x* and *y*, and their part-of-speech tags
	18–19	named entity types of the heads of *x* and *y*
semantic	20	semantic role label linking x_{verb} and *x*
	21–24	number of ARGM-TMP and ARGM-LOC roles in x_{roles} and y_{roles}
	25–26	number of ARGM-TMP and ARGM-LOC roles in the sentence to which *x* and *y* belong
	27	whether x_{verb} and y_{verb} are the same verb

Table 4: Feature set to determine whether *x* is (or is not) located at *y*, and for how long. x_{verb} (y_{verb}) denote the verbs to which *x* (y) attach, and x_{roles} (y_{roles}) denote the semantic roles of x_{verb} (y_{verb}).

In other words, they arrived to *Madison Square Garden* shortly before *honored* and left shortly after, but stayed in *New York City* for some hours.

Statement (3) exemplifies `no` label. Potential additional spatial knowledge includes whether *Maidenform* is located at *University of Wisconsin*, which is never true (`no`). Additionally, *University of Wisconsin* was a location of *Mr. Brawer* while he *taught* there (*during*), but nor *before* or *after*.

Statement (4) exemplifies contrastive coarse-grained labels and `unk` label. Annotators interpreted that *George Koskotas* was in the *jail cell* for months before and during *fighting extradition*, and that it is unknown (`unk`) *after fighting* because the outcome of the fight is unknown.

5 Inferring Temporally-Anchored Spatial Knowledge

We follow a standard machine learning approach, and use the training, development and test sets released by the organizers of the CoNLL-2011 Shared Task (Pradhan et al., 2011). We first generate additional spatial knowledge deterministically as described in Section 4.1. Then, for each additional LOCATION(*x*, *y*), we generate one instance per temporal anchor and discard those annotated `inv`. The total number of instances is $1{,}732 \times 3 - 754 = 4{,}442$. We trained SVM models with RBF kernel using scikit-learn (Pedregosa et al., 2011). The feature set and SVM parameters were tuned using 10-fold cross-validation with the train and development sets, and results are calculated using the test set. During the tuning process, we discovered that it is beneficial to train one SVM per temporal anchor instead of a single model for the 3 temporal anchors.

5.1 Feature Selection

We use a mixture of standard features from semantic role labeling, and semantic features designed for extracting temporally-anchored spatial knowledge from semantic roles. In order to determine whether *x* is (or is not) located at *y* and for how long, we extract features from *x* and *y*, the verbs to which they attach (x_{verb} and y_{verb}) and all semantic roles of x_{verb} and y_{verb} (x_{roles} and y_{roles}).

Basic, *lexical* and *heads* features are standard in role labeling (Gildea and Jurafsky, 2002). *Basic* features are the word form and part-of-speech of x_{verb} and y_{verb}. *Lexical* features capture the first and last words of *x* and *y* and their part-of-speech tags, as well as a binary flag indicating whether *x* occurs before or after *y*. *Heads* features capture the heads of *x* and *y* and their part-of-speech tags, as well as their named entity types, if any.

Semantic features include features 20–27. Feature 20 indicates the semantic role linking *x* and x_{verb} (ARG_0, ARG_1, ARG_2, etc.); recall that the semantic role between *y* and y_{verb} is always ARGM-LOC (Section 4.1). Features 21–24 are counts of ARGM-TMP and ARGM-LOC semantic roles in the verb-argument structures to which *x* and *y* attach. Features 25–26 are the same counts of roles, but taking into account all the roles in the sentence to which *x* and *y* belong. Finally, feature 27 signals whether *x* and *y* attach to the same verb.

We tried many other features, including counts of all roles, heads of all semantic roles present, semantic role ordering, VerbNet (Schuler, 2005) and Levin (Levin, 1993) verb classes, and WordNet hypernyms (Miller, 1995), but they did not yield any improvements during the tuning process.

We exemplify features with pair (*x*: *George Koskotas, self-confessed embezzler*, *y*: *a jail cell in [...], from where*) from Statement 4 in Table 3:

- Basic: features 1–4: {residing, VBG, fighting, VBG}.
- Lexical: feature 5–12: {George, NNP, Koskotas, NNP, a, DT, where, WRB}, features 13: {before}.

Table 5: Results obtained with gold-standard linguistic annotations and coarse-grained labels using the baseline and several feature combinations (basic, lexical, heads and semantic features).

- Head: features 14–17: {Koskotas, NNP, cell, NN}, features 18–19: {person, none},
- Semantic feature 20: $\{\text{ARG}_0\}$, features 21–24: {1, 0, 0, 1}, feature 25–26: {1, 1}, feature 27: {no}.

6 Experiments and Results

We present results using gold-standard (Section 6.1) and predicted (Section 6.2) linguistic annotations. POS tags, parse trees, named entities and semantic roles are taken directly from *gold* or *auto* files in the CoNLL-2011 Shared Task release.

6.1 Gold-Standard Linguistic Annotations

Using gold-standard linguistic annotations has two advantages. First, because we have gold semantic roles and named entities, we generate the same potential additional spatial knowledge generated while creating our annotations (Section 4.1). Second, feature values are guaranteed to be correct.

6.1.1 Predicting Coarse-Grained Labels

Table 5 presents results with coarse-grained labels using a baseline and learning with several combinations of features extracted from gold-standard linguistic annotations (POS tags, parse trees, semantic roles, etc.). The baseline predicts the most frequent label per temporal anchor, i.e., yes for *during*, and no for *before* and *after* (Figure 3).

Best results for all labels and temporal anchors are obtained with all features (basic, lexical, heads and semantics). Overall F-measure is 0.65, and *during* instances obtain higher F-measure (0.78) than *before* (0.60) and *after* (0.52). Regarding labels, yes obtains best results (overall 0.77), followed by no (0.64) and unk (0.36). Not surprisingly, the most frequent label per temporal anchor obtains the best results with all features (*before*: no, 0.71; *during*: yes, 0.90; *after*: no, 0.61).

Before and *after* instances benefit the most from learning with all features with respect to the baseline (before: 0.32 vs. 0.60, after: 0.23 vs. 0.52). While *during* instances also benefit, the difference in F-measure is lower (0.67 vs. 0.78).

Feature Ablation. The bottom 3 blocks in Table 5 present results using several feature types incrementally. *Basic* features yield an overall F-measure of 0.56, and surprisingly good results for *during* instances (0.76). Indeed, the best performance obtained with *during* instances is 0.78 (all features), suggesting that the verbs to which *x* and *y* attach are very strong features.

Lexical and *heads* features are most useful for *before* (0.44 vs. 0.54, +22.7%) and *after* (0.44 vs. 0.50, +13.6%) instances, and are actually detrimental for *during* instances (0.76 vs. 0.74, -2.6%). Including *semantic* features, however, improves results with respect to *basic* features for all temporal anchors: before: 0.44 vs. 0.60, 36.4% during: 0.76 vs. 0.78, 2.6% after: 0.44 vs. 0.52, 18.2%.

Differences in overall F-measure are not statistically significant between *basic* and *basic + lexical + heads* (0.56 vs. 0.61, Z-test, two-tailed, p-value $= 0.05$), but the difference including *semantic* features is significant (0.50 vs. 0.65, Z-test, two-tailed, p-value $= 0.009$).

Table 6: Results obtained with gold linguistic annotations and fine-grained labels using all features.

6.1.2 Predicting Fine-Grained Labels

Table 6 presents results using fine-grained labels and all features. Overall F-measure is lower than with coarse-grained labels (0.57 vs. 0.65). Results for *during* instances barely decreases (0.78 vs. 0.77) because almost 98% of fine-grained labels are entire (Table 1).

Most fine-grained labels for *before* and *after* are infrequent (Table 1), our best model is unable to predict labels secs, hours, weeks and months for *before*, and secs, mins, hours, days, weeks and months for *after* (*other* rows). But these labels account for relatively few instances: individually, between 0.2% and 11.33%, and among all of them, 23.46% for *before* and 34.38% for *after* instances.

It is worth noting that mins, days and inf obtain relatively high F-measures for *before*: 0.80, 0.67 and 0.50 respectively. In other words, we can distinguish whether an entity is somewhere only for a few minutes or days (but not longer) before an event, or at all times before an event.

6.2 Predicted Linguistic Annotations

In order to make an honest evaluation in a realistic environment, we also experiment with predicted linguistic annotations. The major disadvantage of doing so is that predicted semantic roles and named entities are often incorrect or missing, thus we generate spurious additional spatial knowledge and miss some additional spatial knowledge because the potential relation cannot be generated.

Table 7 presents results using predicted linguistic annotations. The additional label spurious is used for instances generated from incorrect semantic roles or named entities, as these instances do not appear in the crowdsourced annotations (Section 4). Due to space constraints, we only present results using coarse-grained labels, but provide results per temporal anchor.

The baseline, which predicts the most likely label per temporal anchor, always predicts spurious since 50% of generated additional potential knowledge does not appear in the crowdsourced annotations. Using all features clearly outperforms *basic* features (overall F-measure:

0.79 vs 0.55), thus we focus on the former.

Using all features, `spurious` is always predicted correctly. While useful to discard additional spatial knowledge that should not have been generated, `spurious` does not allow us to make meaningful inferences. The labels that we are most interested in, `yes` and `no`, obtain overall F-measures of 0.64 and 0.51 (compared to 0.77 and .64 with gold linguistic annotations). Regarding labels, `yes` can only be reliably predicted for *during* instances (F-measure: 0.80), and `no` is predicted with modest F-measures for all temporal anchors: before: 0.55, during: 0.31, after: 0.44.

7 Conclusions

This paper demonstrates that semantic roles are a reliable semantic layer from which one can infer whether entities are located or not located somewhere, and for how long (seconds, minutes, days, years, etc.). Crowdsourced annotations show that this kind of inferences are intuitive to humans. Moreover, most potential additional spatial knowledge generated following a few simple deterministic rules was validated by annotators (`yes` and `no`; before: 67.7%, during: 77.4%, after: 63.1%).

Experimental results with gold-standard semantic roles and named entities show that inference can be done with standard supervised machine learning (overall F-measure: 0.65, `yes`: 0.77, `no`: 0.64). Using predicted linguistic information, results decrease substantially (`yes`: 0.64, `no`: 0.51). This is mostly due to the fact that predicted semantic roles and named entities are often wrong or missing, and this fact unequivocally makes the inference process more challenging.

We believe that combining semantic roles and other semantic representation in a similar fashion to the one used in this paper could be useful to infer knowledge beyond spatial inferences. For example, one could infer who is in POSSESSION of something over time by manipulating the events in which the object in question participates in.

Abstract

There has recently been a lot of interest in unsupervised methods for learning sense distributions, particularly in applications where sense distinctions are needed. This paper analyses a state-of-the-art method for sense distribution learning, and optimises it for application to the entire vocabulary of a given language. The optimised method is then used to produce LEXSEMTM: a sense frequency and semantic dataset of unprecedented size, spanning approximately 88% of polysemous, English simplex lemmas, which is released as a public resource to the community. Finally, the quality of this data is investigated, and the LEXSEMTM sense distributions are shown to be superior to those based on the WORDNET first sense for lemmas missing from SEMCOR, and at least on par with SEMCOR-based distributions otherwise.

1 Introduction

Word sense disambiguation (WSD), as well as more general problems involving word senses, have been of great interest to the NLP community for many years (for a detailed overview, see Agirre and Edmonds (2007) and Navigli (2009)). In particular, there has recently been a lot of work on unsupervised techniques for these problems. This includes unsupervised methods for performing WSD (Postma et al., 2015; Chen et al., 2014; Boyd-Graber et al., 2007; Brody et al., 2006), as well as complementary problems dealing with word senses (Jin et al., 2009; Lau et al., 2014).

One such application has been the automatic learning of sense distributions (McCarthy et al., 2004b; Lau et al., 2014). A sense distribution is a probability distribution over the senses of a given lemma. For example, if the noun *crane* had two senses, `bird` and `machine`, then a hypothetical sense distribution could indicate that the noun is expected to take the `machine` meaning 60% of the time and the `bird` meaning 40% of the time in a representative corpus. Sense distributions (or simple "first sense" information) are used widely in tasks including information extraction (Tandon et al., 2015), novel word sense detection (Lau et al., 2012; Lau et al., 2014), semi-automatic dictionary construction (Cook et al., 2013), lexical simplification (Biran et al., 2011), and textual entailment (Shnarch et al., 2011). Automatically acquired sense distributions themselves are also used to improve unsupervised WSD, for example by providing a most frequent sense heuristic (McCarthy et al., 2004b; Jin et al., 2009) or by improving unsupervised usage sampling strategies (Agirre and Martinez, 2004). Furthermore, the improvement due to the most frequent sense heuristic has been particularly strong when used with domain-specific data (Koeling et al., 2005; Chan and Ng, 2006; Lau et al., 2014).

In addition, there is great scope to use these techniques to improve existing sense frequency resources, which are currently limited by the bottleneck of requiring manual sense annotation. The most prominent example of such a resource is WORDNET (Fellbaum, 1998), where the sense

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1513–1524,
Berlin, Germany, August 7-12, 2016.

frequency data is based on SEMCOR (Miller et al., 1993), a 220,000 word corpus that has been manually tagged with WORDNET senses. This data is full of glaring irregularities due to its age and the limited size of the corpus; for example, the word *pipe* has its most frequent sense listed as `tobacco pipe`, whereas one might expect this to be `tube carrying water or gas` in modern English (McCarthy et al., 2004a). This is likely due to the more common use of the `tobacco pipe` sense in mid-20th century literature. The problem is particularly highlighted by the fact that out of the approximately 28,000 polysemous simplex lemmas in WORDNET 3.0, approximately 61% have no sense annotations at all, and less than half of the remaining lemmas have at least 5 sense annotations!

Unfortunately, there has been a lack of work investigating how to apply sense learning techniques at the scale of a full lexical resource such as WORDNET. Updating language-wide sense frequency resources would require learning sense distributions over the entire vocabularies of languages, which could be extremely computationally expensive. To make things worse, domain differences could require learning numerous distributions per word. Despite this, though, we would not want to make these techniques scalable at the expense of sense distribution quality. Therefore, we would like to understand the tradeoff between the accuracy and computation time of these techniques, and optimise this tradeoff. This could be particularly critical in applying them in an industrial setting.

The current state-of-the-art technique for unsupervised sense distribution learning is HDP-WSI (Lau et al., 2014). In order to address the above concerns, we provide a series of investigations exploring how to best optimise HDP-WSI for large-scale application. We then use our optimised technique to produce LEXSEMTM,[1] a semantic and sense frequency dataset of unprecedented size, spanning the entire vocabulary of English. Finally, we use crowdsourced data to produce a new set of gold-standard sense distributions to accompany LEXSEMTM. We use these to investigate the quality of the sense frequency data in LEXSEMTM with respect to SEMCOR.

[1] LEXSEMTM, as well as code for accessing LEXSEMTM and reproducing our experiments is available via: `https://github.com/awbennett/LexSemTm`

2 Background and Related Work

Given the difficulty and expense of obtaining large-scale and robust annotated data, unsupervised approaches to problems involving word learning and recognising word senses have long been studied in NLP. Perhaps the most famous such problem is word sense disambiguation (WSD), for which many unsupervised solutions have been proposed. Some methods are very complex, performing WSD separately for each word usage using information such as word embeddings of surrounding words (Chen et al., 2014) or POS-tags (Lapata and Brew, 2004). On the other hand, most approaches make use of the difficult-to-beat most frequent sense (MFS) heuristic (McCarthy et al., 2007), which assigns each usage of a given word-type to its most frequent sense.

Given the popularity of the MFS heuristic, much of the past work on unsupervised techniques has focused on identifying the most frequent sense. The original method of this kind was proposed by McCarthy et al. (2004b), which relied on finding distributionally similar words to the target word, and comparing these to the candidate senses. Most subsequent approaches have followed a similar approach, based on the words appearing nearby the target word across its token usages. Boyd-Graber and Blei (2007) formalise the method of McCarthy et al. (2004b) with a probabilistic model, while others take different approaches, such as adapting existing sense frequency data to specific domains (Chan and Ng, 2005; Chan and Ng, 2006), using coarse grained thesaurus-like sense inventories (Mohammad and Hirst, 2006), adapting information retrieval-based methods (Lapata and Keller, 2007), using ensemble learning (Brody et al., 2006), utilising the network structure of WORDNET (Boyd-Graber et al., 2007), or making use of word embeddings (Bhingardive et al., 2015). Alternatively, Jin et al. (2009) focus on how best to use the MFS heuristic, by identifying when best to apply it, based on sense distribution entropy. Perhaps the most promising approach is that of Lau et al. (2014), due to its state-of-the art performance, and the fact that it can easily by applied to any language and any sense repository containing sense glosses.

The task we are interested in — namely, sense distribution learning — is in principle very similar to identifying the MFS. Indeed, of these methods for identifying the MFS, some of them are

explicitly described in terms of sense distribution learning (Chan and Ng, 2005; Chan and Ng, 2006; Lau et al., 2014), while the others implicitly learn sense distributions by calculating some kind of scores used to rank senses.

The state-of-the-art technique of Lau et al. (2014) that we are building upon involves performing unsupervised word sense induction (WSI), which itself is implemented using nonparametric HDP (Teh et al., 2006) topic models, as detailed in Section 3. The WSI component, HDP-WSI, is based on the work of Lau et al. (2012), which at the time was state-of-the-art. Since then, however, other competitive WSI approaches have been developed, involving complex structures such as multi-layer topic models (Chang et al., 2014), or complex word embedding based approaches (Neelakantan et al., 2014). We have not used these approaches in this work on account of their complexity and likely computational cost, however we believe they are worth future exploration. On the other hand, because HDP-WSI is implemented using topic models, it can be customised by replacing HDP with newer, more efficient topic modelling algorithms. Recent work has produced more advanced topic modelling approaches, some of which are extensions of existing approaches using more advanced learning algorithms or expanded models (Buntine and Mishra, 2014), while others are more novel, involving variations such as neural networks (Larochelle and Murray, 2011; Cao et al., 2015), or incorporating distributional similarity of words (Xie et al., 2015). Of these approaches, we chose to experiment with that of Buntine and Mishra (2014) because a working implementation was readily available, it has previously shown very strong performance in terms of accuracy and speed, and it is similar to HDP and thus easy to incorporate into our work.

3 HDP-WSI Sense Learning

HDP-WSI (Lau et al., 2014) is a state-of-the-art unsupervised method for learning sense distributions, given a sense repository with per-sense glosses. It takes as input a collection of example usages of the target lemma[2] and the glosses for each target sense, and produces a probability distribution over the target senses.

At the heart of HDP-WSI is HDP (Teh et al., 2006), a nonparametric topic modelling technique. It is a generative probabilistic model and uses topics as a latent variable to allow statistical sharing between documents, providing a kind of soft-clustering mixture model. Each document is assumed to have a corresponding distribution over these topics, and each topic is assumed to have a corresponding distribution over words. According to the model, each word for a given document is independently generated by first sampling a topic according to that document's distribution over topics, and then sampling a word according to the topic's distribution over words. Unlike older topic modelling methods such as LDA (Blei et al., 2003), HDP is nonparametric, meaning the number of topics used by the model is automatically learnt, and does not need to be set as a hyperparameter. In other words, the model automatically learns the "right" number of topics for each lemma.

HDP-WSI follows a two-step process: word sense induction (WSI), followed by topic–sense alignment. WSI is performed using HDP based on the earlier work of Lau et al. (2012): each usage of the target lemma is treated as a document, and HDP topic modelling is run on this document collection. This gives a variable number of learnt topics, which are the senses induced by WSI. A single topic is then assigned to each document,[3] and a distribution over these topics is learnt using maximum likelihood estimation.

In the second step of HDP-WSI, we align the distribution over topics from WSI to the provided sense inventory. We first create a distribution over words for each sense, from the sense's gloss.[4] Then a prevalence score is calculated for each sense by taking a weighted sum of the similarity of that sense with every topic,[5] weighting each similarity score by the topic's probability. These prevalence scores are finally normalised to give a distribution over senses.

Despite state-of-the-art results with HDP-WSI in past work (Lau et al., 2014), there are some con-

[2]Except where stated otherwise, a lemma usage includes the sentence containing the lemma, and the two immediate neighbouring sentences (if available). It is assumed that each usage has been normalised via lemmatisation and stopword removal, and extra local-context tokens are added, as was done by Lau et al. (2012).

[3]The topic with the maximum probability is assigned.

[4]As with the lemma usages, the text is normalised via lemmatisation and stopword removal. Then a distribution is created using maximum likelihood estimation.

[5]Defined in terms of Jensen Shannon divergence between the respective distributions over words.

cerns in applying it to large-scale learning. Most importantly, in order to make HDP nonparametric, it relies on relatively inefficient MCMC sampling techniques, typically based on a hierarchical Chinese Restaurant Process ("CRP"). On the other hand, recent work has provided very efficient topic modelling techniques given a fixed number of topics. While in previous work it was assumed that performance benefits of HDP over other techniques like LDA were based on it learning the "right" number of topics (Lau et al., 2012; Lau et al., 2014), more recent work challenges this assumption. Rather, it is suggested that it is more important for topic modelling to use high-performance learning algorithms so that topics are learnt in correct proportions, in which case "junk" topics can easily be ignored (Buntine and Mishra, 2014). In other words, it is likely that the previously-found performance advantage of HDP over LDA was actually due to properties of their respective Gibbs sampling algorithms.

Furthermore, in our experience using it for sense distribution learning, HDP seems to use a very consistent number of topics. In experiments we ran on the BNC[6] — the same dataset that Lau et al. (2014) based their experiments on — the number of topics was between 5 and 10 over 80% of the time, and over 99% of the time it was below 14. Because the number of topics is so consistent, it is likely we can safely use a fixed number with little risk that it will be too low.

In addition, there are some theoretical concerns with HDP. Firstly, it models topic and word allocations using Dirichlet Processes (Teh et al., 2006). However, previous research has shown that phenomena such as word and sense frequencies follow power-law distributions according to Zipf's law (Piantadosi, 2014), and thus are better modelled using Pitman-Yor Processes (Pitman and Yor, 1997). Another weakness is that HDP does not model burstiness. This is a phenomenon where words that occur at least once in a given discourse are disproportionately more likely to occur several times, even compared with other discourses about the same topic (Church, 2000; Doyle and Elkan, 2009).

[6]The British National Corpus (Burnard, 1995), which is a balanced corpus of English.

4 HCA-WSI Sense Learning

We now present and evaluate HCA-WSI, which is an alternative to HDP-WSI that addresses the above concerns. It follows the same process as HDP-WSI, except that the HDP topic modelling is replaced with HCA[7] (Buntine and Mishra, 2014), a more advanced software suite for topic modelling.[8] HCA is based on a similar probabilistic model to HDP, except for a few differences: (1) it only has a fixed number of topics; (2) it models word frequencies using a more general Pitman-Yor Process; and (3) it incorporates an extra component to the model to model burstiness (each document can individually have an elevated probability for some words, regardless of its distribution over topics). The second and third of these differences directly answer our theoretical concerns about using HDP.

The learning algorithm for HCA is called "table indicator sampling" (Chen et al., 2011), which is a collapsed Gibbs sampling algorithm. The overall probabilistic model is interpreted as a hierarchical CRP, and some extra latent variables called table indicators are added to the model, which encode the decisions made about creating new tables during the CRP. The use of these latent variables allows for a very efficient collapsed Gibbs sampling process, which is found to converge more quickly than competing Gibbs sampling and variational Bayes techniques. The convergence is also shown to be more accurate, with topic models of lower perplexity being produced given the same underlying stochastic model.

Compared to HDP, HCA has been shown to be orders of magnitude faster, with similar memory overhead (Buntine and Mishra, 2014). Therefore, as long as the quality of the sense distributions given by HCA-WSI are no worse than those from HDP-WSI, it should be worthwhile switching in terms of scalability. This massive reduction in computation time would be of particular benefit to our intended large-scale application.

4.1 Evaluation

We evaluate HCA-WSI in comparison to HDP-WSI using one of the sense tagged datasets of

[7]Version 0.61, obtained from:
`http://www.mloss.org/software/view/527`

[8]For simplicity we use HCA to refer to both the topic modelling algorithm implemented by Buntine and Mishra (2014) as well as the corresponding software suite, whereas elsewhere HCA often only refers to the software.

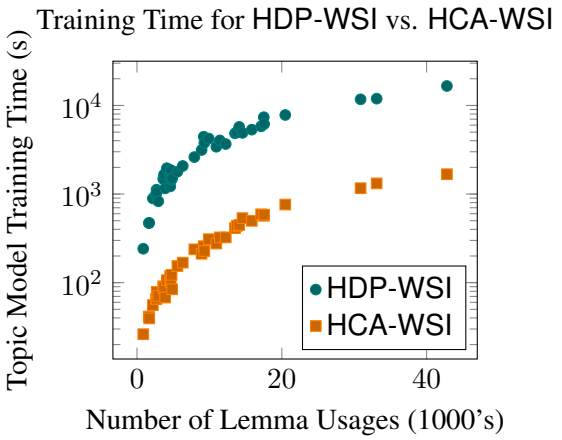

Figure 1: Comparison of the time taken to train the topic models of HDP-WSI and HCA-WSI for each lemma in the BNC dataset. For each method, one data point is plotted per lemma.

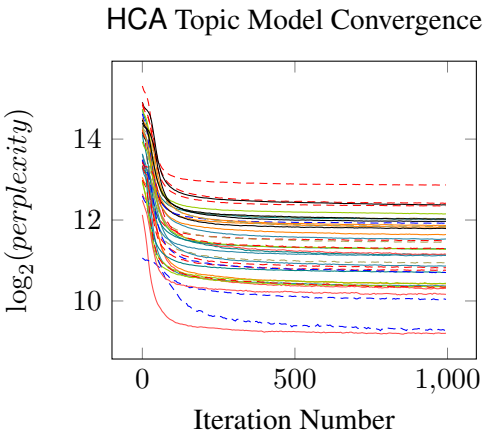

Figure 2: Convergence of log-perplexity of toic model for BNC dataset lemmas, using HCA-WSI. One line per lemma.

Koeling et al. (2005),[9] which was also used by Lau et al. (2014). This dataset consists of 40 English lemmas, and for each lemma it contains a set of usages of varying size from the BNC and a gold-standard sense distribution that was created by hand-annotating a subset of the usages with WORDNET 1.7 senses.

Using this dataset, we can calculate the quality of a candidate sense distribution by calculating its Jensen Shannon divergence (JSD) with respect to the corresponding gold-standard distribution. JSD is a measure of dissimilarity between two probability distributions, so a lower JSD score means the distribution is more similar to the gold-standard, and is therefore assumed to be of higher quality.

Given our finding on topic counts in Section 3, HCA was run using a fixed number of 10 topics. Other settings were configured as recommended in the HCA documentation, or according to the HDP settings used by Lau et al. (2014).[10] This setup is also used in subsequent experiments, except where stated otherwise.

We proceeded by calculating the JSD scores of all lemmas in this dataset, using both methods. We performed a Wilcoxon signed-rank test on the two sequences of JSD scores, in order to test the hypothesis that switching to HCA-WSI has a systematic impact on sense distribution quality. We found that the mean JSD score for HDP-WSI was 0.209 $\pm$ 0.116, slightly lower than the mean JSD score for HCA-WSI of 0.211 $\pm$ 0.117. However the two-sided p-value from the test was 0.221, which is insignificant at any reasonable decision threshold.

In addition, we compared the time taken[11] to run topic modelling for every lemma using both methods, the results of which are displayed in Figure 1. These results show that the computation time of HCA-WSI is consistently lower than that of HDP-WSI, by over an order of magnitude.

We conclude that HCA-WSI is far more computationally efficient than HDP-WSI, and there is no significant evidence that it gives worse sense distributions. Therefore, HCA-WSI is used instead of HDP-WSI for the remainder of the paper.

5 Large-Scale Learning with HCA-WSI

In order to apply HCA-WSI sense distribution learning on a language-wide scale, we need to understand how to optimise it to achieve a reasonable tradeoff between efficiency and sense distribution quality. Most pertinently, we need to know how many lemma usages and iterations of Gibbs sampling are needed for high-quality results, and whether this varies for different kinds of lemmas. To this end, we run experiments ex-

[9] Koeling et al. (2005) also produced domain-specific datasets for the same lemmas, however in order to keep our analysis focussed we only use the domain-neutral BNC dataset.

[10] Initial values for concentration and discount parameters for burstiness were set to 100 and 0.5 respectively, and the number of iterations was set to 300. Other hyperparameters were left with default values.

[11] All benchmarking experiments were run using separate cores on Intel Xeon CPU E5-4650L processors, on a Dell R820 server with 503GiB of main memory.

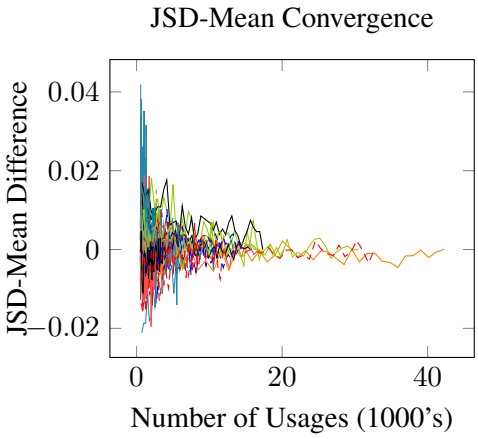

Figure 3: Convergence of mean JSD score for BNC dataset lemmas, using HCA-WSI. One line plotted per lemma, one data-point per bin. For each data-point, the difference between mean JSD within that bin and within the final bin of the lemma is plotted.

ploring how HCA-WSI converges over increasing numbers of lemma usages and topic model iterations. These experiments are all performed using the BNC dataset (see Section 4.1).

In order to explore the convergence of HCA-WSI over Gibbs sampling iterations, we trained HCA topic models for each lemma in the BNC dataset over a large number of iterations. The results of this are displayed in Figure 2, which shows the convergence of log-perplexity for each lemma. We conclude that around 300 iterations of sampling appears to be sufficient for convergence in the vast majority of cases.

Next, we explored the convergence of HCA-WSI over lemma usages by subsampling from our training data. For each lemma in the BNC dataset, we created a large number of sense distributions using random subsets of the lemma's usages.[12] Each distribution was generated by randomly selecting a number of usages between a minimum of 500 and the maximum available (uniformly), and randomly sampling that many usages without replacement. From these usages the sense distribution was created using HCA-WSI, and its JSD score relative to the gold-standard was calculated (as in Section 4.1). Finally, the results for each lemma were partitioned into 40 bins of approximately equal size, according to the number of usages sampled.

[12] Approximately 580 random sense distributions were created per lemma.

The results of our subsampling experiment are plotted in Figure 3, which shows the convergence of mean JSD score for each lemma. We conclude from this that around 5,000–10,000 usages seem to be necessary for convergent results, and that this is fairly consistent across lemmas.[13]

6 LexSemTM Dataset

We now discuss the creation of the LexSemTM ("Lexical Semantic Topic Models") dataset, which contains trained topic models for the majority of simplex English lemmas. These can be aligned to any sense repository with glosses to produce sense distributions, or used directly in other applications. In addition, the dataset contains distributions over WordNet 3.0 senses.

In order to produce domain-neutral sense distributions reflecting usage in modern English, we sampled all lemma usages from English Wikipedia.[14] Our Wikipedia corpus was tokenised and POS-tagged using OpenNLP and lemmatised using Morpha (Minnen et al., 2001).

We trained topic models for every simplex lemma in WordNet 3.0 with at least 20 usages in our processed Wikipedia corpus. This included lemmas for all POS (nouns, verbs, adjectives, and adverbs), and also nonpolysemous lemmas. In Section 5, we concluded that approximately 5,000–10,000 usages were needed for convergent results with the BNC dataset. On the other hand, given that we are working on a different corpus and with a wider range of lemmas there is uncertainty in this number, so we conservatively sampled up to 40,000 usages per lemma, if available.

These usages were sampled from the corpus by locating all sentences where either the surface or lemmatised forms of the sentence contained the target lemma, along with a matching POS-tag. Processing of lemma usages was done almost identically to Lau et al. (2014). However, because we found the usages contained substantially fewer tokens on average compared to the BNC dataset, we included two sentences rather than one on either side of the target lemma location where possible (giving 5 sentences in total), which gave a

[13] We also ran extensive experiments to test the impact of training single topic models over multiple lemmas, using a wide variety of sampling methods, but found the impact to be neutral at best in terms of both the quality of the learned sense distributions and the overall computational cost.

[14] The English Wikipedia dump is dated 2009-11-28.

better match in usage size.

Topic models were trained using HCA, using almost the same setup as described in Section 4.1. However, since some highly-polysemous lemmas may require a greater number of topics than the lemmas in the BNC dataset, we conservatively increased the number of topics used from 10 to 20. We similarly increased the number of Gibbs sampling iterations from 300 to 1,000.[15] Finally, for each polysemous lemma that we trained a topic model for, we also produced a sense distribution over WORDNET 3.0 senses, using the default topic–sense alignment method discussed in Section 3.

In total, 62,721 lemmas were processed, and 8,801 of these had the desired number of at least 5,000 usages. Counting only polysemous lemmas for which we also provide sense distributions, 25,155 were processed in total, and 6,853 of these had at least 5,000 usages. This works out to approximately 88% coverage of polysemous WORDNET 3.0 lemmas in total, or 24% coverage with at least 5,000 usages (as compared to 39% coverage by lemmas in SEMCOR, or 17% with at least 5 sense-tagged occurrences in SEMCOR).

7 Evaluation of LEXSEMTM against SEMCOR

Our final major contribution is an analysis of how our LEXSEMTM sense distributions compare with SEMCOR. We produce a new set of gold-standard sense distributions for a diverse set of simplex English lemmas tagged with WORDNET 3.0 senses, created using crowdsourced annotations of English Wikipedia usages. We use these gold-standard distributions to investigate when LEXSEMTM should be used in place of SEMCOR, and release them as a public resource, to facilitate the evaluation of future work involving LEXSEMTM.

7.1 Gold-Standard Distributions

One of our goals in creating this dataset was to determine whether there is a SEMCOR frequency cutoff,[16] below which our LEXSEMTM distributions are clearly more accurate than SEMCOR. In order to have a diverse set of lemmas and be able to address this question, we partitioned the lemmas in WORDNET 3.0 based on SEMCOR frequency.

In order to keep analysis simple and consistent with previous investigations, we first filtered out multiword lemmas, nonpolysemous lemmas, and non-nouns.[17] Next, since in Section 5 we decided that at least around 5,000 usages were needed for stable and converged sense distributions, we filtered out all lemmas without at least 5,000 usages in our English Wikipedia corpus. The remaining lemmas were then split into 5 groups of approximately equal size based on SEMCOR frequency. The SEMCOR frequencies contained in each group are summarised in Table 1.

From each of the SEMCOR frequency groups, we randomly sampled 10 lemmas, giving 50 lemmas in total. Then for each lemma, we randomly sampled 100 usages to be annotated from English Wikipedia. This was done in the same way as the sampling of lemma usages for LEXSEMTM (see Section 6).

We obtained crowdsourced sense annotations for each lemma using Amazon Mechanical Turk (AMT: Callison-Burch and Dredze (2010)). The sentences for each lemma were split into 4 batches (25 sentences per batch). In addition, two control sentences[18] were created for each lemma, and added to each corresponding batch. Each batch of 27 items was annotated separately by 10 annotators. For each item to be annotated, annotators were provided with the sentence containing the lemma, the gloss for each sense as listed in WORDNET 3.0[19] and a list of hypernyms and synonyms for each sense. Annotators were asked to assign each item to exactly one sense.

From these crowdsourced annotations, our gold-standard sense distributions were created using MACE (Hovy et al., 2013), which is a general-purpose tool for inferring item labels from multi-annotator, multi-item tasks. It provides a Bayesian framework for modelling item annotations, modelling the individual biases of each annotator, and

[15] These changes had a very minor impact on the HCA-WSI evaluation results obtained in Section 4.1, with an average increase in JSD of 0.001 ± 0.004.

[16] The number of sense annotations in SEMCOR.

[17] We chose to restrict our scope in this evaluation to nouns because much of the prior work has also focussed on nouns, and these are the words we would expect others to care the most about disambiguating, since they are more often context bearing. Also, introducing other POS would require a greater quantity of expensive annotated data.

[18] These were created manually, to be as clear and unambiguous as possible.

[19] Example sentences were removed only if they were for a different lemma within the corresponding synset.

supports semi-supervised training. MACE was run separately on the usage annotations of each lemma, with the control sentences included to guide training.

Gold-standard sense distributions were obtained from the output of MACE, which includes a list containing the mode label of each item. For each lemma, we removed the control sentence labels from this list, and constructed the gold-standard distribution from the remaining labels using maximum likelihood estimation.

7.2 Evaluation of LEXSEMTM

We now use these gold-standard distributions to evaluate the sense distributions in LEXSEMTM relative to SEMCOR. For each of the 50 lemmas that we created gold-standard distributions for, we evaluate the corresponding LEXSEMTM distribution against the gold-standard. In addition, we create benchmark sense distributions for each lemma from SEMCOR counts using maximum likelihood estimation,[20] which we also evaluate against the gold-standards. Evaluation of sense distribution quality using gold-standard distributions is done by calculating JSD, as in Section 4.1.

First, we performed this comparison of LEXSEMTM to SEMCOR JSD scores for all 50 lemmas at once. As in Section 4.1, we calculated the JSD scores for every lemma using each method individually, and compared the difference in values pairwise for statistical significance using a Wilcoxon signed-rank test. The results of this comparison are detailed in Table 1 (final row: Group = All), which shows that JSD is clearly lower for LEXSEMTM distributions compared to SEMCOR, as would be hoped. This difference is statistically significant at $p < 0.05$.

We then performed the same comparison separately within each SEMCOR frequency group (Table 1). First of all, we can see that LEXSEMTM sense distributions strongly outperform SEMCOR-based distributions in Group 1 (lemmas missing from SEMCOR). This is as would be expected, since the SEMCOR-based distributions for this group are based on which sense is listed first in WORDNET, which in the absence of SEMCOR counts is arbitrary. On the other hand, in all other groups (lemmas in SEMCOR) the difference between LEXSEMTM and SEMCOR is not statistically significant ($p > 0.1$ in all cases). This still remains true when we pool together the results from these groups (second last row of Table 1: Group = 2–5). While it appears that LEXSEMTM may still be outperforming SEMCOR on average over these groups (lower JSD on average), we do not have enough statistical power to be sure, given the high variance.

Returning to the initial question regarding a SEMCOR frequency cutoff, the only strong conclusion we can make is that LEXSEMTM is clearly superior for lemmas missing from SEMCOR. Although it appears that LEXSEMTM may outperform SEMCOR for lemmas with higher SEMCOR frequencies, the variance in our results is too high to be sure of this, let alone define a frequency cutoff. However, given that LEXSEMTM sense distributions never appear to be worse than SEMCOR-based distributions, regardless of SEMCOR frequency — and may actually be marginally superior — it seems reasonable to use our sense distributions in general in place of SEMCOR.

We can contrast this result to the findings of McCarthy et al. (2007), who found that the automatic first sense learning method of McCarthy et al. (2004b) outperformed SEMCOR for words with SEMCOR frequency less than 5. However, their analysis was based on the accuracy of the first sense heuristic, rather than the entire sense distribution, and they used very different datasets to us.[21] Furthermore, their SEMCOR frequency cutoff result was only statistically significant for some variations of their method, and they evaluated over more lemmas[22] meaning that statistical significance was easier to obtain. Given these reasons, their results likely do not contradict ours.

Given that LEXSEMTM contains sense frequencies for 88% of polysemous simplex lemmas in WORDNET, compared to only 39% for SEMCOR, the strong performance of our LEXSEMTM sense distributions for lemmas missing from SEMCOR is extremely significant. Technically these results are only relevant for lemmas where LEXSEMTM was trained on at least 5,000 us-

[20] For lemmas with no SEMCOR annotations, we assign one count to the first-listed sense in WORDNET 3.0.

[21] Their evaluation on the all words task from SENSEVAL-2, which will have more occurrences of the more frequent words, whereas ours is a lexical sample with 100 instances of each word. However, our experiment has a larger dataset ($50 \times 100 = 5000$ instances, as opposed to 786 in total in the SENSEVAL-2 dataset) which makes it more reliable.

[22] They evaluated over 63 lemmas with SEMCOR frequency between 1 and 5, whereas we only evaluated over 14 lemmas (Group 2, and part of Group 3).

Group	Lemma Count	SEMCOR Freqs.	Mean JSD		p
			LEXSEMTM	SEMCOR	
1	10	0	**.100±.080**	.615±.407	.013
2	10	1–3	**.203±.169**	.214±.250	.959
3	10	4–8	**.100±.049**	.103±.133	.878
4	10	9–20	**.148±.069**	.235±.166	.114
5	10	21+	.162±.121	**.156±.131**	.721
2–5	40	1+	**.153±.118**	.177±.184	.591
All	50	0+	**.142±.113**	.265±.301	.046

Table 1: Sense distribution quality for gold-standard dataset lemmas, comparing LEXSEMTM results to the SEMCOR benchmark.

ages, which reduces the coverage of LEXSEMTM to 24%. However, even then this gives us sense frequencies for 1,602 polysemous lemmas missing from SEMCOR, which accounts for over 5% of polysemous simplex lemmas in WORDNET. Furthermore, based on some additional ongoing analysis comparing LEXSEMTM distributions directly to SEMCOR-based distributions across all of LEXSEMTM (not presented here), it appears the decrease in sense distribution quality for lemmas trained on fewer than 5,000 usages is on average fairly small. This is corroborated by our results in Figure 3: we can observe for the lemmas in the BNC dataset that when the number of usages was reduced to 500, the mean change in JSD for each lemma was almost always less than 0.02 and never greater than 0.04, which is small compared to the difference between LEXSEMTM and SEMCOR in each SEMCOR frequency group. This strongly suggests that our conclusions can be extended to lemmas with low LEXSEMTM frequency, though more work is needed to confirm this.

8 Discussion and Future Work

The most immediate extension of our work would be to apply our sense learning method to a broader range of data. In particular, we intend to expand LEXSEMTM by applying HCA-WSI across the vocabularies of languages other than English, and also to multiword lemmas. Another obvious extension would be to further explore the alignment component of HCA-WSI. We currently use a simple approach, and we believe this process could be improved, e.g. by using word embeddings.

In addition, previous work by Lau et al. (2012) and Lau et al. (2014) also provided methods for detecting novel and unattested senses, using the topic modelling output from the WSI step of HDP-WSI. These could be applied with LEXSEMTM— which contains this WSI output as well as sense frequencies — to search for novel and unattested senses throughout the entire vocabulary of English. This could be used to expand existing sense inventories with new senses, for example using the methodology of Cook et al. (2013). Given that LEXSEMTM also contains WSI output for nonpolysemous WORDNET lemmas (37,566 in total), this could be lead to the discovery of many new polysemous lemmas.

In conclusion, we have created extensive resources for future work in NLP and related disciplines. We have produced LEXSEMTM, which was trained on English Wikipedia and spans approximately 88% of polysemous English lemmas. This dataset contains sense distributions for the majority of polysemous lemmas in WORDNET 3.0. It also contains lemma topic models, for both polysemous and nonpolysemous lemmas, which provide rich semantic information about lemma usage, and can be re-aligned to sense inventories to produce new sense distributions at trivial cost. In addition, we have produced gold-standard distributions for a subset of the lemmas in LEXSEMTM, which we have used to demonstrate that LEXSEMTM sense distributions are at least on-par with those based on SEMCOR for lemmas with a reasonable frequency in Wikipedia, and strongly superior for lemmas missing from SEMCOR. Finally, we demonstrated that HCA topic modelling is more efficient than HDP, providing guidance for others who wish to do large-scale unsupervised sense distribution learning.

Abstract

We introduce LAMBADA, a dataset to evaluate the capabilities of computational models for text understanding by means of a word prediction task. LAMBADA is a collection of narrative passages sharing the characteristic that human subjects are able to guess their last word if they are exposed to the whole passage, but not if they only see the last sentence preceding the target word. To succeed on LAMBADA, computational models cannot simply rely on local context, but must be able to keep track of information in the broader discourse. We show that LAMBADA exemplifies a wide range of linguistic phenomena, and that none of several state-of-the-art language models reaches accuracy above 1% on this novel benchmark. We thus propose LAMBADA as a challenging test set, meant to encourage the development of new models capable of genuine understanding of broad context in natural language text.

1 Introduction

The recent spurt of powerful end-to-end-trained neural networks for Natural Language Processing (Hermann et al., 2015; Rocktäschel et al., 2016; Weston et al., 2015, a.o.) has sparked interest in tasks to measure the progress they are bringing about in genuine language understanding. Special care must be taken in evaluating such systems, since their effectiveness at picking statistical generalizations from large corpora can lead to the illusion that they are reaching a deeper degree of understanding than they really are. For example, the end-to-end system of Vinyals and Le (2015), trained on large conversational datasets, produces dialogues such as the following:

(1) **Human:** what is your job?
Machine: i'm a lawyer
Human: what do you do?
Machine: i'm a doctor

Separately, the system responses are appropriate for the respective questions. However, when taken together, they are incoherent. The system behaviour is somewhat parrot-like. It can locally produce perfectly sensible language fragments, but it fails to take the meaning of the *broader discourse context* into account. Much research effort has consequently focused on designing systems able to keep information from the broader context into memory, and possibly even perform simple forms of reasoning about it (Hermann et al., 2015; Hochreiter and Schmidhuber, 1997; Ji et al., 2015; Mikolov et al., 2015; Sordoni et al., 2015; Sukhbaatar et al., 2015; Wang and Cho, 2015, a.o.).

In this paper, we introduce the LAMBADA dataset (**LA**nguage **M**odeling **B**roadened to **A**ccount for **D**iscourse **A**spects). LAMBADA proposes a word prediction task where the target item is *difficult to guess* (for English speakers) when only the sentence in which it appears is available, but becomes *easy* when a broader context is presented. Consider Example (1) in Figure 1. The sentence *Do you honestly think that I would want you to have a ___?* has a multitude of possible continuations, but the broad context clearly indicates that the missing word is *miscarriage*.

LAMBADA casts language understanding in the classic word prediction framework of language modeling. We can thus use it to test several existing language modeling architectures, including

Berlin, Germany, August 7-12, 2016.

systems with capacity to hold longer-term contextual memories. In our preliminary experiments, none of these models came even remotely close to human performance, confirming that LAMBADA is a challenging benchmark for research on automated models of natural language understanding.

2 Related datasets

The CNN/Daily Mail (CNNDM) benchmark recently introduced by Hermann et al. (2015) is closely related to LAMBADA. CNNDM includes a large set of online articles that are published together with short summaries of their main points. The task is to guess a named entity that has been removed from one such summary. Although the data are not normed by subjects, it is unlikely that the missing named entity can be guessed from the short summary alone, and thus, like in LAMBADA, models need to look at the broader context (the article). Differences between the two datasets include text genres (news vs. novels; see Section 3.1) and the fact that missing items in CNNDM are limited to named entities. Most importantly, the two datasets require models to perform different kinds of inferences over broader passages. For CNNDM, models must be able to *summarize* the articles, in order to make sense of the sentence containing the missing word, whereas in LAMBADA the last sentence is not a summary of the broader passage, but a *continuation* of the same story. Thus, in order to succeed, models must instead understand what is a plausible development of a narrative fragment or a dialogue.

Another related benchmark, CBT, has been introduced by Hill et al. (2016). Like LAMBADA, CBT is a collection of book excerpts, with one word randomly removed from the last sentence in a sequence of 21 sentences. While there are other design differences, the crucial distinction between CBT and LAMBADA is that the CBT passages were not filtered to be human-guessable in the broader context only. Indeed, according to the post-hoc analysis of a sample of CBT passages reported by Hill and colleagues, in a large proportion of cases in which annotators could guess the missing word from the broader context, they could also guess it from the last sentence alone. At the same time, in about one fifth of the cases, the annotators could not guess the word even when the broader context was given. Thus, only a small portion of the CBT passages are really probing the model's ability to understand the broader context, which is instead the focus of LAMBADA.

The idea of a book excerpt completion task was originally introduced in the MSRCC dataset (Zweig and Burges, 2011). However, the latter limited context to single sentences, not attempting to measure broader passage understanding.

Of course, text understanding can be tested through other tasks, including entailment detection (Bowman et al., 2015), answering questions about a text (Richardson et al., 2013; Weston et al., 2015) and measuring inter-clause coherence (Yin and Schütze, 2015). While different tasks can provide complementary insights into the models' abilities, we find word prediction particularly attractive because of its naturalness (it's easy to norm the data with non-expert humans) and simplicity. Models just need to be trained to predict the most likely word given the previous context, following the classic language modeling paradigm, which is a much simpler setup than the one required, say, to determine whether two sentences entail each other. Moreover, models can have access to virtually unlimited amounts of training data, as all that is required to train a language model is raw text. On a more general methodological level, word prediction has the potential to probe almost any aspect of text understanding, including but not limited to traditional narrower tasks such as entailment, co-reference resolution or word sense disambiguation.

3 The LAMBADA dataset

3.1 Data collection[1]

LAMBADA consists of *passages* composed of a *context* (on average 4.6 sentences) and a *target sentence*. The context size is the minimum number of complete sentences before the target sentence such that they cumulatively contain at least 50 tokens (this size was chosen in a pilot study). The task is to guess the last word of the target sentence (the *target word*). The constraint that the target word be the last word of the sentence, while not necessary for our research goal, makes the task more natural for human subjects.

The LAMBADA data come from the Book Corpus (Zhu et al., 2015). The fact that it contains unpublished novels minimizes the potential

[1]Further technical details are provided in the Supplementary Material (SM): `http://clic.cimec.unitn.it/lambada/`

(1) *Context:* “Yes, I thought I was going to lose the baby.” “I was scared too,” he stated, sincerity flooding his eyes. “You were ?” “Yes, of course. Why do you even ask?” “This baby wasn’t exactly planned for.”
Target sentence: “Do you honestly think that I would want you to have a _____ ?”
Target word: miscarriage

(2) *Context:* “Why?” “I would have thought you’d find him rather dry,” she said. “I don’t know about that,” said Gabriel. “He was a great craftsman,” said Heather. “That he was,” said Flannery.
Target sentence: “And Polish, to boot,” said _____.
Target word: Gabriel

(3) *Context:* Preston had been the last person to wear those chains, and I knew what I’d see and feel if they were slipped onto my skin-the Reaper’s unending hatred of me. I’d felt enough of that emotion already in the amphitheater. I didn’t want to feel anymore. “Don’t put those on me,” I whispered. “Please.”
Target sentence: Sergei looked at me, surprised by my low, raspy please, but he put down the _____.
Target word: chains

(4) *Context:* They tuned, discussed for a moment, then struck up a lively jig. Everyone joined in, turning the courtyard into an even more chaotic scene, people now dancing in circles, swinging and spinning in circles, everyone making up their own dance steps. I felt my feet tapping, my body wanting to move.
Target sentence: Aside from writing, I ’ve always loved _____.
Target word: dancing

(5) *Context:* He shook his head, took a step back and held his hands up as he tried to smile without losing a cigarette. “Yes you can,” Julia said in a reassuring voice. “I ’ve already focused on my friend. You just have to click the shutter, on top, here.”
Target sentence: He nodded sheepishly, through his cigarette away and took the _____.
Target word: camera

(6) *Context:* In my palm is a clear stone, and inside it is a small ivory statuette. A guardian angel. “Figured if you’re going to be out at night getting hit by cars, you might as well have some backup.” I look at him, feeling stunned. Like this is some sort of sign.
Target sentence: But as I stare at Harlin, his mouth curved in a confident grin, I don’t care about _____.
Target word: signs

(7) *Context:* Both its sun-speckled shade and the cool grass beneath were a welcome respite after the stifling kitchen, and I was glad to relax against the tree’s rough, brittle bark and begin my breakfast of buttery, toasted bread and fresh fruit. Even the water was tasty, it was so clean and cold.
Target sentence: It almost made up for the lack of _____.
Target word: coffee

(8) *Context:* My wife refused to allow me to come to Hong Kong when the plague was at its height and –” “Your wife, Johanne? You are married at last ?” Johanne grinned. “Well, when a man gets to my age, he starts to need a few home comforts.
Target sentence: After my dear mother passed away ten years ago now, I became _____.
Target word: lonely

(9) *Context:* “Again, he left that up to you. However, he was adamant in his desire that it remain a private ceremony. He asked me to make sure, for instance, that no information be given to the newspaper regarding his death, not even an obituary.
Target sentence: I got the sense that he didn’t want anyone, aside from the three of us, to know that he’d even _____.
Target word: died

(10) *Context:* The battery on Logan’s radio must have been on the way out. So he told himself. There was no other explanation beyond Cygan and the staff at the White House having been overrun. Lizzie opened her eyes with a flutter. They had been on the icy road for an hour without incident.
Target sentence: Jack was happy to do all of the _____.
Target word: driving

Figure 1: Examples of LAMBADA passages. Underlined words highlight when the target word (or its lemma) occurs in the context.

usefulness of general world knowledge and external resources for the task, in contrast to other kinds of texts like news data, Wikipedia text, or famous novels. The corpus, after duplicate removal and filtering out of potentially offensive material with a stop word list, contains 5,325 novels and 465 million words. We randomly divided the novels into equally-sized training and development+testing partitions. We built the LAMBADA dataset from the latter, with the idea that models tackling LAMBADA should be trained on raw text from the training partition, composed of 2662 novels and encompassing more than 200M words. Because novels are pre-assigned to one of the two partitions only, LAMBADA passages are self-contained and cannot be solved by exploiting the knowledge in the remainder of the novels, for example background information about the characters involved or the properties of the fictional world in a given novel. The same novel-based division method is used to further split LAMBADA data between development and testing.

To reduce time and cost of dataset collection, we filtered out passages that are relatively easy for standard language models, since such cases are likely to be guessable based on local context alone. We used a combination of four language models, chosen by availability and/or ease of training: a pre-trained recurrent neural network (RNN) (Mikolov et al., 2011) and three models trained on the Book Corpus (a standard 4-gram model, a RNN and a feed-forward model; see SM for details, and note that these are different from the models we evaluated on LAMBADA as described in Section 4 below). Any passage whose target word had probability $\geq$0.00175 according to any of the language models was excluded.

A random sample of the remaining passages were then evaluated by human subjects through the CrowdFlower crowdsourcing service[2] in three steps. For a given passage,

1. one human subject guessed the target word based on the whole passage (comprising the context and the target sentence); if the guess was right,
2. a second subject guessed the target word based on the whole passage; if that guess was also right,
3. more subjects tried to guess the target word based on the target sentence only, until the word was guessed or the number of unsuccessful guesses reached 10; if no subject was able to guess the target word, the passage was added to the LAMBADA dataset.

The subjects in step 3 were allowed 3 guesses per sentence, to maximize the chances of catching cases where the target words were guessable from the sentence alone. Step 2 was added based on a pilot study that revealed that, while step 3 was enough to ensure that the data could not be guessed with the local context only, step 1 alone did not ensure that the data were easy given the discourse context (its output includes a mix of cases ranging from obvious to relatively difficult, guessed by an especially able or lucky step-1 subject). We made sure that it was not possible for the same subject to judge the same item in both passage and sentence conditions (details in SM).

In the crowdsourcing pipeline, 84–86% items were discarded at step 1, an additional 6–7% at step 2 and another 3–5% at step 3. Only about one in 25 input examples passed all the selection steps.

Subjects were paid \$0.22 per page in steps 1 and 2 (with 10 passages per page) and \$0.15 per page in step 3 (with 20 sentences per page). Overall, each item in the resulting dataset costed \$1.24 on average. Alternative designs, such as having step 3 before step 2 or before step 1, were found to be more expensive. Cost considerations also precluded us from using more subjects at stage 1, which could in principle improve the quality of filtering at this step.

Note that the criteria for passage inclusion were very strict: We required two consecutive subjects to exactly match the missing word, and we made sure that no subject (out of ten) was able to provide it based on local context only, even when given 3 guesses. An alternative to this perfect-match approach would have been to include passages where broad-context subjects provided other plausible or synonymous continuations. However, it is very challenging, both practically and methodologically, to determine which answers other than the original fit the passage well, especially when the goal is to distinguish between items that are solvable in broad-discourse context and those where the local context is enough. Theoretically, substitutability in context could be tested with manual annotation by multiple additional raters, but this would not be financially or practically feasible for a dataset of this scale (human annotators received

[2] http://www.crowdflower.com

over 200,000 passages at stage 1). For this reason we went for the strict hit-or-miss approach, keeping only items that can be unambiguously determined by human subjects.

3.2 Dataset statistics

The LAMBADA dataset consists of 10,022 passages, divided into 4,869 development and 5,153 test passages (extracted from 1,331 and 1,332 disjoint novels, respectively). The average passage consists of 4.6 sentences in the context plus 1 target sentence, for a total length of 75.4 tokens (dev) / 75 tokens (test). Examples of passages in the dataset are given in Figure 1.

The training data for language models to be tested on LAMBADA include the full text of 2,662 novels (disjoint from those in dev+test), comprising 203 million words. Note that the training data consists of text from the same domain as the dev+test passages, in large amounts but not filtered in the same way. This is partially motivated by economic considerations (recall that each data point costs $1.24 on average), but, more importantly, it is justified by the intended use of LAMBADA as a tool to evaluate general-purpose models in terms of how they fare on broad-context understanding (just like our subjects could predict the missing words using their more general text understanding abilities), not as a resource to develop *ad-hoc* models only meant to predict the final word in the sort of passages encountered in LAMBADA. The development data can be used to fine-tune models to the specifics of the LAMBADA passages.

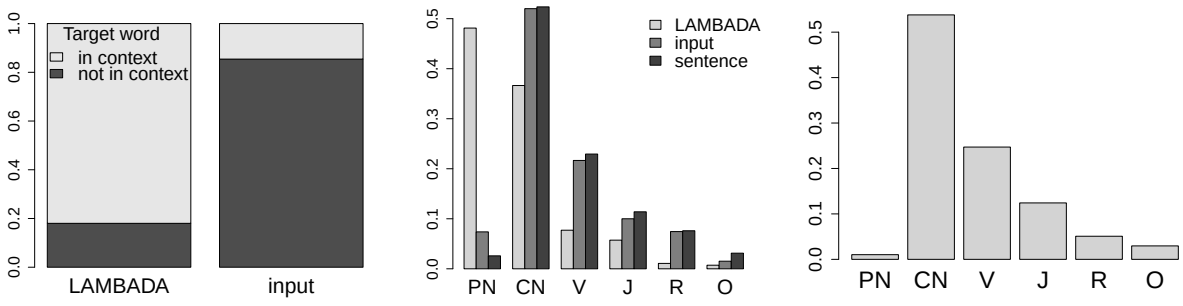
3.3 Dataset analysis

Our analysis of the LAMBADA data suggests that, in order for the target word to be predictable in a broad context only, it must be strongly cued in the broader discourse. Indeed, it is typical for LAMBADA items that the target word (or its lemma) occurs in the context. Figure 2(a) compares the LAMBADA items to a random 5000-item sample from the input data, that is, the passages that were presented to human subjects in the filtering phase (we sampled from all passages passing the automated filters described in Section 3.1 above, including those that made it to LAMBADA). The figure shows that when subjects guessed the word (only) in the broad context, often the word itself occurred in the context: More than 80% of LAMBADA passages include the target word in the context, while in the input data that was the case for less than 15% of the passages. To guess the right word, however, subjects must still put their linguistic and general cognitive skills to good use, as shown by the examples featuring the target word in the context reported in Figure 1.

Figure 2(b) shows that most target words in LAMBADA are proper nouns (48%), followed by common nouns (37%) and, at a distance, verbs (7.7%). In fact, proper nouns are hugely over-represented in LAMBADA, while the other categories are under-represented, compared to the POS distribution in the input. A variety of factors converges in making proper nouns easy for subjects in the LAMBADA task. In particular, when the context clearly demands a referential expression, the constraint that the blank be filled by a single word excludes other possibilities such as noun phrases with articles, and there are reasons to suspect that co-reference is easier than other discourse phenomena in our task (see below). However, although co-reference seems to play a big role, only 0.3% of target words are pronouns.

Common nouns are still pretty frequent in LAMBADA, constituting over one third of the data. Qualitative analysis reveals a mixture of phenomena. Co-reference is again quite common (see Example (3) in Figure 1), sometimes as "partial" co-reference facilitated by bridging mechanisms (*shutter–camera*; Example (5)) or through the presence of a near synonym (*'lose the baby'–miscarriage*; Example (1)). However, we also often find other phenomena, such as the inference of prototypical participants in an event. For instance, if the passage describes someone having breakfast together with typical food and beverages (see Example (7)), subjects can guess the target word *coffee* without it having been explicitly mentioned.

In contrast, verbs, adjectives, and adverbs are rare in LAMBADA. Many of those items can be guessed with local sentence context only, as shown in Figure 2(b), which also reports the POS distribution of the set of items that were guessed by subjects based on the target-sentence context only (step 3 in Section 3.1). Note a higher proportion of verbs, adjectives and adverbs in the latter set in Figure 2(b). While end-of-sentence context skews input distribution in favour of nouns, subject filtering does show a clear differential effect for nouns vs. other POSs. Manual inspection reveals that broad context is not necessary to guess items like



(a) (b) (c)

Figure 2: (a) Target word in or not in context; (b) Target word POS distribution in LAMBADA vs. data presented to human subjects (input) and items guessed with sentence context only (PN=proper noun, CN=common noun, V=verb, J=adjective, R=adverb, O=other); (c) Target word POS distribution of LAMBADA passages where the lemma of the target word is not in the context (categories as in (b)).

frequent verbs (*ask, answer, call*), adjectives, and closed-class adverbs (*now*, *too*, *well*), as well as time-related adverbs (*quickly*, *recently*). In these cases, the sentence context suffices, so few of them end up in LAMBADA (although of course there are exceptions, such as Example (8), where the target word is an adjective). This contrasts with other types of open-class adverbs (e.g., *innocently, confidently*), which are generally hard to guess with both local and broad context. The low proportion of these kinds of adverbs and of verbs among guessed items in general suggests that tracking event-related phenomena (such as script-like sequences of events) is harder for subjects than coreferential phenomena, at least as framed in the LAMBADA task. Further research is needed to probe this hypothesis.

Furthermore, we observe that, while explicit mention in the preceding discourse context is critical for proper nouns, the other categories can often be guessed without having been explicitly introduced. This is shown in Figure 2(c), which depicts the POS distribution of LAMBADA items for which the lemma of the target word is not in the context (corresponding to about 16% of LAMBADA in total).[3] Qualitative analysis of items with verbs and adjectives as targets suggests that the target word, although not present in the passage, is still strongly implied by the context. In about one third of the cases examined, the missing word is "almost there". For instance, the passage contains a word with the same root but a different part of speech (e.g., *death–died* in Example (6)), or a synonymous expression (as mentioned above for "miscarriage"; we find the same phenomenon for verbs, e.g., *'deprived you of water'–dehydrated*).

In other cases, correct prediction requires more complex discourse inference, including guessing prototypical participants of a scene (as in the *coffee* example above), actions or events strongly suggested by the discourse (see Examples (1) and (10), where the mention of an icy road helps in predicting the target *driving*), or qualitative properties of participants or situations (see Example (8)). Of course, the same kind of discourse reasoning takes place when the target word is already present in the context (cf. Examples (3) and (4)). The presence of the word in context does not make the reasoning unnecessary (the task remains challenging), but facilitates the inference.

As a final observation, intriguingly, the LAMBADA items contain (quoted) direct speech significantly more often than the input items overall (71% of LAMBADA items vs. 61% of items in the input sample), see, e.g., Examples (1) and (2). Further analysis is needed to investigate in what way more dialogic discourse might facilitate the prediction of the final target word.

In sum, LAMBADA contains a myriad of phenomena that, besides making it challenging from the text understanding perspective, are of great interest to the broad Computational Linguistics

[3]The apparent 1% of out-of-context proper nouns shown in Figure 2(c) is due to lemmatization mistakes (fictional characters for which the lemmatizer did not recognize a link between singular and plural forms, e.g., *Wynn – Wynns*). A manual check confirmed that all proper noun target words in LAMBADA are indeed also present in the context.

community. To return to Example (1), solving it requires a combination of linguistic skills ranging from (morpho)phonology (the plausible target word *abortion* is ruled out by the indefinite determiner *a*) through morphosyntax (the slot should be filled by a common singular noun) to pragmatics (understanding what the male participant is inferring from the female participant's words), in addition to general reasoning skills. It is not surprising, thus, that LAMBADA is so challenging for current models, as we show next.

4 Modeling experiments

Computational methods We tested several existing language models and baselines on LAMBADA. We implemented a simple **RNN** (Elman, 1990), a Long Short-Term Memory network (**LSTM**) (Hochreiter and Schmidhuber, 1997), a traditional statistical **N-Gram** language model (Stolcke, 2002) with and without **cache**, and a **Memory Network** (Sukhbaatar et al., 2015). We remark that at least LSTM, Memory Network and, to a certain extent, the cache N-Gram model have, among their supposed benefits, the ability to take broader contexts into account. Note moreover that variants of RNNs and LSTMs are at the state of the art when tested on standard language modeling benchmarks (Mikolov, 2014). Our Memory Network implementation is similar to the one with which Hill et al. (2016) reached the best results on the CBT data set (see Section 2 above). While we could not re-implement the models that performed best on CNNDM (see again Section 2), our LSTM is architecturally similar to the Deep LSTM Reader of Hermann et al. (2015), which achieved respectable performance on that data set. Most importantly, we will show below that most of our models reach impressive performance when tested on a more standard language modeling data set sourced from the same corpus used to build LAMBADA. This **control** set was constructed by randomly sampling 5K passages of the same shape and size as the ones used to build LAMBADA from the same test novels, but without filtering them in any way. Based on the control set results, to be discussed below, we can reasonably claim that the models we are testing on LAMBADA are very good at standard language modeling, and their low performance on the latter cannot be attributed to poor quality.

In order to test for strong biases in the data, we constructed **Sup-CBOW**, a baseline model weakly tailored to the task at hand, consisting of a simple neural network that takes as input a bag-of-word representation of the passage and attempts to predict the final word. The input representation comes from adding pre-trained CBOW vectors (Mikolov et al., 2013) of the words in the passage.[4] We also considered an unsupervised variant (**Unsup-CBOW**) where the target word is predicted by cosine similarity between the passage vector and the target word vector. Finally, we evaluated several variations of a random guessing baseline differing in terms of the word pool to sample from. The guessed word could be picked from: the full vocabulary, the words that appear in the current passage and a random uppercased word from the passage. The latter baseline aims at exploiting the potential bias that proper names account for a consistent portion of the LAMBADA data (see Figure 2 above).

Note that LAMBADA was designed to challenge language models with harder-than-average examples where broad context understanding is crucial. However, the average case should not be disregarded either, since we want language models to be able to handle both cases. For this reason, we trained the models entirely on unsupervised data and expect future work to follow similar principles. Concretely, we trained the models, as is standard practice, on predicting each upcoming word given the previous context, using the LAMBADA training data (see Section 3.2 above) as input corpus. The only exception to this procedure was Sup-CBOW where we extracted from the training novels similar-shaped passages to those in LAMBADA and trained the model on them (about 9M passages). Again, the goal of this model was only to test for potential biases in the data and not to provide a full account for the phenomena we are testing. We restricted the vocabulary of the models to the 60K most frequent words in the training set (covering 95% of the target words in the development set). The model hyperparameters were tuned on their accuracy in the development set. The same trained models were tested on the LAMBADA and the control sets. See SM for the tuning details.

Results Results of models and baselines are reported in Table 1. Note that the measure of interest

Table 1: Results of computational methods. Accuracy is expressed in percentage.

for LAMBADA is the average success of a model at predicting the target word, i.e., accuracy (unlike in standard language modeling, we know that the missing LAMBADA words can be precisely predicted by humans, so good models should be able to accomplish the same feat, rather than just assigning a high probability to them). However, as we observe a bottoming effect with accuracy, we also report perplexity and median rank of correct word, to better compare the models.

As anticipated above, and in line with what we expected, all our models have very good performance when called to perform a standard language modeling task on the control set. Indeed, 3 of the models (the N-Gram models and LSTM) can guess the right word in about 1/5 of the cases.

The situation drastically changes if we look at the LAMBADA results, where all models are performing very badly. Indeed, no model is even able to compete with the simple heuristics of picking a random word from the passage, and, especially, a random capitalized word (easily a proper noun). At the same time, the low performance of the latter heuristic in absolute terms (7% accuracy) shows that, despite the bias in favour of names in the passage, simply relying on this will not suffice to obtain good performance on LAMBADA, and models should rather pursue deeper forms of analysis of the broader context (the Sup-CBOW baseline, attempting to directly exploit the passage in a shallow way, performs very poorly). This confirms again that the difficulty of LAMBADA relies mainly on accounting for the information available in a broader context and not on the task of predicting the exact word missing.

In comparative terms (and focusing on perplexity and rank, given the uniformly low accuracy results) we observe a stronger performance of the traditional N-Gram models over the neural-network-based ones, possibly pointing to the difficulty of tuning the latter properly. In particular, the best relative performance on LAMBADA is achieved by N-Gram w/cache, which takes passage statistics into account. While even this model is effectively unable to guess the right word, it achieves a respectable perplexity of 768.

We recognize, of course, that the evaluation we performed is very preliminary, and it must only be taken as a proof-of-concept study of the difficulty of LAMBADA. Better results might be obtained simply by performing more extensive tuning, by adding more sophisticated mechanisms such as attention (Bahdanau et al., 2014), and so forth. Still, we would be surprised if minor modifications of the models we tested led to human-level performance on the task.

We also note that, because of the way we have constructed LAMBADA, standard language models are bound to fail on it by design: one of our first filters (see Section 3.1) was to choose passages where a number of simple language models were failing to predict the upcoming word. However, future research should find ways around this inherent difficulty. After all, humans were still able to solve this task, so a model that claims to have good language understanding ability should be able to succeed on it as well.

5 Conclusion

This paper introduced the new LAMBADA dataset, aimed at testing language models on their ability to take a broad discourse context into account when predicting a word. A number of linguistic phenomena make the target words in LAMBADA easy to guess by human subjects when they can look at the whole passages they come from, but nearly impossible if only the last sentence is considered. Our preliminary experiments suggest that even some cutting-edge neural network approaches that are in principle able to track long-distance effects are far from passing the LAMBADA challenge.

We hope the computational community will be stimulated to develop novel language models that are genuinely capturing the non-local phenomena that LAMBADA reflects. To promote research in this direction, we plan to announce a public competition based on the LAMBADA data.[5]

Our own hunch is that, despite the initially disappointing results of the "vanilla" Memory Network we tested, the ability to store information in a longer-term memory will be a crucial component of successful models, coupled with the ability to perform some kind of reasoning about what's stored in memory, in order to retrieve the right information from it.

On a more general note, we believe that leveraging human performance on word prediction is a very promising strategy to construct benchmarks for computational models that are supposed to capture various aspects of human text understanding. The influence of broad context as explored by LAMBADA is only one example of this idea.

[5]The development set of LAMBADA, along with the training corpus, can be downloaded at `http://clic.cimec.unitn.it/lambada/`. The test set will be made available at the time of the competition.

{dhewlett,allac,llion,ipolosukhin,fto,hanjay,matkelcey,dberth}@google.com

Abstract

We present WIKIREADING, a large-scale natural language understanding task and publicly-available dataset with 18 million instances. The task is to predict textual values from the structured knowledge base Wikidata by reading the text of the corresponding Wikipedia articles. The task contains a rich variety of challenging classification and extraction sub-tasks, making it well-suited for end-to-end models such as deep neural networks (DNNs). We compare various state-of-the-art DNN-based architectures for document classification, information extraction, and question answering. We find that models supporting a rich answer space, such as word or character sequences, perform best. Our best-performing model, a word-level sequence to sequence model with a mechanism to copy out-of-vocabulary words, obtains an accuracy of 71.8%.

1 Introduction

A growing amount of research in natural language understanding (NLU) explores end-to-end deep neural network (DNN) architectures for tasks such as text classification (Zhang et al., 2015), relation extraction (Nguyen and Grishman, 2015), and question answering (Weston et al., 2015). These models offer the potential to remove the intermediate steps traditionally involved in processing natural language data by operating on increasingly raw forms of text input, even unprocessed character or byte sequences. Furthermore, while these tasks are often studied in isolation, DNNs have the potential to combine multiple forms of reasoning within a single model.

Supervised training of DNNs often requires a large amount of high-quality training data. To this end, we introduce a novel prediction task and accompanying large-scale dataset with a range of sub-tasks combining text classification and information extraction. The dataset is made publicly-available at `http://goo.gl/wikireading`. The task, which we call WIKIREADING, is to predict textual values from the open knowledge base *Wikidata* (Vrandečić and Krötzsch, 2014) given text from the corresponding articles on *Wikipedia* (Ayers et al., 2008). Example instances are shown in Table 1, illustrating the variety of subject matter and sub-tasks. The dataset contains 18.58M instances across 884 sub-tasks, split roughly evenly between classification and extraction (see Section 2 for more details).

In addition to its diversity, the WIKIREADING dataset is also at least an order of magnitude larger than related NLU datasets. Many natural language datasets for question answering (QA), such as WIKIQA (Yang et al., 2015), have only thousands of examples and are thus too small for training end-to-end models. Hermann et al. (2015) proposed a task similar to QA, predicting entities in news summaries from the text of the original news articles, and generated a NEWS dataset with 1M instances. The bAbI dataset (Weston et al., 2015) requires multiple forms of reasoning, but is composed of synthetically generated documents. WIKIQA and NEWS only involve pointing to locations within the document, and text classification datasets often have small numbers of output classes. In contrast, WIKIREADING has a rich output space of millions of answers, making it a challenging benchmark for state-of-the-art DNN architectures for QA or text classification.

We implemented a large suite of recent models, and for the first time evaluate them on common grounds, placing the complexity of the task in context and illustrating the tradeoffs inherent in each

approach. The highest score of 71.8% is achieved by a sequence to sequence model (Kalchbrenner and Blunsom, 2013; Cho et al., 2014) operating on word-level input and output sequences, with special handing for out-of-vocabulary words.

2 WIKIREADING

We now provide background information relating to Wikidata, followed by a detailed description of the WIKIREADING prediction task and dataset.

2.1 Wikidata

Wikidata is a free collaborative knowledge base containing information about approximately 16M *items* (Vrandečić and Krötzsch, 2014). Knowledge related to each item is expressed in a set of *statements*, each consisting of a (`property, value`) tuple. For example, the item `Paris` might have associated statements asserting `(instance of, city)` or `(country, France)`. Wikidata contains over 80M such statements across 884 properties. Items may be linked to articles on Wikipedia.

2.2 Dataset

We constructed the WIKIREADING dataset from Wikidata and Wikipedia as follows: We consolidated all Wikidata statements with the same item and property into a single `(item, property, answer)` triple, where `answer` is a set of values. Replacing each `item` with the text of the linked Wikipedia article (discarding unlinked items) yields a dataset of 18.58M `(document, property, answer)` instances. Importantly, all elements in each instance are human-readable strings, making the task entirely textual. The only modification we made to these strings was to convert timestamps into a human-readable format (e.g., "4 July 1776").

The WIKIREADING task, then, is to predict the answer string for each tuple given the document and property strings. This setup can be seen as similar to information extraction, or question answering where the property acts as a "question". We assigned all instances for each document randomly to either training (12.97M instances), validation (1.88M), and test (3.73M) sets following a 70/10/20 distribution. This ensures that, during validation and testing, all documents are unseen.

2.3 Documents

The dataset contains 4.7M unique Wikipedia articles, meaning that roughly 80% of the English-language Wikipedia is represented. Multiple instances can share the same document, with a mean of 5.31 instances per article (median: 4, max: 879). The most common categories of documents are `human`, `taxon`, `film`, `album`, and `human settlement`, making up 48.8% of the documents and 9.1% of the instances. The mean and median document lengths are 489.2 and 203 words.

2.4 Properties

The dataset contains 884 unique properties, though the distribution of properties across instances is highly skewed: The top 20 properties cover 75% of the dataset, with 99% coverage achieved after 180 properties. We divide the properties broadly into two groups: *Categorical* properties, such as `instance of`, `gender` and `country`, require selecting between a relatively small number of possible answers, while *relational* properties, such as `date of birth`,

Property	Frequency	Entropy
instance of	2,574,038	0.431
sex or gender	941,200	0.189
country	803,252	0.536
date of birth	785,049	0.936
given name	767,916	0.763
occupation	716,176	0.589
country of citizenship	674,560	0.501
located in ... entity	478,372	0.802
place of birth	384,951	0.800
date of death	364,910	0.943

Table 2: Training set frequency and scaled answer entropy for the 10 most frequent properties.

`parent`, and `capital`, typically require extracting rare or totally unique answers from the document.

To quantify this difference, we compute the entropy of the answer distribution A for each property p, scaled to the $[0, 1]$ range by dividing by the entropy of a uniform distribution with the same number of values, i.e., $\hat{H}(p) = H(A_p)/\log|A_p|$. Properties that represent essentially one-to-one mappings score near 1.0, while a property with just a single answer would score 0.0. Table 2 lists entropy values for a subset of properties, showing that the dataset contains a spectrum of sub-tasks. We label properties with an entropy less than 0.7 as categorical, and those with a higher entropy as relational. Categorical properties cover 56.7% of the instances in the dataset, with the remaining 43.3% being relational.

2.5 Answers

The distribution of properties described above has implications for the answer distribution. There are a relatively small number of very high frequency "head" answers, mostly for categorical properties, and a vast number of very low frequency "tail" answers, such as names and dates. At the extremes, the most frequent answer `human` accounts for almost 7% of the dataset, while 54.7% of the answers in the dataset are unique. There are some special categories of answers which are systematically related, in particular *dates*, which comprise 8.9% of the dataset (with 7.2% being unique). This distribution means that methods focused on either head or tail answers can each perform moderately well, but only a method that handles both types of answers can achieve maximum performance. Another consequence of the long tail of answers is that many (30.0%) of the answers in the test set never appear in the training set, meaning they must be read out of the document. An answer is present verbatim in the document for 45.6% of the instances.

3 Methods

Recently, neural network architectures for NLU have been shown to meet or exceed the performance of traditional methods (Zhang et al., 2015; Dai and Le, 2015). The move to deep neural networks also allows for new ways of combining the property and document, inspired by recent research in the field of question answering (with the property serving as a question). In sequential models such as Recurrent Neural Networks (RNNs), the question could be prepended to the document, allowing the model to "read" the document differently for each question (Hermann et al., 2015). Alternatively, the question could be used to compute a form of *attention* (Bahdanau et al., 2014) over the document, to effectively focus the model on the most predictive words or phrases (Sukhbaatar et al., 2015; Hermann et al., 2015). As this is currently an ongoing field of research, we implemented a range of recent models and for the first time compare them on common grounds. We now describe these methods, grouping them into broad categories by general approach and noting necessary modifications. Later, we introduce some novel variations of these models.

3.1 Answer Classification

Perhaps the most straightforward approach to WIKIREADING is to consider it as a special case of document classification. To fit WIKIREADING into this framework, we consider each possible answer as a class label, and incorporate features based on the property so that the model can make different predictions for the same document. While the number of potential answers is too large to be practical (and unbounded in principle), a substantial portion of the dataset can be covered by a model with a tractable number of answers.

3.1.1 Baseline

The most common approach to document classification is to fit a linear model (e.g., Logistic Regression) over bag of words (BoW) features. To serve as a baseline for our task, the linear model needs to make different predictions for the same Wikipedia article depending on the property. We enable this behavior by computing two N_{w} element BoW vectors, one each for the document

and property, and concatenating them into a single $2N_{\text{w}}$ feature vector.

3.1.2 Neural Network Methods

All of the methods described in this section encode the property and document into a *joint representation* $\mathbf{y} \in \mathbb{R}^{d_{\text{out}}}$, which serves as input for a final softmax layer computing a probability distribution over the top N_{ans} answers. Namely, for each answer $i \in \{1, \ldots, N_{\text{ans}}\}$, we have:

$$P(i|\mathbf{x}) = e^{\mathbf{y}^\top \mathbf{a}_i} / \sum_{j=1}^{N_{\text{ans}}} e^{\mathbf{y}^\top \mathbf{a}_j}, \qquad (1)$$

where $\mathbf{a}_i \in \mathbb{R}^{d_{\text{out}}}$ corresponds to a learned vector associated with answer i. Thus, these models differ primarily in how they combine the property and document to produce the joint representation. For existing models from the literature, we provide a brief description and note any important differences in our implementation, but refer the reader to the original papers for further details.

Except for character-level models, documents and properties are tokenized into words. The N_{w} most frequent words are mapped to a vector in $\mathbb{R}^{d_{\text{in}}}$ using a learned embedding matrix[1]. Other words are all mapped to a special out of vocabulary (OOV) token, which also has a learned embedding. d_{in} and d_{out} are hyperparameters for these models.

Averaged Embeddings (BoW): This is the neural network version of the baseline method described in Section 3.1.1. Embeddings for words in the document and property are separately averaged. The concatenation of the resulting vectors forms the joint representation of size $2d_{\text{in}}$.

Paragraph Vector: We explore a variant of the previous model where the document is encoded as a *paragraph vector* (Le and Mikolov, 2014). We apply the PV-DBOW variant that learns an embedding for a document by optimizing the prediction of its constituent words. These unsupervised document embeddings are treated as a fixed input to the supervised classifier, with no fine-tuning.

LSTM Reader: This model is a simplified version of the Deep LSTM Reader proposed by Hermann et al. (2015). In this model, an LSTM (Hochreiter and Schmidhuber, 1997) reads the property and document sequences word-by-word and the final state is used as the joint representation. This is the simplest model that respects the order of the words in the document. In our implementation we use a single layer instead of two and a larger hidden size. More details on the architecture can be found in Section 4.1 and in Table 4.

Attentive Reader: This model, also presented in Hermann et al. (2015), uses an attention mechanism to better focus on the relevant part of the document for a given property. Specifically, Attentive Reader first generates a representation $\mathbf{u}$ of the property using the final state of an LSTM while a second LSTM is used to read the document and generate a representation $\mathbf{z}_t$ for each word. Then, conditioned on the property encoding $\mathbf{u}$, a normalized attention is computed over the document to produce a weighted average of the word representations $\mathbf{z}_t$, which is then used to generate the joint representation $\mathbf{y}$. More precisely:

$$\begin{aligned}
\mathbf{m}_t &= \tanh(W_1 \operatorname{concat}(\mathbf{z}_t, \mathbf{u})) \\
\alpha_t &= \exp(\mathbf{v}^\intercal \mathbf{m}_t) \\
\mathbf{r} &= \textstyle\sum_t \frac{\alpha_t}{\sum_\tau \alpha_\tau} \mathbf{z}_t \\
\mathbf{y} &= \tanh(W_2 \operatorname{concat}(\mathbf{r}, \mathbf{u})),
\end{aligned}$$

where W_1, W_2, and $\mathbf{v}$ are learned parameters.

Memory Network: Our implementation closely follows the End-to-End Memory Network proposed in Sukhbaatar et al. (2015). This model maps a property p and a list of sentences $\mathbf{x}_1, \ldots, \mathbf{x}_n$ to a joint representation $\mathbf{y}$ by attending over sentences in the document as follows: The input encoder I converts a sequence of words $\mathbf{x}_i = (x_{i1}, \ldots, x_{iL_i})$ into a vector using an embedding matrix (equation 2), where L_i is the length of sentence i.[2] The property is encoded with the embedding matrix U (eqn. 3). Each sentence is encoded into two vectors, a memory vector (eqn. 4) and an output vector (eqn. 5), with embedding matrices M and C, respectively. The property encoding is used to compute a normalized attention vector over the memories (eqn. 6).[3] The joint representation is the sum of the output vectors weighted

[1] Limited experimentation with initialization from publicly-available word2vec embeddings (Mikolov et al., 2013) yielded no improvement in performance.

[2] Our final results use the position encoding method proposed by Sukhbaatar et al. (2015), which incorporates positional information in addition to word embeddings.

[3] Instead of the linearization method of Sukhbaatar et al. (2015), we applied an entropy regularizer for the softmax attention as described in Kurach et al. (2015).

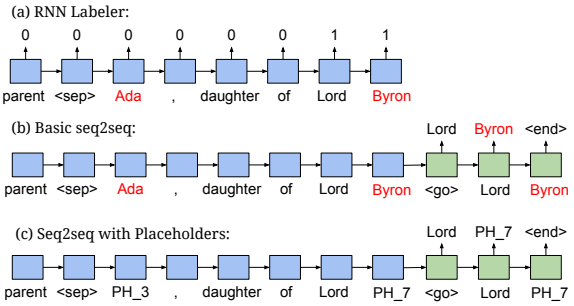

Figure 1: Illustration of RNN models. Blocks with same color share parameters. Red words are out of vocabulary and all share a common embedding.

by this attention (eqn. 7).

$$I(x_i, W) = \sum_j W x_{ij} \quad (2)$$

$$\mathbf{u} = I(p, U) \quad (3)$$

$$\mathbf{m}_i = I(x_i, M) \quad (4)$$

$$\mathbf{c}_i = I(x_i, C) \quad (5)$$

$$\mathbf{p}_i = \text{softmax}(\mathbf{q}^\intercal \mathbf{m}_i) \quad (6)$$

$$\mathbf{y} = \mathbf{u} + \sum_i \mathbf{p}_i \mathbf{c}_i \quad (7)$$

3.2 Answer Extraction

Relational properties involve mappings between arbitrary entities (e.g., `date of birth`, `mother`, and `author`) and thus are less amenable to document classification. For these, approaches from information extraction (especially relation extraction) are much more appropriate. In general, these methods seek to identify a word or phrase in the text that stands in a particular relation to a (possibly implicit) subject. Section 5 contains a discussion of prior work applying NLP techniques involving entity recognition and syntactic parsing to this problem.

RNNs provide a natural fit for extraction, as they can predict a value at every position in a sequence, conditioned on the entire previous sequence. The most straightforward application to WIKIREADING is to predict the probability that a word at a given location is part of an answer. We test this approach using an RNN that operates on the sequence of words. At each time step, we use a sigmoid activation for estimating whether the current word is part of the answer or not. We refer to this model as the *RNN Labeler* and present it graphically in Figure 1a.

For training, we label all locations where any answer appears in the document with a 1, and other positions with a 0 (similar to distant supervision (Mintz et al., 2009)). For multi-word answers, the word sequences in the document and answer must fully match[4]. Instances where no answer appears in the document are discarded for training. The cost function is the average cross-entropy for the outputs across the sequence. When performing inference on the test set, sequences of consecutive locations scoring above a threshold are chunked together as a single answer, and the top-scoring answer is recorded for submission.[5]

3.3 Sequence to Sequence

Recently, sequence to sequence learning (or *seq2seq*) has shown promise for natural language tasks, especially machine translation (Cho et al., 2014). These models combine two RNNs: an *encoder*, which transforms the input sequence into a vector representation, and a *decoder*, which converts the encoder vector into a sequence of output tokens, one token at a time. This makes them capable, in principle, of approximating any function mapping sequential inputs to sequential outputs. Importantly, they are the first model we consider that can perform any combination of answer classification and extraction.

3.3.1 Basic seq2seq

This model resembles LSTM Reader augmented with a second RNN to decode the answer as a sequence of words. The embedding matrix is shared across the two RNNs but their state to state transition matrices are different (Figure 1b). This method extends the set of possible answers to any sequence of words from the document vocabulary.

3.3.2 Placeholder seq2seq

While Basic seq2seq already expands the expressiveness of LSTM Reader, it still has a limited vocabulary and thus is unable to generate some answers. As mentioned in Section 3.2, RNN Labeler can extract any sequence of words present in the document, even if some are OOV. We extend the basic seq2seq model to handle OOV words by adding *placeholders* to our vocabulary, increasing the vocabulary size from N_w to $N_\text{w} + N_\text{doc}$. Then, when an OOV word occurs in the document, it is replaced at random (without replacement). by one of these placeholders. We also replace the corresponding OOV words in the target output se-

[4]Dates were matched semantically to increase recall.

[5]We chose an arbitrary threshold of 0.5 for chunking. The score of each chunk is obtained from the harmonic mean of the predicted probabilities of its elements.

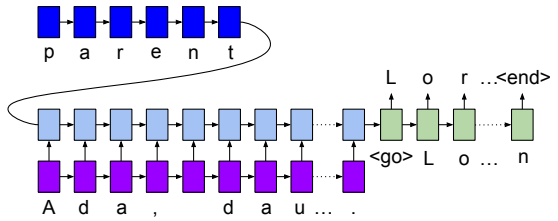

Figure 2: Character seq2seq model. Blocks with the same color share parameters. The same example as in Figure 1 is fed character by character.

quence by the same placeholder,[6] as shown in Figure 1c. Luong et al. (2015) developed a similar procedure for dealing with rare words in machine translation, copying their locations into the output sequence for further processing.

This makes the input and output sequences a mixture of known words and placeholders, and allows the model to produce any answer the RNN Labeler can produce, in addition to the ones that the basic seq2seq model could already produce. This approach is comparable to *entity anonymization* used in Hermann et al. (2015), which replaces named entities with random ids, but simpler because we use word-level placeholders without entity recognition.

3.3.3 Basic Character seq2seq

Another way of handling rare words is to process the input and output text as sequences of characters or bytes. RNNs have shown some promise working with character-level input, including state-of-the-art performance on a Wikipedia text classification benchmark (Dai and Le, 2015). A model that outputs answers character by character can in principle generate any of the answers in the test set, a major advantage for WIKIREADING.

This model, shown in Figure 2, operates only on sequences of mixed-case characters. The property encoder RNN transforms the property, as a character sequence, into a fixed-length vector. This property encoding becomes the initial hidden state for the second layer of a two-layer document encoder RNN, which reads the document, again, character by character. Finally, the answer decoder RNN uses the final state of the previous RNN to decode the character sequence for the answer.

[6]The same OOV word may occur several times in the document. Our simplified approach will attribute a different placeholder for each of these and will use the first occurrence for the target answer.

3.3.4 Character seq2seq with Pretraining

Unfortunately, at the character level the length of all sequences (documents, properties, and answers) is greatly increased. This adds more sequential steps to the RNN, requiring gradients to propagate further, and increasing the chance of an error during decoding. To address this issue in a classification context, Dai and Le (2015) showed that initializing an LSTM classifier with weights from a language model (LM) improved its accuracy. Inspired by this result, we apply this principle to the character seq2seq model with a two-phase training process: In the first phase, we train a character-level LM on the input character sequences from the WIKIREADING training set (no new data is introduced). In the second phase, the weights from this LM are used to initialize the first layer of the encoder and the decoder (purple and green blocks in Figure 2). After initialization, training proceeds as in the basic character seq2seq model.

4 Experiments

We evaluated all methods from Section 3 on the full test set with a single scoring framework. An answer is correct when there is an exact string match between the predicted answer and the gold answer. However, as describe in Section 2.2, some answers are composed from a set of values (e.g. third example in Table 1). To handle this, we define the *Mean F1* score as follows: For each instance, we compute the F1-score (harmonic mean of precision and recall) as a measure of the degree of overlap between the predicted answer set and the gold set for a given instance. The resulting per-instance F1 scores are then averaged to produce a single dataset-level score. This allows a method to obtain partial credit for an instance when it answers with at least one value from the golden set. In this paper, we only consider methods for answering with a single value, and most answers in the dataset are also composed of a single value, so this Mean F1 metric is closely related to accuracy. More precisely, a method using a single value as answer is bounded by a Mean F1 of 0.963.

4.1 Training Details

We implemented all models in a single framework based on TensorFlow (Abadi et al., 2015) with shared pre-processing and comparable hyperparameters whenever possible. All documents are

Method	Mean F1	Bound	Categorical	Relational	Date	Params
Answer Classifier						
Sparse BoW Baseline	0.438	0.831	0.725	0.063	0.004	500.5M
Averaged Embeddings	0.583		0.849	0.234	0.080	120M
Paragraph Vector	0.552		0.787	0.227	0.033	30M
LSTM Reader	0.680		0.880	0.421	0.311	45M
Attentive Reader	0.693		**0.886**	0.441	0.337	56M
Memory Network	0.612		0.861	0.288	0.055	90.1M
Answer Extraction						
RNN Labeler	0.357	0.471	0.240	0.536	0.626	41M
Sequence to Sequence						
Basic seq2seq	0.708	0.925	0.844	0.530	**0.738**	32M
Placeholder seq2seq	**0.718**	0.948	0.835	**0.565**	0.730	32M
Character seq2seq	0.677	**0.963**	0.841	0.462	0.731	4.1M
Character seq2seq (LM)	0.699	**0.963**	0.851	0.501	0.733	4.1M

Table 3: Results for all methods described in Section 3 on the test set. *F1* is the Mean F1 score described in 4. *Bound* is the upper bound on Mean F1 imposed by constraints in the method (see text for details). The remaining columns provide score breakdowns by property type and the number of model parameters.

truncated to the first 300 words except for Character seq2seq, which uses 400 characters. The embedding matrix used to encode words in the document uses $d_{\text{in}} = 300$ dimensions for the $N_{\text{w}} = 100,000$ most frequent words. Similarly, answer classification over the $N_{\text{ans}} = 50,000$ most frequent answers is performed using an answer representation of size $d_{\text{out}} = 300$.[7] The first 10 words of the properties are embedded using the document embedding matrix. Following Cho et al. (2014), RNNs in seq2seq models use a GRU cell with a hidden state size of 1024. More details on parameters are reported in Table 4.

Method	Emb. Dims	Doc. Length	Property Length	Doc. Vocab. Size
Sparse BoW Baseline	N/A	300 words	10 words	50K words
Paragraph Vector	N/A	N/A	10 words	N/A
Character seq2seq	30	400 chars	20 chars	76 chars
All others	300	300 words	10 words	100K words

Table 4: Structural model parameters. Note that the Paragraph Vector method uses the output from a separate, unsupervised model as a document encoding, which is not counted in these parameters.

Optimization was performed with the Adam stochastic optimizer[8] (Kingma and Adam, 2015) over mini-batches of 128 samples. Gradient clipping [9] (Graves, 2013) is used to prevent instability in training RNNs. We performed a search over 50 randomly-sampled hyperparameter configurations for the learning rate and gradient clip threshold, selecting the one with the highest Mean F1 on the validation set. Learning rate and clipping threshold are sampled uniformly, on a logarithmic scale, over the range $[10^{-5}, 10^{-2}]$ and $[10^{-3}, 10^{1}]$ respectively.

4.2 Results and Discussion

Results for all models on the held-out set of test instances are presented in Table 3. In addition to the overall Mean F1 scores, the model families differ significantly in Mean F1 upper bound, and their relative performance on the relational and categorical properties defined in Section 2.4. We also report scores for properties containing dates, a subset of relational properties, as a separate column since they have a distinct format and organization. For examples of model performance on individual properties, see Table 5.

As expected, all classifier models perform well for categorical properties, with more sophisticated classifiers generally outperforming simpler ones. The difference in precision reading ability between models that use broad document statistics, like Averaged Embeddings and Paragraph Vectors, and the RNN-based classifiers is revealed in the scores for relational and especially date properties. As shown in Table 5, this difference is magnified in situations that are more difficult for a classifier, such as relational properties or properties with fewer training examples, where Attentive Reader outperforms Averaged Embeddings by a wide margin. This model family also has a high

[7] For models like Averaged Embedding and Paragraph Vector, the concatenation imposes a greater d_{out}.

[8] Using $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 10^{-8}$.

[9] When the norm of gradient $\mathbf{g}$ exceeds a threshold C, it is scaled down i.e. $\mathbf{g} \leftarrow \mathbf{g} \cdot \min\left(1, \frac{C}{||\mathbf{g}||}\right)$.

Table 5: Property-level Mean F1 scores on the test set for selected methods and properties. For each property type, the two most frequent properties are shown followed by two less frequent properties to illustrate long-tail behavior.

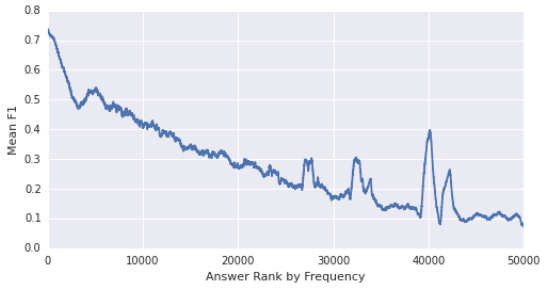

Figure 3: Per-answer Mean F1 scores for Attentive Reader (moving average of 1000), illustrating the decline in prediction quality as the number of training examples per answer decreases.

upper bound, as perfect classification across the 50,000 most frequent answers would yield a Mean F1 of 0.831. However, none of them approaches this limit. Part of the reason is that their accuracy for a given answer decreases quickly as the frequency of the answer in the training set decreases, as illustrated in Figure 3. As these models have to learn a separate weight vector for each answer as part of the softmax layer (see Section 3.1), this may suggest that they fail to generalize across answers effectively and thus require significant number of training examples per answer.

The only answer extraction model evaluated, RNN Labeler, shows a complementary set of strengths, performing better on relational properties than categorical ones. While the Mean F1 upper bound for this model is just 0.434 because it can only produce answers that are present verbatim in the document text, it manages to achieve most of this potential. The improvement on date properties over the classifier models demonstrates its ability to identify answers that are typically present in the document. We suspect that answer extraction may be simpler than answer classification because the model can learn robust patterns that indicate a location without needing to learn about each answer, as the classifier models must.

The sequence to sequence models show a greater degree of balance between relational and categorical properties, reaching performance consistent with classifiers on the categorical questions and with RNN Labeler on relational questions. Placeholder seq2seq can in principle produce any answer that RNN Labeler can, and the performance on relational properties is indeed similar. As shown in Table 5, Placeholder seq2seq performs especially well for properties where the answer typically contains rare words such as the name of a place or person. When the set of possible answer tokens is more constrained, such

as in categorical or date properties, the Basic seq2seq often performs slightly better. Character seq2seq has the highest upper bound, limited to 0.963 only because it cannot produce an answer set with multiple elements. LM pretraining consistently improves the performance of the Character seq2seq model, especially for relational properties as shown in Table 5. The performance of the Character seq2seq, especially with LM pretraining, is a surprising result: It performs comparably to the word-level seq2seq models even though it must copy long character strings when doing extraction and has access to a smaller portion of the document. We found the character based models to be particularly sensitive to hyperparameters. However, using a pretrained language model reduced this issue and significantly accelerated training while improving the final score. We believe that further research on pretraining for character based models could improve this result.

5 Related Work

The goal of automatically extracting structured information from unstructured Wikipedia text was first advanced by Wu and Weld (2007). As Wikidata did not exist at that time, the authors relied on the structured *infoboxes* included in some Wikipedia articles for a relational representation of Wikipedia content. Wikidata is a cleaner data source, as the infobox data contains many slight variations in schema related to page formatting. Partially to get around this issue, the authors restrict their prediction model Kylin to 4 specific infobox classes, and only common attributes within each class.

A substantial body of work in relation extraction (RE) follows the distant supervision paradigm (Craven and Kumlien, 1999), where sentences containing both arguments of a knowledge base (KB) triple are assumed to express the triple's relation. Broadly, these models use these distant labels to identify syntactic features relating the subject and object entities in text that are indicative of the relation. Mintz et al. (2009) apply distant supervision to extracting Freebase triples (Bollacker et al., 2008) from Wikipedia text, analogous to the relational part of WIKIREADING. Extensions to distant supervision include explicitly modelling whether the relation is actually expressed in the sentence (Riedel et al., 2010), and jointly reasoning over larger sets of sentences and relations (Surdeanu et al., 2012). Recently, Rocktäschel et al. (2015) developed methods for reducing the number of distant supervision examples required by sharing information between relations.

6 Conclusion

We have demonstrated the complexity of the WIKIREADING task and its suitability as a benchmark to guide future development of DNN models for natural language understanding. After comparing a diverse array of models spanning classification and extraction, we conclude that end-to-end sequence to sequence models are the most promising. These models simultaneously learned to classify documents and copy arbitrary strings from them. In light of this finding, we suggest some focus areas for future research.

Our character-level model improved substantially after language model pretraining, suggesting that further training optimizations may yield continued gains. Document length poses a problem for RNN-based models, which might be addressed with convolutional neural networks that are easier to parallelize. Finally, we note that these models are not intrinsically limited to English, as they rely on little or no pre-processing with traditional NLP systems. This means that they should generalize effectively to other languages, which could be demonstrated by a multilingual version of WIKIREADING.

Acknowledgments

We thank Jonathan Berant for many helpful comments on early drafts of the paper, and Catherine Finegan-Dollak for an early implementation of RNN Labeler.

Optimizing Spectral Learning for Parsing

Abstract

We describe a search algorithm for optimizing the number of latent states when estimating latent-variable PCFGs with spectral methods. Our results show that contrary to the common belief that the number of latent states for each nonterminal in an L-PCFG can be decided in isolation with spectral methods, parsing results significantly improve if the number of latent states for each nonterminal is globally optimized, while taking into account interactions between the different nonterminals. In addition, we contribute an empirical analysis of spectral algorithms on eight morphologically rich languages: Basque, French, German, Hebrew, Hungarian, Korean, Polish and Swedish. Our results show that our estimation consistently performs better or close to coarse-to-fine expectation-maximization techniques for these languages.

1 Introduction

Latent-variable probabilistic context-free grammars (L-PCFGs) have been used in the natural language processing community (NLP) for syntactic parsing for over a decade. They were introduced in the NLP community by Matsuzaki et al. (2005) and Prescher (2005), with Matsuzaki et al. using the expectation-maximization (EM) algorithm to estimate them. Their performance on syntactic parsing of English at that stage lagged behind state-of-the-art parsers.

Petrov et al. (2006) showed that one of the reasons that the EM algorithm does not estimate state-of-the-art parsing models for English is that the EM algorithm does not control well for the model size used in the parser – the number of latent states associated with the various nonterminals in the grammar. As such, they introduced a coarse-to-fine technique to estimate the grammar. It splits and merges nonterminals (with latent state information) with the aim to optimize the likelihood of the training data. Together with other types of fine tuning of the parsing model, this led to state-of-the-art results for English parsing.

In more recent work, Cohen et al. (2012) described a different family of estimation algorithms for L-PCFGs. This so-called "spectral" family of learning algorithms is compelling because it offers a rigorous theoretical analysis of statistical convergence, and sidesteps local maxima issues that arise with the EM algorithm.

While spectral algorithms for L-PCFGs are compelling from a theoretical perspective, they have been lagging behind in their empirical results on the problem of parsing. In this paper we show that one of the main reasons for that is that spectral algorithms require a more careful tuning procedure for the number of latent states than that which has been advocated for until now. In a sense, the relationship between our work and the work of Cohen et al. (2013) is analogous to the relationship between the work by Petrov et al. (2006) and the work by Matsuzaki et al. (2005): we suggest a technique for optimizing the number of latent states for spectral algorithms, and test it on eight languages.

Our results show that when the number of latent states is optimized using our technique, the parsing models the spectral algorithms yield perform significantly better than the vanilla-estimated models, and for most of the languages – better than the Berkeley parser of Petrov et al. (2006).

As such, the contributions of this parser are twofold:

- We describe a search algorithm for optimiz-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1546–1556,
Berlin, Germany, August 7-12, 2016.

ing the number of latent states for spectral learning.

- We describe an analysis of spectral algorithms on eight languages (until now the results of L-PCFG estimation with spectral algorithms for parsing were known only for English). Our parsing algorithm is rather language-generic, and does not require significant linguistically-oriented adjustments.

In addition, we dispel the common wisdom that more data is needed with spectral algorithms. Our models yield high performance on treebanks of varying sizes from 5,000 sentences (Hebrew and Swedish) to 40,472 sentences (German).

The rest of the paper is organized as follows. In §2 we describe notation and background. §3 further investigates the need for an optimization of the number of latent states in spectral learning and describes our optimization algorithm, a search algorithm akin to beam search. In §4 we describe our experiments with natural language parsing for Basque, French, German, Hebrew, Hungarian, Korean, Polish and Swedish. We conclude in §5.

2 Background and Notation

We denote by $[n]$ the set of integers $\{1, \ldots, n\}$. An L-PCFG is a 5-tuple $(\mathcal{N}, \mathcal{I}, \mathcal{P}, f, n)$ where:

- $\mathcal{N}$ is the set of nonterminal symbols in the grammar. $\mathcal{I} \subset \mathcal{N}$ is a finite set of *interminals*. $\mathcal{P} \subset \mathcal{N}$ is a finite set of *preterminals*. We assume that $\mathcal{N} = \mathcal{I} \cup \mathcal{P}$, and $\mathcal{I} \cap \mathcal{P} = \emptyset$. Hence we have partitioned the set of nonterminals into two subsets.

- $f: \mathcal{N} \rightarrow \mathbb{N}$ is a function that maps each nonterminal a to the number of latent states it uses. The set $[m_a]$ includes the possible hidden states for nonterminal a.

- $[n]$ is the set of possible words.

- For all $a \in \mathcal{I}$, $b \in \mathcal{N}$, $c \in \mathcal{N}$, $h_1 \in [m_a]$, $h_2 \in [m_b]$, $h_3 \in [m_c]$, we have a binary context-free rule $a(h_1) \rightarrow b(h_2)\ \ c(h_3)$.

- For all $a \in \mathcal{P}$, $h \in [m_a]$, $x \in [n]$, we have a lexical context-free rule $a(h) \rightarrow x$.

The estimation of an L-PCFG requires an assignment of probabilities (or weights) to each of the rules $a(h_1) \rightarrow b(h_2)\ \ c(h_3)$ and $a(h) \rightarrow x$, and also an assignment of starting probabilities for each $a(h)$, where $a \in \mathcal{I}$ and $h \in [m_a]$. Estimation is usually assumed to be done from a set of parse trees (a treebank), where the latent states are not included in the data – only the "skeletal" trees which consist of nonterminals in $\mathcal{N}$.

L-PCFGs, in their symbolic form, are related to regular tree grammars, an old grammar formalism, but they were introduced as statistical models for parsing with latent heads more recently by Matsuzaki et al. (2005) and Prescher (2005). Earlier work about L-PCFGs by Matsuzaki et al. (2005) used the expectation-maximization (EM) algorithm to estimate the grammar probabilities. Indeed, given that the latent states are not observed, EM is a good fit for L-PCFG estimation, since it aims to do learning from incomplete data. This work has been further extended by Petrov et al. (2006) to use EM in a coarse-to-fine fashion: merging and splitting nonterminals using the latent states to optimize the number of latent states for each nonterminal.

Cohen et al. (2012) presented a so-called spectral algorithm to estimate L-PCFGs. This algorithm uses linear-algebraic procedures such as singular value decomposition (SVD) during learning. The spectral algorithm of Cohen et al. builds on an estimation algorithm for HMMs by Hsu et al. (2009).[1] Cohen et al. (2013) experimented with this spectral algorithm for parsing English. A different variant of a spectral learning algorithm for L-PCFGs was developed by Cohen and Collins (2014). It breaks the problem of L-PCFG estimation into multiple convex optimization problems which are solved using EM.

The family of L-PCFG spectral learning algorithms was further extended by Narayan and Cohen (2015). They presented a simplified version of the algorithm of Cohen et al. (2012) that estimates sparse grammars and assigns probabilities (instead of weights) to the rules in the grammar, and as such does not suffer from the problem of negative probabilities that arise with the original spectral algorithm (see discussion in Cohen et al., 2013). In this paper, we use the algorithms by Narayan and Cohen (2015) and Cohen

[1] A related algorithm for weighted tree automata (WTA) was developed by Bailly et al. (2010). However, the conversion from L-PCFGs to WTA is not straightforward, and information is lost in this conversion. See also (Rabusseau et al., 2016).

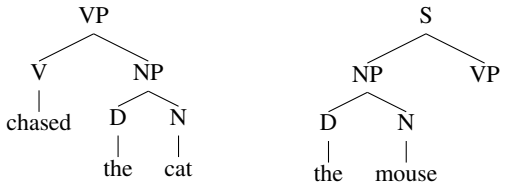

Figure 1: The inside tree (left) and outside tree (right) for the nonterminal `VP` in the parse tree `(S (NP (D the) (N mouse)) (VP (V chased) (NP (D the) (N cat))))` for the sentence *"the mouse chased the cat."*

et al. (2012), and we compare them against state-of-the-art L-PCFG parsers such as the Berkeley parser (Petrov et al., 2006). We also compare our algorithms to other state-of-the-art parsers where elaborate linguistically-motivated feature specifications (Hall et al., 2014), annotations (Crabbé, 2015) and formalism conversions (Fernández-González and Martins, 2015) are used.

3 Optimizing Spectral Estimation

In this section, we describe our optimization algorithm and its motivation.

3.1 Spectral Learning of L-PCFGs and Model Size

The family of spectral algorithms for latent-variable PCFGs rely on feature functions that are defined for *inside* and *outside* trees. Given a tree, the inside tree for a node contains the entire subtree below that node; the outside tree contains everything in the tree excluding the inside tree. Figure 1 shows an example of inside and outside trees for the nonterminal `VP` in the parse tree of the sentence *"the mouse chased the cat"*.

With L-PCFGs, the model dictates that an inside tree and an outside tree that are connected at a node are statistically conditionally independent of each other given the node label and the latent state that is associated with it. As such, one can identify the distribution over the latent states for a given nonterminal a by using the cross-covariance matrix of the inside and the outside trees, Ω^a. For more information on the definition of this cross-covariance matrix, see Cohen et al. (2012) and Narayan and Cohen (2015).

The L-PCFG spectral algorithms use singular value decomposition (SVD) on Ω^a to reduce the dimensionality of the feature functions. If Ω^a is computed from the true L-PCFG distribution then the rank of Ω^a (the number of non-zero singular values) gives the number of latent states according to the model.

In the case of estimating Ω^a from data generated from an L-PCFG, the number of latent states for each nonterminal can be exposed by capping it when the singular values of Ω^a are smaller than some threshold value. This means that spectral algorithms give a natural way for the selection of the number of latent states for each nonterminal a in the grammar.

However, when the data from which we estimate an L-PCFG model are not drawn from an L-PCFG (the model is "incorrect"), the number of non-zero singular values (or the number of singular values which are large) is no longer sufficient to determine the number of latent states for each nonterminal. This is where our algorithm comes into play: it optimizes the number of latent search for each nonterminal by applying a search algorithm akin to beam search.

3.2 Optimizing the Number of Latent States

As mentioned in the previous section, the number of non-zero singular values of Ω^a gives a criterion to determine the number of latent states m_a for a given nonterminal a. In practice, we cap m_a not to include small singular values which are close to 0, because of estimation errors of Ω^a.

This procedure does not take into account the interactions that exist between choices of latent state numbers for the various nonterminals. In principle, given the independence assumptions that L-PCFGs make, choosing the nonterminals based only on the singular values is "statistically correct." However, because in practice the modeling assumptions that we make (that natural language parse trees are drawn from an L-PCFG) do not hold, we can improve further the accuracy of the model by taking into account the nonterminal interaction. Another source of difficulty in choosing the number of latent states based the singular values of Ω^a is sampling error: in practice, we are using data to estimate Ω^a, and as such, even if the model is correct, the rank of the estimated matrix does not have to correspond to the rank of Ω^a according to the true distribution. As a matter of fact, in addition to neglecting small singular values, the spectral methods of Cohen et al. (2013) and Narayan and Cohen (2015) also cap the number of latent states for each nonterminal to an up-

Inputs: An input treebank divided into training and development set. A basic spectral estimation algorithm $\mathcal{S}$ with its default setting. An integer k denoting the size of the beam. An integer m denoting the upper bound on the number of latent states.

Algorithm:
(Step 0: Initialization)

- Set Q, a queue of size k, to be empty.
- Estimate an L-PCFG $G_{\mathcal{S}} : (\mathcal{N}, \mathcal{I}, \mathcal{P}, f_{\mathcal{S}}, n)$ using $\mathcal{S}$.
- Initialize $f = f_{\mathcal{S}}$, a function that maps each nonterminal $a \in \mathcal{N}$ to the number of latent states.
- Let L be a list of nonterminals $(a_1, \ldots, a_M)$ such that $a_i \in \mathcal{N}$ for which to optimize the number of latent states.
- Let s be the F_1 score for the above L-PCFG $G_{\mathcal{S}}$ on the development set.
- Put in Q the element $(s, 1, f, \text{coarse})$.
- The queue is ordered by s, the first element of tuples, in the queue.

(Step 1: Search, repeat until termination happens)

- Dequeue the queue into (s, j, f, t) where j is the index in the input nonterminal list L.
- If $j = (M + 1)$, return f.
- If t is coarse then for each $m_0 \in \{1, 5, 10, \ldots, m\}$:
  - Let f_0 be such that $\forall a \neq a_j \; f_0(a) = f(a)$ and $f_0(a_j) = m_0$.
  - Train an L-PCFG G_0 using $\mathcal{S}$ but with f_0.
  - Let s_0 be the F_1 score for G_0 on the development set.
  - Enqueue into Q: $(s_0, j, f_0, \text{refine})$.
- If t is refine then for each $m_0 \in \{f(a) + \ell \mid \ell \in \{-4, -3, -2, -1, 0, 1, 2, 3, 4\}\}$:
  - Let f_0 be such that $\forall a \neq a_j \; f_0(a) = f(a)$ and $f_0(a_j) = m_0$.
  - Train an L-PCFG G_0 using $\mathcal{S}$ but with f_0.
  - Let s_0 be the F_1 score for G_0 on the development set.
  - Enqueue into Q: $(s_0, j + 1, f_0, \text{coarse})$.

Figure 2: A search algorithm for finding the optimal number of latent states.

per bound to keep the grammar size small.

Petrov et al. (2006) improves over the estimation described in Matsuzaki et al. (2005) by taking into account the interactions between the nonterminals and their latent state numbers in the training data. They use the EM algorithm to split and merge nonterminals using the latent states, and optimize the number of latent states for each nonterminal such that it maximizes the likelihood of a training treebank. Their refined grammar successfully splits nonterminals to various degrees to capture their complexity. We take the analogous step with spectral methods. We propose an algorithm where we first compute Ω^a on the training data and then we optimize the number of latent states for each nonterminal by optimizing the PARSEVAL metric (Black et al., 1991) on a development set.

Our optimization algorithm appears in Figure 2. The input to the algorithm is training and development data in the form of parse trees, a basic spectral estimation algorithm $\mathcal{S}$ in its default setting, an upper bound m on the number of latent states that can be used for the different nonterminals and a beam size k which gives a maximal queue size for the beam. The algorithm aims to learn a function f that maps each nonterminal a to the number of latent states. It initializes f by estimating a default grammar $G_{\mathcal{S}} : (\mathcal{N}, \mathcal{I}, \mathcal{P}, f_{\mathcal{S}}, n)$ using $\mathcal{S}$ and setting $f = f_{\mathcal{S}}$. It then iterates over $a \in \mathcal{N}$, improving f such that it optimizes the PARSEVAL metric on the development set.

The state of the algorithm includes a queue that consists of tuples of the form (s, j, f, t) where f is an assignment of latent state numbers to each nonterminal in the grammar, j is the index of a nonterminal to be explored in the input nonterminal list L, s is the F_1 score on the development set for a grammar that is estimated with f and t is a tag that can either be coarse or refine.

The algorithm orders these tuples by s in the queue, and iteratively dequeues elements from the queue. Then, depending on the label t, it either makes a refined search for the number of latent states for a_j, or a more coarse search. As such, the algorithm can be seen as a variant of a beam search algorithm.

The search algorithm can be used with any training algorithm for L-PCFGs, including the algorithms of Cohen et al. (2013) and Narayan and Cohen (2015). These methods, in their default setting, use a function $f_{\mathcal{S}}$ which maps each nonterminal a to a fixed number of latent states m_a it uses. In this case, $\mathcal{S}$ takes as input training data, in the form of a treebank, decomposes into inside and outside trees at each node in each tree in the training set; and reduces the dimensionality of the inside and outside feature functions by running

Table 1: Statistics about the different datasets used in our experiments for the training ("train"), development ("dev") and test ("test") sets. "sent." denotes the number of sentences in the dataset, "tokens" denotes the total number of words in the dataset, "lex. size" denotes the vocabulary size in the training set and "#nts" denotes the number of nonterminals in the training set after binarization.

SVD on the cross-covariance matrix Ω_a of the inside and the outside trees, for each nonterminal a. Cohen et al. (2013) estimate the parameters of the L-PCFG up to a linear transformation using $f(a)$ non-zero singular values of Ω_a, whereas Narayan and Cohen (2015) use the feature representations induced from the SVD step to cluster instances of nonterminal a in the training data into $f(a)$ clusters; these clusters are then treated as latent states that are "observed." Finally, Narayan and Cohen follow up with a simple frequency count maximum likelihood estimate to estimate the parameters in the L-PCFG with these latent states.

An important point to make is that the learning algorithms of Narayan and Cohen (2015) and Cohen et al. (2013) are relatively fast,[2] in comparison to the EM algorithm. They require only one iteration over the data. In addition, the SVD step of $\mathcal{S}$ for these learning algorithms is computed just once for a large m. The SVD of a lower rank can then be easily computed from that SVD.

4 Experiments

In this section, we describe our setup for parsing experiments on a range of languages.

4.1 Experimental Setup

Datasets We experiment with nine treebanks consisting of eight different morphologically rich languages: Basque, French, German, Hebrew, Hungarian, Korean, Polish and Swedish. Table 1 shows the statistics of 9 different treebanks with their splits into training, development and test sets. Eight out of the nine datasets (Basque, French, German-T, Hebrew, Hungarian, Korean, Polish and Swedish) are taken from the workshop on Statistical Parsing of Morphologically Rich Languages (SPMRL; Seddah et al., 2013). The German corpus in the SPMRL workshop is taken from the TiGer corpus (German-T, Brants et al., 2004). We also experiment with another German corpus, the NEGRA corpus (German-N, Skut et al., 1997), in a standard evaluation split.[3] Words in the SPMRL datasets are annotated with their morphological signatures, whereas the NEGRA corpus does not contain any morphological information.

Data preprocessing and treatment of rare words We convert all trees in the treebanks to a binary form, train and run the parser in that form, and then transform back the trees when doing evaluation using the PARSEVAL metric. In addition, we collapse unary rules into unary chains, so that our trees are fully binarized. The column "#nts" in Table 1 shows the number of nonterminals after binarization in the various treebanks. Before binarization, we also drop all functional information from the nonterminals. We use fine tags for all languages except Korean. This is in line with Björkelund et al. (2013).[4] For Korean, there are 2,825 binarized nonterminals making it impractical to use our optimization algorithm, so we use the coarse tags.

Björkelund et al. (2013) have shown that the morphological signatures for rare words are useful to improve the performance of the Berkeley parser.

[2] It has been documented in several papers that the family of spectral estimation algorithms is faster than algorithms such as EM, not just for L-PCFGs. See, for example, Parikh et al. (2012).

[3] We use the first 18,602 sentences as a training set, the next 1,000 sentences as a development set and the last 1,000 sentences as a test set. This corresponds to an 80%-10%-10% split of the treebank.

[4] In their experiments Björkelund et al. (2013) found that fine tags were not useful for Basque also; they did not find a proper explanation for that. In our experiments, however, we found that fine tags were useful for Basque. To retrieve the fine tags, we concatenate coarse tags with their refinement feature ("AZP") values.

In our preliminary experiments with naïve spectral estimation, we preprocess rare words in the training set in two ways: (i) we replace them with their corresponding POS tags, and (ii) we replace them with their corresponding POS+morphological signatures. We follow Björkelund et al. (2013) and consider a word to be rare if it occurs less than 20 times in the training data. We experimented both with a version of the parser that does not ignore and does ignore letter cases, and discovered that the parser behaves better when case is not ignored.

Spectral algorithms: subroutine choices The latent state optimization algorithm will work with either the clustering estimation algorithm of Narayan and Cohen (2015) or the spectral algorithm of Cohen et al. (2013). In our setup, we first run the latent state optimization algorithm with the clustering algorithm. We then run the spectral algorithm once with the optimized f from the clustering algorithm. We do that because the clustering algorithm is significantly faster to iteratively parse the development set, because it leads to sparse estimates.

Our optimization algorithm is sensitive to the initialization of the number of latent states assigned to each nonterminals as it sequentially goes through the list of nonterminals and chooses latent state numbers for each nonterminal, keeping latent state numbers for other nonterminals fixed. In our setup, we start our search algorithm with the best model from the clustering algorithm, controlling for all hyperparameters; we tune f, the function which maps each nonterminal to a fixed number of latent states m, by running the vanilla version with different values of m for different languages. Based on our preliminary experiments, we set m to 4 for Basque, Hebrew, Polish and Swedish; 8 for German-N; 16 for German-T, Hungarian and Korean; and 24 for French.

We use the same features for the spectral methods as in Narayan and Cohen (2015) for German-N. For the SPMRL datasets we do not use the head features. These require linguistic understanding of the datasets (because they require head rules for propagating leaf nodes in the tree), and we discovered that simple heuristics for constructing these rules did not yield an increase in performance.

We use the `kmeans` function in Matlab to do the clustering for the spectral algorithm of Narayan and Cohen (2015). We experimented with several versions of k-means, and discovered that the version that works best in a set of preliminary experiments is hard k-means.[5]

Decoding and evaluation For efficiency, we use a base PCFG without latent states to prune marginals which receive a value less than 0.00005 in the dynamic programming chart. This is just a bare-bones PCFG that is estimated using maximum likelihood estimation (with frequency count). The parser takes part-of-speech tagged sentences as input. We tag the German-N data using the Turbo Tagger (Martins et al., 2010). For the languages in the SPMRL data we use the MarMot tagger of Müeller et al. (2013) to jointly predict the POS and morphological tags.[6] The parser itself can assign different part-of-speech tags to words to avoid parse failure. This is also particularly important for constituency parsing with morphologically rich languages. It helps mitigate the problem of the taggers to assign correct tags when long-distance dependencies are present.

For all results, we report the F_1 measure of the PARSEVAL metric (Black et al., 1991). We use the `EVALB` program[7] with the parameter file `COLLINS.prm` (Collins, 1999) for the German-N data and the SPMRL parameter file, `spmrl.prm`, for the SPMRL data (Seddah et al., 2013).

In this setup, the latent state optimization algorithm terminates in few hours for all datasets except French and German-T. The German-T data has 762 nonterminals to tune over a large development set consisting of 5,000 sentences, whereas, the French data has a high average sentence length of 31.43 in the development set.[8]

Following Narayan and Cohen (2015), we further improve our results by using multiple spectral models where noise is added to the underlying features in the training set before the estimation of each model.[9] Using the optimized f, we estimate

[5] To be more precise, we use the Matlab function `kmeans` while passing it the parameter `'start'='sample'` to randomly sample the initial centroid positions. In our experiments, we found that default initialization of centroids differs in Matlab14 (random) and in Matlab15 (kmeans++). Our estimation performs better with random initialization.

[6] See Björkelund et al. (2013) for the performance of the MarMot tagger on the SPMRL datasets.

[7] `http://nlp.cs.nyu.edu/evalb/`

[8] To speed up tuning on the French data, we drop sentences with length >46 from the development set, dropping its size from 12,35 to 1,006.

[9] We only use the algorithm of Narayan and Cohen (2015) for the noisy model estimation. They have shown that decoding with noisy models performs better with their sparse

Table 2: Results on the development datasets. "Bk" makes use of the Berkeley parser with its coarse-to-fine mechanism to optimize the number of latent states (Petrov et al., 2006). For Bk, "van" uses the vanilla treatment of rare words using signatures defined by Petrov et al. (2006), whereas "rep." uses the morphological signatures instead. "Cl" uses the algorithm of Narayan and Cohen (2015) and "Sp" uses the algorithm of Cohen et al. (2013). In Cl, "van (pos)" and "van (rep)" are vanilla estimations (i.e., each nonterminal is mapped to fixed number of latent states) replacing rare words by POS or POS+morphological signatures, respectively. The best of these two models is used with our optimization algorithm in "opt". For Sp, "van" uses the best setting for unknown words as Cl. Best result in each column from the first seven rows is in bold. In addition, our best performing models from rows 3-7 are marked with *. "Bk multiple" shows the best results with the multiple models using product-of-grammars procedure (Petrov, 2010) and discriminative reranking (Charniak and Johnson, 2005). "Cl multiple" gives the results with multiple models generated using the noise induction and decoded using the hierarchical decoding (Narayan and Cohen, 2015). Bk results are not available on the development dataset for German-N. For others, we report Bk results from Björkelund et al. (2013). We also include results from Hall et al. (2014) and Crabbé (2015).

Table 3: Results on the test datasets. "Bk" denotes the best Berkeley parser result reported by the shared task organizers (Seddah et al., 2013). For the German-N data, Bk results are taken from Petrov (2010). "Cl van" shows the performance of the best vanilla models from Table 2 on the test set. "Cl opt" and "Sp opt" give the result of our algorithm on the test set. We also include results from Hall et al. (2014), Crabbé (2015) and Fernández-González and Martins (2015).

80 models for each of noise induction mechanisms in Narayan and Cohen: Dropout, Gaussian (additive) and Gaussian (multiplicative). To decode with multiple noisy models, we train the MaxEnt reranker of Charniak and Johnson (2005).[10] Hierarchical decoding with "maximal tree coverage" over MaxEnt models, further improves our accuracy. See Narayan and Cohen (2015) for more details on the estimation of a diverse set of models, and on decoding with them.

4.2 Results

Table 2 and Table 3 give the results for the various languages.[11] Our main focus is on comparing the coarse-to-fine Berkeley parser (Petrov et al., 2006) to our method. However, for the sake of completeness, we also present results for other parsers, such as parsers of Hall et al. (2014), Fernández-González and Martins (2015) and Crabbé (2015).

In line with Björkelund et al. (2013), our preliminary experiments with the treatment of rare words suggest that morphological features are useful for all SPMRL languages except French. Specifically, for Basque, Hungarian and Korean, improvements are significantly large.

Our results show that the optimization of the

estimates than the dense estimates of Cohen et al. (2013).

[10] Implementation: `https://github.com/BLLIP/bllip-parser`. More specifically, we used the programs `extract-spfeatures`, `cvlm-lbfgs` and `best-indices`. `extract-spfeatures` uses head features, we bypass this for the SPMRL datasets by creating a dummy `heads.cc` file. `cvlm-lbfgs` was used with the default hyperparameters from the Makefile.

Table 4: A comparison of the number of latent states for the different nonterminals before and after running our latent state number optimization algorithm. The index i ranges over preterminals and interminals, with x_i denoting the number of latent states for nonterminal i with the vanilla version of the estimation algorithm and y_i denoting the number of latent states for nonterminal i after running the optimization algorithm. The divergence figure ("div.") is a calculation of $\sum_i |x_i - y_i|$.

number of latent states with the clustering and spectral algorithms indeed improves these algorithms performance, and these increases generalize to the test sets as well. This was a point of concern, since the optimization algorithm goes through many points in the hypothesis space of parsing models, and identifies one that behaves optimally on the development set – and as such it could overfit to the development set. However, this did not happen, and in some cases, the increase in accuracy of the test set after running our optimization algorithm is actually larger than the one for the development set.

While the vanilla estimation algorithms (without latent state optimization) lag behind the Berkeley parser for many of the languages, once the number of latent states is optimized, our parsing models do better for Basque, Hebrew, Hungarian, Korean, Polish and Swedish. For German-T we perform close to the Berkeley parser (78.2 vs. 78.3). It is also interesting to compare the clustering algorithm of Narayan and Cohen (2015) to the spectral algorithm of Cohen et al. (2013). In the vanilla version, the spectral algorithm does better in most cases. However, these differences are narrowed, and in some cases, overcome, when the number of latent states is optimized. Decoding with multiple models further improves our accuracy. Our "Cl multiple" results lag behind "Bk multiple." We believe this is the result of the need of head features for the MaxEnt models.[12]

Our results show that spectral learning is a viable alternative to the use of expectation-maximization coarse-to-fine techniques. As we discuss later, further improvements have been introduced to state-of-the-art parsers that are orthogonal to the use of a specific estimation algorithm. Some of them can be applied to our setup.

4.3 Further Analysis

In addition to the basic set of parsing results, we also wanted to inspect the size of the parsing models when using the optimization algorithm in comparison to the vanilla models. Table 4 gives this analysis. In this table, we see that in most cases, on average, the optimization algorithm chooses to enlarge the number of latent states. However, for German-T and Korean, for example, the optimization algorithm actually chooses a smaller model than the original vanilla model.

We further inspected the behavior of the optimization algorithm for the preterminals in German-N, for which the optimal model chose (on average) a larger number of latent states. Table 5 describes this analysis. We see that in most cases, the optimization algorithm chose to decrease the number of latent states for the various preterminals, but in some cases significantly increases the number of latent states.[13]

Our experiments dispel another "common wisdom" about spectral learning and training data size. It has been believed that spectral learning do not behave very well when small amounts of data are available (when compared to maximum likelihood estimation algorithms such as EM) – however we see that our results do better than the Berkeley parser for several languages with small

[12] Björkelund et al. (2013) also use the MaxEnt raranker with multiple models of the Berkeley parser, and in their case also the performance after the raranking step is not always significantly better. See footnote 10 on how we create dummy head-features for our MaxEnt models.

[13] Interestingly, most of the punctuation symbols, such as `$*LRB*`, `$.` and `$,`, drop their latent state number to a significantly lower value indicating that their interactions with other nonterminals in the tree are minimal.

training datasets, such as Basque, Hebrew, Polish and Hungarian. The source of this common wisdom is that ML estimators tend to be statistically "efficient:" they extract more information from the data than spectral learning algorithms do. Indeed, there is no reason to believe that spectral algorithms are statistically efficient. However, it is not clear that indeed for L-PCFGs with the EM algorithm, the ML estimator is statistically efficient either. MLE is statistically efficient under specific assumptions which are not clearly satisfied with L-PCFG estimation. In addition, when the model is "incorrect," (i.e. when the data is not sampled from L-PCFG, as we would expect from natural language treebank data), spectral algorithms could yield better results because they can mimic a higher order model. This can be understood through HMMs. When estimating an HMM of a low order with data which was generated from a higher order model, EM does quite poorly. However, if the number of latent states (and feature functions) is properly controlled with spectral algorithms, a spectral algorithm would learn a "product" HMM, where the states in the lower order model are the product of states of a higher order.[14]

State-of-the-art parsers for the SPMRL datasets improve the Berkeley parser in ways which are orthogonal to the use of the basic estimation algorithm and the method for optimizing the number of latent states. They include transformations of the treebanks such as with unary rules (Björkelund et al., 2013), a more careful handling of unknown words and better use of morphological information such as decorating preterminals with such information (Björkelund et al., 2014; Szántó and Farkas, 2014), with careful feature specifications (Hall et al., 2014) and head-annotations (Crabbé, 2015), and other techniques. Some of these techniques can be applied to our case.

[14]For example, a trigram HMM can be reduced to a bigram HMM where the states are products of the original trigram HMM.

5 Conclusion

We demonstrated that a careful selection of the number of latent states in a latent-variable PCFG with spectral estimation has a significant effect on the parsing accuracy of the L-PCFG. We described a search procedure to do this kind of optimization, and described parsing results for eight languages (with nine datasets). Our results demonstrate that when comparing the expectation-maximization with coarse-to-fine techniques to our spectral algorithm with latent state optimization, spectral learning performs better on six of the datasets. Our results are comparable to other state-of-the-art results for these languages. Using a diverse set of models to parse these datasets further improves the results.

Acknowledgments

Abstract

Traditional syntax models typically leverage part-of-speech (POS) information by constructing features from hand-tuned templates. We demonstrate that a better approach is to utilize POS tags as a *regularizer* of learned representations. We propose a simple method for learning a stacked pipeline of models which we call "stack-propagation". We apply this to dependency parsing and tagging, where we use the hidden layer of the tagger network as a representation of the input tokens for the parser. At test time, our parser does not require predicted POS tags. On 19 languages from the Universal Dependencies, our method is 1.3% (absolute) more accurate than a state-of-the-art graph-based approach and 2.7% more accurate than the most comparable greedy model.

1 Introduction

In recent years, transition-based dependency parsers powered by neural network scoring functions have dramatically increased the state-of-the-art in terms of both speed and accuracy (Chen and Manning, 2014; Alberti et al., 2015; Weiss et al., 2015). Similar approaches also achieve state-of-the-art in other NLP tasks, such as constituency parsing (Durrett and Klein, 2015) or semantic role labeling (FitzGerald et al., 2015). These approaches all share a common principle: replace hand-tuned conjunctions of traditional NLP feature templates with continuous approximations learned by the hidden layer of a feed-forward network.

*Research conducted at Google.

However, state-of-the-art dependency parsers depend crucially on the use of predicted part-of-speech (POS) tags. In the pipeline or *stacking* (Wolpert, 1992) method, these are predicted from an independently trained tagger and used as features in the parser. However, there are two main disadvantages of a pipeline: (1) errors from the POS tagger cascade into parsing errors, and (2) POS taggers often make mistakes precisely because they cannot take into account the syntactic context of a parse tree. The POS tags may also contain only coarse information, such as when using the universal tagset of Petrov et al. (2011).

One approach to solve these issues has been to avoid using POS tags during parsing, e.g. either using semi-supervised clustering instead of POS tags (Koo et al., 2008) or building recurrent representations of words using neural networks (Dyer et al., 2015; Ballesteros et al., 2015). However, the best accuracy for these approaches is still achieved by running a POS tagger over the data first and combining the predicted POS tags with additional representations. As an alternative, a wide range of prior work has investigated jointly modeling both POS and parse trees (Li et al., 2011; Hatori et al., 2011; Bohnet and Nivre, 2012; Qian and Liu, 2012; Wang and Xue, 2014; Li et al., 2014; Zhang et al., 2015; Alberti et al., 2015). However, these approaches typically require sacrificing either efficiency or accuracy compared to the best pipeline model, and often they simply re-rank the predictions of a pipelined POS tagger.

In this work, we show how to improve accuracy for both POS tagging and parsing by incorporating stacking into the architecture of a feed-forward network. We propose a continuous form of stacking that allows for easy backpropagation down the pipeline across multiple tasks, a process we call

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1557–1566,
Berlin, Germany, August 7-12, 2016.

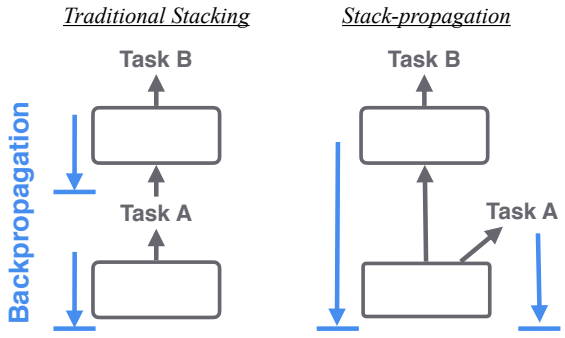

Figure 1: Traditional stacking (left) vs. Stack-propagation (right). Stacking uses the output of Task A as features in Task B, and does not allow backpropagation between tasks. Stack-propagation uses a continuous and differentiable link between Task A and Task B, allowing for backpropagation from Task B into Task A's model. Updates to Task A act as *regularization* on the model for Task B, ensuring the shared component is useful for both tasks.

"stack-propagation" (Figure 1). At the core of this idea is that we use POS tags as *regularization* instead of *features*.

Our model design for parsing is very simple: we use the hidden layer of a window-based POS tagging network as the representation of tokens in a greedy, transition-based neural network parser. Both networks are implemented with a refined version of the feed-forward network (Figure 3) from Chen and Manning (2014), as described in Weiss et al. (2015). We link the tagger network to the parser by translating traditional feature templates for parsing into feed-forward connections from the tagger to the parser (Figure 2). At training time, we unroll the parser decisions and apply stack-propagation by alternating between stochastic updates to the parsing or tagging objectives (Figure 4). The parser's representations of tokens are thus regularized to be individually predictive of POS tags, even as they are trained to be useful for parsing when concatenated and fed into the parser network. This model is similar to the multi-task network structure of Collobert et al. (2011), where Collobert et al. (2011) shares a hidden layer between multiple tagging tasks. The primary difference here is that we show how to unroll parser transitions to apply the same principle to tasks with fundamentally different structure.

The key advantage of our approach is that at test time, we do not require predicted POS tags for parsing. Instead, we run the tagger network up to the hidden layer over the entire sentence, and then dynamically connect the parser network to the tagger network based upon the discrete parser configurations as parsing unfolds. In this way, we avoid cascading POS tagging errors to the parser. As we show in Section 5, our approach can be used in conjunction with joint transition systems in the parser to improve both POS tagging as well as parsing. In addition, because the parser re-uses the representation from the tagger, we can drop all lexicalized features from the parser network, leading to a compact, faster model.

The rest of the paper is organized as follows. In Section 2, we describe the layout of our combined architecture. In Section 3, we introduce stack-propagation and show how we train our model. We evaluate our approach on 19 languages from the Universal Dependencies treebank in Section 4. We observe a $>2\%$ absolute gain in labeled accuracy compared to state-of-the-art, LSTM-based greedy parsers (Ballesteros et al., 2015) and a $>1\%$ gain compared to a state-of-the-art, graph-based method (Lei et al., 2014). We also evaluate our method on the Wall Street Journal, where we find that our architecture outperforms other greedy models, especially when only coarse POS tags from the universal tagset are provided during training. In Section 5, we systematically evaluate the different components of our approach to demonstrate the effectiveness of stack-propagation compared to traditional types of joint modeling. We also show that our approach leads to large reductions in cascaded errors from the POS tagger.

We hope that this work will motivate further research in combining traditional pipelined structured prediction models with deep neural architectures that learn intermediate representations in a task-driven manner. One important finding of this work is that, even *without* POS tags, our architecture outperforms recurrent approaches that build custom word representations using character-based LSTMs (Ballesteros et al., 2015). These results suggest that learning rich embeddings of words may not be as important as building an intermediate representation that takes multiple features of the *surrounding* context into account. Our results also suggest that deep models for dependency parsing may not discover POS classes when trained solely for parsing, even when it is fully within the capacity of the model. Designing architectures to apply stack-propagation in other coupled NLP tasks might yield significant accuracy improvements for deep learning.

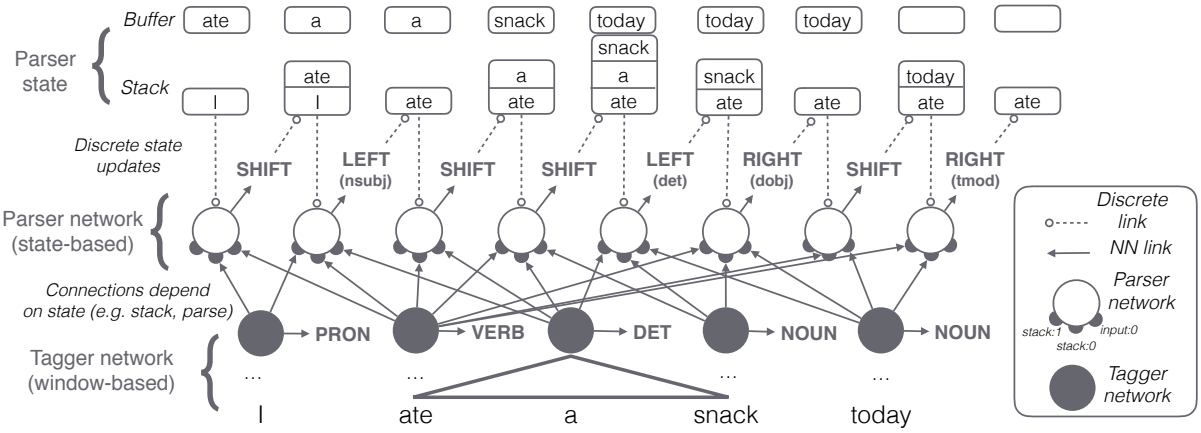

Figure 2: Detailed example of the stacked parsing model. *Top:* The discrete parser state, consisting of the stack and the buffer, is updated by the output of the parser network. In turn, the feature templates used by the parser are a function of the state. In this example, the parser has three templates, `stack:0`, `stack:1`, and `input:0`. *Bottom:* The feature templates create many-to-many connections from the hidden layer of the tagger to the input layer of the parser. For example, the predicted root of the sentence ("ate") is connected to the input of most parse decisions. At test time, the above structure is constructed dynamically as a function of the parser output. Note also that the predicted POS tags are not directly used by the parser.

2 Continuous Stacking Model

In this section, we introduce a novel neural network model for parsing and tagging that incorporates POS tags as a regularization of learned implicit representations. The basic unit of our model (Figure 3) is a simple, feed-forward network that has been shown to work very well for parsing tasks (Chen and Manning, 2014; Weiss et al., 2015). The inputs to this unit are feature matrices which are embedded and passed as input to a hidden layer. The final layer is a softmax prediction.

We use two such networks in this work: a window-based version for tagging and a transition-based version for dependency parsing. In a traditional stacking (pipeline) approach, we would use the discrete predicted POS tags from the tagger as features in the parser (Chen and Manning, 2014). In our model, we instead feed the continuous hidden layer activations of the tagger network as input to the parser. The primary strength of our approach is that the parser has access to all of the features and information used by the POS tagger during training time, but it is allowed to make its own decisions at test time.

To implement this, we show how we can reuse feature templates from Chen and Manning (2014) to specify the feed-forward connections from the tagger network to the parser network. An interesting consequence is that because this structure is a function of the derivation produced by the parser, the final feed-forward structure of the stacked model is not known until *run-time*.

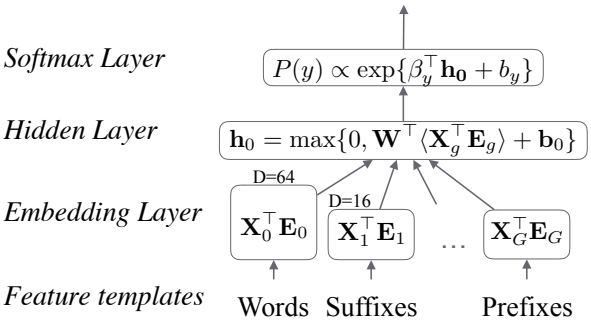

Figure 3: Elementary NN unit used in our model. Feature matrices from multiple channels are embedded, concatenated together, and fed into a rectified linear hidden layer. In the parser network, the feature inputs are continuous representations from the tagger network's hidden layer.

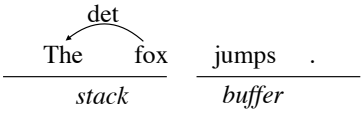
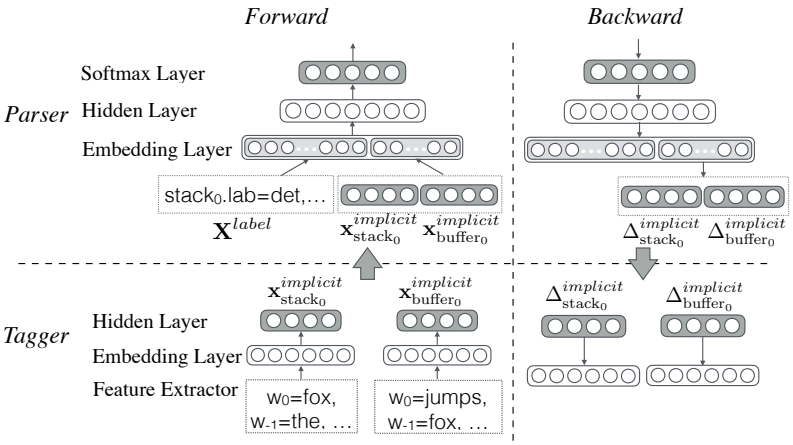
However, because the connections for any specific parsing decision are fixed given the derivation, we can still extract examples for training off-line by unrolling the network structure from gold derivations. In other words, we can utilize our approach with the same simple stochastic optimization techniques used in prior works. Figure 2 shows a fully unrolled architecture on a simple example.

2.1 The Tagger Network

As described above, our POS tagger follows the basic structure from prior work with embedding, hidden, and softmax layers. Like the "window-approach" network of Collobert et al. (2011), the tagger is evaluated per-token, with features extracted from a window of tokens surrounding the target. The input consists of a rich set of fea-



(a) Parser configuration c.



(b) Forward and backward schema for (a).

Figure 4: A schematic for the PARSER stack-propagation update. *a*: Example parser configuration c with corresponding stack and buffer. *b*: Forward and backward stages for the given single example. During the forward phase, the tagger networks compute hidden activations for each feature template (e.g. $stack_0$ and $buffer_0$), and activations are fed as features into the parser network. For the backward update, we backpropagate training signals from the parser network into each linked tagging example.

tures for POS tagging that are deterministically extracted from the training data. As in prior work, the features are divided into *groups* of different sizes that share an embedding matrix $\mathbf{E}$. Features for each group g are represented as a sparse matrix $\mathbf{X}^g$ with dimension $F^g \times V^g$, where F^g is the number of feature templates in the group, and V^g is the vocabulary size of the feature templates. Each row of $\mathbf{X}^g$ is a one-hot vector indicating the appearance of each feature.

The network first looks up the learned embedding vectors for each feature and then concatenates them to form the embedding layer. This embedding layer can be written as:

$$\mathbf{h}_0 = [\mathbf{X}^g \mathbf{E}^g \mid \forall g] \quad (1)$$

where $\mathbf{E}^g$ is a learned $V^g \times D^g$ embedding matrix for feature group. Thus, the final size $|\mathbf{h}_0| = \sum_g F^g D^g$ is the sum of all embedded feature sizes. The specific features and their dimensions used in the tagger are listed in Table 1. Note that for all features, we create additional *null* value that triggers when features are extracted outside the scope of the sentence. We use a single hidden layer in our model and apply rectified linear unit (ReLU) activation function over the hidden layer outputs. A final softmax layer reads in the activations and outputs probabilities for each possible POS tag.

2.2 The Parser Network

The parser component follows the same design as the POS tagger with the exception of the features and the output space. Instead of a window-based classifier, features are extracted from an arc-standard parser configuration[1] c consisting of the stack s, the buffer b and the so far constructed dependencies (Nivre, 2004). Prior implementations of this model used up to four groups of discrete features: words, labels (from previous decisions), POS tags, and morphological attributes (Chen and Manning, 2014; Weiss et al., 2015; Alberti et al., 2015).

Features (g)	Window	D
Symbols	1	8
Capitalization	+/- 1	4
Prefixes/Suffixes ($n = 2, 3$)	+/- 1	16
Words	+/-3	64

Table 1: Window-based tagger feature spaces. "Symbols" indicates whether the word contains a hyphen, a digit or a punctuation.

In this work, we apply the same design principle but we use an *implicitly* learned intermediate representation in the parser to replace traditional discrete features. We only retain discrete features over the labels in the incrementally constructed tree (Figure 4). Specifically, for any token of interest, we feed the hidden layer of the tagger network evaluated for that token as input to the parser. We implement this idea by re-using the feature templates from prior work as indexing functions.

We define this process formally as follows. Let $f_i(c)$ be a function mapping from parser configurations c to indices in the sentence, where i denotes each of our feature templates. For example, in Figure 4(a), when $i = \texttt{stack}_0$, $f_i(c)$ is the in-

[1]Note that the "stack" in the parse configuration is separate from the "stacking" of the POS tagging network and the parser network (Figure 1).

dex of "fox" in the sentence. Let $\mathbf{h}_1^{tagger}(j)$ be the hidden layer activation of the tagger network evaluated at token j. We define the input $\mathbf{X}^{implicit}$ by concatenating these tagger activations according to our feature templates:

$$\mathbf{x}_i^{implicit} \triangleq \mathbf{h}_1^{tagger}(f_i(c)). \quad (2)$$

Thus, the feature group $\mathbf{X}^{implicit}$ is the row-concatenation of the hidden layer activations of the tagger, as indexed by the feature templates. We have that $F^{implicit}$ is the number of feature templates, and $V^{implicit} = H^{tagger}$, the number of possible values is the number of hidden units in the tagger. Just as for other features, we learn an embedding matrix $\mathbf{E}^{implicit}$ of size $H^{implicit} \times F^{implicit}$. Note that as in the POS tagger network, we reserve an additional *null* value for out of scope feature templates. A full example of this lookup process, and the resulting feed-forward network connections created, is shown for a simple three-feature template consisting of the top two tokens on the stack and the first on the buffer in Figure 2. See Table 1 for the full list of 20 tokens that we extract for each state.

3 Learning with Stack-propagation

In this section we describe how we train our stacking architecture. At a high level, we simply apply backpropagation to our proposed continuous form of stacking (hence "stack-propagation.") There are two major issues to address: (1) how to handle the dynamic many-to-many connections between the tagger network and the parser network, and (2) how to incorporate the POS tag labels during training.

Addressing the first point turns out to be fairly easy in practice: we simply unroll the gold trees into a derivation of (state, action) pairs that produce the tree. The key property of our parsing model is that the *connections* of the feed-forward network are constructed incrementally as the parser state is updated. This is different than a generic recurrent model such as an LSTM, which passes activation vectors from one step to the next. The important implication at training time is that, unlike a recurrent network, the parser decisions are conditionally independent given a fixed history. In other words, if we unroll the network structure ahead of time given the gold derivation, we do not need to perform inference when training with respect to these examples. Thus, the overall training procedure is similar to that introduced in Chen and Manning (2014).

To incorporate the POS tags as a regularization during learning, we take a fairly standard approach from multi-task learning. The objective of learning is to find parameters Θ that maximize the data log-likelihood with a regularization on Θ for both parsing and tagging:

$$\max_{\Theta} \lambda \sum_{\mathbf{x},y \in \mathcal{T}} \log(P_\Theta(y \mid \mathbf{x})) + \sum_{c,a \in \mathcal{P}} \log\left(P_\Theta(a \mid c)\right), \quad (3)$$

where $\{\mathbf{x}, y\}$ are POS tagging examples extracted from individual tokens and $\{c, a\}$ are parser (configuration, action) pairs extracted from the unrolled gold parse tree derivations, and λ is a trade-off parameter.

We optimize this objective stochastically by alternating between two updates:

- TAGGER: Pick a POS tagging example and update the tagger network with backpropagation.
- PARSER: (Figure 4) Given a parser configuration c from the set of gold contexts, compute both tagger and parser activations. Backpropagate the parsing loss through the stacked architecture to update both parser and tagger, ignoring the tagger's softmax layer parameters.

While the learning procedure is inspired from multi-task learning—we only update each step with regards one of the two likelihoods—there are subtle differences that are important. While a traditional multi-task learning approach would use the final layer of the parser network to predict both POS tags and parse trees, we predict POS tags from the first hidden layer of our model (the "tagger" network) only. We treat the POS labels as regularization of our parser and simply discard the softmax layer of the tagger network at test time. As we will show in Section 4, this regularization leads to dramatic gains in parsing accuracy. Note that in Section 5, we also show experimentally that stack-propagation is more powerful than the traditional multi-task approach, and by combining them together, we can achieve better accuracy on both POS and parsing tasks.

Table 2: Labeled Attachment Score (LAS) on Universal Dependencies Treebank. *Top:* Results without any POS tag observations. "B'15 LSTM" is the character-based LSTM model (Ballesteros et al., 2015), while "Ours (window)" is our window-based architecture variant without stackprop. *Bottom:* Comparison against state-of-the-art baselines utilizing the POS tags. Paired t-tests show that the gain of Stackprop over all other approaches is significant ($p < 10^{-5}$ for all but RBGParser, which is $p < 0.02$).

3.1 Implementation details

Following Weiss et al. (2015), we use mini-batched averaged stochastic gradient descent (ASGD) (Bottou, 2010) with momentum (Hinton, 2012) to learn the parameters Θ of the network. We use a separate learning rate, moving average, and velocity for the tagger network and the parser; the PARSER updates all averages, velocities, and learning rates, while the TAGGER updates only the tagging factors. We tuned the hyperparameters of momentum rate μ, the initial learning rate η_0 and the learning rate decay step γ using held-out data. The training data for parsing and tagging can be extracted from either the same corpus or different corpora; in our experiments they were always the same.

To trade-off the two objectives, we used a random sampling scheme to perform 10 epochs of PARSER updates and 5 epochs of TAGGER updates. In our experiments, we found that pre-training with TAGGER updates for one epoch before interleaving PARSER updates yielded faster training with better results. We also experimented using the TAGGER updates solely for initializing the parser and found that interleaving updates was crucial to obtain improvements over the baseline.

4 Experiments

In this section, we evaluate our approach on several dependency parsing tasks across a wide variety of languages.

4.1 Experimental Setup

We first investigated our model on 19 languages from the Universal Dependencies Treebanks v1.2.[2] We selected the 19 largest currently spoken languages for which the full data was freely available. We used the coarse universal tagset in our experiments with no explicit morphological annotations. To measure parsing accuracy, we report unlabeled attachment score (UAS) and labeled attachment score (LAS) computed on all tokens (including punctuation), as is standard for non-English datasets.

For simplicity, we use the arc-standard (Nivre, 2004) transition system with greedy decoding. Because this transition system only produces projective trees, we first apply a projectivization step to all treebanks before unrolling the gold derivations during training. We make an exception for Dutch, where we observed a significant gain on development data by introducing the SWAP action (Nivre, 2009) and allowing non-projective trees.

For models that required predicted POS tags, we trained a window-based tagger using the same features as the tagger component of our stacking model. We used 5-fold jackknifing to produce predicted tags on the training set. We found that the window-based tagger was comparable to a state-of-the-art CRF tagger for most languages. For every network we trained, we used the development data to evaluate a small range of hyperparameters, stopping training early when UAS no longer improved on the held-out data. We use $H = 1024$ hidden units in the parser, and $H = 128$ hidden units in the tagger. The parser embeds the tagger activations with $D = 64$. Note that following Ballesteros et al. (2015), we did not use any auxiliary data beyond that in the treebanks, such as pre-trained word embeddings.

For a final set of experiments, we evaluated on the standard Wall Street Journal (WSJ) part of the Penn Treebank (Marcus et al., 1993)), dependencies generated from version 3.3.0 of the Stanford

converter (De Marneffe et al., 2006). We followed standard practice and used sections 2-21 for training, section 22 for development, and section 23 for testing. Following Weiss et al. (2015), we used section 24 to tune any hyperparameters of the model to avoid overfitting to the development set. As is common practice, we use pretrained word embeddings from the `word2vec` package when training on this dataset.

4.2 Results

We present our main results on the Universal Treebanks in Table 2. We directly compare our approach to other baselines in two primary ways. First, we compare the effectiveness of our learned continuous representations with those of Alberti et al. (2015), who use the predicted distribution over POS tags concatenated with word embeddings as input to the parser. Because they also incorporate beam search into training, we re-implement a greedy version of their method to allow for direct comparisons of token representations. We refer to this as the "Pipeline (P_{tag})" baseline. Second, we also compare our architecture trained without POS tags as regularization, which we refer to as "Ours (window-based)". This model has the same architecture as our full model but with no POS supervision and updates. Since this model never observes POS tags in any way, we compare against a recurrent character-based parser (Ballesteros et al., 2015) which is state-of-the-art when no POS tags are provided.[3] Finally, we compare to RGBParser (Lei et al., 2014), a state-of-the art graph-based (non-greedy) approach.

Model Variant	UAS	LAS	POS

Joint parsing & tagging transition system			
Pipeline (P_{tag})	81.61	76.57	95.30
Ours (window-based)	82.58	77.76	94.92
Ours (Stackprop)	**83.21**	**78.64**	**95.43**

Table 4: Averaged parsing and POS tagging results on the UD treebanks for joint variants of stackprop. Given the window-based architecture, stackprop leads to higher parsing accuracies than joint modeling (83.38% vs. 82.58%).

Our greedy stackprop model outperforms all other methods, including the graph-based RBGParser, by a significant margin on the test set (78.9% vs 77.6%). This is despite the limitations of greedy parsing. Stackprop also yields a 2.3% absolute improvement in accuracy compared to using POS tag confidences as features (Pipeline P_{tag}). Finally, we also note that adding stackprop to our window-based model improves accuracy in *every* language, while incorporating predicted POS tags into the LSTM baseline leads to occasional drops in accuracy (most likely due to cascaded errors.)

5 Discussion

Stackprop vs. other representations. One unexpected result was that, even *without* the POS tag labels at training time, our stackprop architecture achieves better accuracy than either the character-based LSTM or the pipelined baselines (Table 2). This suggests that adding window-based representations–which aggregate over many features of the word and surrounding context–is more effective than increasing the expressiveness of individual word representations by using character-based recurrent models. In future work we will explore combining these two complementary approaches.

We hypothesized that stackprop might provide larger gains over the pipelined model when the

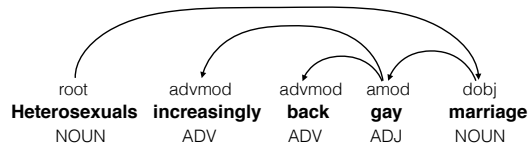
Table 5: Four of examples of tokens in context, along with the three most similar tokens according to the tagger network's activations, and the simple pattern exhibited. Note that this model was trained with the Universal tagset which does not distinguish verb tense.

POS tags are very coarse. We tested this latter hypothesis on the WSJ corpus by training our model using the coarse universal tagsets instead of the fine tagset (Table 3). We found that stackprop achieves similar accuracy using coarse tagsets as the fine tagset, while the pipelined baseline's performance drops dramatically. And while stackprop doesn't achieve the highest reported accuracies on the WSJ, it does achieve competitive accuracies and outperforms prior state-of-the-art for greedy methods (Dyer et al., 2015).

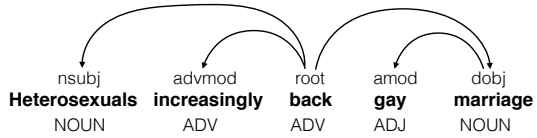
Stackprop vs. joint modeling. An alternative to stackprop would be to train the *final* layer of our architecture to predict both POS tags and dependency arcs. To evaluate this, we trained our window-based architecture with the integrated transition system of Bohnet and Nivre (2012), which augments the SHIFT transition to predict POS tags. Note that if we also apply stackprop, the network learns from POS annotations twice: once in the TAGGER updates, and again the PARSER updates. We therefore evaluated our window-based model both with and without stack-propagation, and with and without the joint transition system.

We compare these variants along with our reimplementation of the pipelined model of Alberti et al. (2015) in Table 4. We find that stackprop is always better, even when it leads to "double counting" the POS annotations; in this case, the result is a model that is significantly better at POS tagging while marginally worse at parsing than stackprop alone.

Reducing cascaded errors. As expected, we observe a significant reduction in cascaded POS tagging errors. An example from the English UD treebank is given in Figure 5. Across the 19 languages in our test set, we observed a 10.9% gain (34.1% vs. 45.0%) in LAS on tokens where the pipelined POS tagger makes a mistake, compared to a 1.8% gain on the rest of the corpora.



(a) Tree by a pipeline model.



(b) Tree by Stackprop model.

Figure 5: Example comparison between predictions by a pipeline model and a joint model. While both models predict a wrong POS tag for the word "back" (ADV rather than VERB), the joint model is robust to this POS error and predict the correct parse tree.

Decreased model size. Previous neural parsers that use POS tags require learning embeddings for words and other features on top of the parameters used in the POS tagger (Chen and Manning, 2014; Weiss et al., 2015). In contrast, the number of total parameters for the combined parser and tagger in the Stackprop model is reduced almost by half compared to the Pipeline model, because the parser and tagger share parameters. Furthermore, compared to our implementation of the pipeline model, we observed that this more compact parser model was also roughly twice as fast.

Contextual embeddings. Finally, we also explored the significance of the representations learned by the tagger. Unlike word embedding models, the representations used in our parser are constructed for each token based on its surrounding context. We demonstrate a few interesting trends we observed in Table 5, where we show the nearest neighbors to sample tokens in this contextual embedding space. These representations tend to represent syntactic patterns rather than individual words, distinguishing between the form (e.g. "judge" as a noun vs. a verb') and context of tokens (e.g. preceded by a personal pronoun).

6 Conclusions

We present a stacking neural network model for dependency parsing and tagging. Through a simple learning method we call "stack-propagation," our model learns effective intermediate representations for parsing by using POS tags as regularization of implicit representations. Our model outperforms all state-of-the-art parsers when evaluated on 19 languages of the Universal Dependencies treebank and outperforms other greedy models on the Wall Street Journal.

We observe that the ideas presented in this work can also be as a principled way to optimize upstream NLP components for down-stream applications. In future work, we will extend this idea beyond sequence modeling to improve models in NLP that utilize parse trees as features. The basic tenet of stack-propagation is that the hidden layers of neural models used to generate annotations can be used instead of the annotations themselves. This suggests a new methodology to building deep neural models for NLP: we can design them from the ground up to incorporate multiple sources of annotation and learn far more effective intermediate representations.

Acknowledgments

Abstract

We examine communications in a social network to study user emotional contrast – the propensity of users to express different emotions than those expressed by their neighbors. Our analysis is based on a large Twitter dataset, consisting of the tweets of 123,513 users from the USA and Canada. Focusing on Ekman's basic emotions, we analyze differences between the emotional tone expressed by these users and their neighbors of different types, and correlate these differences with perceived user demographics. We demonstrate that many perceived demographic traits correlate with the emotional contrast between users and their neighbors. Unlike other approaches on inferring user attributes that rely solely on user communications, we explore the network structure and show that it is possible to accurately predict a range of perceived demographic traits based solely on the emotions emanating from users and their neighbors.

1 Introduction

The explosion of social media services like Twitter, Google+ and Facebook have led to a growing application potential for personalization in human computer systems such as personalized intelligent user interfaces, recommendation systems, and targeted advertising. Researchers have started mining these massive volumes of personalized and diverse data produced in public social media with the goal of learning about their demographics (Burger et al., 2011; Zamal et al., 2012; Volkova et al., 2015) and personality (Golbeck et al., 2011; Kosinski et al., 2013),[1] language variation (Eisenstein et al., 2014; Kern et al., 2014; Bamman et al., 2014),[2] likes and interests (Bachrach et al., 2012; Lewenberg et al., 2015), emotions and opinions they express (Bollen et al., 2011b; Volkova and Bachrach, 2015), their well-being (Schwartz et al., 2013) and their interactions with online environment (Bachrach, 2015; Kalaitzis et al., 2016). The recent study has shown that the environment in a social network has a huge influence on user behavior and the tone of the messages users generate (Coviello et al., 2014; Ferrara and Yang, 2015a).

People vary in the ways they respond to the emotional tone of their environment in a social network. Some people tend to send out messages with a positive emotional tone, while others tend to express more negative emotions such as sadness or fear. Some of us are likely to share peer messages that are angry, whereas others filter out such messages. In this work we focus on the problem of predicting user *perceived demographics* by examining the emotions expressed by users and their immediate neighbors. We first define the user emotional tone, the environment emotional tone, and the user-environment emotional contrast.

Definition 1 Environment emotional tone *is the proportion of tweets with a specific emotion produced by the user's neighbors. For example, if the majority of tweets sent by the user's neighbors express joy, that user has a positive environment. In contrast, a user is in a negative environment if most of his or her neighbors express anger.*

Definition 2 User emotional tone *is the proportion of tweets with a specific emotion produced by a user. If a user mostly sends sad messages, he generates a sad emotional tone, while a user who mostly sends joyful messages has a joyful tone.*

[2] http://demographicvis.uncc.edu/

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1567–1578,
Berlin, Germany, August 7-12, 2016.

Definition 3 User-environment emotional contrast *is a degree to which user emotions differ from the emotions expressed by user neighbors. We say that users express more of an emotion when they express it more frequently than their neighbors, and say they express less of an emotion when they express it less frequently than their environment.*

There are two research questions we address in this work. First, we analyze how user demographic traits are predictive of the way they respond to the emotional tone of their environment in a social network. One hypothesis stipulates that the emotional response is a *universal* human trait, regardless of the specific demographic background (Wierzbicka, 1986; Cuddy et al., 2009). For example, men and women or young and old people should not be different in the way they respond to their emotional environment. An opposite hypothesis is a *demographic dependent emotional contrast hypothesis*, stipulating that user demographic background is predictive of the emotional contrast with the environment. For example, one might expect users with lower income to express negative emotion even when their environment expresses mostly positive emotions (high degree of emotional contrast), while users with higher income are more likely to express joy even if their environment expresses negative emotions (Kahneman and Deaton, 2010).

We provide an empirical analysis based on a large dataset sampled from a Twitter network, supporting the *demographic dependent emotional contrast hypothesis*. We show that users predicted to be younger, without kids and with lower income tend to express more sadness compared to their neighbors but older users, with kids and higher income express less; users satisfied with life express less anger whereas users dissatisfied with life express more anger compared to their neighbors; optimists express more joy compared to their environment whereas pessimists express less.

Furthermore, we investigate whether user demographic traits can be predicted from user emotions and user-environment emotional contrast. Earlier work on inferring user demographics has examined methods that use lexical features in social networks to predict demographic traits of the author (Burger et al., 2011; Van Durme, 2012; Conover et al., 2011; Bergsma et al., 2013; Bamman et al., 2014; Ruths et al., 2014; Sap et al., 2014). However, these are simply features of the text a user produces, and make limited use of the social embedding of the user in the network. Only limited amount of work briefly explored the network structure for user profiling (Pennacchiotti and Popescu, 2011a; Filippova, 2012; Zamal et al., 2012; Volkova et al., 2014; Culotta et al., 2015). In contrast, we investigate the predictive value of features that are completely dependent on the network: the emotional contrast between users and their neighbors. We also combine network (context) and text (content) features to further boost the performance of our models.

Our results show that the emotional contrast of users is very informative regarding their demographic traits. Even a very small set of features consisting of the emotional contrast between users and their environment for each of Ekman's six basic emotions and three sentiment types is sufficient to obtain high quality predictions for a range of user attributes.

Carrying out such an analysis requires using a large dataset consisting of many users annotated with a variety of properties, and a large pool of their communications annotated with emotions and sentiments. Creating such a large dataset with the ground truth annotations is extremely costly; user sensitive demographics e.g., income, age is not available for the majority of social media including Twitter. Therefore, we rely our analysis on a large Twitter dataset annotated with demographics and affects using predictive models that can accurately infer user attributes, emotions and sentiments as discussed in Section 3.

2 Data

User-Neighbor Dataset For the main analysis we collected a sample of $U = 10,741$ Twitter users and randomly sampled their neighbors $n \in N^{(u)}$ of different types including friends – u follows $n^{(u)}$, mentions – u mentions $n^{(u)}$ in his or her tweets *e.g., @modollar1*, and retweets – u retweets $n^{(u)}$ tweets *e.g., RT @GYPSY*. In total we sampled N= $141,034$ neighbors for U=$10,741$

Relation	$\subseteq U$	N_{uniq}	N_{all}	T_{total}
Retweet R	9,751	32,197	48,262	6,345,722
Mention M	9,251	37,199	41,456	7,634,961
Friend F	10,381	43,376	51,316	8,973,783
TOTAL	**10,741**	**112,772**	**141,034**	**24,919,528**

Table 1: Twitter ego-network sample stats: U=$123,513$ unique users with T=$24,919,528$ tweets, and E=$141,034$ edges that represent social relations between Twitter users.

users; on average 15 neighbors per user, 5 neighbors of each type with their 200 tweets; in total T=24,919,528 tweets as reported in Table 1. We also report the number of users with at least one neighbor of each type $\subseteq U$ and the number of unique neighbors N_{uniq}.[3]

Dataset Annotated with Demographics Unlike Facebook (Bachrach et al., 2012; Kosinski et al., 2013), Twitter profiles do not have personal information attached to the profile e.g., gender, age, education. Collecting self-reports (Burger et al., 2011; Zamal et al., 2012) brings data sampling biases which makes the models trained on self-reported data unusable for predictions of random Twitter users (Cohen and Ruths, 2013; Volkova et al., 2014). Asking social media users to fill personality questionnaires (Kosinski et al., 2013; Schwartz et al., 2013) is time consuming. An alternative way to collect attribute annotations is through crowdsourcing as has been effectively done recently (Flekova et al., 2015; Sloan et al., 2015; Preoiuc-Pietro et al., 2015).

Thus, to infer sociodemographic traits for a large set of random Twitter users in our dataset we relied on pre-trained models learned from 5,000 user profiles annotated via crowdsourcing[4] released by Volkova and Bachrach (2015). We annotated 125,513 user and neighbor profiles with eight sociodemographic traits. We only used a subset of sociodemographic traits from their original study to rely our analysis on models trained on annotations with high or moderate inter-annotator agreement. Additionally, we validated the models learned from the crowdsourced annotations on several public datasets labeled with gender as described in Section 2. Table 2 reports attribute class distributions and the number of profiles annotated.

Validating Crowdsourced Annotations To validate the quality of perceived annotations we applied 4,998 user profiles to classify users from the existing datasets annotated with gender using approaches other than crowdsourcing. We ran experiments across three datasets (including perceived annotations): Burger et al.'s data (Burger et al., 2011) – 71,312 users, gender labels were obtained via URL following users' personal blogs; Zamal et al.'s data (Zamal et al., 2012) – 383 users, gender labels were collected via user names. Table 3 presents a cross-dataset comparison results.

Attribute	Class Distribution	Profiles
Age	$\leq$ 25 y.o. (65%), $>$ 25 y.o.	3,883
Children	No (84%), Yes	5,000
Education	High School (68%), Degree	4,998
Ethnicity	Caucasian (59%), Afr. Amer.	4,114
Gender	Female (58%), Male	4,998
Income	$\leq$ \$35K (66%), $>$ \$35K	4,999
Life Satisf.	Satisfied (78%), Dissatisfied	3,789
Optimism	Optimist (75%), Pessimist	3,562

Table 2: Annotation statistics of perceived user properties from Volkova and Bachrach (2015).

We consistently used logistic regression with L2 regularization and relied on word ngram features similar to Volkova and Bachrach (2015). Accuracies on a diagonal are obtained using 10-fold cross-validation. These results show that textual classifiers trained on perceived annotations have a reasonable agreement with the alternative prediction approaches. This provides another indication that the quality of crowdsourced annotations, at least for gender, is acceptable. There are no publicly available datasets annotated with other attributes from Table 2, so we cannot provide a similar comparison for other traits.

Train\Test	Users	Burger	Zamal	Perceived
Burger	71,312	**0.71**	0.71	0.83
Zamal	383	0.47	**0.79**	0.53
Perceived	4,998	0.58	0.66	**0.84**

Table 3: Cross-dataset accuracy for gender prediction on Twitter.

Sentiment Dataset Our sentiment analysis dataset consists of seven publicly available Twitter sentiment datasets described in detail by Hassan Saif, Miriam Fernandez and Alani (2013). It includes $T_S^L = 19,555$ tweets total (35% positive, 30% negative and 35% neutral) from Stanford,[5] Sanders,[6] SemEval-2013,[7] JHU CLSP,[8] SentiStrength,[9] Obama-McCain Debate and Health Care.[10]

Emotion Dataset We collected our emotion dataset by bootstrapping noisy hashtag annota-

[3] Despite the fact that we randomly sample user neighbors, there still might be an overlap between user neighborhoods dictated by the Twitter network design. Users can be reweeted or mentioned if they are in the friend neighborhood $R \subset F, M \subset F$.

[4] Data collection and perceived attribute annotation details are discussed in (Volkova and Bachrach, 2015) and (Preoiuc-Pietro et al., 2015).

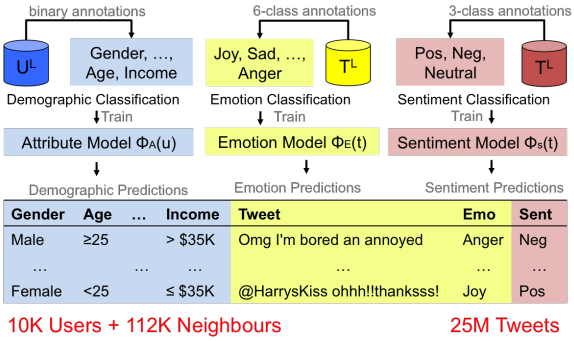

Figure 1: Our approach for predicting user perceived sociodemographics and affects on Twitter.

tions for six basic emotions argued by Ekman[11] as have been successfully done before (De Choudhury et al., 2012; Mohammad and Kiritchenko, 2014). Despite the existing approaches do not disambiguate sarcastic hashtags e.g., *It's Monday #joy* vs. *It's Friday #joy*, they still demonstrate that a hashtag is a reasonable representation of real feelings (González-Ibáñez et al., 2011). Moreover, in this work we relied on emotion hashtag synonyms collected from WordNet-Affect (Valitutti, 2004), GoogleSyns and Roget's thesaurus to overweight the sarcasm factor. Overall, we collected $T_E^L = 52,925$ tweets annotated with anger (9.4%), joy (29.3%), fear (17.1%), sadness (7.9%), disgust (24.5%) and surprise (15.6%).

3 Methodology

Annotating User-Neighbor Data with Sociodemographics and Affects As shown in Figure 1, to perform our analysis we developed three machine learning components. The first component is a user-level demographic classifier $\Phi_A(u)$, which can examine a set of tweets produced by any Twitter user and output a set of predicted demographic traits for that user, including age, education etc. Each demographic classifier relies on features extracted from user content. The second and third components are tweet-level emotion and sentiment classifiers $\Phi_E(t)$ and $\Phi_S(t)$, which can examine any tweet to predict the emotion and sentiment expressed in the tweet.

For inferring user demographics, emotions and sentiments we trained log-linear models with L2 regularization using scikit-learn.[12] Our models rely on word ngram features extracted from user or neighbor tweets and affect-specific features described below.

Perceived Attribute Classification Quality In Section 2 we compared attribute prediction models trained on crowdsourced data vs. other datasets. We showed that models learned from perceived annotations yield higher or comparable performance using the same features and learning algorithms. Given Twitter data sharing restriction,[13] we could only make an indirect comparison with other existing approaches. We found that our models report higher accuracy compared to the existing approaches for gender: +0.12 (Rao et al., 2010), +0.04 (Zamal et al., 2012); and ethnicity: +0.08 (Bergsma et al., 2013), +0.15 (Pennacchiotti and Popescu, 2011b).[14] For previously unexplored attributes we present the ROC AUC numbers obtained using our log-linear models trained on lexical features estimated using 10-fold c.v. in Table 6.

Affect Classification Quality For emotion and opinion classification we trained tweet-level classifiers using lexical features extracted from tweets annotated with sentiments and six basic emotions. In addition to lexical features we extracted a set of *stylistic features including emoticons, elongated words, capitalization, repeated punctuation, number of hashtags and took into account the clause-level negation* (Pang et al., 2002). Unlike other approaches (Wang and Manning, 2012), we observed that adding other linguistic features e.g., higher order ngrams, part-of-speech tags or lexicons did not improve classification performance. We demonstrate our emotion model prediction quality using 10-fold c.v. on our hashtag emotion dataset and compare it to other existing datasets in Table 4. Our results significantly outperform the existing approaches and are comparable with the state-of-the-art system for Twitter sentiment classification (Mohammad et al., 2013; Zhu et al., 2014) (evaluated on the official SemEval-2013 test set our system yields F1 as high as 0.66).

Correlating User-Environment Emotional Contract and Demographics We performed

[11] We prefer Ekman's emotion classification over others e.g., Plutchik's because we would like to compare the performance of our predictive models to other systems.

[12] Scikit-learn toolkit: http://scikit-learn.org/stable/ Email svitlana.volkova@pnnl.gov to get access to pre-trained scikit-learn models and the data.

[13] Twitter policy restricts to sharing only tweet IDs or user IDs rather than complete tweets or user profiles. Thus, some profiles may become private or get deleted over time.

[14] Other existing work on inferring user attributes rely on classification with different categories or use regression e.g., age (Nguyen et al., 2011), income (Preoiuc-Pietro et al., 2015), and education (Li et al., 2014).

#Emotion	Wang (2012)		Roberts (2012)		Qadir (2013)		Mohammad (2014)		This work	
#anger	457,972	0.72	583	0.64	400	0.44	1,555	0.28	4,963	0.80
#disgust	–	–	922	0.67	–	–	761	0.19	12,948	0.92
#fear	11,156	0.44	222	0.74	592	0.54	2,816	0.51	9,097	0.77
#joy	567,487	0.72	716	0.68	1,005	0.59	8,240	0.62	15,559	0.79
#sadness	489,831	0.65	493	0.69	560	0.46	3,830	0.39	4,232	0.62
#surprise	1,991	0.14	324	0.61	–	–	3849	0.45	8,244	0.64
ALL:	**1,991,184**	–	**3,777**	**0.67**	**4,500**	**0.53**	**21,051**	**0.49**	**52,925**	**0.78**

Table 4: Emotion classification results (one vs. all for each emotion and 6 way for ALL) using our models compared to others.

our *user-environment emotional contrast analysis* on a set of users U and neighbors N, where $N^{(u)}$ are the neighbors of u. For each user we defined a set of incoming T^{in} and outgoing T^{out} tweets. We then classified T^{in} and T^{out} tweets containing a sentiment $s \in S$ or emotion $e \in E$, e.g. T^{in}_e, T^{out}_e and T^{in}_s, T^{out}_s where $E \rightarrow$*{anger, joy, fear, surprise, disgust, sad}* and $S \rightarrow$ *{positive, negative, neutral}*.

We measured the proportion of user's incoming and outgoing tweets containing a certain emotion or sentiment e.g., $p^{in}_{sad} = |T^{in}_{sad}|/|T^{in}|$. Then, for every user we estimated *user-environment emotional contrast* using the normalized difference between the incoming p^{in}_e and outgoing p^{out}_e emotion and sentiment proportions:

$$\Delta e = \frac{p^{out}_e - p^{in}_e}{p^{out}_e + p^{in}_e}, \forall e \in E. \quad (1)$$

We estimated *user environment emotional tone* and *user emotional tone* from the distributions over the incoming and outgoing affects e.g., $D^{in}_s = \{p^{in}_{pos}, \ldots, p^{in}_{neut}\}$ and $D^{in}_e = \{p^{in}_{joy}, \ldots, p^{in}_{fear}\}$. We evaluated *user environment emotional tone* – proportions of incoming emotions D^{in}_e and sentiments D^{in}_s on a combined set of friend, mentioned and retweeted users; and *user emotional tone* – proportions of outgoing emotions D^{out}_e and sentiment, D^{out}_s from user tweets. We measure similarity between *user emotional tone* and *environment emotional tone* via Jensen Shannon Divergence (JSD). It is a symmetric and finite KL divergence that measures the difference between two probability distributions.

$$\text{JSD}(D^{in}||D^{out}) = \frac{1}{2}I(D^{in}||D) + \frac{1}{2}I(D^{out}||D), \quad (2)$$

$$\text{where } D = \frac{1}{2}I(D^{in}||D^{out}), I = \sum_e D^{in} \ln \frac{D^{in}}{D^{out}}.$$

Next, we compared emotion and sentiment differences for the groups of users with different demographics $A = \{a_0; a_1\}$ e.g., a_0 = Male and a_1 = Female using a non-parametric Mann-Whitney U test. For example, we measured the means $\mu^{Male}_{\Delta e=joy}$ and $\mu^{Female}_{\Delta e=joy}$ within the group of users predicted to be Males or Females, and estimated whether these means are statistically significantly different. Finally, we used logistic regression to infer a variety of attributes for $U = 10,741$ users using different features below:

- outgoing emotional tone p^{out}_e, p^{out}_s – the overall emotional profile of a user (regardless the emotions projected in his environment);
- user-environment emotional contrast $\Delta e, \Delta s$ – show whether a certain emotion Δe or sentiment Δs is being expressed more or less by the user given the emotions he has been exposed to within his social environment;
- lexical features extracted from user content – represent the distribution of word unigrams over the vocabulary.

4 Experimental Results

For sake of brevity we will refer to a user *predicted* to be male as a male, and a tweet predicted to contain surprise as a simply containing surprise. Despite this needed shorthand it is important to recall that a major contribution of this work is that these results are based on *automatically predicted* properties, as compared to ground truth. We argue here that while such automatically predicted annotations may be less than perfect at the individual user or tweet level, they provide for meaningful analysis when done on the aggregate.

4.1 Similarity between User and Environment Emotional Tones

We report similarities between *user emotional tone* and *environment emotional tone* for different groups of Twitter users using Jensen Shannon Divergence defined in the Eq. 2. We present the mean JSD values estimated over users with two contrasting attributes e.g., predicted to be a_0=Male vs. a_1=Female in Table 5.

	Sentiment Similarities						Emotion Similarities					
Attribute $[a_0, a_1]$	**Retweet**		**Friend**		**All**		**Retweet**		**Friend**		**All**	
Income [$\geq$ \$35K, $<$ \$35K]	22.1	19.4	23.7	21.1	18.6	15.1	18.7	17.8	33.6	33.3	20.0	17.6
Age [$<$ 25 y.o, $\geq$ 25 y.o.]	19.0	22.7	20.2	25.3	14.3	19.7	17.2	19.9	32.8	34.7	17.0	21.1
Education [School, Degree]	19.4	22.1	21.1	23.8	15.2	18.5	18.0	18.1	33.9	32.1	18.1	18.9
Children [Yes, No]	24.2	19.9	28.4	21.4	23.2	15.6	20.9	17.8	35.6	33.2	22.6	18.0
Gender [Male, Female]	19.7	20.5	22.0	21.9	16.5	15.9	18.3	17.9	31.6	34.6	18.2	18.5
Ethnicity [Caucas., Afr. American]	20.5	19.4	21.7	22.5	15.8	16.9	17.2	19.8	32.5	35.2	17.5	20.1
Optimism [Pessimist, Optimist]	19.9	20.3	23.1	21.7	16.8	16.0	18.9	17.9	33.6	33.3	18.6	18.3
Life Satisfaction [Dissatis., Satisfied]	19.4	20.3	21.6	22.0	15.3	16.3	18.6	18.0	33.1	33.4	18.5	16.5

Table 5: Mean Jensen Shannon Divergences (displayed as percentages) between the incoming D^{in} and outgoing D^{out} affects for contrastive attribute values a_0 and a_1. MannWhitney test results for differences between a_0 and a_1 JSD values are shown in blue (p-value ≤ 0.01), green (p-value ≤ 0.05), and gray (p-value ≤ 0.1).

In Table 5 *user environment emotional tones* are estimated over different user-neighbor environments e.g., retweet, friend, and all neighborhoods including user mentions. We found that if *user environment emotional tones* are estimated from mentioned or retweeted neighbors the JSD values are lower compared to the friend neighbors. It means that users are more emotionally similar to the users they mention or retweet than to their friends (users they follow).

We show that *user incoming and outgoing sentiment tones* D_s^{in} and D_s^{out} estimated over all neighbors are significantly different for the majority of attributes except ethnicity. The divergences are consistently pronounced across all neighborhoods for income, age, education, optimism and children attributes (p-value ≤ 0.01). When the *incoming and outgoing emotional tones* D_e^{in} and D_e^{out} are estimated over all neighbors, they are significantly different for all attributes except education and life satisfaction.

4.2 User-Environment Affect Contrast

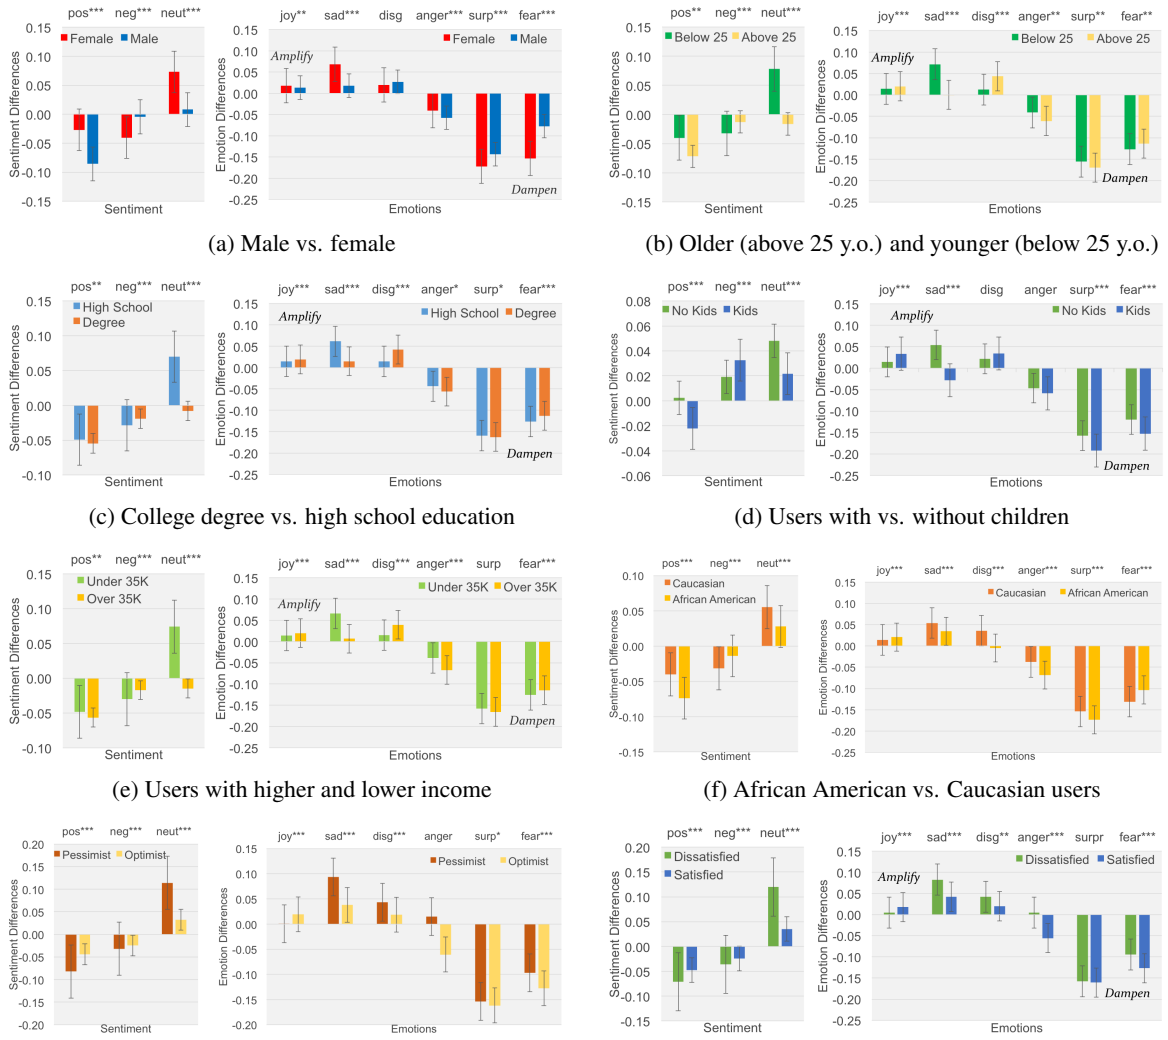
Our key findings discussed below confirm the *demographic dependent emotional contrast hypothesis*. We found that regardless demographics Twitter users tend to express more $(U > N)$ sadness$\uparrow$, disgust$\uparrow$, joy$\uparrow$ and neutral$\uparrow$ opinions and express less $(U < N)$ surprise$\downarrow$, fear$\downarrow$, anger$\downarrow$, positive$\downarrow$ and negative$\downarrow$ opinions compared to their neighbors except some exclusions below.

Users predicted to be older and having kids express less sadness whereas younger users and user without kids express more. It is also known as the *aging positivity effect* recently picked up in social media (Kern et al., 2014). It states that older people are happier than younger people (Carstensen and Mikels, 2005). Users predicted to be pessimists express less joy compared to their neighbors whereas optimists express more. Users predicted to be dissatisfied with life express more anger compared to their environment whereas users predicted to be satisfied with life produce less. Users predicted to be older, with a degree and higher income express neutral opinions compared to their environment whereas users predicted to be younger, with lower income and high school education express more neutral opinions. Users predicted to be male and having kids express more positive opinions compared to their neighbors whereas female users and users without kids express less. We present more detailed analysis on user-environment emotional contrast for different attribute-affect combinations in Figure 2.

Gender Female users have a stronger tendency to express more surprise and fear compared to their environment. They express less sadness compared to male users, supporting the claim that female users are more emotionally driven than male users in social media (Volkova et al., 2013). Male users have a stronger tendency to express more anger compared to female users. Female users tend to express less negative opinions compared to their environment.

Age Younger users express more sadness but older users express similar level of sadness compared to their environment. It is also known as the *aging positivity effect* recently picked up in social media (Kern et al., 2014). It states that older people are happier than younger people (Carstensen and Mikels, 2005). They have a stronger tendency to express less anger but more disgust compared to younger users. Younger users have a stronger tendency to express less fear and negative sentiment compared to older users.

Education Users with a college degree have a weaker tendency to express less sadness but stronger tendency to express more disgust from



(a) Male vs. female

(b) Older (above 25 y.o.) and younger (below 25 y.o.)

(c) College degree vs. high school education

(d) Users with vs. without children

(e) Users with higher and lower income

(f) African American vs. Caucasian users

(g) Optimists vs. pessimists

(h) Satisfied vs. dissatisfied with life

Figure 2: Mean differences in affect proportions between users with contrasting demographics. Error bars show standard deviation for every e and s; p-values are shown as $\leq 0.01^{***}$, $\leq 0.05^{**}$ and $\leq 0.1^{*}$.

their environment compared to users with high school education. They have a stronger tendency to express less anger but weaker tendency to express less fear. Users with high school education are likely to express more neutral opinions whereas users with a college degree express less.

Children Users with children have a stronger tendency to express more joy, less surprise and fear from their environment compared to users without children. Users with children express less sadness and less positive opinions whereas users without children express more.

Income Users with higher annual income have a weaker tendency to express more sadness and have a stronger tendency to express more disgust, less anger and fear from their environment. They tend to express less neutral opinions whereas users with lower income express more.

Ethnicity Caucasian users have a stronger tendency to express more sadness and disgust from their environment whereas African American users have a stronger tendency to express more joy and less disgust. African American users have a stronger tendency to express less anger and surprise, but a weaker tendency to express less fear.

Optimism Optimists express more joy from their environment whereas pessimists do not. Instead, pessimists have a stronger tendency to express more sadness and disgust compared to optimists. Optimists tend to express less fear. Pessimists tend to express less positive but more neutral opinions.

Life Satisfaction User-environment emotional contrast for the life satisfaction attribute highly correlates with the optimism attribute. Users dissatisfied with life have a weaker tendency to ex-

press more joy but a stronger tendency to express more sadness and disgust. They express more anger whereas users satisfied with life express less anger. Users satisfied with life have a stronger tendency to express less fear but weaker tendency to express less positive and negative opinions.

In addition to our analysis on user-environment emotional contrast and demographics, we discovered which users are more "opinionated" relative to their environment on Twitter. In other words, users in which demographic group amplify less neutral but more subjective tweets e.g., positive, negative. As shown in Figure 2 male users are significantly more opinionated $\gg$ than female users, users with kids $>$ users without kids, users with a college degree $\gg$ users with high school education, older users $\gg$ younger users, users with higher income $\gg$ users with lower income, optimists $\gg$ pessimists, satisfied $\gg$ dissatisfied with life, and African American $>$ Caucasian users.

4.3 Inferring User Demographics From User-Environment Emotional Contrast

Our findings in previous sections indicate that predicted demographics correlate with the emotional contrast between users and their environment in social media. We now show that by using user emotional tone and user-environment emotional contrast we can quite accurately predict many demographic properties of the user.

Table 6 presents the quality of demographic predictions in terms of the area and the ROC curve based on different feature sets. These results indicate that most user traits can be quite accurately predicted using solely the emotional tone and emotional contrast features of the users. That is, given the emotions expressed by a user, and contrasting these with the emotions expressed by user environment, one can accurately infer many interesting properties of the user without using any additional information. We note that the emotional features have a strong influence on the prediction quality, resulting in significant absolute ROC AUC improvements over the lexical only feature set.

Furthermore, we analyze correlations between users' emotional-contrast features and their demographic traits. We found that differences between users and their environment in sadness, joy, anger and disgust could be used for predicting whether these users have children or not. Similarly, negative and neutral opinions, as opposed to joy, fear and surprise emotions can be predictive of users with higher education.

Attribute	Lexical	EmoSent	All	Δ
Age	0.63	0.74 (+0.11)	0.83	+0.20
Children	0.72	0.67 (–0.05)	0.80	+0.08
Education	0.77	0.78 (+0.01)	0.88	+0.11
Ethnicity	0.93	0.75 (–0.18)	0.97	+0.04
Gender	0.90	0.77 (–0.13)	0.95	+0.05
Income	0.73	0.77 (+0.04)	0.85	+0.12
Life Satisf.	0.72	0.77 (+0.05)	0.84	+0.12
Optimism	0.72	0.77 (+0.05)	0.83	+0.11

Table 6: Sociodemographic attribute prediction results in ROC AUC using Lexical, EmoSent (user emotional tone + user-environment emotional contrast), and All (EmoSent + Lexical) features extracted from user content.

5 Discussion

We examined the expression of emotions in social media, an issue that has also been the focus of recent work which analyzed emotion contagion using a controlled experiment on Facebook (Coviello et al., 2014). That study had important ethical implications, as it involved manipulating the emotional messages users viewed in a controlled way. It is not feasible for an arbitrary researcher to reproduce that experiment, as it was carried on the proprietary Facebook network. Further, the significant criticism of the ethical implications of the experimental design of that study (McNeal, 2014) indicates how problematic it is to carry out research on emotions in social networks using a controlled/interventional technique.

Our methodology for studying emotions in social media thus uses an *observational* method, focusing on Twitter. We collected subjective judgments on a range of previously unexplored user properties, and trained machine learning models to predict those properties for a large sample of Twitter users. We proposed a concrete quantitative definition of the emotional contrast between users and their network environment, based on the emotions emanating from the users versus their neighbors.

We showed that various demographic traits correlate with the emotional contrast between users and their environment, supporting the *demographic-dependent emotional contrast hypothesis*. We also demonstrated that it is possible to accurately predict many perceived demographic traits of Twitter users based solely on the emotional contrast between them and their neighbors. This suggests that the way in which the emotions we radiate differ from those expressed in our environment reveals a lot about our identity.

We note that our analysis and methodology have several limitations. First, we only study *correlations* between emotional contrast and demographics. As such we do not make any *causal* inference regarding these parameters. Second, our labels regarding demographic traits of Twitter users were the result of subjective reports obtained using human annotations – subjective impressions (Flekova et al., 2016) of people rather than the true traits. Finally, we crawled both user and neighbor tweets within a short time frame (less than a week) and made sure that user and neighbor tweets were produced at the same time. Despite these limitations, our results do indicate higher performance compared to earlier work. Due to the large size of our dataset, we believe our findings are correct.

6 Related Work

Personal Analytics in Social Media Earlier work on predicting latent user attributes based on Twitter data uses supervised models with lexical features for classifying four main attributes including gender (Rao et al., 2010; Burger et al., 2011; Zamal et al., 2012), age (Zamal et al., 2012; Kosinski et al., 2013; Nguyen et al., 2013), political preferences (Volkova and Van Durme, 2015) and ethnicity (Rao et al., 2010; Bergsma et al., 2013).

Similar work characterizes Twitter users by using network structure information (Conover et al., 2011; Zamal et al., 2012; Volkova et al., 2014; Li et al., 2015), user interests and likes (Kosinski et al., 2013; Volkova et al., 2016), profile pictures (Bachrach et al., 2012; Leqi et al., 2016).

Unlike the existing work, we not only focus on previously unexplored attributes e.g., having children, optimism and life satisfaction but also demonstrate that user attributes can be effectively predicted using emotion and sentiment features in addition to commonly used text features.

Emotion and Opinion Mining in Microblogs Emotion analysis[15] has been successfully applied to many kinds of informal and short texts including emails, blogs (Kosinski et al., 2013), and news headlines (Strapparava and Mihalcea, 2007), but *emotions* in social media, including Twitter and Facebook, have only been investigated recently. Researchers have used supervised learning models trained on lexical word ngram features, synsets, emoticons, topics, and lexicon frameworks to determine which emotions are expressed on Twitter (Wang et al., 2012; Roberts et al., 2012; Qadir and Riloff, 2013; Mohammad and Kiritchenko, 2014). In contrast, *sentiment* classification in social media has been extensively studied (Pang et al., 2002; Pang and Lee, 2008; Pak and Paroubek, 2010; Hassan Saif, Miriam Fernandez and Alani, 2013; Nakov et al., 2013; Zhu et al., 2014).

Emotion Contagion in Social Networks Emotional contagion theory states that emotions and sentiments of two messages posted by friends are more likely to be similar than those of two randomly selected messages (Hatfield and Cacioppo, 1994). There have been recent studies about emotion contagion in massively large social networks (Fan et al., 2013; Ferrara and Yang, 2015b; Bollen et al., 2011a; Ferrara and Yang, 2015a).

Unlike these papers, we do not aim to model the spread of emotions or opinions in a social network. Instead, given both homophilic and assortative properties of a Twitter social network, we study how emotions expressed by user neighbors correlate with user emotions, and whether these correlations depend on user demographic traits.

7 Summary

We examined a large-scale Twitter dataset to analyze the relation between perceived user demographics and the emotional contrast between users and their neighbors. Our results indicated that many sociodemographic traits correlate with user-environment emotional contrast. Further, we showed that one can accurately predict a wide range of perceived demographics of a user based solely on the emotions expressed by that user and user's social environment.

Our findings may advance the current understanding of social media population, their online behavior and well-being (Nguyen et al., 2015). Our observations can effectively improve personalized intelligent user interfaces in a way that reflects and adapts to user-specific characteristics and emotions. Moreover, our models for predicting user demographics can be effectively used for a variety of downstream NLP tasks e.g., text classification (Hovy, 2015), sentiment analysis (Volkova et al., 2013), paraphrasing (Preotiuc-Pietro et al., 2016), part-of-speech tagging (Hovy and Søgaard, 2015; Johannsen et al., 2015) and visual analytics (Dou et al., 2015).

Prototype Synthesis for Model Laws

Abstract

State legislatures often rely on existing text when drafting new bills. Resource and expertise constraints, which often drive this copying behavior, can be taken advantage of by lobbyists and special interest groups. These groups provide *model bills*, which encode policy agendas, with the intent that the models become actual law. Unfortunately, model legislation is often opaque to the public–both in source and content. In this paper we present LOBBYBACK, a system that reverse engineers model legislation from observed text. LOBBYBACK identifies clusters of bills which have text reuse and generates "prototypes" that represent a canonical version of the text shared between the documents. We demonstrate that LOBBYBACK accurately reconstructs model legislation and apply it to a dataset of over 550k bills.

1 Introduction

Beginning in 2005, a number of states began passing "Stand Your Ground" laws–legal protections for the use of deadly force in self-defense. Within a few years, at least two dozen states implemented a version of the this legislation (Garrett and Jansa, 2015). Though each state passed its own variant, there is striking similarity in the text of the legislation. While seemingly "viral" the expedient adoption of these laws was not the result of an organic diffusion process, but rather more centralized efforts. An interest group, the American Legislative Exchange Council (ALEC), drafted model legislation (in this case modeled on Florida's law) and lobbied to have the model law enacted in other states. While the influence of the lobbyists through model laws grows, the hidden nature of their original text (and source) creates a troubling opacity.

Reconstructing such hidden text through analysis of observed, potentially highly mutated, copies poses an interesting and challenging NLP problem. We refer to this as the *Dark Corpora* problem. Since legislatures are not required to cite the source of the text that goes into a drafted bill, the bills that share text are unknown beforehand. The first problem therein lies in identifying clusters of bills with reused text. Once a cluster is identified, a second challenge is the reconstruction of the original or prototype bill that corresponds to the observed text. The usual circumstances under which a model law is adopted by individual states involves "mutation." This may be as simple as modifying parameters to the existing policy (*e.g.*, changing the legal limit allowed of medical marijuana possession to 3.0 ounces from 2.5) or can be more substantial, with significant additions or deletions of different conditions of a policy. Interestingly, the need to maintain the objectives of the law creates a pressure to retain a legally meaningful structure and precise language–thus changes need to satisfy the existing laws of the state but carry out the intent of the model. Both subtle changes of this type, and more dramatic ones, are of great interest to political scientists. A specific application, for example, may be predicting likely spots for future modifications as additional states adopt the law. Our challenge is to identify and represent "prototype" sentences that capture the *similarity* of observed sentences while also capturing the *variation*.

In this paper we propose LOBBYBACK, a system that automatically identifies clusters of documents that exhibit text reuse, and generates "prototypes" that represent a canonical version of text shared between the documents. In order to syn-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1579–1588,
Berlin, Germany, August 7-12, 2016.

thesize the prototypes, LOBBYBACK first extracts clusters of sentences, where each sentence pertains to the same policy but can exhibit variation. LOBBYBACK then uses a greedy multi-sequence alignment algorithm to identify an approximation of the optimal alignment between the sentences. Prototype sentences are synthesized by computing a consensus sentence from the multi-sentence alignment. As sentence variants are critical in understanding the effect of the model legislation, we can not simply generate a single "common" summary sentence as a prototype. Rather, LOBBYBACK creates a data structure that captures this variability in text for display to the end-user.

With LOBBYBACK, end-users can quickly identify clusters of text reuse to better understand what type of policies are diffused across states. In other applications, sentence prototypes can be used by journalists and researchers to discover previously unknown model legislation and the involvement of lobbying organizations. For example, prototype text can be compared to the language or policy content of interest groups documents and accompanied with qualitative research it can help discover which lobbyists have drafted this legislation.

We evaluated LOBBYBACK on the task of reconstructing 122 known model legislation documents. Our system was able to achieve an average of 0.6 F1 score based on the number of prototype sentences that had high similarity with sentences from the model legislation. We have also run LOBBYBACK on the entire corpus of state legislation (571,000 documents) from openstates.org as an open task. The system identified 4,446 clusters for which we generated prototype documents. We have released the resulting data set and code at http://github.com/mattburg/LobbyBack. LOBBYBACK is novel in fully automating and scaling the pipeline of model-legislation reconstruction. The output of this pipeline captures both the likely "source sentences" but also the variations of those sentences.

2 Related Work

While no specific system or technique has focused on the problem of legislative document reconstruction, we find related work in a number of domains. Multi-document summarization (MDS), for example, can be used to partially model the underlying problem–generating a representative document from multiple sources. Extractive MDS, in particular, is promising in that representative sentences are identified.

Early work in extractive summarization include greedy approaches such as that proposed by Carbonell and Goldstein (1998). The algorithm uses an objective function which trades off between relevance and redundancy. Global optimization techniques attempt to generate "summaries" (selected sets of sentences or utterances) that maximize an objective based on informativeness, redundancy and/or length of summary. These have shown superior performance to greedy algorithms (Yih et al., 2007; Gillick et al., 2009). Approaches based on neural networks have recently been proposed for ranking candidate sentences (Cao et al., 2015). Graph based methods, such as LexRank (Erkan and Radev, 2004), have also proven effective for MDS. Extensions to this approach combine sentence ranking with clustering in order to minimize redundancy (Qazvinian and Radev, 2008; Wan and Yang, 2008; Cai and Li, 2013). The C-LexRank algorithm (Qazvinian and Radev, 2008), in particular, uses this combination and inspired our high level design. Similar to our approach, Wang and Cardie (2013) propose a method for generating templates of meeting summaries using multi-sequence alignment.

Though related, it is important to note that the objectives of summarization (informativeness, reduced redundancy, etc.) are not entirely consistent with our task. For example, using the n-gram co-occurrence based ROUGE score would not be sufficient at evaluating LOBBYBACK. Our goal is to accurately reconstruct entire sentences of a hidden document given observed mutations of that document. Additionally, our goal is not simply to find a representative sentence that reflects the original document, but to capture the similarity *and* variability of the text within a given "sentence cluster."

Within the political science and legal studies communities research has focused on *manual* approaches to both understanding how model legislation impacts law and how policy ideas diffuse between bill text. As these studies are time consuming, there is no large-scale or broad analysis of legislative materials. Rather, researchers have limited their workload by focusing on a single topic (*e.g.*, abortion (Patton, 2003) and crime (Kent and Carmichael, 2015)) or a single lobbying group (*e.g.*, ALEC (Jackman, 2013). Similarly, those

studying policy diffusion across US states have also limited their analysis to a few topics (*e.g.*, same-sex marriage (Haider-Markel, 2001)).

Recent attempts to automate the analysis of model legislation has had similar problems, as most researchers have limited their analysis to one interest group or a few relevant topics (Hertel-Fernandez and Kashin, 2015; Jansa et al., 2015). Hertel-Fernandez and Kashin proposed a supervised model in which they train on hand labeled examples of state bills that borrow text and/or concepts from ALEC bills. The problem they focus on is different from ours. The motivation behind LOBBYBACK is that there exists many model legislation which we don't have access to and the goal is to try and reconstruct these documents without labeled training data. Jansa *et al.* propose a technique for inferring a network of policy diffusion for manually labeled clusters of bills. Both Jansa *et al.* and Hertel-Fernandaz and Kashin propose techniques that only look at the problem of inferring whether two bills exhibit text reuse but unlike LOBBYBACK they do not attempt to infer whether specific policies (sentences) in the documents are similar/different.

A related "dark corpora" problem, though at a far smaller scale, is the biblical "Q source" where hidden oral sources are reconstructed through textual analysis (Mournet, 2005).

3 Problem Definition

Policy diffusion is a common phenomenon in state bills (Gray, 1973; Shipan and Volden, 2008; Berry and Berry, 1990; Haider-Markel, 2001). Unlike members of the (Federal) Congress, few state legislators have the expertise, time, and staff to draft legislation. It is far easier for a legislator to adapt existing legislative text than to write a bill from scratch. As a consequence, state legislatures have an increased willingness to adopt legislation drafted by interest groups or by legislators in other states (Jansa et al., 2015). In addition to states borrowing text from other legislators and lobbyists, another reason why bills can exhibit text reuse is when a new federal law passes and each state needs to modify its existing policy to conform with the new federal law.

The result of legislative copying, whether caused by diffusion between states, influence from a lobby or the passing of a new federal law, is similar: a cluster of bills will share very similar text, often varying only by implementation details of a given policy. The goal in constructing a prototype document–a representation of the "original" text–is to synthesize this document from the modified copies. In the case when the bill cluster was influenced by one external source, such as lobby or passage of a federal bill, the ideal prototype document would capture the language that each bill borrowed from the source document. In the case when their is not one single document that influenced a cluster of bills, the prototype will still give a summary of a concise description of the diffused text between bills, providing fast insight into what text was shared and changed within a bill cluster.

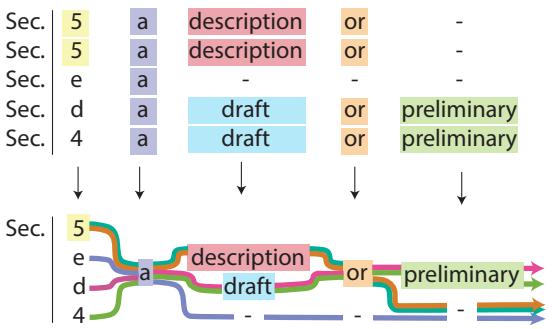

Figure 1: Visualization of a multi-sentence alignment (fragment) and resulting prototype sentence.

3.1 State Legislation Corpus

We obtained the entire openstates.org corpus of state legislation, which includes 550,000 bills and 200,000 resolutions for all 50 states. While for some states this corpus includes data since 2007, for the majority of states we have data from 2010 on. We do not include data from Puerto Rico, where the text is in Spanish, and from Washington DC, which includes many idiosyncrasies (*e.g.*, correspondence from city commissions introduced as bills). On average, each state introduced 10,524 bills, with an average length of 1205 words.

4 LOBBYBACK Architecture

LOBBYBACK consists of 3 major components. The first component identifies clusters of bills that have text reuse. Then for each of these bill clusters, LOBBYBACK extracts and clusters the sentences from all documents. For each of the sentence clusters, LOBBYBACK synthesizes prototype sentences in order to capture the similarity and variability of the sentences in the cluster.

4.1 Clustering Bills

Groups of bills with significant text reuse represent candidates for analysis as they have may have all copied from the same model legislation. There are a number of ways one could identify such clusters through text mining. In our implementation, we have opted to generate a network representation of the bills and then use a network clustering (i.e., "community-finding") algorithm to generate the bill clusters. In our network representation each node represents a state bill and weighted edges represent the degree to which two bills exhibit substantive text reuse. Since most pairs of bills do not have text reuse, we chose to use a network model because community finding algorithms work well on sparse data and do not require any parameter choice for the number of clusters. In the context of this paper, text reuse occurs when two state bills share:

1. Long passages of text, *e.g.* (sections of bills) that *can* differ in details.
2. These passages contain text of substantive nature to the topic of the bill (*i.e.*, text that is *not* boilerplate).

In addition to text that describes policy, state bills also contain boilerplate text that is common to all bills from a particular state or to a particular topic. Examples of legislative boilerplate include: "Read first time 01/29/16. Referred to Committee on Higher Education" (meta-data describing where the bill is in the legislative process); and "Safety clause. The general assembly hereby finds, determines, and declares ..." (a standard clause included in nearly all legislation from Colorado, stating the eligibility of a bill to be petitioned with a referendum).

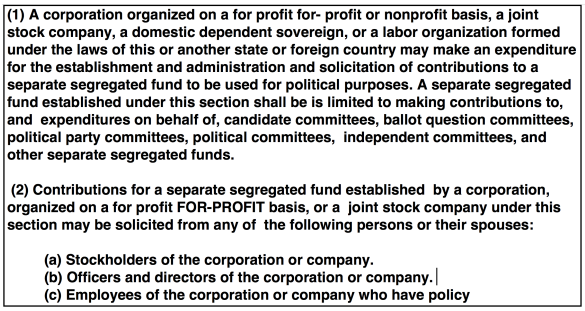
In order to identify pairs of bills that exhibit text reuse, we created an inverted index that contained n-grams ranging from size 4-8. We use ElasticSearch to implement the inverted index and computed the similarity between bills using the "More like This" (MLT) query (Elastic, 2016). The MLT query first selects the 100 highest scoring TF*IDF n-grams from a given document and uses those to form a search query. The MLT query is able to quickly compute the similarity between documents and since it ranks the query terms by using TF*IDF the query text is more likely to be substantive rather then boilerplate. The MLT query we used was configured to only return documents that matched at least 50% of the query's shingles and returned at most 100 documents per query. By implementing the similarity search using a TF*IDF cutoff we were able to scale the similarity computation while still maintaining our desire to identify reuse of substantive text.

The edges of the bill similarity network are computed by calculating pairwise similarity. Each bill is submitted as input for an MLT query and scored matches are returned by the search engine. Since the MLT query extracts n-grams only for the query document, the similarity function between two documents d_i and d_j is not symmetric. We construct a symmetric bill similarity network by taking the average score of each (d_i, d_j) and its reciprocal (d_j, d_i). A non-existent edge is represented as an edge with score 0. We further reduce the occurrence of false-positive edges by removing all edges with a score lower than 0.1. The resulting network is very sparse, consisting of 35,346 bills that have 1 or more neighbors, 125,401 edges, and 3534 connected components that contain an average of 10 bills.

A specific connected component may contain more than one bill cluster. To isolate these clusters in the bill network we use the InfoMap community detection algorithm (Rosvall and Bergstrom, 2008). We use the InfoMap algorithm because it has been to shown to be one of the best community detection algorithms and it is able to detect clusters at a finer granularity than other methods. Our corpus contains both bills that have passed and those that have not. Bills can often be reintroduced in their entirety after failing the previous year. As we do not want to bias the clusters towards bills that are re-introduced more than others, we filter the clusters such that they only include the earliest bill from each state.

4.2 Prototype Synthesis

Once we have identified a cluster of bills that have likely emerged from a single "source" we would like to construct a plausible representation of that source. The prototype synthesizer achieves this by constructing a canonical document that captures the similarity and variability of the content in a given bill cluster. The two main steps in prototype synthesis consists of clustering bill sentences and generating prototype sentences from the clusters.



(1) A corporation organized on a for profit for- profit or nonprofit basis, a joint stock company, a domestic dependent sovereign, or a labor organization formed under the laws of this or another state or foreign country may make an expenditure for the establishment and administration and solicitation of contributions to a separate segregated fund to be used for political purposes. A separate segregated fund established under this section shall be is limited to making contributions to, and expenditures on behalf of, candidate committees, ballot question committees, political party committees, political committees, independent committees, and other separate segregated funds.

(2) Contributions for a separate segregated fund established by a corporation, organized on a for profit FOR-PROFIT basis, or a joint stock company under this section may be solicited from any of the following persons or their spouses:

(a) Stockholders of the corporation or company.
(b) Officers and directors of the corporation or company.
(c) Employees of the corporation or company who have policy

Figure 2: An sample state bill segment from Michigan Senate Bill 571

4.2.1 Sentence Clustering

Most state bills have a common structure, consisting of an introduction that describes the intent of the bill followed by sections that contain the law to be implemented. Each section of a bill is comprised of self-contained policy, usually consisting of a long sentence that describes the policy and the implementation details of that policy. Each document is segmented into these policy sentences using the standard Python NLTK sentence extractor. Sentences are cleaned by removing spurious white space characters, surrounding punctuation and lower-casing each word. Once we have extracted all of the sentences for a given bill cluster, we compute the cosine similarity between all pairs of sentences which are represented using a unigram bag-of-words model. We used a simple unweighted bag of words model because in legal text stop words can be import[1] In this case, we are generating a similarity "matrix" capturing sentence–sentence similarity.

Given the similarity matrix, our next goal is to isolate clusters of variant sentences that likely came from the same source sentence. We elected to use the DBSCAN (Ester et al., 1996) algorithm to generate these clusters. The DBSCAN algorithm provides us with tunable parameters that can isolate better clusters. Specifically, the parameter ϵ controls the maximum distance between any two points in the same neighborhood. By varying ϵ we are able to control both the number of clusters and the amount of sentence variation within a cluster. A second reason for selecting DBSCAN is that the algorithm automatically deals with noisy data points, placing all points that are not close enough to other points in a separate cluster labeled "noise." Since many sentences in a given bill cluster do not contribute to the reused text between bills, the noise cluster is useful for grouping those sentences together rather than having them be outsiders in "good" clusters.

[1]The difference between the words "shall" and "may" for instance is important, the former requires that a specific action be put on a states budget while the later does not

4.2.2 Multi-Sequence Alignment

Once we have sentence clusters we then synthesize a "prototype" sentence from all of the sentences in a given cluster. An ideal prototype "sentence" is one that simultaneously captures the similarity between each sentence in the cluster (the common sentence structures) and the variation between the sentences in a cluster. For a simple pair of (partial) sentences, "The Department of Motor Vehicles retains the right to . . . " and "The Department of Transportation retains the right to . . . ", a prototype might be of the form, "The Department of { Motor Vehicles, Transportation } retains the rights to . . . " Our "sentence" is not strictly a single linear piece of text. Rather, we have a data structure that describes alternative sub-strings and captures variant text.

To generate this structure we propose an algorithm that computes an approximation of the optimal multi-sentence alignment (MSA) in the cluster and then generates a prototype sentence representing a 'consensus' for sentences in the MSA.

We generate an MSA using a modified version of the iterative pairwise alignment algorithm described in (Gusfield, 1997). The greedy algorithm builds a multi-alignment by iteratively applying the Needleman-Wunsch pairwise global alignment algorithm. Needleman-Wunsch computes the optimal pairwise alignment by maximizing the alignment score between two sentences. An alignment score is calculated based on three parameters: word matches, word mismatches (when a word appears in one sentence but not the other), and gaps (when the algorithm inserts a space in one of the sentences).

An MSA is generated by the following steps:

1. Construct an edit-distance matrix for all pairs of sentences
2. Construct an initial alignment between the two sentences with the smallest edit distance
3. Repeat this step k times:
   (a) Select the sentence with the smallest average edit distance to the current MSA.
   (b) Add the chosen sentence to the MSA by aligning it to the existing MSA.

The algorithm stops after the alignment has reached a size that is determined as a free parameter k (user configured, but can be chosen to be the number of sentences in the cluster). As the algorithm execution is ordered on the edit distance between the current MSA and the next sentence to be added, the larger the MSA, the more variation we are allowing in the prototype sentence.

4.2.3 Synthesizing Prototype Sentences

We synthesize a prototype sentence by finding a *consensus* sentence from all of the aligned sentences in the MSA for a given cluster. We achieve this by going through each "column" of the MSA and using the following rules to decide which token will be used in the prototype. A token can be either a word in one of the sentences or a "space" that was inserted during the alignment process.

1. If there is a token that occurs in the majority of alignments ($> 50\%$) then that token is chosen.
2. If no token appears in a majority, then a special variable token is constructed that displays all of the possible tokens in each sentence. For example the 1^{st} and 3^{rd} columns in Figure 1.
3. If a space is the majority token chosen then it is shown as a variable token with the second most common token.

5 Evaluation

We provide experiments that evaluate all three components of LOBBYBACK.

5.1 Model Legislation Corpus

To test the effectiveness of LOBBYBACK in recreating a model bill, we first identified a set of known model bills. Our model legislation corpus consists of 1846 model bills that we found by searching on Google using the keywords "model law", "model policy" and "model legislation." Most of the corpus is comprised of bills from the conservative lobby group, American Legislative Exchange Council (ALEC, 708 documents), its liberal counterpart, the State Innovative Exchange (SIX, 269 documents) and the non-partisan Council of State Governments (CSG, 470 documents), and the remainder (399) from smaller interest groups that focus on specific issues.

Using the clusters we previously described (Section 4.1), we found the most similar cluster to each model bill. This was done by first computing the set of neighbors (ego-network) for a model bill using the same procedure used in creating the bill similarity network. We then matched a bill cluster to the model legislation by finding the bill cluster that had the highest Jaccard similarity (based on the overlapping bills in each cluster) with the neighbor set of a model bill. Each test example in our evaluation data set consists of model bill and its corresponding bill cluster. The total number of model legislation documents that had matches in the state bill corpus was 360 documents.

Once we have an evaluation data set comprised of model bill/cluster pairs our goal is to compare the prototype sentences we infer for a cluster to the model bill that matches that cluster. Since we do not have ground truth on which sentences from the model bill match sentences in the documents that comprise the cluster we need to infer such labels. In order to identify which sentences from the model legislation actually get re-used in the bill cluster, we take the following steps:

1. Extract all sentences from each of the bills in a cluster and the sentences in the corresponding model legislation.
2. Compute the pairwise cosine similarity between bill sentences and each of the model bill sentences using the same unigram bag-of-words model described in Section 4.2.1
3. Compute the "oracle" matching M^* using the Munkres algorithm (Munkres, 1957)

The Munkres algorithm gives the best possible one-to-one matching between the sentences in the model legislation and the sentences in the bill clusters. There are some sentences in the model bill that are never used in actual state legislation (e.g., sentences that describe the intent of a law or instructions of how to implement a model policy). Therefore we label model bill sentences in M^* that match a bill sentence with a score greater than 0.85 as true matches (S^*)[2]. The final set of 122 evaluation examples consists of all model legislation/bill cluster pairs where more than 50% of model bill sentences have true matches.

[2]A threshold of 0.85 was found effective in prior work (Garrett and Jansa, 2015) and we observed good separation between matching sentences and non-matches in our data-set.

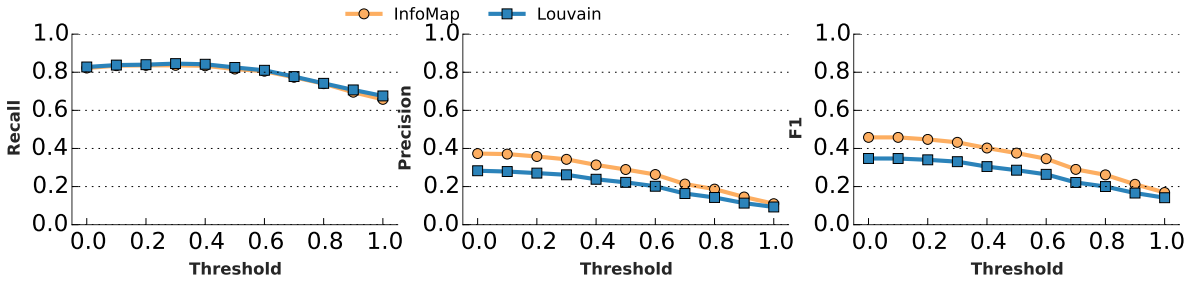


Figure 3: Precision, Recall, and F1 scores for the bill clustering component of LOBBYBACK configured with both the Louvain and InfoMap clustering algorithms.

5.2 Baselines

While no specific baseline exists for our problem, we implemented two alternatives to test against. The first, Random-Baseline, was implemented simply to show the performance of randomly constructing prototype documents. The second, LexRank-Baseline, implements a popular extractive summarization method.

Random-Baseline – The *random-baseline* randomly samples sentences from a given bill cluster. The number of sentences it samples is equal to the number of sentences in the optimal matching $|M^*|$

LexRank-Baseline – The LexRank baseline uses the exact same clustering algorithm as LOBBYBACK except instead of synthesizing prototype sentences, it uses the LexRank algorithm (Erkan and Radev, 2004) to pick the most salient sentence from each of the sentence clusters.

5.3 Evaluating Bill Clusters

As described in Section 5.1, each model bill is associated with a set of bills that comprise its neighbors in the bill network. In order to evaluate how LOBBYBACK clusters bills we compare the inferred clusters to the corresponding neighbor set for each model bill.

The inferred cluster for a given model bill can exhibit false positive and false negative errors. False negatives, in which a bill that exists in the neighbor set of a model bill but is not contained in the inferred cluster, are easy to identify (allowing us to calculate recall). Precision, on the other hand, is more difficult as any "extra" bills in the inferred cluster are not necessarily incorrect. It is possible that there are bills which do exhibit text re-use with the model legislation but did not match via the ElasticSearch query used to construct the network. We have found that in practice the second component of LOBBYBACK, which clusters the sentences extracted from a bill cluster, is robust to false-positives due to DBSCAN's treatment of "noisy" data points. Because of this, we are more concerned with recall in the bill clustering module as any data lost in this step propagates through the rest of the system.

Figure 3 shows the precision, recall, and F1 scores for LOBBYBACK coupled with both the Louvain (Blondel et al., 2008) and InfoMap (Rosvall and Bergstrom, 2008) network clustering algorithms. Because we do not know with absolute certainty which state bills are derived from model legislation, we would like to test our approach at different levels of confidence. To do this we vary the threshold on the similarity scores (edge weights) of the ego-network determined for each model legislation. A normalized weight is computed by taking the score provided by ElasticSearch and dividing that edge weight weight by the maximum edge weight in the neighbor set (to control for the unbounded scores provided by ElasticSearch). We vary the threshold for this weight (ranging from 0 to 1) and calculate the precision, recall, and F1 on a neighborhood set that is comprised of all bills that have a weight greater than the threshold. Higher threshold values means fewer state bills are included in the set, but they are increasingly similar to the model bill.

As shown in Figure 3, recall stays high for the majority of threshold values. This indicates that both clustering algorithms do a good job at recovering the bills that are the most similar to the model legislation. However, the two clustering algorithms differ somewhat in precision. Louvain, in particular performs worse, as it suffer from "resolution" problems. While effective for networks with large clusters, Louvain can not isolate small groups, of which we have many. For this reason,

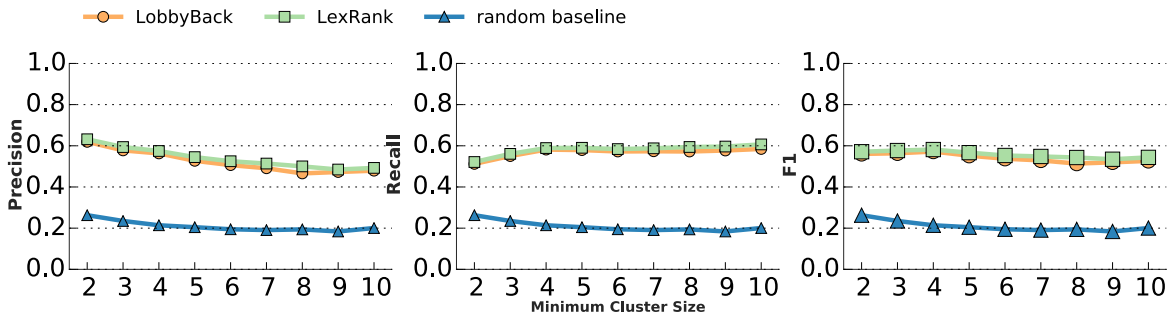

Figure 4: Precision, Recall, and F1 scores of LOBBYBACK and baselines.

we chose InfoMap as the method to use for the final implementation of LOBBYBACK.

5.4 Evaluating Sentence Clusters

We first evaluate the quality of the sentence clusters using the optimal matching M^* described above. For each test example in the evaluation set we generate a prototype document using LOBBYBACK and each of the baselines described above. We then compute a matching M between the prototype sentences and the model bill sentences (using the same procedure described in 5.1), where S is the set of sentences in the prototype and $S_{0.85}$ is the set of sentences that match with a score greater than 0.85. We compute precision, P, as $P = |S_{0.85}|/|S|$, and recall, R, as $R = |S|/|S^*|$.

Figure 4 shows precision, recall and F1 scores for both baselines and LOBBYBACK. Each curve is generated by averaging the precision/recall/F1 scores computed for each of the examples in the test set. The x-axis represents the minimum bill cluster size of the test examples for which the score is computed. For example, a minimum cluster size would average over all test examples with at least 2 bills in a cluster. LOBBYBACK relies on the fact that if text was borrowed from a model bill, then it would have been borrowed by many of the bills in the cluster. By analyzing how LOBBYBACK performs with respect to the minimum cluster size, we can determine how much evidence LOBBYBACK needs in order to construct clusters that correspond to sentences in the model bills. While the performance of LOBBYBACK and the LexRank baseline substantially improves over the random baseline, the different between LOBBYBACK and LexRank for this task is negligible. Since our cut-off similarity is 0.85, all sentences above the threshold are treated as true positives, making the distinction between the LexRank baseline and system small. LOBBYBACK performs a little worse than LexRank for large cluster sizes because it is penalized for having space and variable tokens which don't occur in model bills. Space and variable tokens occur more frequently in prototype sentences in larger clusters because there is more variation in the sentence clusters.

5.5 Evaluating Sentence Synthesis

The experiment in the previous section evaluated the quality of the sentence clusters by treating all matching sentences with a similarity greater than 0.85 as true positives. Here we provide an evaluation of the synthesized sentences that LOBBYBACK generates and compare them to the LexRank baseline, which chooses the most salient sentence from each cluster. We evaluate the quality of the synthesized prototype sentences by computing the word-based edit-distance between the prototype sentence with its corresponding model bill sentence in S for each test example.

Since the prototypes contain variable and space tokens which do not occur in the model bill sentences we modify the standard edit distance algorithm by *not* penalizing space tokens and allowing for any of the tokens that comprise a variable to be positive matches. In addition, we remove punctuation and lowercase all words in all of the sentences, regardless of method. We generate the results in Table 1 by averaging the edit distance for a configuration of LOBBYBACK or LexRank over sentence clusters produced for each test example. LOBBYBACK was configured to run with the number of iterations set to the size of the sentence cluster.

We compared both the performance of LOBBYBACK and LexRank for DBSCAN ϵ values of 0.1 and 0.15 as well as computing the average edit distance for different minimum sizes of cluster values. As the table shows, LOBBYBACK obtains a lower edit distance than LexRank in every config-

uration and as the size of the clusters increase the gap between the two increases. The goal of LOBBYBACK is not to be a better summarization algorithm than LexRank. By comparing to LexRank and showing that the edit distances are smaller on average, we can conclude that the prototype sentences created by LOBBYBACK are capturing the text that is "central" or similar within a given cluster. In addition, the prototype sentences produced by LOBBYBACK are superior because they also capture and describe in a succinct way, the variability of the sentences within a cluster.

6 Discussion

One assumption that we made about the nature of state adoption of model legislation is that the legislatures make modifications that largely preserve the model language in an effort to preserve policy. However, we currently do not consider cases in which a legislature has intentionally obscured the text while still retaining the same meaning. While not as frequent as common text reuse, Hertel-Fernandez and Kashin (2015) observed that some legislatures almost completely changed the text while reusing the concepts. One area of future work would be to try and extend LOBBYBACK to be more robust to these cases. One strategy would be to allow for a more flexible representation of text, such as word vector embeddings. The embeddings might even be used to extend the multi-sentence alignment to include a penalty based on word distance in embedding space.

LOBBYBACK performs well on reconstructing model legislation from automatically generated bill clusters. However, there are a number of improvements that can refine part of the pipeline. A potential change, but one that is more computationally costly, would be to use a deeper parsing of the sentences that we extract from the documents. We used a simple unigram model when computing sentence similarities because we wanted to ensure that stop words were included–due to their importance in legal text. We suspect that by using a parser we could, for example, weight the similarity of noun-phrases, yielding a better similarity matrix and potentially higher precision/recall. Currently LOBBYBACK does not consider the order of the sentences when attempting to construct a prototype document. We envision a future version of LOBBYBACK that tries to reconstruct the original ordering of the prototype sentences.

		Min Cluster Size			
Method	ϵ	2	4	6	8
LOBBYBACK	0.1	**24.4**	**20.4**	**18.2**	**17.2**
LexRank	0.1	25.4	22.5	20.3	19.4
LOBBYBACK	0.15	**25.5**	**21.6**	**19.4**	**17.9**
LexRank	0.15	27.3	25.6	25.0	24.1

Table 1: Mean edit distance scores for LOBBYBACK and LexRank.

7 Conclusion

In this paper we present LOBBYBACK, a system to reconstruct the "dark corpora" that is comprised of model bills which are copied (and modified) by resource constrained state legislatures. LOBBYBACK first identifies clusters of text reuse in a large corpora of state legislation and then generates prototype sentences that summarizes the similarity and variation of the copied text in a bill cluster. We believe that by open-sourcing LOBBYBACK and releasing our data of prototype bills to the public, journalists and legal scholars can use our findings to better understand the origination of U.S state laws.

Which argument is more convincing? Analyzing and predicting convincingness of Web arguments using bidirectional LSTM

Abstract

We propose a new task in the field of computational argumentation in which we investigate qualitative properties of Web arguments, namely their convincingness. We cast the problem as relation classification, where a pair of arguments having the same stance to the same prompt is judged. We annotate a large datasets of 16k pairs of arguments over 32 topics and investigate whether the relation "A is more convincing than B" exhibits properties of total ordering; these findings are used as global constraints for cleaning the crowdsourced data. We propose two tasks: (1) predicting which argument from an argument pair is more convincing and (2) ranking all arguments to the topic based on their convincingness. We experiment with feature-rich SVM and bidirectional LSTM and obtain 0.76-0.78 accuracy and 0.35-0.40 Spearman's correlation in a cross-topic evaluation. We release the newly created corpus *UKPConvArg1* and the experimental software under open licenses.

1 Introduction

What makes a good argument? Despite the recent achievements in computational argumentation, such as identifying argument components (Habernal and Gurevych, 2015; Habernal and Gurevych, 2016), finding evidence for claims (Rinott et al., 2015), or predicting argument structure (Peldszus and Stede, 2015; Stab and Gurevych, 2014), this question remains too hard to be answered.

Even Aristotle claimed that perceiving an argument as a "good" one depends on multiple factors (Aristotle and Kennedy (translator), 1991) — not only the logical structure of the argument (*logos*), but also on the speaker (*ethos*), emotions (*pathos*), or context (*cairos*) (Schiappa and Nordin, 2013). Experiments also show that different audiences perceive the very same arguments differently (Mercier and Sperber, 2011). A solid body of argumentation research has been devoted to the quality of arguments (Walton, 1989; Johnson and Blair, 2006), giving more profound criteria that "good" arguments should fulfill. However, the empirical evidence proving applicability of many theories falls short on everyday arguments (Boudry et al., 2015).

Since the main goal of argumentation is persuasion (Nettel and Roque, 2011; Mercier and Sperber, 2011; Blair, 2011; OKeefe, 2011) we take a pragmatic perspective on qualitative properties of argumentation and investigate a new high-level task. We asked whether we could quantify and predict how convincing an argument is.

Prompt: Should physical education be mandatory in schools? **Stance:** Yes!

Argument 1	Argument 2
physical education should be mandatory cuhz 112,000 people have died in the year 2011 so far and it's because of the lack of physical activity and people are becoming obese!!!!	YES, because some children don't understand anything excect physical education especially rich children of rich parents.

Figure 1: Example of an argument pair.

If we take Argument 1 from Figure 1, assigning a single "convincingness score" is highly subjective, given the lack of context, reader's prejudice, beliefs, etc. However, when comparing both arguments from the same example, one can decide that A1 is probably more convincing than A2, because it uses at least some statistics, addresses the health

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1589–1599,
Berlin, Germany, August 7-12, 2016.

factor, and A2 is just harsh and attacks.[1] We adapt pairwise comparison as our backbone approach.

We propose a novel task of predicting convincingness of arguments in an argument pair, as well as ranking arguments related to a certain topic. Since no data for such a task are available, we create a new annotated corpus. We employ SVM model with rich linguistic features as well as bidirectional Long Short-Term Memory (BLSTM) neural networks because of their excellent performance across various end-to-end NLP tasks (Goodfellow et al., 2016; Piech et al., 2015; Wen et al., 2016; Dyer et al., 2015; Rocktäschel et al., 2016).

Main contributions of this article are (1) large annotated dataset consisting of 16k argument pairs with 56k reasons in natural language (700k tokens), (2) thorough investigation of the annotated data with respect to properties of convincingness as a measure, (3) a SVM model and end-to-end BLSTM model. The annotated data, licensed under CC-BY-SA license, and the experimental code are publicly available at `https://github.com/UKPLab/acl2016-convincing-arguments`. We hope it will foster future research in computational argumentation and beyond.

2 Related Work

Recent years can be seen as a dawn of computational argumentation – an emerging sub-field of NLP in which natural language arguments and argumentation are modeled, searched, analyzed, generated, and evaluated. The main focus has been paid to analyzing argument structures, under the umbrella entitled argumentation mining.

Web discourse as a data source has been exploited in several tasks in argumentation mining, such as classifying propositions in user comments into three classes (verifiable experiential, verifiable non-experiential, and unverifiable) (Park and Cardie, 2014), or mapping argument components to Toulmin's model of argument in user-generated Web discourse (Habernal and Gurevych, 2015), to name a few. While these approaches are crucial for understanding the structure of an argument, they do not directly address any qualitative criteria of argumentation.

Argumentation quality has been an active topic among argumentation scholars. Walton (1989) discusses validity of arguments in informal logic, while Johnson and Blair (2006) elaborate on criteria for practical argument evaluation (namely Relevance, Acceptability, and Sufficiency). Yet, empirical research on argumentation quality does not seem to reflect these criteria and leans toward simplistic evaluation using argument structures, such as how many premises support a claim (Stegmann et al., 2011), or by the complexity of the analyzed argument scheme (Garcia-Mila et al., 2013). To the best of our knowledge, there have been only few attempts in computational argumentation that go deeper than analyzing argument structures (e.g., (Park and Cardie, 2014) mentioned above). Persing and Ng (2015) model argument strength in persuasive essays using a manually annotated corpus of 1,000 documents labeled with a 1–4 score value.

Our newly created corpus of annotated pairs of arguments might resemble recent large-scale corpora for textual inference. Bowman et al. (2015) introduced a 570k sentence pairs written by crowd-workers, the largest corpus to date. Whereas their task is to classify whether the sentence pair represents *entailment*, *contradiction*, or is *neutral* (thus heading towards a deep *semantic* understanding), our goal is to assess the *pragmatical* properties of the given multiple sentence-long arguments (to which extent they fulfill the goal of persuasion). Moreover, each of our annotated argument pairs is accompanied with five textual reasons that explain the rationale behind the labeler's decision. This is, to the best of our knowledge, a unique novel feature of our data.

Pairwise assessment for obtaining relative preference was examined by (Chen et al., 2013), among many others.[2] Their system was tested on ranking documents by their reading difficulty. Relative preference annotations have also been heavily employed in assessing machine translation (Aranberri et al., 2016). By contrast to our work, the underlying relations (reading difficulty 1-12 or better translation) have well known properties of total ordering, while convincingness of arguments is a yet unexplored task, thus no assumptions can be made apriori. There is also a substantial body of work on learning to rank, where also a *pairwise approach* is widely used (Cao et al., 2007). These methods have been traditionally used in IR,

[1] These are actual *reasons* provided by annotators, as will be explained later in Section 3.

[2] See (Shah et al., 2015) for a recent overview.

where the retrieved documents are ranked according to their relevance and pairs of documents are automatically sampled.

Employing LSTM for natural language inference tasks has recently gained popularity (Rocktäschel et al., 2016; Wang and Jiang, 2016; Cheng et al., 2016). These methods are usually tested on the SNLI data introduced above (Bowman et al., 2015).

3 Data annotation

Since assessing convincingness of a single argument directly is a very subjective task with high probability of introducing annotator's bias (because of personal preferences, beliefs, or background), we cast the problem as a relation annotation task. Given two arguments, one should be selected as more convincing, or they might be both equally convincing (see an example in Figure 1).

3.1 Sampling annotation candidates

Sampling large sets of arguments for annotation from the Web poses several challenges. First, we must be sure that the obtained texts are actual arguments. Second, the context of the argument should be known (the prompt and the stance). Finally, we need sources with permissive licenses, which allow us to release the resulting corpus further to the community. These criteria are met by arguments from two *debate portals*.[3]

We will use the following terminology. We use *topic* to refer to a subset of an on-line debate with a given prompt and a certain stance (for example, *"Should physical education be mandatory in schools? – yes"* is considered as a single topic). Each debate has two *topics*, one for each stance. *Argument* is a single comment directly addressing the debate prompt. *Argument pair* is an ordered set of two arguments (*A1* and *A2*) belonging to the same topic; see Figure 1.

We automatically selected debates that contained at least 25 top-level[4] arguments that were 10-110 words long (the mean for all top-level arguments was 66 ± 130 and the median 36, so we excluded the lengthy outliers in our sampling). We manually filtered out obvious silly debates (e.g., *'Superman vs. Batman'*) and ended up with 32 *topics* (the full topic list is presented together with experimental results later in Table 3). From each topic we automatically sampled 25-35 random arguments and created $(n * (n-1)/2)$ *argument pairs* by combining all selected arguments. Sampling argument pairs only from the same topics and not combining opposite stances was a design decision how to mitigate annotators' bias.[5] The order of arguments A1 and A2 in each argument pair was randomly shuffled. In total we sampled 16,927 argument pairs.

3.2 Crowdsourcing annotations

Let us extend our terminology. *Worker* is a single annotator in Amazon Mechanical Turk. *Reason* is an explanation why *A1* is more convincing than *A2* (or the other way round, or why they are equally convincing). *Gold reason* is a reason whose label matches the gold label in the argument pair (see Figure 2).

In the HIT, workers were presented with an argument pair, the prompt, and the stance as in Figure 1. They had to choose either *"A1 is more convincing than A2"* (A1>A2), *"A1 is less convincing than A2"* (A1<A2), or *"A1 and A2 are convincing equally"* (A1=A2). Moreover, they were obliged to write the *reason* 30-140 characters long. An example of fully annotated argument pair is shown in Figure 2. The workers were also provided with clear and crisp instructions (e.g., do not judge the truth of the proposition; be objective; do not express your position; etc.).

All 16,927 argument pairs were annotated by five workers each (85k assignments in total). We also allowed workers to express their own standpoint toward the topics. While 66% of workers had no standpoint, 14% had the opposite view and 20% the same view. This indicates that there should be no systematic bias in the data. Crowdsourcing took about six weeks in 2016 plus two weeks of pilot studies. In total, about 3,900 workers participated. Total costs including pilot studies and bonus payments were 5,520 USD.

3.3 Quality control and agreement

We performed several steps in controlling the quality of the crowdsourced data. First, we allowed only workers from the U.S. with $\geq 96\%$ acceptance rate to work on the task. Second, we employed MACE (Hovy et al., 2013) for estimating

[3] Namely, `createdebate.com` and `procon.org`.

[4] Such arguments directly address the topic and are not a part of a threaded discussion.

[5] As some topics touch the very fundamental human beliefs and values, such as faith, trust, or sexuality, it is hard to put them consciously aside when assessing convincingness.

Argument 1	Argument 2
physical education should be mandatory cuhz 112,000 people have [...]	YES, because some children don't understand anything expect [...]

- A1>A2, *because* A1 uses statistics, and doesn't make assumptions.
- A1>A2, *because* A1 talks about the importance of health.
- A1>A2, *because* A1 provides a health-related argument.
- A1>A2, *because* A2 is very harsh and attacks
- A1=A2, *because* Neither A1 or A2 cite evidence to support their claims.

Figure 2: Example of an *argument pair* annotated by five workers. The arguments are shortened versions of Figure 1. The explanations (called *reasons*) after 'because' are written by workers; the estimated gold label for this pair is probably *A1>A2*, thus there are four *gold reasons*.

the true labels and ranking the annotators. We set the MACE's parameter *threshold* to 0.95 to keep only instances whose entropy is among the 95% best estimates. Third, we manually checked all the *reasons* for each worker. With paying more attention to workers with low MACE scores, we rejected all assignments of workers if they (1) copied&pasted the same or very similar *reasons* across *argument pairs*, (2) were only copying or rephrasing the texts from the arguments, (3) provided their opinion or were arguing, (4) had many typos or provided obvious nonsense. In total, we rejected 1161 assignments.

We do not report any 'standard' inter-annotator agreement measures such as Fleiss' κ or Krippendorff's α, as their suitability for crowdsourcing has been recently disputed (Passonneau and Carpenter, 2014). However, in order to estimate the human performance, we analyzed the output of the pilot study. For each *argument pair*, we took the best-ranked worker for that particular pair (worker ranks are globally estimated by MACE) and computed her accuracy against the estimated gold labels.[6] The best-ranked worker for each argument pair is not necessarily the globally best-ranked worker; in the pilot study, the average global rank of this hypothetical worker was 11 ± 6.6. This rank can be interpreted as a decently performing worker; the obtained score reached 0.935 accuracy.

[6] A similar approach was recently reported by Nakov et al. (2016).

3.4 Examining properties of convincingness

3.4.1 What makes a convincing argument?

We manually examined a small sample of 200 *gold reasons* to find out what makes one argument more convincing than the other. A very common type of answer mentioned **giving examples or actual reasons** (*"A1 cited several reasons to back up their argument."*) and **facts** (*"A1 cites an outside source which can be more credible than opinion"*). This is not surprising, as argumentation is often perceived as reason giving (Freeley and Steinberg, 2008). Others point out strengths in **explaining the reasoning** or **logical coherence** (*"A1 gives a succinct and logical answer to the argument. A2 strays away from the argument in the response."*). The **confirmation bias** (Mercier and Sperber, 2011) also played a role (*"A1 argues both viewpoints, A2 chooses a side."*). Given the noisiness of Web data, some of the arguments might be **non-sense**, which was also pointed out as a reason (*"A1 attempts to argue that since porn exists, we should watch it. A2 doesn't make sense or answer the question."*). Apart from the logical structure of the argument, **emotional aspects** and **rhetorical moves** were also spotted (*"A1 contributes a viewpoint based on morality, which is a stronger argument than A2, which does not argue for anything at all."*, or *"A1 calls for the killing of all politicians, which is an immature knee-jerk reaction to a topic. A2's argument is more intellectually presented."*).

3.4.2 Transitivity evaluation using argument graphs

The previous section shows a variety of reasons that makes one argument more convincing than other arguments. Considering *A1 is more convincing than A2* as a binary relation R, we thus asked the following research question: Is convincingness a measure with total strict order or strict weak order? Namely, is relation R that compares convingcingness of two arguments transitive, antisymmetric, and total?

In particular, does is exhibit properties such that if A$\geq$B and B$\geq$C, then A$\geq$C (total ordering)? We can treat arguments as nodes in a graph and argument pairs as graph edges. We will denote such graph as *argument graph* (and use nodes/arguments and edges/pairs interchangeably in this section).[7] As the sampled argument pairs

[7] Argument pair A>B becomes a directed edge $A \rightarrow B$

contained all argument pair combinations for each topic, we ended up with an almost fully connected argument graph for each topic (remember that we discarded 5% of argument pair annotations with lowest reliability). We further investigate the properties of the argument graphs. Transitivity is only guaranteed, if the argument graph is a DAG (directed acyclic graph).

Building argument graph from crowdsourced argument pairs We build the argument graph iteratively by sampling annotated argument pairs and adding them as graph edges (see Algorithm 1). We consider two possible scenarios in the graph building algorithm. In the first scenario, we accept only argument pairs without equivalency (thus A>B is allowed but A=B is forbidden and discarded). The second scenario accepts all pairs, but since the resulting graph must be DAG, equivalent arguments are merged into one node. We use Johnson's algorithm for finding all elementary cycles in DAG (Johnson, 1975).

Argument pair weights By building argument graph from all pairs, introducing cycles into the graph seems to be inevitable, given a certain amount of noise in the annotations. We asked the following question: to which extent does occurrence of cycles in an argument graph depend on the quality of annotations?

We thus compute a weight for each argument pair. Let e_i be a particular annotation pair (edge). Let G_i be all labels in that pair that match the predicted gold label, and O_i opposite labels (different from the gold label). Let v be a single worker's vote and c_v a global worker's competence score. Then the weight w of edge e_i is computed as follows:

$$w_{e_i} = \sigma\left(\sum_{v \in G_i} c_v - \lambda \sum_{v \in O_i} c_v\right) \qquad (1)$$

where σ is a sigmoid function $\sigma = \frac{1}{1+e^{-x}}$ to squeeze the weight into the $(0, 1)$ interval and λ is a penalty for opposite labels (we set empirically λ to 10.0 to ensure strict penalization). For example, if the predicted gold label from Figure 2 were A1>A2, then G_i would contain four votes and O_i one vote (the last one).

This weight allows us to sort argument pairs before sampling them for building the argument graph. We test three following strategies. As a baseline, we use random shuffling (*Rand*), where no prior information about the weight of the pairs is given. The other two sorting algorithms use the argument pair weight computed by Equation 1. As the worst case scenario, we sort the pairs in ascending order (*Asc*), which means that the "worse" pairs come first to the graph building algorithm. We used this scenario to see how much the prior pair weight information actually matters, because building a graph preferably from bad pair label estimates should cause more harm. Finally, the *Desc* algorithm sorts the pairs given their weight in descending order (the "better" estimates come first).

Algorithm 1: Building DAG from sorted argument pairs.

```
input : argumentPairs; sortingAlg
output: DAG
SortPairs(argumentPairs, sortingAlg);
finalPairs ← [];
foreach pair in argumentPairs do
    currentPairs ← [finalPairs, pair ];
    /* cluster edges labeled as equal so they will be
    treated as a single node */
    clusters ← clusterEqNodes(currentPairs);
    /* wire the pairs into directed graph */
    g ← buildGraph(currentPairs, clusters);
    if hasCycles(g) then
        // report about breaking DAG
    else
        finalPairs += pair;
return buildGraph(finalPairs);
```

Measuring transitivity score We measure how "good" the graph is by a *transitivity score*. Here we assume that the graph is a DAG. Given two nodes A and Z, let P_L be the longest path between these nodes and P_S the shortest path, respectively. For example, let $P_L = A \rightarrow B \rightarrow C \rightarrow Z$ and $P_S = A \rightarrow D \rightarrow Z$. Then the *transitivity score* is the ratio of longest and shortest path $\frac{|P_L|}{|P_S|}$. (which is 1.5 is our example). The *average transitivity score* is then an average of transitivity scores for each pair of nodes from the graph that are connected by two or more paths. Analogically, the *maximum transitivity score* is the maximal value. We restrict the shortest path to be a direct edge only.

The motivation for the *transitivity score* is the following. If the longest path between A and Z ($A \rightarrow \ldots \rightarrow Z$) consists of 10 other nodes, than the total ordering property requires that there also exists a direct edge $A \rightarrow Z$. This is indeed em-

in the argument graph.

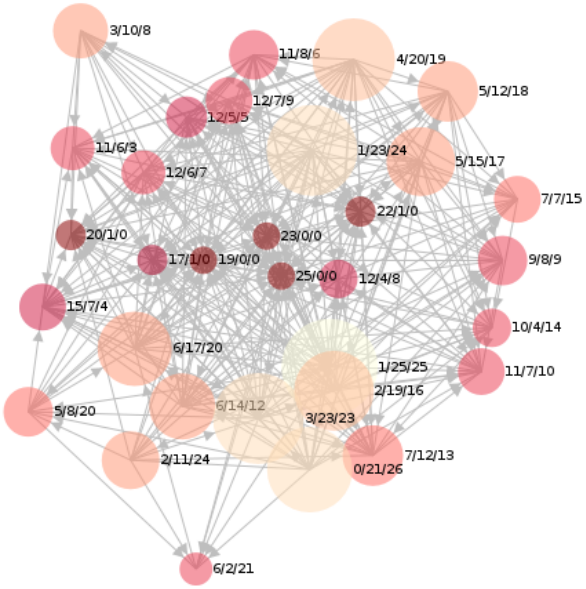

Figure 3: Final argument graph example (topic: *"Christianity or Atheism? Atheism"*). Node labels: *I/O/Tr* (*I*: incoming edges, *O*: outgoing edges, *Tr*: maximum transitivity score). Lighter nodes have prevailing *O*; larger nodes have higher absolute number of *O*.

pirically confirmed by the presence of the shortest path between A and Z. Thus the longer the longest path and the shorter the shortest path are on average, the bigger empirical evidence is given about the transitivity property.

Figure 3 shows an example of argument graph built using only non-equivalent pairs and *desc* prior sort or argument pairs. There are few "bad" arguments in the middle (many incoming edges, none outcoming) and few very convincing arguments (large circles). Notice the high maximum transitivity score even for medium-sized nodes.

Observations First, let us compare the different sorting algorithms for each sampling strategy. As Table 1 shows, on average, 158 pairs are ignored in total when all pairs are used for sampling (26 removed by MACE and 132 by the graph building algorithm), while 164 pairs are ignored when only non-equivalent pairs are sampled (129 had already been removed apriori—26 by MACE and 103 as equivalent pairs—and 35 by the graph algorithm).

The results show a tendency that, when sampling annotated argument pairs for building a DAG, sorting argument pairs by their weight based on workers' scores influences the number of pairs that break the DAG by introducing cycles. In particular, starting with more confident argumentation pairs, the graph grows bigger while keeping its DAG consistency. The presence of the *equal* relation causes cycles to break the DAG sooner as compared to argument pairs in which one argument is more convincing than the other. We interpret this finding as that it is easier for humans to judge A>B than A=B consistently across all possible pairs of arguments from a given topic.

3.4.3 Gold-standard corpora

Our experiments show that convincingness between a pair of arguments exhibits properties of strict total order when the possibility of two equally convincing arguments is prohibited. We thus used the above-mentioned method for graph building as a tool for posterior gold data filtering. We discard the equal argument pairs in advance and filter out argument pairs that break the DAG properties. As a result, a set of 11,650 argument pairs labeled as either A>B or A<B remains, which is summarized in Table 2. We call this corpus *UKPConvArgStrict*.

However, since the total strict ordering property of convincingness is only an empirically confirmed working hypothesis, we also propose another realistic application. We construct a mixed graph by treating equal argument pairs (A=B) as undirected edges. Using PageRank, we rank the arguments (nodes) globally. The higher the PageRank for a particular node is, the "less convincing" the argument is (has a global higher probability of incoming edges). This allows us to rank all arguments for a particular topic. We call this dataset *UKPConvArgRank* (see Table 2).

We also release the full dataset *UKPConvArgAll*. In this data, no global filtering using graph construction methods is applied, only the local pre-filtering using MACE. We believe this dataset can be used as a supporting training data for some tasks that do not rely on the property of total ordering. Along the actual argument texts, all the gold-standard corpora contain the *reasons* as well as full workers' information and debate meta-data.

4 Experiments

We experiment with two machine learning algorithms on two tasks using the two new benchmark corpora (*UKPConvArgStrict* and *UKPConvArgRank*). In both tasks, we perform 32-fold cross-topic cross-validation (one topic is test data, remaining 31 topics are training ones). This rather

		All pairs			No equivalency pairs

	Ignored pairs	162	208	**132**	42	60	**35**

Table 1: Values averaged over all 32 topics reported by different sampling strategies and scenarios for argument graph building.

Dataset	**Size**	**Instance type**	**Size per topic**	**Gold label distribution**			**Gold reasons**	
				a1	a2	eq	**size**	**tokens**
UKPConvArgAll	16,081	argument pair	502.5 ± 91.3	6,398	6,394	3,289	56,446	696,537
UKPConvArgStrict	11,650	argument pair	364.1 ± 71.1	5,872	5,778	0	44,121	547,057
UKPConvArgRank	1,052	argument	32.9 ± 3.2	—			—	

Table 2: Properties of resulting gold data.

challenging setting ensures that no arguments are seen in both training and test data.

4.1 Predicting convincingness of pairs

Since this task is a binary classification and the classes are equally distributed (see Table 2), we report accuracy and average the final score over folds (Forman and Scholz, 2010).

Methods As a "traditional" method, we employ SVM with RBF kernel[8] based on a large set of rich linguistic features. They include **uni- and bi-gram presence**, ratio of **adjective and adverb endings** that may signalize neuroticism (Corney et al., 2002), **contextuality measure** (Heylighen and Dewaele, 2002), **dependency tree depth**, ratio of **exclamation** or **quotation** marks, ratio of **modal verbs**, counts of several **named entity types**, ratio of **past** vs. **future** tense verbs, **POS** n-grams, presence of dependency tree **production rules**, seven different **readability measures** (e.g., *Ari* (Senter and Smith, 1967), *Coleman-Liau* (Coleman and Liau, 1975), *Flesch* (Flesch, 1948), and others), five **sentiment scores** (from very negative to very positive) (Socher et al., 2013), **spell-checking** using standard Unix `words`, ratio of **superlatives**, and some **surface** features such as sentence lengths, longer words count, etc. The resulting feature vector dimension is about 64k.

We also use bidirectional Long Short-Term Memory (BLSTM) neural network for end-to-end processing.[9] The input layer relies on pre-trained word embeddings, in particular *GloVe* (Pennington et al., 2014) trained on 840B tokens from Common Crawl;[10] the embedding weights are further updated during training. The core of the model consists of two bi-directional LSTM networks with 64 output neurons each. Their output is then concatenated into a single drop-out layer and passed to the final sigmoid layer for binary predictions. We train the network with ADAM optimizer (Kingma and Ba, 2015) using binary cross-entropy loss function and regularize by early stopping (5 training epochs) and high drop-out rate (0.5) in the dropout layer. For both models, each training/test instance simply concatenates A1 and A2 from the argument pair.

Results and error analysis As shown in Table 3, SVM (0.78) outperforms BSLTM (0.76) with a subtle but significant difference. It is also apparent that some topics are more challenging regardless of the system (e.g., *"Is it better to have a lousy father or to be fatherless? – Lousy father"*). Both systems outperform a simple baseline (lemma n-gram presence features with SVM, not reported in detail, achieved 0.65 accuracy) but still do not reach the human upper bounds (0.93 as reported in Section 3.3).

Table 3: Accuracy results on *UKPConvArgStrict* data. The difference between **SVM** and bidirectional **LSTM** is significant, $p = 0.0414$ using two-tailed Wilcoxon signed-rank test.

We examined about fifty random false predictions to gain some insight into the limitations of both systems. We looked into argument pairs, in which both methods failed, as well as into instances where only one model was correct. BLSTM won in few cases by properly catching jokes or off-topic arguments; SVM was properly catching all-upper-case arguments (considered as less convincing). By examining failures common to both systems, we found several cases where the prediction was wrong due to very negative sentiment (which might be a sign of the less convincing argument), but in other cases an argument with strong negative sentiment was actually the more convincing one. In general, we did not find any tendency on failures; they were also independent of the worker assignments distribution, thus not caused by likely ambiguous (hard) instances.

	SVM	BLSTM	p-value
Pearson's r	.351	.270	$\ll 0.01$
Spearman's ρ	.402	.354	$\ll 0.01$

Table 4: Correlation results on *UKPConvArgRank*.

4.2 Ranking arguments

We address this problem as a regression task. We use the *UKPConvArgRank* data, in which a real-value score is assigned to each argument so the arguments can be ranked by their convincingness (for each topic independently). The task is thus to predict a real-value score for each argument from the test topic (remember that we use 32-fold cross validation). We measure Spearman's and Pearson's correlation coefficients on all results combined (not on each fold separately).

Without any modifications, we use the same SVM and features as described in Section 4.1. Regarding the BLSTM, we only replace the output layer with a linear activation function and optimize mean absolute error loss. Table 4 shows that SVM outperforms BLSTM. All correlations are highly statistically significant.

4.3 Results discussion

Although the "traditional" SVM with rich linguistic features outperforms BLSTM in both tasks, there are other aspects to be considered. First, the employed features require heavy language-specific preprocessing machinery (lemmatizer, POS tagger, parser, NER, sentiment analyzer). By contrast, BLSTM only requires pre-trained embedding vectors, while delivering comparable results. Second, we only experimented with vanilla LSTMs. Recent developments of deep neural networks (especially attention mechanisms or grid-LSTMs) open up many future possibilities to gain performance in this end-to-end task.

5 Conclusion and future work

We propose a novel task of predicting Web argument convincingness. We crowdsourced a large corpus of 16k argument pairs over 32 topics and used global constraints based on transitivity properties of convincingness relation for cleaning the data. We experimented with feature-rich SVM and bidirectional LSTM and obtain 0.76-0.78 accuracy and 0.35-0.40 Spearman's correlation in a cross-topic scenario. We release the newly created corpus *UKPConvArg1* and the experimental software

under free licenses.[11] To the best of our knowledge, we are the first who deal with argument convincingness in Web data on such a large scale.

In the current article, we have only slightly touched the annotated natural text *reasons*. We believe that the presence of 44k reasons (550k tokens) is another important asset of the newly created corpus, which deserves future investigation.

Abstract

An extensive literature in computational social science examines how features of messages, advertisements, and other corpora affect individuals' decisions, but these analyses must specify the relevant features of the text before the experiment. Automated text analysis methods are able to discover features of text, but these methods cannot be used to obtain the estimates of causal effects—the quantity of interest for applied researchers. We introduce a new experimental design and statistical model to simultaneously discover treatments in a corpora and estimate causal effects for these discovered treatments. We prove the conditions to identify the treatment effects of texts and introduce the supervised Indian Buffet process to discover those treatments. Our method enables us to discover treatments in a training set using a collection of texts and individuals' responses to those texts, and then estimate the effects of these interventions in a test set of new texts and survey respondents. We apply the model to an experiment about candidate biographies, recovering intuitive features of voters' decisions and revealing a penalty for lawyers and a bonus for military service.

1 Introduction

Computational social scientists are often interested in inferring how blocks of text, such as messages from political candidates or advertising content, affect individuals' decisions (Ansolabehere and Iyengar, 1995; Mutz, 2011; Tomz and Weeks, 2013). To do so, they typically attempt to estimate the causal effect of the text: they model the outcome of interest, Y, as a function of the block of text presented to the respondent, t, and define the treatment effect of t relative to some other block of text t' as $Y(t) - Y(t')$ (Rubin, 1974; Holland, 1986). For example, in industrial contexts researchers design A/B tests to compare two potential texts for a use case. Academic researchers often design one text that has a feature of interest and another text that lacks that feature but is otherwise identical (for example, (Albertson and Gadarian, 2015)). Both kinds of experiments assume researchers already know the features of text to vary and offer little help to researchers who would like to discover the features to vary.

Topic models and related methods can discover important features in corpora of text data, but they are constructed in a way that makes it difficult to use the discovered features to estimate causal effects (Blei et al., 2003). Consider, for example, supervised latent Dirichlet allocation (sLDA) (Mcauliffe and Blei, 2007). It associates a topic-prevalence vector, $\boldsymbol{\theta}$, with each document where the estimated topics depend upon both the content of documents and a label associated with each document. If K topics are included in the model, then $\boldsymbol{\theta}$ is defined on the $K-1$-dimensional unit simplex. It is straightforward to define a treatment effect as the difference between two treatments $\boldsymbol{\theta}$ and $\boldsymbol{\theta}'$ (or points on the simplex) $Y(\boldsymbol{\theta}) - Y(\boldsymbol{\theta}')$. It is less clear how to define the *marginal* effect of any one dimension. This is because bigger values on some dimensions implies smaller values on other dimensions, making the effect of any one topic necessarily a combination of the differences obtained when averaging across all the dimensions (Aitchison, 1986; Katz and King, 1999). This problem will befall all topic models because the zero-sum nature of the topic-prevalence vector implies that increasing the prevalence of any one topic necessarily decreases the prevalence of some

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1600–1609,
Berlin, Germany, August 7-12, 2016.

other topic. The result is that it is difficult (or impossible) to interpret the effect of any one topic marginalizing over the other topics. Other applications of topic models to estimate causal effects treat text as the response, rather than the treatment (Roberts et al., 2016). And still other methods require a difficult to interpret assumption of how text might affect individuals' responses (Beauchamp, 2011).

To facilitate the discovery of treatments and to address the limitation of existing unsupervised learning methods, we introduce a new experimental design, framework, and statistical model for discovering treatments within blocks of text and then reliably inferring the effects of those treatments. By doing so, we combine the utility of discovering important features in a topic model with the scientific value of causal treatment effects estimated in a potential outcomes framework. We present a new statistical model—the supervised Indian Buffet Process—to both discover treatments in a training set and infer the effects treatments in a test set (Ghahramani and Griffiths, 2005). We prove that randomly assigning blocks of text to respondents in an experiment is sufficient to identify the effects of latent treatments that comprise blocks of text.

Our framework provides the first of its kind approach to automatically discover treatment effects in text, building on literatures in both social science and machine learning (Blei et al., 2003; Beauchamp, 2011; Mcauliffe and Blei, 2007; Roberts et al., 2016). The use of the training and test set ensures that this discovery does not come at the expense of credibly inferring causal effects, insulating the research design from concerns about "p-hacking" and overfitting (Ioannidis, 2005; Humphreys et al., 2013; Franco et al., 2014). Critically, we use a theoretical justification for our methodology: we select our particular approach because it enables us to estimate causal effect of interest. Rather than demonstrating that our method performs better at some predictive task, we prove that our method is able to estimate useful causal effects from the data.

We apply our framework to study how features of a political candidate's background affect voters' decisions. We use a collection of candidate biographies collected from Wikipedia to automatically discover treatments in the biographies and then infer their effects. This reveals a penalty for lawyers and career politicians and a bonus for military service and advanced degrees. While we describe our procedure throughout the paper, we summarize our experimental protocol and strategy for discovering treatment effects in Table 1.

Table 1: Experimental Protocol for Discovering and Estimating Treatment Effects

1) Randomly assign texts, $\boldsymbol{X}_j$, to respondents
2) Obtain response Y_i for each respondent.
3) Divide texts and responses into training and test set
4) In training set:
    a) Use supervised Indian Buffet Process (sIBP) applied to documents and responses to infer latent treatments in texts
    b) Model selection via quantitative fit and qualitative assessment
5) In test set:
    a) Use sIBP trained on training set to infer latent treatments on test set documents
    b) Estimate effect of treatments with regression, with a bootstrap procedure to estimate uncertainty

2 A Framework for Discovering Treatments from Text

Our goal is to discover a set of features—treatments—underlying texts and then estimate the effect of those treatments on some response from an individual. We first show that randomly assigning texts to respondents is sufficient to identify treatment effects. We then provide a statistical model for using both the text and responses to discover latent features in the text that affect the response. Finally, we show that we can use the mapping from text to features discovered on a training set to estimate the presence of features in a test set, which allows us to estimate treatment effects in the test set.

2.1 Randomizing Texts Identifies Underlying Treatment Effects

When estimating treatment effects, researchers often worry that the respondents who received one treatment systematically differ from those who received some other treatment. In a study of advertising, if all of the people who saw one advertisement were men and all of the people who saw a different advertisement were women, it would be impossible to tell whether differences in their responses were driven by the fact that they saw different advertisements or by their pre-existing differences. Randomized experiments are the gold standard for overcoming this problem (Gerber and Green, 2012). However, in text experiments, individuals are randomly assigned to blocks of text rather than to the latent features of the text that we analyze as the treatments. In this section, we show that randomly assigning blocks of text is sufficient to identify treatment effects.

To establish our result, we suppose we have a corpora of J texts, $\mathcal{X}$. We represent a specific text with $\boldsymbol{X}_j \in \mathcal{X}$, with $\boldsymbol{X}_j \in \Re^D$. Throughout we will assume that we have standardized the variable $\boldsymbol{X}_j$ to be a per-document word usage rate with each column normalized to have mean zero and variance one. We have a sample of N respondents from a population, with the response of individual i to text $j[i]$ given by the potential outcome $Y_i(\boldsymbol{X}_{j[i]})$. We use the notation $j[i]$ because multiple individuals may be assigned to the same text; if i and i' are assigned to the same text, then $j[i] = j[i']$. We suppose that for each document j there is a corresponding vector of K binary treatments $\boldsymbol{Z}_j \in \mathcal{Z}$ where $\mathcal{Z}$ contains all 2^K possible combinations of treatments, $\{0,1\}^K$. The function $g : \mathcal{X} \rightarrow \mathcal{Z}$ maps from the texts to the set of binary treatments: we will learn this function using the supervised Indian Buffet process introduced in the next section. Note that distinct elements of $\mathcal{X}$ may map to the same element of $\boldsymbol{Z}$.

To establish our identification result, we assume (Assumption 1) $Y_i(\boldsymbol{X}) = Y_i(\boldsymbol{X}_{j[i]})$ for all i. This assumption ensures that each respondent's treatment assignment depends only on her assigned text, a version of the Stable Unit Treatment Value Assumption (SUTVA) for our application (Rubin, 1986). We also assume (Assumption 2) that $Y_i(\boldsymbol{X}_{j[i]}) = Y_i(g(\boldsymbol{X}_{j[i]}))$ for all $\boldsymbol{X}_{j[i]} \in \mathcal{X}$ and all i, or that $\boldsymbol{Z}_{j[i]}$ is sufficent to describe the effect of a document on individual i's response. Stated differently, we assume an individual would respond in the same way to two different texts if those texts have the same latent features. We further suppose (Assumption 3) that texts are randomly assigned to respondents according to probability measure h, ensuring that $Y_i(g(\boldsymbol{X}_{j[i]})) \perp\!\!\!\perp \boldsymbol{X}_{j[i]}$ for all $\boldsymbol{X}_{j[i]} \in \mathcal{X}$ and for all individuals i. This assumption ensures unobserved characteristics of individuals are not confounding inferences about the effects of texts. The random assignment of texts to individuals induces a distribution over a probability measure on treatment vectors $\boldsymbol{Z}$, $f(\boldsymbol{Z}) = \int_{\mathcal{X}} 1(\boldsymbol{Z} = g(\boldsymbol{X}))h(\boldsymbol{X})d\boldsymbol{X}$. Finally, we assume (Assumption 4) that $f(\boldsymbol{Z}) > 0$ for all $\boldsymbol{Z} \in \mathcal{Z}$.[1] This requires that every combination of treatment effects is possible from the documents in our corpus. In practice, when designing our study we want to ensure that the treatments are not *aliased* or perfectly correlated. If perfect correlation exists between factors, we are unable to disentangle the effect of individual factors.

In this paper we focus on estimating the Average Marginal Component Specific Effect for factor k (AMCE$_k$) (Hainmueller et al., 2014).[2] The AMCE$_k$ is useful for finding the effect of one feature, k, when k interacts with the other features in some potentially complicated way. It is defined as the difference in outcomes when the feature is present and when it is not present, averaged over the values of all of the other features. Formally, $\text{AMCE}_k = \int_{\boldsymbol{Z}_{-k}} \mathbb{E}\left[Y(Z_k = 1, \boldsymbol{Z}_{-k}) - Y(Z_k = 0, \boldsymbol{Z}_{-k})\right] m(\boldsymbol{Z}_{-k}) d\boldsymbol{Z}_{-k}$ where $m(\boldsymbol{Z}_{-k})$ is some analyst-defined density on all elements but k of the treatment vector. For example, $m(\cdot)$ can be chosen as the density of Z_{-k} in the population to obtain the marginal component effect of k in the empirical population. The most commonly used $m(\cdot)$ in applied work is uniform across all Z_{-k}'s, and we follow this convention here.

We now prove that assumptions 1, 2, 3, and 4 are sufficient to identify the AMCE$_k$ for all k.

Proposition 1. *Assumptions 1, 2, 3, and 4 are suf-*

[1] Note for this assumption to hold it is necessary, but not sufficient that g is a surjection from $\mathcal{X}$ onto $\mathcal{Z}$.

[2] The procedure here can be understood as a method for discovering the treatments that are imposed by assumption in conjoint analysis, as presented by (Hainmueller et al., 2014). We deploy the regression estimator used in conjoint analysis as a subroutine of our procedure (see Step 5b in Table 1), but otherwise our experimental design, statistical method, and proof is distinct.

ficient to identify the AMCE$_k$ for arbitrary k.

Proof. To obtain a useful form, we first marginalize over the documents to obtain, $\int_{\boldsymbol{Z}_{-k}} \int_{\mathcal{X}} \mathbb{E}\left[Y(Z_k = 1, \boldsymbol{Z}_{-k})\right] f(\boldsymbol{Z}_{-k}|Z_k = 1, \boldsymbol{X}) - \mathbb{E}\left[Y(Z_k = 0, \boldsymbol{Z}_{-k})\right] f(\boldsymbol{Z}_{-k}|Z_k = 0, \boldsymbol{X}) h(\boldsymbol{X}) d\boldsymbol{X} d\boldsymbol{Z}_{-k} =$

$$\int_{\boldsymbol{Z}_{-k}} \mathbb{E}\left[Y(Z_k = 1, \boldsymbol{Z}_{-k})\right] f(\boldsymbol{Z}_{-k}|Z_k = 1) - \mathbb{E}\left[Y(Z_k = 0, \boldsymbol{Z}_{-k})\right] f(\boldsymbol{Z}_{-k}|Z_k = 0) d\boldsymbol{Z}_{-k}$$

.

Where $f(\boldsymbol{Z}_{-k}|Z_k = 1)$ and $f(\boldsymbol{Z}_{-k}|Z_k = 0)$ are the induced distributions over latent features from averaging over documents. If $f(\boldsymbol{Z}_{-k}|Z_k = 0) = f(\boldsymbol{Z}_{-k}|Z_k = 1) = m(\boldsymbol{Z}_{-k})$ then this is the AMCE$_k$. Otherwise consider $m(\boldsymbol{Z}) > 0$ for all $\boldsymbol{Z} \in \mathcal{Z}$. Because $f(\boldsymbol{Z}) > 0$, $f(\boldsymbol{Z}_{-k}|Z_k = 0) > 0$ and $f(\boldsymbol{Z}_{-k}|Z_k = 1) > 0$. Thus, there exists conditional densities $h(\boldsymbol{Z}|Z_k = 1)$ and $h(\boldsymbol{Z}|Z_k = 0)$ such that $\frac{f(\boldsymbol{Z}_{-k}|Z_k=1)}{h(\boldsymbol{Z}_{-k}|Z_k=1)} = \frac{f(\boldsymbol{Z}_{-k}|Z_k=0)}{h(Z_{-k}|Z_k=0)} = m(\boldsymbol{Z}_{-k})$ □

2.2 A Statistical Model for Identifying Features

The preceding section shows that if we are able to discover features in the data, we can estimate their AMCEs by randomly assigning texts to respondents. We now present a statistical model for discovering those features. As we argued in the introduction, it is difficult to use the topics obtained from topic models like sLDA because the topic vector exists on the simplex. When we compare the outcomes associated with two different topic vectors, we do not know whether the change in the response is caused by increasing the degree to which the document about one topic or decreasing the degree to which it is about another, because the former mathematically entails the latter. Other models, such as LASSO regression, would necessarily suppose that the presence and absence of words are the treatments (Hastie et al., 2001; Beauchamp, 2011). This is problematic substantively, because it is hard to know exactly what the presence or absence of a single word implies as a treatment in text.

We therefore develop the supervised Indian Buffet Process (sIBP) to discover features in the document. For our purposes, the sIBP has two essential properties. First, it produces a binary topic vector, avoiding the complications of treatments assigned on the simplex. Second, unlike the Indian Buffet Process upon which it builds (Ghahramani and Griffiths, 2005), it incorporates information about the outcome associated with various texts, and therefore discovers features that explain both the text and the response.[3]

Figure 1 describes the posterior distribution for the sIBP and a summary of the posterior is given in Equation 1. We describe the model in three steps: the treatment assignment process, document creation, and response. The result is a model that creates a link between document content and response through a vector of treatment assignments.

Treatment Assignment We assume that $\boldsymbol{\pi}$ is a K-vector (where we take the limit as $K \to \infty$) where π_k describes the population proportion of documents that contain latent feature k. We suppose that $\boldsymbol{\pi}$ is generated by the stick-breaking construction (Doshi-Velez et al., 2009). Specifically, we suppose that $\eta_k \sim \text{Beta}(\alpha, 1)$ for all K. We label $\pi_1 = \eta_1$ and for each remaining topic, we assume that $\pi_k = \prod_{z=1}^{k} \eta_z$. For document j and topic k, we suppose that $z_{j,k} \sim \text{Bernoulli}(\pi_k)$, which importantly implies that the occurrence of treatments are not zero sum. We collect the treatment vector for document j into $\boldsymbol{Z}_j$ and collect all the treatment vectors into $\mathbf{Z}$ an $N_{\text{texts}} \times K$ binary matrix, where N_{texts} refers to number of unique documents. Throughout we will assume that $N_{\text{texts}} = N$ or that the number of documents and responses are equal and index the documents with i.

Document Creation We suppose that the documents are created as a combination of latent factors. For topic k we suppose that $\boldsymbol{A}_k$ is a $D-$dimensional vector that maps latent features onto observed text. We collect the vectors into $\boldsymbol{A}$, a $K \times D$ matrix, and suppose that $\boldsymbol{X}_i \sim \text{MVN}(\boldsymbol{Z}_i \boldsymbol{A}, \sigma_n^2 I_D)$, where $X_{i,d}$ is the standardized number of times word d appears in document i. While it is common to model texts as draws from multinomial distributions, the multi-

[3] We note that there is a different model also called the supervised Indian Buffet Process (Quadrianto et al., 2013). There are fundamental differences between the model presented here and the sIBP in (Quadrianto et al., 2013). Their outcome is a preference relation tuple, while ours is a real-valued scalar. Because of this difference, the two models are fundamentally different. This leads to a distinct data generating process, model inference procedures, and inferences of features on the test set. To leverage the analogy between LDA and sLDA vis a vis IBP and sIBP, we overload the term sIBP in our paper. We expect that in future applications of sIBP, it will be clear from the context which sIBP is being employed.

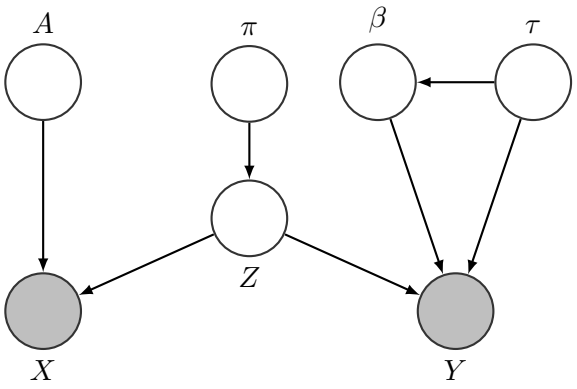

Figure 1: Graphical Model for the Supervised Indian Buffet Process

variate normal distribution is useful for our purposes for two reasons. First, we normalize our data by transforming each column $\boldsymbol{X}_{\cdot,d}$ to be mean 0 and variance 1, ensuring that the multivariate normal distribution captures the overall contours of the data. Note that this implies that $X_{i,d}$ can be negative. Second, we show that assuming a multivariate normal for document generation results in parameters that capture the distinctive rate words are used for each latent feature (Doshi-Velez et al., 2009).

Response to Treatment Vector We assume that a $K-$vector of parameters $\boldsymbol{\beta}$ describes the relationship between the treatment vector and response. Specifically, we use a standard parameterization and suppose that $\tau \sim \text{Gamma}(a, b)$, $\boldsymbol{\beta} \sim \text{MVN}(0, \tau^{-1})$ and that $Y_i \sim \text{Normal}(\boldsymbol{Z}_i\boldsymbol{\beta}, \tau^{-1})$.

$$\begin{aligned}
\pi_k &\sim \text{Stick-Breaking}\,(\alpha) \\
z_{i,k} &\sim \text{Bernoulli}(\pi_k) \\
\mathbf{X}_i|\mathbf{Z}_i, \mathbf{A} &\sim \text{MVN}(\mathbf{Z}_i\mathbf{A}, \sigma_X^2 I_D) \\
\mathbf{A}_k &\sim \text{MVN}(\mathbf{0}, \sigma_A^2 I_D) \\
\mathbf{Y}_i|\mathbf{Z}_i, \boldsymbol{\beta} &\sim \text{Normal}(\mathbf{Z}_i\boldsymbol{\beta}, \tau^{-1}) \\
\tau &\sim \text{Gamma}(a, b) \\
\boldsymbol{\beta}|\tau &\sim \text{MVN}(\mathbf{0}, \tau^{-1} I_K) \qquad (1)
\end{aligned}$$

2.2.1 Inference for the Supervised Indian Buffet Process

We approximate the posterior distribution with a variational approximation, building on the algorithm introduced in (Doshi-Velez et al., 2009). We approximate the non-parametric posterior setting K to be large and use a factorized approximation, assuming that $p(\boldsymbol{\pi}, \boldsymbol{Z}, \boldsymbol{A}, \boldsymbol{\beta}, \tau|\boldsymbol{X}, \boldsymbol{Y}, \alpha, \sigma_A^2, \sigma_X^2, a, b) = q(\boldsymbol{\pi})q(\boldsymbol{A})q(\boldsymbol{Z})q(\boldsymbol{\beta}, \tau)$

A standard derivation that builds on (Doshi-Velez et al., 2009) leads to the following distributional forms and update steps:

- $q(\pi_K) = \text{Beta}(\pi_k|\boldsymbol{\lambda}_k)$. The update values are $\lambda_{k,1} = \frac{\alpha}{K} + \sum_{i=1}^N \nu_{i,k}$ and $\lambda_{k,2} = 1 + \sum_{i=1}^N (1 - \nu_{i,k})$.
- $q(\boldsymbol{A}_k) = \text{Multivariate Normal}(\boldsymbol{A}_k|\bar{\boldsymbol{\phi}}_k, \boldsymbol{\Phi}_k)$. The updated parameter values are,

  $$\bar{\phi}_k = \left[\frac{1}{\sigma_X^2}\sum_{i=1}^N \nu_{i,k}\left(\mathbf{X}_i - \left(\sum_{l:l\neq k}\nu_{i,l}\bar{\phi}_l\right)\right)\right]\boldsymbol{\Phi}_k$$

  $$\boldsymbol{\Phi}_k = \left(\frac{1}{\sigma_A^2} + \frac{\sum_{i=1}^N \nu_{i,k}}{\sigma_X^2}\right)^{-1} I$$

- $q(\boldsymbol{\beta}, \boldsymbol{\tau}) = \text{Multivariate Normal}(\boldsymbol{\beta}|\boldsymbol{m}, \boldsymbol{S}) \times \text{Gamma}(\tau|c, d)$. The updated parameter values are,

  $$\begin{aligned}
  \boldsymbol{m} &= \mathbf{S}\mathbb{E}[\mathbf{Z}^T]\mathbf{Y} \\
  \boldsymbol{S} &= (\mathbb{E}[\mathbf{Z}^T\mathbf{Z}] + I_K)^{-1} \\
  c &= a + \frac{N}{2} \\
  d &= b + \frac{\mathbf{Y}^T\mathbf{Y} - \mathbf{Y}^T\mathbb{E}[\mathbf{Z}]\mathbf{S}\mathbb{E}[\mathbf{Z}^T]\mathbf{Y}}{2}
  \end{aligned}$$

  Where typical element of $\mathbb{E}[\boldsymbol{Z}^T]_{j,k} = \nu_{j,k}$ and typical on-diagonal element of $\mathbb{E}[\boldsymbol{Z}^T\boldsymbol{Z}]_{k,k} = \sum_{i=1}^N \nu_{i,k}$ and off-diagonal element is $\mathbb{E}[\boldsymbol{Z}^T\boldsymbol{Z}]_{j,k} = \sum_{i=1}^N \nu_{i,j}\nu_{i,k}$.
- $q(z_{i,k}) = \text{Bernoulli}(z_{i,k}|\nu_{i,k})$. The updated parameter values are
  $v_{i,k} = \psi(\lambda_{k,1}) - \psi(\lambda_{k,2}) - \frac{1}{2\sigma_X^2}[-2\bar{\phi}_k\mathbf{X}_i^T$
  $+(\text{tr}(\boldsymbol{\Phi}_k) + \bar{\phi}_k\bar{\phi}_k^T) + 2\bar{\phi}_k\left(\sum_{l:l\neq k}\nu_{i,l}\bar{\phi}_l^T\right)]$
  $-\frac{c}{2d}(-2m_kY_i + \left(\frac{dS_{k,k}}{c-1} + m_k^Tm_k\right) +$
  $2m_k\left(\sum_{l:l\neq k}\nu_{i,l}m_l\right))$
  $\nu_{i,k} = \frac{1}{1+\exp(-v_{i,k})}$
  where $\psi(\cdot)$ is the digamma function. We repeat the algorithm until the change in the parameter vector drops below a threshold.

To select the final model using the training set data, we perform a two-dimensional line search over values of α and σ_X.[4] We then run the model

[4]We assign σ_A, a, and b values which lead to diffuse priors.

several times for each combination of values for α and σ_X to evaluate the output at several different local modes. To create a candidate set of models, we use a quantitative measure that balances coherence and exclusivity (Mimno et al., 2011; Roberts et al., 2014). Let $\mathcal{I}_k$ be the set of documents for which $\nu_{i,k} \geq 0.5$, and let $\mathcal{I}_k^C$ be the complement of this set. We identify the top ten words for intervention k as the ten words with the largest value in $\boldsymbol{A}_k$, $\boldsymbol{t}_k$ and define $N_k = \sum_{i=1}^{N} I\{\nu_{i,k} \geq 0.5\}$. We then obtain measure CE for a particular model $\text{CE} = \sum_{k=1}^{K} N_k \sum_{l,c \in t_k} \text{cov}(\boldsymbol{X}_{\mathcal{I}_k,l}, \boldsymbol{X}_{\mathcal{I}_k,c}) - \sum_{k=1}^{K} (N - N_k) \sum_{l,c \in t_k} \text{cov}(\boldsymbol{X}_{\mathcal{I}_k^C,l}, \boldsymbol{X}_{\mathcal{I}_k^C,c})$ where here $X_{\mathcal{I}_k,l}$ refers to the l^{th} column and $\mathcal{I}_k$th rows of $\boldsymbol{X}$. We make a final model selection based on the model that provides the most substantively clear treatments.

2.3 Inferring Treatments and Estimating Effects in Test Set

To discover the treatment effects, we first suppose that we have randomly assigned a set of respondents a text based treatment $\boldsymbol{X}_i$ according to some probability measure $h(\cdot)$ and that we have observed their response Y_i. We collect the assigned texts into $\boldsymbol{X}$ and the responses into $\boldsymbol{Y}$. As we describe below, we will often assign each respondent their own distinctive message, with the probability of receiving any one message at $\frac{1}{N}$ for all respondents and messages. We use the sIBP model trained our training set documents and responses to infer the effect of those treatments among the test set documents. Separating the documents and responses into training and test sets ensures that Assumption 1, SUTVA, holds. We learn the mapping from texts to binary vectors in the training set, $\hat{g}(\cdot)$ and then apply this mapping to the test set to infer the latent treatments present in the test set documents, without considering the test set responses. Dividing texts and responses into training and test sets provides a solution to SUTVA violations present in other attempts at causal inference in text analysis (Roberts et al., 2014).

We approximate the posterior distribution for the treatment vectors using the variational approximation from the training set parameters $(\widehat{\boldsymbol{\lambda}}, \widehat{\bar{\boldsymbol{\phi}}}, \widehat{\boldsymbol{\Phi}}, \widehat{\boldsymbol{m}}, \widehat{\boldsymbol{S}}, \widehat{c}, \widehat{d}, \widehat{\sigma_X^2}, \widehat{\sigma_A^2})$ and a modified update step on $q(z_{i,k}^{\text{test}})$. In this modified update step, we remove the component of the update that incorporates information about the outcome. Specifically for individual i in the test set for category k we have the following update step $v_{i,k}^{\text{test}} = \psi(\widehat{\lambda_{k,1}}) - \psi(\widehat{\lambda_{k,2}}) - \frac{1}{2(\widehat{\sigma_X^2})} \times [-2\widehat{\bar{\phi}_k}(\mathbf{X}_i^T) + (tr(\widehat{\boldsymbol{\Phi}_k}) + \widehat{\bar{\phi}_k}(\widehat{\bar{\phi}_k})^T) + 2\widehat{\bar{\phi}_k}\left(\sum_{l:l \neq k} \nu_{i,l} \left(\widehat{\bar{\phi}_l}^T\right)\right)]$
$\nu_{i,k}^{\text{test}} = \frac{1}{1+\exp(-v_{i,k}^{\text{test}})}$.
For each text in the test set we repeat this update several times until $\boldsymbol{\nu}^{\text{test}}$ has converged. Note that for the test set we have excluded the component of the model that links the latent features to the response, ensuring that SUTVA holds.

With the approximating distribution $q(\boldsymbol{Z}^{\text{test}})$ we then measure the effect of the treatments in the test set. Using the treatments, the most straightforward model to estimate assumes that there are no interactions between each of the components. Under the no interactions assumption, we estimate the effects of the treatments and infer confidence intervals using the following bootstrapping procedure that incorporates uncertainty both from estimation of treatments and uncertainty about the effects of those treatments:

1) For each respondent i and component k we draw $\tilde{z}_{i,k} \sim \text{Bernoulli}(\nu_{i,k}^{\text{test}})$, resulting in matrix $\tilde{\boldsymbol{Z}}$.

2) Given the matrix $\tilde{\boldsymbol{Z}}$, we sample $(\boldsymbol{Y}^{\text{test}}, \tilde{\boldsymbol{Z}})$ with replacement and for each sample estimate the regression $\boldsymbol{Y}^{\text{test}} = \boldsymbol{\beta}^{\text{test}} \tilde{\boldsymbol{Z}} + \boldsymbol{\epsilon}$.

We repeat the bootstrap steps 1000 times, keeping $\boldsymbol{\beta}^{\text{test}}$ for each iteration. The result of the procedure is a point estimate of the effects and confidence interval of the treatments under no interactions. Technically, it is possible to estimate the treatment effects in our variational approximation. But we estimate the effects in a second-stage regression because variational approximations tend to understate uncertainty, the bootstrap provides a straightforward method for including uncertainty from estimation of the latent features and the effect estimates, and it ensures that SUTVA is not violated.

3 Application: Voter Evaluations of an Ideal Candidate

We demonstrate our method in an experiment to assess how features of a candidate's background affect respondents evaluations of the candidates. There is a rich literature in political science about

the ideal attributes of political candidates (Canon, 1990; Popkin, 1994; Carnes, 2012; Campbell and Cowley, 2014). We build on this literature and use a collection of candidate biographies to discover features of candidates' backgrounds that voters find appealing. To uncover the features of candidate biographies that voters are responsive to we acquired a collection of 1,246 Congressional candidate biographies from Wikipedia. We then anonymize the biographies—replacing names and removing other identifiable information—to ensure that the only information available to the respondent was explicitly present in the text.

In Section 2.1 we show that a necessary condition for this experiment to uncover latent treatments is that each vector of treatments has nonzero probability of occuring. This is equivalent to assuming that none of the treatments are *aliased*, or perfectly correlated (Hainmueller et al., 2014). Aliasing would be more likely if there are only a few distinct texts that are provided to participants in our experiment. Therefore, we assign each respondent in each evaluation round a distinct candidate biography. To bolster our statistical power, we ask our respondents to evaluate up to four distinct candidate biographies, resulting in each respondent evaluating 2.8 biographies on average.[5] After presenting the respondents with a candidate's biography, we ask each respondent to rate the candidate using a *feeling thermometer*: a well-established social science scale that goes from 0 when a respodent is "cold" to a candidate to 100 when a respondent is "warm" to the candidate.

We recruited a sample of 1,886 participants using Survey Sampling International (SSI), an online survey platform. Our sample is census matched to reflect US demographics on sex, age, race, and education. Using the sample we obtain 5,303 total observations. We assign 2,651 responses to the training set and 2,652 to the test set. We then apply the sIBP process to the training data. To apply the model, we standardize the feeling thermometer to have mean zero and standard deviation 1. We set K to a relatively low value ($K = 10$) reflecting a quantitative and qualitative search over K. We then select the final model varying the parameters and evaluating the CE score.

Table 2 provides the top words for each of the ten treatments the sIBP discovered in the training set. We selected ten treatments using a combination of guidance from the sIBP, assessment using CE scores, and our own qualitative assessment of the models (Grimmer and Stewart, 2013). While it is true that our final selection depends on human input, some reliance on human judgment at this stage is appropriate. If one set includes a treatment about military service but not legal training and another set includes a treatment about legal training but not military service, then model selection is tantamount to deciding which hypotheses are most worthy of investigation. Our CE scores identify sets of treatments that are most likely to be interesting, but the human analyst should make the final decision about which hypotheses he would like to test. However, it is extremely important for the analyst to select a set of treatments first and only afterwards estimate the effects of those treatments. If the analyst observes the effects of some treatments and then decides he would like to test other sets, then the integrity of any p-values he might calculate are undermined by the multiple testing problem. A key feature of our procedure is that it draws a clear line between the selection of hypotheses to test (which leverages human judgment) and the estimation of effects (which is purely mechanical).

The estimated treatments cover salient features of Congressional biographies from the time period that we analyze. For example, treatments 6 and 10 capture a candidate's military experience. Treatment 5 and 7 are about previous political experience and Treatment 3 and 9 refer to a candidate's education experience. Clearly, there are many features of a candidate's background missing, but the treatments discovered provide a useful set of dimensions to assess how voters respond to a candidate's background. Further, the discovered treatments are a combination of those that are both prevalent in the biographies and have an effect on the thermometer rating. The absence of biographical features that we might think matters for candidate evaluation could be because there are few of those biographies in our data set, or because the respondents were unresponive to those features.

After training the model on the training set, we apply it to the test set to infer the treatments in the biographies. We assume there are no interactions

[5]The multiple evaluations of candidate biographies is problematic if there is spillover across rounds of our experiment. We have little reason to believe observing one candidate biography would systematically affect the response in subsequent rounds.

Table 2: Top Words for 10 Treatments sIBP Discovered

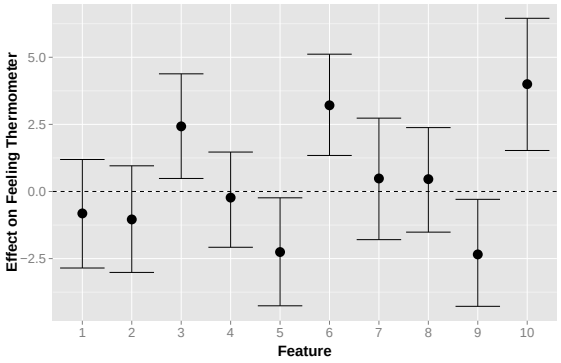

Figure 2: 95% Confidence Intervals for Effects of Discovered Treatments: The mean value of the feeling thermometer is 62.3

between the discovered treatments in order to estimate their effects.[6] Figure 2 shows the point estimate and 95-percent confidence intervals, which take into account uncertainty in inferring the treatments from the texts and the relationship between those treatments and the response.

The treatment effects reveal intuitive, though interesting, features of candidate biographies that affect respondent's evaluations. For example, Figure 2 reveals a distaste for political and legal experience—even though a large share of Congressional candidates have previous political experience and a law degree. Treatment 5, which describes a candidate's previous political experience, causes an 2.26 point reduction in feeling thermometer evaluation (95 percent confidence interval, [-4.26,-0.24]). Likewise, Treatment 9 shows that respondents dislike lawyers, with the presence of legal experience causing a 2.34 point reduction in feeling thermometer (95-percent confidence interval, [-4.28,-0.29]). The aversion to lawyers is not, however, an aversion to education. Treatment 3, a treatment that describes advanced degrees, causes a 2.43 point increase in feeling thermometer evaluations (95-percent confidence interval, [0.49,4.38]).

In contrast, Figure 2 shows that there is a consistent bonus for military experience. This is consistent with intuition from political observers that the public supports veterans. For example, treatment 6, which describes a candidate's military record, causes a 3.21 point increase in feeling thermometer rating (95-percent confidence interval, [1.34,5.12]) and treatment 10 causes a 4.00 point increase (95-percent confidence interval, [1.53,6.45]).

Because simultaneously discovering treatments from labeled data and estimating their average marginal component effects is a novel task, we cannot compare the performance of our framework against any benchmark. Even so, one natural question is whether the user could obtain much more coherent topics by foresaking the estimation of causal effects and using a more traditional topic

[6]This assumption is not necessary for the framework we propose here. Interaction effects could be modeled, but it would require us to make much stronger parametric assumptions using a method for heterogeneous treatments such as (Imai and Ratkovic, 2013).

modeling method. We provide the topics discovered by sLDA in Table 3. sIBP discovered most of the same features sLDA did. Both find military service, legal training, political background, and higher education. The Greek life feature is less coherent in sIBP than it is in sLDA, and sLDA finds business and ancestry features that sIBP does not. Both have a few incoherent treatments. This comparison suggests that sIBP does almost as well as sLDA at identifying coherent latent features, while also facilitating the estimation of marginal treatment effects.

4 Conclusion

We have presented a methodology for discovering treatments in text and then inferring the effect of those treatments on respondents' decisions. We prove that randomizing texts is sufficient to identify the underlying treatments and introduce the supervised Indian Buffet process for discovering the effects. The use of a training and test set ensures that our method provides accurate confidence intervals and avoids the problems of overfitting or "p-hacking" in experiments. In an application to candidate biographies, we discover a penalty for political and legal experience and a bonus for military service and non-legal advanced degrees.

Our methodology has a wide variety of applications. This includes numerous alternative experimental designs, providing a methodology that computational social scientists could use widely to discover and then confirm the effects of messages in numerous domains—including images and other high dimensional data. The methodology is also useful for observational data—for studying the effects of complicated treatments, such as how a legislator's roll call voting record affects their electoral support.

Abstract

Structured prediction from bandit feedback describes a learning scenario where instead of having access to a gold standard structure, a learner only receives partial feedback in form of the loss value of a predicted structure. We present new learning objectives and algorithms for this interactive scenario, focusing on convergence speed and ease of elicitability of feedback. We present supervised-to-bandit simulation experiments for several NLP tasks (machine translation, sequence labeling, text classification), showing that bandit learning from relative preferences eases feedback strength and yields improved empirical convergence.

1 Introduction

Structured prediction from partial information can be described by the following learning protocol: On each of a sequence of rounds, the learning algorithm makes a prediction, and receives partial information in terms of feedback on the predicted point. This single-point feedback is used to construct a parameter update that is an unbiased estimate of the respective update rule for the full information objective. In difference to the full information scenario, the learner does not know what the correct prediction looks like, nor what would have happened if it had predicted differently. This learning scenario has been investigated under the names of *learning from bandit feedback*[1] or *reinforcement learning*[2], and has (financially) important real world applications such as online advertising (Chapelle et al., 2014). In this application, the probability that an ad will be clicked (and the advertiser has to pay) is estimated by trading off exploration (a new ad needs to be displayed in order to learn its click-through rate) and exploitation (displaying the ad with the current best estimate is better in the short term) in displaying ads to users. Similar to the online advertising scenario, there are many potential applications to interactive learning in NLP. For example, in interactive statistical machine translation (SMT), user feedback in form of post-edits of predicted translations is used for model adaptation (Bertoldi et al., 2014; Denkowski et al., 2014; Green et al., 2014). Since post-editing feedback has a high cost and requires professional expertise of users, weaker forms of feedback are desirable. Sokolov et al. (2015) showed in a simulation experiment that partial information in form of translation quality judgements on predicted translations is sufficient for model adaptation in SMT. However, one drawback of their *bandit expected loss minimization* algorithm is the slow convergence speed, meaning that impractically many rounds of user feedback would be necessary for learning in real-world interactive SMT. Furthermore, their algorithms requires feedback in form of numerical assessments of translation quality. Such absolute feedback is arguably harder to elicit from human users than relative judgements.

The goal of this work is a preparatory study of different objectives and algorithms for structured prediction from partial information with real-world interactive scenarios in mind. Since the algorithm of Sokolov et al. (2015) can be characterized as stochastic optimization of a non-convex

[*]The work for this paper was done while the authors were at Heidelberg University.

[1]The name is inherited from a model where in each round a gambler pulls an arm of a different slot machine ("one-armed bandit"), with the goal of maximizing his reward relative to the maximal possible reward, without apriori knowledge of the optimal slot machine. See Bubeck and Cesa-Bianchi (2012) for an overview.

[2]See Szepesvári (2009) for an overview of algorithms for reinforcement learning and their relation to bandit learning.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1610–1620,
Berlin, Germany, August 7-12, 2016.

objective, a possible avenue to address the problem of convergence speed is a (strong) convexification of the learning objective, which we formalize as *bandit cross-entropy minimization*. To the aim of easing elicitability of feedback, we present a *bandit pairwise preference learning* algorithm that requires only relative feedback in the form of pairwise preference rankings.

The focus of this paper is on an experimental evaluation of the empirical performance and convergence speed of the different algorithms. We follow the standard practice of early stopping by measuring performance on a development set, and present results of an extensive evaluation on several tasks with different loss functions, including BLEU for SMT, Hamming loss for optical character recognition, and F1 score for chunking. In our experiments, we use a standard supervised-to-bandit transformation where a reward signal is simulated by evaluating a task loss against gold standard structures without revealing them to the learning algorithm (Agarwal et al., 2014). From the perspective of real-world interactive applications, bandit pairwise preference learning is the preferred algorithm since it only requires comparative judgements for learning. This type of relative feedback been shown to be advantageous for human decision making (Thurstone, 1927). However, in our simulation experiments we found that relative feedback also results in improved empirical convergence speed for bandit pairwise preference learning. The picture of fastest empirical convergence of bandit pairwise preference learning is consistent across different tasks, both compared to bandit expected loss minimization and bandit cross-entropy minimization. Given the improved convergence and the ease of elicitability of relative feedback, the presented bandit pairwise preference learner is an attractive choice for interactive NLP tasks.

2 Related Work

Reinforcement learning (RL) has the goal of maximizing the expected reward for choosing an action at a given state in a Markov Decision Process (MDP) model, where rewards are received at each state or once at the final state. The algorithms in this paper can be seen as one-state MDPs where choosing an action corresponds to predicting a structured output. Most closely related are RL approaches that use gradient-based optimization of a parametric policy for action selection (Bertsekas and Tsitsiklis, 1996; Sutton et al., 2000). Policy gradient approaches have been applied to NLP tasks by Branavan et al. (2009), Chang et al. (2015) or Ranzato et al. (2016).

Bandit learning operates in a similar scenario of maximizing the expected reward for selecting an arm of a multi-armed slot machine. Similar to our case, the models consist of a single state, however, arms are usually selected from a small set of options while structures are predicted over exponential output spaces. While bandit learning is mostly formalized as online regret minimization with respect to the best fixed arm in hindsight, we investigate asymptotic convergence of our algorithms. In the spectrum of stochastic (Auer et al., 2002a) versus adversarial bandits (Auer et al., 2002b), our approach takes a middle path by making stochastic assumptions on inputs, but not on rewards. Most closely related are algorithms that optimize parametric models, e.g., contextual bandits (Langford and Zhang, 2007; Li et al., 2010) or combinatorial bandits (Dani et al., 2007; Cesa-Bianchi and Lugosi, 2012). To the best of our knowledge, these types of algorithms have not yet been applied in the area of NLP.

Pairwise preference learning has been studied in the full information supervised setting (see Herbrich et al. (2000), Joachims (2002), Freund et al. (2003), Cortes et al. (2007), Fürnkranz and Hüllermeier (2010), *inter alia*) where given preference pairs are assumed. Stochastic optimization from two-point (or multi-point) feedback has been investigated in the framework of gradient-free optimization (see Yue and Joachims (2009), Agarwal et al. (2010), Ghadimi and Lan (2012), Jamieson et al. (2012), Duchi et al. (2015), *inter alia*), while our algorithms can be characterized as stochastic gradient descent algorithms.

3 Probabilistic Structured Prediction

3.1 Full Information vs. Bandit Feedback

The objectives and algorithms presented in this paper are based on the well-known expected loss criterion for probabilistic structured prediction (see Och (2003), Smith and Eisner (2006), Gimpel and Smith (2010), Yuille and He (2012), He and Deng (2012), *inter alia*). The objective is defined as a minimization of the expectation of a given task loss function with respect to the conditional distribution over structured outputs. This criterion

has the form of a continuous, differentiable, and in general, non-convex objective function. More formally, let $\mathcal{X}$ be a structured input space, let $\mathcal{Y}(x)$ be the set of possible output structures for input x, and let $\Delta_y : \mathcal{Y} \rightarrow [0, 1]$ quantify the loss $\Delta_y(y')$ suffered for predicting y' instead of the gold standard structure y; as a rule, $\Delta_y(y') = 0$ iff $y = y'$. In the full information setting, for a data distribution $p(x, y)$, the learning criterion is defined as minimization of the expected loss with respect to $w \in \mathbb{R}^d$ where

$$\mathbb{E}_{p(x,y)p_w(y'|x)}\left[\Delta_y(y')\right] = \sum_{x,y} p(x,y) \sum_{y' \in \mathcal{Y}(x)} \Delta_y(y') p_w(y'|x). \quad (1)$$

Assume further that output structures given inputs are distributed according to an underlying Gibbs distribution (a.k.a. conditional exponential or log-linear model)

$$p_w(y|x) = \exp(w^\top \phi(x, y))/Z_w(x),$$

where $\phi : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^d$ is a joint feature representation of inputs and outputs, $w \in \mathbb{R}^d$ is an associated weight vector, and $Z_w(x)$ is a normalization constant. For this model, the gradient of objective (1) is as follows:

$$\nabla \mathbb{E}_{p(x,y)p_w(y'|x)}\left[\Delta_y(y')\right] = \mathbb{E}_{p(x,y)p_w(y'|x)}\Big[\Delta_y(y')\left(\phi(x, y') - \mathbb{E}_{p_w(y'|x)}[\phi(x, y')]\right)\Big]. \quad (2)$$

Unlike in the full information scenario, bandit feedback in structured prediction means that the gold standard output structure y, with respect to which the objective function is evaluated, is not revealed to the learner. Thus we can neither evaluate the task loss Δ nor calculate the gradient (2) of the objective function (1). A solution to this problem is to pass the evaluation of the loss function to the user, i.e, we access the loss directly through user feedback without assuming existence of a fixed reference y. We indicate this by dropping the subscript referring to the gold standard structure in the definition of Δ. In all algorithms presented below we need to make the following assumptions:

1. We assume a sequence of input structures $x_t, t = 1, \ldots, T$ that are generated by a fixed, unknown distribution $p(x)$.

Algorithm 1 Bandit Expected Loss Minimization

Input: sequence of learning rates γ_t
Initialize w_0
for $t = 0, \ldots, T$ **do**
  Observe x_t
  Calculate $\mathbb{E}_{p_{w_t}(y|x_t)}[\phi(x_t, y)]$
  Sample $\tilde{y}_t \sim p_{w_t}(y|x_t)$

  $w_{t+1} = w_t - \gamma_t \, \Delta(\tilde{y}_t)$
    $\times\big(\phi(x_t, \tilde{y}_t) - \mathbb{E}_{p_{w_t}}[\phi(x_t, y)]\big)$

Algorithm 2 Bandit Pairwise Preference Learning

Input: sequence of learning rates γ_t
Initialize w_0
for $t = 0, \ldots, T$ **do**
  Observe x_t
  Calculate $\mathbb{E}_{p_{w_t}(\langle y_i, y_j\rangle|x_t)}[\phi(x_t, \langle y_i, y_j\rangle)]$
  Sample $\langle \tilde{y}_i, \tilde{y}_j \rangle_t \sim p_{w_t}(\langle y_i, y_j\rangle \,|x_t)$
  Obtain feedback $\Delta(\langle \tilde{y}_i, \tilde{y}_j \rangle_t)$
  $w_{t+1} = w_t - \gamma_t \, \Delta(\langle \tilde{y}_i, \tilde{y}_j \rangle_t)$
    $\times\big(\phi(x_t, \langle \tilde{y}_i, \tilde{y}_j \rangle_t) - \mathbb{E}_{p_{w_t}}[\phi(x_t, \langle y_i, y_j\rangle)]\big)$

2. We use a Gibbs model as sampling distribution to perform simultaneous exploitation (use the current best estimate) / exploration (get new information) on output structures.

3. We use feedback to the sampled output structures to construct a parameter update rule that is an unbiased estimate of the true gradient of the respective objective.

3.2 Learning Objectives and Algorithms

Bandit Expected Loss Minimization. Algorithm 1 has been presented in Sokolov et al. (2015) and minimizes the objective below by stochastic gradient descent optimization. It is non-convex for the specific instantiations in this paper:

$$\mathbb{E}_{p(x)p_w(y|x)}\left[\Delta(y)\right] = \sum_{x} p(x) \sum_{y \in \mathcal{Y}(x)} \Delta(y) p_w(y|x). \quad (3)$$

Intuitively, the algorithm compares the sampled feature vector to the average feature vector, and performs a step into the opposite direction of this difference, the more so the higher the loss of the sampled structure is. In the extreme case, if the sampled structure is correct ($\Delta(\tilde{y}_t) = 0$), no update is performed.

Algorithm 3 Bandit Cross-Entropy Minimization

Input: sequence of learning rates γ_t
Initialize w_0
for $t = 0, \ldots, T$ **do**
  Observe x_t
  Sample $\tilde{y}_t \sim p_{w_t}(y|x_t)$
  Obtain feedback $g(\tilde{y}_t)$
  $w_{t+1} = w_t - \gamma_t \frac{g(\tilde{y}_t)}{p_{w_t}(\tilde{y}_t|x_t)}$
    $\times\big(- \phi(x_t, \tilde{y}_t) + \mathbb{E}_{p_{w_t}}[\phi(x_t, \tilde{y}_t)]\big)$

Bandit Pairwise Preference Learning. Decomposing complex problems into a series of pairwise comparisons has been shown to be advantageous for human decision making (Thurstone, 1927) and for machine learning (Fürnkranz and Hüllermeier, 2010). For our case, this idea can be formalized as an expected loss objective with respect to a conditional distribution of pairs of structured outputs. Let $\mathcal{P}(x) = \{\langle y_i, y_j\rangle \,|y_i, y_j \in \mathcal{Y}(x)\}$ denote the set of output pairs for an input x, and let $\Delta(\langle y_i, y_j\rangle) : \mathcal{P}(x) \to [0, 1]$ denote a task loss function that specifies a dispreference of y_i compared to y_j. Instantiating objective (3) to the case of pairs of output structures defines the following objective:

$$\mathbb{E}_{p(x)p_w(\langle y_i,y_j\rangle|x)}\left[\Delta(\langle y_i, y_j\rangle)\right]. \tag{4}$$

Stochastic gradient descent optimization of this objective leads to Algorithm 2. The objective is again non-convex in the use cases in this paper. Minimization of this objective will assure that high probabilities are assigned to pairs with low loss due to misranking y_j over y_i. Stronger assumptions on the learned probability ranking can be made if assumptions of transitivity and asymmetry of the ordering of feedback structures are made. For efficient sampling and calculation of expectations, we assume a Gibbs model that factorizes as follows:

$$\begin{aligned} p_w(\langle y_i, y_j\rangle\,|x) &= \frac{e^{w^\top(\phi(x,y_i)-\phi(x,y_j))}}{\sum\limits_{\langle y_i,y_j\rangle\in\mathcal{P}(x)} e^{w^\top(\phi(x,y_i)-\phi(x,y_j))}} \\ &= p_w(y_i|x)p_{-w}(y_j|x). \end{aligned}$$

If a sample from the p_{-w} distribution is preferred over a sample from the p_w distribution, this is a strong signal for model correction.

Bandit Cross-Entropy Minimization. The standard theory of stochastic optimization predicts considerable improvements in convergence speed depending on the functional form of the objective. This motivates the formalization of convex upper bounds on expected normalized loss as presented in Green et al. (2014). Their objective is based on a gain function $g : \mathcal{Y} \to [0, 1]$ (in this work, $g(y) = 1 - \Delta(y)$) that is normalized over n-best lists where $\bar{g}(y) = \frac{g(y)}{Z_g(x)}$ and $Z_g(x) = \sum_{y\in n\text{-best}(x)} g(y)$. It can be seen as the cross-entropy of model $p_w(y|x)$ with respect the "true" distribution $\bar{g}(y)$:

$$\begin{aligned} &\mathbb{E}_{p(x)\bar{g}(y)}\left[-\log p_w(y|x)\right] \\ &\quad = -\sum_x p(x) \sum_{y\in\mathcal{Y}(x)} \bar{g}(y) \log p_w(y|x). \end{aligned} \tag{5}$$

For a proper probability distribution $\bar{g}(y)$, an application of Jensen's inequality to the convex negative logarithm function shows that objective (5) is a convex upper bound on objective (3). However, normalizing the gain function is prohibitive in a bandit setting since it would require to elicit user feedback for each structure in the output space or n-best list. We thus work with an unnormalized gain function which sacrifices the upper bound but preserves convexity. This can be seen by rewriting the objective as the sum of a linear and a convex function in w:

$$\begin{aligned} &\mathbb{E}_{p(x)g(y)}\left[-\log p_w(y|x)\right] \\ &\quad = -\sum_x p(x) \sum_{y\in\mathcal{Y}(x)} g(y) w^\top \phi(x, y) \\ &\qquad + \sum_x p(x)(\log \sum_{y\in\mathcal{Y}(x)} \exp(w^\top\phi(x, y)))\alpha(x), \end{aligned} \tag{6}$$

where $\alpha(x) = \sum_{y\in\mathcal{Y}(x)} g(y)$ is a constant factor not depending on w. The gradient of objective (6) is as follows:

$$\begin{aligned} &\nabla(-\sum_x p(x) \sum_{y\in\mathcal{Y}(x)} g(y) \log p_w(y|x)) \\ &\quad = \mathbb{E}_{p(x)p_s(y|x)}\big[\frac{g(y)}{p_s(y|x)}\big(- \phi(x, y) \\ &\qquad\qquad + \mathbb{E}_{p_w(y|x)}[\phi(x, y)]\big)\big]. \end{aligned}$$

Minimization of this objective will assign high probabilities to structures with high gain, as desired. Algorithm 3 minimizes this objective by sampling from a distribution $p_s(y|x)$, receiving feedback, and updating according to the ratio of gain versus current probability of the sampled structure. A positive ratio expresses a preference

of the sampled structure under the gain function compared to the current probability estimate. We compare the sampled feature vector to the average feature vector, and we update towards the sampled feature vector relative to this ratio. We instantiate $p_s(y|x)$ to the current update of $p_{w_t}(y|x)$ in order to present progressively more useful structures to the user. In contrast to Algorithms 1 and 2, each update is thus affected by a probability that changes over time and is unreliable when training is started. This further increases the variance already present in stochastic optimization. We deal with this problem by clipping too small sampling probabilities (Ionides, 2008) or by reducing variance using momentum techniques (Polyak, 1964).

3.3 Remarks on Theoretical Analysis

Convergence of our algorithms can be analyzed using results of standard stochastic approximation theory. For example, Sokolov et al. (2015) analyze the convergence of Algorithm 1 in the pseudogradient framework of Polyak and Tsypkin (1973), relying on the fact that a positive inner product of the update vector with the gradient in expectation suffices for convergence. Sokolov et al. (2016) analyze convergence in the framework of stochastic first-order optimization of Ghadimi and Lan (2012), relying on the fact that the update vectors of the algorithms are stochastic gradients of the respective objectives, that is, the update vectors are unbiased gradient measurements that equal the gradient of the full information objective in expectation. Note that the latter analysis covers the use of constant learning rates.

Convergence speed is analyzed in standard stochastic approximation theory in terms of the number of iterations needed to reach an accuracy of ϵ for a gradient-based criterion

$$\mathbb{E}[\|\nabla J(w_t)\|^2] \leq \epsilon, \tag{7}$$

where $J(w_t)$ denotes the objective to be minimized. Following Ghadimi and Lan (2012), the iteration complexity of the non-convex objectives underlying our Algorithms 1 and 2 can be given as $\mathcal{O}(1/\epsilon^2)$ (see Sokolov et al. (2016)). Algorithm 3 can be seen as stochastic optimization of a strongly convex objective that is attained by adding an ℓ_2 regularizer $\frac{\lambda}{2}\|w\|^2$ with constant $\lambda > 0$ to objective (6). In the standard stochastic approximation theory, the iteration complexity of stochastic gradient algorithms using decreasing learning rates can be given as $\mathcal{O}(1/\epsilon)$ for an objective value-based criterion

$$\mathbb{E}[J(w_t)] - J(w^*) \leq \epsilon,$$

where $w^* = \arg\min_w J(w)$ (Polyak, 1987). For constant learning rates, even faster convergence can be shown provided certain additional conditions are met (Solodov, 1998).

While the asymptotic iteration complexity bounds predict faster convergence for Algorithm 3 compared to Algorithms 1 and 2, and equal convergence speed for the latter two, Sokolov et al. (2016) show that the hidden constant of variance of the stochastic gradient can offset this advantage empirically. They find smallest variance of stochastic updates and fastest empirical convergence under the gradient-based criterion (7) for Algorithm 2. In the next section we will present experimental results that show similar relations of fastest convergence of Algorithm 2 under a convergence criterion based on task loss evaluation on heldout data.

4 Experiments

Experimental design. Our experiments follow an online learning protocol where on each of a sequence of rounds, an output structure is randomly sampled, and feedback to it is used to update the model (Shalev-Shwartz, 2012). We simulate bandit feedback by evaluating Δ against gold standard structures which are never revealed to the learner (Agarwal et al., 2014). Training is started from $w_0 = \mathbf{0}$ or from an out-of-domain model (for SMT).

Following the standard practice of early stopping by performance evaluation on a development set, we compute convergence speed as the number of iterations needed to find the point of optimal performance before overfitting on the development set occurs. The convergence criterion is thus based on the respective task loss function $\Delta(\hat{y}_{w_t}(x))$ under MAP prediction $\hat{y}_w(x) = \arg\max_{y \in \mathcal{Y}(x)} p_w(y|x)$, microaveraged on the development data. This lets us compare convergence across different objectives, and is justified by the standard practice of performing online-to-batch conversion by early stopping on a development set (Littlestone, 1989), or by tolerant training to avoid overfitting (Solodov, 1998). As a further measure for comparability of convergence

	task	Algorithm 1	Algorithm 2	Algorithm 3
	Text classification	$\gamma_t = 1.0$	$\gamma_t = 10^{-0.75}$	$\gamma_t = 10^{-1}$
CRF	OCR	$T_0 = 0.4, \gamma_t = 10^{-3.5}$	$T_0 = 0.1, \gamma_t = 10^{-4}$	$\lambda = 10^{-5}, k = 10^{-2}, \gamma_t = 10^{-6}$
CRF	Chunking	$\gamma_t = 10^{-4}$	$\gamma_t = 10^{-4}$	$\lambda = 10^{-6}, k = 10^{-2}, \gamma_t = 10^{-6}$

SMT	News (h-graph, sparse)	$\gamma_t = 10^{-5}$	$\gamma_t = 10^{-4}$	$\lambda = 10^{-6}, k = 5 \cdot 10^{-3}, \gamma_t = 10^{-6}$

Table 1: Metaparameter settings determined on *dev* sets for constant learning rate γ_t, temperature coefficient T_0 for annealing under the schedule $T = T_0/\sqrt[3]{\text{epoch} + 1}$ (Rose, 1998; Arun et al., 2010), momentum coefficient $\min\{1 - 1/(t/2 + 2), \mu\}$ (Polyak, 1964; Sutskever et al., 2013), clipping constant k used to replace $p_{w_t}(\tilde{y}_t|x_t)$ with $\max\{p_{w_t}(\tilde{y}_t|x_t), k\}$ in line 7 of Algorithm 3 (Ionides, 2008), ℓ_2 regularization constant λ. Unspecified parameters are set to zero.

speeds across algorithms, we employ small constant learning rates in all experiments. The use of constant learning rates for Algorithms 1 and 2 is justified by the analysis of Ghadimi and Lan (2012). For Algorithm 3, the use of constant learning rates effectively compares convergence speed towards an area in close vicinity of a local minimum in the search phase of the algorithm (Bottou, 2004).

The development data are also used for metaparameter search. Optimal configurations are listed in Table 1. Final testing was done by computing Δ on a further unseen test set using the model found by online-to-batch conversion. For bandit-type algorithms, final results are averaged over 3 runs with different random seeds. For statistical significance testing of results against baselines we use Approximate Randomization testing (Noreen, 1989).

Multiclass classification. Multiclass text classification on the Reuters RCV1 dataset (Lewis et al., 2004) is a standard benchmark for (simplified) structured prediction that has been used in a bandit setup by Kakade et al. (2008). The simplified problem uses a binary Δ function indicating incorrect assignment of one out of 4 classes. Following Kakade et al. (2008), we used documents with exactly one label from the set of labels {CCAT, ECAT, GCAT, MCAT} and converted them to *tfidf* word vectors of dimension 244,805 in training. The data were split into the sets *train* (509,381 documents from original `test_pt[0-2].dat` files), *dev* (19,486 docs: every 8th entry from `test_pt3.dat` and *test* (19,806 docs from `train.dat`).

As shown in Table 2 (row 1), all loss results are small and comparable since the task is relatively easy. For comparison, the partial information classification algorithm Banditron (Kakade et al., 2008) (after adjusting the exploration/exploitation constant on the dev set) scored 0.047 on the test set. However, our main interest is in convergence speed. Table 3 (row 1) shows that pairwise ranking (Algorithm 2) yields fastest convergence by a factor of 2-4 compared to the other bandit algorithms. Table 1 confirms that this improvement is not attributable to larger learning rates (Algorithm 2 employs a similar or smaller learning rate than Algorithms 1 and 3, respectively.)

Sequence labeling for OCR and chunking. Handwritten optical character recognition (OCR) is a standard benchmark task for structured prediction (Taskar et al., 2003), where the Hamming distance between the predicted word and the gold standard labeling (normalized by word length) is assumed as the Δ function. We used their dataset of 6,876 handwritten words, from 150 human subjects, under a split where 5,546 examples (folds 2-9) were used as *train* set, 704 examples (fold 1) as *dev*, and 626 (fold 0) as *test* set. We assumed the classical linear-chain Conditional Random Field (CRF) (Lafferty et al., 2001) model with input images x^i at every ith node, tabular state-transition probabilities between 28 possible labels of the $(i-1)$th and ith node (Latin letters plus two auxiliary `start` and `stop` states).[3]

To test the CRF-based model also with sparse features, we followed Sha and Pereira (2003) in applying CRFs to the noun phrase chunking task

[3]The feature set is composed of a 16×8 binary pixel representation for each character, yielding $28 \times 16 \times 8 + 28^2 = 4,368$ features for the training set. We based our code on the `pystruct` kit (Müller and Behnke, 2014).

Table 2: Test set evaluation for full information lower and upper bounds and partial information bandit learners (expected loss, pairwise loss, cross-entropy). ↑ and ↓ indicate the direction of improvement for the respective evaluation metric.

on the CoNLL-2000 dataset[4]. We split the original training set into a *dev* set (top 1,000 sent.) and used the rest as *train* set (7,936 sent.); the *test* set was kept intact (2,012 sent.). For an input sentence x, each CRF node x^i carries an observable word and its part-of-speech tag, and has to be assigned a chunk tag c^i out of 3 labels: **B**eginning, **I**nside, or **O**utside (of a noun phrase). Chunk labels are not nested. As in Sha and Pereira (2003), we use second order Markov dependencies (bigram chunk tags), such that for sentence position i, the state is $y^i = c^{i-1}c^i$, increasing the label set size from 3 to 9. Out of the full list of Sha and Pereira (2003)'s features we implemented all except two feature templates, $y^i = y$ and $c(y^i) = c$, to simplify implementation. Impossible bigrams (OI) and label transitions of the pattern $\star O \rightarrow I\star$ were prohibited by setting the respective potentials to $-\infty$. As the active feature count in the train set was just under 2M, we hashed all features and weights into a sparse array of 2M entries. Despite the reduced train size and feature set, and hashing, our full information baseline trained with log-likelihood attained the test F1-score of 0.935, which is comparable to the original result of 0.9438.

Table 2 (rows 2-3) and Table 3 (rows 2-3) show evaluation and convergence results for the OCR and chunking tasks. For the chunking task, the F1-score results obtained for bandit learning are close to the full-information baseline. For the OCR task, bandit learning does decrease Hamming loss, but it does not quite achieve full-information performance. However, pairwise ranking (Algorithm 2) again converges faster than the alternative bandit algorithms by a factor of 2-4, despite similar learning rates for Algorithms 1 and 2 and a compensation of smaller learning rates in Algorithm 3 by variance reduction and regularization.

Discriminative ranking for SMT. Following Sokolov et al. (2015), we apply bandit learning to simulate personalized MT where a given SMT system is adapted to user style and domain based on feedback to predicted translations. We perform French-to-English domain adaptation from Europarl to NewsCommentary domains using the data of Koehn and Schroeder (2007). One difference of our experiment compared to Sokolov et al. (2015) is our use of the SCFG decoder `cdec` (Dyer et al., 2010) (instead of the phrase-based `Moses` decoder). Furthermore, in addition to bandit learning for re-ranking on unique 5,000-best lists, we perform ranking on hypergraphs with re-decoding after each update. Sampling and computation of expectations on the hypergraph uses the Inside-Outside algorithm over the expectation semiring (Li and Eisner, 2009). The re-ranking model used 15 dense features (6 lexicalized reordering features, two (out-of- and in-domain) language models, 5 translation model features, distortion and word penalty). The hypergraph experiments used additionally lexicalized sparse features: rule-id features, rule source and target bigram features, and rule shape features.

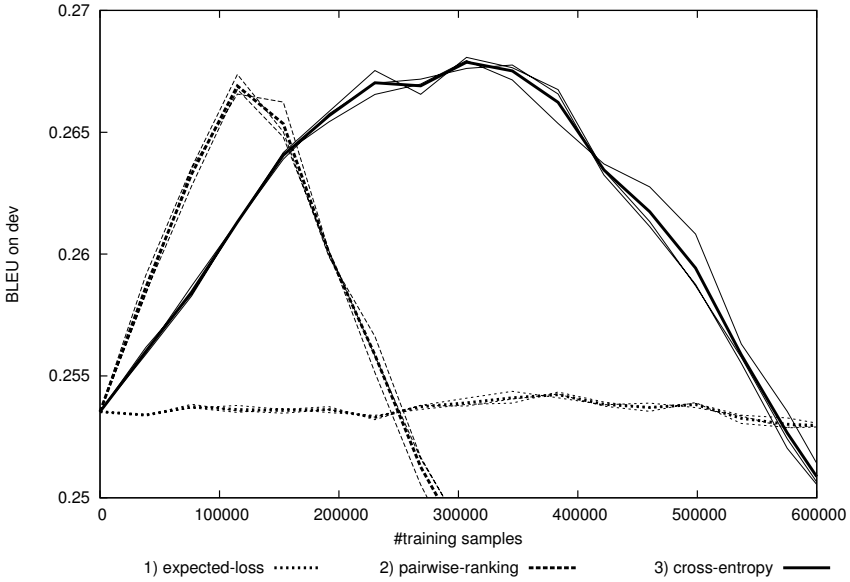

Figure 1: Learning curves for task loss BLEU on development data for SMT hypergraph re-decoding models, together with averages over three runs of the respective algorithms.

For all SMT experiments we tokenized, lowercased and aligned words using `cdec` tools, trained 4-gram in-domain and out-of-domain language models (on the English sides of Europarl and in-domain NewsCommentary) For dense feature models, the *out-of-domain* baseline SMT model was trained on 1.6M parallel Europarl data and tuned with `cdec`'s lattice MERT (Och, 2003) on out-of-domain Europarl `dev2006` dev set (2,000 sent.). The full-information *in-domain* SMT model tuned by MERT on news in-domain sets (`nc-dev2007`, 1,057 sent.) gives the range of possible improvements by the difference of its BLEU score to the one of the out-of-domain model (2.5 BLEU points). For sparse feature models, in-domain and out-of-domain baselines were trained on the same data using MIRA (Chiang, 2012). The in-domain MIRA model contains 133,531 active features, the out-of-domain MIRA model 214,642. MERT and MIRA runs for both settings were repeated 7 times and median results are reported.

Learning under *bandit feedback* starts at the learned weights of the out-of-domain median models. It uses the parallel in-domain data (`news-commentary`, 40,444 sent.) to simulate bandit feedback, by evaluating the sampled translation against the reference using as loss function Δ a smoothed per-sentence $1 - \text{BLEU}$ (zero n-gram counts being replaced with 0.01). For pairwise preference learning we use binary feedback resulting from the comparison of the BLEU scores of the sampled translations. To speed up training for hypergraph re-decoding, the training instances were reduced to those with at most 60 words (38,350 sent.). Training is distributed across 38 shards using multitask-based feature selection for sparse models (Simianer et al., 2012), where after each epoch of distributed training, the top 10k features across all shards are selected, all other features are set to zero. The meta-parameters were adjusted on the in-domain dev sets (`nc-devtest2007`, 1,064 parallel sentences). The final results are obtained on separate in-domain test sets (`nc-test2007`, 2,007 sentences) by averaging three independent runs for the optimal dev set meta-parameters.

The results for n-best re-ranking in Table 2 (4th row) show statistically significant improvements of 1-2 BLEU points over the out-of-domain SMT model (that includes an in-domain language model) for all bandit learning methods, confirming the results of Sokolov et al. (2015) for a different decoder. Similarly, the results for hypergraph re-coding with sparse feature models (row 5 in Table 2) show significant improvements over the out-of-domain baseline for all bandit learners. Table 3 (row 4) shows the convergence speed for n-best re-ranking, which is similar for Algorithms 2 and 3, and improved over Algorithm 1 by a factor of 3. For hypergraph re-decoding, Table 3 (row 5) shows fastest convergence for Algorithm 2 com-

pared to Algorithms 1 and 3 by a factor of 2-4.[5] Again, we note that for both n-best re-ranking and hypergraph re-decoding, learning rates are similar for Algorithms 1 and 2, and smaller learning rates in Algorithm 3 are compensated by variance reduction or regularization.

Figure 1 shows the learning curves of BLEU for SMT hypergraph re-decoding on the development set that were used to find the stopping points. For each algorithm, we show learning curves for three runs with different random seeds, together with an average learning curve. We see that Algorithm 2, optimizing the pairwise preference ranking objective, reaches the stopping point of peak performance on development data fastest, followed by Algorithms 1 and 3. Furthermore, the larger variance of the runs of Algorithm 3 is visible, despite the smallest learning rate used.

5 Conclusion

We presented objectives and algorithms for structured prediction from bandit feedback, with a focus on improving convergence speed and ease of elicitability of feedback. We investigated the performance of all algorithms by test set performance on different tasks, however, the main interest of this paper was a comparison of convergence speed across different objectives by early stopping on a convergence criterion based on heldout data performance. Our experimental results on different NLP tasks showed a consistent advantage of convergence speed under this criterion for bandit pairwise preference learning. In light of the standard stochastic approximation analysis, which predicts a convergence advantage for strongly convex objectives over convex or non-convex objectives, this result is surprising. However, the result can be explained by considering important empirical factors such as the variance of stochastic updates. Our experimental results support the numerical results of smallest stochastic variance and fastest convergence in gradient norm (Sokolov et al., 2016) by consistent fastest empirical convergence for bandit pairwise preference learning under the criterion of early stopping on heldout data performance. Given the advantages of faster convergence and the fact that only relative feedback in terms of comparative evaluations is required, bandit pairwise preference learning is a promising framework for future real-world interactive learning.

[5]The faster convergence speed hypergraph re-decoding compared to n-best re-ranking is due to the distributed feature selection and thus orthogonal to the comparison of objective functions that is of interest here.

Abstract

This paper introduces a novel architecture for reinforcement learning with deep neural networks designed to handle state and action spaces characterized by natural language, as found in text-based games. Termed a deep reinforcement relevance network (DRRN), the architecture represents action and state spaces with separate embedding vectors, which are combined with an interaction function to approximate the Q-function in reinforcement learning. We evaluate the DRRN on two popular text games, showing superior performance over other deep Q-learning architectures. Experiments with paraphrased action descriptions show that the model is extracting meaning rather than simply memorizing strings of text.

1 Introduction

This work is concerned with learning strategies for sequential decision-making tasks, where a system takes actions at a particular state with the goal of maximizing a long-term reward. More specifically, we consider tasks where both the states and the actions are characterized by natural language, such as in human-computer dialog systems, tutoring systems, or text-based games. In a text-based game, for example, the player (or system, in this case) is given a text string that describes the current state of the game and several text strings that describe possible actions one could take. After selecting one of the actions, the environment state is updated and revealed in a new textual description. A reward is given either at each transition or in the end. The objective is to understand, at each step, the state text and all the action texts to pick the most relevant action, navigating through the sequence of texts so as to obtain the highest long-term reward. Here the notion of relevance is based on the joint state/action impact on the reward: an action text string is said to be "more relevant" (to a state text string) than the other action texts if taking that action would lead to a higher long-term reward. Because a player's action changes the environment, reinforcement learning (Sutton and Barto, 1998) is appropriate for modeling long-term dependency in text games.

There is a large body of work on reinforcement learning. Of most interest here are approaches leveraging neural networks because of their success in handling a large state space. Early work — TD-gammon — used a neural network to approximate the state value function (Tesauro, 1995). Recently, inspired by advances in deep learning (LeCun et al., 2015; Hinton et al., 2012; Krizhevsky et al., 2012; Dahl et al., 2012), significant progress has been made by combining deep learning with reinforcement learning. Building on the approach of Q-learning (Watkins and Dayan, 1992), the "Deep Q-Network" (DQN) was developed and applied to Atari games (Mnih et al., 2013; Mnih et al., 2015) and shown to achieve human level performance by applying convolutional neural networks to the raw image pixels. Narasimhan et al. (2015) applied a Long Short-Term Memory network to characterize the state space in a DQN framework for learning control policies for parser-based text games. More recently, Nogueira and Cho (2016) have also proposed a goal-driven web navigation task for language based sequential decision making study. Another stream of work focuses on continuous control with deep reinforcement learning (Lillicrap et al., 2016), where an actor-critic algorithm operates over a known continuous action space.

Inspired by these successes and recent work using neural networks to learn phrase- or sentence-

level embeddings (Collobert and Weston, 2008; Huang et al., 2013; Le and Mikolov, 2014; Sutskever et al., 2014; Kiros et al., 2015), we propose a novel deep architecture for text understanding, which we call a deep reinforcement relevance network (DRRN). The DRRN uses separate deep neural networks to map state and action text strings into embedding vectors, from which "relevance" is measured numerically by a general interaction function, such as their inner product. The output of this interaction function defines the value of the Q-function for the current state-action pair, which characterizes the optimal long-term reward for pairing these two text strings. The Q-function approximation is learned in an end-to-end manner by Q-learning.

The DRRN differs from prior work in that earlier studies mostly considered action spaces that are bounded and known. For actions described by natural language text strings, the action space is inherently discrete and potentially unbounded due to the exponential complexity of language with respect to sentence length. A distinguishing aspect of the DRRN architecture — compared to simple DQN extensions — is that two different types of meaning representations are learned, reflecting the tendency for state texts to describe scenes and action texts to describe potential actions from the user. We show that the DRRN learns a continuous space representation of actions that successfully generalize to paraphrased descriptions of actions unseen in training.

2 Deep Reinforcement Relevance Network

2.1 Text Games and Q-learning

We consider the sequential decision making problem for text understanding. At each time step t, the agent will receive a string of text that describes the state s_t (i.e., "state-text") and several strings of text that describe all the potential actions a_t (i.e., "action-text"). The agent attempts to understand the texts from both the state side and the action side, measuring their relevance to the current context s_t for the purpose of maximizing the long-term reward, and then picking the best action. Then, the environment state is updated $s_{t+1} = s'$ according to the probability $p(s'|s, a)$, and the agent receives a reward r_t for that particular transition. The *policy* of the agent is defined to be the probability $\pi(a_t|s_t)$ of taking action a_t at state s_t. Define the Q-function $Q^\pi(s, a)$ as the expected return starting from s, taking the action a, and thereafter following policy $\pi(a|s)$ to be:

$$Q^\pi(s,a) = \mathbb{E}\left\{\sum_{k=0}^{+\infty} \gamma^k r_{t+k} \middle| s_t = s, a_t = a\right\}$$

where γ denotes a discount factor. The optimal policy and Q-function can be found by using the Q-learning algorithm (Watkins and Dayan, 1992):

$$Q(s_t,a_t) \leftarrow Q(s_t,a_t) + \eta_t \cdot \left(r_t + \gamma \cdot \max_a Q(s_{t+1},a) - Q(s_t,a_t)\right) \quad (1)$$

where η_t is the learning rate of the algorithm. In this paper, we use a softmax selection strategy as the exploration policy during the learning stage, which chooses the action a_t at state s_t according to the following probability:

$$\pi(a_t = a_t^i|s_t) = \frac{\exp(\alpha \cdot Q(s_t, a_t^i))}{\sum_{j=1}^{|\mathcal{A}_t|} \exp(\alpha \cdot Q(s_t, a_t^j))}, \quad (2)$$

where $\mathcal{A}_t$ is the set of feasible actions at state s_t, a_t^i is the i-th feasible action in $\mathcal{A}_t$, $|\cdot|$ denotes the cardinality of the set, and α is the scaling factor in the softmax operation. α is kept constant throughout the learning period. All methods are initialized with small random weights, so initial Q-value differences will be small, thus making the Q-learning algorithm more explorative initially. As Q-values better approximate the true values, a reasonable α will make action selection put high probability on the optimal action (exploitation), but still maintain a small exploration probability.

2.2 Natural language action space

Let $\mathcal{S}$ denote the state space, and let $\mathcal{A}$ denote the entire action space that includes all the unique actions over time. A vanilla Q-learning recursion (1) needs to maintain a table of size $|\mathcal{S}| \times |\mathcal{A}|$, which is problematic for a large state/action space. Prior work using a DNN in Q-function approximation has shown high capacity and scalability for handling a large state space, but most studies have used a network that generates $|\mathcal{A}|$ outputs, each of which represents the value of $Q(s, a)$ for a particular action a. It is not practical to have a DQN architecture of a size that is explicitly dependence on the large number of natural language actions. Further, in many text games, the feasible action set $\mathcal{A}_t$ at each time t is an unknown subset of the unbounded action space $\mathcal{A}$ that varies over time.

For the case where the maximum number of possible actions at any point in time ($\max_t |\mathcal{A}_t|$) is known, the DQN can be modified to simply use that number of outputs ("Max-action DQN"), as illustrated in Figure 1(a), where the state and action vectors are concatenated (i.e., as an extended state vector) as its input. The network computes the Q-function values for the actions in the current feasible set as its outputs. For a complex game, $\max_t |\mathcal{A}_t|$ may be difficult to obtain, because $\mathcal{A}_t$ is usually unknown beforehand. Nevertheless, we will use this modified DQN as a baseline.

An alternative approach is to use a function approximation using a neural network that takes a state-action pair as input, and outputs a single Q-value for each possible action ("Per-action DQN" in Figure 1(b)). This architecture easily handles a varying number of actions and represents a second baseline.

We propose an alternative architecture for handling a natural language action space in sequential text understanding: the deep reinforcement relevance network (DRRN). As shown in Figure 1(c), the DRRN consists of a pair of DNNs, one for the state text embedding and the other for action text embeddings, which are combined using a pairwise interaction function. The texts used to describe states and actions could be very different in nature, e.g., a state text could be long, containing sentences with complex linguistic structure, whereas an action text could be very concise or just a verb phrase. Therefore, it is desirable to use two networks with different structures to handle state/action texts, respectively. As we will see in the experimental sections, by using two separate deep neural networks for state and action sides, we obtain much better results.

2.3 DRRN architecture: Forward activation

Given any state/action text pair (s_t, a_t^i), the DRRN estimates the Q-function $Q(s_t, a_t^i)$ in two steps. First, map both s_t and a_t^i to their embedding vectors using the corresponding DNNs, respectively. Second, approximate $Q(s_t, a_t^i)$ using an interaction function such as the inner product of the embedding vectors. Then, given a particular state s_t, we can select the optimal action a_t among the set of actions via $a_t = \arg\max_{a_t^i} Q(s_t, a_t^i)$.

More formally, let $h_{l,s}$ and $h_{l,a}$ denote the l-th hidden layer for state and action side neural networks, respectively. For the state side, $W_{l,s}$ and $b_{l,s}$ denote the linear transformation weight matrix and bias vector between the $(l-1)$-th and l-th hidden layers. $W_{l,a}$ and $b_{l,a}$ denote the equivalent parameters for the action side. In this study, the DRRN has L hidden layers on each side.

$$h_{1,s} = f(W_{1,s}s_t + b_{1,s}) \quad (3)$$

$$h_{1,a}^i = f(W_{1,a}a_t^i + b_{1,a}) \quad (4)$$

$$h_{l,s} = f(W_{l-1,s}h_{l-1,s} + b_{l-1,s}) \quad (5)$$

$$h_{l,a}^i = f(W_{l-1,a}h_{l-1,a}^i + b_{l-1,a}) \quad (6)$$

where $f(\cdot)$ is the nonlinear activation function at the hidden layers, which, for example, could be chosen as $\tanh(x)$, and $i = 1, 2, 3, ..., |\mathcal{A}_t|$ is the action index. A general interaction function $g(\cdot)$ is used to approximate the Q-function values, $Q(s, a)$, in the following parametric form:

$$Q(s, a^i; \Theta) = g\left(h_{L,s},\ h_{L,a}^i\right) \quad (7)$$

where Θ denotes all the model parameters. The interaction function could be an inner product, a bilinear operation, or a nonlinear function such as a deep neural network. In our experiments, the inner product and bilinear operation gave similar results. For simplicity, we present our experiments mostly using the inner product interaction function.

The success of the DRRN in handling a natural language action space $\mathcal{A}$ lies in the fact that the state-text and the action-texts are mapped into separate finite-dimensional embedding spaces. The end-to-end learning process (discussed next) makes the embedding vectors in the two spaces more aligned for "good" (or relevant) action texts compared to "bad" (or irrelevant) choices, resulting in a higher interaction function output (Q-function value).

2.4 Learning the DRRN: Back propagation

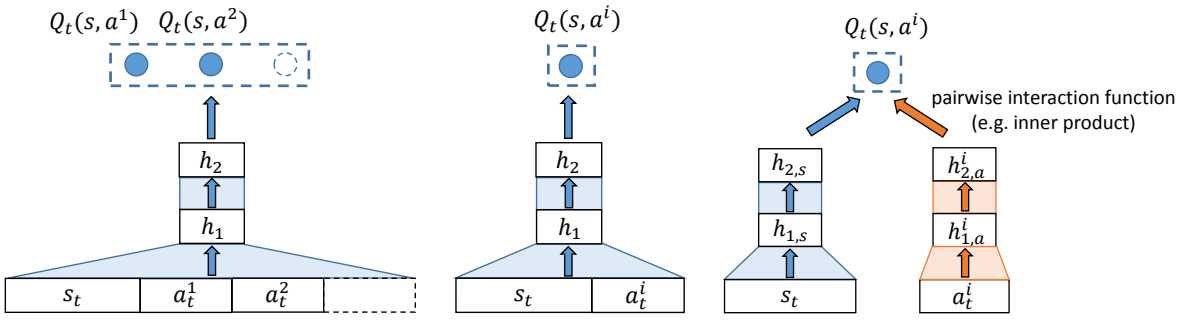
To learn the DRRN, we use the "experience-replay" strategy (Lin, 1993), which uses a fixed exploration policy to interact with the environment to obtain a sample trajectory. Then, we randomly sample a transition tuple (s_k, a_k, r_k, s_{k+1}), compute the temporal difference error for sample k:

$$d_k = r_k + \gamma \max_a Q(s_{k+1}, a; \Theta_{k-1}) - Q(s_k, a_k; \Theta_{k-1}),$$

and update the model according to the recursions:

$$W_{v,k} = W_{v,k-1} + \eta_k d_k \cdot \frac{\partial Q(s_k, a_k; \Theta_{k-1})}{\partial W_v} \quad (8)$$

$$b_{v,k} = b_{v,k-1} + \eta_k d_k \cdot \frac{\partial Q(s_k, a_k; \Theta_{k-1})}{\partial b_v} \quad (9)$$



(a) Max-action DQN (b) Per-action DQN (c) DRRN

Figure 1: Different deep Q-learning architectures: Max-action DQN and Per-action DQN both treat input text as concantenated vectors and compute output Q-values with a single NN. DRRN models text embeddings from state/action sides separately, and use an interaction function to compute Q-values.

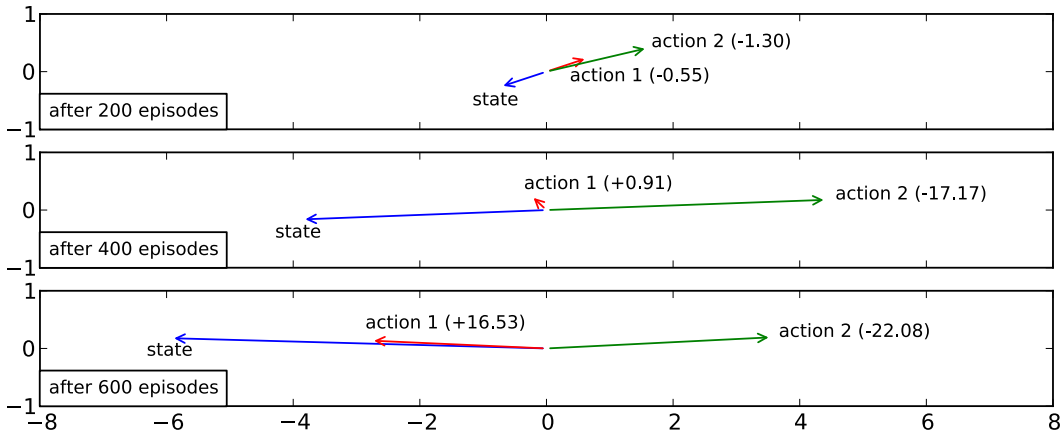


Figure 2: PCA projections of text embedding vectors for state and associated action vectors after 200, 400 and 600 training episodes. The state is "As you move forward, the people surrounding you suddenly look up with terror in their faces, and flee the street." Action 1 (good choice) is "Look up", and action 2 (poor choice) is "Ignore the alarm of others and continue moving forward."

for $v \in \{s, a\}$. Expressions for $\frac{\partial Q}{\partial W_v}$, $\frac{\partial Q}{\partial b_v}$ and other algorithm details are given in supplementary materials. Random sampling essentially scrambles the trajectory from experience-replay into a "bag-of-transitions", which has been shown to avoid oscillations or divergence and achieve faster convergence in Q-learning (Mnih et al., 2015). Since the models on the action side share the same parameters, models associated with all actions are effectively updated even though the back propagation is only over one action. We apply back propagation to learn how to pair the text strings from the reward signals in an end-to-end manner. The representation vectors for the state-text and the action-text are *automatically learned* to be aligned with each other in the text embedding space from the reward signals. A summary of the full learning algorithm is given in Algorithm 1.

Figure 2 illustrates learning with an inner product interaction function. We used Principal Component Analysis (PCA) to project the 100-dimension last hidden layer representation (before the inner product) to a 2-D plane. The vector embeddings start with small values, and after 600 episodes of experience-replay training, the embeddings are very close to the converged embedding (4000 episodes). The embedding vector of the optimal action (Action 1) converges to a positive inner product with the state embedding vector, while Action 2 converges to a negative inner product.

3 Experimental Results

3.1 Text games

Text games, although simple compared to video games, still enjoy high popularity in online communities, with annual competitions held online

Algorithm 1 Learning algorithm for DRRN

Initialize replay memory $\mathcal{D}$ to capacity N.
Initialize DRRN with small random weights.
Initialize game simulator and load dictionary.
for $episode = 1, \ldots, M$ **do**
  Restart game simulator.
  Read raw state text and a list of action text from the simulator, and convert them to representation s_1 and $a_1^1, a_1^2, \ldots, a_1^{|\mathcal{A}_1|}$.
  for $t = 1, \ldots, T$ **do**
    Compute $Q(s_t, a_t^i; \Theta)$ for the list of actions using DRRN forward activation (Section 2.3).
    Select an action a_t based on probability distribution $\pi(a_t = a_t^i | s_t)$ (Equation 2)
    Execute action a_t in simulator
    Observe reward r_t. Read the next state text and the next list of action texts, and convert them to representation s_{t+1} and $a_{t+1}^1, a_{t+1}^2, \ldots, a_{t+1}^{|\mathcal{A}_{t+1}|}$.
    Store transition $(s_t, a_t, r_t, s_{t+1}, A_{t+1})$ in $\mathcal{D}$.
    Sample random mini batch of transitions $(s_k, a_k, r_k, s_{k+1}, A_{k+1})$ from $\mathcal{D}$.
    Set $y_k = \begin{cases} r_k & \text{if } s_{k+1} \text{ is terminal} \\ r_k + \gamma \max_{a' \in A_{k+1}} Q(s_{k+1}, a'; \Theta)) & \text{otherwise} \end{cases}$
    Perform a gradient descent step on $(y_k - Q(s_k, a_k; \Theta))^2$ with respect to the network parameters Θ (Section 2.4). Back-propagation is performed only for a_k even though there are $|\mathcal{A}_k|$ actions at time k.

end for

since 1995. Text games communicate to players in the form of a text display, which players have to understand and respond to by typing or clicking text (Adams, 2014). There are three types of text games: parser-based (Figure 3(a)), choice-based (Figure 3(b)), and hypertext-based (Figure 3(c)). Parser-based games accept typed-in commands from the player, usually in the form of verb phrases, such as "eat apple", "get key", or "go east". They involve the least complex action language. Choice-based and hypertext-based games present actions after or embedded within the state text. The player chooses an action, and the story continues based on the action taken at this particular state. With the development of web browsing and richer HTML display, choice-based and hypertext-based text games have become more popular, increasing in percentage from 8% in 2010 to 62% in 2014.[1]

For parser-based text games, Narasimhan et al. (2015) have defined a fixed set of 222 actions, which is the total number of possible phrases the parser accepts. Thus the parser-based text game is reduced to a problem that is well suited to a fixed-action-set DQN. However, for choice-based and hypertext-based text games, the size of the action space could be exponential with the length of the action sentences, which is handled here by using a continuous representation of the action space.

Game	Saving John	Machine of Death
Text game type	Choice	Choice & Hypertext
Vocab size	1762	2258
Action vocab size	171	419
Avg. words/description	76.67	67.80
State transitions	Deterministic	Stochastic
# of states (underlying)	≥ 70	≥ 200

Table 1: Statistics for the games "Saving John" and and "Machine of Death".

In this study, we evaluate the DRRN with two games: a deterministic text game task called "Saving John" and a larger-scale stochastic text game called "Machine of Death" from a public archive.[2] The basic text statistics of these tasks are shown in Table 1. The maximum value of feasible actions (i.e., $\max_t |\mathcal{A}_t|$) is four in "Saving John", and nine in "Machine of Death". We manually annotate fi-

Figure 3: Different types of text games

nal rewards for all distinct endings in both games (as shown in supplementary materials). The magnitude of reward scores are given to describe sentiment polarity of good/bad endings. On the other hand, each non-terminating step we assign with a small negative reward, to encourage the learner to finish the game as soon as possible. For the text game "Machine of Death", we restrict an episode to be no longer than 500 steps.

In "Saving John" all actions are choice-based, for which the mapping from text strings to a_t are clear. In "Machine of Death", when actions are hypertext, the actions are substrings of the state. In this case s_t is associated with the full state description, and a_t are given by the substrings without any surrounding context. For text input, we use raw bag-of-words as features, with different vocabularies for the state side and action side.

3.2 Experiment setup

We apply DRRNs with both 1 and 2 hidden layer structures. In most experiments, we use dot-product as the interaction function and set the hidden dimension to be the same for each hidden layer. We use DRRNs with 20, 50 and 100-dimension hidden layer(s) and build learning curves during experience-replay training. The learning rate is constant: $\eta_t = 0.001$. In testing, as in training, we apply softmax selection. We record average final rewards as performance of the model.

The DRRN is compared to multiple baselines: a linear model, two max-action DQNs (MA DQN) ($L = 1$ or 2 hidden layers), and two per-action DQNs (PA DQN) (again, $L = 1, 2$). All baselines use the same Q-learning framework with different function approximators to predict $Q(s_t, a_t)$ given the current state and actions. For the linear and MA DQN baselines, the input is the text-based state and action descriptions, each as a bag of words, with the number of outputs equal to the maximum number of actions. When there are fewer actions than the maximum, the highest scoring available action is used. The PA DQN baseline takes each pair of state-action texts as input, and generates a corresponding Q-value.

Eval metric	Average reward		
hidden dimension	20	50	100
Linear	4.4 (0.4)

Table 2: The final average rewards and standard deviations on "Saving John".

We use softmax selection, which is widely applied in practice, to trade-off exploration vs. exploitation. Specifically, for each experience-replay, we first generate 200 episodes of data (about 3K tuples in "Saving John" and 16K tuples in "Machine of Death") using the softmax selection rule in (2), where we set $\alpha = 0.2$ for the first game and $\alpha = 1.0$ for the second game. The α is picked according to an estimation of range of the optimal Q-values. We then shuffle the generated data tuples (s_t, a_t, r_t, s_{t+1}) update the model as described in Section 2.4. The model is trained with multiple epochs for all configurations, and is evaluated after each experience-replay. The discount factor γ is set to 0.9. For DRRN and all baselines, network weights are initialized with small random values. To prevent algorithms from "remembering" state-action ordering and make choices based on action wording, each time the algorithm/player reads text from the simulator, we randomly shuffle the list of actions.[3] This will encourage the algorithms to make decisions based on the understanding of the texts that describe the states and actions.

3.3 Performance

In Figure 4, we show the learning curves of different models, where the dimension of the hid-

[3]When in a specific state, the simulator presents the possible set of actions in random order, i.e. they may appear in a different order the next time a player is in this same state.

den layers in the DQNs and DRRN are all set to 100. The error bars are obtained by running 5 independent experiments. The proposed methods and baselines all start at about the same performance (roughly -7 average rewards for Game 1, and roughly -8 average rewards for Game 2), which is the random guess policy. After around 4000 episodes of experience-replay training, all methods converge. The DRRN converges much faster than the other three baselines and achieves a higher average reward. We hypothesize this is because the DRRN architecture is better at capturing relevance between state text and action text. The faster convergence for "Saving John" may be due to the smaller observation space and/or the deterministic nature of its state transitions (in contrast to the stochastic transitions in the other game).

The final performance (at convergence) for both baselines and proposed methods are shown in Tables 2 and 3. We test for different model sizes with 20, 50, and 100 dimensions in the hidden layers. The DRRN performs consistently better than all baselines, and often with a lower variance. For Game 2, due to the complexity of the underlying state transition function, we cannot compute the exact optimal policy score. To provide more insight into the performance, we averaged scores of 8 human players for initial trials (novice) and after gaining experience, yielding scores of -5.5 and 16.0, respectively. The experienced players do outperform our algorithm. The converged performance is higher with two hidden layers for all models. However, deep models also converge more slowly than their 1 hidden layer versions, as shown for the DRRN in Figure 4.

Besides an inner-product, we also experimented with more complex interaction functions: a) a bilinear operation with different action side dimensions; and b) a non-linear deep neural network using the concatenated state and action space embeddings as input and trained in an end-to-end fashion to predict Q values. For different configurations, we fix the state side embedding to be 100 dimensions and vary the action side embedding dimensions. The bilinear operation gave similar results, but the concatenation input to a DNN degraded performance. Similar behaviors have been observed on a different task (Luong et al., 2015).

3.4 Actions with paraphrased descriptions

To investigate how our models handle actions with "unseen" natural language descriptions, we had two people paraphrase all actions in the game "Machine of Death" (used in testing phase), except a few single-word actions whose synonyms are out-of-vocabulary (OOV). The word-level OOV rate of paraphrased actions is 18.6%,

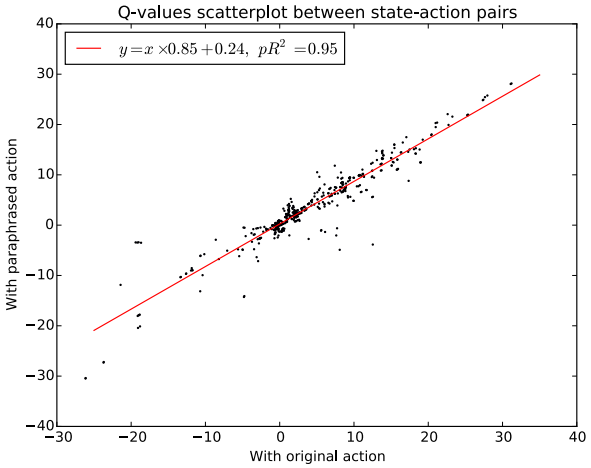

Figure 5: Scatterplot and strong correlation between Q-values of paraphrased actions versus original actions

and standard 4-gram BLEU score between the paraphrased and original actions is 0.325. The resulting 153 paraphrased action descriptions are associated with 532 unique state-action pairs.

We apply a well-trained 2-layer DRRN model (with hidden dimension 100), and predict Q-values for each state-action pair with fixed model parameters. Figure 5 shows the correlation between Q-values associated with paraphrased actions versus original actions. The predictive R-squared is 0.95, showing a strong positive correlation. We also run Q-value correlation for the NN interaction and $pR^2 = 0.90$. For baseline MA-DQN and PA-DQN, their corresponding pR^2 is 0.84 and 0.97, indicating they also have some generalization ability. This is confirmed in the paraphrasing-based experiments too, where the test reward on the paraphrased setup is close to the original setup. This supports the claim that deep learning is useful in general for this language understanding task, and our findings show that a decoupled architecture most effectively leverages that approach.

In Table 4 we provide examples with predicted Q-values of original descriptions and paraphrased descriptions. We also include alternative action descriptions with in-vocabulary words that will lead to positive / negative / irrelevant game development at that particular state. Table 4 shows actions that are more likely to result in good endings are predicted with high Q-values. This indicates that the DRRN has some generalization ability and gains a useful level of language understanding in the game scenario.

We use the baseline models and proposed DRRN model trained with the original action descriptions for "Machine of Death", and test on paraphrased action descriptions. For this game, the underlying state transition mechanism has not changed. The only change to the game interface is that during testing, every time the player reads the actions from the game simulator, it reads the paraphrased descriptions and performs selection based on these paraphrases. Since the texts in test time are "unseen" to the player, a good model needs to have some level of language understanding, while a naive model that memorizes all unique action texts in the original game will do poorly. The results for these models are shown in Table 5. All methods have a slightly lower average reward in this setting (10.5 vs. 11.2 for the original actions), but the DRRN still gives a high reward and significantly outperforms other methods. This shows that the DRRN can generalize well to "unseen" natural language descriptions of actions.

4 Related Work

There has been increasing interest in applying deep reinforcement learning to a variety problems, but only a few studies address problems with natural language state or action spaces. In language processing, reinforcement learning has been applied to a dialogue management system that converses with a human user by taking actions that generate natural language (Scheffler and Young, 2002; Young et al., 2013). There has also been interest in extracting textual knowledge to improve game control performance (Branavan et al., 2011), and mapping text instructions to sequences of executable actions (Branavan et al., 2009). In some applications, it is possible to manually design features for state-action pairs, which are then used in reinforcement learning to learn a near-optimal policy (Li et al., 2009). Designing such features, however, require substantial domain knowledge.

The work most closely related to our study involves application of deep reinforcement to learning decision policies for parser-based text games. Narasimhan et al. (2015) applied a Long Short-Term Memory DQN framework, which achieves higher average reward than the random and Bag-of-Words DQN baselines. In this work, actions are constrained to a set of known fixed command structures (one action and one argument object),

	Text (with predicted Q-values)
State	As you move forward, the people surrounding you suddenly look up with terror in their faces, and flee the street.
Actions in the original game	Ignore the alarm of others and continue moving forward. (-21.5) Look up. (16.6)
Paraphrased actions (not original)	Disregard the caution of others and keep pushing ahead. (-11.9) Turn up and look. (17.5)
Positive actions (not original)	Stay there. (2.8) Stay calmly. (2.0)
Negative actions (not original)	Screw it. I'm going carefully. (-17.4) Yell at everyone. (-13.5)
Irrelevant actions (not original)	Insert a coin. (-1.4) Throw a coin to the ground. (-3.6)

Table 5: The final average rewards and standard deviations on paraphrased game "Machine of Death".

based on a limited action-side vocabulary size. The overall action space is defined by the action-argument product space. This pre-specified product space is not feasible for the more complex text strings in other forms of text-based games. Our proposed DRRN, on the other hand, can handle the more complex text strings, as well as parser-based games. In preliminary experiments with the parser-based game from (Narasimhan et al., 2015), we find that the DRRN using a bag-of-words (BOW) input achieves results on par with their BOW DQN. The main advantage of the DRRN is that it can also handle actions described with more complex language.

The DRRN experiments described here leverage only a simple bag-of-words representation of phrases and sentences. As observed in (Narasimhan et al., 2015), more complex sentence-based models can give further improvements. In preliminary experiments with "Machine of Death", we did not find LSTMs to give improved performance, but we conjecture that they would be useful in larger-scale tasks, or when the word embeddings are initialized by training on large data sets.

As mentioned earlier, other work has applied deep reinforcement learning to a problem with a continuous action space (Lillicrap et al., 2016). In the DRRN, the action space is inherently discrete, but we learn a continuous representation of it. As indicated by the paraphrasing experiment, the continuous space representation seems to generalize reasonably well.

5 Conclusion

In this paper we develop a deep reinforcement relevance network, a novel DNN architecture for handling actions described by natural language in decision-making tasks such as text games. We show that the DRRN converges faster and to a better solution for Q-learning than alternative architectures that do not use separate embeddings for the state and action spaces. Future work includes: (i) adding an attention model to robustly analyze which part of state/actions text correspond to strategic planning, and (ii) applying the proposed methods to more complex text games or other tasks with actions defined through natural language.

Abstract

We address an important problem in sequence-to-sequence (Seq2Seq) learning referred to as copying, in which certain segments in the input sequence are selectively replicated in the output sequence. A similar phenomenon is observable in human language communication. For example, humans tend to repeat entity names or even long phrases in conversation. The challenge with regard to copying in Seq2Seq is that new machinery is needed to decide when to perform the operation. In this paper, we incorporate copying into neural network-based Seq2Seq learning and propose a new model called COPYNET with encoder-decoder structure. COPYNET can nicely integrate the regular way of word generation in the decoder with the new copying mechanism which can choose subsequences in the input sequence and put them at proper places in the output sequence. Our empirical study on both synthetic data sets and real world data sets demonstrates the efficacy of COPYNET. For example, COPYNET can outperform regular RNN-based model with remarkable margins on text summarization tasks.

1 Introduction

Recently, neural network-based sequence-to-sequence learning (Seq2Seq) has achieved remarkable success in various natural language processing (NLP) tasks, including but not limited to Machine Translation (Cho et al., 2014; Bahdanau et al., 2014), Syntactic Parsing (Vinyals et al., 2015b), Text Summarization (Rush et al., 2015) and Dialogue Systems (Vinyals and Le, 2015). Seq2Seq is essentially an encoder-decoder model, in which the encoder first transform the input sequence to a certain representation which can then transform the representation into the output sequence. Adding the attention mechanism (Bahdanau et al., 2014) to Seq2Seq, first proposed for automatic alignment in machine translation, has led to significant improvement on the performance of various tasks (Shang et al., 2015; Rush et al., 2015). Different from the canonical encoder-decoder architecture, the attention-based Seq2Seq model revisits the input sequence in its raw form (array of word representations) and dynamically fetches the relevant piece of information based mostly on the feedback from the generation of the output sequence.

In this paper, we explore another mechanism important to the human language communication, called the "copying mechanism". Basically, it refers to the mechanism that locates a certain segment of the input sentence and puts the segment into the output sequence. For example, in the following two dialogue turns we observe different patterns in which some subsequences (colored blue) in the response (R) are copied from the input utterance (I):

I: Hello Jack, my name is Chandralekha.
R: Nice to meet you, Chandralekha.

I: This new guy doesn't perform exactly as we expected.
R: What do you mean by "doesn't perform exactly as we expected"?

Both the canonical encoder-decoder and its variants with attention mechanism rely heavily on the representation of "meaning", which might not be sufficiently inaccurate in cases in which the system needs to refer to sub-sequences of input like entity names or dates. In contrast, the

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1631–1640,
Berlin, Germany, August 7-12, 2016.

copying mechanism is closer to the rote memorization in language processing of human being, deserving a different modeling strategy in neural network-based models. We argue that it will benefit many Seq2Seq tasks to have an elegant unified model that can accommodate both understanding and rote memorization. Towards this goal, we propose COPYNET, which is not only capable of the regular generation of words but also the operation of copying appropriate segments of the input sequence. Despite the seemingly "hard" operation of copying, COPYNET can be trained in an end-to-end fashion. Our empirical study on both synthetic datasets and real world datasets demonstrates the efficacy of COPYNET.

2 Background: Neural Models for Sequence-to-sequence Learning

Seq2Seq Learning can be expressed in a probabilistic view as maximizing the likelihood (or some other evaluation metrics (Shen et al., 2015)) of observing the output (target) sequence given an input (source) sequence.

2.1 RNN Encoder-Decoder

RNN-based Encoder-Decoder is successfully applied to real world Seq2Seq tasks, first by Cho et al. (2014) and Sutskever et al. (2014), and then by (Vinyals and Le, 2015; Vinyals et al., 2015a). In the Encoder-Decoder framework, the source sequence $X = [x_1, ..., x_{T_S}]$ is converted into a fixed length vector $\mathbf{c}$ by the encoder RNN, i.e.

$$\mathbf{h}_t = f(x_t, \mathbf{h}_{t-1}); \quad \mathbf{c} = \phi(\{\mathbf{h}_1, ..., \mathbf{h}_{T_S}\}) \quad (1)$$

where $\{\mathbf{h}_t\}$ are the RNN states, $\mathbf{c}$ is the so-called context vector, f is the dynamics function, and ϕ summarizes the hidden states, e.g. choosing the last state $\mathbf{h}_{T_S}$. In practice it is found that gated RNN alternatives such as LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014) often perform much better than vanilla ones.

The decoder RNN is to unfold the context vector $\mathbf{c}$ into the target sequence, through the following dynamics and prediction model:

$$\begin{aligned} \mathbf{s}_t &= f(y_{t-1}, \mathbf{s}_{t-1}, \mathbf{c}) \\ p(y_t|y_{<t}, X) &= g(y_{t-1}, \mathbf{s}_t, \mathbf{c}) \end{aligned} \quad (2)$$

where $\mathbf{s}_t$ is the RNN state at time t, y_t is the predicted target symbol at t (through function $g(\cdot)$) with $y_{<t}$ denoting the history $\{y_1, ..., y_{t-1}\}$. The prediction model is typically a classifier over the vocabulary with, say, 30,000 words.

2.2 The Attention Mechanism

The attention mechanism was first introduced to Seq2Seq (Bahdanau et al., 2014) to release the burden of summarizing the entire source into a fixed-length vector as context. Instead, the attention uses a dynamically changing context $\mathbf{c}_t$ in the decoding process. A natural option (or rather "soft attention") is to represent $\mathbf{c}_t$ as the weighted sum of the source hidden states, i.e.

$$\mathbf{c}_t = \sum_{\tau=1}^{T_S} \alpha_{t\tau}\mathbf{h}_\tau; \quad \alpha_{t\tau} = \frac{e^{\eta(\mathbf{s}_{t-1}, \mathbf{h}_\tau)}}{\sum_{\tau'} e^{\eta(s_{t-1}, \mathbf{h}_{\tau'})}} \quad (3)$$

where η is the function that shows the correspondence strength for attention, approximated usually with a multi-layer neural network (DNN). Note that in (Bahdanau et al., 2014) the source sentence is encoded with a Bi-directional RNN, making each hidden state $\mathbf{h}_\tau$ aware of the contextual information from both ends.

3 COPYNET

From a cognitive perspective, the copying mechanism is related to rote memorization, requiring less understanding but ensuring high literal fidelity. From a modeling perspective, the copying operations are more rigid and symbolic, making it more difficult than soft attention mechanism to integrate into a fully differentiable neural model. In this section, we present COPYNET, a differentiable Seq2Seq model with "copying mechanism", which can be trained in an end-to-end fashion with just gradient descent.

3.1 Model Overview

As illustrated in Figure 1, COPYNET is still an encoder-decoder (in a slightly generalized sense). The source sequence is transformed by **Encoder** into representation, which is then read by **Decoder** to generate the target sequence.

Encoder: Same as in (Bahdanau et al., 2014), a bi-directional RNN is used to transform the source sequence into a series of hidden states with equal length, with each hidden state $\mathbf{h}_t$ corresponding to word x_t. This new representation of the source, $\{\mathbf{h}_1, ..., \mathbf{h}_{T_S}\}$, is considered to be a short-term memory (referred to as $\mathbf{M}$ in the remainder of the paper), which will later be accessed in multiple ways in generating the target sequence (decoding).

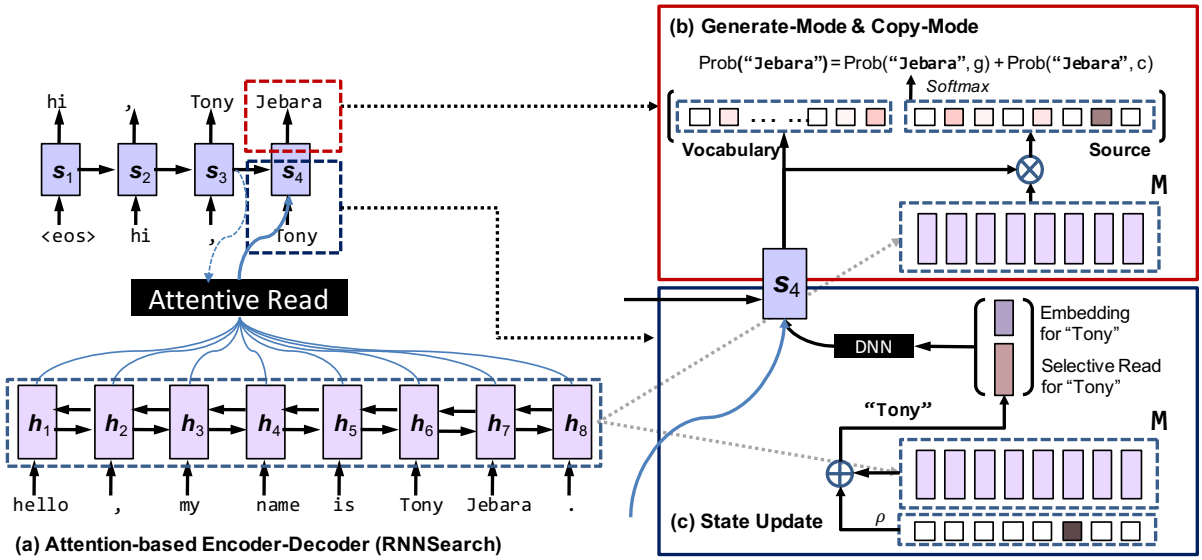

Figure 1: The overall diagram of COPYNET. For simplicity, we omit some links for prediction (see Sections 3.2 for more details).

Decoder: An RNN that reads $\mathbf{M}$ and predicts the target sequence. It is similar with the canonical RNN-decoder in (Bahdanau et al., 2014), with however the following important differences

- **Prediction:** COPYNET predicts words based on a mixed probabilistic model of two modes, namely the **generate-mode** and the **copy-mode**, where the latter picks words from the source sequence (see Section 3.2);
- **State Update:** the predicted word at time t–1 is used in updating the state at t, but COPYNET uses not only its word-embedding but also its corresponding location-specific hidden state in $\mathbf{M}$ (if any) (see Section 3.3 for more details);
- **Reading $\mathbf{M}$:** in addition to the attentive read to $\mathbf{M}$, COPYNET also has"selective read" to $\mathbf{M}$, which leads to a powerful hybrid of content-based addressing and location-based addressing (see both Sections 3.3 and 3.4 for more discussion).

3.2 Prediction with Copying and Generation

We assume a vocabulary $\mathcal{V} = \{v_1, ..., v_N\}$, and use UNK for any out-of-vocabulary (OOV) word. In addition, we have another set of words $\mathcal{X}$, for all the *unique* words in source sequence $X = \{x_1, ..., x_{T_S}\}$. Since $\mathcal{X}$ may contain words not in $\mathcal{V}$, copying sub-sequence in X enables COPYNET to output some OOV words. In a nutshell, the instance-specific vocabulary for source X is $\mathcal{V} \cup \text{UNK} \cup \mathcal{X}$.

Given the decoder RNN state $\mathbf{s}_t$ at time t together with $\mathbf{M}$, the probability of generating any target word y_t, is given by the "mixture" of probabilities as follows

$$p(y_t|\mathbf{s}_t, y_{t-1}, \mathbf{c}_t, \mathbf{M}) = p(y_t, \mathsf{g}|\mathbf{s}_t, y_{t-1}, \mathbf{c}_t, \mathbf{M}) + p(y_t, \mathsf{c}|\mathbf{s}_t, y_{t-1}, \mathbf{c}_t, \mathbf{M}) \quad (4)$$

where g stands for the generate-mode, and c the copy mode. The probability of the two modes are given respectively by

$$p(y_t, \mathsf{g}|\cdot) = \begin{cases} \frac{1}{Z} e^{\psi_g(y_t)}, & y_t \in \mathcal{V} \\ 0, & y_t \in \mathcal{X} \cap \bar{V} \\ \frac{1}{Z} e^{\psi_g(\text{UNK})} & y_t \notin \mathcal{V} \cup \mathcal{X} \end{cases} \quad (5)$$

$$p(y_t, \mathsf{c}|\cdot) = \begin{cases} \frac{1}{Z} \sum_{j:x_j=y_t} e^{\psi_c(x_j)}, & y_t \in \mathcal{X} \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

where $\psi_g(\cdot)$ and $\psi_c(\cdot)$ are score functions for generate-mode and copy-mode, respectively, and Z is the normalization term shared by the two modes, $Z = \sum_{v \in \mathcal{V} \cup \{\text{UNK}\}} e^{\psi_g(v)} + \sum_{x \in X} e^{\psi_c(x)}$. Due to the shared normalization term, the two modes are basically competing through a softmax function (see Figure 1 for an illustration with example), rendering Eq.(4) different from the canonical definition of the mixture model (McLachlan and Basford, 1988). This is also pictorially illustrated in Figure 2. The score of each mode is calculated:

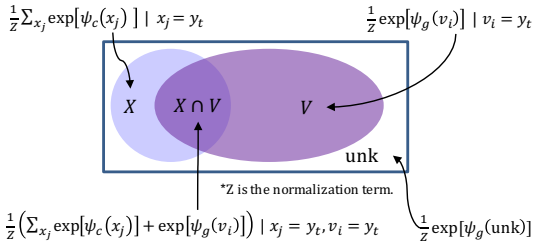

Figure 2: The illustration of the decoding probability $p(y_t|\cdot)$ as a 4-class classifier.

Generate-Mode: The same scoring function as in the generic RNN encoder-decoder (Bahdanau et al., 2014) is used, i.e.

$$\psi_g(y_t = v_i) = \mathbf{v}_i^\top \mathbf{W}_o \mathbf{s}_t, \quad v_i \in \mathcal{V} \cup \text{UNK} \quad (7)$$

where $\mathbf{W}_o \in \mathbb{R}^{(N+1)\times d_s}$ and $\mathbf{v}_i$ is the one-hot indicator vector for v_i.

Copy-Mode: The score for "copying" the word x_j is calculated as

$$\psi_c(y_t = x_j) = \sigma\left(\mathbf{h}_j^\top \mathbf{W}_c\right)\mathbf{s}_t, \quad x_j \in \mathcal{X} \quad (8)$$

where $\mathbf{W}_c \in \mathbb{R}^{d_h \times d_s}$, and σ is a non-linear activation function, considering that the non-linear transformation in Eq.(8) can help project s_t and h_j in the same semantic space. Empirically, we also found that using the $\tanh$ non-linearity worked better than linear transformation, and we used that for the following experiments. When calculating the copy-mode score, we use the hidden states $\{\mathbf{h}_1, ..., \mathbf{h}_{T_S}\}$ to "represent" each of the word in the source sequence $\{x_1, ..., x_{T_S}\}$ since the bi-directional RNN encodes not only the content, but also the location information into the hidden states in $\mathbf{M}$. The location informaton is important for copying (see Section 3.4 for related discussion). Note that we sum the probabilities of all x_j equal to y_t in Eq. (6) considering that there may be multiple source symbols for decoding y_t. Naturally we let $p(y_t, \mathsf{c}|\cdot) = 0$ if y_t does not appear in the source sequence, and set $p(y_t, \mathsf{g}|\cdot) = 0$ when y_t only appears in the source.

3.3 State Update

CopyNet updates each decoding state $\mathbf{s}_t$ with the previous state $\mathbf{s}_{t-1}$, the previous symbol y_{t-1} and the context vector $\mathbf{c}_t$ following Eq. (2) for the generic attention-based Seq2Seq model. However, there is some minor changes in the $y_{t-1} \longrightarrow \mathbf{s}_t$ path for the copying mechanism. More specifically, y_{t-1} will be represented as $[\mathbf{e}(y_{t-1}); \zeta(y_{t-1})]^\top$, where $\mathbf{e}(y_{t-1})$ is the word embedding associated with y_{t-1}, while $\zeta(y_{t-1})$ is the weighted sum of hidden states in $\mathbf{M}$ corresponding to y_t

$$\zeta(y_{t-1}) = \sum_{\tau=1}^{T_S} \rho_{t\tau}\mathbf{h}_\tau$$
$$\rho_{t\tau} = \begin{cases} \frac{1}{K}p(x_\tau, \mathsf{c}|\mathbf{s}_{t-1}, \mathbf{M}), & x_\tau = y_{t-1} \\ 0 & \text{otherwise} \end{cases} \quad (9)$$

where K is the normalization term which equals $\sum_{\tau':x_{\tau'}=y_{t-1}} p(x_{\tau'}, c|\mathbf{s}_{t-1}, \mathbf{M})$, considering there may exist multiple positions with y_{t-1} in the source sequence. In practice, $\rho_{t\tau}$ is often concentrated on one location among multiple appearances, indicating the prediction is closely bounded to the location of words.

In a sense $\zeta(y_{t-1})$ performs a type of read to $\mathbf{M}$ similar to the attentive read (resulting $\mathbf{c}_t$) with however higher precision. In the remainder of this paper, $\zeta(y_{t-1})$ will be referred to as *selective read*. $\zeta(y_{t-1})$ is specifically designed for the copy mode: with its pinpointing precision to the corresponding y_{t-1}, it naturally bears the location of y_{t-1} in the source sequence encoded in the hidden state. As will be discussed more in Section 3.4, this particular design potentially helps copy-mode in covering a consecutive sub-sequence of words. If y_{t-1} is not in the source, we let $\zeta(y_{t-1}) = \mathbf{0}$.

3.4 Hybrid Addressing of M

We hypothesize that CopyNet uses a hybrid strategy for fetching the content in $\mathbf{M}$, which combines both content-based and location-based addressing. Both addressing strategies are coordinated by the decoder RNN in managing the attentive read and selective read, as well as determining when to enter/quit the copy-mode.

Both the semantics of a word and its location in X will be encoded into the hidden states in $\mathbf{M}$ by a properly trained encoder RNN. Judging from our experiments, the attentive read of CopyNet is driven more by the semantics and language model, therefore capable of traveling more freely on $\mathbf{M}$, even across a long distance. On the other hand, once CopyNet enters the copy-mode, the selective read of $\mathbf{M}$ is often guided by the location information. As the result, the selective read often takes rigid move and tends to cover consecutive words, including UNKs. Unlike the explicit design for hybrid addressing in Neural Turing Machine (Graves et al., 2014; Kurach et al., 2015), CopyNet is more subtle: it provides the archi-

tecture that can facilitate some particular location-based addressing and lets the model figure out the details from the training data for specific tasks.

Location-based Addressing: With the location information in $\{\mathbf{h}_i\}$, the information flow

$$\zeta(y_{t-1}) \xrightarrow{\text{update}} \mathbf{s}_t \xrightarrow{\text{predict}} y_t \xrightarrow{\text{sel. read}} \zeta(y_t)$$

provides a simple way of "moving one step to the right" on X. More specifically, assuming the selective read $\zeta(y_{t-1})$ concentrates on the ℓ^{th} word in X, the state-update operation $\zeta(y_{t-1}) \xrightarrow{\text{update}} \mathbf{s}_t$ acts as "`location` $\leftarrow$ `location+1`", making $\mathbf{s}_t$ favor the $(\ell+1)^{th}$ word in X in the prediction $\mathbf{s}_t \xrightarrow{\text{predict}} y_t$ in copy-mode. This again leads to the selective read $\hat{h}_t \xrightarrow{\text{sel. read}} \zeta(y_t)$ for the state update of the next round.

Handling Out-of-Vocabulary Words Although it is hard to verify the exact addressing strategy as above directly, there is strong evidence from our empirical study. Most saliently, a properly trained COPYNET can copy a fairly long segment full of OOV words, despite the lack of semantic information in its $\mathbf{M}$ representation. This provides a natural way to extend the effective vocabulary to include all the words in the source. Although this change is small, it seems quite significant empirically in alleviating the OOV problem. Indeed, for many NLP applications (e.g., text summarization or spoken dialogue system), much of the OOV words on the target side, for example the proper nouns, are essentially the replicates of those on the source side.

4 Learning

Although the copying mechanism uses the "hard" operation to copy from the source and choose to paste them or generate symbols from the vocabulary, COPYNET is fully differentiable and can be optimized in an end-to-end fashion using back-propagation. Given the batches of the source and target sequence $\{X\}_N$ and $\{Y\}_N$, the objectives are to minimize the negative log-likelihood:

$$\mathcal{L} = -\frac{1}{N}\sum_{k=1}^{N}\sum_{t=1}^{T}\log\left[p(y_t^{(k)}|y_{<t}^{(k)}, X^{(k)})\right], \quad (10)$$

where we use superscripts to index the instances. Since the probabilistic model for observing any target word is a mixture of generate-mode and copy-mode, there is no need for any additional labels for modes. The network can learn to coordinate the two modes from data. More specifically, if one particular word $y_t^{(k)}$ can be found in the source sequence, the copy-mode will contribute to the mixture model, and the gradient will more or less encourage the copy-mode; otherwise, the copy-mode is discouraged due to the competition from the shared normalization term Z. In practice, in most cases one mode dominates.

5 Experiments

We report our empirical study of COPYNET on the following three tasks with different characteristics

1. A synthetic dataset on with simple patterns;
2. A real-world task on text summarization;
3. A dataset for simple single-turn dialogues.

5.1 Synthetic Dataset

Dataset: We first randomly generate transformation rules with 5$\sim$20 symbols and variables $\mathbf{x}$ & $\mathbf{y}$, e.g.

a b **x** c d **y** e f $\longrightarrow$ g h **x** m,

with {a b c d e f g h m} being regular symbols from a vocabulary of size 1,000. As shown in the table below, each rule can further produce a number of instances by replacing the variables with randomly generated subsequences (1$\sim$15 symbols) from the same vocabulary. We create five types of rules, including "$\mathbf{x} \rightarrow \emptyset$". The task is to learn to do the Seq2Seq transformation from the training instances. This dataset is designed to study the behavior of COPYNET on handling simple and rigid patterns. Since the strings to repeat are random, they can also be viewed as some extreme cases of rote memorization.

Rule-type	Examples (e.g. **x** = i h k, **y** = j c)
$\mathbf{x} \rightarrow \emptyset$	a b c d **x** e f $\rightarrow$ c d g
$\mathbf{x} \rightarrow \mathbf{x}$	a b c d **x** e f $\rightarrow$ c d **x** g
$\mathbf{x} \rightarrow \mathbf{x}\,\mathbf{x}$	a b c d **x** e f $\rightarrow$ **x** d **x** g
$\mathbf{x}\,\mathbf{y} \rightarrow \mathbf{x}$	a b **y** d **x** e f $\rightarrow$ **x** d i g
$\mathbf{x}\,\mathbf{y} \rightarrow \mathbf{x}\,\mathbf{y}$	a b **y** d **x** e f $\rightarrow$ **x** d **y** g

Experimental Setting: We select 200 artificial rules from the dataset, and for each rule 200 instances are generated, which will be split into training (50%) and testing (50%). We compare the accuracy of COPYNET and the RNN Encoder-Decoder with (i.e. RNNsearch) or without attention (denoted as Enc-Dec). For a fair comparison, we use bi-directional GRU for encoder and another GRU for decoder for all Seq2Seq models, with hidden layer size = 300 and word embedding dimension = 150. We use bin size = 10 in beam search for testing. The prediction is considered

Rule-type	x $\rightarrow \emptyset$	x $\rightarrow$ x	x $\rightarrow$ xx	xy $\rightarrow$ x	xy $\rightarrow$ xy
Enc-Dec	**100**	3.3	1.5	2.9	0.0
RNNSearch	99.0	69.4	22.3	40.7	2.6
COPYNET	97.3	**93.7**	**98.3**	**68.2**	**77.5**

Table 1: The test accuracy (%) on synthetic data.

correct only when the generated sequence is exactly the same as the given one.

It is clear from Table 1 that COPYNET significantly outperforms the other two on all rule-types except "x $\rightarrow \emptyset$", indicating that COPYNET can effectively learn the patterns with variables and accurately replicate rather long subsequence of symbols at the proper places.This is hard to Enc-Dec due to the difficulty of representing a long sequence with very high fidelity. This difficulty can be alleviated with the attention mechanism. However attention alone seems inadequate for handling the case where strict replication is needed.

A closer look (see Figure 3 for example) reveals that the decoder is dominated by copy-mode when moving into the subsequence to replicate, and switch to generate-mode after leaving this area, showing COPYNET can achieve a rather precise coordination of the two modes.

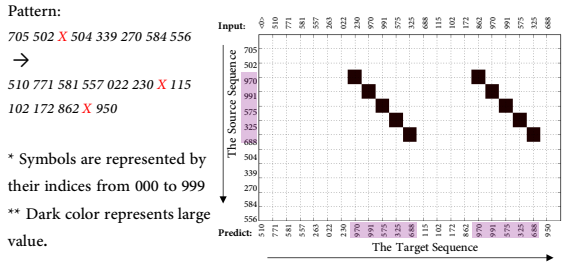

Figure 3: Example output of COPYNET on the synthetic dataset. The heatmap represents the activations of the copy-mode over the input sequence (left) during the decoding process (bottom).

5.2 Text Summarization

Automatic text summarization aims to find a condensed representation which can capture the core meaning of the original document. It has been recently formulated as a Seq2Seq learning problem in (Rush et al., 2015; Hu et al., 2015), which essentially gives *abstractive* summarization since the summary is generated based on a representation of the document. In contrast, *extractive* summarization extracts sentences or phrases from the original text to fuse them into the summaries, therefore making better use of the overall structure of the original document. In a sense, COPYNET for summarization lies somewhere between two categories, since part of output summary is actually extracted from the document (via the copying mechanism), which are fused together possibly with the words from the generate-mode.

Dataset: We evaluate our model on the recently published LCSTS dataset (Hu et al., 2015), a large scale dataset for short text summarization. The dataset is collected from the news medias on Sina Weibo[1] including pairs of (short news, summary) in Chinese. Shown in Table 2, PART II and III are manually rated for their quality from 1 to 5. Following the setting of (Hu et al., 2015) we use Part I as the training set and and the subset of Part III scored from 3 to 5 as the testing set.

Dataset	PART I	PART II	PART III
no. of pairs	2,400,591	10,666	1106
no. of score ≥ 3	-	8685	725

Table 2: Some statistics of the LCSTS dataset.

Experimental Setting: We try COPYNET that is based on character (+C) and word (+W). For the word-based variant the word-segmentation is obtained with jieba[2]. We set the vocabulary size to 3,000 (+C) and 10,000 (+W) respectively, which are much smaller than those for models in (Hu et al., 2015). For both variants we set the embedding dimension to 350 and the size of hidden layers to 500. Following (Hu et al., 2015), we evaluate the test performance with the commonly used ROUGE-1, ROUGE-2 and ROUGE-L (Lin, 2004), and compare it against the two models in (Hu et al., 2015), which are essentially canonical Encoder-Decoder and its variant with attention.

Models		ROUGE scores on LCSTS (%) R-1	R-2	R-L
RNN	+C	21.5	8.9	18.6
(Hu et al., 2015)	+W	17.7	8.5	15.8
RNN context	+C	29.9	17.4	27.2
(Hu et al., 2015)	+W	26.8	16.1	24.1
COPYNET	+C	**34.4**	**21.6**	**31.3**
	+W	**35.0**	**22.3**	**32.0**

Table 3: Testing performance of LCSTS, where "RNN" is canonical Enc-Dec, and "RNN context" its attentive variant.

It is clear from Table 3 that COPYNET beats the competitor models with big margin. Hu et al. (2015) reports that the performance of a word-based model is inferior to a character-based

Figure 4: Examples of COPYNET on LCSTS compared with RNN context. Word segmentation is applied on the input, where OOV words are underlined. The highlighted words (with different colors) are those words with copy-mode probability higher than the generate-mode. We also provide literal English translation for the document, the golden, and COPYNET, while omitting that for RNN context since the language is broken.

one. One possible explanation is that a word-based model, even with a much larger vocabulary (50,000 words in Hu et al. (2015)), still has a large proportion of OOVs due to the large number of entity names in the summary data and the mistakes in word segmentation. COPYNET, with its ability to handle the OOV words with the copying mechanism, performs however slightly better with the word-based variant.

5.2.1 Case Study

As shown in Figure 4, we make the following interesting observations about the summary from COPYNET: 1) most words are from copy-mode, but the summary is usually still fluent; 2) COPYNET tends to cover consecutive words in the original document, but it often puts together segments far away from each other, indicating a sophisticated coordination of content-based addressing and location-based addressing; 3) COPYNET handles OOV words really well: it can generate acceptable summary for document with many OOVs, and even the summary itself often contains many OOV words. In contrast, the canonical RNN-based approaches often fail in such cases.

It is quite intriguing that COPYNET can often find important parts of the document, a behavior with the characteristics of extractive summarization, while it often generate words to "connect" those words, showing its aspect of abstractive summarization.

5.3 Single-turn Dialogue

In this experiment we follow the work on neural dialogue model proposed in (Shang et al., 2015; Vinyals and Le, 2015; Sordoni et al., 2015), and test COPYNET on single-turn dialogue. Basically, the neural model learns to generate a response to user's input, from the given (input, response) pairs as training instances.

Dataset: We build a simple dialogue dataset based on the following three instructions:

1. Dialogue instances are collected from Baidu Tieba[3] with some coverage of conversations of real life e.g., greeting and sports, etc.
2. Patterns with slots like

   `hi, my name is` **x** $\rightarrow$ `hi,` **x**

   are mined from the set, with possibly multiple responding patterns to one input.
3. Similar with the synthetic dataset, we enlarge the dataset by filling the slots with suitable subsequence (e.g. name entities, dates, etc.)

To make the dataset close to the real conversations, we also maintain a certain proportion of instances with the response that 1) do not contain entities or 2) contain entities not in the input.

Experimental Setting: We create two datasets: DS-I and DS-II with slot filling on 173 collected patterns. The main difference between the two datasets is that the filled substrings for training and testing in DS-II have no overlaps, while in DS-I they are sampled from the same pool. For each dataset we use 6,500 instances for training and 1,500 for testing. We compare COPYNET with canonical RNNSearch, both character-based, with the same model configuration in Section 5.1.

	DS-I (%)		DS-II (%)	
Models	Top1	Top10	Top1	Top10
RNNSearch	44.1	57.7	13.5	15.9
COPYNET	**61.2**	**71.0**	**50.5**	**64.8**

Table 4: The decoding accuracy on the two testing sets. Decoding is admitted success only when the answer is found exactly in the Top-K outputs.

We compare COPYNET and RNNSearch on DS-I and DS-II in terms of top-1 and top-10 accuracy (shown in Table 4), estimating respectively the chance of the top-1 or one of top-10 (from beam search) matching the golden. Since there are often many good responses to an input, top-10 accuracy appears to be closer to the real world setting.

As shown in Table 4, COPYNET significantly outperforms RNNsearch, especially on DS-II. It suggests that introducing the copying mechanism helps the dialogue system master the patterns in dialogue and correctly identify the correct parts of input, often proper nouns, to replicate in the response. Since the filled substrings have no overlaps in DS-II, the performance of RNNSearch drops significantly as it cannot handle words unseen in training data. In contrast, the performance of COPYNET only drops slightly as it has learned to fill the slots with the copying mechanism and relies less on the representation of the words.

5.3.1 Case Study

As indicated by the examples in Figure 5, COPYNET accurately replicates the critical segments from the input with the copy-mode, and generates

[3] http://tieba.baidu.com

Figure 5: Examples from the testing set of DS-II shown as the input text and golden, with the outputs of RNNSearch and CopyNet. Words in red rectangles are unseen in the training set. The highlighted words (with different colors) are those words with copy-mode probability higher than the generate-mode. Green cirles (meaning correct) and red cross (meaning incorrect) are given based on human judgment on whether the response is appropriate.

the rest of the answers smoothly by the generate-mode. Note that in (2) and (3), the decoding sequence is not exactly the same with the standard one, yet still correct regarding to their meanings. In contrast, although RNNSearch usually generates answers in the right formats, it fails to catch the critical entities in all three cases because of the difficulty brought by the unseen words.

6 Related Work

Our work is partially inspired by the recent work of Pointer Networks (Vinyals et al., 2015a), in which a pointer mechanism (quite similar with the proposed copying mechanism) is used to predict the output sequence directly from the input. In addition to the difference with ours in application, (Vinyals et al., 2015a) cannot predict outside of the set of input sequence, while COPYNET can naturally combine generating and copying.

COPYNET is also related to the effort to solve the OOV problem in neural machine translation. Luong et al. (2015) introduced a heuristics to post-process the translated sentence using annotations on the source sentence. In contrast COPYNET addresses the OOV problem in a more systemic way with an end-to-end model. However, as COPYNET copies the exact source words as the output, it cannot be directly applied to machine translation. However, such copying mechanism can be naturally extended to any types of references except for the input sequence, which will help in applications with heterogeneous source and target sequences such as machine translation.

The copying mechanism can also be viewed as carrying information over to the next stage without any nonlinear transformation. Similar ideas are proposed for training very deep neural networks in (Srivastava et al., 2015; He et al., 2015) for classification tasks, where shortcuts are built between layers for the direct carrying of information.

Recently, we noticed some parallel efforts towards modeling mechanisms similar to or related to copying. Cheng and Lapata (2016) devised a neural summarization model with the ability to extract words/sentences from the source. Gulcehre et al. (2016) proposed a pointing method to handle the OOV words for summarization and MT. In contrast, COPYNET is more general, and not limited to a specific task or OOV words. Moreover, the softmaxCOPYNET is more flexible than gating in the related work in handling the mixture of two modes, due to its ability to adequately model the content of copied segment.

7 Conclusion and Future Work

We proposed COPYNET to incorporate copying into the sequence-to-sequence learning framework. For future work, we will extend this idea to the task where the source and target are in heterogeneous types, for example, machine translation.

Cross-domain Text Classification with Multiple Domains and Disparate Label Sets

Himanshu S. Bhatt, Manjira Sinha and Shourya Roy

Abstract

Advances in transfer learning have let go the limitations of traditional supervised machine learning algorithms for being dependent on annotated training data for training new models for every new domain. However, several applications encounter scenarios where models need to transfer/adapt across domains when the label sets vary both in terms of count of labels as well as their connotations. This paper presents first-of-its-kind transfer learning algorithm for cross-domain classification with multiple source domains and disparate label sets. It starts with identifying transferable knowledge from across multiple domains that can be useful for learning the target domain task. This knowledge in the form of selective labeled instances from different domains is congregated to form an auxiliary training set which is used for learning the target domain task. Experimental results validate the efficacy of the proposed algorithm against strong baselines on a real world social media and the 20 Newsgroups datasets.

1 Introduction

A fundamental assumption in supervised statistical learning is that training and test data are independently and identically distributed (i.i.d.) samples drawn from a distribution. Otherwise, good performance on test data cannot be guaranteed even if the training error is low. On the other hand, transfer learning techniques allow domains, tasks, and distributions used in training and testing to be different, but related. It works in contrast to traditional supervised techniques on the principle of transferring learned knowledge across domains. Pan and Yang, in their survey paper (2010), described different transfer learning settings depending on if domains and tasks vary as well as labeled data is available in one/more/none of the domains. In this paper, we propose a generic solution for multi-source transfer learning where domains and tasks are different and no labeled data is available in the target domain. This is a relatively less chartered territory and arguably a more generic setting of transfer learning.

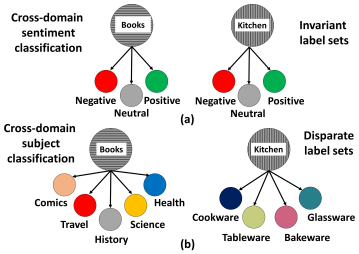

Figure 1: Cross-domain (a) sentiment classification and (b) subject classification. Illustrates (a) invariant and (b) disparate label sets.

Motivating example: Consider a social media consulting company helping brands to monitor their social media channels. Two problems typically of interest are: (i) sentiment classification (*is a post positive/negative/neutral?*) and (ii) subject classification (*what was the subject of a post?*). While sentiment classification attempts to classify a post based on its polarity, subject classification is towards identifying the subject (or topic) of the post, as illustrated in Figure 1. The company has been using standard classification techniques from an off-the-shelf machine learning toolbox. While machine learning toolkit helps them to create and apply statistical models efficiently, the same model can not be applied on a new collection due to variations in data distributions across collections[1]. It requires a few hundreds of manually labeled posts for every task on every collec-

[1]A collection comprises comments/posts pertaining to a particular client/product/services. Domain and collection are used interchangeably.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1641–1650,
Berlin, Germany, August 7-12, 2016.

tion. As social media are extremely high velocity and low retention channels, human labeling efforts act like that proverbial narrow bottleneck. Need of the hour was to reduce, if not eliminate, the human-intensive labeling stage while continue to use machine learning models for new collections.

Several transfer learning techniques exist in the literature which can reduce labeling efforts required for performing tasks in new collections. Tasks such as sentiment classification, named entity recognition (NER), part of speech (POS) tagging that have invariant label sets across domains, have shown to be greatly benefited from these works. On the other hand, tasks like subject classification that have disparate label sets across domains have not been able to gain at pace with the advances in transfer learning. Towards that we formulate the problem of *Cross-domain classification with disparate label sets* as learning an accurate model for the new unlabeled target domain given labeled data from multiple source domains where all domains have (possibly) different label sets.

Our contributions: To the best of our knowledge, this is the first work to explore the problem of cross-domain text classification with multiple source domains and disparate label sets. The other contributions of this work includes a simple yet efficient algorithm which starts with identifying transferable knowledge from across multiple source domains useful for learning the target domain task. Specifically, it identifies relevant class-labels from the source domains such that the instances in those classes can induce class-separability in the target domain. This transferable knowledge is accumulated as an auxiliary training set for an algorithm to learn the target domain classification task followed by suitable transformation of the auxiliary training instances.

Organization of the paper is as follows: Section 2 presents the preliminaries and notation, Section 3 summarizes the related work. Section 4 and 5 present the proposed algorithm and experimental results respectively. Section 6 concludes the paper.

2 Preliminaries and Notations

A domain $\mathcal{D} = \{\mathcal{X}, P(X)\}$ is characterized by two components: a feature space $\mathcal{X}$ and a marginal probability distribution $P(X)$, where $X = \{x_1, x_2, ...x_n\} \in \mathcal{X}$. A task $\mathcal{T} = \{\mathcal{Y}, f(\cdot)\}$ also consists of two components: a label space $\mathcal{Y}$ and an objective predictive function $f(\cdot)$.

In our settings for cross-domain classification with disparate label sets, we assume M source domains, denoted as $\mathcal{D}_{S_i}$, where $i = \{1, 2, ..M\}$. Each source domain has different marginal distribution i.e. $P(X_{S_i}) \neq P(X_{S_j})$ and different label space i.e. $\mathcal{Y}_{S_i} \neq \mathcal{Y}_{S_j}, \forall i, j \in M$. The label space across domains vary both in terms of count of class-labels as well as their connotations; however, a finite set of labeled instances are available from each source domain. The target domain ($\mathcal{D}_T$) consists of a finite set of unlabeled instances, denoted as t_i where $i = \{1, .., N\}$. Let $\mathcal{Y}_T$ be the target domain label space with K class-labels. We assume that the number of classes in the target domain i.e. K is known (analogous to clustering where the number of clusters is given).

3 Related Work

Table 1 summarizes different settings of transfer learning (Pan and Yang, 2010) and how this work differentiates from the existing literature[2]. The first scenario represents the ideal settings of traditional machine learning (Mitchell, 1997) where a model is trained on a fraction of labeled data and performs well for the same task on the future unseen instances from the same domain.

The second scenario where the domains vary while the tasks remain the same is referred to as transductive transfer learning. This is the most extensively studied settings in the transfer learning literature and can be broadly categorized as single and multi-source adaptation. Single source adaptation (Chen et al., 2009; Ando and Zhang, 2005; Daumé III, 2009) primarily aims at minimizing the divergence between the source and target domains either at instance or feature levels. The general idea being identifying a suitable low dimensional space where transformed source and target domains data follow similar distributions and hence, a standard supervised learning algorithm can be trained (Daumé III, 2009; Jiang and Zhai, 2007; Pan et al., 2011; Blitzer et al., 2007; Pan et al., 2010; Dai et al., 2007; Bhatt et al., 2015).

While several existing single source adaptation techniques can be extended to multi-source adaptation, the literature in multi-source adaptation can be broadly categorized as: 1) feature representation approaches (Chattopadhyay et al., 2012; Sun et al., 2011; Duan et al., 2009; Duan et al., 2012;

[2]This is not the complete view of the transfer learning literature; however, covers relevant work that helps motivate/differentiate the novel features of this paper.

Table 1: Summarizing the related work and differentiating the novel features of the proposed algorithm.

Scenario	Settings	Nature of Data	Learning Paradigm	Main Concepts	Our Differentiation
$\mathcal{D}_S = \mathcal{D}_T$, $\mathcal{T}_S = \mathcal{T}_T$	Traditional Machine learning	Labelled data in source domain(s) and unlabeled data in target domain	Source and target domains are exactly the same	Learn models on training set and test on future unseen data	Allows tasks across domains to be different;a more general setting
$\mathcal{D}_S \neq \mathcal{D}_T$, $\mathcal{T}_S = \mathcal{T}_T$	Transductive Transfer Learning	Labelled data in source domain(s) and unlabeled data from the target domain $\mathcal{P}(\mathcal{X}_S) \neq \mathcal{P}(\mathcal{X}_T)$	Single source domain adaptation	Learning common shared representation; instance weighing, parameter transfer	Exploits multiple sources each with disparate label sets.
			Multi-source adaptation	Classifier combination; efficient combination of information from multiple sources; Feature representation	Intelligent selection of transferable knowledge from multiple sources for adaptation.
No conditions on $\mathcal{D}_S$ & $\mathcal{D}_T$, but, $\mathcal{T}_S \neq \mathcal{T}_T$	Inductive Transfer Learning	Unlabeled data in source domain(s) and labeled data in target domain	Self-taught learning	Extracts higher level representations from unlabeled auxiliary data to learn instance-to-label mapping with labeled target instances	Learns instance-to-label mapping in the unlabeled target domain using multiple labeled source domains having different data distributions and label spaces.
		Labeled data is available in all domains	Multi-task learning	Simultaneously learns multiple tasks within (or across) domain(s) by exploiting the common feature subspace shared across the tasks	Learns the optimal class distribution in an unlabeled target domain by minimizing the differences with multiple labeled source domains.
$\mathcal{D}_S \neq \mathcal{D}_T$, $\mathcal{T}_S \neq \mathcal{T}_T$	Kim *et al.* (2015)	Labeled data in source and target domains	Transfer learning with disparate label set	Disparate fine grained label sets across domains, however, same coarse grained labels set can be invoked across domains	No coarse-to-fine label mapping due to heterogeneity of label sets, Assumes no labelled data in target domain.

Bollegala et al., 2013; Crammer et al., 2008; Mansour et al., 2009; Ben-David et al., 2010; Bhatt et al., 2016) and 2) combining pre-trained classifiers (Schweikert and Widmer, 2008; Sun and Shi, 2013; Yang et al., 2007; Xu and Sun, 2012; Sun et al., 2013). Our work differentiates in intelligently exploiting selective transferable knowledge from multiple sources unlike existing approaches where multiple sources contribute in a brute-force manner.

The third scenario where the tasks differ irrespective of the relationship among domains is referred to as inductive transfer learning. Self-taught learning (Raina et al., 2007) and multi-task (Jiang, 2009; Maurer et al., 2012; Xu et al., 2015; Kumar and Daume III, 2012) learning are the two main learning paradigms in this scenario and Table 1 differentiates our work from these.

This work closely relates to the fourth scenario where we allow domains to vary in the marginal probability distributions and the tasks to vary due to different label spaces[3]. The closest prior work by Kim *et al.* (2015) address a sequential labeling problem in NLU where the fine grained label sets across domains differ. However, they assume that there exists a bijective mapping between the coarse and fine-grained label sets across domains. They learn this mapping using labeled instances from the target domain to reduce the problem to a standard domain adaptation problem (Scenario 2).

[3]This work do not consider scenario when domains vary in feature spaces and tasks vary in the objective predictive functions.

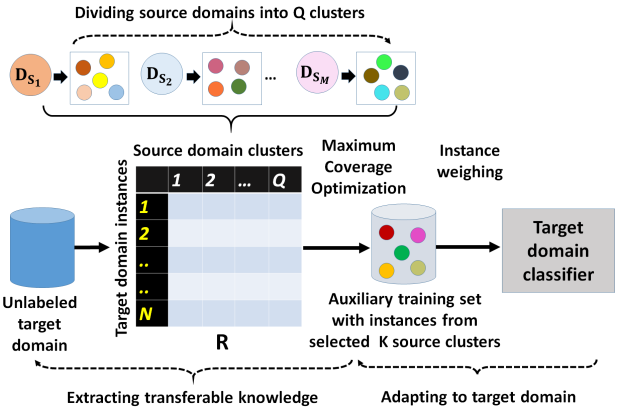

Figure 2: Illustrates different stages of the proposed algorithm.

However, this paper caters to multiple source domains with disparate label sets without assuming availability of any labeled data from the target domain or fine-to-coarse label mappings across domains.

4 Cross-domain Classification with Disparate Label Set

The underlying philosophy of the proposed algorithm is to learn the target domain task by using the available information from multiple source domains. To accomplish this, we have developed an algorithm to identify and extract partial transferable knowledge from multiple sources. This knowledge is then suitably transformed to induce classes in the target domain using the class separation from the source domains. Different stages of the proposed algorithm, as shown in Figure 2, are

elaborated in the next sections.

4.1 Exploiting Multiple Domains

If we had the mappings between the source and target domain label sets, we could have leveraged existing transfer learning approaches. However, heterogeneity of label sets across domains and the unlabeled data from the target domain exacerbate the problem. Our objective is to leverage the knowledge from multiple source domains to induce class-separability in the target domain. Inducing class-separability refers to segregating the target domain into K classes using labeled instances from selective K source domain classes.

Towards this, the proposed algorithm divides each source domain into clusters/groups based on the class-labels such that instances with the same label are grouped in one cluster. All source domains are divided into Q clusters where $Q = \sum_{m=1}^{M} ||Y_m||$ represents the count of class-labels across all sources. $||Y_m||$ being the count of class-labels in the m^{th} source domain. C_q denotes the q^{th} cluster and μ_q denotes its centroid computed as the average of all the members in the cluster. We assert that the target domain instances that have high similarity to a particular source domain cluster can be grouped together. Given N target domain instances and Q source domain clusters, a matrix R (dimension $N \times Q$) is computed based on the similarity of the target domain instances with the source clusters. The i^{th} row of the matrix captures the similarity of the i^{th} target domain instance (t_i) with all the source domain clusters. It captures how different source domain class-labels are associated with the target domain instances and hence, can induce class-separability in the target domain.

4.2 Extracting Transferable Knowledge

The similarity matrix R associates target domain instances to the source domain clusters in proportion to their similarity. However, the objective is to select the optimal K source domain clusters that fit the maximum number of target domain instances. This problem is similar to the well-known combinatorial optimization problem of Maximum Coverage (Vazirani, 2003) where given a collection of P sets, we need to select A sets ($A < P$) such that the size of the union of the selected sets is maximized. In this paper, we are given Q source domain clusters and need to select K clusters such that the corresponding number of associated target domain instances is maximized. As the Maximum Coverage problem is **NP**-hard, we implement a greedy algorithm for selecting the k source domain clusters, as illustrated in Algorithm 1.

Algorithm 1 Selecting K Source Clusters

Input: A matrix R, K = number target domain classes, l= number of selected cluster.
Initialize: $l = 0$, Normalize R such that each row sums up to 1.
repeat:
1: Pick the column in R which has maximum sum of similarity scores for uncovered target domain instances.
2: Mark elements in the chosen column as covered.
3: $l = l + 1$
until: $l = K$
Output: K source domain clusters.

A source domain contributes partially in terms of zero or more class-labels (clusters) identified using the Algorithm 1. Therefore, we refer to the labeled instances from the selected clusters of a source domain as the partial transferable knowledge from that domain. This partial transferable knowledge from across multiple source domains is congregated to form an auxiliary training set, referred to as (AUX).

4.3 Adapting to the Target Domain

The auxiliary training set comprises labeled instances from selected K source domain clusters[4]. Since, the auxiliary set is pulled out from multiple source domains, it follows different data distribution as compared to the target domain. For a classifier, trained on the K-class auxiliary training set, the distributional variations have to be normalized so that it can generalize well on the target domain.

In this research, we proposed to use an instance weighting technique (Jiang and Zhai, 2007) to minimize the distributional variations by deferentially weighting instances in the auxiliary set. Intuitively, the auxiliary training instances similar to the target domain are assigned higher weights while training the classifier and vice versa. The weight for the i^{th} instance in the auxiliary set should be proportional to the ratio $\frac{(P_t(x_i))}{(P_a(x_i))}$. However, since the actual probability distributions

[4]The K classes in auxiliary set induce class-separability in the target domain, however, the actual class-labels across these two may not have any sort of coarse-to-fine mapping.

Algorithm 2 Cross-domain Classification with Disparate Label Sets

Input: M source domains, target domain instances (t_i), $i = (1, ..., N)$, K = number of target domain classes.

Process: Divide M sources into Q clusters *s.t.* $Q = \sum_{q=1}^{M} |Y_m|$. C_q be the q^{th} cluster & μ_q be its centroid computed as shown in Eq 1.

A: Exploiting Multiple Sources:
for $i = 0$: till N **do**
  for $q = 0$: till Q **do**
    $R[i, q] = Sim(\mu_q, t_i)$
  end for
end for

B: Extracting partial knowledge:
1: Pick K columns from R using Algorithm 1.
2: Construct AUX by congregating instances from the selected K source domain class-labels.

C: Adapting to target domain:
1: Minimize distributional variations using instance weighing technique.
2: Train a K-class classifier using AUX.

Output: K-class target domain classifier.

($P_a(x)$ and $P_t(x)$ for the auxiliary set and target domain respectively) are unknown, the instance difference is approximated as $\frac{(P_t(x_i|d=target))}{(P_a(x_i|d=auxilliary))}$, where d is a random variable used to represent whether x_i came from the auxiliary set or the target domain. To calculate this ratio, a binary classifier is trained using the auxiliary set and target domain data with labels {-1} and {+1} respectively. The predicted probabilities from the classifier are used to estimate the ratio as the weight for the i^{th} auxiliary instance x_i. Finally, a K-class classifier is trained on the weighted auxiliary training set to perform classification on the target domain data.

4.4 Algorithm

As shown in Figure 2, the step-by-step flow of the proposed algorithm is summarized below:

1. Divide M source domains into Q clusters, each represented as C_q, $q = \{1, 2, .., Q\}$.

2. Compute centroid of each cluster as the average of the cluster members, as shown in Eq. 1.

$$\mu_q = \frac{1}{||C_q||} \sum_{(i=1;\mathbf{x}_i \in C_q)}^{||C_q||} \mathbf{x}_i \qquad (1)$$

where μ_q is the centroid, $||C_q||$ is the membership count and $\mathbf{x}_i$ is the i^{th} member of C_q.

3. For target instances t_i $\forall i \in N$, compute cosine similarity with all the source domain cluster centroids to form the matrix R (dimensions: $N \times Q$), as shown in Eq. 2

$$R[i, q] = Sim(\mu_q, \mathbf{t}_i) = \frac{\mu_q \cdot \mathbf{t}_i}{||\mu_q||\ ||\mathbf{t}_i||} \qquad (2)$$

4. Run Algorithm 1 on R to select K optimal source clusters (i.e. columns of R).

5. Congregate labeled instances from the selected source domain clusters to form the K-class auxiliary training set.

6. Minimize the divergence between the auxiliary set and target domain using the instance weighing technique, described in Section 4.3.

7. Finally, train a K-class classifier on deferentially weighted auxiliary training instances to perform classification in the target domain.

The K-class classifier trained on the auxiliary training set is an SVM classifier (Chih-Wei Hsu and Lin, 2003) with $L2 - loss$ from the LIBLINEAR library (Fan et al., 2008). The classifier used in the instance weighing technique is again an SVM classifier with RBF kernel. The proposed algorithm uses distributional embedding i.e. Doc2Vec (Le and Mikolov, 2014) to represent instances from the multiple source and target domains. We used an open-source implementation of Doc2Vec (Le and Mikolov, 2014) for learning 400 dimensional vector representation using DBoW.

5 Experimental Evaluation

Comprehensive experiments are performed to evaluate the efficacy of the proposed algorithm for cross-domain classification with disparate label sets across domains on two datasets.

5.1 Datasets

The first dataset is a real-world Online Social Media (OSM) dataset which consists of 74 collections. Each collection comprises comments/tweets that are collected based on user-defined keywords. These keywords are fed to a listening engine which crawls the social media (i.e. Twitter.com) and fetches comments matching the keywords. The task is to classify the comments in a collection

Table 2: Illustrates variability in label sets across some collections from the OSM dataset.

Apple iPhone 6	Apple iOS 8	Apple iPad mini3
Camera	Locking apps & features	Release date & Features
Design	Extensibility features	Apple play & NFC
Review link	General features related marketing	Apple sim card
Apple Play/NFC	Camera features	Touch ID
Comparison to Android	Password with touch integration	iPad mini3 - disappoints
Price	Health & fitness app	
Apple watch	Location & Maps	
	Firmware updates	

Table 3: Table illustrates the collections from the EMPATH database used in this research.

Collection ID	Domain	#Categories
Coll 1	Huwaei	5
Coll 2	Healthcare	9
Coll 3	Whattsapp	8
Coll 4	Apple iOS 8	8
Coll 5	Apple iPhone 6	7

into user-defined categories. These user-defined categories may vary across collections in terms of count as well as their connotations. Table 2 shows an example of the user-defined categories for a few collections related to "Apple" products. In the experiments, one collection is used as unlabeled target collection and the remaining collections are used as the labeled source collections. We randomly selected 5 target collections to report the performance, as described in Table 3.

The second dataset is the 20 Newsgroups (NG) (Lang, 1995) dataset which comprises $20,000$ news articles organized into 6 groups with different sub-groups both in terms of count as well as connotations, as shown in Figure 3(a). Two different experiments are performed on this dataset. In the first experiment ("**Exp-1**"), one group is considered as the target domain and the remaining 5 groups as the source domains. In the second experiment ("**Exp-2**"), one sub-group from each of the first five groups[5] is randomly selected to synthesize a target domain while all the groups (with the remaining sub-groups) are used as source domains. Figure 3(b) shows an example on how to synthesize target domains in "Exp-2". There are 720 possible target domains in this experiment and we report the average performance across all possible target domains, referred to as "Grp 7". The task in both the experiments is to categorize the target domain into its K categories (sub-groups) using labeled data from multiple source domains.

[5]Group-6 has only 1 sub-group, therefore, it is considered for synthesizing target domain in the experiments.

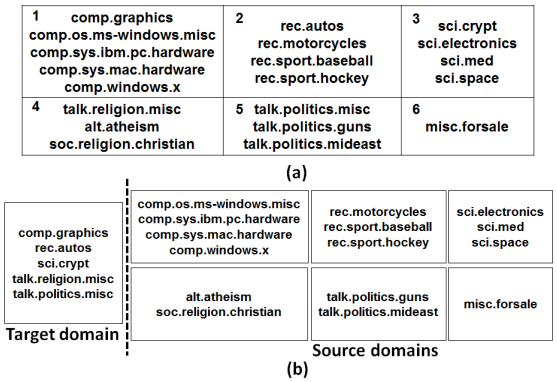

Figure 3: Illustrates (a) different groups (b) target domain synthesis ("EXP 2") on the NG dataset.

5.2 Evaluation Metric

The performance is reported in terms of classification accuracy on the target domain. There is no definite mapping between the actual class-labels in the target domain and the K categories (i.e. induced categories) in the auxiliary training set. Therefore, we sequentially evaluate all possible one-to-one mappings between the K categories in the auxiliary training set and target domain to report results for the best performing mapping.

5.3 Experimental Protocol

The performance of the proposed algorithm is skylined by the in-domain performance (**Gold**), i.e. a classifier trained and tested on the labeled target domain data. We also compared the performance with spherical K-means clustering (Dhillon and Modha, 2001) used to group the target domain data into K categories against the ground truth, referred to **CL**. Spherical K-means clustering is based on cosine similarity and performs better for high-dimensional sparse data such as text.

To compare with a baseline and an existing adaptation algorithm, we selected the most similar source domain[6] with exactly K number of class-labels and report the performance on the best possible mapping, as described in Section 5.2. To compute the baseline (**BL**), a classifier trained on the source domain is used to categorize the target domain. A widely used domain adaptation algorithm, namely structural correspondence learning (**SCL**) (Blitzer et al., 2007) is also applied using the selected source domain.

[6]The most similar source domain is selected using proxy-$\mathcal{A}$ distance (Blitzer et al., 2007) which has good correlation with domain adaptation performance.

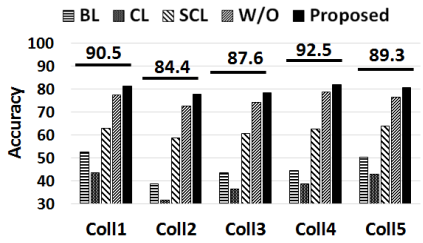

Figure 4: Compares the performance of different techniques on the OSM dataset.

Table 4: Summarizes the performance of the proposed algorithm on the OSM dataset.

Coll ID (#)	BL	CL	SCL	W/O	Proposed	Gold
Coll 1 (5)	52.6	43.7	62.8	77.4	81.4	90.5
Coll 2 (9)	38.6	31.8	58.8	72.5	77.6	84.4
Coll 3 (8)	43.6	36.4	60.7	74.2	78.5	87.6
Coll 4 (8)	44.7	38.8	62.5	78.8	82.1	92.5
Coll 5 (7)	50.5	42.8	64.4	76.6	80.5	89.3

5.4 Results and Analysis

Key observations and analysis from the experimental evaluations are summarized below:

5.4.1 Results on the OSM Dataset

Results in Figure 4 and Table 4 show the efficacy of the proposed algorithm for cross-domain classification with disparate label sets as it outperforms other approaches by at least 15%. Coll ID(#) refers to the target collection and the corresponding count of class-labels. Results in Table 4 also compare the performance of the proposed technique without the distributional normalization of the auxiliary training set, referred to as "W/O". Results suggest that suitably weighing instances from the auxiliary training set mitigates the distributional variations and enhances the cross-domain performance by at least 3.3%.

5.4.2 Results on the 20Newsgroups Dataset

Results in Table 5 show that the proposed algorithm outperforms other techniques for both the experiments by at least 15 % and 18% respectively on the 20 Newsgroups dataset. In Table 5, "-" refers to the cases where a single source domain with the same number of class-labels as in the target domain is not available. In "Exp-1" where the source and target categories vary in terms of counts as well as their connotations, the proposed algorithm efficiently induces the classes in the unlabeled target domain using the partial transferable knowledge from multiple sources. For "Exp-2", it is observed that the performance of the proposed algorithm is better than the performance in "Exp-1" as the target categories have closely related categories (from the same group) in the source domains. Table 5 reports the average performance across all the 720 possible combinations of target domains with a standard deviation of 2.6.

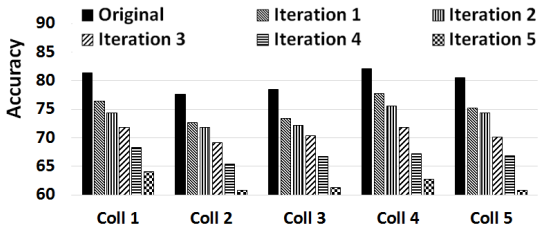

Figure 5: Effects of selected source collections on the OSM dataset.

Table 5: Summarizes the performance of the proposed algorithm on the 20Newsgroups dataset.

5.4.3 Effect of Multiple Source Domains

Table 6 validates our assertion that multiple sources are necessary to induce class-separability in the target domain as a single source is not sufficient to cater to the heterogeneity of class-labels across domains. It also suggests that the proposed algorithm can learn class-separability in the target domain by using arbitrary diverse class-labels from different sources and does not necessarily require class-labels to follow any sort of coarse-to-fine mapping across domains.

To evaluate the effects of using multiple sources, further experiments were performed by varying the number of available source domains. For the OSM dataset, we varied the number of available source collections from 1 to 73 starting with the most similar source collection and repeatedly adding the next most similar collection in the pool of available collections. We observe that even the most similar collection was not independently sufficient to induce classes in the target collection and it was favorable to exploit multiple collections. Moreover, adding collections based on similarity to the target collection had a better likelihood of achieving higher performance as compared to adding random collections.

In another experiment, we first identified the source collections which contributed to learning the target task. We removed these collections and applied the proposed algorithm on the remaining source collections. Figure 5 shows the perfor-

Table 6: Actual target domain class-labels and the corresponding source domain class clusters used to build the auxiliary training set.

Target Collection: Apple iOS 8	Associated Class-labels from multiple source collections
Locking apps & security	Anti Theft Features (**Coll ID:** 776 **on Apple iOS 6 plus**)
Extensibility features	Application update (**Coll ID:**720 **on Apple iOS Features**)

mance of the proposed algorithm on 5 such iterations of removing the contributing source collections from the previous iteration. We observed a significant drop in the performance with each iteration which signifies the effectiveness of the proposed algorithm in extracting highly discriminating transferable knowledge from multiple sources.

5.4.4 Comparing with Domain Adaptation

We applied domain adaptation techniques considering the auxiliary training set to be a single source domain with the same number of classes as that in the target domain. We applied two of the widely used domain adaptation techniques, namely SCL (Blitzer et al., 2007) and SFA (Pan et al., 2010) referred to as "AuxSCL" and "AuxSFA" respectively. Results in Table 7 suggest that the proposed algorithm significantly outperforms "AuxSCL" and "AuxSFA" on the two datasets. Generally, existing domain adaptation techniques are built on the co-occurrences of the common features with the domain specific features and hence, capture how domain specific features in one domain behaves w.r.t to the domain specific features in the other domain. They assume homogeneous labels and expect the aligned features across domains to behave similarly for the prediction task. However, these features are misaligned when the label set across domains vary in terms of their connotations.

5.4.5 Effect of Different Representations

The proposed algorithm uses Doc2Vec (Le and Mikolov, 2014) for representing instances from multiple domains. However, the proposed algorithm can build on different representations and hence, we compare its performance with traditional TF-IDF representation (including unigrams and bigrams) and a dense representation using TF-IDF+PCA (reduced to a dimension such that it covers 90% of the variance). We observe that Doc2Vec representation clearly outperforms the other two representations as it addresses the drawbacks of bag-of n-gram models in terms of implicitly inheriting the semantics of the words in a document and offering a more generalizable concise vector representation.

Table 7: Comparing the proposed algorithm with existing domain adaptation algorithms.

6 Conclusions

This paper presented the first study on cross-domain text classification in presence of multiple domains with disparate label sets and proposed a novel algorithm for the same. It proposed to extract partial transferable knowledge from across multiple source domains which was beneficial for inducing class-separability in the target domain. The transferable knowledge was assimilated in terms of selective labeled instances from different source domain to form a K-class auxiliary training set. Finally, a classifier was trained using this auxiliary training set, following a distribution normalizing instance weighing technique, to perform the classification task in the target domain. The efficacy of the proposed algorithm for cross-domain classification across disparate label sets will expand the horizon for ML-based algorithms to be more widely applicable in more general and practically observed scenarios.

Abstract

Languages with rich inflectional morphology exhibit lexical data sparsity, since the word used to express a given concept will vary with the syntactic context. For instance, each count noun in Czech has 12 forms (where English uses only singular and plural). Even in large corpora, we are unlikely to observe all inflections of a given lemma. This reduces the vocabulary coverage of methods that induce continuous representations for words from distributional corpus information. We solve this problem by exploiting existing morphological resources that can enumerate a word's component morphemes. We present a latent-variable Gaussian graphical model that allows us to extrapolate continuous representations for words not observed in the training corpus, as well as smoothing the representations provided for the observed words. The latent variables represent embeddings of morphemes, which combine to create embeddings of words. Over several languages and training sizes, our model improves the embeddings for words, when evaluated on an analogy task, skip-gram predictive accuracy, and word similarity.

1 Introduction

Representations of words as high-dimensional real vectors have been shown to benefit a wide variety of NLP tasks. Because of this demonstrated utility, many aspects of vector representations have been explored recently in the literature. One of the most interesting discoveries is that these representations capture meaningful morpho-syntactic and semantic properties through very simple linear relations: in a semantic vector space, we observe that

$$v_{talked} - v_{talk} \approx v_{drank} - v_{drink}. \quad (1)$$

That this equation approximately holds across many morphologically related 4-tuples indicates that the learned embeddings capture a feature of English morphology—adding the past tense feature roughly corresponds to adding a certain vector. Moreover, manipulating this equation yields what we will call the **vector offset method** (Mikolov et al., 2013c) for approximating other vectors. For instance, if we only know the vectors for the Spanish words *comieron* (*ate*), *comemos* (*eat*) and *bebieron* (*drank*), we can produce an approximation of the vector for *bebemos* (*drink*), as shown in Figure 1.

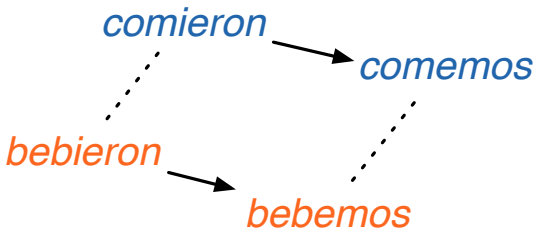

Figure 1: A visual depiction of the vector offset method for morpho-syntactic analogies in $\mathbb{R}^2$. We expect *bebieron* and *bebemos* to have the same relation (vector offset shown as solid vector) as *comieron* and *comemos*.

Many languages exhibit much richer morphology than English. While English nouns commonly take two forms – singular and plural—Czech nouns take 12 and Turkish nouns take over 30. This increase in word forms per lemma creates considerable data sparsity. Fortunately, for many languages there exist large morphological lexicons, or better yet, morphological tools that can analyze *any* word form—meaning that we have analyses (usually accurate) for forms that were unobserved or rare in our training corpus.

Our proposed method runs as a fast post-processor (taking under a minute to process 100-dimensional embeddings of a million observed word types) on the output of any existing tool that constructs word embeddings, such as WORD2VEC.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1651–1660,
Berlin, Germany, August 7-12, 2016.

	Indicative		Subjunctive	
	Sg	Pl	Sg	Pl
1	bebo	bebemos	beba	bebamos
2	bebes	bebéis	bebas	bebáis
3	bebe	beben	beba	beban

Table 1: The paradigm of the Spanish verb BEBER (to drink). The paradigm actually consists of > 40 word forms; only the present tense portion is shown here.

In this output, some embeddings are noisy or missing, due to sparse training data. We correct these problems by using a Gaussian graphical model that jointly models the embeddings of morphologically related words. Inference under this model can smooth the noisy embeddings that were observed in the WORD2VEC output. In the limiting case of a word for which no embedding was observed (equivalent to infinite noise), inference can extrapolate one based on the observed embeddings of related words—a kind of global version of the vector offset method. The *structure* of our graphical model is defined using morphological lexicons, which supply analyses for each word form.

We conduct a comprehensive study of our ability to modify and generate vectors across five languages. Our model also dramatically improves performance on the morphological analogy task in many cases: e.g., accuracy at selecting the nominative plural forms of Czech nouns is 89%, ten times better than the standard analogy approach.

2 Background: Inflectional Morphology

Many languages require every verb token to be inflected for certain properties, such as person, number, tense, and mood. A verbal **paradigm** such as Table 1 lists all the inflected forms of a given verb. We may refer to this verb in the abstract by its **lemma**, BEBER—but when using it in a sentence, we must instead select from its paradigm the word type, such as *bebéis*, that expresses the contextually appropriate properties. Noun tokens in a language may similarly be required to be inflected for properties such as case, gender, and number.

A content word is chosen by specifying a lemma (which selects a particular paradigm) together with some inflectional attributes (which select a particular slot within that paradigm). For example, [Lemma=EAT, Person=3, Number=SINGULAR, Tense=PRESENT] is a bundle of attribute-value pairs that would be jointly expressed in English by the word form *eats* (Sylak-Glassman et al., 2015).

The regularities observed by Mikolov et al. (2013c) hold between words with similar attribute-value pairs. In Spanish, the word *beben* "they drink" (Table 1) can be analyzed as expressing the bundle [Lemma=BEBER, Person=3, Number=PLURAL, Tense=PRESENT]. Its vector similarity to *bebemos* "we drink" is due to the fact that both word forms have the same lemma BEBER. Likewise, the vector similarity of *beben* to *comieron* "they ate" is due to the conceptual similarity of their lemmas, BEBER "drink" and COMER "eat". Conversely, that *beben* is similar to *preguntan* "they ask" is caused by shared inflectional attributes [Person=3, Number=PLURAL, Tense=PRESENT]. Under cosine similarity, the most similar words are often related on both axes at once: e.g., one of the word forms closest to *beben* typically is *comen* "they eat".

3 Approach

Following this intuition, we fit a directed Gaussian graphical model (GGM) that simultaneously considers (i) each word's embedding (obtained from an embedding model like WORD2VEC) and (ii) its morphological analysis (obtained from a lexical resource). We then use this model to smooth the provided embeddings, and to generate embeddings for unseen inflections. For a lemma covered by the resource, the GGM can produce embeddings for all its forms (if at least one of these forms has a known embedding); this can be extended to words not covered using a guesser like MORFESSOR (Creutz and Lagus, 2007) or CHIPMUNK (Cotterell et al., 2015a).

A major difference of our approach from related techniques is that our model uses existing morphological resources (e.g., morphological lexicons or finite-state analyzers) rather than semantic resources (e.g., WordNet (Miller et al., 1990) and PPDB (Ganitkevitch et al., 2013)). The former tend to be larger: we often can analyze more words than we have semantic representations for.

It would be possible to *integrate* our GGM into the training procedure for a word embedding system, making that system sensitive to morphological attributes. However, the *postprocessing* approach in our present paper lets us use any existing word embedding system as a black box. It is simple to implement, and turns out to get excellent results, which will presumably improve further as

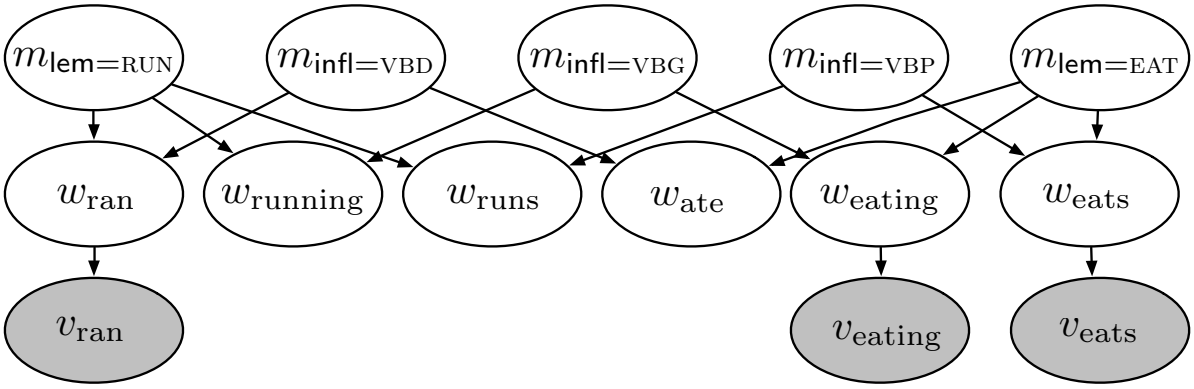

Figure 2: A depiction of our directed Gaussian graphical model (GGM) for the English verbal paradigm. Each variable represents a vector in $\mathbb{R}^n$; thus, this is not the traditional presentation of a GGM in which each node would be a *single real-valued random variable*, but each node represents a *real-valued random vector*. The shaded nodes v_i at the bottom are observed word embeddings. The nodes w_i at the middle layer are smoothed or extrapolated word embeddings. The nodes m_k at the top are latent embeddings of morphemes.

better black boxes become available.

4 A Generative Model

Figure 2 draws our GGM's structure as a Bayes net. In this paper, we loosely use the term "morpheme" to refer to an attribute-value pair (possibly of the form Lemma=...). Let $\mathcal{M}$ be the set of all morphemes. In our model, each morpheme $k \in \mathcal{M}$ has its *own* latent embedding $m_k \in \mathbb{R}^n$. These random variables are shown as the top layer of Figure 2. We impose an IID spherical Gaussian prior on them (similar to L_2 regularization with strength $\lambda > 0$):

$$m_k \sim \mathcal{N}(\mathbf{0}, \lambda^{-1} I), \ \forall k \tag{2}$$

Let $\mathcal{L}$ be the lexicon of all word types that appear in our lexical resource. (The noun and verb senses of *bat* are separate entries in $\mathcal{L}$.) In our model, each word $i \in \mathcal{L}$ has a latent embedding $w_i \in \mathbb{R}^n$. These random variables are shown as the middle layer of Figure 2. We assume that each w_i is simply a *sum* of the m_k for its component morphemes $M_i \subseteq \mathcal{M}$ (shown in Figure 2 as w_i's parents), *plus* a Gaussian perturbation:

$$w_i \sim \mathcal{N}(\sum_{k \in M_i} m_k, \Sigma_i), \ \forall i \tag{3}$$

This perturbation models idiosyncratic usage of word i that is not predictable from its morphemes. The covariance matrix Σ_i is shared for all words i with the same coarse POS (e.g., VERB).

Our system's *output* will be a guess of all of the w_i. Our system's *input* consists of noisy estimates v_i for some of the w_i, as provided by a black-box word embedding system run on some large corpus $\mathcal{C}$. (Current systems estimate the same vector for both senses of *bat*.) These observed random variables are shown as the bottom layer of Figure 2. We assume that the black-box system would have recovered the "true" w_i if given enough data, but instead it gives a noisy small-sample estimate

$$v_i \sim \mathcal{N}(w_i, \tfrac{1}{n_i}\Sigma_i'), \ \forall i \tag{4}$$

where n_i is the count of word i in training corpus $\mathcal{C}$.

This formula is inspired by the central limit theorem, which guarantees that v_i's distribution would approach (4) (as $n_i \to \infty$) if it were estimated by averaging a set of n_i noisy vectors drawn IID from *any* distribution with mean w_i (the truth) and covariance matrix Σ_i'. A system like WORD2VEC does not precisely do that, but it does choose v_i by aggregating (if not averaging) the influences from the contexts of the n_i tokens.

The parameters $\lambda, \Sigma_i, \Sigma_i'$ now have likelihood

$$p(\boldsymbol{v}) = \int p(\boldsymbol{v}, \boldsymbol{w}, \boldsymbol{m}) \, d\boldsymbol{w} \, d\boldsymbol{m}, \text{ where} \tag{5}$$

$$p(\boldsymbol{v}, \boldsymbol{w}, \boldsymbol{m}) = \prod_{k \in \mathcal{M}} p(m_k) \cdot \prod_{i \in \mathcal{L}} p(w_i \,|\, m_k : k \in M_i) \cdot p(v_i \,|\, w_i) \tag{6}$$

Here $\boldsymbol{m} = \{m_k : k \in \mathcal{M}\}$ represents the collection of all latent morpheme embeddings, and similarly $\boldsymbol{w} = \{w_i : i \in \mathcal{L}\}$ and $\boldsymbol{v} = \{v_i : i \in \mathcal{L}\}$. We take $p(v_i \mid w_i) = 1$ if no observation v_i exists.

How does the model behave qualitatively? If $\hat{w}_i$ is the MAP estimate of w_i, then $\hat{w}_i \to v_i$ as $n_i \to \infty$, but $\hat{w}_i \to \sum_{k \in M_i} m_k$ as $n_i \to 0$. This

is because (3) and (4) are in tension; when n_i is small, (4) is weaker and we get more smoothing. The morpheme embeddings m_k are largely determined from the observed embeddings v_i of the frequent words (since m_k aims via (2)–(3) to explain w_i, which $\approx v_i$ when i is frequent). That determines the compositional embedding $\sum_{k \in M_i} m_k$ toward which the w_i of a rarer word is smoothed (away from v_i). If v_i is not observed or if $n_i = 0$, then $\hat{w}_i = \sum_{k \in M_i} m_k$ exactly.

5 Inference

Suppose first that the model parameters are known, and we want to reconstruct the latent vectors w_i. Because the joint density $p(\boldsymbol{v}, \boldsymbol{w}, \boldsymbol{m})$ in (6) is a product of (sometimes degenerate) Gaussian densities, it is itself a highly multivariate Gaussian density over all elements of all vectors.[1] Thus, the posterior marginal distribution of each w_i is Gaussian as well. A good deal is known about how to exactly compute these marginal distributions of a Gaussian graphical model (e.g., by matrix inversion) or at least their means (e.g., by belief propagation) (Koller and Friedman, 2009).

For this paper, we adopt a simpler method—MAP estimation of all latent vectors. That is, we seek the $\boldsymbol{w}, \boldsymbol{m}$ that jointly maximize (6). This is equivalent to minimizing

$$\sum_k \lambda ||m_k||_2^2 + \sum_i ||w_i - \sum_{k \in M_i} m_k||_{\Sigma_i}^2 + \sum_i ||v_i - w_i||_{\Sigma_i'/n_i}^2, \quad (7)$$

which is a simple convex optimization problem.[2] We apply block coordinate descent until numerical convergence, in turn optimizing each vector m_k or w_i with all other vectors held fixed. This finds the global minimum (convex objective) and is extremely fast even when we have over a hundred million real variables. Specifically, we update

$$m_k \leftarrow \big(\lambda I + \sum_{i \in W_k} \mathfrak{T}_i\big)^{-1} \sum_{i \in W_k} \mathfrak{T}_i (w_i - \sum_{j \in M_i, j \neq k} m_j),$$

where $\mathfrak{T} \stackrel{\text{def}}{=} \Sigma^{-1}$ is the inverse covariance matrix and $W_k \stackrel{\text{def}}{=} \{i : k \in M_i\}$. This updates m_k so the partial derivatives of (7) with respect to the components of m_k are 0. In effect, this updates m_k to a *weighted average* of several vectors. Morpheme k participates in words $i \in W_k$, so its vector m_k is updated to the average of the contributions $(w_i - \sum_{j \in M_i, j \neq k} m_j)$ that m_k would *ideally* make to the embeddings w_i of those words. The contribution of w_i is "weighted" by the inverse covariance matrix $\mathfrak{T}_i$. Because of prior (2), $\mathbf{0}$ is also included in the average, "weighted" by λI.

Similarly, the update rule for w_i is

$$w_i \leftarrow (n_i \mathfrak{T}_i' + \mathfrak{T}_i)^{-1} \big(n_i \mathfrak{T}_i' v_i + \mathfrak{T}_i \sum_{k \in M_i} m_k\big),$$

which can similarly be regarded as a weighted average of the observed and compositional representations.[3] See Appendix C for the derivations.

6 Parameter Learning

We wish to optimize the model parameters $\lambda, \Sigma_i, \Sigma_i'$ by empirical Bayes. That is, we do not have a prior on these parameters, but simply do maximum likelihood estimation. A standard approach is the Expectation-Maximization or EM algorithm (Dempster et al., 1977) to *locally* maximize the likelihood. This alternates between reconstructing the latent vectors given the parameters (E step) and optimizing the parameters given the latent vectors (M step). In this paper, we use the Viterbi approximation to the E step, that is, MAP inference as described in section 5. Thus, our overall method is Viterbi EM.

As all conditional probabilities in the model are Gaussian, the M step has closed form. MLE estimation of a covariance matrix is a standard result—in our setting the update to Σ_i takes the form:

$$\Sigma_c \leftarrow \frac{1}{N_c} \sum_{i : c \in C(i)} (w_i - \sum_{k \in M_i} m_k)(w_i - \sum_{k \in M_i} m_k)^T,$$

where $C(i)$ are i's POS tags, $N_c = |\{i | c \in C(i)\}|$ and Σ_c is the matrix for the c^{th} POS tag (the matrices are tied by POS). In this paper we simply fix $\Sigma_i' = I$ rather than fitting it.[4] Also, we tune the hyperparameter λ on a development set, using grid search over the values $\{0.1, 0.5, 1.0\}$.

[1] Its inverse covariance matrix is highly sparse: its pattern of non-zeros is related to the graph structure of Figure 2. (Since the graphical model in Figure 2 is *directed*, the inverse covariance matrix has a sparse Cholesky decomposition that is even more directly related to the graph structure.)

[2] By definition, $||\boldsymbol{x}||_A^2 \stackrel{\text{def}}{=} \boldsymbol{x}^T A \boldsymbol{x}$.

[3] If v_i is not observed, take $n_i = 0$. In fact it is not necessary to represent this w_i during optimization. Simply omit i from all W_k. *After* convergence, set $w_i \leftarrow \sum_{k \in M_i} m_k$.

[4] Note that it is not necessary to define it as $\lambda' I$, introducing a new scale parameter λ', since doubling λ' would have the same effect on the MAP update rules as halving λ and Σ_i.

Viterbi EM can be regarded as block coordinate descent on the negative log-likelihood function, with E and M steps both improving this common objective along different variables. We update the parameters (M step above) after each 10 passes of updating the latent vectors (section 5's E step).

7 Related Work

Our postprocessing strategy is inspired by Faruqui et al. (2015), who designed a retrofitting procedure to modify pre-trained vectors such that their relations match those found in semantic lexicons. We focus on morphological resources, rather than semantic lexicons, and employ a generative model. More importantly, in addition to modifying vectors of observed words, our model can generate vectors for forms not observed in the training data.

Wieting et al. (2015) compute compositional embeddings of *phrases*, with their simplest method being additive (like ours) over the phrase's words. Their embeddings are tuned to fit observed phrase similarity scores from PPDB (Ganitkevitch et al., 2013), which allows them to smooth and extend PPDB just as we do to WORD2VEC output.

Using morphological resources to enhance embeddings at *training* time has been examined by numerous authors. Luong et al. (2013) used MORFESSOR (Creutz and Lagus, 2007), an unsupervised morphological induction algorithm, to segment the training corpus. They then trained a recursive neural network (Goller and Kuchler, 1996; Socher, 2014) to generate compositional word embeddings. Our model is much simpler and faster to train. Their evaluation was limited to English and focused on rare English words. dos Santos and Zadrozny (2014) introduced a neural tagging architecture (Collobert et al., 2011) with a character-level convolutional layer. Qiu et al. (2014) and Botha and Blunsom (2014) both use MORFESSOR segmentations to augment WORD2VEC and a log-bilinear (LBL) language model (Mnih and Hinton, 2007), respectively. Similar to us, they have an additive model of the semantics of morphemes, i.e., the embedding of the word form is the *sum* of the embeddings of its constituents. In contrast to us, however, both include the word form itself in the sum. Finally, Cotterell and Schütze (2015) jointly trained an LBL language model and a morphological tagger (Hajič, 2000) to encourage the embeddings to encode rich morphology. With the exception of (Cotterell and Schütze, 2015), all of the above methods use *unsupervised* methods to infuse word embeddings with morphology. Our approach is supervised in that we use a morphological lexicon, i.e., a manually built resource.

Our model is also related to other generative models of real vectors common in machine learning. The simplest of them is probabilistic principal component analysis (Roweis, 1998; Tipping and Bishop, 1999), a generative model of matrix factorization that explains a set of vectors via latent low-dimensional vectors. Probabilistic canonical correlation analysis similarly explains a set of *pairs* of vectors (Bach and Jordan, 2005).

Figure 2 has the same topology as our graphical model in (Cotterell et al., 2015b). In that work, the random variables were *strings* rather than vectors. Morphemes were combined into words by concatenating strings rather than adding vectors, and then applying a stochastic edit process (modeling phonology) rather than adding Gaussian noise.

8 Experiments

We perform three experiments to test the ability of our model to improve on WORD2VEC. To reiterate, our approach does not generate or analyze a word's spelling. Rather, it uses an *existing* morphological analysis of a word's spelling (constructed manually or by a rule-based or statistical system) as a resource to improve its embedding.

In our first experiment, we attempt to identify a corpus word that expresses a given set of morphological attributes. In our second experiment, we attempt to use a word's embedding to predict the words that appear in its context, i.e., the skip-gram objective of Mikolov et al. (2013a). Our third example attempts to use word embeddings to predict human similarity judgments.

We experiment on 5 languages: Czech, English, German, Spanish and Turkish. For each language, our corpus data consists of the full Wikipedia text. Table 5 in Appendix A reports the number of types and tokens and their ratio. The lexicons we use are characterized in Table 6: MorfFlex CZ for Czech (Hajič and Hlaváčová, 2013), CELEX for English and German (Baayen et al., 1993) and lexicons for Spanish and Turkish that were scraped from Wiktionary by Sylak-Glassman et al. (2015).

Given a finite training corpus $\mathcal{C}$ and a lexicon $\mathcal{L}$,[5] we generate embeddings v_i for all word

[5] $\mathcal{L}$ is finite in our experiments. It could be infinite (though still incomplete) if a morphological guesser were used.

Table 2: The two tables show how the Gaussian graphical model (GGM) compares to various analogies on Czech nouns (left) and Spanish verbs (right).The numbers in each cell represent the accuracy (larger is better). The columns represent the inflection of the word i to be predicted. Our GGM model is the top row. The other rows subdivide the baseline analogy results according to the inflection of source word a. Abbreviations: in the Czech noun table (left), the first word indicates the case and the second the number, e.g., Dat Sg = Dative Singular. In the Spanish verb table (right), the first word is the person and number and the second the tense, e.g., 3pp Pt = 3rd-person plural past.

types $i \in \mathcal{C}$, using the GENSIM implementation (Řehůřek and Sojka, 2010) of the WORD2VEC hierarchical softmax skip-gram model (Mikolov et al., 2013a), with a context size of 5. We set the dimension n to 100 for all experiments.[6]

We then apply our GGM to generate smoothed embeddings w_i for all word types $i \in \mathcal{C} \cap \mathcal{L}$. (Recall that the noun and verb sense of *bats* are separate types in $\mathcal{L}$, even if conflated in $\mathcal{C}$, and get separate embeddings.) How do we handle other word types? For an out-of-vocabulary (OOV) test word $i \notin \mathcal{C}$, we will extrapolate $w_i \leftarrow \sum_{k \in M_i} m_k$ on demand, as the GGM predicts, provided $i \in \mathcal{L}$. If any of these morphemes m_k were themselves never seen in $\mathcal{C}$, we back off to the mode of the prior to take $m_k = \mathbf{0}$.[7] Our experiments also encounter out-of-lexicon (OOL) test words $i \notin \mathcal{L}$, for which we have no morphological analysis; here we take $w_i = v_i$ (unsmoothed) if $i \in \mathcal{C}$ and $w_i = \mathbf{0}$ otherwise.

8.1 Experiment 1: Extrapolation vs. Analogy

Our first set of experiments uses embeddings for word selection. Our prediction task is to identify the unique word $i \in \mathcal{C}$ that expresses the morphological attributes M_i. To do this, we predict a target embedding x, and choose the most similar unsmoothed word by cosine distance, $\hat{\imath} = \text{argmax}_{j \in \mathcal{C}}\, v_j \cdot x$. We are scored correct if $\hat{\imath} = i$. Our experimental design ensures that $i \notin \mathcal{L}$, since if it were, we could trivially find i simply by consulting $\mathcal{L}$. The task is to identify *missing* lexical entries, by exploiting the distributional properties in $\mathcal{C}$.[8] Given the input bundle M_i, our method predicts the embedding $x = \sum_{k \in M_i} m_k$, and so looks for a word $j \in \mathcal{C}$ whose unsmoothed embedding $v_j \approx x$. The GGM's role here is to predict that the bundle M_i will be realized by something like x.

The baseline method is the analogy method of equation (1). This predicts the embedding x via the vector-offset formula $v_a + (v_b - v_c)$, where $a, b, c \in \mathcal{C} \cap \mathcal{L}$ are three other words sharing i's coarse part of speech such that M_i can be expressed as $M_a + (M_b - M_c)$.[9] Specifically, the baseline chooses a, b, c uniformly at random from all possibilities. (This is not too inefficient: given a, at most one choice of (b, c) is possible.) Note that the baseline extrapolates from the unsmoothed embeddings of 3 other words, whereas the GGM considers *all* words in $\mathcal{C} \cap \mathcal{L}$ that share i's morphemes.

[6] An additional important hyperparameter is the number of epochs. The default value in the GENSIM package is 5, which is suitable for larger corpora. We use this value for Experiments 1 and 3. Experiment 2 involves training on smaller corpora and we found it necessary to set the number of epochs to 10.

[7] One could in principle learn "backoff morphemes." For instance, if *borogoves* is analyzed as [Lemma=OOV_NOUN, Num=PL], we might want $m_{\text{Lemma=OOV\_NOUN}} \neq \mathbf{0}$ to represent novel *nouns*.

[8] The argmax selection rule does not exploit the fact that the entry is missing: it is free to incorrectly return some $\hat{\imath} \in \mathcal{L}$.

[9] More formally, $\overline{M_i} = \overline{M_a} + (\overline{M_b} - \overline{M_c})$, if we define $\overline{M}$ by $(\overline{M})_k = \mathbb{I}(k \in M)$ for all morphemes $k \in \mathcal{M}$. This converts morpheme bundle M to a $\{0, 1\}$ indicator vector $\overline{M}$ over $\mathcal{M}$.

Table 3: Test results for Experiment 1. The rows indicate the inflection of the test word i to be predicted (superscript ^{P} indicates plural, superscript ^{S} singular). The columns indicate the prediction method. Each number is an average over 10 training-test splits. Improvements marked with a $\star$ are statistically significant ($p < 0.05$) under a paired permutation test over these 10 runs.

Experimental Setup: A lexical resource consists of pairs (word form i, analysis M_i). For each language, we take a random 80% of these pairs to serve as the training lexicon $\mathcal{L}$ that is seen by the GGM. The remaining pairs are used to construct our prediction problems (given M_i, predict i), with a random 10% each as dev and test examples. We compare our method against the baseline method on ten such random training-test splits. We are releasing all splits for future research.

For some dev and test examples, the baseline method has no choice of the triple a, b, c. Rather than score these examples as incorrect, our baseline results do not consider them at all (which inflates performance). For each remaining example, to reduce variance, the baseline method reports the average performance on up to 100 a, b, c triples sampled uniformly without replacement.

The automatically created analogy problems ($a, b, c \rightarrow i$) solved by the baseline are similar to those of Mikolov et al. (2013c). However, most previous analogy evaluation sets evaluate only on 4-tuples of frequent words (Nicolai et al., 2015), to escape the need for smoothing, while ours also include infrequent words. Previous evaluation sets also tend to be translations of the original English datasets—leaving them impoverished as they therefore *only* test morpho-syntactic properties found *in English*. E.g., the German analogy problems of Köper et al. (2015) do not explore the four cases and two numbers in the German adjectival system. Thus our baseline analogy results are useful as a more comprehensive study *of the vector offset method for randomly sampled words*.

Results: Overall results for 5 languages are shown in Table 3. Additional rows break down performance by the inflection of the target word i. (The inflections shown are the ones for which the *baseline* method is most accurate.)

For almost all target inflections, GGM is significantly better than the analogy baseline. An extreme case is the vocative plural in Czech, for which GGM predicts vectors better by more than 70%. In other cases, the margin is slimmer; but GGM loses only on predicting the Spanish feminine singular participle. For Czech, German, English and Spanish the results are clear—GGM yields better predictions. This is not surprising as our method incorporates information from *multiple* morphologically related forms.

More detailed results for two languages are given in Table 2. Here, each row constrains the source word a to have a certain inflectional tag; again we average over up to 100 analogies, now chosen under this constraint, and again we discard a test example i from the test set if no such analogy exists. The GGM row considers all test examples.

Past work on morphosyntactic analogies has generally constrained a to be the unmarked (lemma) form (Nicolai et al., 2015). However, we observe that it is easier to predict one word form from another starting from a form that is "closer" in morphological space. For instance, it is easier to predict Czech forms inflected in the genitive plural from forms in nominative plural, rather than the nominative singular. Likewise, it is easier to predict a singular form from another singular form rather than from a plural form. It also is easier to predict partially syncretic forms, i.e., two inflected forms that share the same orthographic string; e.g., in Czech the nominative plural and the accusative plural are identical for inanimate nouns.

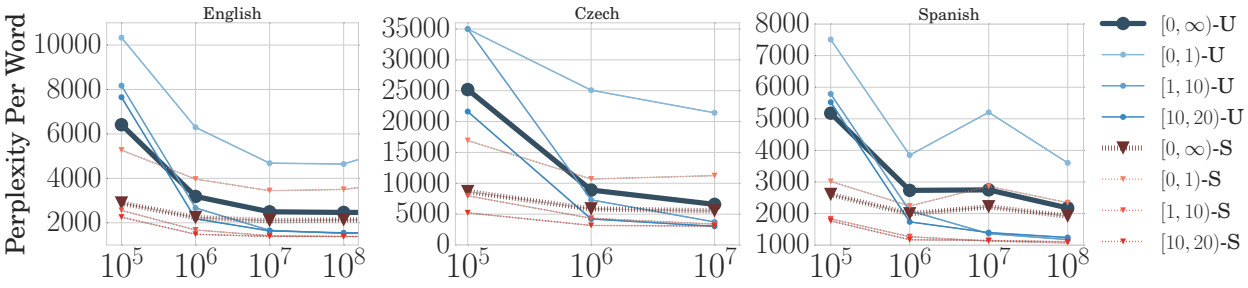

Figure 3: Results for the WORD2VEC skip-gram objective score (perplexity per predicted context word) on a held-out test corpus. The x-axis measures the size in tokens of the training corpus used to generate the model. We plot the held-out perplexity for the skip-gram model with Unsmoothed observed vectors $\boldsymbol{v}$ (solid ●) and Smoothed vectors $\boldsymbol{w}$ (barred ▼). The thickest, darkest curves show aggregate performance. The thinner, lighter versions show a breakdown according to whether the *predicting* word's frequency in the *smallest* training corpus falls in the range $[0, 1)$, $[1, 10)$, or $[10, 20)$ (from lightest to darkest and roughly from top to bottom). (These are the words whose representations we smooth; footnote 10 explains why we do not smooth the predicted context word.) We do not show $[20, \infty)$ since WORD2VEC randomly removes some tokens of high-frequency words ("subsampling"), similar in spirit to removing stop words. See Appendix B for more graphs.

8.2 Experiment 2: Held-Out Evaluation

We now evaluate the smoothed and extrapolated representations w_i. Fundamentally, we want to know if our approach improves the embeddings of the entire vocabulary, as if we had seen more evidence. But we cannot simply compare our smoothed vectors to "gold" vectors trained on much more data, since two different runs of WORD2VEC will produce incomparable embedding schemes. We must ask whether our embeddings improve results on a downstream task.

To avoid choosing a downstream task with a narrow application, we evaluate our embedding using the WORD2VEC skip-gram objective on *held-out* data—as one would evaluate a language model. If we believe that a better score on the WORD2VEC objective indicates generally more useful embeddings—which indeed we do as we optimize for it—then improving this score indicates that our smoothed vectors are superior. Concretely, the objective is

$$\sum_s \sum_t \sum_{j \in [t-5, t+5], j \neq t} \log_2 p_{\text{word2vec}}(T_{sj} \mid T_{st}), \quad (8)$$

where T_s is the s^{th} sentence in the *test* corpus, t indexes its tokens, and j indexes tokens near t. The probability model p_{word2vec} is defined in Eq. (3) of (Mikolov et al., 2013b). It relies on an embedding of the word form T_{st}.[10] Our baseline approach simply uses WORD2VEC's embeddings (or **0** for OOV words $T_{st} \notin \mathcal{C}$). Our GGM approach substitutes "better" embeddings when T_{st} appears in the lexicon $\mathcal{L}$ (if T_{st} is ambiguous, we use the mean w_i vector from all $i \in \mathcal{L}$ with spelling T_{st}).

Note that (8) is itself a kind of task of predicting words in context, resembling language modeling or a "cloze" task. Also, Taddy (2015) showed how to use this objective for document classification.

Experimental Setup: We evaluate GGM on the same 5 languages, but now hold out part of the corpus instead of part of the lexicon. We take the training corpus $\mathcal{C}$ to be the initial portion of Wikipedia of size 10^5, 10^6, 10^7 or 10^8. (We skip the 10^8 case for the smaller datasets: Czech and Turkish). The 10^7 tokens after that are the dev corpus; the next 10^7 tokens are the test corpus.

Results: We report results on three languages in Figure 3 and all languages in Appendix B. Smoothing from v_i to w_i helps a lot, reducing perplexity by up to 48% (Czech) with 10^5 training tokens and up to 10% (Spanish) even with 10^8 training tokens. This roughly halves the perplexity, which in the case of 10^5 training tokens, is equivalent to $8\times$ more training data. This is a clear win for lower-resource languages. We get larger gains from smoothing the rarer predicting words, but even words with frequency $\geq 10^{-4}$ benefit. (The exception is Turkish, where the large gains are confined to rare predicting words.) See Appendix B for more analysis.

[10] In the hierarchical softmax version, it also relies on a *separate* embedding for a variable-length bit-string encoding of the context word T_{sj}. Unfortunately, we do *not* currently know of a way to smooth these bit-string encodings (also found by WORD2VEC). However, it might be possible to directly incorporate morphology into the construction of the vocabulary tree that defines the bit-strings.

	English	German	Spanish
Forms / Lemma	1.8	6.3	8.1

GGM	**58.9**	**37.6**	**40.3**

Table 4: Word similarity results (correlations) using the WS-353 dataset in the three languages, in which it is available. Since all the words in WS-353 are lemmata, we report the average inflected form to lemma ratio for forms *appearing in* the datasets.

8.3 Experiment 3: Word Similarity

As a third and final experiment, we consider word similarity using the WS-353 data set (Finkelstein et al., 2001), translated into Spanish (Hassan and Mihalcea, 2009) and German (Leviant, 2016).[11] The datasets are composed of 353 pairs of words. Multiple native speakers were then asked to give an integral value between 1 and 10 indicating the similarity of that pair, and those values were then averaged. In each case, we train the GGM on the *whole* Wikipedia corpus for the language. Since in each language every word in the WS-353 set is in fact a lemma, we use the latent embedding our GGM learns in the experiment. In Spanish, for example, we use the learned latent morpheme embedding for the lemma BEBER (recall this takes information from every element in the paradigm, e.g., *bebemos* and *beben*), rather than the embedding for the infinitival form *beber*. In highly inflected languages we expect this to improve performance, because to get the embedding of a lemma, it leverages the distributional signal from *all* inflected forms of that lemma, not just a single one. Note that unlike previous retrofitting approaches, we do not introduce new semantic information into the model, but rather simply allow the model to better exploit the distributional properties already in the text, by considering words with related lemmata together. In essence, our approach embeds a lemma as the average of all words containing that lemma, *after* "correcting" those forms by subtracting off their other morphemes (e.g., inflectional affixes).

Results: As is standard in the literature, we report Spearman's correlation cofficient ρ between the averaged human scores and the cosine distance between the embeddings. We report results in Table 4. We additionally report the average number of forms per lemma. We find that we improve performance on the Spanish and German datasets over the original skip-gram vectors, but only equal the performance on English. This is not surprising as German and Spanish have roughly 3 and 4 times more forms per lemma than English. We speculate that cross-linguistically the GGM will improve word similarity scores more for languages with richer morphology.

[11] This dataset has yet to be translated into Czech or Turkish, nor are there any comparable resources in these languages.

9 Conclusion and Future Work

For morphologically rich languages, we generally will *not* observe, even in a large corpus, a high proportion of the word forms that exist in lexical resources. We have presented a Gaussian graphical model that exploits lexical relations documented in existing morphological resources to smooth vectors for observed words and extrapolate vectors for new words. We show that our method achieves large improvements over strong baselines for the tasks of morpho-syntactic analogies and predicting words in context. Future work will consider the role of derivational morphology in embeddings as well as noncompositional cases of inflectional morphology.

Abstract

Despite interest in using cross-lingual knowledge to learn word embeddings for various tasks, a systematic comparison of the possible approaches is lacking in the literature. We perform an extensive evaluation of four popular approaches of inducing cross-lingual embeddings, each requiring a different form of supervision, on four typologically different language pairs. Our evaluation setup spans four different tasks, including intrinsic evaluation on mono-lingual and cross-lingual similarity, and extrinsic evaluation on downstream semantic and syntactic applications. We show that models which require expensive cross-lingual knowledge almost always perform better, but cheaply supervised models often prove competitive on certain tasks.

1 Introduction

Learning word vector representations using monolingual distributional information is now a ubiquitous technique in NLP. The quality of these word vectors can be significantly improved by incorporating cross-lingual distributional information (Klementiev et al., 2012; Zou et al., 2013; Vulić and Moens, 2013b; Mikolov et al., 2013b; Faruqui and Dyer, 2014; Hermann and Blunsom, 2014; Chandar et al., 2014, *inter alia*), with improvements observed both on monolingual (Faruqui and Dyer, 2014; Rastogi et al., 2015) and cross-lingual tasks (Guo et al., 2015; Søgaard et al., 2015; Guo et al., 2016).

Several models for inducing cross-lingual embeddings have been proposed, each requiring a different form of cross-lingual supervision – some can use document-level alignments (Vulić and Moens, 2015), others need alignments at the sentence (Hermann and Blunsom, 2014; Gouws et al., 2015) or word level (Faruqui and Dyer, 2014; Gouws and Søgaard, 2015), while some require both sentence and word alignments (Luong et al., 2015). However, a systematic comparison of these models is missing from the literature, making it difficult to analyze which approach is suitable for a particular NLP task. In this paper, we fill this void by empirically comparing four cross-lingual word embedding models each of which require different form of alignment(s) as supervision, across several dimensions. To this end, we train these models on four different language pairs, and evaluate them on both monolingual and cross-lingual tasks.[1]

First, we show that different models can be viewed as instances of a more general framework for inducing cross-lingual word embeddings. Then, we evaluate these models on both extrinsic and intrinsic tasks. Our intrinsic evaluation assesses the quality of the vectors on monolingual (§4.2) and cross-lingual (§4.3) word similarity tasks, while our extrinsic evaluation spans semantic (cross-lingual document classification §4.4) and syntactic tasks (cross-lingual dependency parsing §4.5).

Our experiments show that word vectors trained using expensive cross-lingual supervision (word alignments or sentence alignments) perform the best on semantic tasks. On the other hand, for syntactic tasks like cross-lingual dependency parsing, models requiring weaker form of cross-lingual supervision (such as context agnostic translation dictionary) are competitive to models requiring expensive supervision. We also show qualitatively how the nature of cross-lingual supervision used to train word vectors affects the proximity of translation pairs across languages, and of words with similar meaning in the same language in the vector-space.

Algorithm 1 General Algorithm

1: Initialize $\mathbf{W} \leftarrow \mathbf{W}^0$,$\mathbf{V} \leftarrow \mathbf{V}^0$
2: $(\mathbf{W}^*, \mathbf{V}^*) \leftarrow \arg\min \alpha A(\mathbf{W}) + \beta B(\mathbf{V}) + C(\mathbf{W}, \mathbf{V})$

Figure 1: (**Above**) A general schema for induction of cross-lingual word vector representations. The word vector model generates embeddings which incorporates distributional information *cross-lingually*. (**Below**) A general algorithm for inducing bilingual word embeddings, where $\alpha, \beta, \mathbf{W}^0, \mathbf{V}^0$ are parameters and A, B, C are suitably defined losses.

2 Bilingual Embeddings

A general schema for inducing bilingual embeddings is shown in Figure 1. Our comparison focuses on dense, fixed-length distributed embeddings which are obtained using some form of cross-lingual supervision. We briefly describe the embedding induction procedure for each of the selected bilingual word vector models, with the aim to provide a unified algorithmic perspective for all methods, and to facilitate better understanding and comparison. Our choice of models spans across different forms of supervision required for inducing the embeddings, illustrated in Figure 2.

Notation. Let $W = \{w_1, w_2, \ldots, w_{|W|}\}$ be the vocabulary of a language l_1 with $|W|$ words, and $\mathbf{W} \in \mathbb{R}^{|W| \times l}$ be the corresponding word embeddings of length l. Let $V = \{v_1, v_2, \ldots, v_{|V|}\}$ be the vocabulary of another language l_2 with $|V|$ words, and $\mathbf{V} \in \mathbb{R}^{|V| \times m}$ the corresponding word embeddings of length m. We denote the word vector for a word w by $\mathbf{w}$.

2.1 Bilingual Skip-Gram Model (BiSkip)

Luong et al. (2015) proposed Bilingual Skip-Gram, a simple extension of the monolingual skip-gram model, which learns bilingual embeddings by using a parallel corpus along with word alignments (both sentence and word level alignments).

The learning objective is a simple extension of the skip-gram model, where the context of a word is expanded to include bilingual links obtained from word alignments, so that the model is trained to predict words cross-lingually. In particular, given a word alignment link from word $v \in V$ in language l_2 to $w \in W$ in language l_1, the model predicts the context words of w using v and vice-versa. Formally, the cross lingual part of the objective is,

$$D_{12}(\mathbf{W}, \mathbf{V}) = -\sum_{(v,w) \in Q} \sum_{w_c \in \text{NBR}_1(w)} \log P(w_c \mid v) \quad (1)$$

where $\text{NBR}_1(w)$ is the context of w in language l_1, Q is the set of word alignments, and $P(w_c \mid v) \propto \exp(\mathbf{w}_c^T \mathbf{v})$. Another similar term D_{21} models the objective for v and $\text{NBR}_2(v)$. The objective can be cast into Algorithm 1 as,

$$C(\mathbf{W}, \mathbf{V}) = D_{12}(\mathbf{W}, \mathbf{V}) + D_{21}(\mathbf{W}, \mathbf{V}) \quad (2)$$

$$A(\mathbf{W}) = -\sum_{w \in W} \sum_{w_c \in \text{NBR}_1(w)} \log P(w_c \mid w) \quad (3)$$

$$B(\mathbf{V}) = -\sum_{v \in V} \sum_{v_c \in \text{NBR}_2(v)} \log P(v_c \mid v) \quad (4)$$

where $A(\mathbf{W})$ and $B(\mathbf{V})$ are the familiar skip-gram formulation of the monolingual part of the objective. α and β are chosen hyper-parameters which set the relative importance of the monolingual terms.

2.2 Bilingual Compositional Model (BiCVM)

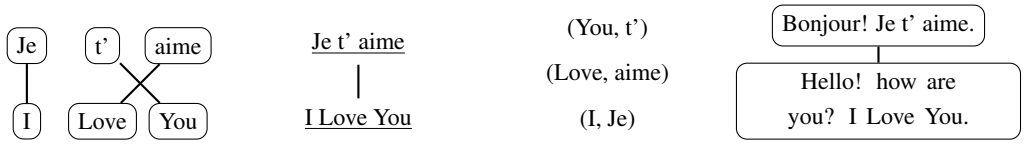
Hermann and Blunsom (2014) present a method that learns bilingual word vectors from a sentence aligned corpus. Their model leverages the fact that aligned sentences have equivalent meaning, thus their sentence representations should be similar.

We denote two aligned sentences, $\vec{v} = \langle \boldsymbol{x}_1, \ldots, \rangle$ and $\vec{w} = \langle \boldsymbol{y}_1, \ldots \rangle$, where $\boldsymbol{x}_i \in \mathbf{V}, \boldsymbol{y}_i \in \mathbf{W}$, are vectors corresponding to the words in the sentences. Let functions $f : \vec{v} \rightarrow \mathbb{R}^n$ and $g : \vec{w} \rightarrow \mathbb{R}^n$, map sentences to their semantic representations in $\mathbb{R}^n$. BiCVM generates word vectors by minimizing the squared ℓ_2 norm between the sentence representations of aligned sentences. In order to prevent the degeneracy arising from directly minimizing the ℓ_2 norm, they use a noise-contrastive large-margin update, with randomly drawn sentence pairs $(\vec{v}, \vec{w}^n)$ as negative samples. The loss for the sentence pairs $(\vec{v}, \vec{w})$ and $(\vec{v}, \vec{w}^n)$ can be written as,

$$E(\vec{v}, \vec{w}, \vec{w}^n) = \max\left(\delta + \Delta E(\vec{v}, \vec{w}, \vec{w}^n), 0\right) \quad (5)$$

where,

$$E(\vec{v}, \vec{w}) = \|f(\vec{v}) - g(\vec{w})\|^2 \quad (6)$$



(a) **BiSkip** (b) **BiCVM** (c) **BiCCA** (d) **BiVCD**

Figure 2: Forms of supervision required by the four models compared in this paper. From left to right, the cost of the supervision required varies from expensive (BiSkip) to cheap (BiVCD). BiSkip requires a parallel corpus annotated with word alignments (Fig. 2a), BiCVM requires a sentence-aligned corpus (Fig. 2b), BiCCA only requires a bilingual lexicon (Fig. 2c) and BiVCD requires comparable documents (Fig. 2d).

and,

$$\Delta E(\vec{v}, \vec{w}, \vec{w}^n) = E(\vec{v}, \vec{w}) - E(\vec{v}, \vec{w}^n) \quad (7)$$

This can be cast into Algorithm 1 by,

$$C(\mathbf{W}, \mathbf{V}) = \sum_{\substack{\text{aligned } (\vec{v},\vec{w}) \\ \text{random } \vec{w}^n}} E(\vec{v}, \vec{w}, \vec{w}^n) \quad (8)$$

$$A(\mathbf{W}) = \|\mathbf{W}\|^2 \quad B(\mathbf{V}) = \|\mathbf{V}\|^2 \quad (9)$$

with $A(\mathbf{W})$ and $B(\mathbf{V})$ being regularizers, with $\alpha = \beta$.

2.3 Bilingual Correlation Based Embeddings (BiCCA)

The BiCCA model, proposed by Faruqui and Dyer (2014), showed that when (independently trained) monolingual vector matrices $\mathbf{W}, \mathbf{V}$ are projected using CCA (Hotelling, 1936) to respect a translation lexicon, their performance improves on word similarity and word analogy tasks. They first construct $\mathbf{W}' \subseteq \mathbf{W}, \mathbf{V}' \subseteq \mathbf{V}$ such that $|\mathbf{W}'| = |\mathbf{V}'|$ and the corresponding words (w_i, v_i) in the matrices are translations of each other. The projection is then computed as:

$$\mathbf{P}_W, \mathbf{P}_V = \text{CCA}(\mathbf{W}', \mathbf{V}') \quad (10)$$

$$\mathbf{W}^* = \mathbf{W}\mathbf{P}_W \quad \mathbf{V}^* = \mathbf{V}\mathbf{P}_V \quad (11)$$

where, $\mathbf{P}_V \in \mathbb{R}^{l \times d}, \mathbf{P}_W \in \mathbb{R}^{m \times d}$ are the projection matrices with $d \leq \min(l, m)$ and the $\mathbf{V}^* \in \mathbb{R}^{|V| \times d}, \mathbf{W}^* \in \mathbb{R}^{|W| \times d}$ are the word vectors that have been "enriched" using bilingual knowledge.

The BiCCA objective can be viewed[2] as the following instantiation of Algorithm 1:

$$\mathbf{W}^0 = \mathbf{W}', \mathbf{V}^0 = \mathbf{V}' \quad (12)$$

$$C(\mathbf{W}, \mathbf{V}) = \|\mathbf{W} - \mathbf{V}\|^2 + \gamma \left(\mathbf{V}^T \mathbf{W}\right) \quad (13)$$

$$A(\mathbf{W}) = \|\mathbf{W}\|^2 - 1 \quad B(\mathbf{V}) = \|\mathbf{V}\|^2 - 1 \quad (14)$$

where $\mathbf{W} = \mathbf{W}^0 \mathbf{P}_W$ and $\mathbf{V} = \mathbf{V}^0 \mathbf{P}_V$, where we set $\alpha = \beta = \gamma = \infty$ to set hard constraints.

[2] described in Section 6.5 of (Hardoon et al., 2004)

2.4 Bilingual Vectors from Comparable Data (BiVCD)

Another approach of inducing bilingual word vectors, which we refer to as BiVCD, was proposed by Vulić and Moens (2015). Their approach is designed to use *comparable* corpus between the source and target language pair to induce cross-lingual vectors.

Let d_e and d_f denote a pair of comparable documents with length in words p and q respectively (assume $p > q$). BiVCD first merges these two comparable documents into a single pseudo-bilingual document using a deterministic strategy based on length ratio of two documents $R = \lfloor \frac{p}{q} \rfloor$. Every R^{th} word of the merged pseudo-bilingual document is picked sequentially from d_f. Finally, a skip-gram model is trained on the corpus of pseudo-bilingual documents, to generate vectors for all words in $\mathbf{W}^* \cup \mathbf{V}^*$. The vectors constituting $\mathbf{W}^*$ and $\mathbf{V}^*$ can then be easily identified.

Instantiating BiVCD in the general algorithm is obvious: $C(\mathbf{W}, \mathbf{V})$ assumes the familiar word2vec skip-gram objective over the pseudo-bilingual document,

$$C(\mathbf{W}, \mathbf{V}) = -\sum_{s \in W \cup V} \sum_{t \in \text{NBR}(s)} \log P(t \mid s) \quad (15)$$

where $\text{NBR}(s)$ is defined by the pseudo-bilingual document and $P(t \mid s) \propto \exp(\mathbf{t}^T \mathbf{s})$. Note that $t, s \in W \cup V$.

Although BiVCD is designed to use comparable corpus, we provide it with parallel data in our experiments (to ensure comparability), and treat two aligned sentences as comparable.

3 Data

We train cross-lingual embeddings for 4 language pairs: English-German (en-de), English-French (en-fr), English-Swedish (en-sv) and English-Chinese (en-zh). For en-de and en-sv we use the

l_1	l_2	#sent	#l_1-words	#l_2-words
en	de	1.9	53	51
	fr	2.0	55	61
	sv	1.7	46	42
	zh	2.0	58	50

Table 1: The size of parallel corpora (in millions) of different language pairs used for training cross-lingual word vectors.

Europarl v7 parallel corpus[3] (Koehn, 2005). For en-fr, we use Europarl combined with the news-commentary and UN-corpus dataset from WMT 2015.[4] For en-zh, we use the FBIS parallel corpus from the news domain (LDC2003E14). We use the Stanford Chinese Segmenter (Tseng et al., 2005) to preprocess the en-zh parallel corpus. Corpus statistics for all languages is shown in Table 1.

4 Evaluation

We measure the quality of the induced cross-lingual word embeddings in terms of their performance, when used as features in the following tasks:

- monolingual word similarity for English
- Cross-lingual dictionary induction
- Cross-lingual document classification
- Cross-lingual syntactic dependency parsing

The first two tasks intrinsically measure how much can monolingual and cross-lingual similarity benefit from cross-lingual training. The last two tasks measure the ability of cross-lingually trained vectors to extrinsically facilitate model transfer across languages, for semantic and syntactic applications respectively. These tasks have been used in previous works (Klementiev et al., 2012; Luong et al., 2015; Vulić and Moens, 2013a; Guo et al., 2015) for evaluating cross-lingual embeddings, but no comparison exists which uses them in conjunction.

To ensure fair comparison, all models are trained with embeddings of size 200. We provide all models with parallel corpora, irrespective of their requirements. Whenever possible, we also report statistical significance of our results.

[3] `www.statmt.org/europarl/v7/{de, sv}-en.tgz`

[4] `www.statmt.org/wmt15/translation-task.html`

4.1 Parameter Selection

We follow the **BestAvg** parameter selection strategy from Lu et al. (2015): we selected the parameters for all models by tuning on a set of values (described below) and picking the parameter setting which did best on an average across all tasks.

BiSkip. All models were trained using a window size of 10 (tuned over $\{5, 10, 20\}$), and 30 negative samples (tuned over $\{10, 20, 30\}$). The cross-lingual weight was set to 4 (tuned over $\{1, 2, 4, 8\}$). The word alignments for training the model (available at `github.com/lmthang/bivec`) were generated using `fast_align` (Dyer et al., 2013). The number of training iterations was set to 5 (no tuning) and we set $\alpha = 1$ and $\beta = 1$ (no tuning).

BiCVM. We use the tool (available at `github.com/karlmoritz/bicvm`) released by Hermann and Blunsom (2014) to train all embeddings. We train an additive model (that is, $f(\vec{x}) = g(\vec{x}) = \sum_i x_i$) with hinge loss margin set to 200 (no tuning), batch size of 50 (tuned over $50, 100, 1000$) and noise parameter of 10 (tuned over $\{10, 20, 30\}$). All models are trained for 100 iterations (no tuning).

BiCCA. First, monolingual word vectors are trained using the skip-gram model[5] with negative sampling (Mikolov et al., 2013a) with window of size 5 (tuned over $\{5, 10, 20\}$). To generate a cross-lingual dictionary, word alignments are generated using cdec from the parallel corpus. Then, word pairs $(a, b), a \in l_1, b \in l_2$ are selected such that a is aligned to b the most number of times and vice versa. This way, we obtained dictionaries of approximately 36k, 35k, 30k and 28k word pairs for en-de, en-fr, en-sv and en-zh respectively.

The monolingual vectors are aligned using the above dictionaries with the tool (available at `github.com/mfaruqui/eacl14-cca`) released by Faruqui and Dyer (2014) to generate the cross-lingual word embeddings. We use $k = 0.5$ as the number of canonical components (tuned over $\{0.2, 0.3, 0.5, 1.0\}$). Note that this results in a embedding of size 100 after performing CCA.

BiVCD. We use word2vec's skip gram model for training our embeddings, with a window size of 5 (tuned on $\{5, 10, 20, 30\}$) and negative sampling parameter set to 5 (tuned on $\{5, 10, 25\}$). Every pair of parallel sentences is treated as a

[5] `code.google.com/p/word2vec`

pair of comparable documents, and merging is performed using the sentence length ratio strategy described earlier.[6]

4.2 Monolingual Evaluation

We first evaluate if the inclusion of cross-lingual knowledge improves the quality of English embeddings.

Word Similarity. Word similarity datasets contain word pairs which are assigned similarity ratings by humans. The task evaluates how well the notion of word similarity according to humans is emulated in the vector space. Evaluation is based on the Spearman's rank correlation coefficient (Myers and Well, 1995) between human rankings and rankings produced by computing cosine similarity between the vectors of two words.

We use the SimLex dataset for English (Hill et al., 2014) which contains 999 pairs of English words, with a balanced set of noun, adjective and verb pairs. SimLex is claimed to capture word similarity exclusively instead of WordSim-353 (Finkelstein et al., 2001) which captures both word similarity and relatedness. We declare significant improvement if $p < 0.1$ according to Steiger's method (Steiger, 1980) for calculating the statistical significant differences between two dependent correlation coefficients.

Table 2 shows the performance of English embeddings induced by all the models by training on different language pairs on the SimLex word similarity task. The score obtained by monolingual English embeddings trained on the respective English side of each language is shown in column marked Mono. In all cases (except BiCCA on en-sv), the bilingually trained vectors achieve better scores than the mono-lingually trained vectors.

Overall, across all language pairs, BiCVM is the best performing model in terms of Spearman's correlation, but its improvement over BiSkip and BiVCD is often insignificant. It is notable that 2 of the 3 top performing models, BiCVM and BiVCD, need sentence aligned and document-aligned corpus only, which are easier to obtain than parallel data with word alignments required by BiSkip.

QVEC. Tsvetkov et al. (2015) proposed an intrinsic evaluation metric for estimating the quality of English word vectors. The score produced by QVEC measures how well a given set of word vectors is able to quantify linguistic properties of words, with higher being better. The metric is shown to have strong correlation with performance on downstream semantic applications. As it can be currently only used for English, we use it to evaluate the English vectors obtained using cross-lingual training of different models. Table 3 shows that on average across language pairs, BiSkip achieves the best score, followed by Mono (mono-lingually trained English vectors), BiVCD and BiCCA. A possible explanation for why Mono scores are better than those obtained by some of the cross-lingual models is that QVEC measures monolingual semantic content based on a linguistic oracle made for English. Cross-lingual training might affect these semantic properties arbitrarily.

Interestingly, BiCVM which was the best model according to SimLex, ranks last according to QVEC. The fact that the best models according to QVEC and word similarities are different reinforces observations made in previous work that performance on word similarity tasks alone does not reflect quantification of linguistic properties of words (Tsvetkov et al., 2015; Schnabel et al., 2015).

[6]We implemented the code for performing the merging as we could not find a tool provided by the authors.

pair	Mono	BiSkip	BiCVM	BiCCA	BiVCD

Scores which are significantly better (per McNemar's Test with $p < 0.05$) than the next lower score are underlined. For example, for sv→en, BiVCD is significantly better than BiSkip, which in turn is significantly better than BiCVM.

4.3 Cross-lingual Dictionary Induction

The task of cross-lingual dictionary induction (Vulić and Moens, 2013a; Gouws et al., 2015; Mikolov et al., 2013b) judges how good cross-lingual embeddings are at detecting word pairs that are semantically similar across languages. We follow the setup of Vulić and Moens (2013a), but instead of manually creating a gold cross-lingual dictionary, we derived our gold dictionaries using the Open Multilingual WordNet data released by Bond and Foster (2013). The data includes synset alignments across 26 languages with over 90% accuracy. First, we prune out words from each synset whose frequency count is less than 1000 in the vocabulary of the training data from §3. Then, for each pair of aligned synsets $s_1 = \{k_1, k_2, \cdots\}$ $s_2 = \{g_1, g_2, \cdots\}$, we include all elements from the set $\{(k, g) \mid k \in s_1, g \in s_2\}$ into the gold dictionary, where k and g are the lemmas. Using this approach we generated dictionaries of sizes 1.5k, 1.4k, 1.0k and 1.6k pairs for en-fr, en-de, en-sv and en-zh respectively.

We report top-10 accuracy, which is the fraction of the entries (e, f) in the gold dictionary, for which f belongs to the list of top-10 neighbors of the word vector of e, according to the induced cross-lingual embeddings. From the results (Table 4), it can be seen that for dictionary induction, the performance improves with the quality of supervision. As we move from cheaply supervised methods (eg. BiVCD) to more expensive supervision (eg. BiSkip), the accuracy improves. This suggests that for cross lingual similarity tasks, the more expensive the cross-lingual knowledge available, the better. Models using weak supervision like BiVCD perform poorly in comparison to models like BiSkip and BiCVM, with performance gaps upwards of 10 pts on an average.

4.4 Cross-lingual Document Classification

We follow the cross-lingual document classification (CLDC) setup of Klementiev et al. (2012), but extend it to cover all of our language pairs. We use the RCV2 Reuters multilingual corpus[7] for our experiments. In this task, for a language pair (l_1, l_2), a document classifier is trained using the document representations derived from word embeddings in language l_1, and then the trained model is tested on documents from language l_2 (and vice-versa). By using supervised training data in one language and evaluating without further supervision in another, CLDC assesses whether the learned cross-lingual representations are semantically coherent across multiple languages.

All embeddings are learned on the data described in §3, and we only use the RCV2 data to learn document classification models. Following previous work, we compute document representation by taking the tf-idf weighted average of vectors of the words present in it.[8] A multi-class classifier is trained using an averaged perceptron (Freund and Schapire, 1999) for 10 iterations, using the document vectors of language l_1 as features[9]. Majority baselines for $en \rightarrow l_2$ and $l_1 \rightarrow en$ are 49.7% and 46.7% respectively, for all languages. Table 5 shows the performance of different models across different language pairs. We computed confidence values using the McNemar test (McNe-

[7] http://trec.nist.gov/data/reuters/reuters.html

[8] tf-idf (Salton and Buckley, 1988) was computed using all documents for that language in RCV2.

[9] We use the implementation of Klementiev et al. (2012).

mar, 1947) and declare significant improvement if $p < 0.05$.

Table 5 shows that in almost all cases, BiSkip performs significantly better than the remaining models. For transferring semantic knowledge across languages via embeddings, sentence and word level alignment proves superior to sentence or word level alignment alone. This observation is consistent with the trend in cross-lingual dictionary induction, where too the most expensive form of supervision performed the best.

4.5 Cross-lingual Dependency Parsing

Using cross lingual similarity for direct-transfer of dependency parsers was first shown in Täckström et al. (2012). The idea behind direct-transfer is to train a dependency parsing model using embeddings for language l_1 and then test the trained model on language l_2, replacing embeddings for language l_1 with those of l_2. The transfer relies on coherence of the embeddings across languages arising from the cross lingual training. For our experiments, we use the cross lingual transfer setup of Guo et al. (2015).[10] Their framework trains a transition-based dependency parser using nonlinear activation function, with the source-side embeddings as lexical features. These embeddings can be replaced by target-side embeddings at test time.

All models are trained for 5000 iterations with fixed word embeddings during training. Since our goal is to determine the utility of word embeddings in dependency parsing, we turn off other features that can capture distributional information like brown clusters, which were originally used in Guo et al. (2015). We use the universal dependency treebank (McDonald et al., 2013) version-2.0 for our evaluation. For Chinese, we use the treebank released as part of the CoNLL-X shared task (Buchholz and Marsi, 2006).

We first evaluate how useful the word embeddings are in cross-lingual model transfer of dependency parsers (Table 6). On an average, BiCCA does better than other models. BiSkip is a close second, with an average performance gap of less than 1 point. BiSkip outperforms BiCVM on German and French (over 2 point improvement), owing to word alignment information BiSkip's model uses during training. It is not surprising that English-Chinese transfer scores are low, due to the significant difference in syntactic structure of the two languages. Surprisingly, unlike the semantic tasks considered earlier, the models with expensive supervision requirements like BiSkip and BiCVM could not outperform a cheaply supervised BiCCA.

Table 6: Labeled attachment score (LAS) for cross-lingual dependency parsing when trained on language l_1, and evaluated on language l_2. The best score for each language is shown in **bold**.

We also evaluate whether using cross-lingually trained vectors for learning dependency parsers is better than using mono-lingually trained vectors in Table 7. We compare against parsing models trained using mono-lingually trained word vectors (column marked Mono in Table 7). These vectors are the same used as input to the BiCCA model. All other settings remain the same. On an average across language pairs, improvement over the monolingual embeddings was obtained with the BiSkip and BiCCA models, while BiCVM and BiVCD consistently performed worse. A possible reason for this is that BiCVM and BiVCD operate on sentence level contexts to learn the embeddings, which only captures the semantic meaning of the sentences and ignores the internal syntactic structure. As a result, embedding trained using BiCVM and BiVCD are not informative for syntactic tasks. On the other hand, BiSkip and BiCCA both utilize the word alignment information to train their embeddings and thus do better in capturing some notion of syntax.

5 Qualitative Analysis

Figure 3 shows the PCA projection of some of the most frequent words in the English-French corpus. It is clear that BiSkip and BiCVM produce cross-lingual vectors which are the most comparable, the English and French words which are translations of each other are represented by almost the same point in the vector-space. In BiCCA and BiVCD

the translated words are more distant than BiSkip and BiCVM. This is not surprising because BiSkip and BiCVM require more expensive supervision at the sentence level in contrast to the other two models.

An interesting observation is that BiCCA and BiVCD are better at separating antonyms. The words *peace* and *war*, (and their French translations *paix* and *guerre*) are well separated in BiCCA and BiVCD. However, in BiSkip and BiCVM these pairs are very close together. This can be attributed to the fact that BiSkip and BiCVM are trained on parallel sentences, and if two antonyms are present in the same sentence in English, they will also be present together in its French translation. However, BiCCA uses bilingual dictionary and BiVCD use comparable sentence context, which helps in pulling apart the synonyms and antonyms.

6 Discussion

The goal of this paper was to formulate the task of learning cross-lingual word vector representations in a unified framework, and conduct experiments to compare the performance of existing

models in a unbiased manner. We chose existing cross-lingual word vector models that can be trained on two languages at a given time. In recent work, Ammar et al. (2016) train multilingual word vectors using more than two languages; our comparison does not cover this setting. It is also worth noting that we compare here different cross-lingual word embeddings, which are not to be confused with a collection of monolingual word embeddings trained for different languages individually (Al-Rfou et al., 2013).

The paper does not cover *all* approaches that generate cross-lingual word embeddings. Some methods do not have publicly available code (Coulmance et al., 2015; Zou et al., 2013); for others, like BilBOWA (Gouws et al., 2015), we identified problems in the available code, which caused it to consistently produced results that are inferior even to mono-lingually trained vectors.[11] However, the models that we included for comparison in our survey are representative of other cross-lingual models in terms of the form of cross-lingual supervision required by them. For example, BilBOWA (Gouws et al., 2015) and cross-lingual Auto-encoder (Chandar et al., 2014) are similar to BiCVM in this respect. Multi-view CCA (Rastogi et al., 2015) and deep CCA (Lu et al., 2015) can be viewed as extensions of BiCCA. Our choice of models was motivated to compare different forms of supervision, and therefore, adding these models, would not provide additional insight.

7 Conclusion

We presented the first systematic comparative evaluation of cross-lingual embedding methods on several downstream NLP tasks, both intrinsic and extrinsic. We provided a unified representation for all approaches, showing them as instances of a general algorithm. Our choice of methods spans a diverse range of approaches, in that each requires a different form of supervision.

Our experiments reveal interesting trends. When evaluating on intrinsic tasks such as monolingual word similarity, models relying on cheaper forms of supervision (such as BiVCD) perform almost on par with models requiring expensive supervision. On the other hand, for cross-lingual semantic tasks, like cross-lingual document classification and dictionary induction, the model with the most informative supervision performs best overall. In contrast, for the syntactic task of dependency parsing, models that are supervised at a word alignment level perform slightly better. Overall this suggests that semantic tasks can benefit more from richer cross-lingual supervision, as compared to syntactic tasks.

Abstract

Recent work has shown that simple vector subtraction over word embeddings is surprisingly effective at capturing different lexical relations, despite lacking explicit supervision. Prior work has evaluated this intriguing result using a word analogy prediction formulation and hand-selected relations, but the generality of the finding over a broader range of lexical relation types and different learning settings has not been evaluated. In this paper, we carry out such an evaluation in two learning settings: (1) spectral clustering to induce word relations, and (2) supervised learning to classify vector differences into relation types. We find that word embeddings capture a surprising amount of information, and that, under suitable supervised training, vector subtraction generalises well to a broad range of relations, including over unseen lexical items.

1 Introduction

Learning to identify lexical relations is a fundamental task in natural language processing ("NLP"), and can contribute to many NLP applications including paraphrasing and generation, machine translation, and ontology building (Banko et al., 2007; Hendrickx et al., 2010).

Recently, attention has been focused on identifying lexical relations using word embeddings, which are dense, low-dimensional vectors obtained either from a "predict-based" neural network trained to predict word contexts, or a "count-based" traditional distributional similarity method combined with dimensionality reduction. The skip-gram model of Mikolov et al. (2013a) and other similar language models have been shown to perform well on an analogy completion task (Mikolov et al., 2013b; Mikolov et al., 2013c; Levy and Goldberg, 2014a), in the space of *relational similarity* prediction (Turney, 2006), where the task is to predict the missing word in analogies such as *A*:*B* :: *C*:*–?–*. A well-known example involves predicting the vector $\mathbf{queen}$ from the vector combination $\mathbf{king} - \mathbf{man} + \mathbf{woman}$, where linear operations on word vectors appear to capture the lexical relation governing the analogy, in this case OPPOSITE-GENDER. The results extend to several semantic relations such as CAPITAL-OF ($\mathbf{paris} - \mathbf{france} + \mathbf{poland} \approx \mathbf{warsaw}$) and morphosyntactic relations such as PLURALISATION ($\mathbf{cars} - \mathbf{car} + \mathbf{apple} \approx \mathbf{apples}$). Remarkably, since the model is not trained for this task, the relational structure of the vector space appears to be an emergent property.

The key operation in these models is *vector difference*, or *vector offset*. For example, the $\mathbf{paris} - \mathbf{france}$ vector appears to encode CAPITAL-OF, presumably by cancelling out the features of $\mathbf{paris}$ that are France-specific, and retaining the features that distinguish a capital city (Levy and Goldberg, 2014a). The success of the simple offset method on analogy completion suggests that the difference vectors ("DIFFVEC" hereafter) must themselves be meaningful: their direction and/or magnitude encodes a lexical relation.

Previous analogy completion tasks used with word embeddings have limited coverage of lexical relation types. Moreover, the task does not explore the full implications of DIFFVECs as meaningful vector space objects in their own right, because it only looks for a one-best answer to the particular lexical analogies in the test set. In this paper, we introduce a new, larger dataset covering many well-known lexical relation types from the linguistics and cognitive science literature. We then apply DIFFVECs to two new tasks: unsupervised and supervised relation extraction. First, we cluster the DIFFVECs to test whether the clusters map onto true lexical relations. We find that the clustering

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1671–1682,
Berlin, Germany, August 7-12, 2016.

works remarkably well, although syntactic relations are captured better than semantic ones.

Second, we perform classification over the DIFFVECs and obtain remarkably high accuracy in a closed-world setting (over a predefined set of word pairs, each of which corresponds to a lexical relation in the training data). When we move to an open-world setting including random word pairs — many of which do not correspond to any lexical relation in the training data — the results are poor. We then investigate methods for better attuning the learned class representation to the lexical relations, focusing on methods for automatically synthesising negative instances. We find that this improves the model performance substantially.

We also find that hyper-parameter optimised count-based methods are competitive with predict-based methods under both clustering and supervised relation classification, in line with the findings of Levy et al. (2015a).

2 Background and Related Work

A lexical relation is a binary relation r holding between a word pair (w_i, w_j); for example, the pair $(cart, wheel)$ stands in the WHOLE-PART relation. Relation learning in NLP includes relation extraction, relation classification, and relational similarity prediction. In relation extraction, related word pairs in a corpus and the relevant relation are identified. Given a word pair, the relation classification task involves assigning a word pair to the correct relation from a pre-defined set. In the Open Information Extraction paradigm (Banko et al., 2007; Weikum and Theobald, 2010), also known as unsupervised relation extraction, the relations themselves are also learned from the text (e.g. in the form of text labels). On the other hand, relational similarity prediction involves assessing the degree to which a word pair (A, B) stands in the same relation as another pair (C, D), or to complete an analogy $A{:}B :: C{:}{-?-}$. Relation learning is an important and long-standing task in NLP and has been the focus of a number of shared tasks (Girju et al., 2007; Hendrickx et al., 2010; Jurgens et al., 2012).

Recently, attention has turned to using vector space models of words for relation classification and relational similarity prediction. Distributional word vectors have been used for detection of relations such as hypernymy (Geffet and Dagan, 2005; Kotlerman et al., 2010; Lenci and Benotto, 2012; Weeds et al., 2014; Rimell, 2014; Santus et al., 2014) and qualia structure (Yamada et al., 2009). An exciting development, and the inspiration for this paper, has been the demonstration that vector difference over word embeddings (Mikolov et al., 2013c) can be used to model word analogy tasks. This has given rise to a series of papers exploring the DIFFVEC idea in different contexts. The original analogy dataset has been used to evaluate predict-based language models by Mnih and Kavukcuoglu (2013) and also Zhila et al. (2013), who combine a neural language model with a pattern-based classifier. Kim and de Marneffe (2013) use word embeddings to derive representations of adjective scales, e.g. *hot—warm—cool—cold*. Fu et al. (2014) similarly use embeddings to predict hypernym relations, in this case clustering words by topic to show that hypernym DIFFVECs can be broken down into more fine-grained relations. Neural networks have also been developed for joint learning of lexical and relational similarity, making use of the WordNet relation hierarchy (Bordes et al., 2013; Socher et al., 2013; Xu et al., 2014; Yu and Dredze, 2014; Faruqui et al., 2015; Fried and Duh, 2015).

Another strand of work responding to the vector difference approach has analysed the structure of predict-based embedding models in order to help explain their success on the analogy and other tasks (Levy and Goldberg, 2014a; Levy and Goldberg, 2014b; Arora et al., 2015). However, there has been no systematic investigation of the range of relations for which the vector difference method is most effective, although there have been some smaller-scale investigations in this direction. Makrai et al. (2013) divide antonym pairs into semantic classes such as quality, time, gender, and distance, finding that for about two-thirds of antonym classes, DIFFVECs are significantly more correlated than random. Necşulescu et al. (2015) train a classifier on word pairs, using word embeddings to predict coordinates, hypernyms, and meronyms. Roller and Erk (2016) analyse the performance of vector concatenation and difference on the task of predicting lexical entailment and show that vector concatenation overwhelmingly learns to detect Hearst patterns (e.g., *including*, *such as*). Köper et al. (2015) undertake a systematic study of morphosyntactic and semantic relations on word embeddings produced with `word2vec` ("`w2v`" hereafter; see §3.1) for English and German. They test a variety of relations including word similarity, antonyms, synonyms, hypernyms, and meronyms, in a novel analogy task. Although the set of relations tested by

Köper et al. (2015) is somewhat more constrained than the set we use, there is a good deal of overlap. However, their evaluation is performed in the context of relational similarity, and they do not perform clustering or classification on the DIFFVECs.

3 General Approach and Resources

We define the task of lexical relation learning to take a set of (ordered) word pairs $\{(w_i, w_j)\}$ and a set of binary lexical relations $R = \{r_k\}$, and map each word pair (w_i, w_j) as follows: (a) $(w_i, w_j) \mapsto r_k \in R$, i.e. the "closed-world" setting, where we assume that all word pairs can be uniquely classified according to a relation in R; or (b) $(w_i, w_j) \mapsto r_k \in R \cup \{\phi\}$ where ϕ signifies the fact that none of the relations in R apply to the word pair in question, i.e. the "open-world" setting.

Our starting point for lexical relation learning is the assumption that important information about various types of relations is implicitly embedded in the offset vectors. While a range of methods have been proposed for composing word vectors (Baroni et al., 2012; Weeds et al., 2014; Roller et al., 2014), in this research we focus exclusively on DIFFVEC (i.e. $\mathbf{w_2} - \mathbf{w_1}$). A second assumption is that there exist dimensions, or directions, in the embedding vector spaces responsible for a particular lexical relation. Such dimensions could be identified and exploited as part of a clustering or classification method, in the context of identifying relations between word pairs or classes of DIFFVECs.

In order to test the generalisability of the DIFFVEC method, we require: (1) word embeddings, and (2) a set of lexical relations to evaluate against. As the focus of this paper is not the word embedding pre-training approaches so much as the utility of the DIFFVECs for lexical relation learning, we take a selection of four pre-trained word embeddings with strong currency in the literature, as detailed in §3.1. We also include the state-of-the-art count-based approach of Levy et al. (2015a), to test the generalisability of DIFFVECs to count-based word embeddings.

For the lexical relations, we want a range of relations that is representative of the types of relational learning tasks targeted in the literature, and where there is availability of annotated data. To this end, we construct a dataset from a variety of sources, focusing on lexical semantic relations (which are less well represented in the analogy dataset of Mikolov et al. (2013c)), but also including morphosyntactic and morphosemantic relations (see §3.2).

Name	Dimensions	Training data
w2v	300	100×10^9
GloVe	200	6×10^9
SENNA	100	37×10^6
HLBL	200	37×10^6
w2v_{wiki}	300	50×10^6
$\text{GloVe}_{\text{wiki}}$	300	50×10^6
SVD_{wiki}	300	50×10^6

Table 1: The pre-trained word embeddings used in our experiments, with the number of dimensions and size of the training data (in word tokens). The models trained on English Wikipedia ("wiki") are in the lower half of the table.

3.1 Word Embeddings

We consider four highly successful word embedding models in our experiments: w2v (Mikolov et al., 2013a; Mikolov et al., 2013b), GloVe (Pennington et al., 2014), SENNA (Collobert and Weston, 2008), and HLBL (Mnih and Hinton, 2009), as detailed below. We also include SVD (Levy et al., 2015a), a count-based model which factorises a positive PMI (PPMI) matrix. For consistency of comparison, we train SVD as well as a version of w2v and GloVe (which we call w2v_{wiki} and $\text{GloVe}_{\text{wiki}}$, respectively) on the English Wikipedia corpus (comparable in size to the training data of SENNA and HLBL), and apply the preprocessing of Levy et al. (2015a). We additionally normalise the w2v_{wiki} and SVD_{wiki} vectors to unit length; $\text{GloVe}_{\text{wiki}}$ is natively normalised by column.[1]

w2v CBOW (Continuous Bag-Of-Words; Mikolov et al. (2013a)) predicts a word from its context using a model with the objective:

$$J = \frac{1}{T}\sum_{i=1}^{T} \log \frac{\exp\left(\mathbf{w}_i^\top \sum\limits_{j\in[-c,+c],j\neq 0} \tilde{\mathbf{w}}_{i+j}\right)}{\sum_{k=1}^{V} \exp\left(\mathbf{w}_k^\top \sum\limits_{j\in[-c,+c],j\neq 0} \tilde{\mathbf{w}}_{i+j}\right)}$$

where $\mathbf{w}_i$ and $\tilde{\mathbf{w}}_i$ are the vector representations for the ith word (as a focus or context word, respectively), V is the vocabulary size, T is the number of tokens in the corpus, and c is the context window size.[2] Google News data was used

[1] We ran a series of experiments on normalised and unnormalised w2v models, and found that normalisation tends to boost results over most of our relations (with the exception of $\text{LEXSEM}_{\text{Event}}$ and $\text{NOUN}_{\text{Coll}}$). We leave a more detailed investigation of normalisation to future work.

[2] In a slight abuse of notation, the subscripts of $\mathbf{w}$ do double

Table 2: Description of the 15 lexical relations.

to train the model. We use the focus word vectors, $W = \{\mathbf{w}_k\}_{k=1}^{V}$, normalised such that each $\|\mathbf{w}_k\| = 1$.

The GloVe model (Pennington et al., 2014) is based on a similar bilinear formulation, framed as a low-rank decomposition of the matrix of corpus co-occurrence frequencies:

$$J = \frac{1}{2}\sum_{i,j=1}^{V} f(P_{ij})(\mathbf{w}_i^\top \tilde{\mathbf{w}}_j - \log P_{ij})^2 \,,$$

where w_i is a vector for the left context, w_j is a vector for the right context, P_{ij} is the relative frequency of word j in the context of word i, and f is a heuristic weighting function to balance the influence of high versus low term frequencies. The model was trained on English Wikipedia and the English Gigaword corpus version 5.

The SVD model (Levy et al., 2015a) uses positive pointwise mutual information (PMI) matrix defined as:

$$\text{PPMI}(w, c) = \max(\log \frac{\hat{P}(w, c)}{\hat{P}(w)\hat{P}(c)}, 0) \,,$$

where $\hat{P}(w, c)$ is the joint probability of word w and context c, and $\hat{P}(w)$ and $\hat{P}(c)$ are their marginal probabilities. The matrix is factorised by singular value decomposition.

HLBL (Mnih and Hinton, 2009) is a log-bilinear formulation of an n-gram language model, which predicts the ith word based on context words $(i - n, \ldots, i-2, i-1)$. This leads to the following training objective:

$$J = \frac{1}{T}\sum_{i=1}^{T} \frac{\exp(\tilde{\mathbf{w}}_i^\top \mathbf{w}_i + b_i)}{\sum_{k=1}^{V} \exp(\tilde{\mathbf{w}}_i^\top \mathbf{w}_k + b_k)} \,,$$

where $\tilde{\mathbf{w}}_i = \sum_{j=1}^{n-1} C_j \mathbf{w}_{i-j}$ is the context embedding, C_j is a scaling matrix, and b_* is a bias term.

The final model, SENNA (Collobert and Weston, 2008), was initially proposed for multi-task training of several language processing tasks, from language modelling through to semantic role labelling. Here we focus on the statistical language modelling component, which has a pairwise ranking objective to maximise the relative score of each word in its local context:

$$J = \frac{1}{T}\sum_{i=1}^{T}\sum_{k=1}^{V} \max\big[0, 1 - f(\mathbf{w}_{i-c}, \ldots, \mathbf{w}_{i-1}, \mathbf{w}_i) + f(\mathbf{w}_{i-c}, \ldots, \mathbf{w}_{i-1}, \mathbf{w}_k)\big] \,,$$

where the last $c-1$ words are used as context, and $f(x)$ is a non-linear function of the input, defined as a multi-layer perceptron.

For HLBL and SENNA, we use the pre-trained embeddings from Turian et al. (2010), trained on the Reuters English newswire corpus. In both cases, the embeddings were scaled by the global standard deviation over the word-embedding matrix, $W_{\text{scaled}} = 0.1 \times \frac{W}{\sigma(W)}$.

For w2v$_{\text{wiki}}$, GloVe$_{\text{wiki}}$ and SVD$_{\text{wiki}}$ we used English Wikipedia. We followed the same preprocessing procedure described in Levy et al. (2015a),[3] i.e., lower-cased all words and removed non-textual elements. During the training phase, for each model we set a word frequency threshold of 5. For the SVD model, we followed the recommendations of Levy et al. (2015a) in setting the context window size to 2, negative sampling parameter to 1, eigenvalue weighting to 0.5, and context distribution smoothing to 0.75; other parameters were assigned

duty, denoting either the embedding for the ith token, $\mathbf{w}_i$, or kth word type, $\mathbf{w}_k$.

[3] Although the w2v model trained without preprocessing performed marginally better, we used preprocessing throughout for consistency.

their default values. For the other models we used the following parameter values: for w2v, context window = 8, negative samples = 25, hs = 0, sample = 1e-4, and iterations = 15; and for GloVe, context window = 15, x_max = 10, and iterations = 15.

3.2 Lexical Relations

In order to evaluate the applicability of the DIFFVEC approach to relations of different types, we assembled a set of lexical relations in three broad categories: lexical semantic relations, morphosyntactic paradigm relations, and morphosemantic relations. We constrained the relations to be binary and to have fixed directionality.[4] Consequently we excluded symmetric lexical relations such as synonymy. We additionally constrained the dataset to the words occurring in all embedding sets. There is some overlap between our relations and those included in the analogy task of Mikolov et al. (2013c), but we include a much wider range of lexical semantic relations, especially those standardly evaluated in the relation classification literature. We manually filtered the data to remove duplicates (e.g., as part of merging the two sources of LEXSEM$_{\text{Hyper}}$ intances), and normalise directionality.

The final dataset consists of 12,458 triples $\langle \text{relation}, \text{word}_1, \text{word}_2 \rangle$, comprising 15 relation types, extracted from SemEval'12 (Jurgens et al., 2012), BLESS (Baroni and Lenci, 2011), the MSR analogy dataset (Mikolov et al., 2013c), the light verb dataset of Tan et al. (2006a), Princeton WordNet (Fellbaum, 1998), Wiktionary,[5] and a web lexicon of collective nouns,[6] as listed in Table 2.[7]

4 Clustering

Assuming DIFFVECs are capable of capturing all lexical relations equally, we would expect clustering to be able to identify sets of word pairs with high relational similarity, or equivalently clusters of similar offset vectors. Under the additional assumption that a given word pair corresponds to a unique lexical relation (in line with our definition of the lexical relation learning task in §3), a hard clustering approach is appropriate. In order to test these assumptions, we cluster our 15-relation closed-world dataset in the first instance, and evaluate against the lexical resources in §3.2.

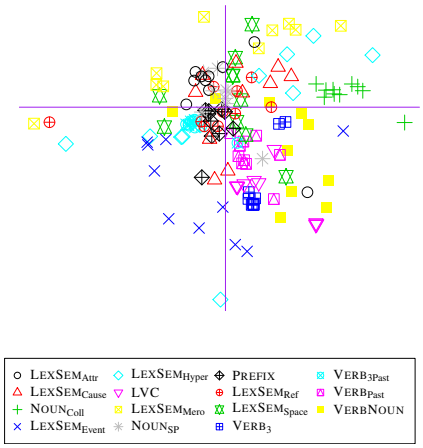

Figure 1: t-SNE projection (Van der Maaten and Hinton, 2008) of DIFFVECs for 10 sample word pairs of each relation type, based on w2v. The intersection of the two axes identify the projection of the zero vector. Best viewed in colour.

As further motivation, we projected the DIFFVEC space for a small number of samples of each class using t-SNE (Van der Maaten and Hinton, 2008), and found that many of the morphosyntactic relations (VERB$_3$, VERB$_{\text{Past}}$, VERB$_{3\text{Past}}$, NOUN$_{\text{SP}}$) form tight clusters (Figure 1).

We cluster the DIFFVECs between all word pairs in our dataset using spectral clustering (Von Luxburg, 2007). Spectral clustering has two hyperparameters: the number of clusters, and the pairwise similarity measure for comparing DIFFVECs. We tune the hyperparameters over development data, in the form of 15% of the data obtained by random sampling, selecting the configuration that maximises the V-Measure (Rosenberg and Hirschberg, 2007). Figure 2 presents V-Measure values over the test data for each of the four word embedding models. We show results for different numbers of clusters, from $N = 10$ in steps of 10, up to $N = 80$ (beyond which the clustering quality diminishes).[8] Observe that w2v achieves the best results, with a V-Measure value of around 0.36,[9] which is relatively constant over varying numbers of clusters. GloVe and SVD mirror this result, but are consistently below w2v at a V-Measure of around 0.31. HLBL and SENNA performed very

[4] Word similarity is not included; it is not easily captured by DIFFVEC since there is no homogeneous "content" to the lexical relation which could be captured by the direction and magnitude of a difference vector (other than that it should be small).

Table 3: The entropy for each lexical relation over the clustering output for each set of pre-trained word embeddings.

similarly, at a substantially lower V-Measure than w2v or GloVe, closer to 0.21. As a crude calibration for these results, over the related clustering task of word sense induction, the best-performing systems in SemEval-2010 Task 4 (Manandhar et al., 2010) achieved a V-Measure of under 0.2.

The lower V-measure for w2v$_{\text{wiki}}$ and GloVe$_{\text{wiki}}$ (as compared to w2v and GloVe, respectively) indicates that the volume of training data plays a role in the clustering results. However, both methods still perform well above SENNA and HLBL, and w2v has a clear empirical advantage over GloVe. We note that SVD$_{\text{wiki}}$ performs almost as well as w2v$_{\text{wiki}}$, consistent with the results of Levy et al. (2015a).

We additionally calculated the entropy for each lexical relation, based on the distribution of instances belonging to a given relation across the different clusters (and simple MLE). For each embedding method, we present the entropy for the cluster size where V-measure was maximised over the development data. Since the samples are distributed nonuniformly, we normalise entropy results for each method by $\log(n)$ where n is the number of samples in a particular relation. The results are in Table 3, with the lowest entropy (purest clustering) for each relation indicated in bold.

Looking across the different lexical relation types, the morphosyntactic paradigm relations (NOUN$_{\text{SP}}$ and the three VERB relations) are by far the easiest to capture. The lexical semantic relations, on the other hand, are the hardest to capture for all embeddings.

Considering w2v embeddings, for VERB$_3$ there was a single cluster consisting of around 90% of VERB$_3$ word pairs. Most errors resulted from POS ambiguity, leading to confusion with VERB-NOUN in particular. Example VERB$_3$ pairs incorrectly clustered are: (*study*, *studies*), (*run*, *runs*), and (*like*, *likes*). This polysemy results in the distance represented in the DIFFVEC for such pairs being above average for VERB$_3$, and consequently clustered with other cross-POS relations.

For VERB$_{\text{Past}}$, a single relatively pure cluster was generated, with minor contamination due to pairs such as (*hurt*, *saw*), (*utensil*, *saw*), and (*wipe*, *saw*). Here, the noun *saw* is ambiguous with a high-frequency past-tense verb; *hurt* and *wipe* also have ambigous POS.

A related phenomenon was observed for NOUN$_{\text{Coll}}$, where the instances were assigned to a large mixed cluster containing word pairs where the second word referred to an animal, reflecting the fact that most of the collective nouns in our dataset relate to animals, e.g. (*stand*, *horse*), (*ambush*, *tigers*), (*antibiotics*, *bacteria*). This is interesting from a DIFFVEC point of view, since it shows that the lexical semantics of one word in the pair can overwhelm the semantic content of the DIFFVEC (something that we return to investigate in §5.4). LEXSEM$_{\text{Mero}}$ was also split into multiple clusters along topical lines, with separate clusters for weapons, dwellings, vehicles, etc.

Given the encouraging results from our clustering experiment, we next evaluate DIFFVECs in a supervised relation classification setting.

5 Classification

A natural question is whether we can accurately characterise lexical relations through supervised learning over the DIFFVECs. For these experiments we use the w2v, w2v_{wiki}, and SVD_{wiki} embeddings exclusively (based on their superior performance in the clustering experiment), and a subset of the relations which is both representative of the breadth of the full relation set, and for which we have sufficient data for supervised training and evaluation, namely: $\text{NOUN}_{\text{Coll}}$, $\text{LEXSEM}_{\text{Event}}$, $\text{LEXSEM}_{\text{Hyper}}$, $\text{LEXSEM}_{\text{Mero}}$, NOUN_{SP}, PREFIX, VERB_{3}, $\text{VERB}_{3\text{Past}}$, and $\text{VERB}_{\text{Past}}$ (see Table 2).

We consider two applications: (1) a CLOSED-WORLD setting similar to the unsupervised evaluation, in which the classifier only encounters word pairs which correspond to one of the nine relations; and (2) a more challenging OPEN-WORLD setting where random word pairs — which may or may not correspond to one of our relations — are included in the evaluation. For both settings, we further investigate whether there is a lexical memorisation effect for a broad range of relation types of the sort identified by Weeds et al. (2014) and Levy et al. (2015b) for hypernyms, by experimenting with disjoint training and test vocabulary.

5.1 CLOSED-WORLD Classification

For the CLOSED-WORLD setting, we train and test a multiclass classifier on datasets comprising $\langle \text{DIFFVEC}, r \rangle$ pairs, where r is one of our nine relation types, and DIFFVEC is based on one of w2v, w2v_{wiki} and SVD. As a baseline, we cluster the data as described in §4, running the clusterer several times over the 9-relation data to select the optimal V-Measure value based on the development data, resulting in 50 clusters. We label each cluster with the majority class based on the training instances, and evaluate the resultant labelling for the test instances.

We use an SVM with a linear kernel, and report results from 10-fold cross-validation in Table 4.

The SVM achieves a higher F-score than the baseline on almost every relation, particularly on $\text{LEXSEM}_{\text{Hyper}}$, and the lower-frequency NOUN_{SP}, $\text{NOUN}_{\text{Coll}}$, and PREFIX. Most of the relations — even the most difficult ones from our clustering experiment — are classified with very high F-score. That is, with a simple linear transformation of the embedding dimensions, we are able to achieve near-perfect results. The PREFIX relation achieved markedly lower recall, resulting in a lower F-score, due to large differences in the predominant usages associated with the respective words (e.g., (*union*, *reunion*), where the vector for *union* is heavily biased by contexts associated with trade unions, but *reunion* is heavily biased by contexts relating to social get-togethers; and (*entry*, *reentry*), where *entry* is associated with competitions and entrance to schools, while *reentry* is associated with space travel). Somewhat surprisingly, given the small dimensionality of the input (vectors of size 300 for all three methods), we found that the linear SVM slightly outperformed a non-linear SVM using an RBF kernel. We observe no real difference between w2v_{wiki} and SVD_{wiki}, supporting the hypothesis of Levy et al. (2015a) that under appropriate parameter settings, count-based methods achieve high results. The impact of the training data volume for pre-training of the embeddings is also less pronounced than in the case of our clustering experiment.

Relation	Baseline	w2v	w2v_{wiki}	SVD_{wiki}
$\text{LEXSEM}_{\text{Hyper}}$	0.60	0.93	0.91	0.91
$\text{LEXSEM}_{\text{Mero}}$	0.90	0.97	0.96	0.96
$\text{LEXSEM}_{\text{Event}}$	0.87	0.98	0.97	0.97

5.2 OPEN-WORLD Classification

We now turn to a more challenging evaluation setting: a test set including word pairs drawn at random. This setting aims to illustrate whether a DIFFVEC-based classifier is capable of differentiating related word pairs from noise, and can be applied to open data to learn new related word pairs.[10]

For these experiments, we train a binary classifier for each relation type, using $\frac{2}{3}$ of our relation data for training and $\frac{1}{3}$ for testing. The test data is augmented with an equal quantity of random pairs, generated as follows:

(1) sample a seed lexicon by drawing words proportional to their frequency in Wikipedia;[11]

[10] Hereafter we provide results for w2v only, as we found that SVD achieved similar results.

[11] Filtered to consist of words for which we have embed-

Table 5: Precision ($\mathcal{P}$) and recall ($\mathcal{R}$) for OPEN-WORLD classification, using the binary classifier without ("Orig") and with ("+neg") negative samples .

(2) take the Cartesian product over pairs of words from the seed lexicon;
(3) sample word pairs uniformly from this set.

This procedure generates word pairs that are representative of the frequency profile of our corpus.

We train 9 binary RBF-kernel SVM classifiers on the training partition, and evaluate on our randomly augmented test set. Fully annotating our random word pairs is prohibitively expensive, so instead, we manually annotated only the word pairs which were positively classified by one of our models. The results of our experiments are presented in the left half of Table 5, in which we report on results over the combination of the original test data from §5.1 and the random word pairs, noting that recall ($\mathcal{R}$) for OPEN-WORLD takes the form of relative recall (Pantel et al., 2004) over the positively-classified word pairs. The results are much lower than for the closed-word setting (Table 4), most notably in terms of precision ($\mathcal{P}$). For instance, the random pairs (*have*, *works*), (*turn*, *took*), and (*works*, *started*) were incorrectly classified as VERB$_3$, VERB$_{\text{Past}}$ and VERB$_{\text{3Past}}$, respectively. That is, the model captures syntax, but lacks the ability to capture lexical paradigms, and tends to overgenerate.

5.3 OPEN-WORLD Training with Negative Sampling

To address the problem of incorrectly classifying random word pairs as valid relations, we retrain the classifier on a dataset comprising both valid and automatically-generated negative distractor samples. The basic intuition behind this approach is to construct samples which will force the model to learn decision boundaries that more tightly capture the true scope of a given relation. To this end, we automatically generated two types of negative distractors:

opposite pairs: generated by switching the order of word pairs, $\mathit{Oppos}_{w1,w2} = \mathbf{word_1} - \mathbf{word_2}$. This ensures the classifier adequately captures the asymmetry in the relations.

shuffled pairs: generated by replacing w_2 with a random word w_2' from the same relation, $\mathit{Shuff}_{w1,w2} = \mathbf{word_2'} - \mathbf{word_1}$. This is targeted at relations that take specific word classes in particular positions, e.g., (VB, VBD) word pairs, so that the model learns to encode the relation rather than simply learning the properties of the word classes.

Both types of distractors are added to the training set, such that there are equal numbers of valid relations, opposite pairs and shuffled pairs.

After training our classifier, we evaluate its predictions in the same way as in §5.2, using the same test set combining related and random word pairs.[12] The results are shown in the right half of Table 5 (as "+neg"). Observe that the precision is much higher and recall somewhat lower compared to the classifier trained with only positive samples. This follows from the adversarial training scenario: using negative distractors results in a more conservative classifier, that correctly classifies the vast majority of the random word pairs as not corresponding to a given relation, resulting in higher precision at the expense of a small drop in recall. Overall this leads to higher F-scores, as shown in Figure 3, other than for hypernyms (LEXSEM$_{\text{Hyper}}$) and prefixes (PREFIX). For example, the standard classifier for NOUN$_{\text{Coll}}$ learned to match word pairs including an animal name (e.g., (*plague*, *rats*)), while training with negative samples resulted in much more conservative predictions and consequently much lower recall. The classifier was able to capture (*herd*, *horses*) but not (*run*, *salmon*), (*party*, *jays*) or (*singular*, *boar*) as instances of NOUN$_{\text{Coll}}$, possibly because of polysemy. The most striking difference in performance was for LEXSEM$_{\text{Mero}}$, where the standard classifier generated many false positive noun pairs (e.g. (*series*, *radio*)), but the false positive rate was considerably reduced with negative sampling.

5.4 Lexical Memorisation

Weeds et al. (2014) and Levy et al. (2015b) recently showed that supervised methods using DIFFVECs achieve artificially high results as a result of "lexical memorisation" over frequent words asso-

dings.

[12] But noting that relative recall for the random word pairs is based on the pool of positive predictions from both models.

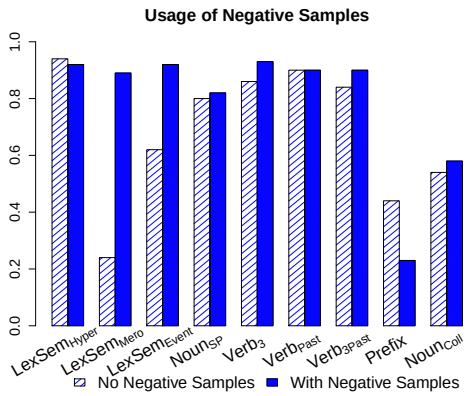

Figure 3: F-score for OPEN-WORLD classification, comparing models trained with and without negative samples.

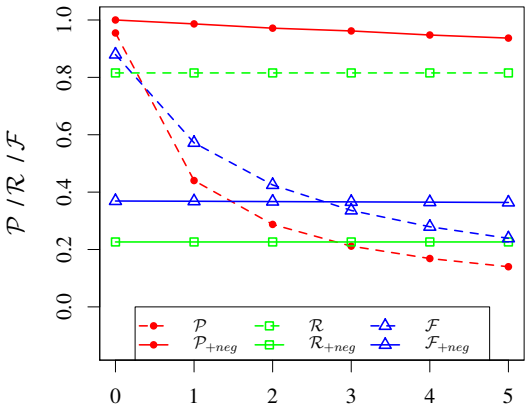

Figure 4: Evaluation of the OPEN-WORLD model when trained on split vocabulary, for varying numbers of random word pairs in the test dataset (expressed as a multiplier relative to the number of CLOSED-WORLD test instances).

ciated with the hypernym relation. For example, (*animal*, *cat*), (*animal*, *dog*), and (*animal*, *pig*) all share the superclass *animal*, and the model thus learns to classify as positive any word pair with *animal* as the first word.

To address this effect, we follow Levy et al. (2015b) in splitting our vocabulary into training and test partitions, to ensure there is no overlap between training and test vocabulary. We then train classifiers with and without negative sampling (§5.3), incrementally adding the random word pairs from §5.2 to the test data (from no random word pairs to five times the original size of the test data) to investigate the interaction of negative sampling with greater diversity in the test set when there is a split vocabulary. The results are shown in Figure 4.

Observe that the precision for the standard classifier decreases rapidly as more random word pairs are added to the test data. In comparison, the precision when negative sampling is used shows only a small drop-off, indicating that negative sampling is effective at maintaining precision in an OPEN-WORLD setting even when the training and test vocabulary are disjoint. This benefit comes at the expense of recall, which is much lower when negative sampling is used (note that recall stays relatively constant as random word pairs are added, as the vast majority of them do not correspond to any relation). At the maximum level of random word pairs in the test data, the F-score for the negative sampling classifier is higher than for the standard classifier.

6 Conclusions

This paper is the first to test the generalisability of the vector difference approach across a broad range of lexical relations (in raw number and also variety). Using clustering we showed that many types of morphosyntactic and morphosemantic differences are captured by DIFFVECs, but that lexical semantic relations are captured less well, a finding which is consistent with previous work (Köper et al., 2015). In contrast, classification over the DIFFVECs works extremely well in a closed-world setting, showing that dimensions of DIFFVECs encode lexical relations. Classification performs less well over open data, although with the introduction of automatically-generated negative samples, the results improve substantially. Negative sampling also improves classification when the training and test vocabulary are split to minimise lexical memorisation. Overall, we conclude that the DIFFVEC approach has impressive utility over a broad range of lexical relations, especially under supervised classification.

Abstract

We propose minimum risk training for end-to-end neural machine translation. Unlike conventional maximum likelihood estimation, minimum risk training is capable of optimizing model parameters directly with respect to arbitrary evaluation metrics, which are not necessarily differentiable. Experiments show that our approach achieves significant improvements over maximum likelihood estimation on a state-of-the-art neural machine translation system across various languages pairs. Transparent to architectures, our approach can be applied to more neural networks and potentially benefit more NLP tasks.

1 Introduction

Recently, end-to-end neural machine translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015) has attracted increasing attention from the community. Providing a new paradigm for machine translation, NMT aims at training a single, large neural network that directly transforms a source-language sentence to a target-language sentence without explicitly modeling latent structures (e.g., word alignment, phrase segmentation, phrase reordering, and SCFG derivation) that are vital in conventional statistical machine translation (SMT) (Brown et al., 1993; Koehn et al., 2003; Chiang, 2005).

Current NMT models are based on the *encoder-decoder* framework (Cho et al., 2014; Sutskever et al., 2014), with an encoder to read and encode a source-language sentence into a vector, from which a decoder generates a target-language sentence. While early efforts encode the input into a fixed-length vector, Bahdanau et al. (2015) advocate the attention mechanism to dynamically generate a context vector for a target word being generated.

Although NMT models have achieved results on par with or better than conventional SMT, they still suffer from a major drawback: the models are optimized to maximize the likelihood of training data instead of evaluation metrics that actually quantify translation quality. Ranzato et al. (2015) indicate two drawbacks of *maximum likelihood estimation* (MLE) for NMT. First, the models are only exposed to the training distribution instead of model predictions. Second, the loss function is defined at the word level instead of the sentence level.

In this work, we introduce *minimum risk training* (MRT) for neural machine translation. The new training objective is to minimize the expected loss (i.e., risk) on the training data. MRT has the following advantages over MLE:

1. *Direct optimization with respect to evaluation metrics*: MRT introduces evaluation metrics as loss functions and aims to minimize expected loss on the training data.

2. *Applicable to arbitrary loss functions*: our approach allows arbitrary sentence-level loss functions, which are not necessarily differentiable.

3. *Transparent to architectures*: MRT does not assume the specific architectures of NMT and can be applied to any end-to-end NMT systems.

While MRT has been widely used in conventional SMT (Och, 2003; Smith and Eisner, 2006; He and Deng, 2012) and deep learning based MT (Gao et al., 2014), to the best of our knowledge, this work is the first effort to introduce MRT

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1683–1692,
Berlin, Germany, August 7-12, 2016.

into end-to-end NMT. Experiments on a variety of language pairs (Chinese-English, English-French, and English-German) show that MRT leads to significant improvements over MLE on a state-of-the-art NMT system (Bahdanau et al., 2015).

2 Background

Given a source sentence $\mathbf{x} = \mathbf{x}_1, \ldots, \mathbf{x}_m, \ldots, \mathbf{x}_M$ and a target sentence $\mathbf{y} = \mathbf{y}_1, \ldots, \mathbf{y}_n, \ldots, \mathbf{y}_N$, end-to-end NMT directly models the translation probability:

$$P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) = \prod_{n=1}^{N} P(\mathbf{y}_n|\mathbf{x}, \mathbf{y}_{<n};\boldsymbol{\theta}), \quad (1)$$

where $\boldsymbol{\theta}$ is a set of model parameters and $\mathbf{y}_{<n} = \mathbf{y}_1, \ldots, \mathbf{y}_{n-1}$ is a partial translation.

Predicting the n-th target word can be modeled by using a recurrent neural network:

$$P(\mathbf{y}_n|\mathbf{x}, \mathbf{y}_{<n};\boldsymbol{\theta}) \propto \exp\Big\{q(\mathbf{y}_{n-1}, \mathbf{z}_n, \mathbf{c}_n, \boldsymbol{\theta})\Big\}, \quad (2)$$

where $\mathbf{z}_n$ is the n-th hidden state on the target side, $\boldsymbol{c}_n$ is the context for generating the n-th target word, and $q(\cdot)$ is a non-linear function. Current NMT approaches differ in calculating $\mathbf{z}_n$ and $\mathbf{c}_n$ and defining $q(\cdot)$. Please refer to (Sutskever et al., 2014; Bahdanau et al., 2015) for more details.

Given a set of training examples $D = \{\langle \mathbf{x}^{(s)}, \mathbf{y}^{(s)} \rangle\}_{s=1}^{S}$, the standard training objective is to maximize the log-likelihood of the training data:

$$\hat{\boldsymbol{\theta}}_{\mathrm{MLE}} = \operatorname*{argmax}_{\boldsymbol{\theta}} \Big\{\mathcal{L}(\boldsymbol{\theta})\Big\}, \quad (3)$$

where

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{s=1}^{S} \log P(\mathbf{y}^{(s)}|\mathbf{x}^{(s)};\boldsymbol{\theta}) \quad (4)$$

$$= \sum_{s=1}^{S} \sum_{n=1}^{N^{(s)}} \log P(\mathbf{y}_n^{(s)}|\mathbf{x}^{(s)}, \mathbf{y}_{<n}^{(s)};\boldsymbol{\theta}). \quad (5)$$

We use $N^{(s)}$ to denote the length of the s-th target sentence $\mathbf{y}^{(s)}$.

The partial derivative with respect to a model parameter $\boldsymbol{\theta}_i$ is calculated as

$$\frac{\partial \mathcal{L}(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}_i} = \sum_{s=1}^{S} \sum_{n=1}^{N^{(s)}} \frac{\partial P(\mathbf{y}_n^{(s)}|\mathbf{x}^{(s)}, \mathbf{y}_{<n}^{(s)};\boldsymbol{\theta})/\partial \boldsymbol{\theta}_i}{P(\mathbf{y}_n^{(s)}|\mathbf{x}^{(s)}, \mathbf{y}_{<n}^{(s)};\boldsymbol{\theta})}. \quad (6)$$

Ranzato et al. (2015) point out that MLE for end-to-end NMT suffers from two drawbacks. First, while the models are trained only on the training data distribution, they are used to generate target words on previous model predictions, which can be erroneous, at test time. This is referred to as *exposure bias* (Ranzato et al., 2015). Second, MLE usually uses the cross-entropy loss focusing on word-level errors to maximize the probability of the next correct word, which might hardly correlate well with corpus-level and sentence-level evaluation metrics such as BLEU (Papineni et al., 2002) and TER (Snover et al., 2006).

As a result, it is important to introduce new training algorithms for end-to-end NMT to include model predictions during training and optimize model parameters directly with respect to evaluation metrics.

3 Minimum Risk Training for Neural Machine Translation

Minimum risk training (MRT), which aims to minimize the expected loss on the training data, has been widely used in conventional SMT (Och, 2003; Smith and Eisner, 2006; He and Deng, 2012) and deep learning based MT (Gao et al., 2014). The basic idea is to introduce evaluation metrics as loss functions and assume that the optimal set of model parameters should minimize the expected loss on the training data.

Let $\langle \mathbf{x}^{(s)}, \mathbf{y}^{(s)} \rangle$ be the s-th sentence pair in the training data and $\mathbf{y}$ be a model prediction. We use a *loss function* $\Delta(\mathbf{y}, \mathbf{y}^{(s)})$ to measure the discrepancy between the model prediction $\mathbf{y}$ and the gold-standard translation $\mathbf{y}^{(s)}$. Such a loss function can be negative smoothed sentence-level evaluation metrics such as BLEU (Papineni et al., 2002), NIST (Doddington, 2002), TER (Snover et al., 2006), or METEOR (Lavie and Denkowski, 2009) that have been widely used in machine translation evaluation. Note that a loss function is not parameterized and thus not differentiable.

In MRT, the *risk* is defined as the expected loss with respect to the posterior distribution:

$$\mathcal{R}(\boldsymbol{\theta}) = \sum_{s=1}^{S} \mathbb{E}_{\mathbf{y}|\mathbf{x}^{(s)};\boldsymbol{\theta}}\Big[\Delta(\mathbf{y}, \mathbf{y}^{(s)})\Big] \quad (7)$$

$$= \sum_{s=1}^{S} \sum_{\mathbf{y} \in \mathcal{Y}(\mathbf{x}^{(s)})} P(\mathbf{y}|\mathbf{x}^{(s)};\boldsymbol{\theta}) \Delta(\mathbf{y}, \mathbf{y}^{(s)}), \quad (8)$$

where $\mathcal{Y}(\mathbf{x}^{(s)})$ is a set of all possible candidate translations for $\mathbf{x}^{(s)}$.

	$\Delta(\mathbf{y}, \mathbf{y}^{(s)})$	$P(\mathbf{y}\|\mathbf{x}^{(s)};\boldsymbol{\theta})$			
$\mathbf{y}_1$	-1.0	0.2	0.3	0.5	0.7
$\mathbf{y}_2$	-0.3	0.5	0.2	0.2	0.1
$\mathbf{y}_3$	-0.5	0.3	0.5	0.3	0.2
$\mathbb{E}_{\mathbf{y}\|\mathbf{x}^{(s)};\boldsymbol{\theta}}[\Delta(\mathbf{y}, \mathbf{y}^{(s)})]$	-0.50	-0.61	-0.71	-0.83	

Table 1: Example of minimum risk training. $\mathbf{x}^{(s)}$ is an observed source sentence, $\mathbf{y}^{(s)}$ is its corresponding gold-standard translation, and $\mathbf{y}_1$, $\mathbf{y}_2$, and $\mathbf{y}_3$ are model predictions. For simplicity, we suppose that the full search space contains only three candidates. The loss function $\Delta(\mathbf{y}, \mathbf{y}^{(s)})$ measures the difference between model prediction and gold-standard. The goal of MRT is to find a distribution (the last column) that correlates well with the gold-standard by minimizing the expected loss.

The training objective of MRT is to minimize the risk on the training data:

$$\hat{\boldsymbol{\theta}}_{\text{MRT}} = \underset{\boldsymbol{\theta}}{\text{argmin}} \Big\{ \mathcal{R}(\boldsymbol{\theta}) \Big\}. \tag{9}$$

Intuitively, while MLE aims to maximize the likelihood of training data, our training objective is to discriminate between candidates. For example, in Table 1, suppose the candidate set $\mathcal{Y}(\mathbf{x}^{(s)})$ contains only three candidates: $\mathbf{y}_1$, $\mathbf{y}_2$, and $\mathbf{y}_3$. According to the losses calculated by comparing with the gold-standard translation $\mathbf{y}^{(s)}$, it is clear that $\mathbf{y}_1$ is the best candidate, $\mathbf{y}_3$ is the second best, and $\mathbf{y}_2$ is the worst: $\mathbf{y}_1 > \mathbf{y}_3 > \mathbf{y}_2$. The right half of Table 1 shows four models. As model 1 (column 3) ranks the candidates in a reverse order as compared with the gold-standard (i.e., $\mathbf{y}_2 > \mathbf{y}_3 > \mathbf{y}_1$), it obtains the highest risk of -0.50. Achieving a better correlation with the gold-standard than model 1 by predicting $\mathbf{y}_3 > \mathbf{y}_1 > \mathbf{y}_2$, model 2 (column 4) reduces the risk to -0.61. As model 3 (column 5) ranks the candidates in the same order with the gold-standard, the risk goes down to -0.71. The risk can be further reduced by concentrating the probability mass on $\mathbf{y}_1$ (column 6). As a result, by minimizing the risk on the training data, we expect to obtain a model that correlates well with the gold-standard.

In MRT, the partial derivative with respect to a model parameter $\boldsymbol{\theta}_i$ is given by

$$\frac{\partial \mathcal{R}(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}_i} = \sum_{s=1}^{S} \mathbb{E}_{\mathbf{y}|\mathbf{x}^{(s)};\boldsymbol{\theta}} \Bigg[\Delta(\mathbf{y}, \mathbf{y}^{(s)}) \times \sum_{n=1}^{N^{(s)}} \frac{\partial P(\mathbf{y}_n|\mathbf{x}^{(s)}, \mathbf{y}_{<n}; \boldsymbol{\theta}) / \partial \boldsymbol{\theta}_i}{P(\mathbf{y}_n|\mathbf{x}^{(s)}, \mathbf{y}_{<n}; \boldsymbol{\theta})} \Bigg]. \tag{10}$$

Since Eq. (10) suggests there is no need to differentiate $\Delta(\mathbf{y}, \mathbf{y}^{(s)})$, MRT allows arbitrary non-differentiable loss functions. In addition, our approach is transparent to architectures and can be applied to arbitrary end-to-end NMT models.

Despite these advantages, MRT faces a major challenge: the expectations in Eq. (10) are usually intractable to calculate due to the exponential search space of $\mathcal{Y}(\mathbf{x}^{(s)})$, the non-decomposability of the loss function $\Delta(\mathbf{y}, \mathbf{y}^{(s)})$, and the context sensitiveness of NMT.

To alleviate this problem, we propose to only use a subset of the full search space to approximate the posterior distribution and introduce a new training objective:

$$\tilde{\mathcal{R}}(\boldsymbol{\theta}) = \sum_{s=1}^{S} \mathbb{E}_{\mathbf{y}|\mathbf{x}^{(s)};\boldsymbol{\theta},\alpha} \Big[\Delta(\mathbf{y}, \mathbf{y}^{(s)}) \Big] \tag{11}$$

$$= \sum_{s=1}^{S} \sum_{\mathbf{y} \in \mathcal{S}(\mathbf{x}^{(s)})} Q(\mathbf{y}|\mathbf{x}^{(s)}; \boldsymbol{\theta}, \alpha) \Delta(\mathbf{y}, \mathbf{y}^{(s)}), \tag{12}$$

where $\mathcal{S}(\mathbf{x}^{(s)}) \subset \mathcal{Y}(\mathbf{x}^{(s)})$ is a sampled subset of the full search space, and $Q(\mathbf{y}|\mathbf{x}^{(s)}; \boldsymbol{\theta}, \alpha)$ is a distribution defined on the subspace $\mathcal{S}(\mathbf{x}^{(s)})$:

$$Q(\mathbf{y}|\mathbf{x}^{(s)}; \boldsymbol{\theta}, \alpha) = \frac{P(\mathbf{y}|\mathbf{x}^{(s)}; \boldsymbol{\theta})^{\alpha}}{\sum_{\mathbf{y}' \in \mathcal{S}(\mathbf{x}^{(s)})} P(\mathbf{y}'|\mathbf{x}^{(s)}; \boldsymbol{\theta})^{\alpha}}. \tag{13}$$

Note that α is a hyper-parameter that controls the sharpness of the Q distribution (Och, 2003).

Algorithm 1 shows how to build $\mathcal{S}(\mathbf{x}^{(s)})$ by sampling the full search space. The sampled subset initializes with the gold-standard translation (line 1). Then, the algorithm keeps sampling a target word given the source sentence and the partial translation until reaching the end of sentence (lines 3-16). Note that sampling might produce duplicate candidates, which are removed when building

Input: the s-th source sentence in the training data $\mathbf{x}^{(s)}$, the s-th target sentence in the training data $\mathbf{y}^{(s)}$, the set of model parameters $\boldsymbol{\theta}$, the limit on the length of a candidate translation l, and the limit on the size of sampled space k.

Output: sampled space $\mathcal{S}(\mathbf{x}^{(s)})$.

$\mathcal{S}(\mathbf{x}^{(s)}) \leftarrow \{\mathbf{y}^{(s)}\}$; // the gold-standard translation is included
$i \leftarrow 1$;
while $i \leq k$ **do**
  $\mathbf{y} \leftarrow \emptyset$; // an empty candidate translation
  $n \leftarrow 1$;
  while $n \leq l$ **do**
    $y \sim P(\mathbf{y}_n|\mathbf{x}^{(s)}, \mathbf{y}_{<n}; \boldsymbol{\theta})$; // sample the n-th target word
    $\mathbf{y} \leftarrow \mathbf{y} \cup \{y\}$;
    if $y = \text{EOS}$ **then**
      break; // terminate if reach the end of sentence
    end
    $n \leftarrow n + 1$;
  end
  $\mathcal{S}(\mathbf{x}^{(s)}) \leftarrow \mathcal{S}(\mathbf{x}^{(s)}) \cup \{\mathbf{y}\}$;
  $i \leftarrow i + 1$;
end

Algorithm 1: Sampling the full search space.

the subspace. We find that it is inefficient to force the algorithm to generate exactly k distinct candidates because high-probability candidates can be sampled repeatedly, especially when the probability mass highly concentrates on a few candidates. In practice, we take advantage of GPU's parallel architectures to speed up the sampling. [1]

Given the sampled space, the partial derivative with respect to a model parameter $\boldsymbol{\theta}_i$ of $\tilde{\mathcal{R}}(\boldsymbol{\theta})$ is given by

$$\frac{\partial \tilde{R}(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}_i} = \alpha \sum_{s=1}^{S} \mathbb{E}_{\mathbf{y}|\mathbf{x}^{(s)};\boldsymbol{\theta},\alpha} \left[\frac{\partial P(\mathbf{y}|\mathbf{x}^{(s)};\boldsymbol{\theta})/\partial \boldsymbol{\theta}_i}{P(\mathbf{y}|\mathbf{x}^{(s)};\boldsymbol{\theta})} \times \Big(\Delta(\mathbf{y}, \mathbf{y}^{(s)}) - \mathbb{E}_{\mathbf{y}'|\mathbf{x}^{(s)};\boldsymbol{\theta},\alpha}[\Delta(\mathbf{y}', \mathbf{y}^{(s)})] \Big) \right]. \quad (14)$$

Since $|\mathcal{S}(\mathbf{x}^{(s)})| \ll |\mathcal{Y}(\mathbf{x}^{(s)})|$, the expectations in Eq. (14) can be efficiently calculated by explicitly enumerating all candidates in $\mathcal{S}(\mathbf{x}^{(s)})$. In our experiments, we find that approximating the full space with 100 samples (i.e., $k = 100$) works very well and further increasing sample size does not lead to significant improvements (see Section 4.3).

[1] To build the subset, an alternative to sampling is computing top-k translations. We prefer sampling to computing top-k translations for efficiency: sampling is more efficient and easy-to-implement than calculating k-best lists, especially given the extremely parallel architectures of GPUs.

4 Experiments

4.1 Setup

We evaluated our approach on three translation tasks: Chinese-English, English-French, and English-German. The evaluation metric is BLEU (Papineni et al., 2002) as calculated by the `multi-bleu.perl` script.

For Chinese-English, the training data consists of 2.56M pairs of sentences with 67.5M Chinese words and 74.8M English words, respectively. We used the NIST 2006 dataset as the validation set (hyper-parameter optimization and model selection) and the NIST 2002, 2003, 2004, 2005, and 2008 datasets as test sets.

For English-French, to compare with the results reported by previous work on end-to-end NMT (Sutskever et al., 2014; Bahdanau et al., 2015; Jean et al., 2015; Luong et al., 2015b), we used the same subset of the WMT 2014 training corpus that contains 12M sentence pairs with 304M English words and 348M French words. The concatenation of news-test 2012 and news-test 2013 serves as the validation set and news-test 2014 as the test set.

For English-German, to compare with the results reported by previous work (Jean et al., 2015; Luong et al., 2015a), we used the same subset of the WMT 2014 training corpus that contains 4M sentence pairs with 91M English words and 87M German words. The concatenation of news-test 2012 and news-test 2013 is used as the validation set and news-test 2014 as the test set.

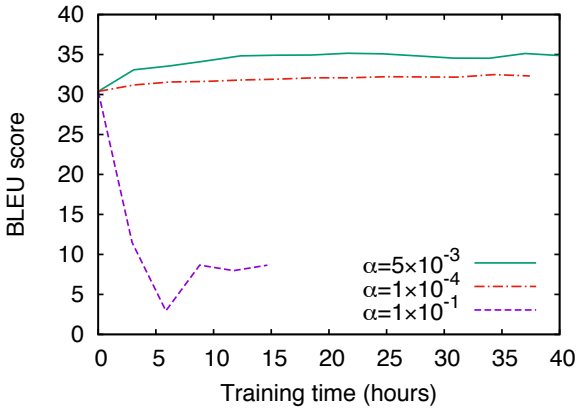

Figure 1: Effect of α on the Chinese-English validation set.

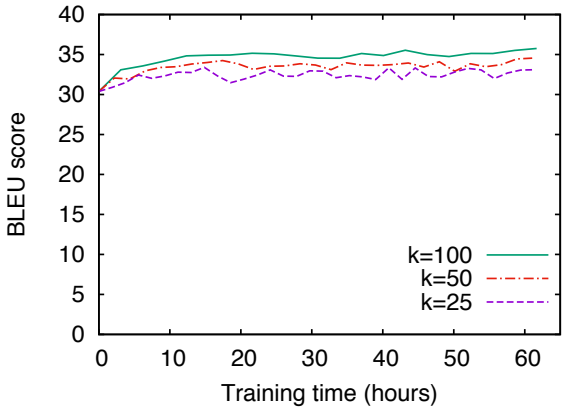

Figure 2: Effect of sample size on the Chinese-English validation set.

criterion	loss	BLEU	TER	NIST
MLE	N/A	30.48	60.85	8.26
MRT	−sBLEU	**36.71**	**53.48**	**8.90**
	sTER	30.14	53.83	6.02
	−sNIST	32.32	56.85	**8.90**

Table 2: Effect of loss function on the Chinese-English validation set.

We compare our approach with two state-of-the-art SMT and NMT systems:

1. MOSES (Koehn and Hoang, 2007): a phrase-based SMT system using minimum error rate training (Och, 2003).

2. RNNSEARCH (Bahdanau et al., 2015): an attention-based NMT system using maximum likelihood estimation.

MOSES uses the parallel corpus to train a phrase-based translation model and the target part to train a 4-gram language model using the SRILM toolkit (Stolcke, 2002). [2] The log-linear model Moses uses is trained by the minimum error rate training (MERT) algorithm (Och, 2003) that directly optimizes model parameters with respect to evaluation metrics.

RNNSEARCH uses the parallel corpus to train an attention-based neural translation model using the maximum likelihood criterion.

On top of RNNSEARCH, our approach replaces MLE with MRT. We initialize our model with the RNNsearch50 model (Bahdanau et al., 2015). We set the vocabulary size to 30K for Chinese-English and English-French and 50K for English-German. The beam size for decoding is 10. The default loss function is negative smoothed sentence-level BLEU.

4.2 Effect of α

The hyper-parameter α controls the smoothness of the Q distribution (see Eq. (13)). As shown in Figure 1, we find that α has a critical effect on BLEU scores on the Chinese-English validation set. While $\alpha = 1 \times 10^{-1}$ deceases BLEU scores dramatically, $\alpha = 5 \times 10^{-3}$ improves translation quality significantly and consistently. Reducing α further to 1×10^{-4}, however, results in lower BLEU scores. Therefore, we set $\alpha = 5 \times 10^{-3}$ in the following experiments.

4.3 Effect of Sample Size

For efficiency, we sample k candidate translations from the full search space $\mathcal{Y}(\mathbf{x}^{(s)})$ to build an approximate posterior distribution Q (Section 3). Figure 2 shows the effect of sample size k on the Chinese-English validation set. It is clear that BLEU scores consistently rise with the increase of k. However, we find that a sample size larger than 100 (e.g., $k = 200$) usually does not lead to significant improvements and increases the GPU memory requirement. Therefore, we set $k = 100$ in the following experiments.

4.4 Effect of Loss Function

As our approach is capable of incorporating evaluation metrics as loss functions, we investigate the effect of different loss functions on BLEU, TER

[2] It is possible to exploit larger monolingual corpora for both MOSES and RNNSEARCH (Gulcehre et al., 2015; Sennrich et al., 2015). We leave this for future work.

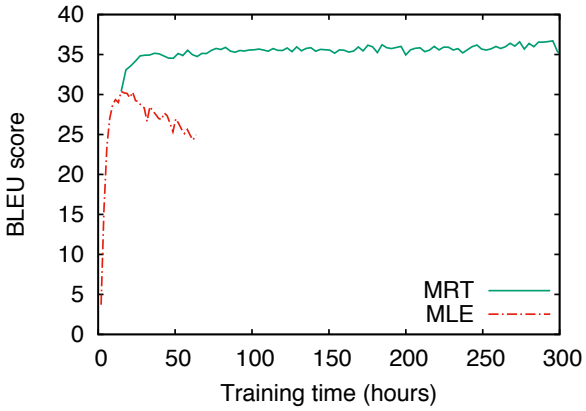

Figure 3: Comparison of training time on the Chinese-English validation set.

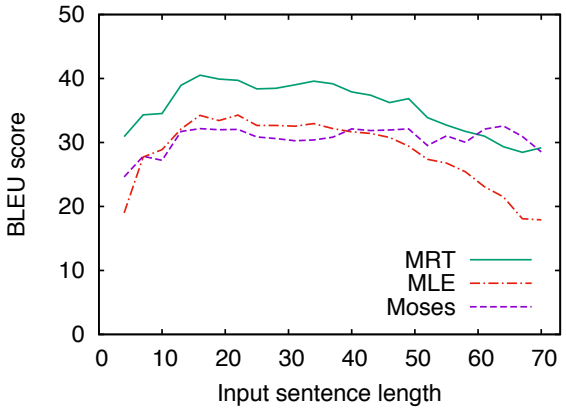

Figure 4: BLEU scores on the Chinese-English test set over various input sentence lengths.

and NIST scores on the Chinese-English validation set. As shown in Table 2, negative smoothed sentence-level BLEU (i.e, $-$sBLEU) leads to statistically significant improvements over MLE ($p < 0.01$). Note that the loss functions are all defined at the sentence level while evaluation metrics are calculated at the corpus level. This discrepancy might explain why optimizing with respect to sTER does not result in the lowest TER on the validation set. As $-$sBLEU consistently improves all evaluation metrics, we use it as the default loss function in our experiments.

4.5 Comparison of Training Time

We used a cluster with 20 Telsa K40 GPUs to train the NMT model. For MLE, it takes the cluster about one hour to train 20,000 mini-batches, each of which contains 80 sentences. The training time for MRT is longer than MLE: 13,000 mini-batches can be processed in one hour on the same cluster.

Figure 3 shows the learning curves of MLE and MRT on the validation set. For MLE, the BLEU score reaches its peak after about 20 hours and then keeps going down dramatically. Initializing with the best MLE model, MRT increases BLEU scores dramatically within about 30 hours. [3] Afterwards, the BLEU score keeps improving gradually but there are slight oscillations.

4.6 Results on Chinese-English Translation

4.6.1 Comparison of BLEU Scores

Table 3 shows BLEU scores on Chinese-English datasets. For RNNSEARCH, we follow Luong et al. (2015b) to handle rare words. We find that introducing minimum risk training into neural MT leads to surprisingly substantial improvements over MOSES and RNNSEARCH with MLE as the training criterion (up to +8.61 and +7.20 BLEU points, respectively) across all test sets. All the improvements are statistically significant.

[3] Although it is possible to initialize with a randomized model, it takes much longer time to converge.

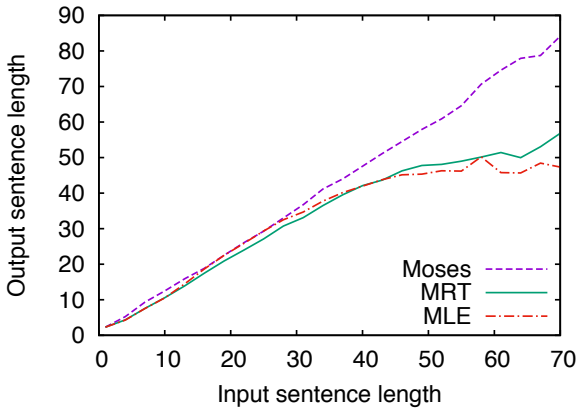

Figure 5: Comparison of output sentences lengths on the Chinese-English test set.

4.6.2 Comparison of TER Scores

Table 4 gives TER scores on Chinese-English datasets. The loss function used in MRT is $-$sBLEU. MRT still obtains dramatic improvements over MOSES and RNNSEARCH with MLE as the training criterion (up to -10.27 and -8.32 TER points, respectively) across all test sets. All the improvements are statistically significant.

4.6.3 BLEU Scores over Sentence Lengths

Figure 4 shows the BLEU scores of translations generated by MOSES, RNNSEARCH with MLE,

System	Training	MT06	MT02	MT03	MT04	MT05	MT08
MOSES	MERT	32.74	32.49	32.40	33.38	30.20	25.28
RNNSEARCH	MLE	30.70	35.13	33.73	34.58	31.76	23.57
	MRT	37.34	40.36	40.93	41.37	38.81	29.23

Table 3: Case-insensitive BLEU scores on Chinese-English translation.

System	Training	MT06	MT02	MT03	MT04	MT05	MT08
MOSES	MERT	59.22	62.97	62.44	61.20	63.44	62.36
RNNSEARCH	MLE	60.74	58.94	60.10	58.91	61.74	64.52
	MRT	52.86	52.87	52.17	51.49	53.42	57.21

Table 4: Case-insensitive TER scores on Chinese-English translation.

	MLE vs. MRT		
	$<$	$=$	$>$
evaluator 1	54%	24%	22%
evaluator 2	53%	22%	25%

Table 5: Subjective evaluation of MLE and MRT on Chinese-English translation.

and RNNSEARCH with MRT on the Chinese-English test set with respect to input sentence lengths. While MRT consistently improves over MLE for all lengths, it achieves worse translation performance for sentences longer than 60 words.

One reason is that RNNSEARCH tends to produce short translations for long sentences. As shown in Figure 5, both MLE and MRE generate much shorter translations than MOSES. This results from the length limit imposed by RNNSEARCH for efficiency reasons: a sentence in the training set is no longer than 50 words. This limit deteriorates translation performance because the sentences in the test set are usually longer than 50 words.

4.6.4 Subjective Evaluation

We also conducted a subjective evaluation to validate the benefit of replacing MLE with MRT. Two human evaluators were asked to compare MLE and MRT translations of 100 source sentences randomly sampled from the test sets without knowing from which system a candidate translation was generated.

Table 5 shows the results of subjective evaluation. The two human evaluators made close judgements: around 54% of MLE translations are worse than MRE, 23% are equal, and 23% are better.

4.6.5 Example Translations

Table 6 shows some example translations. We find that MOSES translates a Chinese string "*yi wei fuze yu pingrang dangju da jiaodao de qian guowuyuan guanyuan*" that requires long-distance reordering in a wrong way, which is a notorious challenge for statistical machine translation. In contrast, RNNSEARCH-MLE seems to overcome this problem in this example thanks to the capability of gated RNNs to capture long-distance dependencies. However, as MLE uses a loss function defined only at the word level, its translation lacks sentence-level consistency: "chinese" occurs twice while "two senate" is missing. By optimizing model parameters directly with respect to sentence-level BLEU, RNNSEARCH-MRT seems to be able to generate translations more consistently at the sentence level.

4.7 Results on English-French Translation

Table 7 shows the results on English-French translation. We list existing end-to-end NMT systems that are comparable to our system. All these systems use the same subset of the WMT 2014 training corpus and adopt MLE as the training criterion. They differ in network architectures and vocabulary sizes. Our RNNSEARCH-MLE system achieves a BLEU score comparable to that of Jean et al. (2015). RNNSEARCH-MRT achieves the highest BLEU score in this setting even with a vocabulary size smaller than Luong et al. (2015b) and Sutskever et al. (2014). Note that our approach does not assume specific architectures and can in principle be applied to any NMT systems.

4.8 Results on English-German Translation

Table 8 shows the results on English-German translation. Our approach still significantly out-

performs MLE and achieves comparable results with state-of-the-art systems even though Luong et al. (2015a) used a much deeper neural network. We believe that our work can be applied to their architecture easily.

Despite these significant improvements, the margins on English-German and English-French datasets are much smaller than Chinese-English. We conjecture that there are two possible reasons. First, the Chinese-English datasets contain four reference translations for each sentence while both English-French and English-German datasets only have single references. Second, Chinese and English are more distantly related than English, French and German and thus benefit more from MRT that incorporates evaluation metrics into optimization to capture structural divergence.

5 Related Work

Our work originated from the minimum risk training algorithms in conventional statistical machine translation (Och, 2003; Smith and Eisner, 2006; He and Deng, 2012). Och (2003) describes a smoothed error count to allow calculating gradients, which directly inspires us to use a parameter α to adjust the smoothness of the objective function. As neural networks are non-linear, our approach has to minimize the expected loss on the sentence level rather than the loss of 1-best translations on the corpus level. Smith and Eisner (2006) introduce minimum risk annealing for training log-linear models that is capable of gradually annealing to focus on the 1-best hypothesis. He et al. (2012) apply minimum risk training to learning phrase translation probabilities. Gao et al. (2014) leverage MRT for learning continuous phrase representations for statistical machine translation. The difference is that they use MRT to optimize a sub-model of SMT while we are interested in directly optimizing end-to-end neural translation models.

The Mixed Incremental Cross-Entropy Reinforce (MIXER) algorithm (Ranzato et al., 2015) is in spirit closest to our work. Building on the REINFORCE algorithm proposed by Williams (1992), MIXER allows incremental learning and the use of hybrid loss function that combines both REINFORCE and cross-entropy. The major difference is that Ranzato et al. (2015) leverage reinforcement learning while our work resorts to minimum risk training. In addition, MIXER only samples one candidate to calculate reinforcement reward while MRT generates multiple samples to calculate the expected risk. Figure 2 indicates that multiple samples potentially increases MRT's capability of discriminating between diverse candidates and thus benefit translation quality. Our experiments confirm their finding that taking evaluation metrics into account when optimizing model parameters does help to improve sentence-level text generation.

More recently, our approach has been successfully applied to summarization (Ayana et al., 2016). They optimize neural networks for headline generation with respect to ROUGE (Lin, 2004) and also achieve significant improvements, confirming the effectiveness and applicability of our approach.

6 Conclusion

In this paper, we have presented a framework for minimum risk training in end-to-end neural machine translation. The basic idea is to minimize the expected loss in terms of evaluation metrics on the training data. We sample the full search space to approximate the posterior distribution to improve efficiency. Experiments show that MRT leads to significant improvements over maximum likelihood estimation for neural machine translation, especially for distantly-related languages such as Chinese and English.

In the future, we plan to test our approach on more language pairs and more end-to-end neural MT systems. It is also interesting to extend minimum risk training to minimum risk annealing following Smith and Eisner (2006). As our approach is transparent to loss functions and architectures, we believe that it will also benefit more end-to-end neural architectures for other NLP tasks.

A Character-Level Decoder without Explicit Segmentation for Neural Machine Translation

Junyoung Chung

Abstract

The existing machine translation systems, whether phrase-based or neural, have relied almost exclusively on word-level modelling with explicit segmentation. In this paper, we ask a fundamental question: can neural machine translation generate a character sequence without any explicit segmentation? To answer this question, we evaluate an attention-based encoder–decoder with a subword-level encoder and a character-level decoder on four language pairs–En-Cs, En-De, En-Ru and En-Fi–using the parallel corpora from WMT'15. Our experiments show that the models with a character-level decoder outperform the ones with a subword-level decoder on all of the four language pairs. Furthermore, the ensembles of neural models with a character-level decoder outperform the state-of-the-art non-neural machine translation systems on En-Cs, En-De and En-Fi and perform comparably on En-Ru.

1 Introduction

The existing machine translation systems have relied almost exclusively on word-level modelling with explicit segmentation. This is mainly due to the issue of data sparsity which becomes much more severe, especially for n-grams, when a sentence is represented as a sequence of characters rather than words, as the length of the sequence grows significantly. In addition to data sparsity, we often have a priori belief that a word, or its segmented-out lexeme, is a basic unit of meaning, making it natural to approach translation as mapping from a sequence of source-language words to a sequence of target-language words.

This has continued with the more recently proposed paradigm of neural machine translation, although neural networks do not suffer from character-level modelling and rather suffer from the issues specific to word-level modelling, such as the increased computational complexity from a very large target vocabulary (Jean et al., 2015; Luong et al., 2015b). Therefore, in this paper, we address a question of whether *neural machine translation can be done directly on a sequence of characters without any explicit word segmentation*.

To answer this question, we focus on representing the target side as a character sequence. We evaluate neural machine translation models with a character-level decoder on four language pairs from WMT'15 to make our evaluation as convincing as possible. We represent the source side as a sequence of subwords extracted using byte-pair encoding from Sennrich et al. (2015), and vary the target side to be either a sequence of subwords or characters. On the target side, we further design a novel recurrent neural network (RNN), called *bi-scale recurrent network*, that better handles multiple timescales in a sequence, and test it in addition to a naive, stacked recurrent neural network.

On all of the four language pairs–En-Cs, En-De, En-Ru and En-Fi–, the models with a character-level decoder outperformed the ones with a subword-level decoder. We observed a similar trend with the ensemble of each of these configurations, outperforming both the previous best neural and non-neural translation systems on En-Cs, En-De and En-Fi, while achieving a comparable result on En-Ru. We find these results to be a strong evidence that neural machine translation can indeed learn to translate at the character-level and that in fact, it benefits from doing so.

2 Neural Machine Translation

Neural machine translation refers to a recently proposed approach to machine translation (Cho et

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1693–1703,
Berlin, Germany, August 7-12, 2016.

al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015). This approach aims at building an end-to-end neural network that takes as input a source sentence $X = (x_1, \ldots, x_{T_x})$ and outputs its translation $Y = (y_1, \ldots, y_{T_y})$, where x_t and $y_{t'}$ are respectively source and target symbols. This neural network is constructed as a composite of an encoder network and a decoder network.

The encoder network encodes the input sentence X into its continuous representation. In this paper, we closely follow the neural translation model proposed in Bahdanau et al. (2015) and use a bidirectional recurrent neural network, which consists of two recurrent neural networks. The forward network reads the input sentence in a forward direction: $\overrightarrow{\mathbf{z}}_t = \overrightarrow{\phi}(e_x(x_t), \overrightarrow{\mathbf{z}}_{t-1})$, where $e_x(x_t)$ is a continuous embedding of the t-th input symbol, and ϕ is a recurrent activation function. Similarly, the reverse network reads the sentence in a reverse direction (right to left): $\overleftarrow{\mathbf{z}}_t = \overleftarrow{\phi}(e_x(x_t), \overleftarrow{\mathbf{z}}_{t+1})$. At each location in the input sentence, we concatenate the hidden states from the forward and reverse RNNs to form a context set $C = \{\mathbf{z}_1, \ldots, \mathbf{z}_{T_x}\}$, where $\mathbf{z}_t = \left[\overrightarrow{\mathbf{z}}_t; \overleftarrow{\mathbf{z}}_t\right]$.

Then the decoder computes the conditional distribution over all possible translations based on this context set. This is done by first rewriting the conditional probability of a translation: $\log p(Y|X) = \sum_{t'=1}^{T_y} \log p(y_{t'}|y_{<t'}, X)$. For each conditional term in the summation, the decoder RNN updates its hidden state by

$$\mathbf{h}_{t'} = \phi(e_y(y_{t'-1}), \mathbf{h}_{t'-1}, \mathbf{c}_{t'}), \quad (1)$$

where e_y is the continuous embedding of a target symbol. $\mathbf{c}_{t'}$ is a context vector computed by a soft-alignment mechanism:

$$\mathbf{c}_{t'} = f_{\text{align}}(e_y(y_{t'-1}), \mathbf{h}_{t'-1}, C)). \quad (2)$$

The soft-alignment mechanism f_{align} weights each vector in the context set C according to its relevance given what has been translated. The weight of each vector $\mathbf{z}_t$ is computed by

$$\alpha_{t,t'} = \frac{1}{Z} e^{f_{\text{score}}(e_y(y_{t'-1}), \mathbf{h}_{t'-1}, \mathbf{z}_t)}, \quad (3)$$

where f_{score} is a parametric function returning an unnormalized score for $\mathbf{z}_t$ given $\mathbf{h}_{t'-1}$ and $y_{t'-1}$. We use a feedforward network with a single hidden layer in this paper.[1] Z is a normalization constant: $Z = \sum_{k=1}^{T_x} e^{f_{\text{score}}(e_y(y_{t'-1}), \mathbf{h}_{t'-1}, \mathbf{z}_k)}$. This procedure can be understood as computing the alignment probability between the t'-th target symbol and t-th source symbol.

The hidden state $\mathbf{h}_{t'}$, together with the previous target symbol $y_{t'-1}$ and the context vector $\mathbf{c}_{t'}$, is fed into a feedforward neural network to result in the conditional distribution:

$$p(y_{t'} \mid y_{<t'}, X) \propto e^{f_{\text{out}}^{y_{t'}}(e_y(y_{t'-1}), \mathbf{h}_{t'}, \mathbf{c}_{t'})}. \quad (4)$$

The whole model, consisting of the encoder, decoder and soft-alignment mechanism, is then tuned end-to-end to minimize the negative log-likelihood using stochastic gradient descent.

3 Towards Character-Level Translation

3.1 Motivation

Let us revisit how the source and target sentences (X and Y) are represented in neural machine translation. For the source side of any given training corpus, we scan through the whole corpus to build a vocabulary V_x of unique tokens to which we assign integer indices. A source sentence X is then built as a sequence of the indices of such tokens belonging to the sentence, i.e., $X = (x_1, \ldots, x_{T_x})$, where $x_t \in \{1, 2, \ldots, |V_x|\}$. The target sentence is similarly transformed into a target sequence of integer indices.

Each token, or its index, is then transformed into a so-called one-hot vector of dimensionality $|V_x|$. All but one elements of this vector are set to 0. The only element whose index corresponds to the token's index is set to 1. This one-hot vector is the one which any neural machine translation model sees. The embedding function, e_x or e_y, is simply the result of applying a linear transformation (the embedding matrix) to this one-hot vector.

The important property of this approach based on one-hot vectors is that the neural network is oblivious to the underlying semantics of the tokens. To the neural network, each and every token in the vocabulary is equal distance away from every other token. The semantics of those tokens are simply *learned* (into the embeddings) to maximize the translation quality, or the log-likelihood of the model.

This property allows us great freedom in the choice of tokens' unit. Neural networks have been shown to work well with word tokens (Bengio et al., 2001; Schwenk, 2007; Mikolov et al., 2010) but also with finer units, such as subwords (Sennrich et al., 2015; Botha and Blunsom, 2014; Lu-

[1] For other possible implementations, see (Luong et al., 2015a).

ong et al., 2013) as well as symbols resulting from compression/encoding (Chitnis and DeNero, 2015). Although there have been a number of previous research reporting the use of neural networks with characters (see, e.g., Mikolov et al. (2012) and Santos and Zadrozny (2014)), the dominant approach has been to preprocess the text into a sequence of symbols, each associated with a sequence of characters, after which the neural network is presented with those symbols rather than with characters.

More recently in the context of neural machine translation, two research groups have proposed to directly use characters. Kim et al. (2015) proposed to represent each word not as a single integer index as before, but as a sequence of characters, and use a convolutional network followed by a highway network (Srivastava et al., 2015) to extract a continuous representation of the word. This approach, which effectively replaces the embedding function e_x, was adopted by Costa-Jussà and Fonollosa (2016) for neural machine translation. Similarly, Ling et al. (2015b) use a bidirectional recurrent neural network to replace the embedding functions e_x and e_y to respectively encode a character sequence to and from the corresponding continuous word representation. A similar, but slightly different approach was proposed by Lee et al. (2015), where they explicitly mark each character with its relative location in a word (e.g., "B"eginning and "I"ntermediate).

Despite the fact that these recent approaches work at the level of characters, it is less satisfying that they all rely on knowing how to segment characters into words. Although it is generally easy for languages like English, this is not always the case. This word segmentation procedure can be as simple as tokenization followed by some punctuation normalization, but also can be as complicated as morpheme segmentation requiring a separate model to be trained in advance (Creutz and Lagus, 2005; Huang and Zhao, 2007). Furthermore, these segmentation[2] steps are often tuned or designed separately from the ultimate objective of translation quality, potentially contributing to a suboptimal quality.

Based on this observation and analysis, in this paper, we ask ourselves and the readers a question which should have been asked much earlier: *Is it possible to do character-level translation without any explicit segmentation?*

3.2 Why Word-Level Translation?

(1) Word as a Basic Unit of Meaning A word can be understood in two different senses. In the abstract sense, a word is a basic unit of meaning (lexeme), and in the other sense, can be understood as a "concrete word as used in a sentence." (Booij, 2012). A word in the former sense turns into that in the latter sense via a process of morphology, including inflection, compounding and derivation. These three processes do alter the meaning of the lexeme, but often it stays close to the original meaning. Because of this view of words as basic units of meaning (either in the form of lexemes or derived form) from linguistics, much of previous work in natural language processing has focused on using words as basic units of which a sentence is encoded as a sequence. Also, the potential difficulty in finding a mapping between a word's character sequence and meaning[3] has likely contributed to this trend toward word-level modelling.

(2) Data Sparsity There is a further technical reason why much of previous research on machine translation has considered words as a basic unit. This is mainly due to the fact that major components in the existing translation systems, such as language models and phrase tables, are a count-based estimator of probabilities. In other words, a probability of a subsequence of symbols, or pairs of symbols, is estimated by counting the number of its occurrences in a training corpus. This approach severely suffers from the issue of data sparsity, which is due to a large state space which grows exponentially w.r.t. the length of subsequences while growing only linearly w.r.t. the corpus size. This poses a great challenge to character-level modelling, as any subsequence will be on average 4–5 times longer when characters, instead of words, are used. Indeed, Vilar et al. (2007) reported worse performance when the character sequence was directly used by a phrase-based machine translation system. More recently, Neubig et al. (2013) proposed a method to improve character-level translation with phrase-based translation systems, however, with only a limited success.

[2]From here on, the term *segmentation* broadly refers to any method that splits a given character sequence into a sequence of subword symbols.

[3]For instance, "quit", "quite" and "quiet" are one edit-distance away from each other but have distinct meanings.

(3) Vanishing Gradient Specifically to neural machine translation, a major reason behind the wide adoption of word-level modelling is due to the difficulty in modelling long-term dependencies with recurrent neural networks (Bengio et al., 1994; Hochreiter, 1998). As the lengths of the sentences on both sides grow when they are represented in characters, it is easy to believe that there will be more long-term dependencies that must be captured by the recurrent neural network for successful translation.

3.3 Why Character-Level Translation?

Why *not* Word-Level Translation? The most pressing issue with word-level processing is that we do not have a perfect word segmentation algorithm for any one language. A perfect segmentation algorithm needs to be able to segment any given sentence into a sequence of lexemes and morphemes. This problem is however a difficult problem on its own and often requires decades of research (see, e.g., Creutz and Lagus (2005) for Finnish and other morphologically rich languages and Huang and Zhao (2007) for Chinese). Therefore, many opt to using either a rule-based tokenization approach or a suboptimal, but still available, learning based segmentation algorithm.

The outcome of this naive, sub-optimal segmentation is that the vocabulary is often filled with many similar words that share a lexeme but have different morphology. For instance, if we apply a simple tokenization script to an English corpus, "run", "runs", "ran" and "running" are all separate entries in the vocabulary, while they clearly share the same lexeme "run". This prevents any machine translation system, in particular neural machine translation, from modelling these morphological variants efficiently.

More specifically in the case of neural machine translation, each of these morphological variants– "run", "runs", "ran" and "running"– will be assigned a d-dimensional word vector, leading to four independent vectors, while it is clear that if we can segment those variants into a lexeme and other morphemes, we can model them more efficiently. For instance, we can have a d-dimensional vector for the lexeme "run" and much smaller vectors for "s" and"ing". Each of those variants will be then a composite of the lexeme vector (shared across these variants) and morpheme vectors (shared across words sharing the same suffix, for example) (Botha and Blunsom, 2014). This makes use of distributed representation, which generally yields better generalization, but seems to require an optimal segmentation, which is unfortunately almost never available.

In addition to inefficiency in modelling, there are two additional negative consequences from using (unsegmented) words. First, the translation system cannot generalize well to novel words, which are often mapped to a token reserved for an unknown word. This effectively ignores any meaning or structure of the word to be incorporated when translating. Second, even when a lexeme is common and frequently observed in the training corpus, its morphological variant may not be. This implies that the model sees this specific, rare morphological variant much less and will not be able to translate it well. However, if this rare morphological variant shares a large part of its spelling with other more common words, it is desirable for a machine translation system to exploit those common words when translating those rare variants.

Why Character-Level Translation? All of these issues can be addressed to certain extent by directly modelling characters. Although the issue of data sparsity arises in character-level translation, it is elegantly addressed by using a parametric approach based on recurrent neural networks instead of a non-parametric count-based approach. Furthermore, in recent years, we have learned how to build and train a recurrent neural network that can well capture long-term dependencies by using more sophisticated activation functions, such as long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997) and gated recurrent units (Cho et al., 2014).

Kim et al. (2015) and Ling et al. (2015a) recently showed that by having a neural network that converts a character sequence into a word vector, we avoid the issues from having many morphological variants appearing as separate entities in a vocabulary. This is made possible by sharing the character-to-word neural network across all the unique tokens. A similar approach was applied to machine translation by Ling et al. (2015b).

These recent approaches, however, still rely on the availability of a good, if not optimal, segmentation algorithm. Ling et al. (2015b) indeed states that "[m]uch of the prior information regarding morphology, cognates and rare word translation

among others, should be incorporated".

It however becomes unnecessary to consider these prior information, if we use a neural network, be it recurrent, convolution or their combination, directly on the unsegmented character sequence. The possibility of using a sequence of unsegmented characters has been studied over many years in the field of deep learning. For instance, Mikolov et al. (2012) and Sutskever et al. (2011) trained a recurrent neural network language model (RNN-LM) on character sequences. The latter showed that it is possible to generate sensible text sequences by simply sampling a character at a time from this model. More recently, Zhang et al. (2015) and Xiao and Cho (2016) successfully applied a convolutional net and a convolutional-recurrent net respectively to character-level document classification without any explicit segmentation. Gillick et al. (2015) further showed that it is possible to train a recurrent neural network on unicode bytes, instead of characters or words, to perform part-of-speech tagging and named entity recognition.

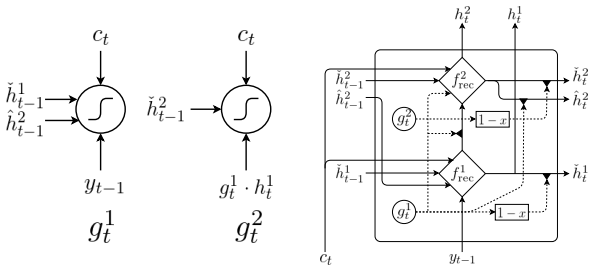
These previous works suggest the possibility of applying neural networks for the task of machine translation, which is often considered a substantially more difficult problem compared to document classification and language modelling.

3.4 Challenges and Questions

There are two overlapping sets of challenges for the source and target sides. On the source side, it is unclear how to build a neural network that learns a highly nonlinear mapping from a spelling to the meaning of a sentence.

On the target side, there are two challenges. The first challenge is the same one from the source side, as the decoder neural network needs to summarize what has been translated. In addition to this, the character-level modelling on the target side is more challenging, as the decoder network must be able to generate a long, coherent sequence of characters. This is a great challenge, as the size of the state space grows exponentially w.r.t. the number of symbols, and in the case of characters, it is often 300-1000 symbols long.

All these challenges should first be framed as questions; whether the current recurrent neural networks, which are already widely used in neural machine translation, are able to address these challenges as they are. In this paper, we aim at answering these *questions* empirically and focus on the challenges on the target side (as the target side shows both of the challenges).



(a) Gating units (b) One-step processing

Figure 1: Bi-scale recurrent neural network

4 Character-Level Translation

In this paper, we try to answer the questions posed earlier by testing two different types of recurrent neural networks on the target side (decoder).

First, we test an existing recurrent neural network with gated recurrent units (GRUs). We call this decoder a *base* decoder.

Second, we build a novel two-layer recurrent neural network, inspired by the gated-feedback network from Chung et al. (2015), called a *bi-scale* recurrent neural network. We design this network to facilitate capturing two timescales, motivated by the fact that characters and words may work at two separate timescales.

We choose to test these two alternatives for the following purposes. Experiments with the base decoder will clearly answer whether the existing neural network is enough to handle character-level decoding, which has not been properly answered in the context of machine translation. The alternative, the bi-scale decoder, is tested in order to see whether it is possible to design a better decoder, if the answer to the first question is positive.

4.1 Bi-Scale Recurrent Neural Network

In this proposed bi-scale recurrent neural network, there are two sets of hidden units, $\mathbf{h}^1$ and $\mathbf{h}^2$. They contain the same number of units, i.e., $\dim(\mathbf{h}^1) = \dim(\mathbf{h}^2)$. The first set $\mathbf{h}^1$ models a fast-changing timescale (thereby, a *faster layer*), and $\mathbf{h}^2$ a slower timescale (thereby, a *slower layer*). For each hidden unit, there is an associated gating unit, to which we refer by $\mathbf{g}^1$ and $\mathbf{g}^2$. For the description below, we use $y_{t'-1}$ and $\mathbf{c}_{t'}$ for the previous target symbol and the context vector (see Eq. (2)), respectively.

Let us start with the faster layer. The faster layer outputs two sets of activations, a normal output $\mathbf{h}^1_{t'}$ and its gated version $\check{\mathbf{h}}^1_{t'}$. The activation of the faster layer is computed by

$$\mathbf{h}^1_{t'} = \tanh\left(\mathbf{W}^{h^1}\left[e_y(y_{t'-1}); \check{\mathbf{h}}^1_{t'-1}; \hat{\mathbf{h}}^2_{t'-1}; \mathbf{c}_{t'}\right]\right),$$

where $\check{\mathbf{h}}^1_{t'-1}$ and $\hat{\mathbf{h}}^2_{t'-1}$ are the gated activations of the faster and slower layers respectively. These gated activations are computed by

$$\check{\mathbf{h}}^1_{t'} = (1 - \mathbf{g}^1_{t'}) \odot \mathbf{h}^1_{t'}, \;\; \hat{\mathbf{h}}^2_{t'} = \mathbf{g}^1_{t'} \odot \mathbf{h}^2_{t'}.$$

In other words, the faster layer's activation is based on the adaptive combination of the faster and slower layers' activations from the previous time step. Whenever the faster layer determines that it needs to reset, i.e., $\mathbf{g}^1_{t'-1} \approx 1$, the next activation will be determined based more on the slower layer's activation.

The faster layer's gating unit is computed by

$$\mathbf{g}^1_{t'} = \sigma\left(\mathbf{W}^{g^1}\left[e_y(y_{t'-1}); \check{\mathbf{h}}^1_{t'-1}; \hat{\mathbf{h}}^2_{t'-1}; \mathbf{c}_{t'}\right]\right),$$

where σ is a sigmoid function.

The slower layer also outputs two sets of activations, a normal output $\mathbf{h}^2_{t'}$ and its gated version $\check{\mathbf{h}}^2_{t'}$. These activations are computed as follows:

$$\mathbf{h}^2_{t'} = (1 - \mathbf{g}^1_{t'}) \odot \mathbf{h}^2_{t'-1} + \mathbf{g}^1_{t'} \odot \tilde{\mathbf{h}}^2_{t'},$$
$$\check{\mathbf{h}}^2_{t'} = (1 - \mathbf{g}^2_{t'}) \odot \mathbf{h}^2_{t'},$$

where $\tilde{\mathbf{h}}^2_{t'}$ is a candidate activation. The slower layer's gating unit $\mathbf{g}^2_{t'}$ is computed by

$$\mathbf{g}^2_{t'} = \sigma\left(\mathbf{W}^{g^2}\left[(\mathbf{g}^1_{t'} \odot \mathbf{h}^1_{t'}); \check{\mathbf{h}}^2_{t'-1}; \mathbf{c}_{t'}\right]\right).$$

This adaptive leaky integration based on the gating unit from the faster layer has a consequence that the slower layer updates its activation only when the faster layer resets. This puts a soft constraint that the faster layer runs at a faster rate by preventing the slower layer from updating while the faster layer is processing a current chunk.

The candidate activation is then computed by

$$\tilde{\mathbf{h}}^2_{t'} = \tanh\left(\mathbf{W}^{h^2}\left[(\mathbf{g}^1_{t'} \odot \mathbf{h}^1_{t'}); \check{\mathbf{h}}^2_{t'-1}; \mathbf{c}_{t'}\right]\right). \quad (5)$$

$\check{\mathbf{h}}^2_{t'-1}$ indicates the *reset* activation from the previous time step, similarly to what happened in the faster layer, and $\mathbf{c}_{t'}$ is the input from the context.

According to $\mathbf{g}^1_{t'} \odot \mathbf{h}^1_{t'}$ in Eq. (5), the faster layer influences the slower layer, only when the faster layer has finished processing the current chunk and is about to *reset* itself ($\mathbf{g}^1_{t'} \approx 1$). In other words, the slower layer does not receive any input from the faster layer, until the faster layer has quickly processed the current chunk, thereby running at a slower rate than the faster layer does.

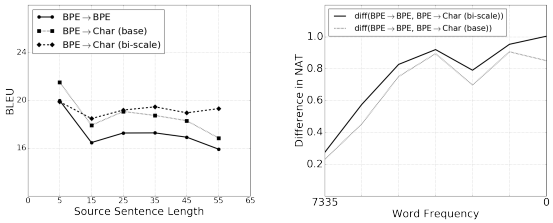


Figure 2: (left) The BLEU scores on En-Cs w.r.t. the length of source sentences. (right) The difference of word negative log-probabilities between the subword-level decoder and either of the character-level base or bi-scale decoder.

At each time step, the final output of the proposed bi-scale recurrent neural network is the concatenation of the output vectors of the faster and slower layers, i.e., $\left[\mathbf{h}^1; \mathbf{h}^2\right]$. This concatenated vector is used to compute the probability distribution over all the symbols in the vocabulary, as in Eq. (4). See Fig. 1 for graphical illustration.

5 Experiment Settings

For evaluation, we represent a source sentence as a sequence of subword symbols extracted by byte-pair encoding (BPE, Sennrich et al. (2015)) and a target sentence either as a sequence of BPE-based symbols or as a sequence of characters.

Corpora and Preprocessing We use all available parallel corpora for four language pairs from WMT'15: En-Cs, En-De, En-Ru and En-Fi. They consist of 12.1M, 4.5M, 2.3M and 2M sentence pairs, respectively. We tokenize each corpus using a tokenization script included in Moses.[4] We only use the sentence pairs, when the source side is up to 50 subword symbols long and the target side is either up to 100 subword symbols or 500 characters. We do not use any monolingual corpus.

For all the pairs other than En-Fi, we use newstest-2013 as a development set, and newstest-2014 (Test$_1$) and newstest-2015 (Test$_2$) as test sets. For En-Fi, we use newsdev-2015 and newstest-2015 as development and test sets, respectively.

[4]Although tokenization is not necessary for character-level modelling, we tokenize the all target side corpora to make comparison against word-level modelling easier.

Table 1: BLEU scores of the subword-level, character-level base and character-level bi-scale decoders for both single models and ensembles. The best scores among the single models per language pair are bold-faced, and those among the ensembles are underlined. When available, we report the median value, and the minimum and maximum values as a subscript and a superscript, respectively. (*) `http://matrix.statmt.org/` as of 11 March 2016 (constrained only). (1) Freitag et al. (2014). (2, 6) Williams et al. (2015). (3, 5) Durrani et al. (2014). (4) Haddow et al. (2015). (7) Rubino et al. (2015).

Models and Training We test three models settings: (1) BPE→BPE, (2) BPE→Char (base) and (3) BPE→Char (bi-scale). The latter two differ by the type of recurrent neural network we use. We use GRUs for the encoder in all the settings. We used GRUs for the decoders in the first two settings, (1) and (2), while the proposed bi-scale recurrent network was used in the last setting, (3). The encoder has 512 hidden units for each direction (forward and reverse), and the decoder has 1024 hidden units per layer.

We train each model using stochastic gradient descent with Adam (Kingma and Ba, 2014). Each update is computed using a minibatch of 128 sentence pairs. The norm of the gradient is clipped with a threshold 1 (Pascanu et al., 2013).

Decoding and Evaluation We use beamsearch to approximately find the most likely translation given a source sentence. The beam widths are 5 and 15 respectively for the subword-level and character-level decoders. They were chosen based on the translation quality on the development set. The translations are evaluated using BLEU.[5]

Multilayer Decoder and Soft-Alignment Mechanism When the decoder is a multilayer recurrent neural network (including a stacked network as well as the proposed bi-scale network), the decoder outputs multiple hidden vectors– $\left\{\mathbf{h}^1, \ldots, \mathbf{h}^L\right\}$ for L layers, at a time. This allows an extra degree of freedom in the soft-alignment mechanism (f_{score} in Eq. (3)). We evaluate using alternatives, including (1) using only $\mathbf{h}^L$ (slower layer) and (2) using all of them (concatenated).

Ensembles We also evaluate an ensemble of neural machine translation models and compare its performance against the state-of-the-art phrase-based translation systems on all four language pairs. We decode from an ensemble by taking the average of the output probabilities at each step.

6 Quantitative Analysis

Slower Layer for Alignment On En-De, we test which layer of the decoder should be used

[5]We used the multi-bleu.perl script from Moses.

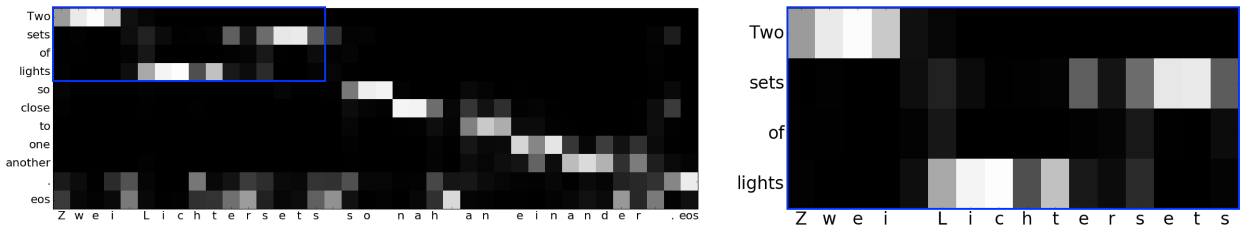

Figure 3: Alignment matrix of a test example from En-De using the BPE→Char (bi-scale) model.

for computing soft-alignments. In the case of subword-level decoder, we observed no difference between choosing any of the two layers of the decoder against using the concatenation of all the layers (Table 1 (a–b)) On the other hand, with the character-level decoder, we noticed an improvement when only the slower layer ($\mathbf{h}^2$) was used for the soft-alignment mechanism (Table 1 (c–g)). This suggests that the soft-alignment mechanism benefits by aligning a larger chunk in the target with a subword unit in the source, and we use only the slower layer for all the other language pairs.

Single Models In Table 1, we present a comprehensive report of the translation qualities of (1) subword-level decoder, (2) character-level base decoder and (3) character-level bi-scale decoder, for all the language pairs. We see that the both types of character-level decoder outperform the subword-level decoder for En-Cs and En-Fi quite significantly. On En-De, the character-level base decoder outperforms both the subword-level decoder and the character-level bi-scale decoder, validating the effectiveness of the character-level modelling. On En-Ru, among the single models, the character-level decoders outperform the subword-level decoder, but in general, we observe that all the three alternatives work comparable to each other.

These results clearly suggest that *it is indeed possible to do character-level translation without explicit segmentation.* In fact, what we observed is that character-level translation often surpasses the translation quality of word-level translation. Of course, we note once again that our experiment is restricted to using an unsegmented character sequence at the decoder only, and a further exploration toward replacing the source sentence with an unsegmented character sequence is needed.

Ensembles Each ensemble was built using eight independent models. The first observation we make is that in all the language pairs, neural machine translation performs comparably to, or often better than, the state-of-the-art non-neural translation system. Furthermore, the character-level decoders outperform the subword-level decoder in all the cases.

7 Qualitative Analysis

(1) Can the character-level decoder generate a long, coherent sentence? The translation in characters is dramatically longer than that in words, likely making it more difficult for a recurrent neural network to generate a coherent sentence in characters. This belief turned out to be false. As shown in Fig. 2 (left), there is no significant difference between the subword-level and character-level decoders, even though the lengths of the generated translations are generally 5–10 times longer in characters.

(2) Does the character-level decoder help with rare words? One advantage of character-level modelling is that it can model the composition of any character sequence, thereby better modelling rare morphological variants. We empirically confirm this by observing the growing gap in the average negative log-probability of words between the subword-level and character-level decoders as the frequency of the words decreases. This is shown in Fig. 2 (right) and explains one potential cause behind the success of character-level decoding in our experiments (we define $\mathrm{diff}(x, y) = x - y$).

(3) Can the character-level decoder soft-align between a source word and a target character? In Fig. 3 (left), we show an example soft-alignment of a source sentence, "Two sets of light so close to one another". It is clear that the character-level translation model well captured the alignment between the source subwords and target characters. We observe that the character-level decoder correctly aligns to "lights" and "sets of" when generating a German compound word

"Lichtersets" (see Fig. 3 (right) for the zoomed-in version). This type of behaviour happens similarly between "one another" and "einander". Of course, this does not mean that there exists an alignment between a source word and a target character. Rather, this suggests that the internal state of the character-level decoder, the base or bi-scale, well captures the meaningful chunk of characters, allowing the model to map it to a larger chunk (subword) in the source.

(4) How fast is the decoding speed of the character-level decoder? We evaluate the decoding speed of subword-level base, character-level base and character-level bi-scale decoders on newstest2013 corpus (En-De) with a single Titan X GPU. The subword-level base decoder generates 31.9 words per second, and the character-level base decoder and character-level bi-scale decoder generate 27.5 words per second and 25.6 words per second, respectively. Note that this is evaluated in an online setting, performing consecutive translation, where only one sentence is translated at a time. Translating in a batch setting could differ from these results.

8 Conclusion

In this paper, we addressed a fundamental question on whether a recently proposed neural machine translation system can directly handle translation at the level of characters without any word segmentation. We focused on the target side, in which a decoder was asked to generate one character at a time, while soft-aligning between a target character and a source subword. Our extensive experiments, on four language pairs–En-Cs, En-De, En-Ru and En-Fi– strongly suggest that it is indeed possible for neural machine translation to translate at the level of characters, and that it actually benefits from doing so.

Our result has one limitation that we used subword symbols in the source side. However, this has allowed us a more fine-grained analysis, but in the future, a setting where the source side is also represented as a character sequence must be investigated.

Abstract

Discriminative translation models utilizing source context have been shown to help statistical machine translation performance. We propose a novel extension of this work using target context information. Surprisingly, we show that this model can be efficiently integrated directly in the decoding process. Our approach scales to large training data sizes and results in consistent improvements in translation quality on four language pairs. We also provide an analysis comparing the strengths of the baseline source-context model with our extended source-context and target-context model and we show that our extension allows us to better capture morphological coherence. Our work is freely available as part of Moses.

1 Introduction

Discriminative lexicons address some of the core challenges of phrase-based MT (PBMT) when translating to morphologically rich languages, such as Czech, namely sense disambiguation and morphological coherence. The first issue is semantic: given a source word or phrase, which of its possible meanings (i.e., which stem or lemma) should we choose? Previous work has shown that this can be addressed using a discriminative lexicon. The second issue has to do with morphology (and syntax): given that we selected the correct meaning, which of its inflected surface forms is appropriate? In this work, we integrate such a model directly into the SMT decoder. This enables our classifier to extract features not only from the full source sentence but also from a limited target-side context. This allows the model to not only help with semantics but also to improve morphological and syntactic coherence.

For *sense disambiguation*, source context is the main source of information, as has been shown in previous work (Vickrey et al., 2005), (Carpuat and Wu, 2007), (Gimpel and Smith, 2008) inter alia. Consider the first set of examples in Figure 1, produced by a strong baseline PBMT system. The English word "shooting" has multiple senses when translated into Czech: it may either be the act of firing a weapon or making a film. When the cue word "film" is close, the phrase-based model is able to use it in one phrase with the ambiguous "shooting", disambiguating correctly the translation. When we add a single word in between, the model fails to capture the relationship and the most frequent sense is selected instead. Wider source context information is required for correct disambiguation.

While word/phrase senses can usually be inferred from the source sentence, the correct *selection of surface forms* requires also information from the target. Note that we can obtain *some* information from the source. For example, an English subject is often translated into a Czech subject; in which case the Czech word should be in nominative case. But there are many decisions that happen during decoding which determine morphological and syntactic properties of words – verbs can have translations which differ in valency frames, they may be translated in either active or passive voice (in which case subject and object would be switched), nouns may have different possible translations which differ in gender, etc.

The correct selection of surface forms plays a crucial role in preserving meaning in morphologically rich languages because it is morphology rather than word order that expresses relations between words. (Word order tends to be

relatively free and driven more by semantic constraints rather than syntactic constraints.)

The language model is only partially able to capture this phenomenon. It has a limited scope and perhaps more seriously, it suffers from data sparsity. The units captured by both the phrase table and the LM are mere sequences of words. In order to estimate their probability, we need to observe them in the training data (many times, if the estimates should be reliable). However, the number of possible n-grams grows exponentially as we increase n, leading to unrealistic requirements on training data sizes. This implies that the current models can (and often do) miss relationships between words even within their theoretical scope.

The second set of sentences in Figure 1 demonstrates the problem of data sparsity for morphological coherence. While the phrase-based system can correctly transfer the morphological case of "cat" and even "black cat", the less usual "yellowish cat" is mistranslated into nominative case, even though the correct phrase "yellowish ||| nažloutlou" exists in the phrase table. A model with a suitable representation of two preceding words could easily infer the correct case in this example.

Our contributions are the following:

- We show that the addition of a feature-rich discriminative model significantly improves translation quality even for large data sizes and that target-side context information consistently further increases this improvement.
- We provide an analysis of the outputs which confirms that source-context features indeed help with semantic disambiguation (as is well known). Importantly, we also show that our novel use of target context improves morphological and syntactic coherence.
- In addition to extensive experimentation on translation from English to Czech, we also evaluate English to German, English to Polish and English to Romanian tasks, with improvements on translation quality in all tasks, showing that our work is broadly applicable.
- We describe several optimizations which allow target-side features to be used efficiently in the context of phrase-based decoding.
- Our implementation is freely available in the widely used open-source MT toolkit Moses, enabling other researchers to explore discriminative modelling with target context in MT.

2 Discriminative Model with Target-Side Context

Several different ways of using feature-rich models in MT have been proposed, see Section 6. We describe our approach in this section.

2.1 Model Definition

Let f be the source sentence and e its translation. We denote source-side phrases (given a particular phrasal segmentation) $(\bar{f}_1, \ldots, \bar{f}_m)$ and the individual words $(f_1, \ldots, f_n)$. We use a similar notation for target-side words/phrases.

For simplicity, let e_{prev}, e_{prev-1} denote the words preceding the current target phrase. Assuming target context size of two, we model the following probability distribution:

$$P(e|f) \propto \prod_{(\bar{e}_i, \bar{f}_i) \in (e,f)} P(\bar{e}_i | \bar{f}_i, f, e_{prev}, e_{prev-1}) \quad (1)$$

The probability of a translation is the product of phrasal translation probabilities which are conditioned on the source phrase, the full source sentence and several previous target words.

Let $\mathrm{GEN}(\bar{f}_i)$ be the set of possible translations of the source phrase $\bar{f}_i$ according to the phrase table. We also define a "feature vector" function $\mathrm{fv}(\bar{e}_i, \bar{f}_i, f, e_{prev}, e_{prev-1})$ which outputs a vector of features given the phrase pair and its context information. We also have a vector of feature weights w estimated from the training data. Then our model defines the phrasal translation probability simply as follows:

$$P(\bar{e}_i | \bar{f}_i, f, e_{prev}, e_{prev-1}) = \frac{\exp(w \cdot \mathrm{fv}(\bar{e}_i, \bar{f}_i, f, e_{prev}, e_{prev-1}))}{\sum_{\bar{e}' \in \mathrm{GEN}(\bar{f}_i)} \exp(w \cdot \mathrm{fv}(\bar{e}', \bar{f}_i, f, e_{prev}, e_{prev-1}))} \quad (2)$$

This definition implies that we have to locally normalize the classifier outputs so that they sum to one.

In PBMT, translations are usually scored by a log-linear model. Our classifier produces a single score (the conditional phrasal probability) which we add to the standard log-linear model as an additional feature. The MT system therefore does not have direct access to the *classifier* features, only to the final score.

2.2 Global Model

We use the Vowpal Wabbit (VW) classifier[1] in this work. Tamchyna et al. (2014) already integrated VW into Moses. We started from their implementation in order to carry out our work. Classifier features are divided into two "namespaces":

- **S.** Features that do not depend on the current phrasal translation (i.e., source- and target-context features).
- **T.** Features of the current phrasal translation.

We make heavy use of feature processing available in VW, namely quadratic feature expansions and label-dependent features. When generating features for a particular set of translations, we first create the *shared* features (in the namespace S). These only depend on (source and target) context and are therefore constant for all possible translations of a given phrase. (Note that target-side context naturally depends on the current partial translation. However, when we process the possible translations for a single source phrase, the target context is constant.)

Then for each translation, we extract its features and store them in the namespace T. Note that we do not provide a label (or class) to VW – it is up to these *translation* features to describe the target phrase. (And this is what is referred to as "label-dependent features" in VW.)

Finally, we add the Cartesian product between the two namespaces to the feature set: every *shared* feature is combined with every *translation* feature.

This setting allows us to train only a single, global model with powerful feature sharing. For example, thanks to the label-dependent format, we can decompose both the source phrase and the target phrase into words and have features such as `s_cat_t_kočka` which capture phrase-internal word translations. Predictions for rare phrase pairs are then more robust thanks to the rich statistics collected for these word-level feature pairs.

2.3 Extraction of Training Examples

Discriminative models in MT are typically trained by creating one training instance per extracted phrase from the entire training data. The target side of the extracted phrase is a positive label, and all other phrases observed aligned to the extracted phrase (anywhere in the training data) are the negative labels.

We train our model in a similar fashion: for each sentence in the parallel training data, we look at all possible phrasal segmentations. Then for each source span, we create a training example. We obtain the set of possible translations $\mathrm{GEN}(\bar{f})$ from the phrase table. Because we do not have actual classes, each translation is defined by its label-dependent features and we associate a loss with it: 0 loss for the correct translation and 1 for all others.

Because we train both our model and the standard phrase table on the same dataset, we use leaving-one-out in the classifier training to avoid

over-fitting. We look at phrase counts and co-occurrence counts in the training data, we subtract one from the number of occurrences for the current source phrase, target phrase and the phrase pair. If the count goes to zero, we skip the training example. Without this technique, the classifier might learn to simply trust very long phrase pairs which were extracted from the same training sentence.

For target-side context features, we simply use the true (gold) target context. This leads to training which is similar to language model estimation; this model is somewhat similar to the neural joint model for MT (Devlin et al., 2014), but in our case implemented using a linear (maximum-entropy-like) model.

2.4 Training

We use Vowpal Wabbit in the `--csoaa_ldf mc` setting which reduces our multi-class problem to one-against-all binary classification. We use the logistic loss as our objective. We experimented with various settings of L2 regularization but were not able to get an improvement over not using regularization at all. We train each model with 10 iterations over the data.

We evaluate all of our models on a held-out set. We use the same dataset as for MT system tuning because it closely matches the domain of our test set. We evaluate model accuracy after each pass over the training data to detect over-fitting and we select the model with the highest held-out accuracy.

2.5 Feature Set

Our feature set requires some linguistic processing of the data. We use the factored MT setting (Koehn and Hoang, 2007) and we represent each type of information as an individual factor. On the source side, we use the word surface form, its lemma, morphological tag, analytical function (such as *Subj* for subjects) and the lemma of the parent node in the dependency parse tree. On the target side, we only use word lemmas and morphological tags.

Table 1 lists our feature sets for each language pair. We implemented *indicator* features for both the source and target side; these are simply concatenations of the words in the current phrase into a single feature. *Internal* features describe words within the current phrase. *Context* features are extracted either from a window of a fixed size around the current phrase (on the source side) or from a limited left-hand side context (on the target side). *Bilingual context* features are concatenations of target-side context words and their source-side counterparts (according to word alignment); these features are similar to bilingual tokens in bilingual LMs (Niehues et al., 2011). Each of our feature types can be configured to look at any individual factors or their combinations.

The features in Table 1 are divided into three sets. The first set contains label-independent (=shared) features which only depend on the source sentence. The second set contains shared features which depend on target-side context; these can only be used when VW is applied during decoding. We use target context size two in all our experiments.[2] Finally, the third set contains label-dependent features which describe the currently predicted phrasal translation.

[2]In preliminary experiments we found that using a single word was less effective and larger context did not bring improvements, possibly because of over-fitting.

Going back to the examples from Figure 1, our model can disambiguate the translation of "shooting" based on the source-context features (either the full form or lemma). For the morphological disambiguation of the translation of "yellowish cat", the model has access to the morphological tags of the preceding target words which can disambiguate the correct morphological case.

We used slightly different subsets of the full feature set for different languages. In particular, we left out surface form features and/or bilingual features in some settings because they decreased performance, presumably due to over-fitting.

3 Efficient Implementation

Originally, we assumed that using target-side context features in decoding would be too expensive, considering that we would have to query our model roughly as often as the language model. In preliminary experiments, we therefore focused on n-best list re-ranking. We obtained small gains but all of our results were substantially worse than with the integrated model, so we omit them from the paper.

We find that decoding with a feature-rich target-context model is in fact feasible. In this section, we describe optimizations at different stages of our pipeline which make training and inference with our model practical.

3.1 Feature Extraction

We implemented the code for feature extraction only once; identical code is used at training time and in decoding. At training time, the generated features are written into a file whereas at test time, they are fed directly into the classifier via its library interface.

This design decision not only ensures consistency in feature representation but also makes the process of feature extraction efficient. In training, we are easily able to use multi-threading (already implemented in Moses) and because the processing of training data is a trivially parallel task, we can also use distributed computation and run separate instances of (multi-threaded) Moses on several machines. This enables us to easily produce training files from millions of parallel sentences within a short time.

3.2 Model Training

VW is a very fast classifier by itself, however for very large data, its training can be further sped up by using parallelization. We take advantage of its implementation of the *AllReduce* scheme which we utilize in a grid engine environment. We shuffle and shard the data and then assign each shard to a worker job. With AllReduce, there is a master job which synchronizes the learned weight vector with all workers. We have compared this approach with the standard single-threaded, single-process training and found that we obtain identical model accuracy. We usually use around 10-20 training jobs.

This way, we can process our large training files quickly and train the full model (using multiple passes over the data) within hours; effectively, neither feature extraction nor model training become a significant bottleneck in the full MT system training pipeline.

3.3 Decoding

In phrase-based decoding, translation is generated from left to right. At each step, a partial translation (initially empty) is extended by translating a previously uncovered part of the source sentence. There are typically many ways to translate each source span, which we refer to as translation options. The decoding process gradually extends the generated partial translations until the whole source sentence is covered; the final translation is then the full translation hypothesis with the highest model score. Various pruning strategies are applied to make decoding tractable.

Evaluating a feature-rich classifier during decoding is a computationally expensive operation. Because the features in our model depend on target-side context, the feature function which computes the classifier score cannot evaluate the translation options in isolation (independently of the partial translation). Instead, similarly to a language model, it needs to look at previously generated words. This also entails maintaining a state which captures the required context information.

A naive integration of the classifier would simply generate all source-context features, all target-context features and all features describing the translation option each time a partial hypothesis is evaluated. This is a computationally very expensive approach.

We instead propose several technical solutions

which make decoding reasonably fast. Decoding a single sentence with the naive approach takes 13.7 seconds on average. With our optimization, this average time is reduced to 2.9 seconds, i.e. almost by 80 per cent. The baseline system produces a translation in 0.8 seconds on average.

Separation of source-context and target-context evaluation. Because we have a linear model, the final score is simply the dot product between a weight vector and a (sparse) feature vector. It is therefore trivial to separate it into two components: one that only contains features which depend on the source context and the other with target context features. We can pre-compute the source-context part of the score before decoding (once we have all translation options for the given sentence). We cache these partial scores and when the translation option is evaluated, we add the partial score of the target-context features to arrive at the final classifier score.

Caching of feature hashes. VW uses feature hashing internally and it is possible to obtain the hash of any feature that we use. When we encounter a previously unseen target context (=state) during decoding, we store the hashes of extracted features in a cache. Therefore for each context, we only run the expensive feature extraction once. Similarly, we pre-compute feature hash vectors for all translation options.

Caching of final results. Our classifier locally normalizes the scores so that the probabilities of translations for a given span sum to one. This cannot be done without evaluating all translation options for the span at the same time. Therefore, when we get a translation option to be scored, we fetch all translation options for the given source span and evaluate all of them. We then normalize the scores and add them to a cache of final results. When the other translation options come up, their scores are simply fetched from the cache. This can also further save computation when we get into a previously seen state (from the point of view of our classifier) and we evaluate the same set of translation options in that state; we will simply find the result in cache in such cases.

When we combine all of these optimizations, we arrive at the query algorithm shown in Figure 2.

```
function EVALUATE(t, s)
    span = t.getSourceSpan()
    if not resultCache.has(span, s) then
        scores = ()
        if not stateCache.has(s) then
            stateCache[s] = CtxFeatures(s)
        end if
        for all t' ← span.tOpts() do
            srcScore = srcScoreCache[t']
            c.addFeatures(stateCache[s])
            c.addFeatures(translationCache[t'])
            tgtScore = c.predict()
            scores[t'] = srcScore + tgtScore
        end for
        normalize(scores)
        resultCache[span, s] = scores
    end if
    return resultCache[span, s][t]
end function
```

Figure 2: Algorithm for obtaining classifier predictions during decoding. The variable t stands for the current translation, s is the current state and c is an instance of the classifier.

4 Experimental Evaluation

We run the main set of experiments on English to Czech translation. To verify that our method is applicable to other language pairs, we also present experiments in English to German, Polish, and Romanian.

In all experiments, we use Treex (Popel and Žabokrtský, 2010) to lemmatize and tag the source data and also to obtain dependency parses of all English sentences.

4.1 English-Czech Translation

As parallel training data, we use (subsets of) the CzEng 1.0 corpus (Bojar et al., 2012). For tuning, we use the WMT13 test set (Bojar et al., 2013) and we evaluate the systems on the WMT14 test set (Bojar et al., 2014). We lemmatize and tag the Czech data using Morphodita (Straková et al., 2014).

Our baseline system is a standard phrase-based Moses setup. The phrase table in both cases is factored and outputs also lemmas and morphological tags. We train a 5-gram LM on the target side of parallel data.

We evaluate three settings in our experiments:

- baseline – vanilla phrase-based system,
- +source – our classifier with source-context features only,

- +target – our classifier with both source-context and target-context features.

For each of these settings, we vary the size of the training data for our classifier, the phrase table and the LM. We experiment with three different sizes: small (200 thousand sentence pairs), medium (5 million sentence pairs), and full (the whole CzEng corpus, over 14.8 million sentence pairs).

For each setting, we run system weight optimization (tuning) using minimum error rate training (Och, 2003) five times and report the average BLEU score. We use MultEval (Clark et al., 2011) to compare the systems and to determine whether the differences in results are statistically significant. We always compare the baseline with +source and +source with +target.

Table 2 shows the obtained results. Statistically significant differences (α=0.01) are marked in bold. The source-context model does not help in the small data setting but brings a substantial improvement of 0.7-0.8 BLEU points for the medium and full data settings, which is an encouraging result.

Target-side context information allows our model to push the translation quality further: even for the small data setting, it brings a substantial improvement of 0.5 BLEU points and the gain remains significant as the data size increases. Even in the full data setting, target-side features improve the score by roughly 0.2 BLEU points.

Our results demonstrate that feature-rich models scale to large data size both in terms of technical feasibility and of translation quality improvements. Target side information seems consistently beneficial, adding further 0.2-0.5 BLEU points on top of the source-context model.

data size	small	medium	full
baseline	10.7	15.2	16.7
+source	10.7	**16.0**	**17.3**
+target	**11.2**	**16.4**	**17.5**

Table 2: BLEU scores obtained on the WMT14 test set. We report the performance of the baseline, the source-context model and the full model.

Intrinsic Evaluation. For completeness, we report intrinsic evaluation results. We evaluate the classifier on a held-out set (WMT13 test set) by extracting all phrase pairs from the test input aligned with the test reference (similarly as we would in training) and scoring each phrase pair (along with other possible translations of the source phrase) with our classifier. An instance is classified correctly if the true translation obtains the highest score by our model. A baseline which always chooses the most frequent phrasal translation obtains accuracy of 51.5. For the source-context model, the held-out accuracy was 66.3, while the target context model achieved accuracy of 74.8. Note that this high difference is somewhat misleading because in this setting, the target-context model has access to the true target context (i.e., it is cheating).

4.2 Additional Language Pairs

We experiment with translation from English into German, Polish, and Romanian.

Our English-German system is trained on the data available for the WMT14 translation task: Europarl (Koehn, 2005) and the Common Crawl corpus,[3] roughly 4.3 million sentence pairs altogether. We tune the system on the WMT13 test set and we test on the WMT14 set. We use TreeTagger (Schmid, 1994) to lemmatize and tag the German data.

English-Polish has not been included in WMT shared tasks so far, but was present as a language pair for several IWSLT editions which concentrate on TED talk translation. Full test sets are only available for 2010, 2011, and 2012. The references for 2013 and 2014 were not made public. We use the development set and test set from 2010 as development data for parameter tuning. The remaining two test sets (2011, 2012) are our test data. We train on the concatenation of Europarl and WIT^3 (Cettolo et al., 2012), ca. 750 thousand sentence pairs. The Polish half has been tagged using WCRFT (Radziszewski, 2013) which produces full morphological tags compatible with the NKJP tagset (Przepiórkowski, 2009).

English-Romanian was added in WMT16. We train our system using the available parallel data – Europarl and SETIMES2 (Tiedemann, 2009), roughly 600 thousand sentence pairs. We tune the English-Romanian system on the official development set and we test on the WMT16 test set. We use the online tagger by Tufis et al. (2008) to preprocess the data.

Table 3 shows the obtained results. Similarly to English-Czech experiments, BLEU scores are av-

eraged over 5 independent optimization runs. Our system outperforms the baseline by 0.5-0.7 BLEU points in all cases, showing that the method is applicable to other languages with rich morphology.

5 Analysis

We manually analyze the outputs of English-Czech systems. Figure 3 shows an example sentence from the WMT14 test set translated by all the system variants. The baseline system makes an error in verb valency; the Czech verb "došlo" could be used but this verb already has an (implicit) subject and the translation of "mining" ("těžba") would have to be in a different case and at a different position in the sentence. The second error is more interesting, however: the baseline system fails to correctly identify the word sense of the particle "to" and translates it in the sense of purpose, as in "in order to". The source-context model takes the context (span of years) into consideration and correctly disambiguates the translation of "to", choosing the temporal meaning. It still fails to translate the main verb correctly, though. Only the full model with target-context information is able to also correctly translate the verb and inflect its arguments according to their roles in the valency frame. The translation produced by this final system in this case is almost flawless.

In order to verify that the automatically measured results correspond to visible improvements in translation quality, we carried out two annotation experiments. We took a random sample of 104 sentences from the test set and blindly ranked two competing translations (the selection of sentences was identical for both experiments). In the first experiment, we compared the baseline system with +source. In the other experiment, we compared the baseline with +target. The instructions for annotation were simply to compare overall translation quality; we did not ask the annotator to look for any specific phenomena. In terms of automatic measures, our selection has similar characteristics as the full test set: BLEU scores obtained on our sample are 15.08, 16.22 and 16.53 for the baseline, +source and +target respectively.

In the first case, the annotator marked 52 translations as equal in quality, 26 translations produced by +source were marked as better and in the remaining 26 cases, the baseline won the ranking. Even though there is a difference in BLEU, human annotation does not confirm this measurement, ranking both systems equally.

In the second experiment, 52 translations were again marked as equal. In 34 cases, +target produced a better translation while in 18 cases, the baseline output won. The difference between the baseline and +target suggests that the target-context model may provide information which is useful for translation quality as perceived by humans.

Our overall impression from looking at the system outputs was that both the source-context and target-context model tend to fix many morpho-syntactic errors. Interestingly, we do not observe as many improvements in the word/phrase sense disambiguation, though the source context does help semantics in some sentences. The target-context model tends to preserve the overall agreement and coherence better than the system with a source-context model only. We list several such examples in Figure 4. Each of them is fully cor-

rected by the target-context model, producing an accurate translation of the input.

6 Related Work

Discriminative models in MT have been proposed before. Carpuat and Wu (2007) trained a maximum entropy classifier for each source phrase type which used source context information to disambiguate its translations. The models did not capture target-side information and they were independent; no parameters were shared between classifiers for different phrases. They used a strong feature set originally developed for word sense disambiguation. Gimpel and Smith (2008) also used wider source-context information but did not train a classifier; instead, the features were included directly in the log-linear model of the decoder. Mauser et al. (2009) introduced the "discriminative word lexicon" and trained a binary classifier for each target word, using as features only the bag of words (from the whole source sentence). Training sentences where the target word occurred were used as positive examples, other sentences served as negative examples. Jeong et al. (2010) proposed a discriminative lexicon with a rich feature set tailored to translation into morphologically rich languages; unlike our work, their model only used source-context features.

Subotin (2011) included target-side context information in a maximum-entropy model for the prediction of morphology. The work was done within the paradigm of hierarchical PBMT and assumes that cube pruning is used in decoding. Their algorithm was tailored to the specific problem of passing non-local information about morphological agreement required by individual rules (such as explicit rules enforcing subject-verb agreement). Our algorithm only assumes that hypotheses are constructed left to right and provides a general way for including target context information in the classifier, regardless of the type of features. Our implementation is freely available and can be further extended by other researchers in the future.

7 Conclusions

We presented a discriminative model for MT which uses both source and target context information. We have shown that such a model can be used directly during decoding in a relatively efficient way. We have shown that this model consistently significantly improves the quality of English-Czech translation over a strong baseline with large training data. We have validated the effectiveness of our model on several additional language pairs. We have provided an analysis showing concrete examples of improved lexical selection and morphological coherence. Our work is available in the main branch of Moses for use by other researchers.

Neural Machine Translation of Rare Words with Subword Units

Rico Sennrich and **Barry Haddow** and **Alexandra Birch**
School of Informatics, University of Edinburgh
{rico.sennrich,a.birch}@ed.ac.uk, bhaddow@inf.ed.ac.uk

Abstract

Neural machine translation (NMT) models typically operate with a fixed vocabulary, but translation is an open-vocabulary problem. Previous work addresses the translation of out-of-vocabulary words by backing off to a dictionary. In this paper, we introduce a simpler and more effective approach, making the NMT model capable of open-vocabulary translation by encoding rare and unknown words as sequences of subword units. This is based on the intuition that various word classes are translatable via smaller units than words, for instance names (via character copying or transliteration), compounds (via compositional translation), and cognates and loanwords (via phonological and morphological transformations). We discuss the suitability of different word segmentation techniques, including simple character n-gram models and a segmentation based on the *byte pair encoding* compression algorithm, and empirically show that subword models improve over a back-off dictionary baseline for the WMT 15 translation tasks English→German and English→Russian by up to 1.1 and 1.3 BLEU, respectively.

1 Introduction

Neural machine translation has recently shown impressive results (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015). However, the translation of rare words is an open problem. The vocabulary of neural models is typically limited to 30 000–50 000 words, but translation is an open-vocabulary problem, and especially for languages with productive word formation processes such as agglutination and compounding, translation models require mechanisms that go below the word level. As an example, consider compounds such as the German *Abwasser|behandlungs|anlange* 'sewage water treatment plant', for which a segmented, variable-length representation is intuitively more appealing than encoding the word as a fixed-length vector.

For word-level NMT models, the translation of out-of-vocabulary words has been addressed through a back-off to a dictionary look-up (Jean et al., 2015; Luong et al., 2015b). We note that such techniques make assumptions that often do not hold true in practice. For instance, there is not always a 1-to-1 correspondence between source and target words because of variance in the degree of morphological synthesis between languages, like in our introductory compounding example. Also, word-level models are unable to translate or generate unseen words. Copying unknown words into the target text, as done by (Jean et al., 2015; Luong et al., 2015b), is a reasonable strategy for names, but morphological changes and transliteration is often required, especially if alphabets differ.

We investigate NMT models that operate on the level of subword units. Our main goal is to model open-vocabulary translation in the NMT network itself, without requiring a back-off model for rare words. In addition to making the translation process simpler, we also find that the subword models achieve better accuracy for the translation of rare words than large-vocabulary models and back-off dictionaries, and are able to productively generate new words that were not seen at training time. Our analysis shows that the neural networks are able to learn compounding and transliteration from subword representations.

This paper has two main contributions:

- We show that open-vocabulary neural ma-

The research presented in this publication was conducted in cooperation with Samsung Electronics Polska sp. z o.o. - Samsung R&D Institute Poland.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1715–1725,
Berlin, Germany, August 7-12, 2016.

chine translation is possible by encoding (rare) words via subword units. We find our architecture simpler and more effective than using large vocabularies and back-off dictionaries (Jean et al., 2015; Luong et al., 2015b).

- We adapt *byte pair encoding* (BPE) (Gage, 1994), a compression algorithm, to the task of word segmentation. BPE allows for the representation of an open vocabulary through a fixed-size vocabulary of variable-length character sequences, making it a very suitable word segmentation strategy for neural network models.

2 Neural Machine Translation

We follow the neural machine translation architecture by Bahdanau et al. (2015), which we will briefly summarize here. However, we note that our approach is not specific to this architecture.

The neural machine translation system is implemented as an encoder-decoder network with recurrent neural networks.

The encoder is a bidirectional neural network with gated recurrent units (Cho et al., 2014) that reads an input sequence $x = (x_1, ..., x_m)$ and calculates a forward sequence of hidden states $(\overrightarrow{h}_1, ..., \overrightarrow{h}_m)$, and a backward sequence $(\overleftarrow{h}_1, ..., \overleftarrow{h}_m)$. The hidden states $\overrightarrow{h}_j$ and $\overleftarrow{h}_j$ are concatenated to obtain the annotation vector h_j.

The decoder is a recurrent neural network that predicts a target sequence $y = (y_1, ..., y_n)$. Each word y_i is predicted based on a recurrent hidden state s_i, the previously predicted word y_{i-1}, and a context vector c_i. c_i is computed as a weighted sum of the annotations h_j. The weight of each annotation h_j is computed through an *alignment model* α_{ij}, which models the probability that y_i is aligned to x_j. The alignment model is a single-layer feedforward neural network that is learned jointly with the rest of the network through backpropagation.

A detailed description can be found in (Bahdanau et al., 2015). Training is performed on a parallel corpus with stochastic gradient descent. For translation, a beam search with small beam size is employed.

3 Subword Translation

The main motivation behind this paper is that the translation of some words is transparent in that they are translatable by a competent translator even if they are novel to him or her, based on a translation of known subword units such as morphemes or phonemes. Word categories whose translation is potentially transparent include:

- named entities. Between languages that share an alphabet, names can often be copied from source to target text. Transcription or transliteration may be required, especially if the alphabets or syllabaries differ. Example:
  Barack Obama (English; German)
  Барак Обама (Russian)
  バラク・オバマ (ba-ra-ku o-ba-ma) (Japanese)
- cognates and loanwords. Cognates and loanwords with a common origin can differ in regular ways between languages, so that character-level translation rules are sufficient (Tiedemann, 2012). Example:
  claustrophobia (English)
  Klaustrophobie (German)
  Клаустрофобия (Klaustrofobiâ) (Russian)
- morphologically complex words. Words containing multiple morphemes, for instance formed via compounding, affixation, or inflection, may be translatable by translating the morphemes separately. Example:
  solar system (English)
  Sonnensystem (Sonne + System) (German)
  Naprendszer (Nap + Rendszer) (Hungarian)

In an analysis of 100 rare tokens (not among the 50 000 most frequent types) in our German training data[1], the majority of tokens are potentially translatable from English through smaller units. We find 56 compounds, 21 names, 6 loanwords with a common origin (*emancipate→emanzipieren*), 5 cases of transparent affixation (*sweetish* 'sweet' + '-ish' → *süßlich* 'süß' + '-lich'), 1 number and 1 computer language identifier.

Our hypothesis is that a segmentation of rare words into appropriate subword units is sufficient to allow for the neural translation network to learn transparent translations, and to generalize this knowledge to translate and produce unseen words.[2] We provide empirical support for this hy-

[1] Primarily parliamentary proceedings and web crawl data.

[2] Not every segmentation we produce is transparent. While we expect no performance benefit from opaque segmentations, i.e. segmentations where the units cannot be translated independently, our NMT models show robustness towards oversplitting.

pothesis in Sections 4 and 5. First, we discuss different subword representations.

3.1 Related Work

For Statistical Machine Translation (SMT), the translation of unknown words has been the subject of intensive research.

A large proportion of unknown words are names, which can just be copied into the target text if both languages share an alphabet. If alphabets differ, transliteration is required (Durrani et al., 2014). Character-based translation has also been investigated with phrase-based models, which proved especially successful for closely related languages (Vilar et al., 2007; Tiedemann, 2009; Neubig et al., 2012).

The segmentation of morphologically complex words such as compounds is widely used for SMT, and various algorithms for morpheme segmentation have been investigated (Nießen and Ney, 2000; Koehn and Knight, 2003; Virpioja et al., 2007; Stallard et al., 2012). Segmentation algorithms commonly used for phrase-based SMT tend to be conservative in their splitting decisions, whereas we aim for an aggressive segmentation that allows for open-vocabulary translation with a compact network vocabulary, and without having to resort to back-off dictionaries.

The best choice of subword units may be task-specific. For speech recognition, phone-level language models have been used (Bazzi and Glass, 2000). Mikolov et al. (2012) investigate subword language models, and propose to use syllables. For multilingual segmentation tasks, multilingual algorithms have been proposed (Snyder and Barzilay, 2008). We find these intriguing, but inapplicable at test time.

Various techniques have been proposed to produce fixed-length continuous word vectors based on characters or morphemes (Luong et al., 2013; Botha and Blunsom, 2014; Ling et al., 2015a; Kim et al., 2015). An effort to apply such techniques to NMT, parallel to ours, has found no significant improvement over word-based approaches (Ling et al., 2015b). One technical difference from our work is that the attention mechanism still operates on the level of words in the model by Ling et al. (2015b), and that the representation of each word is fixed-length. We expect that the attention mechanism benefits from our variable-length representation: the network can learn to place attention on different subword units at each step. Recall our introductory example *Abwasserbehandlungsanlange*, for which a subword segmentation avoids the information bottleneck of a fixed-length representation.

Neural machine translation differs from phrase-based methods in that there are strong incentives to minimize the vocabulary size of neural models to increase time and space efficiency, and to allow for translation without back-off models. At the same time, we also want a compact representation of the text itself, since an increase in text length reduces efficiency and increases the distances over which neural models need to pass information.

A simple method to manipulate the trade-off between vocabulary size and text size is to use shortlists of unsegmented words, using subword units only for rare words. As an alternative, we propose a segmentation algorithm based on byte pair encoding (BPE), which lets us learn a vocabulary that provides a good compression rate of the text.

3.2 Byte Pair Encoding (BPE)

Byte Pair Encoding (BPE) (Gage, 1994) is a simple data compression technique that iteratively replaces the most frequent pair of bytes in a sequence with a single, unused byte. We adapt this algorithm for word segmentation. Instead of merging frequent pairs of bytes, we merge characters or character sequences.

Firstly, we initialize the symbol vocabulary with the character vocabulary, and represent each word as a sequence of characters, plus a special end-of-word symbol '·', which allows us to restore the original tokenization after translation. We iteratively count all symbol pairs and replace each occurrence of the most frequent pair ('A', 'B') with a new symbol 'AB'. Each merge operation produces a new symbol which represents a character n-gram. Frequent character n-grams (or whole words) are eventually merged into a single symbol, thus BPE requires no shortlist. The final symbol vocabulary size is equal to the size of the initial vocabulary, plus the number of merge operations – the latter is the only hyperparameter of the algorithm.

For efficiency, we do not consider pairs that cross word boundaries. The algorithm can thus be run on the dictionary extracted from a text, with each word being weighted by its frequency. A minimal Python implementation is shown in Al-

Algorithm 1 Learn BPE operations

```
import re, collections

def get_stats(vocab):
  pairs = collections.defaultdict(int)
  for word, freq in vocab.items():
    symbols = word.split()
    for i in range(len(symbols)-1):
      pairs[symbols[i],symbols[i+1]] += freq
  return pairs

def merge_vocab(pair, v_in):
  v_out = {}
  bigram = re.escape(' '.join(pair))
  p = re.compile(r'(?<!\S)' + bigram + r'(?!\S)')
  for word in v_in:
    w_out = p.sub(''.join(pair), word)
    v_out[w_out] = v_in[word]
  return v_out

vocab = {'l o w </w>' : 5, 'l o w e r </w>' : 2,
         'n e w e s t </w>':6, 'w i d e s t </w>':3}
num_merges = 10
for i in range(num_merges):
  pairs = get_stats(vocab)
  best = max(pairs, key=pairs.get)
  vocab = merge_vocab(best, vocab)
  print(best)
```

r ·	→	r·
l o	→	lo
lo w	→	low
e r·	→	er·

Figure 1: BPE merge operations learned from dictionary {'low', 'lowest', 'newer', 'wider'}.

gorithm 1. In practice, we increase efficiency by indexing all pairs, and updating data structures incrementally.

The main difference to other compression algorithms, such as Huffman encoding, which have been proposed to produce a variable-length encoding of words for NMT (Chitnis and DeNero, 2015), is that our symbol sequences are still interpretable as subword units, and that the network can generalize to translate and produce new words (unseen at training time) on the basis of these subword units.

Figure 1 shows a toy example of learned BPE operations. At test time, we first split words into sequences of characters, then apply the learned operations to merge the characters into larger, known symbols. This is applicable to any word, and allows for open-vocabulary networks with fixed symbol vocabularies.[3] In our example, the OOV 'lower' would be segmented into 'low er·'.

[3]The only symbols that will be unknown at test time are unknown characters, or symbols of which all occurrences in the training text have been merged into larger symbols, like 'safeguar', which has all occurrences in our training text merged into 'safeguard'. We observed no such symbols at test time, but the issue could be easily solved by recursively reversing specific merges until all symbols are known.

We evaluate two methods of applying BPE: learning two independent encodings, one for the source, one for the target vocabulary, or learning the encoding on the union of the two vocabularies (which we call *joint BPE*).[4] The former has the advantage of being more compact in terms of text and vocabulary size, and having stronger guarantees that each subword unit has been seen in the training text of the respective language, whereas the latter improves consistency between the source and the target segmentation. If we apply BPE independently, the same name may be segmented differently in the two languages, which makes it harder for the neural models to learn a mapping between the subword units. To increase the consistency between English and Russian segmentation despite the differing alphabets, we transliterate the Russian vocabulary into Latin characters with ISO-9 to learn the joint BPE encoding, then transliterate the BPE merge operations back into Cyrillic to apply them to the Russian training text.[5]

4 Evaluation

We aim to answer the following empirical questions:

- Can we improve the translation of rare and unseen words in neural machine translation by representing them via subword units?
- Which segmentation into subword units performs best in terms of vocabulary size, text size, and translation quality?

We perform experiments on data from the shared translation task of WMT 2015. For English→German, our training set consists of 4.2 million sentence pairs, or approximately 100 million tokens. For English→Russian, the training set consists of 2.6 million sentence pairs, or approximately 50 million tokens. We tokenize and truecase the data with the scripts provided in Moses (Koehn et al., 2007). We use newstest2013 as development set, and report results on newstest2014 and newstest2015.

We report results with BLEU (*mteval-v13a.pl*), and CHRF3 (Popović, 2015), a character n-gram F_3 score which was found to correlate well with

[4]In practice, we simply concatenate the source and target side of the training set to learn joint BPE.

[5]Since the Russian training text also contains words that use the Latin alphabet, we also apply the Latin BPE operations.

human judgments, especially for translations out of English (Stanojević et al., 2015). Since our main claim is concerned with the translation of rare and unseen words, we report separate statistics for these. We measure these through unigram F_1, which we calculate as the harmonic mean of clipped unigram precision and recall.[6]

We perform all experiments with Groundhog[7] (Bahdanau et al., 2015). We generally follow settings by previous work (Bahdanau et al., 2015; Jean et al., 2015). All networks have a hidden layer size of 1000, and an embedding layer size of 620. Following Jean et al. (2015), we only keep a shortlist of $\tau = 30000$ words in memory.

During training, we use Adadelta (Zeiler, 2012), a minibatch size of 80, and reshuffle the training set between epochs. We train a network for approximately 7 days, then take the last 4 saved models (models being saved every 12 hours), and continue training each with a fixed embedding layer (as suggested by (Jean et al., 2015)) for 12 hours. We perform two independent training runs for each models, once with cut-off for gradient clipping (Pascanu et al., 2013) of 5.0, once with a cut-off of 1.0 – the latter produced better single models for most settings. We report results of the system that performed best on our development set (newstest2013), and of an ensemble of all 8 models.

We use a beam size of 12 for beam search, with probabilities normalized by sentence length. We use a bilingual dictionary based on fast-align (Dyer et al., 2013). For our baseline, this serves as back-off dictionary for rare words. We also use the dictionary to speed up translation for all experiments, only performing the softmax over a filtered list of candidate translations (like Jean et al. (2015), we use $K = 30000$; $K' = 10$).

4.1 Subword statistics

Apart from translation quality, which we will verify empirically, our main objective is to represent an open vocabulary through a compact fixed-size subword vocabulary, and allow for efficient training and decoding.[8]

Statistics for different segmentations of the German side of the parallel data are shown in Table 1. A simple baseline is the segmentation of words into character n-grams.[9] Character n-grams allow for different trade-offs between sequence length (# tokens) and vocabulary size (# types), depending on the choice of n. The increase in sequence length is substantial; one way to reduce sequence length is to leave a shortlist of the k most frequent word types unsegmented. Only the unigram representation is truly open-vocabulary. However, the unigram representation performed poorly in preliminary experiments, and we report translation results with a bigram representation, which is empirically better, but unable to produce some tokens in the test set with the training set vocabulary.

We report statistics for several word segmentation techniques that have proven useful in previous SMT research, including frequency-based compound splitting (Koehn and Knight, 2003), rule-based hyphenation (Liang, 1983), and Morfessor (Creutz and Lagus, 2002). We find that they only moderately reduce vocabulary size, and do not solve the unknown word problem, and we thus find them unsuitable for our goal of open-vocabulary translation without back-off dictionary.

BPE meets our goal of being open-vocabulary, and the learned merge operations can be applied to the test set to obtain a segmentation with no unknown symbols.[10] Its main difference from the character-level model is that the more compact representation of BPE allows for shorter sequences, and that the attention model operates on variable-length units.[11] Table 1 shows BPE with 59 500 merge operations, and joint BPE with 89 500 operations.

In practice, we did not include infrequent subword units in the NMT network vocabulary, since there is noise in the subword symbol sets, e.g. because of characters from foreign alphabets. Hence, our network vocabularies in Table 2 are typically slightly smaller than the number of types in Table 1.

[6] Clipped unigram precision is essentially 1-gram BLEU without brevity penalty.

[7] `github.com/sebastien-j/LV_groundhog`

[8] The time complexity of encoder-decoder architectures is at least linear to sequence length, and oversplitting harms efficiency.

[9] Our character n-grams do not cross word boundaries. We mark whether a subword is word-final or not with a special character, which allows us to restore the original tokenization.

[10] Joint BPE can produce segments that are unknown because they only occur in the English training text, but these are rare (0.05% of test tokens).

[11] We highlighted the limitations of word-level attention in section 3.1. At the other end of the spectrum, the character level is suboptimal for alignment (Tiedemann, 2009).

4.2 Translation experiments

English→German translation results are shown in Table 2; English→Russian results in Table 3.

Our baseline **WDict** is a word-level model with a back-off dictionary. It differs from **WUnk** in that the latter uses no back-off dictionary, and just represents out-of-vocabulary words as UNK[12]. The back-off dictionary improves unigram F_1 for rare and unseen words, although the improvement is smaller for English→Russian, since the back-off dictionary is incapable of transliterating names.

All subword systems operate without a back-off dictionary. We first focus on unigram F_1, where all systems improve over the baseline, especially for rare words (36.8%→41.8% for EN→DE; 26.5%→29.7% for EN→RU). For OOVs, the baseline strategy of copying unknown words works well for English→German. However, when alphabets differ, like in English→Russian, the subword models do much better.

[12]We use *UNK* for words that are outside the model vocabulary, and *OOV* for those that do not occur in the training text.

Unigram F_1 scores indicate that learning the BPE symbols on the vocabulary union (**BPE-J90k**) is more effective than learning them separately (**BPE-60k**), and more effective than using character bigrams with a shortlist of 50 000 unsegmented words (**C2-50k**), but all reported subword segmentations are viable choices and outperform the back-off dictionary baseline.

Our subword representations cause big improvements in the translation of rare and unseen words, but these only constitute 9-11% of the test sets. Since rare words tend to carry central information in a sentence, we suspect that BLEU and CHRF3 underestimate their effect on translation quality. Still, we also see improvements over the baseline in total unigram F_1, as well as BLEU and CHRF3, and the subword ensembles outperform the WDict baseline by 0.3–1.3 BLEU and 0.6–2 CHRF3. There is some inconsistency between BLEU and CHRF3, which we attribute to the fact that BLEU has a precision bias, and CHRF3 a recall bias.

For English→German, we observe the best BLEU score of 25.3 with C2-50k, but the best CHRF3 score of 54.1 with BPE-J90k. For comparison to the (to our knowledge) best non-neural MT system on this data set, we report syntax-based SMT results (Sennrich and Haddow, 2015). We observe that our best systems outperform the syntax-based system in terms of BLEU, but not in terms of CHRF3. Regarding other neural systems, Luong et al. (2015a) report a BLEU score of 25.9 on newstest2015, but we note that they use an ensemble of 8 independently trained models, and also report strong improvements from applying dropout, which we did not use. We are confident that our improvements to the translation of rare words are orthogonal to improvements achievable through other improvements in the network archi-

tecture, training algorithm, or better ensembles.

For English→Russian, the state of the art is the phrase-based system by Haddow et al. (2015). It outperforms our WDict baseline by 1.5 BLEU. The subword models are a step towards closing this gap, and BPE-J90k yields an improvement of 1.3 BLEU, and 2.0 CHRF3, over WDict.

As a further comment on our translation results, we want to emphasize that performance variability is still an open problem with NMT. On our development set, we observe differences of up to 1 BLEU between different models. For single systems, we report the results of the model that performs best on dev (out of 8), which has a stabilizing effect, but how to control for randomness deserves further attention in future research.

5 Analysis

5.1 Unigram accuracy

Our main claims are that the translation of rare and unknown words is poor in word-level NMT models, and that subword models improve the translation of these word types. To further illustrate the effect of different subword segmentations on the translation of rare and unseen words, we plot target-side words sorted by their frequency in the training set.[13] To analyze the effect of vocabulary size, we also include the system **C2-3/500k**, which is a system with the same vocabulary size as the WDict baseline, and character bigrams to represent unseen words.

Figure 2 shows results for the English–German ensemble systems on newstest2015. Unigram F_1 of all systems tends to decrease for lower-frequency words. The baseline system has a spike in F_1 for OOVs, i.e. words that do not occur in the training text. This is because a high proportion of OOVs are names, for which a copy from the source to the target text is a good strategy for English→German.

The systems with a target vocabulary of 500 000 words mostly differ in how well they translate words with rank > 500 000. A back-off dictionary is an obvious improvement over producing UNK, but the subword system C2-3/500k achieves better performance. Note that all OOVs that the back-off dictionary produces are words that are copied from the source, usually names, while the subword systems can productively form new words such as compounds.

For the 50 000 most frequent words, the representation is the same for all neural networks, and all neural networks achieve comparable unigram F_1 for this category. For the interval between frequency rank 50 000 and 500 000, the comparison between C2-3/500k and C2-50k unveils an interesting difference. The two systems only differ in the size of the shortlist, with C2-3/500k representing words in this interval as single units, and C2-50k via subword units. We find that the performance of C2-3/500k degrades heavily up to frequency rank 500 000, at which point the model switches to a subword representation and performance recovers. The performance of C2-50k remains more stable. We attribute this to the fact that subword units are less sparse than words. In our training set, the frequency rank 50 000 corresponds to a frequency of 60 in the training data; the frequency rank 500 000 to a frequency of 2. Because subword representations are less sparse, reducing the size of the network vocabulary, and representing more words via subword units, can lead to better performance.

The F_1 numbers hide some qualitative differences between systems. For English→German, WDict produces few OOVs (26.5% recall), but with high precision (60.6%) , whereas the subword systems achieve higher recall, but lower precision. We note that the character bigram model C2-50k produces the most OOV words, and achieves relatively low precision of 29.1% for this category. However, it outperforms the back-off dictionary in recall (33.0%). BPE-60k, which suffers from transliteration (or copy) errors due to segmentation inconsistencies, obtains a slightly better precision (32.4%), but a worse recall (26.6%). In contrast to BPE-60k, the joint BPE encoding of BPE-J90k improves both precision (38.6%) and recall (29.8%).

For English→Russian, unknown names can only rarely be copied, and usually require transliteration. Consequently, the WDict baseline performs more poorly for OOVs (9.2% precision; 5.2% recall), and the subword models improve both precision and recall (21.9% precision and 15.6% recall for BPE-J90k). The full unigram F_1 plot is shown in Figure 3.

[13] We perform binning of words with the same training set frequency, and apply bezier smoothing to the graph.

5.2 Manual Analysis

Table 4 shows two translation examples for the translation direction English→German, Table 5 for English→Russian. The baseline system fails for all of the examples, either by deleting content (*health*), or by copying source words that should be translated or transliterated. The subword translations of *health research institutes* show that the subword systems are capable of learning translations when oversplitting (*research→Fo|rs|ch|un|g*), or when the segmentation does not match morpheme boundaries: the segmentation *Forschungs|instituten* would be linguistically more plausible, and simpler to align to the English *research institutes*, than the segmentation *Forsch|ungsinstitu|ten* in the BPE-60k system, but still, a correct translation is produced. If the systems have failed to learn a translation due to data sparseness, like for *asinine*, which should be translated as *dumm*, we see translations that are wrong, but could be plausible for (partial) loanwords (*asinine Situation→Asinin-Situation*).

The English→Russian examples show that the subword systems are capable of transliteration. However, transliteration errors do occur, either due to ambiguous transliterations, or because of non-consistent segmentations between source and target text which make it hard for the system to learn a transliteration mapping. Note that the BPE-60k system encodes *Mirzayeva* inconsistently for the two language pairs (*Mirz|ayeva*→Мир|за|ева *Mir|za|eva*). This example is still translated correctly, but we observe spurious insertions and deletions of characters in the BPE-60k system. An example is the transliteration of *rakfisk*, where a п is inserted and a к is deleted. We trace this error back to translation pairs in the training data with inconsistent segmentations, such as (*p|rak|ri|ti*→пра|крит|и

(pra|krit|i)), from which the translation (*rak*→пра) is erroneously learned. The segmentation of the joint BPE system (BPE-J90k) is more consistent (*pra*|*krit*|*i*→пра|крит|и (pra|krit|i)).

6 Conclusion

The main contribution of this paper is that we show that neural machine translation systems are capable of open-vocabulary translation by representing rare and unseen words as a sequence of subword units.[14] This is both simpler and more effective than using a back-off translation model. We introduce a variant of byte pair encoding for word segmentation, which is capable of encoding open vocabularies with a compact symbol vocabulary of variable-length subword units. We show performance gains over the baseline with both BPE segmentation, and a simple character bigram segmentation.

Our analysis shows that not only out-of-vocabulary words, but also rare in-vocabulary words are translated poorly by our baseline NMT system, and that reducing the vocabulary size of subword models can actually improve performance. In this work, our choice of vocabulary size is somewhat arbitrary, and mainly motivated by comparison to prior work. One avenue of future research is to learn the optimal vocabulary size for a translation task, which we expect to depend on the language pair and amount of training data, automatically. We also believe there is further potential in bilingually informed segmentation algorithms to create more alignable subword units, although the segmentation algorithm cannot rely on the target text at runtime.

While the relative effectiveness will depend on language-specific factors such as vocabulary size, we believe that subword segmentations are suitable for most language pairs, eliminating the need for large NMT vocabularies or back-off models.

[14]The source code of the segmentation algorithms is available at `https://github.com/rsennrich/subword-nmt`.

Acknowledgments

We thank Maja Popović for her implementation of CHRF, with which we verified our re-implementation. The research presented in this publication was conducted in cooperation with Samsung Electronics Polska sp. z o.o. - Samsung R&D Institute Poland. This project received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement 645452 (QT21).

Abstract

Word pairs, which are one of the most easily accessible features between two text segments, have been proven to be very useful for detecting the discourse relations held between text segments. However, because of the data sparsity problem, the performance achieved by using word pair features is limited. In this paper, in order to overcome the data sparsity problem, we propose the use of word embeddings to replace the original words. Moreover, we adopt a gated relevance network to capture the semantic interaction between word pairs, and then aggregate those semantic interactions using a pooling layer to select the most informative interactions. Experimental results on Penn Discourse Tree Bank show that the proposed method without using manually designed features can achieve better performance on recognizing the discourse level relations in all of the relations.

1 Introduction

In a well-written document, no unit of the text is completely isolated, discourse relations describe how two units (e.g. clauses, sentences, and larger multi-clause groupings) of discourse are logically connected. Many downstream NLP applications such as opinion mining, summarization, and event detection, can benefit from those relations.

The task of automatically identify discourse relation is relatively simple when explicit connectives such as *however* and *because* are given (Pitler et al., 2009). However, the identification becomes much more challenging when such connectives are missing. In fact, such implicit discourse relations outnumber explicit relations in naturally occurring text, and identify those relations have been shown to be the performance bottleneck of an end-to-end discourse parser (Lin et al., 2014).

Most of the existing researches used rich linguistic features and supervised learning methods to achieve the task (Soricut and Marcu, 2003; Pitler et al., 2009; Rutherford and Xue, 2014). Among their works, word pairs are heavily used as an important feature, since word pairs like *(warm,cold)* might directly trigger a contrast relation. However, because of the data sparsity problem (McKeown and Biran, 2013) and the lack of metrics to measure the semantic relation between those pairs, which is so-called the *semantic gap* problem (Zhao and Grosky, 2002), the classifiers based on word pairs in the previous studies did not work well. Moreover, some text segment pairs are more complicated, it is hard to determine the relation held between them using only word pairs. Consider the following sentence pair with a *casual* relation as an example:

S1: Psyllium's not a good crop.

S2: You get a rain at the wrong time and the crop is ruined.

Intuitively, *(good, wrong)* and *(good, ruined)*, seem to be the most informative word pairs, and it is likely that they will trigger a contrast relation. Therefore, we can see that another main disadvantage of using word pairs is the lack of contextual information, and using n-gram pairs will again suffer from data sparsity problem.

Recently, the distributed word representations (Bengio et al., 2006; Mikolov et al., 2013) have shown an advantage when dealing with data sparsity problem (Braud and Denis, 2015), and many deep learning based models are generating substantial interests in text semantic matching and have achieved some significant progresses (Hu

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1726–1735,
Berlin, Germany, August 7-12, 2016.

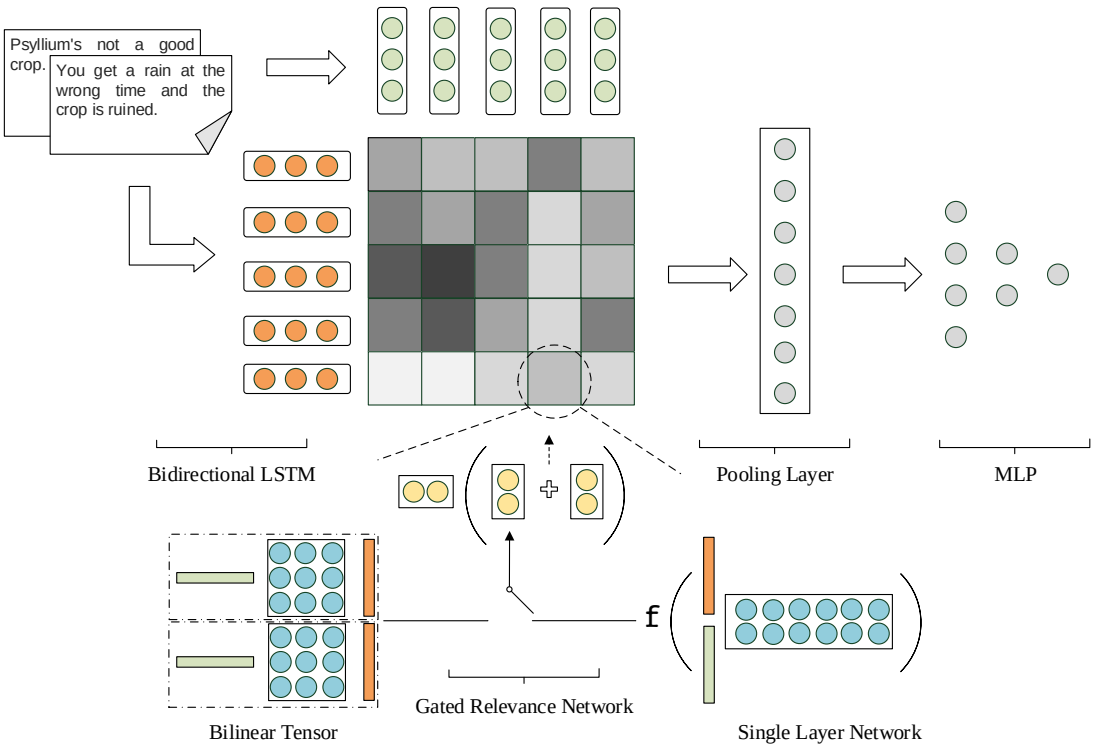

Figure 1: The processing framework of the proposed approach.

et al., 2014; Qiu and Huang, 2015; Wan et al., 2015). Inspired by their work, we in this paper propose the use of word embeddings to replace the original words in the text segments to fight against the data sparsity problem. Further more, in order to preserve the contextual information around the word embeddings, we encode the text segment to its positional representation via a recurrent neural network, specifically, we use a bidirectional LSTM (Hochreiter and Schmidhuber, 1997). Then, to overcome the *semantic gap*, we propose the use of a gated relevance network to capture the semantic interaction between those positional representations. Finally, all the interactions generated by the relevance network are fed to a max pooling layer to get the strongest interactions. We then aggregate them to predict the discourse relation through a multi-layer perceptron (MLP). Our model is trained end to end by Back-Propagation and Adagrad.

The main contribution of this paper can be summarized as follows:

- We use word embeddings to replace the original words in the text segments to overcome data sparsity problem. In order to preserve the contextual information, we further encode the text segment to its positional representation through a recurrent neural network.
- To deal with the semantic gap problem, we adopt a gated relevance network to capture the semantic interaction between the intermediate representations of the text segments.
- Experimental results on PDTB (Prasad et al., 2008) show that the proposed method can achieve better performance in recognizing discourse level relations in all of the relations than the previous methods.

2 The Proposed Method

The architecture of our proposed method is shown in figure 1. In the following of this section, we will illustrate the details of the proposed framework.

2.1 Embedding Layer

To model the sentences with neural model, we firstly need to transform the one-hot representation of word into the distributed representation. All words of two text segments X and Y will be mapped into low dimensional vector representations, which are taken as input of the network.

Through this layer, we can filter the words appear in low frequency, and we then map these words to a special OOV (out of vocabulary) word embedding. In addition, all the text segments in our experiment are padded to have the same length.

2.2 Sentence Modeling with LSTM

Long Short-Term Memory network (LSTM) (Hochreiter and Schmidhuber, 1997) is a type of recurrent neural network (RNN), and specifically addresses the issue of learning long-term dependencies. Given a variable-length sentence $S = (x_0, x_1, ..., x_T)$, LSTM processes it by incrementally adding up new content into a single slot of maintained memory, with gates controlling the extent to which new content should be memorized, old content should be erased and current content should be exposed. At position t, the memory c_t and the hidden state h_t are updated with the following equations:

$$\begin{bmatrix} \tilde{\mathbf{c}}_t \\ \mathbf{o}_t \\ \mathbf{i}_t \\ \mathbf{f}_t \end{bmatrix} = \begin{bmatrix} \tanh \\ \sigma \\ \sigma \\ \sigma \end{bmatrix} T_{\mathbf{A},\mathbf{b}} \begin{bmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{bmatrix}, \quad (1)$$

$$\mathbf{c}_t = \tilde{\mathbf{c}}_t \odot \mathbf{i}_t + \mathbf{c}_{t-1} \odot \mathbf{f}_t, \quad (2)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t), \quad (3)$$

where i_t, f_t, o_t, denote the input, forget and output gate at time step t respectively, and $T_{\mathbf{A},\mathbf{b}}$ is an affine transformation which depends on parameters of the network $\mathbf{A}$ and $\mathbf{b}$. σ denotes the logistic sigmoid function and $\odot$ denotes elementwise multiplication.

Notice that the LSTM defined above only get context information from the past. However, context information from the future could also be crucial. To capture the context from both past and the future, we propose to use the bidirectional LSTM (Schuster and Paliwal, 1997). Bidirectional LSTM preserves the previous and future context information by two separate LSTMs, one encodes the sentence from start to the end, and the other encodes the sentence from end to the start. Therefore, at each position t of the sentence, we can obtain two representations $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$. It is natural to concatenate them to get the intermediate representation at position t, i.e. $h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}]$. A illustration for the bidirectional LSTM are shown in Figure 2.

Given a sentence $S = (x_0, x_1, ..., x_T)$, we can now encode it with a bidirectional LSTM, and replace the word w_t with h_t, we can interpret h_t as a representation summarizing the word at position t and its contextual information.

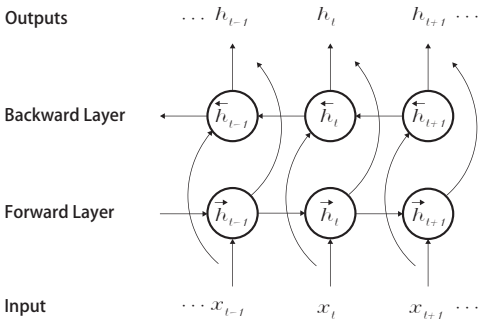

Figure 2: A illustration of bidirectional LSTM.

2.3 Gated Relevance Network

Given two text segments $X = x_1, x_2, ..., x_n$ and $Y = y_1, y_2, ..., y_m$, after the encoding procedure with a bidirectional LSTM, we can get their positional representation $X_h = x_{h_1}, x_{h_2}, ..., x_{h_n}$ and $Y_h = y_{h_1}, y_{h_2}, ..., y_{h_m}$. We then compute the relevance score between every intermediate representation pair x_{h_i} and y_{h_j} with dimension d_h. Traditional ways to measure their relevance includes cosine distance, bilinear model (Sutskever et al., 2009; Jenatton et al., 2012), single layer neural network (Collobert and Weston, 2008), etc. We then illustrate the bilinear model and the single layer neural network in details.

Bilinear Model is defined as follows:

$$s(h_{x_i}, h_{y_j}) = h_{x_i}^T M h_{y_j}, \quad (4)$$

where the only parameter $M \in \mathbf{R}^{d_h \times d_h}$. The bilinear model is a simple but efficient way to incorporate the strong linear interactions between two vectors, while the main weakness of it is the lack of ability to deal with nonlinear interaction.

Single Layer Network is defined as:

$$s(h_{x_i}, h_{y_j}) = u^T f(V \begin{bmatrix} h_{x_i} \\ h_{y_j} \end{bmatrix} + b), \quad (5)$$

where f is a standard nonlinearity applied element-wise, $V \in \mathbf{R}^{k \times 2d_h}$, $b \in \mathbf{R}^k$, and $u \in \mathbf{R}^k$. The single layer network could capture nonlinear interaction, while at the expense of a weak interaction between two vectors.

Each of the two models have its own advantages, and they can not take the place of each other.

In our work, we propose to incorporate the two models through the gate mechanism, so that the model is more powerful to capture more complex semantic interactions. The incorporated model, namely **gated relevance network** (GRN), is defined as:

$$s(h_{x_i}, h_{y_j}) = u^T(g \odot h_{x_i}^T M^{[1:r]} h_{y_j} + (1-g) \odot f(V \begin{bmatrix} h_{x_i} \\ h_{y_j} \end{bmatrix}) + b), \quad (6)$$

where f is a standard nonlinearity applied element-wise, $M^{[1:r]} \in \mathbf{R}^{r \times d_h \times d_h}$ is a bilinear tensor and the tensor product $h_{x_i}^T M^{[1:r]} h_{y_j}$ results in a vector $m \in \mathbf{R}^r$, where each entry is computed by one slice $k = 1, 2, ..., r$ of the tensor: $m_k = h_{x_i}^T M^k h_{y_j}$, $V \in \mathbf{R}^{r \times 2d_h}$, $b \in \mathbf{R}^r$, and $u \in \mathbf{R}^r$, g is a gate expressing how the output is produced by the linear and nonlinear semantic interactions between the input, defined as:

$$g = \sigma(W_g \begin{bmatrix} h_{x_i} \\ h_{y_j} \end{bmatrix} + b_g), \quad (7)$$

where $W_g \in \mathbf{R}^{r \times 2d_h}$, $b \in \mathbf{R}^r$ and σ denotes the logistic sigmoid function.

The gated relevance network is a little bit similar to the Neural Tensor Network (NTN) proposed by Socher et al. (2013):

$$s(h_{x_i}, h_{y_j}) = u^T f(h_{x_i}^T M^{[1:r]} h_{y_j} + V \begin{bmatrix} h_{x_i} \\ h_{y_j} \end{bmatrix} + b). \quad (8)$$

Compared with NTN, the main advantage of our model is we use a gate to tell how the linear and nonlinear interaction should be combined, while in NTN, the interaction generated by bilinear model and single layer network are treated equally. Also, NTN feeds the incorporated interaction to a nonlinearity, while we are not.

As we can see, for each pair of the intermediate representation, the gated relevance network will produce a semantic interaction score, thus, the entire output of two text segments is an interaction score matrix.

2.4 Max-Pooling Layer and MLP

The relation between two text segments is often determined by some strong semantic interactions, therefore, we adopt max-pooling strategy which partitions the score matrix as shown in Figure 1 into a set of non-overlapping sub-regions, and for each such sub-region, outputs the maximum value. The pooling scores are further reshaped to a vector and fed to a multi-layer perceptron (MLP). More specifically, the vector obtained by the pooling layer is fed into a full connection hidden layer to get a more abstractive representation first, and then connect to the output layer. For the task of classification, the outputs are probabilities of different classes, which is computed by a softmax function after the fully-connected layer. We name the full architecture of our model **Bi-LSTM+GRN**.

2.5 Model Training

Given a text segment pair (X, Y) and its label l, the training objective is to minimize the cross-entropy of the predicted and the true label distributions, defined as:

$$L(X, Y; \boldsymbol{l}, \hat{\boldsymbol{l}}) = -\sum_{j=1}^{C} \boldsymbol{l}_j \log(\hat{\boldsymbol{l}}_j), \quad (9)$$

where $\boldsymbol{l}$ is one-hot representation of the ground-truth label l; $\hat{\boldsymbol{l}}$ is the predicted probabilities of labels; C is the class number.

To minimize the objective, we use stochastic gradient descent with the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatches. The parameter update for the i-th parameter $\theta_{t,i}$ at time step t is as follows:

$$\theta_{t,i} = \theta_{t-1,i} - \frac{\alpha}{\sqrt{\sum_{\tau=1}^{t} g_{\tau,i}^2}} g_{t,i}, \quad (10)$$

where α is the initial learning rate and $g_\tau \in \mathbf{R}^{|\theta_{\tau,i}|}$ is the gradient at time step τ for parameter $\theta_{\tau,i}$.

3 Experiment

3.1 Dataset

The dataset we used in this work is Penn Discourse Treebank 2.0 (Prasad et al., 2008), which is one of the largest available annotated corpora of discourse relations. It contains 40,600 relations, which are manually annotated from the same 2,312 Wall Street Journal (WSJ) articles as the Penn Treebank. We follow the recommended section partition of PDTB 2.0, which is to use sections 2-20 for training, sections 21-22 for testing and the other sections for validation (Prasad et al., 2008). For comparison with the previous work (Pitler et al., 2009; Zhou et al., 2010; Park

Table 1: The unbalanced sample distribution of PDTB.

Relation	Train	Dev	Test
Comparison	1894	401	146
Contingency	3281	628	276
Expansion	6792	1253	556
Temporal	665	93	68

Table 2: Hyperparameters for our model in the experiment.

Word Embedding size	$n_w = 50$
Initial learning rate	$\rho = 0.01$
Minibatch size	$m = 32$
Pooling Size	$(p, q) = (3, 3)$
Number of tensor slice	$r = 2$

and Cardie, 2012; Rutherford and Xue, 2014; Ji and Eisenstein, 2015), we train four binary classifiers to identify each of the top level relations, the *EntRel* relations are merged with *Expansion* relations. For each classifier, we use an equal number of positive and negative samples as training data, because each of the relations except *Expansion* is infrequent (Pitler et al., 2009) as what shows in Table 1. The negative samples were chosen randomly from training sections 2-20.

3.2 Experiment Protocols

In this part, we will mainly introduce the experiment settings, including baselines and parameter setting.

3.2.1 Baselines

The baselines for comparison with our proposed method are listed as follows:

- LSTM: We use two single LSTM to encode the two text segments, then concatenate them and feed to a MLP to do the relation detection.
- Bi-LSTM: We use two single bidirectional LSTM to encode the two text segments, then concatenate them and feed to a MLP to do the relation detection.
- Word+NTN: We use the neural tensor defined in (8) to capture the semantic interaction scores between every word embedding pair, the rest of the method is the same as our proposed method.
- LSTM+NTN: We use two single LSTM to generate the positional text segments representation. The rest of the method is the same as Word-NTN.
- BLSTM+NTN: We use two single bidirectional LSTM to generate the positional text segments representation. The rest of the method is the same as Word-NTN.
- Word+GRN: We use the gated relevance network proposed in this paper to capture the semantic interaction scores between every word embedding pair of the two text segments. The rest of the method is the same as our model.
- LSTM+GRN: We use the gated relevance network proposed in this paper to capture the semantic interaction scores between every intermediate representation pair of the two text segments generated by LSTM. The rest of the method is the same as our model.

3.2.2 Parameter Setting

For the initialization of the word embeddings used in our model, we use the 50-dimensional pre-trained embeddings provided by Turian et al. (2010), and the embeddings are fixed during training. We only preserve the top 10,000 words according to its frequency of occurrence in the training data, all the text segments are padded to have the same length of 50, the intermediate representations of LSTM are also set to 50. The other parameters are initialized by randomly sampling from uniform distribution in [-0.1,0.1].

For other hyperparameters of our proposed model, we take those hyperparameters that achieved best performance on the development set, and keep the same parameters for other competitors. The final hyper-parameters are show in Table 2.

3.3 Result

The results on PDTB are show in Table3, from the results, we have several experiment findings.

First of all, it is easy to notice that LSTM and Bi-LSTM achieve lower performance than all of the methods of using a tensor to capture the semantic interactions between word pairs and the intermediate representation pairs. Because the main

Table 3: The performances of different approaches on the PDTB.

Bi-LSTM+GRN	**40.17**%	**54.76**%	**80.62**%	**31.32**%

disadvantage of using LSTM and Bi-LSTM to encode the text segment into a single representation is that some important local information such as key words can not be fully preserved when compressing a long sentence into a single representation.

Second, the performance improves a lot when using LSTM and Bi-LSTM to encode the text segments to positional representations instead of using word representations directly. We conclude it is mainly because the following two reasons: for one thing, some words are important only when they are associated with their context, for the other, the intermediate representations are the high-level representation of the sentence at each position, there is no doubt for they can obtain much more semantic information than the words along. In addition, Bi-LSTM also takes the future information of the text segments into consideration, resulting in a consistently better performance than LSTM.

Third, take a comparison to the methods using NTN and the methods using GRN, we can find that the GRN performs consistently better. Such results show that the gate we proposed to combine the information of two aspects is actually useful.

At last, our proposed model, namely, Bi-LSTM+GRN achieves best performance on all of the relations. It not only shows the interaction between word pairs is useful, but also shows the way we proposed to capture such information is useful too. Further more, compared with the previous methods (Pitler et al., 2009; Park and Cardie, 2012; Rutherford and Xue, 2014), which used either a lot of complex textual features and contextual information about the two text segments or a larger unannotated corpus to help the prediction, our model only uses the the information of the two text segments themselves, but yet achieves better performance. It demonstrates that our model is powerful in modeling the discourse relations.

3.4 Parameter Sensitivity

In this section, we evaluate our model through different settings of the proposed gated relevance network, the other hyperparameters are the same as mentioned above and we use a bidirectional LSTM to encode the text segments. The settings are shown as follows:

- **GRN-1** We set the parameters $r = 1$, $M^{[1]} = I$, $V = 0$, $b = 0$ and $g = 1$. The model can be regarded as cosine similarity.

	Cmp	Ctg	Exp	Tmp
GRN-1	34.01%	50.23%	78.66%	21.33%
GRN-2	35.74%	50.91%	79.40%	23.28%
GRN-3	34.15%	51.78%	79.33%	26.16%
GRN-4	37.18%	52.36%	79.86%	25.60%
GRN-5	**40.17**%	**54.76**%	**80.62**%	**31.32**%
GRN-6	38.26%	52.08%	80.02%	28.51%

Table 4: Comparison of our model with different parameter settings to the gated relevance network. *Cmp* denotes the comparison relation, *Ctg* denotes the contingency relation, *Exp* denotes the expansion relation and *Tmp* denotes the temporal relation.

- **GRN-2** We set the parameters $r = 1$, $V = 0$, $b = 0$, and $g = 1$. The model can be regarded as the bilinear model.
- **GRN-3** We set the parameters $r = 1$, $M^{[1]} = 0$, and $g = 0$. The model can be regarded as a single layer network.
- **GRN-4** We set the parameters $r = 1$. This model is the full GRN model.
- **GRN-5** We set the parameters $r = 2$. This model is the full GRN model.
- **GRN-6** We set the parameters $r = 3$. This model is the full GRN model.

The results for different parameter settings are shown in Table 4. It is obvious that **GRN-1** achieves a relatively lower performance, showing that the cosine similarity is not enough to capture the complex semantic interaction. Take a comparison on **GRN-2** and **GRN-3**, we can see that **GRN-2** outperforms **GRN-3** on *Comparison* and *Expansion* relation, while achieves a lower performance on the other two relations, moreover, the combination method **GRN-4** outperforms both of the methods, demonstrating that the semantic interactions captured by the bilinear model and the single layer network are different. Hence, they can not take the place of each other, and it is reasonable to use a gate to combine them.

Among the methods of using the full GRN model, **GRN-5** which has 2 bilinear tensor slices achieves the best performance. We explain this phenomenon on two aspects, on one hand, we can see each slice of the bilinear tensor as being responsible for one type of the relation, a bilinear tensor with 2 slices is more suitable for training a binary classifier than the original bilinear model. On the other hand, increasing the number of slices will increase the complexity of the model, thus making it harder to train.

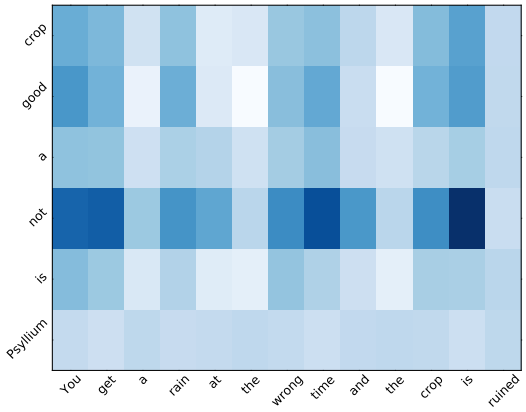
3.5 Case Study

In this section, we go back to the example mentioned above to show see what information between the text segment pairs is captured, and how the positional sentence representations affect the performance of our model.

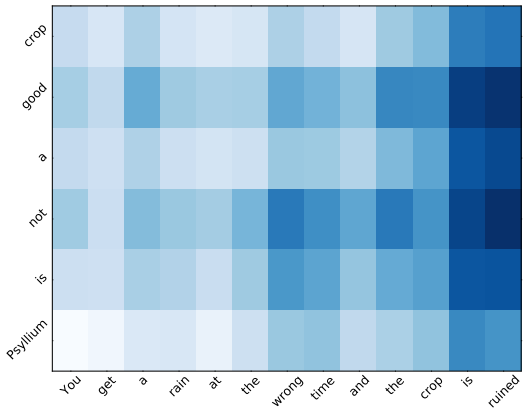
The examples is listed below:

S1: Psyllium's not a good crop.

S2: You get a rain at the wrong time and the crop is ruined.



(a) Word+GRN



(b) Bi-LSTM+GRN

Figure 3: A visualization of the interaction score matrix between two relatively complex sentences. The darker patches denote the corresponding scores generated by the gated relevance network are higher.

In this case, the relation between the sentence pair is *Contingency*, and the implicit connective annotated by human is "because". The pair is likely to be classified to a wrong contrast relation if we only focus on the informative word pairs *(good,wrong)* and *(good,ruined)*. It is mainly because their relation is highly depended on the semantic of the whole sentence, and the words should be considered with their context.

Figure 3 explains this phenomenon, in Figure 3a, we can see that the word pairs which associate with "not" get high scores, scores on the other pairs are relatively arbitrary. It demonstrates the word embedding model failed to learn which part of the sentence should be focused, although the useless word such as "Psyllium" and "a" are

ignored, thus making it harder to identify the relation.

Take Figure 3b for a comparison, from the figure we can observe the pairs that associate with "not" and "good" which are import context to determine the semantic of the sentence get much higher scores. Moreover, the scores increase along with the sentence encoding procedure, especially when the last informative word "ruined" appears. Once again, some useless word are also ignored by this model. It demonstrates the bidirectional LSTM we used in our model could encode the contextual information to the intermediate representations, thus these information could help to determine which part of the two sentence should be focused when identifying their relation.

4 Related Work

Discourse relations, which link clauses in text, are used to represent the overall text structure. Many downstream NLP tasks such as text summarization, question answering, and textual entailment can benefit from the task. Along with the increasing requirement, many works have been constructed to automatically identify these relations from different aspects (Pitler et al., 2008; Pitler et al., 2009; Zhou et al., 2010; McKeown and Biran, 2013; Rutherford and Xue, 2014; Xue et al., 2015).

For training and comparing the performance of different methods, the Penn Discourse Treebank (PDTB) 2.0, which is large annotated discourse corpuses, were released in 2008 (Prasad et al., 2008). The annotation methodology of it follows the lexically grounded, predicate-argument approach. In PDTB, the discourse relations were predefined by Webber (2004). PDTB-styled discourse relations hold in only a local contextual window, and these relations are organized hierarchically. Also, every relation in PDTB has either an *explicit* or an *implicit* marker. Since explicit relations are easy to identify (Pitler et al., 2008), existing methods achieved good performance on the relations with explicit maker. In recent years, researchers mainly focused on implicit relations. For easily comparing with other methods, in this work, we also use PDTB as the training and testing corpus.

As we mentioned above, various approaches have been proposed to do the task. Pitler et al. (2009) proposed to train four binary classifiers using word pairs as well as other rich linguistic features to automatically identify the top-level PDTB relations. Park and Cardie (2012) achieved a higher performance by optimizing the feature set. McKeown and Biran (2013) aims at solving the data sparsity problem, and they extended the work of Pitler et al. (2009) by aggregating word pairs. Rutherford and Xue (2014) used Brown clusters and coreferential patterns as new features and improved the baseline a lot. Braud and Denis (2015) compared different word representations for implicit relation classification. The word pairs feature have been studied by all of the work above, showing its importance on discourse relation. We follow their work, and incorporate word embedding to deal with this problem.

There also exist some work performing this task from other perspectives. Zhou et al. (2010) studied the problem from predicting *implicit marker*. They used a language model to add implicit markers as an additional feature to improve performance. Their approach can be seen as a semi-supervised method. Ji and Eisenstein (2015) computes distributed meaning representations for each discourse argument by composition up the syntactic parse tree. Chen et al. (2016) used vector offsets to represent this relation between sentence pairs, and aggregate this offsets through the Fisher vector. Liu et al. (2016) used a a mutil-task deep learning framework to deal with this problem, they incorporate other similar corpus to deal with the data sparsity problem.

Most of the previous works mentioned above used rich linguistic features and supervised learning methods to achieve the task. In this paper, we propose a deep architecture, which does not need these manually selected features and additional linguistic knowledge base to do it.

5 Conclusion

In this work, we propose to use word embeddings to fight against the data sparsity problem of word pairs. In order to preserve contextual information, we encode a sentence to its positional representation via a recurrent neural network, specifically, a LSTM. To solve the semantic gap between the word pairs, we propose to use a gated relevance network which incorporates both the linear and nonlinear interactions between pairs. Experiment results on PDTB show the proposed model outperforms the existing methods using traditional fea-

tures on all of the relations.

Model Architectures for Quotation Detection

Christian Scheible, Roman Klinger and **Sebastian Padó**

Abstract

Quotation detection is the task of locating spans of quoted speech in text. The state of the art treats this problem as a sequence labeling task and employs linear-chain conditional random fields. We question the efficacy of this choice: The Markov assumption in the model prohibits it from making joint decisions about the begin, end, and internal context of a quotation. We perform an extensive analysis with two new model architectures. We find that (a), simple boundary classification combined with a greedy prediction strategy is competitive with the state of the art; (b), a semi-Markov model significantly outperforms all others, by relaxing the Markov assumption.

1 Introduction

Quotations are occurrences of reported speech, thought, and writing in text. They play an important role in computational linguistics and digital humanities, providing evidence for, e.g., speaker relationships (Elson et al., 2010), inter-speaker sentiment (Nalisnick and Baird, 2013) or politeness (Faruqui and Pado, 2012). Due to a lack of general-purpose automatic systems, such information is often obtained through manual annotation (e.g., Agarwal et al. (2012)), which is labor-intensive and costly. Thus, models for *automatic quotation detection* form a growing research area (e.g., Pouliquen et al. (2007); Pareti et al. (2013)).

Quotation detection looks deceptively simple, but is challenging, as the following example shows:

> [The pipeline], the company said, [would be built by a proposed joint venture ..., and Trunkline ... will "build and operate" the system ...].[1]

[1]Penn Attributions Relation Corpus (PARC), wsj_0260

Note that quotations can (i) be signalled by lexical cues (e.g., communication verbs) without quotation marks, (ii) contain misleading quotation marks; (iii) be discontinuous, and (iv) be arbitrarily long.

Early approaches to quotation detection use hand-crafted rules based on syntactic markers (Pouliquen et al., 2007; Krestel et al., 2008). While yielding high precision, they suffered from low recall. The state of the art (Pareti et al., 2013; Pareti, 2015) treats the task as a sequence classification problem and uses a linear-chain conditional random field (CRF). This approach works well for the prediction of the approximate location of quotations, but yields a lower performance detecting their exact span.

In this paper, we show that linear-chain sequence models are a sub-optimal choice for this task. The main reason is their *length*, as remarked above: Most sequence labeling tasks in NLP (such as most cases of named entity recognition) deal with spans of a few tokens. In contrast, the median quotation length on the Penn Attributions Relation Corpus (PARC, Pareti et al. (2013)) is 16 tokens and the longest span has over 100 tokens. As a result of the strong Markov assumptions that linear-chain CRFs make to ensure tractability, they cannot capture "global" properties of (almost all) quotations and are unable to make joint decisions about the begin point, end point, and content of quotations.

As our first main contribution in this paper, we propose two novel model architectures designed to investigate this claim. The first is *simpler* than the CRF. It uses token-level classifiers to predict quotation boundaries and combines the boundaries greedily to predict spans. The second model is *more expressive*. It is a semi-Markov sequence model which relaxes the Markov assumption, enabling it to consider global features of quotation spans. In our second main contribution, an analysis of the models' performances, we find that the sim-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1736–1745,
Berlin, Germany, August 7-12, 2016.

pler model is competitive with the state-of-the-art CRF. The semi-Markov model outperforms both of them significantly by 3 % F_1. This demonstrates that the relaxed Markov assumptions help improve performance. Our final contribution is to make implementations of all models publicly available.[2]

2 The Task: Quotation Detection

Problem Definition Following the terminology established by Pareti et al. (2013), we deal with the detection of *content spans*, the parts of the text that are being quoted. To locate such spans, it is helpful to first detect *cues* which often mark the beginning or end of a quotation. The following example shows an annotated sentence from the PARC corpus; each content span (CONT) is associated with exactly one cue span (CUE):

> Mr. Kaye [denies]$_{\text{CUE}}$ [the suit's charges]$_{\text{CONT}}$ and [says]$_{\text{CUE}}$ [his only mistake was taking on Sony in the marketplace]$_{\text{CONT}}$.[3]

Pareti et al. (2013) distinguish three types of quotations. *Direct* quotations are fully enclosed in quotation marks and are a verbatim reproduction of the original utterance. *Indirect* quotations paraphrase the original utterance and have no quotation marks. *Mixed* quotations contain both verbatim and paraphrase content and may thus contain quotation marks. Note that the type of a content span is assigned automatically based on its surface form using the definitions just given.

Quotation Detection as Sequence Modeling In this paper, we compare our new model architectures to the state-of-the-art approach by Pareti (2015), an extension of Pareti et al. (2013). Their system is a pipeline: Its first component is the *cue model*, a token-level k-NN classifier applied to the syntactic heads of all verb groups. After cues are detected, content spans are localized using the *content model*, a linear-chain conditional random field (CRF) which makes use of the location of cues in the document through features.

As their system is not publicly available, we reimplement it. Our cue classifier is an averaged perceptron (Collins, 2002) which we describe in more detail in the following section. It uses the features in Table 1.[4] Our content model is a CRF with BIOE labels. It uses all features from Table 1 plus features that build on the output of the cue classifier, shown in Table 2.

C1. Surface form, lemma, and PoS tag for all tokens within a window of ± 5.
C2. Bigrams of surface form, lemma, and PoS tag
C3. Shape of t_i
C4. Is any token in a window of ± 5 a named entity?
C5. Does a quotation mark open or close at t_i (determined by counting)? Is t_i within quotation marks?
C6. Is t_i in the list of reporting verbs, noun cue verbs, titles, WordNet persons or organizations, and its VerbNet class
C7. Do a sentence, paragraph, or the document begin or end at t_i, t_{i-1}, or t_{i+1}?
C8. Distance to sentence begin and end; sentence length
C9. Does the sentence contain t_i a pronoun/named entity/quotation mark?
C10. Does a syntactic constituent starts or ends at t_i?
C11. Level of t_i in the constituent tree
C12. Label and level of the highest constituent in the tree starting at t_i; label of t_i's the parent node
C13. Dependency relation with parent or any child of t_i (with and without parent surface form)
C14. Any conjunction of C5, C9, C10

Table 1: Cue detection features for a token t_i at position i, mostly derived from Pareti (2015)

S1. Is a direct or indirect dependency parent of t_i classified as a cue, in the cue list, or the phrase "according to"?
S2. Was any token in a window of ± 5 classified as a cue?
S3. Distance to the previous and next cue
S4. Does the sentence containing t_i have a cue?
S5. Conjunction of S4 and all features from C14

Table 2: Additional features for content span detection, mostly derived from Pareti (2015)

3 New Model Architectures

While Pareti (2015) apply sequence modeling for quotation detection, they do not provide an analysis what the model learns. In this paper, we follow the intuition that a linear-chain CRF mostly makes local decisions about spans, while ignoring their global structure, such as joint information about the context of the begin and end points. If this is true, then (a) a model might work as well as the CRF without learning from label sequences, and (b) a model which makes joint decisions with global information might improve over the CRF.

This motivates our two new model architectures for the task. We illustrate the way the different architectures make use of information in Figure 1. Our simpler model (GREEDY) makes strictly local classification decisions, completely ignoring

[2] http://www.ims.uni-stuttgart.de/data/qsample

[3] PARC, `wsj_2418`

[4] For replicability, we give more detailed definitions of the features in the supplementary notes.

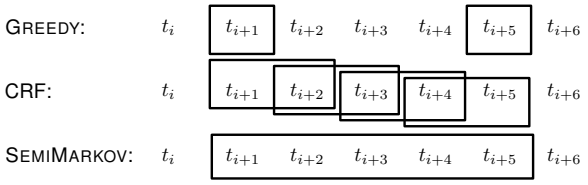

Figure 1: Information usage by model architecture. Frames indicate joint decisions on token labels.

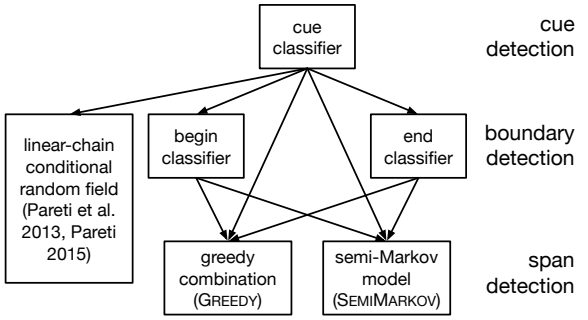

Figure 2: Information flow in all three models

those around it. The CRF is able to coordinate decisions within a window, which is propagated through Viterbi decoding. The more powerful model (SEMIMARKOV) takes the full span into account and makes a joint decision about the begin and end points.

Our intuition about the shortcomings of the CRF is based on an empirical analysis. However, to simplify the presentation, we postpone the presentation of this analysis to Section 6 where we can discuss and compare the results of all three models.

3.1 Model Decomposition and Formalization

We first introduce a common formalization for our model descriptions. Our problem of interest is *content span detection*, the task of predicting a set $\mathcal{S}$ of content spans (t_b, t_e) delimited by their begin and end tokens. The CRF solves this task by classifying tokens as begin/end/inside/outside tokens and thus solves a proxy problem. The problem is difficult because corresponding begin and end points need to be matched up over long distances, a challenge for probabilistic finite state automata such as CRFs.

In our model, *cue detection*, the task of detecting cue tokens t_c (cf. Section 2), remains the first step. However, we then decompose the content span problem solved by the CRF by introducing the intermediary task of *boundary detection*. As illustrated in Figure 2, this means identifying the sets of all *begin* and *end* tokens, t_b and t_e, ignoring their interdependencies. We then recombine these

Algorithm 1 GREEDY content span algorithm

Input: List of documents D; feature functions $\boldsymbol{f}_x$ for cue, begin, and end ($x \in c, b, e$); distance parameter $d_{\max}$; length parameter $\ell_{\max}$
Output: Content span labeling $\mathcal{S}$

$\boldsymbol{\theta}_c, \boldsymbol{\theta}_b, \boldsymbol{\theta}_e \leftarrow$ TRAINCLASSIFIERS$(D, \boldsymbol{f}_c, \boldsymbol{f}_b, \boldsymbol{f}_e)$
for d in D **do**
  $\mathcal{S} \leftarrow \varnothing$
  for token t in d **do**
    if $\boldsymbol{\theta}_c \cdot \boldsymbol{f}_c(t) > 0$ **then**
      $t_b \leftarrow$ next token right of t where $\boldsymbol{\theta}_b \cdot \boldsymbol{f}_b(t) > 0$ ▷ next begin
      $t_e \leftarrow$ next token right of t_b where $\boldsymbol{\theta}_e \cdot \boldsymbol{f}_e(t) > 0$ ▷ next end
      if $|t_b - t_c| \leq d_{\max}$ **and** $|t_e - t_b| \leq \ell_{\max}$ **and** OVERLAPPING$(t_b, t_e) = \varnothing$ **then**
        $\mathcal{S} \leftarrow \mathcal{S} \cup \{(t_b, t_e)\}$ ▷ add span

predictions with two different strategies, as detailed in Section 3.2 and Section 3.3. This decomposition has two advantages: (a), we expect that boundary detection is easier than content span detection, as we remove the combinatorial complexity of matching begin and end tokens; (b), begin, end, and cue detection are now three identical classification tasks that can be solved by the same machinery.

We model each of the three tasks (cue/begin/end detection) with a linear classifier of the form

$$\text{score}_x(t) = \boldsymbol{\theta}_x \cdot \boldsymbol{f}_x(t) \quad (1)$$

for a token t, a class $x \in \{c, b, e\}$ (for *cue*, *begin*, and *end*), a feature extraction function $\boldsymbol{f}_x(t)$, and a weight vector $\boldsymbol{\theta}_x$. We re-use the feature templates from Section 2 to remain comparable to the CRF.

We estimate all parameters $\boldsymbol{\theta}_x$ with the perceptron algorithm, and use parameter averaging (Collins, 2002). Since class imbalances, which occur in the boundary detection tasks, can have strong effects (Barandela et al., 2003), we train the perceptron with uneven margins (Li et al., 2002). This variant introduces two learning margins: τ_{-1} for the negative class and τ_{+1} for the positive class. Increasing τ_{+1} at a constant τ_{-1} increases recall (as failure to predict this class is punished more), potentially at the loss of precision, and vice versa.

3.2 Greedy Span Detection

Our first new model, GREEDY (Figure 2, bottom center), builds on the assumption that the modeling of sequence properties in a linear-chain CRF is weak enough that sequence learning can be replaced by a greedy procedure. Algorithm 1 shows how we generate a span labeling based on the output of the boundary classifiers. Starting at each cue,

we add all spans within a given distance $d_{\max}$ from the cue whose length is below a given maximum $\ell_{\max}$. If the candidate span is OVERLAPPING with any existing spans, we discard it. Analogously, we search for spans to the left of the cue. The algorithm is motivated by the structure of attribution relations: each content span has one associated cue.

3.3 Semi-Markov Span Detection

Our second model extends the CRF into a semi-Markov architecture which is able to handle *global features* of quotation span candidates (SEMIMARKOV, Figure 2 bottom right). Following previous work (Sarawagi and Cohen, 2004), we relax the Markov assumption inside spans. This allows for extracting arbitrary features on each span, such as conjunctions of features on the begin and end tokens or occurrence counts within the span.

Unfortunately, the more powerful model architecture comes at the cost of a more difficult prediction problem. Sarawagi and Cohen (2004) propose a variant of the Viterbi algorithm. This however does not scale to our application, since the maximum length of a span factors into the prediction runtime, and quotations can be arbitrarily long. As an alternative, we propose a sampling-based approach: we draw candidate spans (*proposals*) from an informed, non-uniform distribution of spans. We score these spans to decide whether they should be added to the document (*accepted*) or not (*rejected*). This way, we efficiently traverse the space of potential span assignments while still being able to make informed decisions (cf. Wick et al. (2011)).

To obtain a distribution over spans, we adapt the approach by Zhang et al. (2015). We introduce two independent probability distributions: P_b is the distribution of probabilities of a token being a *begin token*; P_e is the distribution of probabilities of a token being an *end token*. We sample a single content span proposal (DRAWPROPOSAL) by first sampling the *order* in which the boundaries are to be determined (begin token or end token first) by sampling a binary variable $d \sim \text{Bernoulli}(0.5)$. If the begin token is to be sampled first, we continue by drawing a begin token $t_b \sim P_b$ and finally draw an end token $t_e \sim P_e$ within a window of up to $\ell_{\max}$ tokens to the right of t_b. If the end token is to be sampled first, we proceed conversely. We also propose empty spans, i.e., the removal of existing spans without an replacement.

For the distributions P_b and P_e, we reuse our boundary detection models from Section 3.1. For each class $x \in \{b, e\}$ we form a distribution

$$P_x(t) \propto \exp(\text{score}_x(t)/T_x) \quad (2)$$

over the tokens t of a document using the scores from Equation 1. T_x is a temperature hyperparameter. Temperature controls the pronouncedness of peaks in the distribution. Higher temperature flattens the distribution and encourages the selection of tokens with lower scores. This is useful when exploration of the sample space is desired.

Algorithm 2 SEMIMARKOV inference algorithm

Input: Document d; probability distributions for begin and end (P_b, P_e); feature function for spans $\boldsymbol{g}$; maximum span length $\ell_{\max}$; number of proposals N
Output: Set of content spans $\mathcal{S}$

$\mathcal{S} \leftarrow \varnothing$
$\boldsymbol{\theta} \leftarrow \mathbf{0}$
for $n = 1$ to N **do**
  $(t_b, t_e) \leftarrow$ DRAWPROPOSAL(P_b, P_e)
  score $\leftarrow \boldsymbol{\theta} \cdot \boldsymbol{g}(t_b, t_e)$
  $\mathcal{O} \leftarrow$ OVERLAPPING(t_b, t_e)
  score$_{\mathcal{O}} \leftarrow \sum_{(t'_b, t'_e) \in \mathcal{O}} \boldsymbol{\theta} \cdot \boldsymbol{g}(t'_b, t'_e)$
  if score $>$ score$_{\mathcal{O}}$ **then**
    $\mathcal{S} \leftarrow \mathcal{S} \setminus \mathcal{O}$ ▷ remove overlapping
    $\mathcal{S} \leftarrow \mathcal{S} \cup \{(t_b, t_e)\}$ ▷ accept proposal
    if ISTRAINING **and** $\neg$CORRECT(t_b, t_e) **then**
      PERCEPTRONUPDATE ▷ wrongly accepted
  else
    REJECT(t_b, t_e)
    if ISTRAINING **and** CORRECT(t_b, t_e) **then**
      PERCEPTRONUPDATE ▷ wrongly rejected

The proposed candidates enter into the decision algorithm shown in Algorithm 2. As shown, the candidates are scored using a linear model (again as defined in Equation 1). We use the features of the previous models (Table 1 and 2) on the begin and end tokens. As we now judge complete span assignments rather than local label assignments to tokens, we can add a new span-global feature function $\boldsymbol{g}(t_b, t_e)$. We introduce the features shown in Table 3. If the candidate's score is higher than the sum of scores of all spans overlapping with it, we accept it and remove all overlapping ones.

This model architecture can be seen as a modification of the pipeline of the GREEDY model (cf. Figure 2). We again detect cues and boundaries, but then make an informed decision for combining begin and end candidates. In addition, the sampler makes "soft" selections of begin and end tokens based on the model scores rather than simply accepting the classifier decisions.

For training, we again use perceptron updates (cf. Section 3.2). If the model accepts a wrong

Table 4: Results on the test set of PARC3. Best overall strict results in bold. Models as in Figure 2. g: significantly better than GREEDY; c: significantly better than CRF (both with $\alpha = 0.05$).

G1. Numbers of named entities, lowercased tokens, commas, and pronouns inside the span
G2. Binned percentage of tokens that depend on a cue
G3. Location of the closest cue (left/right?), percentage of dependents on that cue
G4. Number of cues overlapped by the span
G5. Is there a cue before the first token and/or after the last token of the span (within the same sentence)? first or after the last token of the span?, and their conjunction
G6. Do both the first and the last token depend on a cue?
G7. Binned length of the span
G8. Does the span match a sentence exactly/off by one token?
G9. Number of sentences covered by the span
G10. Does the span match one or more constituents exactly?
G11. Is the span direct, indirect, or mixed?
G12. Is the # of quotation marks in the span odd or even?
G13. Is the span is direct and does it contain more than two quotation marks?

Table 3: Global features for content span detection

span, we perform a negative update (Line 12 in Algorithm 2). If a correct span is rejected, we make a positive update (Line 16). We iterate over the documents in random order for a fixed number E of epochs. As the sampling procedure takes long to fully label documents, we employ GREEDY to make initial assignments. This does not constitute additional supervision, as the sampler can remove any initial span and thus refute the initialization. This reduces runtime without affecting the result in practice.

4 Experimental Setup

Data We use the Penn Attribution Relations Corpus, version 3 (henceforth *PARC3*), by Pareti (2015).[5] It contains AR annotations on the Wall Street Journal part of the Penn Treebank (2,294 news documents). As in related work, we use sections 1–22 as training set, section 23 as test set, and section 24 as development set. We perform the same preprocessing as Pareti: We use gold tokenization, lemmatization, part-of-speech tags, constituency parses, gold named entity annotations (Weischedel and Brunstein, 2005), and Stanford parser dependency analyses (Manning et al., 2014).

Evaluation We report precision, recall, and micro-averaged F_1, adopting the two metrics introduced by Pareti et al. (2013): *Strict match* considers cases as correct where the boundaries of the spans match exactly. *Partial match* measures correctness as the ratio of overlap of the predicted and true spans. In both cases, we report numbers for each of the three quotation types (*direct*, *indirect*, *mixed*) and their micro averages. Like Pareti (2015), we exclude single-token content spans from the evaluation. To test for statistical significance of differences, we use the approximate randomization test (Noreen, 1989) at a significance level of $\alpha = 0.05$.

Implementation and Hyperparameters We use the CRF implementation in MALLET (McCallum, 2002). We optimize all hyperparameters of the models on the development set. Our best models use positive margins of $\tau_+ = 25$ for the boundary and $\tau_+ = 15$ for the span models, favoring recall. The SEMIMARKOV sampler uses a temperature of $T_x = 10$ for all classes. We perform 15 epochs of training after which the models have converged, and draw 1,000 samples for each document. For the GREEDY model, we obtain the best results with $d_{\max} = 30$ and $\ell_{\max} = 55$. For the SEMIMARKOV sampler, $\ell_{\max} = 75$ is optimal.

[5] Note that the data and thus the results differ from those previously published in (Pareti et al., 2013).

The high values mirror the presence of very long spans in the data.

5 Results

Cue We first evaluate the cue classifier. We obtain an F_1 of 86 %, with both precision and recall at 86 %, which is very close to the 85 % F_1 of Pareti.

CRF Table 4 summarizes the content span results. First, we compare Pareti's results to our reimplementation (the rows denoted with *Pareti (2015)* and *CRF*). There are some differences in how well the model performs on certain types of spans: while our precision is lower for indirect spans, it is higher on mixed spans. Additionally, our implementation generally has higher recall than Pareti's. Her system includes several features using proprietary lists (such as a manually curated list of titles) we were unable to obtain, and complex feature templates that we may interpret differently. We suspect that these differences are due to the typical replication problems in NLP (cf. Fokkens et al. (2013)). Overall, however, our model performs quite similarly to Pareti's, with our model scoring an overall F_1 of 72 % (vs. Pareti's 71 %) and a partial F_1 of 83 % (vs. 82 %).

GREEDY Next, we compare the GREEDY model to the CRF. We find its overall performance to be comparable to the CRF, confirming our expectations. While strict precision is statistically significantly lower for GREEDY (75 % vs. 79 %), strict recall is not significantly different (bot at 67 %). Considering partial matches, GREEDY has significantly higher recall (81 % vs. 77 %) but significantly lower precision (88 % vs. 90 %) than the CRF, with an overall comparable F_1. This result bolsters our hypothesis that the CRF learn only a small amount of useful sequence information. Although GREEDY ignores label sequences in training completely, it is able to compete with the CRF. Furthermore, the partial match result that GREEDY is a particularly good choice if the main interest is the approximate location of content spans in a document: The simpler model architecture makes it easier and more efficient to train and apply. The caveat is that GREEDY is particularly bad at locating mixed spans (as indicated by a precision of only 72 %): Quotation marks are generally good indicators for span boundaries and are often returned as false positives by the boundary detection models, so GREEDY tends to incorrectly pick them.

SEMIMARKOV Overall, the SEMIMARKOV model outperforms the CRF significantly in terms of strict recall (71 % vs. 67 %) and F_1 (75 % vs. 72 %), while precision remains unaffected (at 79 %). The model performs particularly well on indirect quotations (increasing F_1 by 5 points to 69 %), the most difficult category, where local context is insufficient. Meanwhile, on partial match, the SEMIMARKOV model has a comparable recall (80 vs. 77 %), but significantly lower precision (88 % vs. 90 %). The overall partial F_1 results are not significantly different. The improvement on the strict measures supports our intuition that better features help in particular in identifying the *exact* boundaries of quotations, a task that evidently profits from global information.

Model Combination The complementary strengths of the CRF and SEMIMARKOV (CRF detects direct quotations well, SEMIMARKOV indirect quotations) suggest a simple model combination algorithm based on the surface form of the spans: First take all *direct* and *mixed* spans predicted by the CRF; then add all *indirect* spans from the SEMIMARKOV model (except for those which would overlap). This result is our overall best model under strict evaluation, although it is not significantly better than the SEMIMARKOV model. Considering partial match, its results are essentially identical to the SEMIMARKOV model.

6 Analysis

We now proceed to a more detailed analysis of the performance of the three models (CRF, GREEDY, and SEMIMARKOV) and their differences in order to gain insights into the nature of the quotation detection task. In the interest of readability, we organize this section by major findings instead of the actual analyses that we have performed, and adduce for each finding all relevant analysis results.

Finding 1: Variation in length does not explain the differences in model performance. A possible intuition about our models it that the improvement of SEMIMARKOV over CRF is due to a better handling of longer quotations. However, this is not the case. Figure 3 shows the recall of the three models for quotations binned by lengths. The main patterns hold across all three models: Medium-length spans are the easiest to detect. Short spans are difficult to detect as they are often part of discontinuous content spans. Long spans are also

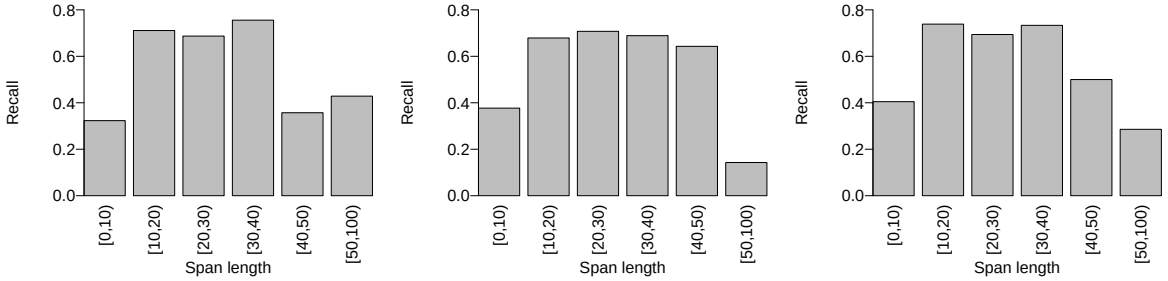

Figure 3: Strict recall by span length for CRF (left), GREEDY (center), and SEMIMARKOV model (right)

Category	Count		
	B	I	E
looking left	27	14	7
looking right	1	13	30
cue	11	10	7
other lexical	31	21	22
structural/syntactic	27	44	35
punctuation	31	25	36

Table 5: Categories of top positive and negative CRF features for begin (B), inside (I), and end (E)

difficult since any wrong intermediary decision can falsify the prediction. In fact, the CRF model is even the best model among the three for very long spans (which are rare). Those spans exceed the 55 and 75 token limits $\ell_{\max}$ of the GREEDY and SEMIMARKOV models. Intuitively, for the CRF, most spans are long: even spans which are short in comparison to other quotations are longer than the window within which the CRF operates. This is why span length does not have an influence.

Finding 2: Quotations are mostly defined by their immediate external context. A feature analysis of the CRF model reveals that many important features refer to material *outside* the quotation itself. For each label (B, I, E), we collect the 50 features with the highest positive and negative values, respectively. We first identify the subset of those features that looks look left or right. As the upper part of Table 5 shows, a substantial number of B (begin) features look to the left, and a number of E (end) features look to the right. Thus, these features do not look at the quotation itself, but at its immediate external context.

We next divide the features into four broad categories (cues, other lexical information, structural and syntactic features, and punctuation including quotation marks). The results in the lower part of Table 5 show that the begin and end classes rely on a range of categories, including lexical, cue and punctuation *outside* the quotation. The situation is different for inside tokens (I), where most features express structural and syntactic properties of the quotation such as the length of a sentence and its syntactic relation to a cue. Together, these observations suggest that one crucial piece of information about quotations is their lexical and orthographic context: the factors that mark a quotation as a quotation. Another crucial piece are internal structural properties of the quotation, while lexical properties of the quotation are not very important: which makes sense, since almost anything can be quoted.

The feature analysis is bolstered by an error analysis of the false negatives in the high-precision low-recall CRF. The first reason for false negatives is indeed the occurrence of infrequent cues which the cue model fails to identify (e.g., *read* or *acknowledge*). The second one is that the model does attempt to learn syntactic features, but that the structural features that can be learned by the CRF (such as C7, C10 or S4) can model only local windows of the quality of the quotation, but not its global quality. This leads us to our third finding.

Finding 3: Simple models cannot capture dependencies between begin and end boundaries well. Given the importance of cues, as evidenced by our Finding 2, we can ask whether the boundary of the quotation that is adjacent to its associated cue ("cue-near") is easier to identify than the other boundary ("cue-far") whose context is less informative. To assess this question, we evaluate the recall of individual boundary detection at the token level. For the CRF, "cue-far" boundaries of spans indeed tend to be more difficult to detect than "cue-near" ones. The results in Table 6 show that both the GREEDY and the CRF model show a marked asym-

	GREEDY	CRF	SEMIMARKOV
cue-near	76	74	76
cue-far	72	71	75

Table 6: Recall on boundaries by cue position

metry and perform considerably worse (3 % and 4 %, respectively) on the cue-far boundary. This asymmetry is considerably weaker for the SEMIMARKOV model, where both boundary types are recognized almost on par. The reason behind this finding is that neither the GREEDY model nor the CRF can condition the choice of the cue-far boundary on the cue-near boundary or on global properties of the quotation – the GREEDY model, because its choices are completely independent, and the CRF model, because its choices are largely independent due to the Markov assumption.

Finding 4: The SEMIMARKOV model benefits the most from its ability to handle global features about content spans. This leads us to our final finding about why the SEMIMARKOV model outperforms the CRF – whether it is the model architecture itself, or the new global features that it allows us to formulate. We perform an ablation study whose results are shown in Figure 4. We begin with only the token-level features on the begin, end, and interior tokens of the span, as introduced in Section 2, i.e., the features that the CRF has at its disposal. We find that this model performs on par with the CRF, thus the model architecture on its own does not help. We then incrementally add the feature templates containing count statistics of the internal tokens (Template G1 in Table 3) and advanced cue information (G2–G6). Both give the model incremental boosts. Adding syntactic coherence features (G7–G13) completes our full feature set and yields the best results.

Thus, the difference comes from features that describe global properties of the quotation. One of the most informative (negative) features is the conjunction from G6. It enforces the constraint that each content span is associated with a single cue. As in the CRF, the actual content of a content span does not play a large role. The only semantic features the model considers concern the presence of named entities within the span.

These observations are completed by analysis of the quotation spans that were correctly detected by the SEMIMARKOV model, but not the CRF (in terms of strict recall). We find a large amount of spans with highly ambiguous cue-near tokens such as *to* (10 % of the cases) *that* (16 %). We find that often the errors are also related to the frequency or location of cues. As an example, in the sentence

> [...] he has said [that when he was on the winning side in the 1960s, he knew that the tables might turn in the future]$_{\text{CONT}}$.[6]

the CRF model incorrectly splits the content span at the second cue candidate *knew*. This is, however, an embedded quotation that the model should ignore. In contrast, the SEMIMARKOV model makes use of the fact the tokens of the span depend on the same cue, and predicts the span correctly. For these tokens, the distinction between reported speech and factual descriptions is difficult. Arguably, it is the global features that help the model make its call.

7 Related Work

Quotation detection has been tackled with a number of different strategies. Pouliquen et al. (2007) use a small set of rules which has high precision but low recall on multilingual text. Krestel et al. (2008) also pursue a rule-based approach, focusing on the roles of cue verbs and syntactic markers. They evaluate on a small set of annotated WSJ documents and again report high precision but low recall. Pareti et al. (2013) develop the state-of-the-art sequence labeling approach discussed in this paper.

Our sampling approach builds on that of Zhang et al. (2015), who pursue a similar strategy for parsing, PoS tagging, and sentence segmentation. Similar semi-Markov model approaches have been used for other applications, e.g. by Yang and Cardie

[6] PARC, `wsj_2347`

(2012) and Klinger and Cimiano (2013) for sentiment analysis. They also predict spans by sampling, but they draw proposals based on the token or syntactic level. This is not suitable for quotation detection as we deal with much longer spans.

8 Conclusion

We have considered the task of quotation detection, starting from the hypothesis that linear-chain CRFs cannot take advantage of all available sequence information due to its Markov assumptions. Indeed, our analyses find that the features most important to recognize a quotation consider its direct context of orthographic evidence (such as quotation marks) and lexical evidence (such as cue words). A simple, greedy algorithm using non-sequential models of quotation boundaries rivals the CRF's performance. For further improvements, we introduce a semi-Markov model capable of taking into account *global* information about the complete span not available to a linear-chain CRF, such as the presence of cues on both sides of the quotation candidate. This leads to a significant improvement of 3 points F_1 over the state of the art.

On a more general level, we believe that quotation detection is interesting as a representative of tasks involving long sequences, where Markov assumptions become inappropriate. Other examples of such tasks include the identification of chemical compound names (Krallinger et al., 2015) and the detection of annotator rationales (Zaidan and Eisner, 2008). We have shown that a more expressive semi-Markov model which avoids these assumptions can improve performance. More expressive models however come with harder inference problems which are compounded when applied to long-sequence tasks. The informed sampling algorithm we have described performs such efficient inference for our semi-Markov quotation detection model.

Speech Act Modeling of Written Asynchronous Conversations with Task-Specific Embeddings and Conditional Structured Models

Shafiq Joty and **Enamul Hoque**
ALT Research Group
Qatar Computing Research Institute — HBKU, Qatar Foundation
{sjoty, mprince}@qf.org.qa

Abstract

This paper addresses the problem of speech act recognition in written asynchronous conversations (e.g., fora, emails). We propose a class of conditional structured models defined over arbitrary graph structures to capture the conversational dependencies between sentences. Our models use sentence representations encoded by a long short term memory (LSTM) recurrent neural model. Empirical evaluation shows the effectiveness of our approach over existing ones: (*i*) LSTMs provide better task-specific representations, and (*ii*) the global joint model improves over local models.

1 Introduction

Asynchronous conversations, where participants communicate with each other at different times (e.g., fora, emails), have become very common for discussing events, issues, queries and life experiences. In doing so, participants interact with each other in complex ways, performing certain communicative acts like asking questions, requesting information or suggesting something. These are called **speech acts** (Austin, 1962).

For example, consider the excerpt of a forum conversation from our corpus in Figure 1. The participant who posted the first comment C_1, describes his situation by the first two sentences and then asks a *question* in the third sentence. Other participants respond to the query by *suggesting* something or *asking* for clarification. In this process, the participants get into a conversation by taking turns, each of which consists of one or more speech acts. The two-part structures across posts like 'question-answer' and 'request-grant' are called **adjacency pairs** (Schegloff, 1968).

Figure 1: Example conversation with **Human** annotations and automatic predictions by a **Local** classifier and a **Global** classifier. The labels **st**, **ques**, **sug**, and **pol** refers to *Statement*, *Question*, *Suggestion*, and *Polite* speech acts, respectively.

Identification of speech acts is an important step towards deep conversation analysis in these media (Bangalore et al., 2006), and has been shown to be useful in many downstream applications including summarization (McKeown et al., 2007) and question answering (Hong and Davison, 2009).

Previous attempts to automatic (sentence-level)

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1746–1756,
Berlin, Germany, August 7-12, 2016.

speech act recognition in asynchronous conversation (Qadir and Riloff, 2011; Jeong et al., 2009; Tavafi et al., 2013; Oya and Carenini, 2014) suffer from at least one of the two major flaws.

Firstly, they use bag-of-word (BOW) *representation* (e.g., unigram, bigram) to encode lexical information in a sentence. However, consider the *suggestion* sentences in the example. Arguably, a model needs to consider the structure (e.g., word order) and the compositionality of phrases to identify the right speech act. Furthermore, BOW representation could be quite sparse and may not generalize well when used in classification models.

Secondly, existing approaches mostly disregard conversational dependencies between sentences. For instance, consider the example again, where we tag the sentences with the human annotations ('Human') and with the predictions of a local ('Local') classifier that considers word order for sentence representation but classifies each sentence separately. Prediction errors are underlined and highlighted in red. Notice the first and second sentences of comment 4, which are tagged mistakenly as *statement* and *response*, respectively, by our best local classifier. We hypothesize that some of the errors made by the local classifier could be corrected by employing a global joint model that performs a collective classification taking into account the conversational dependencies between sentences (e.g., adjacency relations).

However, unlike synchronous conversations (e.g., phone, meeting), modeling conversational dependencies between sentences in asynchronous conversation is challenging, especially in those where explicit thread structure (reply-to relations) is missing, which is also our case. The conversational flow often lacks sequential dependencies in its temporal order. For example, if we arrange the sentences as they arrive in the conversation, it becomes hard to capture any dependency between the act types because the two components of the adjacency pairs can be far apart in the sequence. This leaves us with one open research question: how to model the dependencies between sentences in a single comment and between sentences across different comments? In this paper, we attempt to address this question by designing and experimenting with conditional structured models over arbitrary graph structure of the conversation.

More concretely, we make the following contributions. Firstly, we propose to use Recurrent Neural Network (RNN) with Long Short Term Memory (LSTM) hidden layer to perform composition of phrases and to represent sentences using distributed condensed vectors (i.e., embeddings). We experiment with both unidirectional and bidirectional RNNs. Secondly, we propose conditional structured models in the form of pairwise Conditional Random Field (Murphy, 2012) over arbitrary conversational structures. We experiment with different variations of this model to capture different types of interactions between sentences inside the comments and across the comments. These models use the LSTM encoded vectors as feature vectors for performing the classification task jointly. As a secondary contribution, we also present and release a forum dataset annotated with a standard speech act tagset.

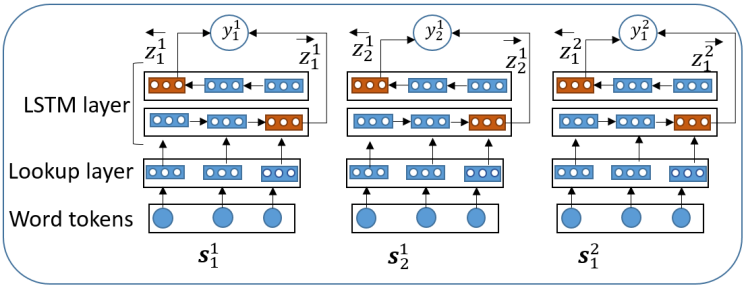
We train our models on different settings using synchronous and asynchronous corpora, and evaluate on two forum datasets. Our main findings are: (*i*) LSTM RNNs provide better representation than BOW; (*ii*) Bidirectional LSTMs, which encode a sentence using two vectors provide better representation than the unidirectional ones; and (*iii*) Global joint models improve over local models given that it considers the right graph structure. The source code and the new dataset are available at `http://alt.qcri.org/tools/speech-act/`

2 Our Approach

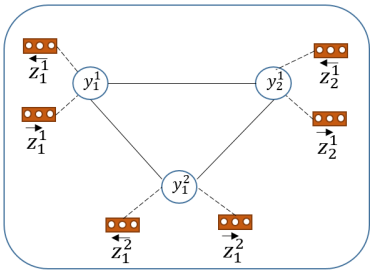
Let $\mathbf{s}_m^n$ denote the m-th sentence of comment n in a conversation. Our framework works in two steps as demonstrated in Figure 2. First, we use a recurrent neural network (RNN) to compose sentence representations semantically from their words and to represent them with distributed condensed vectors $\mathbf{z_m^n}$, i.e., sentence embeddings (Figure 2a). In the second step, a multivariate (graphical) model, which operates on the sentence embeddings, captures conversational dependencies between sentences in the conversation (Figure 2b). In the following, we describe the two steps in detail.

2.1 Sentence Representation

One of our main hypotheses is that a sentence representation method should consider the word order of the sentence. To this end, we use an LSTM RNN (Hochreiter and Schmidhuber, 1997) to encode a sentence into a vector by processing its words sequentially, at each time step combining



(a) Bidirectional LSTM-based RNN model



(b) Fully connected CRF model

Figure 2: Our two-step framework for speech act recognition in asynchronous conversation: (a) a bidirectional LSTM encodes each sentence $\mathbf{s}_m^n$ into a condensed vector $\mathbf{z_m^n}$ and classifies them separately; (b) a fully-connected CRF that takes the encoded vectors as input and performs joint learning and inference.

the current input with the previous hidden state. Figure 4b demonstrates the process for three sentences. Each word in the vocabulary V is represented by a D dimensional vector in a shared lookup table $L \in \mathbb{R}^{|V| \times D}$. L is considered a model parameter to be learned. We can initialize L randomly or by pretrained word embedding vectors like word2vec (Mikolov et al., 2013a).

Given an input sentence $\mathbf{s} = (w_1, \cdots, w_T)$, we first transform it into a feature sequence by mapping each token $w_t \in \mathbf{s}$ to an index in L. The lookup layer then creates an input vector $\mathbf{x_t} \in \mathbb{R}^D$ for each token w_t. The input vectors are then passed to the LSTM recurrent layer, which computes a compositional representation $\overrightarrow{\mathbf{h}}_t$ at every time step t by performing nonlinear transformations of the current input $\mathbf{x}_t$ and the output of the previous time step $\overrightarrow{\mathbf{h}}_{t-1}$. Specifically, the recurrent layer in a LSTM RNN is constituted with hidden units called *memory blocks*. A memory block is composed of four elements: (*i*) a memory cell c (a neuron) with a self-connection, (*ii*) an input gate i to control the flow of input signal into the neuron, (*iii*) an output gate o to control the effect of the neuron activation on other neurons, and (*iv*) a forget gate f to allow the neuron to adaptively reset its current state through the self-connection. The following sequence of equations describe how the memory blocks are updated at every time step t:

$$\mathbf{i}_t = \text{sigh}(U_i \mathbf{h}_{t-1} + V_i \mathbf{x}_t + \mathbf{b}_i) \quad (1)$$

$$\mathbf{f}_t = \text{sigh}(U_f \mathbf{h}_{t-1} + V_f \mathbf{x}_t + \mathbf{b}_f) \quad (2)$$

$$\mathbf{c}_t = \mathbf{i}_t \odot \tanh(U_c \mathbf{h}_{t-1} + V_c \mathbf{x}_t) + \mathbf{f}_t \odot \mathbf{c}_{t-1} \quad (3)$$

$$\mathbf{o}_t = \text{sigh}(U_o \mathbf{h}_{t-1} + V_o \mathbf{x}_t + \mathbf{b}_o) \quad (4)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t) \quad (5)$$

where U_k and V_k are the weight matrices between two consecutive hidden layers, and between the input and the hidden layers, respectively, which are associated with gate k (input, output, forget and cell); and and $\mathbf{b}_k$ is the corresponding bias vector. The symbols sigh and tanh denote hard sigmoid and hard tan, respectively, and the symbol $\odot$ denotes a element-wise product of two vectors.

LSTM by means of its specifically designed gates (as opposed to simple RNNs) is capable of capturing long range dependencies. We can interpret $\mathbf{h}_t$ as an intermediate representation summarizing the past. The output of the last time step $\overrightarrow{\mathbf{h}}_T = \mathbf{z}$ thus represents the sentence, which can be fed to the output layer of the neural network (Fig. 4b) or to other models (e.g, a fully-connected CRF in Fig. 2b) for classification. The output layer of our LSTM-RNN uses a `softmax` for multiclass classification. Formally, the probability of k-th class for classification into K classes is

$$p(y = k|\mathbf{s}, \theta) = \frac{exp\ (\mathbf{w}_k^T \mathbf{z})}{\sum_{k=1}^{K} exp\ (\mathbf{w}_k^T \mathbf{z})} \quad (6)$$

where $\mathbf{w}$ are the output layer weights.

Bidirectionality The RNN described above encodes information that it gets only from the past. However, information from the future could also be crucial for recognizing speech acts. This is specially true for longer sentences, where a unidirectional LSTM can be limited in encoding the necessary information into a single vector. Bidirectional RNNs (Schuster and Paliwal, 1997) capture dependencies from both directions, thus provide two different views of the same sentence. This amounts to having a backward counterpart for each of the equations from 1 to 5. For classification, we use the concatenated vector $[\overrightarrow{\mathbf{h}}_T, \overleftarrow{\mathbf{h}}_T]$,

where $\overrightarrow{\mathbf{h}_T}$ and $\overleftarrow{\mathbf{h}_T}$ are the encoded vectors summarizing the past and the future, respectively.

2.2 Conditional Structured Model

Given the vector representation of the sentences in an asynchronous conversation, we explore two different approaches to learn classification functions. The first and the traditional approach is to learn a local classifier ignoring the structure in the output and to use it for predicting the label of each sentence separately. This is the approach we took above when we fed the output layer of the LSTM RNN with the sentence-level embeddings. However, this approach does not model the conversational dependency (e.g., *adjacency* relations between question-answer and request-accept pairs).

The second approach, which we adopt in this paper, is to model the dependencies between the output variables (labels) while learning the classification functions jointly by optimizing a global performance criterion. We represent each conversation by a graph $G{=}(V, E)$. Each node $i{\in}V$ is associated with an input vector $\mathbf{z}_i = \mathbf{z}_m^n$, representing the features of the sentence $\mathbf{s}_m^n$, and an output variable $y_i{\in}\{1, 2, \cdots, K\}$, representing the class label. Similarly, each edge $(i, j){\in}E$ is associated with an input feature vector $\phi(\mathbf{z}_i, \mathbf{z}_j)$, derived from the node-level features, and an output variable $y_{i,j}{\in}\{1, 2, \cdots, L\}$, representing the state transitions for the pair of nodes. We define the following conditional joint distribution:

$$p(\mathbf{y}|\mathbf{v}, \mathbf{w}, \mathbf{z}) = \frac{1}{Z(\mathbf{v}, \mathbf{w}, \mathbf{z})} \prod_{i \in V} \psi_n(y_i|\mathbf{z}, \mathbf{v}) \prod_{(i,j) \in E} \psi_e(y_{i,j}|\mathbf{z}, \mathbf{w}) \quad (7)$$

where ψ_n and ψ_e are node and the edge *factors*, and $Z(.)$ is the global normalization constant that ensures a valid probability distribution. We use a log-linear representation for the factors:

$$\psi_n(y_i|\mathbf{z}, \mathbf{v}) = \exp(\mathbf{v}^T \phi(y_i, \mathbf{z})) \quad (8)$$

$$\psi_e(y_{i,j}|\mathbf{z}, \mathbf{w}) = \exp(\mathbf{w}^T \phi(y_{i,j}, \mathbf{z})) \quad (9)$$

where $\phi(.)$ is a feature vector derived from the inputs and the labels. This model is essentially a pairwise conditional random field or PCRF (Murphy, 2012). The global normalization allows CRFs to surmount the so-called *label bias* problem (Lafferty et al., 2001), allowing them to take long-range interactions into account. The log likelihood for one data point $(\mathbf{z}, \mathbf{y})$ (i.e., a conversation) is:

$$f(\theta) = \sum_{i \in V} \mathbf{v}^T \phi(y_i, \mathbf{z}) + \sum_{(i,j) \in E} \mathbf{w}^T \phi(y_{i,j}, \mathbf{z}) - \log Z(\mathbf{v}, \mathbf{w}, \mathbf{z}) \quad (10)$$

This objective is convex, so we can use gradient-based methods to find the global optimum. The gradients have the following form:

$$f'(\mathbf{v}) = \sum_{i \in V} \phi(y_i, \mathbf{z}) - \mathbb{E}[\phi(y_i, \mathbf{z})] \quad (11)$$

$$f'(\mathbf{w}) = \sum_{(i,j) \in E} \phi(y_{i,j}, \mathbf{z}) - \mathbb{E}[\phi(y_{i,j}, \mathbf{z})] \quad (12)$$

where $\mathbb{E}[\phi(.)]$ denote the expected feature vector.

Training and Inference Traditionally, CRFs have been trained using offline methods like limited-memory BFGS (Murphy, 2012). Online training of CRFs using stochastic gradient descent (SGD) was proposed by Vishwanathan et al. (2006). Since RNNs are trained with online methods, to compare our two methods, we use SGD to train our CRFs. Algorithm 1 in the Appendix gives a pseudocode of the training procedure.

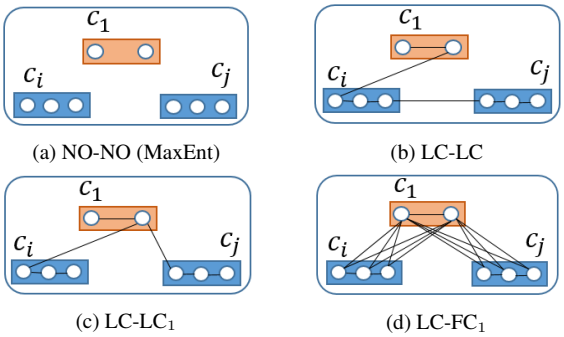
We use Belief Propagation or BP (Pearl, 1988) for inference in our graphical models. BP is guaranteed to converge to an exact solution if the graph is a tree. However, exact inference is intractable for graphs with loops. Despite this, it has been advocated by Pearl (1988) to use BP in loopy graphs as an approximation; see also (Murphy, 2012), page 768. The algorithm is then called "loopy" BP, or LBP. Although LBP gives approximate solutions for general graphs, it often works well in practice (Murphy et al., 1999), outperforming other methods such as mean field (Weiss, 2001).

Variations of Graph Structures One of the main advantages of our pairwise CRF is that we can define this model over arbitrary graph structures, which allows us to capture conversational dependencies at various levels. We distinguish between two types of dependencies: (*i*) *intra-comment*, which defines how the labels of the sentences in a comment are connected; and (*ii*) *across-comment*, which defines how the labels of the sentences across comments are connected.

Table 1 summarizes the connection types that we have explored in our models. Each configuration of intra- and across- connections yields a different pairwise CRF model. Figure 3 shows four such CRFs with three comments — C_1 being the first comment, and C_i and C_j being two other comments in the conversation.

Tag	Connection type	Applicable to
NO	No connection between nodes	intra & across
LC	Linear chain connection	intra & across
FC	Fully connected	intra & across
FC_1	Fully connected with first comment only	across
LC_1	Linear chain with first comment only	across

Table 1: Connection types in CRF models.



(a) NO-NO (MaxEnt) (b) LC-LC

(c) $LC\text{-}LC_1$ (d) $LC\text{-}FC_1$

Figure 3: CRFs over different graph structures.

Figure 3a shows the structure for **NO-NO** configuration, where there is no link between nodes of both intra- and across- comments. In this setting, the CRF model is equivalent to MaxEnt. Figure 3b shows the structure for **LC-LC**, where there are linear chain relations between nodes of both intra- and across- comments. The linear chain across comments refers to the structure, where the last sentence of each comment is connected to the first sentence of the comment that comes next in the temporal order (i.e., posting time). Figures 3c shows the CRF for **LC-LC**$_1$, where sentences inside a comment have linear chain connections, and the last sentence of the first comment is connected to the first sentence of the other comments. Similarly, Figure 3d shows the graph structure for **LC-FC**$_1$ configuration, where sentences inside comments have linear chain connections, and sentences of the first comment are fully connected with the sentences of the other comments.

3 Corpora

There exist large corpora of utterances annotated with speech acts in synchronous spoken domains, e.g., Switchboard-DAMSL or SWBD (Jurafsky et al., 1997) and Meeting Recorder Dialog Act or MRDA (Dhillon et al., 2004). However, such large corpus does not exist in asynchronous domains. Some prior work (Cohen et al., 2004; Ravi and Kim, 2007; Feng et al., 2006; Bhatia et al., 2014) tackles the task at the comment level, and uses task-specific tagsets. In contrast, in this work we are interested in identifying speech acts at the sentence level, and also using a standard tagset like the ones defined in SWBD and MRDA.

	TA	BC3
Total number of conv.	200	39
Avg. nb of comments per conv.	4.02	6.54
Avg. nb of sentences per conv.	18.56	34.15
Avg. nb of words per sentence	14.90	12.61

Table 2: Statistics about TA and BC3 corpora.

Tag	Description	TA	BC3	MRDA
SU	Suggestion	7.71%	5.48%	5.97%
R	Response	2.4%	3.75%	15.63%
Q	Question	14.71%	8.41%	8.62%
P	Polite	9.57%	8.63%	3.77%
ST	Statement	65.62%	73.72%	66.00%

Table 3: Distribution of speech acts in our corpora.

More recent studies attempt to solve the task at the sentence level. Jeong et al. (2009) first created a dataset of TripAdvisor (TA) forum conversations annotated with the standard 12 act types defined in MRDA. They also remapped the BC3 email corpus (Ulrich et al., 2008) according to this tagset. Table 10 in the Appendix presents the tags and their relative frequency in the two datasets. Subsequent studies (Joty et al., 2011; Tavafi et al., 2013; Oya and Carenini, 2014) use these datasets. We also use these datasets in our work. Table 2 shows some basic statistics about these datasets. On average, BC3 conversations are longer than TA in both number of comments and number of sentences.

Since these datasets are relatively small in size, we group the 12 acts into 5 coarser classes to learn a reasonable classifier.[1] More specifically, all the question types are grouped into one general class *Question*, all response types into *Response*, and appreciation and polite mechanisms into *Polite* class. Also since deep neural models like LSTM RNNs require a lot of training data, we also utilize the MRDA meeting corpus. Table 3 shows the label distribution of the resultant datasets. Statement is the most dominant class, followed by Question, Polite and Suggestion.

QC3 Conversational Corpus Since both TA and BC3 are quite small to make a general comment about model performance in asynchronous

[1] Some prior work (Tavafi et al., 2013; Oya and Carenini, 2014) also took the same approach.

Speech Act	Distribution	κ
Suggestion	17.38%	0.86
Response	5.24%	0.43
Question	12.59%	0.87
Polite	6.13%	0.75
Statement	58.66%	0.78

Table 4: Corpus statistics for QC3.

Corpora	Type	Train	Dev.	Test
QC3	asynchronous	1252	157	156
TA	asynchronous	2968	372	371
BC3	asynchronous	1065	34	133
MRDA	synchronous	50865	8366	10492
Total	asyn. + sync.	56150	8929	11152

Table 5: Number of sentences in train, development and test sets for different datasets.

conversation, we have created a new dataset called Qatar Computing Conversational Corpus or QC3.

We selected 50 conversations from a popular community question answering site named Qatar Living[2] for our annotation. We used 3 conversations for our pilot study and used the remaining 47 for the actual study. The resultant corpus on average contains 13.32 comments and 33.28 sentences per conversation, and 19.78 words per sentence.

Two native speakers of English annotated each conversation using a web-based annotation framework. They were asked to annotate each sentence with the most appropriate speech act tag from the list of 5 speech act types. Since this task is not always obvious, we gave them detailed annotation guidelines with real examples. We use Cohens Kappa κ to measure the agreement between the annotators. Table 4 presents the distribution of the speech acts and their respective κ values.After Statement, Suggestion is the most frequent class, followed by Question and Polite. The κ varies from 0.43 (for Response) to 0.87 (for Question).

Finally, in order to create a consolidated dataset, we collected the disagreements and employed a third annotator to resolve those cases.

4 Experiments and Analysis

In this section we present our experimental settings, results and analysis. We evaluate our models on the two forum corpora QC3 and TA. For performance comparison, we use both *accuracy* and *macro-averaged* F_1 score. Accuracy gives the overall performance of a classifier but could be biased to most populated ones. Macro-averaged F_1 weights equally every class and is not influenced by class imbalance. Statistical significance tests are done using an *approximate randomization* test based on the accuracy.[3] We used SIGF V.2 (Padó, 2006) with 10,000 iterations.

[2]http://www.qatarliving.com/

[3]Significance tests operate on individual instances rather than individual classes; thus not applicable for macro F_1.

Because of the noise and informal nature of conversational texts, we performed a series of preprocessing steps. We normalize all characters to their lower-cased forms, truncate elongations to two characters, spell out every digit and URL. We further tokenized the texts using the CMU TweetNLP tool (Gimpel et al., 2011).

In the following, we first demonstrate the effectiveness of LSTM RNNs for learning representations of sentences automatically to identify their speech acts. Then in subsection 4.2, we show the usefulness of pairwise CRFs for capturing conversational dependencies in speech act recognition.

4.1 Effectiveness of LSTM RNNs

To show the effectiveness of LSTMs for learning sentence representations, we split each of our asynchronous corpora randomly into 70% *sentences* for training, 10% for development, and 20% for testing. For MRDA, we use the same train-test-dev split as Jeong et al. (2009). Table 5 summarizes the resultant datasets.

We compare the performance of LSTMs with that of MaxEnt (**ME**) and Multi-layer Perceptron (**MLP**) with one hidden layer.[4] Both ME and MLP were fed with the bag-of-word (**BOW**) representations of the sentence, i.e., vectors containing binary values indicating the presence or absence of a word in the training set vocabulary.

We train the models by optimizing the cross entropy using the gradient-based online learning algorithm ADAM (Kingma and Ba, 2014).[5] The learning rate and other parameters were set to the values as suggested by the authors. To avoid overfitting, we use dropout (Srivastava et al., 2014) of hidden units and early stopping based on the loss on the development set.[6] Maximum number of epochs was set to 25 for RNNs and 100 for ME and MLP. We experimented with $\{0.0, 0.2, 0.4\}$

[4]More hidden layers worsened the performance.

[5]Other algorithms (SGD, Adagrad) gave similar results.

[6]l_1 and l_2 regularization on weights did not work well.

dropout rates, $\{16, 32, 64\}$ minibatch sizes, and $\{100, 150, 200\}$ hidden layer units in MLP and in LSTMs. The vocabulary (V) in LSTMs was limited to the most frequent $P\%$ ($P \in \{85, 90, 95\}$) words in the training corpus. We initialize the word vectors in the loop-up table L in one of two ways: (*i*) by sampling randomly from the small uniform distribution $\mathcal{U}(-0.05, 0.05)$, and (*ii*) by using pretrained 300 dimensional Google word embeddings from Mikolov et al. (2013b). The dimension for random initialization was set to 128.

We experimented with four LSTM variations: (*i*) U-LSTM$_r$, referring to unidirectional with random initialization; (*ii*) U-LSTM$_p$, referring to unidirectional with pretrained initialization; (*iii*) B-LSTM$_r$, referring to bidirectional with random initialization; and (*iv*) B-LSTM$_p$, referring to bidirectional with pretrained initialization.

Table 6 shows the results for different models for the data splits in Table 5. The first two rows show the best results reported so far on the MRDA corpus from (Jeong et al., 2009) for classifying into 12 act types. The first row shows the results of the model that uses *n-grams* and the second row shows the results using *all* the features including speaker, part-of-speech, and dependency structure. Our LSTM RNNs and their n-gram model therefore use the same word sequence information. To compare our results with the state of the art, we ran our models on MRDA for both 5-class and 12-class classification tasks. The results are shown at the right most part of Table 6.

Notice that all of our LSTMs achieve state of the art results and B-LSTM$_p$ achieves even significantly better with 99% confidence level. This is remarkable since our LSTMs learn the sentence representation automatically from the word sequence and do not use any hand-engineered features.

Now consider the asynchronous domains QC3 and TA, where we show the results of our models based on 5-fold cross validation, in addition to the random (20%) testset. The 5-fold setting allows us to get more general performance of the models on a particular corpus. The comparison between our LSTMs shows that: (*i*) pretrained Google vectors provide better initialization to LSTMs than the random ones; (*ii*) bidirectional LSTMs outperform their unidirectional counterparts. When we compare these results with those of our baselines, the results are disappointing; the ME and MLP using BOW outperform LSTMs by a good margin.

	SU	R	Q	P	ST
SU	34	0	1	0	27

ST	8	2	0	2	316

(b) MLP

Figure 4: Confusion matrices for (a) B-LSTM$_p$ and (b) MLP on the testsets of QC3 and TA.

However, this is not surprising since deep neural networks like LSTMs have a lot of parameters, for which they require a lot of data to learn from.

To validate our claim, we create another *training* setting CAT by merging the training and development sets of the four corpora in Table 5 (see the Train and Dev. columns in the last row); the testset for each dataset however remains the same. Table 7 shows the results of the baselines and the B-LSTM$_p$ on the QC3 and TA testsets. In both datasets, B-LSTM$_p$ outperforms ME and MLP significantly. When we compare these results with those in Table 6, we notice that B-LSTM$_p$, by virtue of its distributed and condensed representation, generalizes well across different domains. In contrast, ME and MLP, because of their BOW representation, suffer from data diversity of different domains. These results also confirm that B-LSTM$_p$ gives better sentence representation than BOW, when it is given enough data.

To analyze further the cases where B-LSTM$_p$ makes a difference, Figure 4 shows the corresponding confusion matrices for B-LSTM$_p$ and MLP on the concatenated testsets of QC3 and TA. It is noticeable that B-LSTM$_p$ is less affected by class imbalance and it can detect more *suggestions* than MLP. This indicates that LSTM RNNs can model the grammar of the sentence when composing the words into phrases sequentially.

4.2 Effectiveness of CRFs

To demonstrate the effectiveness of CRFs for capturing inter-sentence dependencies in an asynchronous conversation, we create another dataset setting called CON, in which the random splits are done at the *conversation* (as opposed to sentence) level for the asynchronous corpora. This is required because our CRF models perform joint learning and inference based on a full conversation. As presented in Table 8, this setting contains 197 and 24 conversations for training and devel-

	QC3		TA		MRDA

CRF (LC-LC$_1$)	**65.94 (80.33*)**	61.58 (86.54)
CRF (LC-FC$_1$)	61.18 (77.87)	60.00 (85.36)
CRF (FC-FC)	64.54 (79.51*)	**61.64 (86.81*)**

Table 9: Results of CRFs on CON dataset.

opment, respectively.[7] The testsets contain 5 and 20 conversations for QC3 and TA, respectively.

As baselines, we use three models: (*i*) **ME**$_b$, a MaxEnt using BOW representation; (*ii*) **B-LSTM**$_p$, which is now trained on the concatenated set of sentences from MRDA and CON training sets; and (*iii*) **ME**$_e$, a MaxEnt using sentence embeddings extracted from the B-LSTM$_p$, i.e., the sentence embeddings are used as feature vectors.

We experiment with the CRF variants in Table 1. The CRFs are trained on the CON training set using the sentence embeddings that are extracted by applying the B-LSTM$_p$ model, as was done with ME$_e$. Table 9 shows our results. We notice that CRFs generally outperform MEs in accuracy. This indicates that there are conversational dependencies between the sentences in a conversation.

When we compare between CRF variants, we notice that the model that does not consider any link across comments perform the worst; see CRF (LC-NO). A simple linear chain connection between sentences in their temporal order does not improve much (CRF (LC-LC)), which indicates that the widely used linear chain CRF (Lafferty et al., 2001) is not the most appropriate model for capturing conversational dependencies in these conversations. The CRF (LC-LC$_1$) is one of the best performing models and perform significantly (with 99% confidence) better than B-LSTM$_p$.[8] This model considers linear chain connections between sentences inside comments and only to the first comment. Note that both QC3 and TA are forum sites, where participants in a conversation interact mostly with the person who posts the first comment asking for some information. This is interesting that our model can capture this aspect.

Another interesting observation is that when we change the above model to consider relations with every sentence in the first comment (CRF (LC-FC$_1$)), this degrades the performance. This could be due to the fact that the information seeking person first explains her situation, and then asks for the information. Others tend to respond to the requested information rather than to her situation. The CRF (FC-FC) also yields as good results as CRF (LC-LC$_1$). This could be attributed to the robustness of the fully-connected CRF, which learns

[7] We use the concatenated sets as train and dev. sets.

[8] Significance was computed on the concatenated testset.

from all possible relations.

To see some real examples in which CRF by means of its global learning and inference makes a difference, let us consider the example in Figure 1 again. We notice that the two sentences in comment C_4 were mistakenly identified as Statement and Response, respectively, by the B-LSTM$_p$ local model. However, by considering these two sentences together with others in the conversation, the global CRF (FC-FC) model could correct them.

5 Related Work

Three lines of research are related to our work: (*i*) semantic compositionality with LSTM RNNs, (*ii*) conditional structured models, and (*iii*) speech act recognition in asynchronous conversations.

LSTM RNNs for composition Li et al. (2015) compare recurrent neural models with recursive (syntax-based) models for several NLP tasks and conclude that recurrent models perform on par with the recursive for most tasks (or even better). For example, recurrent models outperform recursive on sentence level sentiment classification. This finding motivated us to use recurrent models rather than recursive. The application of LSTM RNNs to speech act recognition is novel to the best of our knowledge. LSTM RNNs have also been applied to sequence tagging in opinion mining (Irsoy and Cardie, 2014; Liu et al., 2015).

Conditional structured models There has been an explosion of interest in CRFs for solving structured output problems in NLP; see (Smith, 2011) for an overview. Linear chain (for sequence labeling) and tree structured CRFs (for parsing) are the common ones in NLP. However, speech act recognition in asynchronous conversation posits a different problem, where the challenge is to model arbitrary conversational structures. In this work we propose a general class of models based on pairwise CRFs that work on arbitrary graph structures.

Speech act recognition in asynchronous conversation Jeong et al. (2009) use semi-supervised boosting to tag the sentences in email and forum discussions with speech acts by adapting knowledge from spoken conversations. Other sentence-level approaches use supervised classifiers and sequence taggers (Qadir and Riloff, 2011; Tavafi et al., 2013; Oya and Carenini, 2014).

Cohen et al. (2004) first use the term *email speech act* for classifying emails based on their acts (deliver, meeting). Their classifiers do not capture any contextual dependencies between the acts. To model contextual dependencies, Carvalho and Cohen (2005) use a collective classification approach with two different classifiers, one for content and one for context, in an iterative algorithm. Our approach is similar in spirit to their approach with three crucial differences: (*i*) our CRFs are globally normalized to surmount the *label bias* problem, where their classifiers are normalized locally; (*ii*) the graph structure of the conversation is given in their case, which is not the case with ours; and (*iii*) their approach works at the comment level, where we work at the sentence level.

6 Conclusions and Future Work

We have presented a two-step framework for speech act recognition in asynchronous conversation. A LSTM RNN first composes sentences into vector representations by considering the word order. Then a pairwise CRF jointly models the inter-sentence dependencies in the conversation. We experimented with different LSTM variants (uni- vs. bi-directional, random vs. pretrained initialization), and different CRF variants depending on the underlying graph structure. We trained our models on many different settings using synchronous and asynchronous corpora and evaluated on two forum datasets, one of which is presented in this work.

Our results show that LSTM RNNs provide better representations but requires more data, and global joint models improve over local models given that it considers the right graph structure.

In the future, we would like to combine CRFs with LSTMs for doing the two steps jointly, so that the LSTMs can learn the embeddings using the global thread-level feedback. This would require the backpropagation algorithm to take error signals from the loopy BP inference. We would also like to apply our models to conversations, where the graph structure is extractable using the meta data or other clues, e.g., the fragment quotation graphs for email threads (Carenini et al., 2008).

Situation entity types: automatic classification of clause-level aspect

Annemarie Friedrich[1] **Alexis Palmer**[2] **Manfred Pinkal**[1]

Abstract

This paper describes the first robust approach to automatically labeling clauses with their situation entity type (Smith, 2003), capturing aspectual phenomena at the clause level which are relevant for interpreting both semantics at the clause level and discourse structure. Previous work on this task used a small data set from a limited domain, and relied mainly on words as features, an approach which is impractical in larger settings. We provide a new corpus of texts from 13 genres (40,000 clauses) annotated with situation entity types. We show that our sequence labeling approach using distributional information in the form of Brown clusters, as well as syntactic-semantic features targeted to the task, is robust across genres, reaching accuracies of up to 76%.

1 Introduction

Clauses in text have different aspectual properties, and thus contribute to the discourse in different ways. Distinctions that have been made in the linguistic and semantic theory literature include the classification of states, events and processes (Vendler, 1957; Bach, 1986), and whether clauses introduce particular eventualities or report regularities generalizing either over events or members of a kind (Krifka et al., 1995). Such aspectual distinctions are relevant to natural language processing tasks requiring text understanding such as information extraction (Van Durme, 2010) or temporal processing (Costa and Branco, 2012).

In this paper, we are concerned with automatically identifying the **type** of a **situation entity (SE)**, which we assume to be expressed by a clause. Specifically, we present a system for automatically labeling clauses using the inventory of SE types shown in Figure 1 (Smith, 2003, 2005; Palmer et al., 2007). The original motivation for the above inventory of SE types is the observation that different *modes of discourse*, a classification of linguistic properties of text at the passage level, have different distributions of SE types. For example, EVENTs and STATEs are predominant in *narrative* passages, while GENERIC SENTENCEs occur frequently in *information* passages.

STATE: *The colonel owns the farm.*
EVENT: *John won the race.*
REPORT: "...", *said Obama.*
GENERIC SENTENCE: Generalizations over kinds. *The lion has a bushy tail.*
GENERALIZING SENTENCE: Generalizations over events (*habituals*). *Mary often fed the cat last year.*
QUESTION: *Who wants to come?*
IMPERATIVE: *Hand me the pen!*

Figure 1: SE types, adapted from Smith (2003).

A previous approach to automatically labeling SE types (Palmer et al., 2007) – referred to here as UT07 – captures interesting insights, but is trained and evaluated on a relatively small amount of text (about 4300 clauses), mainly from one rather specialized subsection of the Brown corpus. The data shows a highly skewed distribution of SE types and was annotated in an intuitive fashion with only moderate agreement. In addition, the UT07 system relies mostly on part-of-speech tags and words as features. The latter are impractical when dealing with larger data sets and capture most of the corpus vocabulary, overfitting the model to the data set. Despite this overfitting, the system's accuracy is only around 53%.

We address these shortcomings, developing a robust system that delivers high performance compared to the human upper bound across a range of genres. Our approach uses features which increase

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1757–1768,
Berlin, Germany, August 7-12, 2016.

robustness: Brown clusters and syntactic-semantic features. Our models for labeling texts with the aspectual properties of clauses in the form of SE types reach accuracies of up to 76%.

In an oracle experiment, Palmer et al. (2007) show that including the gold labels of the previous clauses as features into their maximum entropy model is beneficial. We implement the first true sequence labeling model for SE types, using conditional random fields to find the globally-best sequence of labels for the clauses in a document. Performance increases by around 2% absolute compared to predicting labels for clauses separately; much of this effect stems from the fact that GENERIC SENTENCEs often occur together.

Moving well beyond the single-domain setting, our models are trained and evaluated on a multi-genre corpus of approximately 40,000 clauses from MASC (Ide et al., 2008) and Wikipedia which have been annotated with substantial agreement. We train and test our models both within genres and across genres, highlighting differences between genres and creating models that are robust across genres. Both the corpus and the code for an SE type labeler are freely available.[1] These form the basis for future research on SE types and related aspectual phenomena and will enable the inclusion of SE type information as a preprocessing step into various NLP tasks.

2 Linguistic background

The inventory of SE types proposed by Smith (2003) consists of three high-level categories, each with two subtypes. *Eventualities* comprise EVENT and STATE, categories for clauses representing actual happenings, states of the world, or attributes of entities or situations. *General Statives* include GENERIC SENTENCE and GENERALIZING SENTENCE and reflect regularities in the world or general information predicated over classes or kinds. Finally, *Abstract Entities* (Figure 2) have the subtypes FACT and PROPOSITION. Although *Abstract Entities* are part of the label inventory for UT07, we treat them in a separate identification step, for reasons discussed in Section 7. The inventory was expanded by Palmer et al. (2007) to include three additional types: REPORT, QUESTION and IMPERATIVE. The latter two categories were added to accommodate exhaustive annotation of text; REPORT is a subtype of event for attributions of quoted speech.

FACT: Objects of knowledge.
I know that Mary refused the offer.
PROPOSITION: Objects of belief.
I believe that Mary refused the offer.

Figure 2: *Abstract Entity* SE types.

Two parts of a clause provide important information for determining the SE type (Friedrich and Palmer, 2014b): a clause's **main verb** and its **main referent**. The latter is loosely defined as the main entity that the segment is about; in English this is usually the subject. For example, main referents of GENERIC SENTENCEs are kinds or classes as in "*Elephants are huge*", while the main referents of *Eventualities* and GENERALIZING SENTENCEs are particular individuals ("*John is short*"). For English, the main verb is the non-auxiliary verb ranked highest in the dependency parse (e.g. "*kiss*" in "*John has kissed Joe*"). STATEs and EVENTs differ in the *fundamental lexical aspectual class* (Siegel and McKeown, 2000) of their main verbs (e.g. **dynamic** in "*She filled the glass with water*" vs. **stative** in "*Water fills the glass*"). While fundamental lexical aspectual class is a word-sense level attribute of the clause's main verb, *habituality* is a property of the entire clause which is helpful to determine the clause's SE type. For example, EVENT and GENERALIZING SENTENCE differ in habituality (e.g. **episodic** in "*John cycled to work yesterday*" vs. **habitual** in "*John cycles to work*").

Like habituality, SE types are a categorization at the clause level. Properties of the clause such as modals, negation, or the perfect influence the SE type: for instance, "*John might win*" is treated as a STATE as it describes a possible state of the world rather than an EVENT. Such coercions happen only for clauses which, without the trigger for aspectual shift, would be EVENTs; other SEs retain their type even under coercions such as negation, e.g., "*Elephants are not small*" is a GENERIC SENTENCE. SE types aim to capture how clauses behave in discourse, and the types STATE and EVENT are aspectual rather than ontological categories. The types reflect not so much semantic content of a clause as its manner of presentation, and all parts of a clause contribute to determining its SE type.

3 Related work

SE types model aspect at the clause level; thus they are most closely related to other works performing automatic classification for various aspect-related phenomena of the verb or the clause. For example, Vendler classes (Vendler, 1957) ascribe four categories as lexical properties of verbs, distinguishing states from three types of events (accomplishment, achievement, and activity), differing according to temporal and aspectual properties (e.g. telicity and punctuality). The work of Siegel and McKeown (2000) is a major inspiration in computational work on modeling these linguistic phenomena, introducing the use of linguistic indicators (see Section 5.1). Hermes et al. (2015) model Vendler classes computationally on a verb-type level for 95 different German verbs, combining distributional vectors with supervised classification. Zarcone and Lenci (2008) investigate both supervised and unsupervised classification frameworks for occurrences of 28 Italian verbs, and Friedrich and Palmer (2014a) predict lexical aspectual class for English verbs in context.

The only previous approach to automatic classification of SE types comes from Palmer et al. (2007). This system (UT07) uses word and POS tag features as well as a number of lexical features adopted from theoretical work on aspectual classification. The model is described in Section 6.1.

Another related body of work has to do with determining event class as a precursor to temporal relation classification. The inventory of event classes, described in detail in the TimeML annotation guidelines (Saurí et al., 2006), combines semantic (REPORTING, PERCEPTION), aspectual (ASPECTUAL, STATE, OCCURRENCE), and intensional (I_ACTION, I_STATE) properties of events.

Finally, there are close connections to systems which predict genericity of noun phrases (Reiter and Frank, 2010; Friedrich and Pinkal, 2015a), and habituality of clauses (Mathew and Katz, 2009; Friedrich and Pinkal, 2015b).

4 Data sets

The experiments presented in this paper make use of two data sets labeled with SE types.

Brown data. This data set consists of 20 texts from the *popular lore* section of the Brown corpus (Francis and Kučera, 1979), manually segmented into 4391 clauses and marked by two annotators in an intuitive way with κ=0.52 (Cohen, 1960). Final labels were created via adjudication. The texts are essays and personal stories with topics ranging from maritime stories to marriage advice.

corpus	tokens	SEs	Fleiss' κ
MASC	357078	30333	0.69
Wikipedia	148040	10607	0.66

Table 1: SE-labeled corpora: **size** and **agreement**.

QUESTION	3.3	0.1	0.91
IMPERATIVE	3.2	0.2	0.94
undecided	2.4	2.1	-

Table 2: **Distribution of SE types** in gold standard (%). *Krippendorff's diagnostics.

MASC and Wikipedia. Our main data set consists of documents from MASC (Ide et al., 2010) and Wikipedia. The MASC data covers 12 of the written genres (see Table 11). Texts are split into clauses using SPADE (Soricut and Marcu, 2003) with some heuristic post-processing, and the clauses are labeled by three annotators independently. Annotators, all student assistants with basic linguistic training, were given an extensive annotation manual. Table 1 reports agreement over types in terms of Fleiss' κ (Fleiss, 1971). As we do not force annotators to assign a label to each clause, we compute κ using all pairings of labels where both annotators assigned an SE type. The gold standard is constructed via majority voting.

Table 2 shows the distribution of SE types. The largest proportion of segments in MASC are STATEs, while the largest proportion in Wikipedia are GENERIC SENTENCEs. The Wikipedia data was collected to supplement MASC, which contains few generics and no data from an encyclopedic genre. Within MASC, the various genres' distributions of SE types differ as well, and agreement scores also vary: some genres contain many instances of easily classifiable SE types, while others (e.g., essays or journal) are more difficult to annotate (more details in Section 6.6).

The rightmost column of Table 2 shows the values for Krippendorff's diagnostics (Krippendorff, 1980), a tool for determining which categories hu-

group	explanation	examples
mv	features describing the SE's **main verb** & its arguments	tense, lemma, lemma of object, auxiliary, WordNet sense and hypernym sense, progressive, POS, perfect, particle, voice, linguistic indicators
mr	features describing the **main referent**, i.e., the NP denoting the main verb's subject	lemma, determiner type, noun type, number, WordNet sense and supersense, dependency relations linked to this token, person, countability, bare plural
cl	features describing entire **clause** that invokes the SE	presence of adverbs / prepositional clauses, conditional, modal, whether subject before verb, negated, verbs embedding the clause

Table 3: Overview of feature set **B**. The full and detailed list is available (together with the implementation) at `http://www.coli.uni-saarland.de/projects/sitent`.

mans had most difficulties with. For each category, one computes κ for an artificial set-up in which all categories except one are collapsed into an artificial OTHER category. A high value indicates that annotators can distinguish this SE type well from others. GENERALIZING SENTENCEs are most difficult to agree upon. For all frequently occurring types as well as QUESTIONs and IMPERATIVEs, agreement is substantial.

Agreement on QUESTION and IMPERATIVEs is not perfect even for humans, as identifying them requires recognizing cases in reported speech, which is not a trivial task (e.g., Brunner, 2013). To illustrate another difficult case, consider the example "You must never confuse faith", which was marked as both IMPERATIVE and GENERIC SENTENCE, by different annotators.

5 Method

This section describes the feature sets and classification methods used in our approach, which models SE type labeling as a supervised sequence labeling task.

5.1 Feature sets

Our feature sets are designed to work well on large data sets, across genres and domains. Features are grouped into two sets: **A** consists of standard NLP features including POS tags and Brown clusters. Set **B** targets SE labeling, focusing on syntactic-semantic properties of the main verb and main referent, as well as properties of the clause which indicate its aspectual nature. Texts are pre-processed with Stanford CoreNLP (Manning et al., 2014), including tokenization, POS tagging (Toutanova et al., 2003) and dependency parsing (Klein and Manning, 2002) using the UIMA-based DKPro framework (Ferrucci and Lally, 2004; Eckart de Castilho and Gurevych, 2014).

A-pos: part-of-speech tags. These features count how often each POS tag occurs in a clause.

A-bc: Brown cluster features. UT07 relies mostly on words and word/POS tag pairs. These simple features work well on the small Brown data set, but the approach quickly becomes impractical with increasing corpus size. We instead turn to distributional information in the form of Brown clusters (Brown et al., 1992), which can be learned from raw text and represent word classes in a hierarchical way. Originally developed in the context of n-gram language modeling, they aim to assign words to classes such that the average mutual information of the words in the clusters is maximized. We use existing, freely-available clusters trained on news data by Turian et al. (2010) using the implementation by Liang (2005).[2] Clusterings with 320 and 1000 Brown clusters work best for our task. We use one feature per cluster, counting how often a word in the clause was assigned to this cluster (0 for most clusters).

B-mv: main verb. Using dependency parses, we extract the verb ranked highest in the clause's parse as the main verb, and extract the set of features listed in Table 3 for that token. Features based on WordNet (Fellbaum, 1998) use the most frequent sense of the lemma. Tense and voice information is extracted from sequences of POS tags using a set of rules (Loaiciga et al., 2014). Linguistic indicators (Siegel and McKeown, 2000) are features collected per verb type over a large parsed background corpus, encoding how often a verb type occurred with each linguistic marker, e.g., in past tense or with an *in*-PP. We use values collected from Gigaword (Graff et al., 2003); these are freely available at our project web site (Friedrich and Palmer, 2014a).

B-mr: main referent. We extract the grammatical subject of the main verb (i.e., `nsubj` or `nsubjpass`) as the clause's main referent. While the main verb must occur within the clause, the

[2] `http://metaoptimize.com/projects/wordreprs`

main referent may be a token either within or outside the clause. In the latter case, it still functions as the clause's main referent, as in most cases it can be considered an implicit argument within the clause. Table 3 lists the features extracted for the main referent.

B-cl: clause. These features (see also Table 3) describe properties at the clause level, capturing both grammatical phenomena such as word order and lexical phenomena including presence of particular adverbials or prepositional phrases, as well as semantic information such as modality. If the clause's main verb is embedded in a `ccomp` relation, we also use features describing the respective governing verb.

5.2 Classification / sequence labeling model

Our core modeling assumption is to view a document as a sequence of SE type labels, each associated with a clause; this motivates the choice of using a conditional random field (CRF, Lafferty et al. (2001)) for label prediction. The conditional probability of label sequence $\vec{y}$ given an observation sequence $\vec{x}$ is given by:

$$P(\vec{y}|\vec{x}) = \frac{1}{Z(\vec{x})} exp(\sum_{j=1}^{n}\sum_{i=1}^{m} \lambda_i f_i(y_{j-1}, y_j, \vec{x}, j)),$$

with $Z(\vec{x})$ being a normalization constant (see also Klinger and Tomanek (2007)). λ_i, the weights of the feature functions, are learned via L-BGFS (Wright and Nocedal, 1999).

We create a linear chain CRF using the CRF++ toolkit[3] with default parameters, applying two forms of feature functions: $f_i(y_j, x_j)$ and $f_i(y_{j-1}, y_j)$. The former consists of indicator functions for combinations of SE type labels and each of the features listed above. The latter type of feature function (also called "bigram" features in CRF++ terminology) gets instantiated as indicator functions for each combination of labels, thereby enabling the model to take sequence information into account. When using only the former type of feature function, our classifier is equivalent to a maximum entropy (MaxEnt) model.

Side remark: pipeline approach. Feature set **B** is inspired by previous work on two subtasks of assigning an SE type to a clause (see Section 3): (a) identifying the genericity of a noun phrase in its clausal context, and (b) identifying whether a clause is episodic, habitual or static. This information can in turn be used to determine a clause's SE type label in a rule-based way, e.g., GENERALIZING SENTENCES are habitual clauses with a non-generic main referent. As our corpus is also annotated with this information, we also trained separate models for these subtasks and assigned the SE type label accordingly. However, such a pipeline approach is not competitive with the model trained directly on SE types (see Section 6.3).

6 Experiments

Here we present our experiments on SE type classification, beginning with a (near) replication of the UT07 system, and moving on to evaluate our new approach from multiple perspectives.

6.1 Replication and extension of UT07

As a first step, we implement a system similar to UT07, which relies on the features summarized in Table 4. For W and T features, we set a frequency threshold of 7 occurrences. Feature set L comprises sets of predicates assumed to correlate with particular SE types, and whether or not the clause contains a modal or finite verb. Set G includes all verbs of the clause and their POS-tags. UT07 additionally uses CCG supertags and grammatical function information. The UT07 system approximates a sequence labeling model by adding the predicted labels of previous clauses as *lookback* (LB) features. To parallel their experiments, we train both MaxEnt and CRF models, as explained in Section 5.2. Results on the Brown data, with the same training/test split, appear in Table 5. Unlike the LB model, our CRF predicts the label sequence jointly and outperforms UT07 on the Brown data by up to 7% accuracy. We assume that the performance boost in the MaxEnt setting is at least partially due to having better parses.

In sum, on the small Brown data set, a CRF approach successfully leverages sequence information, and a simple set of features works well. Preliminary experiments applying our new features on Brown data yield no improvements, suggesting that word-based features overfit this domain.

W	words
T	POS tags, word/POS tag combinations
L	linguistic cues
G	grammatical cues

Table 4: Features used in baseline UT07.

features	Palmer et al. (2007) MaxEnt	LB	our implementation MaxEnt	CRF

Table 5: **Accuracy** on Brown. Test set majority class (STATE) is 35.3%. LB = results for best look-back settings in MaxEnt. 787 test instances.

6.2 Experimental settings

We develop our models using **10-fold cross validation (CV)** on 80% (counted in terms of the number of SEs) of the MASC and Wikipedia data (a total of 32,855 annotated SEs), keeping the remaining 20% as a held-out test set. Development and test sets each contain distinct sets of documents; the documents of each MASC genre and of Wikipedia are distributed over the folds. We report results in terms of macro-average precision, macro-average recall, macro-average F1-measure (harmonic mean of macro-average precision and macro-average recall), and accuracy. We apply McNemar's test (McNemar, 1947) with $p < 0.01$ to test significance of differences in accuracy. In the following tables, we mark numerically-close scores with the same symbols if they are found to be significantly different.

Upper bound: human performance. Labeling clauses with their SE types is a non-trivial task even for humans, as there are many borderline cases (see Sections 4 and 8). We compute an upper bound for system performance by iterating over all clauses: for each pair of human annotators, two entries are added to a co-occurrence matrix (similar to a confusion matrix), with each label serving once as "gold standard" and once as the "prediction." From this matrix, we can compute scores in the same manner as for system predictions. Precision and recall scores are symmetric in this case, and accuracy corresponds to observed agreement.

6.3 Impact of feature sets

We now compare various configurations of our CRF-based SE type labeler, experimenting with the feature sets as described in Section 5.1. Table 6 shows the results for 10-fold CV on the dev portion of the MASC+Wiki corpus.

Each feature set on its own outperforms the majority class baseline. Of the individual feature groups, **bc** and **mv** have the highest predictive power; both capture lexical information of the main verb. Using sets **A** and **B** individually results in similar scores; their combination increases accuracy on the dev set by an absolute 3.6-4.3%. Within **A** and **B**, each subgroup contributes to the increase in performance (not shown in table).

feature set	P	R	F	acc.
maj. class (STATE)	6.4	14.3	8.8	45.0
A	70.1	61.4	65.4	∗†72.1
pos	49.3	40.3	44.3	58.7
bc	67.5	55.8	61.1	∗70.6
B	69.5	62.7	66.9	⋆‡72.8
mr	36.4	26.8	30.9	51.7
mv	62.3	52.4	56.9	⋆70.8
cl	53.3	41.2	46.6	52.8
A+B	**74.1**	**68.6**	**71.2**	‡†**76.4**
upper bound (humans)	78.6	78.6	78.6	79.6

Table 6: **Impact of different feature sets.** Wiki+MASC dev set, CRF, 10-fold CV.

feature set	P	R	F	acc.
maj. class (STATE)	6.4	14.3	8.8	44.7
A	67.6	60.6	63.9	∗69.8
B	69.9	61.7	65.5	†71.4
A+B	**73.4**	**65.5**	**69.3**	∗†**74.7**

Table 7: Results on MASC+Wiki **held-out test set** (7937 test instances).

Finally, having developed exclusively on the dev set, we run the system on the held-out test set, training on the entire dev set. Results (in Table 7) show the same tendencies as for the dev set: each feature set contributes to the final score, and the syntactic-semantic features targeted at classifying SE types (i.e. **B**) are helpful.

Ablation. To gain further insight, we ablate each feature subgroup from the full system, see Table 8. Again, **bc** features and **mv** features are identified as the most important ones. The other feature groups partially carry redundant information when combining **A** and **B**. Next, we rank features by their information gain with respect to the SE types. In Table 3, the features of each group are ordered by this analysis. Ablating single features from the full system does not result in significant performance losses. However, using only selected, top features for our system decreased performance, possibly because some features cover rare but important cases, and because the feature selection algorithm does not take into account the information features may provide regarding tran-

feature set	P	R	F	acc.
A+B	**74.1**	**68.6**	**71.2**	**76.4**

- pos	73.4	67.4	70.2	76.0
- mr	73.7	67.4	70.4	75.9
- mv	72.3	64.2	68.0	73.6
- cl	73.1	67.6	70.2	76.0

Table 8: **Impact of feature groups: ablation** Wiki+MASC dev set, CRF, 10-fold CV. All accuracies for ablation settings are significantly different from A+B.

sitions (Klinger and Friedrich, 2009). In addition, CRFs are known to be able to deal with a large number of potentially dependent features.

Side remark: pipeline approach. We here use the subset of SEs labeled as EVENT, STATE, GENERIC SENTENCE or GENERALIZING SENTENCE because noun phrase genericity and habituality is not labeled for IMPERATIVE and QUESTION, and REPORT is identified lexically based on the main verb rather than these semantic features. Models for subtasks of SE type identification, i.e., (a) genericity of noun phrases and (b) habituality reach accuracies of (a) 86.8% and (b) 83.6% (on the relevant subset). Applying the labels output by these two systems as (the only) features in a rule-based way using a J48 decision tree (Witten et al., 1999) results in an accuracy of 75.5%, which is lower than 77.2%, the accuracy of the CRF which directly models SE types (when using only the above four types).

6.4 Impact of amount of training data

Next we test how much training data is required to get stable results for SE type classification. Figure 3 shows accuracy and F1 for 10-fold CV using **A+B**, with training data downsampled to different extents in each run by randomly removing documents. Up to the setting which uses about 60% of the training data, performance increases steadily. Afterwards, the curves start to level off. We conclude that robust models can be learned from our corpus. Adding training data, especially in-domain data, will, as always, be beneficial.

6.5 Impact of sequence labeling approach

Palmer et al. (2007) suggest that SE types of nearby clauses are a useful source of information. We further test this hypothesis by comparing our sequence labeling model (CRF) to two additional

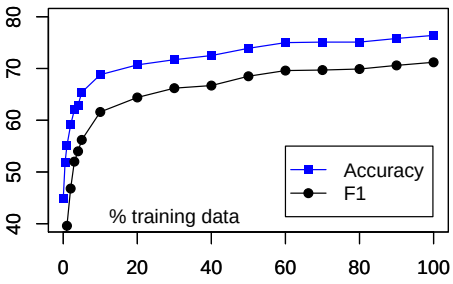

Figure 3: **Learning curve** for MASC+Wiki dev.

models: (1) a MaxEnt model, which labels clauses in isolation, and (2) a MaxEnt model including the correct label of the preceding clause (seq-oracle), simulating an upper bound for the impact of sequence information on our system.

Table 9 shows the results. Scores for GENERALIZING SENTENCE are the lowest as this class is very infrequent in the data set. The most striking improvement of the two sequence labeling settings over MaxEnt concerns the identification of GENERIC SENTENCES. These often "cluster" in texts (Friedrich and Pinkal, 2015b) and hence their identification profits from using sequence information. The results for seq-oracle show that the sequence information is useful for STATE, GENERIC and GENERALIZING SENTENCES, but that no further improvement is to be expected from this method for the other SE types. We conclude that the CRF model is to be preferred over the MaxEnt model; in almost all of our experiments it performs significantly better or equally well.

SE type	MaxEnt	CRF	seq-oracle
STATE	79.1	**80.6**	81.7
EVENT	77.5	**78.6**	78.3
REPORT	78.2	**78.9**	78.3
GENERIC	61.3	**68.3**	73.5
GENERALIZING	25.0	**29.4**	38.1
IMPERATIVE	72.3	**75.3**	74.7
QUESTION	84.4	**84.4**	83.8
macro-avg P	71.5	**74.1**	75.5
macro-avg R	66.1	**68.6**	70.4
macro-avg F1	68.7	**71.2**	73.9
accuracy	∗74.1	∗†**76.4**	†77.9

Table 9: **Impact of sequence information:** (**F1** by SE type): CRF, Masc+Wiki, 10-fold CV.

6.6 Impact of genre

In this section, we test to what extent our models are robust across genres. Table 10 shows F1-scores for each SE type for two settings: the 10-

SE type	genre-CV	10-fold CV	humans
STATE	78.2	80.6	82.8
EVENT	77.0	78.6	80.5
REPORT	76.8	78.9	81.5
GENERIC	44.8	68.3	75.1
GENERALIZING	27.4	29.4	45.8
IMPERATIVE	70.8	75.3	93.6
QUESTION	81.8	84.4	90.7
macro-avg F1	66.6	71.2	78.6
accuracy	∗71.8	∗76.4	79.6

Table 10: **Impact of in-genre training data**. F1-score by SE type, CRF, MASC+Wiki dev.

fold CV setting as explained in section 6.2, and a **genre-CV** setting, simulating the case where no in-genre training data is available, treating each genre as one cross validation fold. As expected, in the latter setting, both overall accuracy and macro-average F1 are lower compared to the case when in-genre training data is available. Nevertheless, our model is able to capture the nature of SE types across genres: the prediction of STATE, EVENT, REPORT and QUESTION is relatively stable even in the case of not having in-genre training data. An EVENT seems to be easily identifiable regardless of the genre. GENERIC SENTENCE is a problematic case; in the genre-CV setting, its F1-score drops by 23.5%. The main reason for this is that the distribution of SE types in Wikipedia differs completely from the other genres (see section 4). Precision for GENERIC SENTENCE is at 70.5% in the genre-CV setting, but recall is only 32.8% (compared to 70.1% and 66.6% in the 10-fold CV setting). Genericity seems to work differently in the various genres: most generics in Wikipedia clearly refer to kinds (e.g., lions or plants), while many generics in essays or letters are instances of more abstract concepts or generic *you*.

Results by genre. Next, we drill down in the evaluation of our system by separately inspecting results for individual genres. Table 11 shows that performance differs greatly depending on the genre. In some genres, the nature of SE types seems clearer to our annotators than in others, and this is reflected in the system's performance. The majority class is GENERIC SENTENCE in wiki, and STATE in all other genres. In the 'same genre' setting, 10-fold CV was performed within each genre. Adding out-of-genre training data improves macro-average F1 especially for genres with low scores in the 'same genre' setting. This boost is

		training data

Table 11: **Macro-avg. F1 by genre**, CRF, 10-fold CV. Majority class given in % of clauses.

due to adding training data for types that are infrequent in that genre. Accuracy (not shown in table) improves significantly for blog, essays, govt-docs, jokes, and journal, and does not change for the remaining genres. We conclude that it is extremely beneficial to use our full corpus for training, as robustness of the system is increased, especially for SE types occurring infrequently in some genres.

7 Identification of Abstract Entities

Our system notably does not address one of Smith's main SE categories: *Abstract Entities*, introduced in Section 2. These SEs are expressed as clausal arguments of certain predicates such as (canonically) *know* or *believe*. Note that the *Abstract Entity* subtypes FACT and PROPOSITION do not imply that a clause's propositional content is true or likely from an objective point of view, they rather indicate that the clause's content is introduced to the discourse as an object of knowledge or belief, respectively. Following Smith (2003), we use PROPOSITION in a different sense than the usual meaning of "proposition" in semantics - naturally situation entities of any type may have propositional content. Smith's use of the term (and thus ours too) contrasts PROPOSITION with FACT - our PROPOSITIONS are simply sentences presented as a belief (or with uncertain evidential status) of the writer or speaker. This use of "proposition" also occurs in linguistic work by Peterson (1997) on factive vs. propositional predicates.

During the creation of the corpus, annotators

were asked to give one label out of the SE types included in our classification task, and to mark the clause with one of the *Abstract Entity* subtypes in addition if applicable. Analysis of the data shows that our annotators frequently forgot to mark clauses as *Abstract Entities*, which makes it difficult to model these categories correctly. As a first step toward resolving this issue, we implement a filter which automatically identifies *Abstract Entities* by looking for clausal complements of certain predicates. The list of predicates is compiled using WordNet synonyms of *know*, *think*, and *believe*, as well as predicates extracted from FactBank (Sauri and Pustejovsky, 2009) and TruthTeller (Lotan et al., 2013). Many of the clauses automatically identified as *Abstract Entities* are cases that annotators missed during annotation. We thus performed a post-hoc evaluation, presenting these clauses in context to annotators and asking whether the clause is an *Abstract Entity*. The so-estimated precision of our filter is 85.8% (averaged over 3 annotators). Agreement for this annotation task is $\kappa = 0.54$, with an observed agreement of 88.7%. Our filter finds 80% of the clauses labeled as *Abstract Entity* by at least one annotator in the gold standard; this is *approximately* its recall.

8 Conclusion

We have presented a system for automatically labeling clauses with their SE type which is mostly robust to changes in genre and which reaches accuracies of up to 76%, comparing favorably to the human upper bound of 80%. The system benefits from capturing contexual effects by using a linear chain CRF with label bigram features. In addition, the distributional and targeted syntactic-semantic features we introduce enable SE type prediction for large and diverse data sets. Our publicly available system can readily be applied to any written English text, making it easy to explore the utility of SE types for other NLP tasks.

Discussion. Our annotation scheme and guidelines for SE types (Friedrich and Palmer, 2014b) follow established traditions in linguistics and semantic theory. When applying these to a large number of natural texts, though, we came across a number of borderline cases where it is not easy to select just one SE type label. As we have reported before (Friedrich et al., 2015), the most difficult case is the identification of GENERIC SENTENCEs, which are defined as making a statement about a kind or class. We find that making this task becomes particularly difficult for argumentative essays (Becker et al., to appear).

Future work. A next major step in our research agenda is to integrate SE type information into various applications, including argument mining, temporal reasoning, and summarization. Together with the mode of progression through the text, e.g., temporal or spatial, SE type distribution is a key factor for a reader or listener's intuitive recognition of the discourse mode of a text passage. Therefore the automatic labeling of clauses with their SE type is a prerequisite for automatically identifying a passage's discourse mode, which in turn has promising applications in many areas of NLP, as the mode of a text passage has implications for the linguistic phenomena to be found in the passage. Examples include temporal processing of text (Smith, 2008), summarization, or machine translation (for work on genres see van der Wees et al., 2015). Here we focus on the automatic identification of SE types, leaving the identification of discourse modes to future work.

The present work, using the SE type inventory introduced by Smith (2003), is also the basis for research on more fine-grained aspectual type inventories. Among others, we plan to create subtypes of the STATE label, which currently subsumes clauses stativized by negation, modals, lexical information or other aspectual operators. Distinguishing these is relevant for temporal relation processing or veridicality recognition.

Acknowledgments

We thank the anonymous reviewers and Andrea Horbach for their helpful comments related to this work, and our annotators Melissa Peate Sørensen, Christine Bocionek, Kleo-Isidora Mavridou, Fernando Ardente, Damyana Gateva, Ruth Kühn and Ambika Kirkland. Abstract

Activities and events in our lives are structural, be it a vacation, a camping trip, or a wedding. While individual details vary, there are characteristic patterns that are specific to each of these scenarios. For example, a wedding typically consists of a sequence of events such as walking down the aisle, exchanging vows, and dancing. In this paper, we present a data-driven approach to learning event knowledge from a large collection of photo albums. We formulate the task as constrained optimization to induce the prototypical temporal structure of an event, integrating both visual and textual cues. Comprehensive evaluation demonstrates that it is possible to learn multimodal knowledge of event structure from noisy web content.

1 Introduction

Many common scenarios in our lives, such as a wedding or a camping trip, show characteristic structural patterns. As illustrated in Figure 1, these patterns can be sequential, such as in a wedding, where exchanging vows generally happens before cutting the cake. In other scenarios, there may be a set of composing events, but no prominent temporal relations. A camping trip, for example, might include events such as hiking, which can happen either before or after setting up a tent.

This observation on the prototypical patterns in everyday scenarios goes back to early artificial intelligence research. Scripts (Schank and Abelson, 1975), an early formalism, were developed to encode the necessary background knowledge to support an inference engine for common sense reasoning in limited domains. However, early approaches based on hand-coded symbolic representations proved to be brittle and difficult to scale.

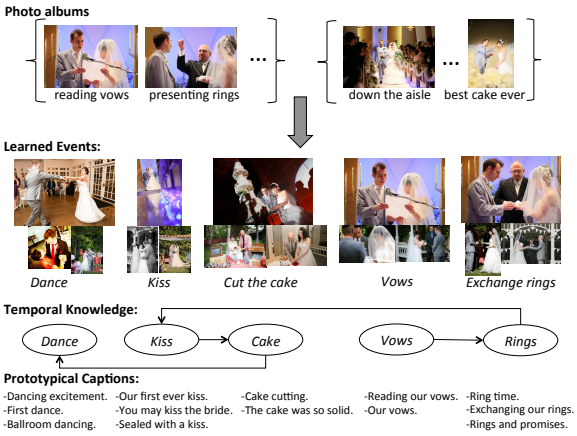

Figure 1: We collect photo albums of common scenarios (e.g., weddings) and cluster their images and captions to learn the hierarchical events that make up these scenarios. We use constrained optimization to decode the temporal order of these events, and we extract the prototypical descriptions that define them.

An alternative direction in recent years has been statistical knowledge induction, i.e., learning script or common sense knowledge bottom-up from large-scale data. While most prior work is based on text (Pichotta and Mooney, 2014; Jans et al., 2012; Chambers and Jurafsky, 2008; Chambers, 2013), recent work begins exploring the use of images as well (Bagherinezhad et al., 2016; Vedantam et al., 2015).

In this paper, we present the first study for learning knowledge about common life scenarios (e.g., weddings, camping trips) from a large collection of online photo albums with time-stamped images and their captions. The resulting dataset includes 34,818 time-stamped photo albums corresponding to 12 distinct event scenarios with 1.5 million images and captions (see Table 1 for more details).

We cast unsupervised learning of event structure as a sequential multimodal clustering prob-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1769–1779,
Berlin, Germany, August 7-12, 2016.

lem, which requires solving two subproblems concurrently: identifying the boundaries of events and assigning identities to each of these events. We formulate this process as constrained optimization, where constraints encode the temporal event patterns that are induced directly from the data. The outcome is a statistically induced prototypical structure of events characterized by their visual and textual representations.

We evaluate the quality and utility of the learned knowledge in three tasks: temporal event ordering, segmentation prediction, and multimodal summarization. Our experimental results show the performance of our model in predicting the order of photos in albums, partitioning photo albums into event sequences, and summarizing albums.

2 Overview

The high-level goal of this work is unsupervised induction of the prototypical event structure of common scenarios from multimodal data. We assume a two-level structure: high-level events, which we refer to as *scenarios* (e.g., wedding, funeral), are given, and low-level events (e.g., dance, kiss, vows), which we refer to as *events*, are to be automatically induced. In this section, we provide the overview of the paper (Section 2.1), and introduce our new dataset (Section 2.2).

2.1 Approach

Given a large collection of photo albums corresponding to a scenario, we want to learn three aspects of event knowledge by (1) identifying events common to the given scenario (Section 4.1), (2) learning temporal relations across events (Section 4.2), and (3) extracting prototypical captions for each event (Section 4.3).

To induce the prototypical event structure, an important subproblem we consider is individual photo album analysis, where the task is (1) partitioning each photo album into a sequence of segments, and (2) assigning the event identity to each segment. We present an inference model based on Integer Linear Programming (ILP) in Section 3 to perform both segmentation and event identification simultaneously, in consideration of the learned knowledge that we describe in Section 4.

Finally, we evaluate the utility of the automatically induced knowledge in the context of three concrete tasks: temporal ordering of photos (Section 6.1), album segmentation (Section 6.2), and photo album summarization (Section 6.3).

scenario	# of albums	# of images

CHRISTMAS	3449	98K
INDEPENDENCE DAY	548	22K
TOTAL	34,818	1.5M

Table 1: Dataset Statistics: the number of albums and images compiled for each scenario. The middle horizontal line separates the scenarios we predict have a well-defined temporal structure (top) from those we predict do not (bottom).

2.2 Dataset

For this study, we have compiled a new corpus of multimodal photo albums across 12 distinct scenarios. It comprises of 34,818 albums containing 1.5 million pairs of online photographs and their textual descriptions. Table 1 shows the list of scenarios and the corresponding data statistics. We choose six scenarios (the top half of Table 1) that we expect have an inherent temporal event structure that can be learned and six that we expect do not (the bottom half of Table 1).

The dataset is collected using the Flickr API[1,2]. We use the scenario names and variations of them (e.g., Paris Trip, Paris Vacation) as queries for images. We then form albums from these images by grouping images by user, sorting them by timestamp, and extracting groups that are within a contained time frame (e.g., 24 hours for a wedding, 5 days for a trip). For all images, we extract the first sentences of the corresponding textual descriptions as captions and also store their timestamps. This data is publicly available at `https://www.cs.washington.edu/projects/nlp/protoevents`.

3 Inference Model for Multimodal Event Segmentation and Identification

Given a photo album, the goal of the inference is to assign events to photos and to segment albums by event. More formally, given a sequence of M photos $P = \{p_1, \ldots, p_M\}$, and N learned events $E = \{e_1, \ldots, e_N\}$, the task is to assign each photo to a

[1]https://www.flickr.com/services/api/

[2]https://pypi.python.org/pypi/flickrapi/1.4.5

Figure 2: The events learned in Section 4 are assigned to photos based on textual (A^c) and visual (A^v) affinities, which encode how well a photo represents an event (ϕ_{event}). Segmentation scores (ϕ_{seg}) between adjacent photos encourage similar photos to be assigned the same event. Local transition, P_L, and global pairwise ordering, P_G, probabilities encode the learned temporal knowledge between events. $\phi_{temporal}$ encourages event assignments toward a learned temporal structure of the scenario.

single event. The event assignment can be viewed as a latent variable for each photo. We formulate a constrained optimization (depicted in Figure 2) that maximizes the objective function, F, which consists of three scoring components: (a) event assignment scores ϕ_{event} (Section 3.1), (b) segmentation scores ϕ_{seg} (Section 3.2), and (c) temporal knowledge scores $\phi_{temporal}$ (Section 3.3):

$$F = \phi_{event} + \phi_{seg} + \phi_{temporal} \quad (1)$$

Decision Variables. The binary decision variable $\mathbf{X}_{i,k}$ indicates that photo p_i is assigned to event e_k. The binary decision variable $\mathbf{Z}_{i,j,k,l}$ indicates that photos p_i and p_j are assigned to events e_k and e_l, respectively:

$$\mathbf{Z}_{i,j,k,l} := \mathbf{X}_{i,k} \wedge \mathbf{X}_{j,l} \quad (2)$$

3.1 Event Assignment Scores

Event assignment scores quantify the textual and visual affinity between a photo p_i and an event e_k. Affinities are measures of representation similarity between photos and events. These scores push photos displaying a certain event to be assigned to that event. For now we assume the textual affinity matrix $\mathbf{A}^c \in [0,1]^{M\times N}$ and the visual affinity matrix $\mathbf{A}^v \in [0,1]^{M\times N}$ are given. We describe how we obtain these affinity matrices in Section 4.1. Event assignment scores are defined as the weighted sum of both textual and visual affinity:

$$\phi_{event} = \sum_{i=1}^{M}\sum_{k=1}^{N}\left(\gamma_{ce}\mathbf{A}^c_{i,k} + \gamma_{ve}\mathbf{A}^v_{i,k}\right)\mathbf{X}_{i,k} \quad (3)$$

where $\mathbf{X}_{i,k}$ is a photo-event assignment decision variable, and γ_{ce} and γ_{ve} are hyperparameters that balance the contribution of both affinities.

3.2 Segmentation Scores

Segmentation scores quantify textual and visual similarities between adjacent photos. These scores encourage similar adjacent photos to be assigned to the same event. We define a similarity score between adjacent photos equal to the weighted sum of their textual ($\mathbf{b}^c$) and visual ($\mathbf{b}^v$) similarities:

$$\phi_{seg} = \sum_{i=1}^{M-1}\sum_{k=1}^{N}\left(\gamma_{cs}\mathbf{b}^c_i + \gamma_{vs}\mathbf{b}^v_i\right)\mathbf{Z}_{i,i+1,k,k} \quad (4)$$

where $\mathbf{b}^c$, $\mathbf{b}^v \in [0,1]^{(M-1)\times 1}$ are vectors of textual and visual similarity scores between adjacent photos whose i^{th} element corresponds to the similarity score between photos p_i and p_{i+1}, $\mathbf{Z}$ is a decision variable defined by Equation 2, and γ_{cs} and γ_{vs} are hyperparameters balancing the contribution of both types of similarity. The similarity scores in the $\mathbf{b}$ vectors are computed using cosine similarity of the feature representations of adjacent images in both the textual and visual modes.

3.3 Temporal Knowledge Scores

Temporal knowledge scores quantify the compatibilities across different event assignments in terms of their relative ordering. For now, we assume two types of temporal knowledge matrices are given: $\mathbf{L} \in [0,1]^{N\times N}$ which stores local transition probabilities for every pair of events, e_k and e_l, and $\mathbf{G} \in [0,1]^{N\times N}$ which stores global pairwise ordering probabilities for every pair of events, e_k

and e_l. We describe how we obtain these temporal knowledge matrices in Section 4.2. The temporal knowledge score, defined below, encourages the inference model to assign events that are compatible with the learned temporal knowledge:

$$\phi_{temporal} = \gamma_{lp} \sum_{i=0}^{M} \sum_{k,l=1}^{N} \mathbf{L}_{k,l} \mathbf{Z}_{i,i+1,k,l} \quad (5)$$
$$+ \gamma_{gp} \sum_{i=1}^{M} \sum_{j=i}^{M} \sum_{k,l=1}^{N} \mathbf{G}_{k,l} \mathbf{Z}_{i,j,k,l}$$

where $\mathbf{Z}$ is a decision variable defined by Equation 2, and γ_{lp} and γ_{gp} are hyperparameters that balance the contribution of local and global temporal knowledge in the objective.

3.4 Constraints

We include hard constraints that force each photo to be assigned to exactly one event:

$$\sum_{k=1}^{N} \mathbf{X}_{i,k} = 1 \quad (6)$$

The number of these constraints is linear in the number of photos in an album. We also include hard constraints to ensure consistencies among binary decision variables $\mathbf{X}$ and $\mathbf{Z}$:

$$\frac{1}{2}(\mathbf{X}_{i,k} + \mathbf{X}_{j,l}) - \mathbf{Z}_{i,j,k,l} \geq 0 \quad (7)$$

which states that $\mathbf{Z}_{i,j,k,l}$ can be 1 only if both $\mathbf{X}_{i,k}$ and $\mathbf{X}_{j,l}$ are 1. The number of constraints for segmentation scores and local transition probabilities is $O(MN^2)$ because they model interactions between adjacent photos for all event pairs. The number of these constraints for global pairwise ordering probabilities is $O(M^2N^2)$ because they model interactions between all pairs of photos in an album for all event pairs.

4 Learned Event Knowledge

We learn base events for each scenario by clustering photos from training albums related to that scenario (Figure 3). As described in Section 3, these base events and their temporal knowledge are incorporated in a joint model for event induction in unseen albums.

4.1 Learned Event Representation

We perform k-means clustering over captions to create a base event model. We perform text-only clustering at first since visual cues are significantly noisier. Because not all photos have informative captions, it is expected that this base clustering will form meaningful clusters only over a subset of the data. For each scenario, the largest cluster corresponds to the "miscellaneous" cluster as the captions in it tend to be relatively uninformative about specific events. This cluster is excluded when computing temporal knowledge probabilities (Section 4.2).

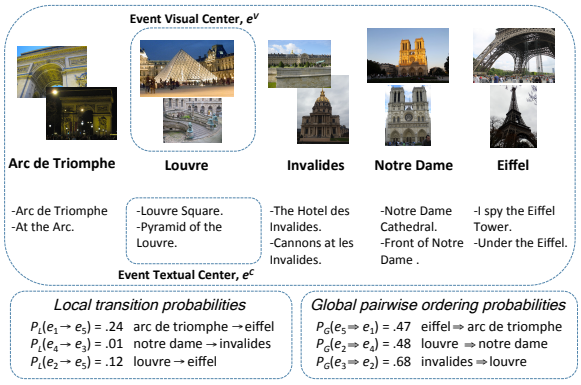

Figure 3: Photos are clustered by their captions. We can compute the visual, e_k^v, and caption, e_k^c, centers for all the clusters, as well as the local transition, P_L, and global pairwise ordering, P_G, probabilities between these events based on the sequential patterns they exhibit in the training set.

The visual and textual representations of an event are computed using the average of the visual and textual features, respectively, of photos assigned to that event. We compute each textual affinity $\mathbf{A}_{i,k}^c$ in the event assignment scores (Equation 3) as the cosine similarity between the textual features of the caption for photo p_i and the textual representation of event e_k. For textual features, we extract noun and verb unigrams using TurboTagger (Martins et al., 2013) and weigh them by their discriminativeness relative to their scenario, $P(S|w)$. Given scenario S and word w, $P(S|w)$ is defined as the number of albums for the scenario the word occurs in divided by the total number of albums in that scenario. The visual affinity $\mathbf{A}_{i,k}^v$ is the similarity between the visual features of photo p_i and the visual representation of event e_k. For visual features, we use the convolutional features from the final layer activations of the 16-layer VGGNet model (Simonyan and Zisserman, 2015).

4.2 Temporal Knowledge

Local transition probabilities. These probabilities, denoted as P_L, encode an expected sequence of events using temporal patterns among adjacent

Wedding		Camping		Funeral

dance	First Dance Everybody Dancing Dancing the Night Away	*sunset*	Watching the Sunset Sunset from camp Sunset on the first night	*goodbye*	Saying Goodbye

Table 2: Sample learned events and prototypical captions

photos. We model P_L for each pair of events as a multinomial distribution,

$$P_L(e_k \rightarrow e_l) = \frac{C(e_k \rightarrow e_l)}{\sum_{m=1}^{N} C(e_k \rightarrow e_m)} \quad (8)$$

where C is the observed counts of that specific event transition. This is the likelihood that an event e_k is immediately followed by event e_l.

Global pairwise ordering probabilities. These probabilities, denoted as P_G, encode global structural patterns about events. We model P_G for each pair of events as a binomial distribution by computing the likelihood that an event occurs before another at any point in an album,

$$P_G(e_k \Rightarrow e_l) = \frac{C(e_k \Rightarrow e_l)}{C(e_k \Rightarrow e_l) + C(e_l \Rightarrow e_k)} \quad (9)$$

where $C(e_k \Rightarrow e_l)$ is the observed counts of e_k occurring anytime before e_l in all photo albums. These global probabilities model relations among events assigned to all photos in the album, not just events assigned to photos that are adjacent to one another. This distinction is important because these probabilities can encode global patterns between events and are not limited to modeling a sequential event chain.

We use these learned temporal probabilities, P_L and P_G, in matrices $\mathbf{L}$ and $\mathbf{G}$ from $\phi_{temporal}$ (Equation 5). These matrices are used to index local transition probabilities and global pairwise ordering probabilities for pairs of events when computing temporal knowledge scores in the inference model (Section 3.3).

4.3 Prototypical Captions

After clustering the photos, the representative language of the captions in each cluster begins to tell a story about each scenario. The event names are automatically extracted using the most common content words among captions in the cluster. For each cluster, we also compile *prototypical captions* by extracting captions whose lemmatized forms are frequently observed throughout multiple albums in the scenario. Sample events and their prototypical captions from three scenarios are displayed in Table 2.

5 Experimental Setup

Data split. For scenarios with more than 1000 albums, we use 100 albums for each of the development and test sets and use the rest for training. For scenarios with less than 1000 albums, we use 50 albums for each of the development and test sets, and the rest for training.

Implementation details. We optimize our objective function using integer linear programming (Roth and Yih, 2004) with the Gurobi solver (Inc., 2015). For computational efficiency, temporally close sets of consecutive photos are treated as one unit during the optimization. We use these units to reduce the number of variables and constraints in the model from a function of the number of photos to a function of the number of units. We form these units heuristically by merging images agglomeratively when their timestamps are within a certain range of the closest image in a unit. When merging photos, the textual affinity of each unit for a particular event is the maximum affinity for that event among photos in that unit. The visual affinity of each unit is the average of all affinities for that event among photos in that unit. The textual and visual similarities of consecutive units are defined in terms of the similarities between the two photos at the units' boundary. Temporal information for events not aligned well with a particular unit should not influence the objective, so we include temporal scores only for unit-event pairs which have both textual and visual event assignment scores greater than 0.05.

Hyperparameters. We tune the hyperparameters using grid search on the development set. In models where the corresponding objective components are included, we set $\gamma_{ce} = 1$, $\gamma_{ve} = 1$, $\gamma_{cs} = .5$, $\gamma_{vs} = .15$, $\gamma_{lp} = 1$, and $\gamma_{gp} = \frac{4}{Q}$ (where Q is the

number of event units). For k-means clustering, we use 10 random restarts and 40 cluster centers for the WEDDING, CAMPING, PARIS TRIP, and NY TRIP scenarios. For all other scenarios, we use 30 cluster centers.

6 Experimental Results

We evaluate the performance of our model on three tasks. The first task evaluates the effect of learned temporal knowledge in predicting the correct order of photos in an unseen album (Section 6.1). The second task evaluates the model's ability to segment albums into logical groupings (Section 6.2). The third task evaluates the quality of prototypical captions and their use in photo album summarization (Section 6.3).

6.1 Temporal Ordering of Photos

We evaluate the model's ability to capture the temporal relationships between events in the scenario. Given two randomly selected photos p_i and p_j from an album, the task is to predict which of the photos appears earlier in the album using their event assignments. We compare the full model that assigns events to photos using ILP (Section 3) with two baselines: k-MEANS , which assigns events to photos using k-means clustering over captions (Section 4), and NO TEMPORAL: a variant of the full model that does not use temporal knowledge scores ($\phi_{temporal}$ in Equation 1) for optimization.

We run each method over a test photo album, in which the events e_k and e_l are assigned to the photos p_i and p_j, respectively. We then use the learned global pairwise ordering probabilities (Section 4.2) to predict which photo appears earlier in the album. We report the accuracy of each method in predicting the order of photos compared to the actual order of photos in the albums. We perform this experiment 50 times for each album and average the number of correct choices across every album and every trial.

Results. Table 3 reports the results of the full model compared to the baselines. The results show that temporal knowledge generally helps in predicting photo ordering. We observe that the full model achieves higher scores for scenarios for which we expect would have a sequential structure (e.g., WEDDING, BABY BIRTH, MARATHON). Conversely, the full model achieves lower overall scores in non-sequential scenarios (e.g., PARIS TRIP, NEW YORK TRIP). Qualitatively, we notice interesting temporal patterns such as the fact that during a marathon, the starting line occurs before the medal awards with 92.3% probability, or that Parisian tourists have a 24% chance ($\sim$10$\times$ higher than random chance) of visiting the Eiffel Tower immediately after the Arc de Triomphe (a high local transition probability that correctly implies their real world proximity).

6.2 Album Segmentation

Our model partitions photos in albums into coherent events. The album segmentation evaluation tests if the model recovers the same sequences of photos that a human would identify in a photo album as events.

Evaluation. We had an impartial annotator label where they thought events began and ended in 10 candidate albums of greater than 100 photos for three scenarios: WEDDING, FUNERAL, CAMPING. We evaluate how well our model can replicate these boundaries with two metrics. The first metric is the F_1 score of recovering the same boundaries annotated by humans. The second metric is d, the difference between the number of events segmented by the model compared to the annotated albums. We report results for exact event boundaries as well as relaxed boundaries where the start of an event can be r photos away from the start of an annotated event, where r is the relaxation coefficient. For reference, we note that albums in the wedding scenario were dual annotated and the agreement between annotators is 56.9% for $r = 0$ and 77.5% for $r = 2$.

Results. Table 4 shows comparison of the the full ILP model with same baselines we described before, k-MEANS and NO TEMPORAL. The table shows that the full model generally outperforms the k-MEANS baseline for all three scenarios.

In the WEDDING scenario, the F_1 score for the full

- Visual Event Affinity	37.7	37.0	35.3	-1.7
- Textual Segmentation	37.1	41.5	37.4	.8
- Visual Segmentation	35.1	42.1	36.5	1.7
- Local Ordering Probs.	36.9	40.3	36.9	**.2**
- Global Ordering Probs.	**40.5**	25.0	29.5	-5.8

Table 5: Ablation study of objective function components for the wedding scenario. P, R, and F_1 are the precision, recall and F-measure of recovering the same boundaries annotated by humans. d is the average difference between the number of events identified by our models and the annotators.

model is consistently higher. The k-MEANS baseline oversamples the number of events in albums, which is indicated by an average d significantly greater than 0. For the FUNERAL scenario, the NO TEMPORAL baseline outperforms the full model. We attribute this difference to the smaller data subset (see Table 1) making it harder to learn the temporal relations in the scenario, which makes the contributions of the local and global temporal probabilities unexpected. In the CAMPING scenario, the F_1 score for the k-MEANS baseline is higher than that of the full model when $r = 0$. At a high-level, CAMPING is a scenario we expect has less of a known structure compared to other scenarios and may be harder to segment into its events.

Ablation Study. Table 5 depicts the performance of ablations of the full model for the wedding scenario. Results show that removing any component of the objective functions yields lower recall and F_1 scores than the full model for $r = 0$. The exception is removing local ordering probabilities, which yields a higher d. These observations support the hypothesis that all of the components of the objective function contribute to segmenting the album into subsequences of photos depicting the same event. Particularly, we note the degradation when removing the global ordering probabilities, indicating that approaches which model only local event transitions such as hidden Markov models would not be suitable for this task.

6.3 Photo Album Summarization

The final experiment evaluates how our learned prototypical captions can improve downstream tasks such as summarization and captioning.

6.3.1 Summaries

The goal of a good summary is to select the most salient pictures of an album. In our setting, a good summary should have a high coverage of the events in an album and choose the photos that most appropriately depict these events. Given a photo budget b, we choose a subset of photos that aims for these goals. To summarize a test album, we run our model over the entire album. This will yield h unique events assigned to the photos in the album. For each of these h events, we choose the photo with the highest event assignment score for that event (Equation 3) to be in the summary. If $h > b$, we count the number of photos in the training set assigned to each of the h events and choose the photos corresponding to the b events with the largest membership of photos in the training set. If $h < b$, we complete the summary with $b - h$ photos from the "miscellaneous" event that are spaced evenly throughout the album. Finally, we replace the caption of each selected photo with a prototypical caption (Section 4.3) for the assigned event.

Baseline. We evaluate against two baselines. The first baseline, KTH, involves including a photo in the summary every $k = M/b$ photos. The second baseline, k-MEANS, uses the events assigned to photos from k-means clustering and then picks b photos in the same manner as our main model.

Evaluation. We evaluate the summaries produced by each method with a human evaluation using Amazon Mechanical Turk (AMT). We use albums from the test set that contain more than 40 photos for the wedding scenario. For each album, at random, we present two summaries generated by two algorithms. AMT workers are instructed to choose the better summary considering both the images and the captions. For each comparison of two summaries for an album, we aggregate answers from three workers by majority voting. We set $b = 7$. The number of assigned events in an album, h, varies by album.

Results. As seen in Table 6, the summary from the full model is preferred 57.7% of the time compared to the KTH baseline. The summaries generated using the full model perform slightly better than the summaries from k-MEANS. We attribute

Figure 4: Example summaries from the wedding, Paris trip, and baby birth scenarios. In cases where the album had less events than b, the additionally chosen photos are outlined in red. These photos do not have their caption replaced by a prototypical captions and merely fill out the summary.

Method	Selection Rates	
FULL MODEL vs. KTH	**57.7**	42.3
FULL MODEL vs. k-MEANS	**53.8**	47.2
k-MEANS vs. KTH	**53.8**	47.2

Table 6: Summarization results. The selection rates indicate the percentage of time the corresponding method in the left-most column was picked.

Method	Scenario Relevance	Image Relevance	Grammar
LSTM	**4.90**	2.85	3.74
FULL MODEL	4.55	**3.66**	**4.08**
RAW CAPTIONS	4.10	4.36	4.28

Table 7: Captioning results. We evaluate the caption quality of the prototypical captions of the full model, those generated by an LSTM trained on the raw captions, and original captions. Captions were evaluated on 3 metrics: grammatical correctness, how relevant they were to the scenario, and how relevant they were to their assigned image.

the superior performance of the full model to the fact that it redistributes photos with noisy captions throughout the events, allowing for a larger sample to estimate visual representations of events, yielding more accurate visual affinity measurements to choose the summarization photos. As can be seen from qualitative examples in Figure 4, the photos chosen and the captions assigned cover key events that would occur during the scenario and describe them in a coherent way. Additional examples are available at `https://www.cs.washington.edu/projects/nlp/protoevents`.

6.3.2 Prototypical Captions

We also evaluate the quality of the prototypical captions assigned to every photo in the summaries. For each album, we use the same sets of b photos from the full model in the summarization task and evaluate the quality of the prototypical captions paired with that group of photos.

Evaluation. We evaluate the quality of captions assigned to every photo by asking AMT workers to rate the captions on three different metrics: grammaticality, relevance to the scenario to which the image belongs, and relevance to its paired image. Five AMT workers rate each group of b photos on a five point Likert scale for each metric. We compare the prototypical captions for every photo in the summary with captions generated by an LSTM model[3] trained on every photo-caption pair in the training set for a scenario. We also compare with the original raw captions for each image in the summary. Because we chose photos with the highest event assignment scores (Equation 3) to be in the summary, the raw captions for this evaluation are cleaner and more descriptive than most captions in the dataset.

Results. Our model outperforms the LSTM-generated captions in the image relevance and grammaticality scores, but did worse in scenario

[3]We use a single-layer encoder-decoder LSTM. The cell state and the input embedding dimensions are 256. Visual inputs are the final layer convolutional features of the VGG-16 model and are fine-tuned during training. We use RMSprop to train the network with a base learning rate of .0001 and 30% dropout. We train the model for 45 epochs on a single NVIDIA Titan X GPU with mini batch size 100. To decode, we use beam search with beam size 5.

relevance. We attribute this result to LSTM captions having little caption variation because the model learns frequency statistics without any knowledge of latent events. Almost all LSTM captions mention the words *bride, wedding*, or *groom*, yielding a very high scenario score for the caption, even if that caption is grammatically incorrect or irrelevant to the image. As expected the raw captions have high relevance to the original image, and they are grammatical, but can be less relevant to the corresponding scenario.

7 Related Work

Previous studies have explored unsupervised induction of salient content structure in newswire texts (Barzilay and Lee, 2004), temporal graph representations (Bramsen et al., 2006), and storyline extraction and event summarization (Xu et al., 2013). Another line of research finds the common event structure from children's stories (McIntyre and Lapata, 2009), where the learned plot structure is used to stochastically generate new stories (Goyal et al., 2010; Goyal et al., 2013). Our work similarly aims to learn the typical temporal patterns and compositional elements that define common scenarios, but with multimodal integration.

Compared to studies that learn narrative schemas from natural language (Pichotta and Mooney, 2014; Jans et al., 2012; Chambers and Jurafsky, 2009; Chambers, 2013; Cassidy et al., 2014), or compile script knowledge from crowdsourcing (Regneri et al., 2010), our work explores a new source of knowledge that allows grounded event learning with temporal dimensions, resulting in a new dataset of scenario types that are not naturally accessible from newswire or literature.

While recent studies have explored videos and photo streams as a source of discovering complex events and learning their sequential patterns (Kim and Xing, 2014; Kim and Xing, 2013; Tang et al., 2012; Tschiatschek et al., 2014), their focus was mostly on the visual modality. Zhang et al. (2015) explored multimodal information extraction focusing specifically on identifying video clips that referred to the same event in television news. This contrasts to the goal of our study that aims to learn the temporal structure by which common scenarios unfold.

Integrating language and vision has attracted increasing attention in recent years across diverse tasks such as image captioning (Karpathy and Fei-Fei, 2015; Vinyals et al., 2015; Fang et al., 2015; Xu et al., 2015; Chen et al., 2015), cross modal semantic modeling (Lazaridou et al., 2015), information extraction (Morency et al., 2011; Rosas et al., 2013; Zhang et al., 2015; Izadinia et al., 2015), common-sense knowledge (Vedantam et al., 2015; Bagherinezhad et al., 2016), and visual storytelling (Huang et al., 2016). Our work is similar to both common sense knowledge learning and visual story completion. Our model learns commonsense knowledge on the hierarchical and temporal event structure from scenario-specific multimodal photo albums, which can be viewed as visual stories about common life events.

Recent work focused on photo album summarization using visual (Sadeghi et al., 2015) and multimodal representations (Sinha et al., 2011). Our work identifies the nature of common events in scenarios and learns their timelines and characteristic forms.

8 Conclusion

We introduce a novel exploration to learn script-like knowledge from photo albums. We model stochastic event structure to learn both the event representations (textual and visual) and the temporal relations among those events. Our event induction method incorporates learned knowledge about events, partitions photo albums into segments, and assigns events to those segments. We show the significance of our model in learning and using learned knowledge for photo ordering, album segmentation, and summarization. Finally, we provide a dataset depicting 12 scenarios with $\sim$1.5 M images for future research. Future directions could include exploring nuances in the type of temporal knowledge that can be learned across different scenarios.

Abstract

Automatically generating a natural language description of an image is a fundamental problem in artificial intelligence. This task involves both computer vision and natural language processing and is called "image caption generation." Research on image caption generation has typically focused on taking in an image and generating a caption in English as existing image caption corpora are mostly in English. The lack of corpora in languages other than English is an issue, especially for morphologically rich languages such as Japanese. There is thus a need for corpora sufficiently large for image captioning in other languages. We have developed a Japanese version of the MS COCO caption dataset and a generative model based on a deep recurrent architecture that takes in an image and uses this Japanese version of the dataset to generate a caption in Japanese. As the Japanese portion of the corpus is small, our model was designed to transfer the knowledge representation obtained from the English portion into the Japanese portion. Experiments showed that the resulting bilingual comparable corpus has better performance than a monolingual corpus, indicating that image understanding using a resource-rich language benefits a resource-poor language.

1 Introduction

Automatically generating image captions by describing the content of an image using natural language sentences is a challenging task. It is especially challenging for languages other than English due to the sparsity of annotated resources in the target language. A promising solution to this problem is to create a comparable corpus. To support the image caption generation task in Japanese, we have annotated images taken from the MS COCO caption dataset (Chen et al., 2015b) with Japanese captions. We call our corpus the "YJ Captions 26k Dataset." While the size of our dataset is comparatively large with 131,740 captions, it greatly trails the 1,026,459 captions in the MS COCO dataset. We were thus motivated to transfer the resources in English (source language) to Japanese and thereby improve image caption generation in Japanese (target language). In natural language processing, a task involving transferring information across languages is known as a cross-lingual natural language task, and well known tasks include cross-lingual sentiment analysis (Chen et al., 2015a), cross-lingual named entity recognition (Zirikly and Hagiwara, 2015), cross-lingual dependency parsing (Guo et al., 2015), and cross-lingual information retrieval (Funaki and Nakayama, 2015).

Existing work in the cross-lingual setting is usually formulated as follows. First, to overcome the language barrier, create a connection between the source and target languages, generally by using a dictionary or parallel corpus. Second, develop an appropriate knowledge transfer approach to leverage the annotated data from the source language for use in training a model in the target language, usually supervised or semi-supervised. These two steps typically amount to automatically generating and expanding the pseudo-training data for the target language by exploiting the knowledge obtained from the source language.

We propose a very simple approach to cross-lingual image caption generation: exploit the English corpus to improve the performance of image caption generation in another language. In this ap-

* Both authors contributed equally to this work.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1780–1790,
Berlin, Germany, August 7-12, 2016.

proach, no resources besides the images found in the corpus are used to connect the languages, and we consider our dataset to be a comparable corpus. Paired texts in a comparable corpus describe the same topic, in this case an image, but unlike a parallel corpus, the texts are not exact translations of each other. This unrestrictive setting enables the model to be used to create image caption resources in other languages. Moreover, this model scales better than creating a parallel corpus with exact translations of the descriptions.

Our transfer model is very simple. We start with a neural image caption model (Vinyals et al., 2015) and pretrain it using the English portion of the corpus. We then remove all of the trained neural network layers except for one crucial layer, the one closest to the vision system. Next we attach an untrained Japanese generation model and train it using the Japanese portion of the corpus. This results in improved generation in Japanese compared to using only the Japanese portion of the corpus. To the best of our knowledge, this is the first paper to address the problem of cross-lingual image caption generation.

Our contribution is twofold. First, we have created and plan to release the first ever significantly large corpus for image caption generation for the Japanese language, forming a comparable corpus with existing English datasets. Second, we have created a very simple model based on neural image caption generation for Japanese that can exploit the English portion of the dataset. Again, we are the first to report results in cross-lingual image caption generation, and our surprisingly simple method improves the evaluation metrics significantly. This method is well suited as a baseline for future work on cross-lingual image caption generation.

The paper is organized as follows. In the next section, we describe related work in image caption generation and list the corpora currently available for caption generation. Then in Section 3 we present the statistics for our corpus and explain how we obtained them. We then explain our model in Section 4 and present the results of our experimental evaluation in Section 5. We discuss the results in Section 6, and conclude in Section 7 with a summary of the key points.

2 Related Work

Recent advances in computer vision research have led to halving the error rate between 2012 and 2014 at the Large Scale Visual Recognition Challenge (Russakovsky et al., 2015), largely driven by the adoption of deep neural networks (Krizhevsky et al., 2012; Simonyan and Zisserman, 2014; Donahue et al., 2014; Sharif Razavian et al., 2014). Similarly, we have seen increased adaptation of deep neural networks for natural language processing. In particular, sequence-to-sequence training using recurrent neural networks has been successfully applied to machine translation (Cho et al., 2014; Bahdanau et al., 2015; Sutskever et al., 2014; Kalchbrenner and Blunsom, 2013).

These developments over the past few years have led to renewed interest in connecting vision and language. The encoder-decoder framework (Cho et al., 2014) inspired the development of many methods for generating image captions since generating an image caption is analogous to translating an image into a sentence.

Since 2014, many research groups have reported a significant improvement in image caption generation due to using a method that combines a convolutional neural network with a recurrent neural network. Vinyals et al. used a convolutional neural network (CNN) with inception modules for visual recognition and long short-term memory (LSTM) for language modeling (Vinyals et al., 2015). Xu et al. introduced an attention mechanism that aligns visual information and sentence generation for improving captions and understanding of model behavior (Xu et al., 2015). The interested reader can obtain further information elsewhere (Bernardi et al., 2016).

These developments were made possible due to a number of available corpora. The following is a list of available corpora that align images with crowd-sourced captions. A comprehensive list of other kinds of corpora connecting vision and language, e.g., visual question answering, is available elsewhere (Ferraro et al., 2015).

1. UIUC Pascal Dataset (Farhadi et al., 2010) includes 1,000 images with 5 sentences per image; probably one of the first datasets.
2. Abstract Scenes Dataset (Clipart) (Zitnick et al., 2013) contains 10,020 images of children playing outdoors associated with 60,396 descriptions.

3. Flickr 30K Images (Young et al., 2014) extends Flickr datasets (Rashtchian et al., 2010) and contains 31,783 images of people involved in everyday activities.
4. Microsoft COCO Dataset (MS COCO) (Lin et al., 2014; Chen et al., 2015b) includes about 328,000 images of complex everyday scenes with common objects in naturally occurring contexts. Each image is paired with five captions.
5. Japanese UIUC Pascal Dataset (Funaki and Nakayama, 2015) is a Japanese translation of the UIUC Pascal Dataset.

To the best of our knowledge, there are no large datasets for image caption generation except for English. With the release of the YJ Captions 26k dataset, we aim to remedy this situation and thereby expand the research horizon by exploiting the availability of bilingual image caption corpora.

3 Statistics for Data Set

In this section we describe the data statistics and how we gathered data for the YJ Captions 26k dataset. For images, we used the Microsoft COCO dataset (Chen et al., 2015b). The images in this dataset were gathered by searching for pairs of 80 object categories and various scene types on Flickr. They thus tended to contain multiple objects in their natural context. Objects in the scene were labeled using per-instance segmentations. This dataset contains pictures of 91 basic object types with 2.5 million labeled instances. To collect Japanese descriptions of the images, we used Yahoo! Crowdsourcing [1], a microtask crowdsourcing service operated by Yahoo Japan Corporation.

Given 26,500 images taken from the training part of the MS COCO dataset, we collected 131,740 captions in total. The images had on average 4.97 captions; the maximum number was 5 and the minimum was 3. On average, each caption had 23.23 Japanese characters. We plan to release the YJ Captions 26k dataset [2].

3.1 Crowdsourcing Procedure

Our captions were human generated using Yahoo! Crowdsourcing. As this crowdsourcing platform is operated in Japan, signing up for the service and participating require Japanese proficiency. Thus, we assumed that the participants were fluent in Japanese.

Figure 1: User Interface

First, we posted a pilot task that asked the participants to describe an image. We then examined the results and selected promising participants (comprising a "white list") for future task requests. That is, only the participants on the white list could see the next task. This selection process was repeated, and the final white list included about 600 participants. About 150 of them regularly participated in the actual image caption collection task. We modified the task request page and user interface on the basis of our experience with the pilot task. In order to prevent their fatigue, the tasks were given in small batches so that the participants were unable to work over long hours.

In our initial trials, we tried a direct translation of the instructions used in the MS-COCO English captions. This however did not produce Japanese captions comparable to those in English. This is because people describe what appears unfamiliar to them and do not describe things they take for granted. Our examination of the results from the pilot tasks revealed that the participants generally thought that the pictures contained non-Japanese people and foreign places since the images originated from Flickr and no scenery from Japan was included in the image dataset. When Japanese

[1] http://crowdsourcing.yahoo.co.jp
[2] http://research-lab.yahoo.co.jp/software/index.html

crowds are shown pictures with scenery in the US or Europe in MS-COCO dataset, the scenes themselves appear exotic and words such as 'foreign' and 'oversea' would be everywhere in the descriptions. As such words are not common in the original dataset, and to make the corpus nicer complement to the English dataset and to reduce the effects of such cultural bias, we modified the instructions: "2. Please give only factual statements"; "3. Please do not specify place names or nationalities." We also strengthened two sections in the task request page and added more examples.

The interface is shown in Figure 1. The instructions in the user interface can be translated into English as "Please explain the image using 16 or more Japanese characters. Write a single sentence as if you were writing an example sentence to be included in a textbook for learning Japanese. Describe all the important parts of the scene; do not describe unimportant details. Use correct punctuation. Write a single sentence, not multiple sentences or a phrase."

Potential participants are shown task request pages, and the participants select which crowdsourcing task(s) to perform. The task request page for our task had the following instructions (English translation):

1. Please explain an image using 16 or more Japanese characters. Please write a single sentence as if you were writing an example sentence to be included in a textbook for learning Japanese.
   (a) Do not use incorrect Japanese.
   (b) Use a polite style of speech (*desu*/*masu* style) as well as correct punctuation.
   (c) Write a single complete sentence that ends with a period. Do not write just a phrase or multiple sentences.
2. Please give only factual statements.
   (a) Do not write about things that might have happened or might happen in the future. Do not write about sounds.
   (b) Do not speculate. Do not write about something about which you feel uncertain.
   (c) Do not state your feelings about the scene in the picture. Do not use an overly poetic style.
   (d) Do not use a demonstrative pronoun such as 'this' or 'here.'
3. Please do not specify place names or nationalities.
   (a) Please do not give proper names.
4. Please describe all the important parts of the scene; do not describe unimportant details.

Together with the instructions, we provided 15 examples (1 good example; 14 bad examples).

Upon examining the collected data, manual checks of first 100 images containing 500 captions revealed that 9 captions were clearly bad, and 12 captions had minor problems in descriptions. In order to further improve the quality of the corpus, we crowdsourced a new data-cleaning task. We showed each participant an image and five captions that describe the image and asked to fix them.

The following is the instructions (English translation) for the task request page for our data-cleaning task.

1. There are five sentences about a hyper-linked image, and several sentences require fixes in order to satisfy the conditions below. Please fix the sentences, and while doing so, tick a checkbox of the item (condition) being fixed.
2. The conditions that require fixes are:
   (a) Please fix typographical errors, omissions and input-method-editor conversion misses.
   (b) Please remove or rephrase expressions such as 'oversea', 'foreign' and 'foreigner.'
   (c) Please remove or rephrase expressions such as 'image', 'picture' and 'photographed.'
   (d) Please fix the description if it does not match the contents of the image.
   (e) Please remove or rephrase subjective expressions and personal impressions.
   (f) If the statement is divided into several sentences, please make it one sentence.
   (g) If the sentence is in a question form, please make it a declarative sentence.
   (h) Please rewrite the entire sentence if meeting all above conditions requires extensive modifications.
   (i) If there are less than 16 characters, please provide additional descriptions so that the sentence will be longer than 16 characters.

For each condition, we provided a pair of examples (1 bad example and 1 fixed example).

To gather participants for the data-cleaning task, we crowdsourced a preliminary user qualification task that explained each condition requiring fixes in the first half, then quizzed the participants in the second half. This time we obtained over 900 qualified participants. We posted the data-cleaning task to these qualified participants.

The interface is shown in Figure 2. The instructions in the user interface are very similar to the task request page, except that we have an additional checkbox:

(j) All conditions are satisfied and no fixes were necessary.

We provided these checkboxes to be used as a checklist, so as to reduce failure by compensating for potential limits of participants' memory and attention, and to ensure consistency and completeness in carrying out the data-cleaning task.

For this data-cleaning task, we had 26,500 images totaling 132,500 captions checked by 267 participants. The number of fixed captions are

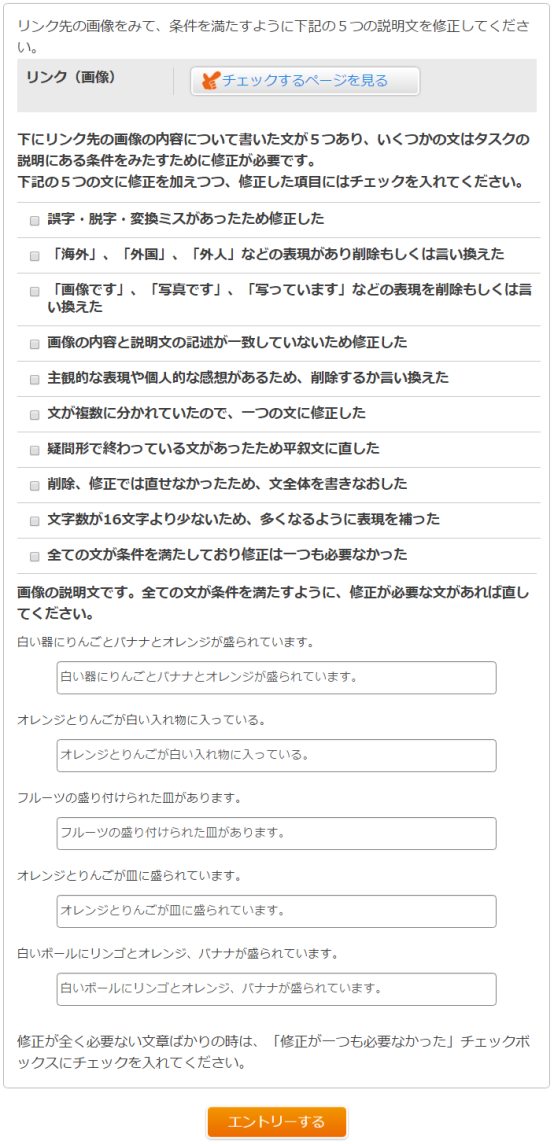

Figure 2: Data Cleaning Task User Interface

45,909. To our surprise, a relatively large portion of the captions were fixed by the participants. We suspect that in our data-cleaning task, the condition (e) was especially ambiguous for the participants, and they errored on the cautious side, fixing "a living room" to just "a room", thinking that a room that looks like a living room may not be a living room for the family who occupies the house, for example. Another example includes fixing "beautiful flowers" to just "flowers" because beauty is in the eye of the beholder and thought to be subjective. The percentage of the ticked checkboxes is as follows: (a) 27.2%, (b) 5.0%, (c) 12.3%, (d) 34.1%, (e) 28.4%, (f) 3.9%, (g) 0.3%, (h) 11.6%, (i) 18.5%, and (j) 24.0%. Note that a checkbox is ticked if there is at least one sentence out of five that meets the condition. In machine learning, this setting is called multiple-instance multiple-label problem (Zhou et al., 2012). We cannot directly infer how many captions correspond to a condition ticked by the participants.

After this data-cleaning task, we further removed a few more bad captions that came to our attention. The resulting corpus finally contains 131,740 captions as noted in the previous section.

4 Methodology

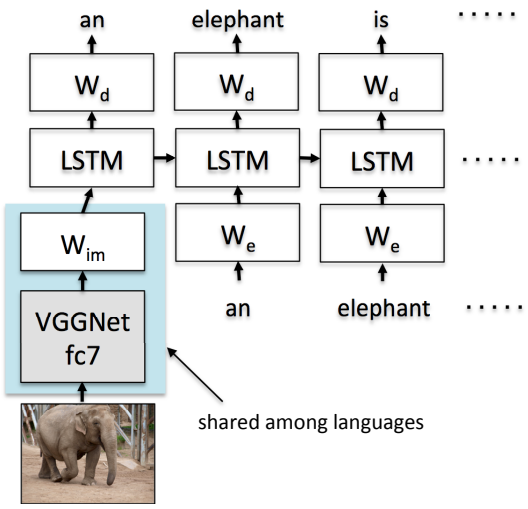

Figure 3: Model Overview

4.1 Model Overview

Figure 3 shows an overview of our model. Following the approach of Vinyals et al. (Vinyals et al., 2015), we used a discriminative model that maximizes the probability of the correct description given the image. Our model is formulated as

$$\theta^* = \arg\max_{\theta} \sum_{(I,S)} \sum_{t=0}^{N} \log p(S_t|I, S_0, ..., S_{t-1}; \theta), \quad (1)$$

where the first summation is over pairs of an image I and its correct transcription S. For the second summation, the sum is over all words S_t in S, and N is the length of S. θ represents the model parameters. Note that the second summation represents the probability of the sentence with respect to the joint probability of its words.

We modeled $p(S_t|I, S_0, ..., S_{t-1}; \theta)$ by using a recurrent neural network (RNN). To model the sequences in the RNN, we let a fixed length hidden state or memory h_t express the variable number of words to be conditioned up to $t-1$. The h_t

is updated after obtaining a new input x_t using a non-linear function f, so that $h_{t+1} = f(h_t, x_t)$. Since an LSTM network has state-of-the art performance in sequence modeling such as machine translation, we use one for f, which we explain in the next section.

A combination of LSTM and CNN are used to model $p(S_t|I, S_0, ..., S_{t-1}; \theta)$.

$$x_{-1} = W_{im}CNN(I) \quad (2)$$

$$x_t = W_e S_t, t \in \{0...N-1\} \quad (3)$$

$$p_{t+1} = Softmax(W_d LSTM(x_t)), \quad t \in \{0...N-1\} \quad (4)$$

where W_{im} is an image feature encoding matrix, W_e is a word embedding matrix, and W_d is a word decoding matrix.

4.2 LSTM-based Language Model

An LSTM is an RNN that addresses the vanishing and exploding gradients problem and that handles longer dependencies well. An LSTM has a memory cell and various gates to control the input, the output, and the memory behaviors. We use an LSTM with input gate i_t, input modulation gate g_t, output gate o_t, and forgetting gate f_t. The number of hidden units h_t is 256. At each time step t, the LSTM state c_t, h_t is as follows:

$$i_t = \sigma(W_{ix}x_t + W_{ih}h_{t-1} + b_i) \quad (5)$$

$$f_t = \sigma(W_{fx}x_t + W_{fh}h_{t-1} + b_f) \quad (6)$$

$$o_t = \sigma(W_{ox}x_t + W_{oh}h_{t-1} + b_o) \quad (7)$$

$$g_t = \phi(W_{cx}x_t + W_{ch}h_{t-1} + b_c) \quad (8)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot g_t \quad (9)$$

$$h_t = o_t \odot \phi(c_t), \quad (10)$$

where $\sigma(x) = (1 + e^{-x})^{-1}$ is a sigmoid function, $\phi(x) = (e^x - e^{-x})/(e^x + e^{-x})$ is a hyperbolic tangent function, and $\odot$ denotes the element-wise product of two vectors. W and b are parameters to be learned. From the values of the hidden units h_t, the probability distribution of words is calculated as

$$p_{t+1} = Softmax(W_d h_t). \quad (11)$$

We use a simple greedy search to generate captions as a sequence of words, and, at each time step t, the predicted word is obtained using $S_t = \arg\max_S p_t$.

4.3 Image Feature Extraction with Deep Convolutional Neural Network

The image recognition performance of deep convolutional neural network models has rapidly advanced in recent years, and they are now widely used for various image recognition tasks. We used a 16-layer VGGNet (Simonyan and Zisserman, 2014), which was a top performer at the ImageNet Large Scale Visual Recognition Challenge in 2014. A 16-layer VGGNet is composed of 13 convolutional layers having small 3x3 filter kernels and 3 fully connected layers. An image feature is extracted as a 4096-dimensional vector of the VGGNet's fc7 layer, which is the second fully connected layer from the output layer. VGGNet was pretrained using the ILSVRC2014 subset of the ImageNet dataset, and its weights were not updated through training.

4.4 Dataset Split

Because our caption dataset is annotated for only 26,500 images of the MS COCO training set, we reorganized the dataset split for our experiments. Training and validation set images of the MS COCO dataset were mixed and split into four blocks, and these blocks were assigned to training, validation, and testing as shown in Table 1. All blocks were used for the English caption dataset. Blocks B, C, and D were used for the Japanese caption dataset.

block	no. of images	split	language
A	96,787	train	En
B	22,500	train	En, Ja
C	2,000	val	En, Ja
D	2,000	test	En, Ja
total	123,287		

Table 1: Dataset Split

4.5 Training

The models were trained using minibatch stochastic gradient descent, and the gradients were computed by backpropagation through time. Parameter optimization was done using the RMSprop algorithm (Tieleman and Hinton, 2012) with an initial learning rate of 0.001, a decay rate of 0.999, and ϵ of 1.0^{-8}. Each image minibatch contained 100 image features, and the corresponding caption minibatch contained one sampled caption per image. To evaluate the effectiveness of Japanese

image caption generation, we used three learning schemes.

Monolingual learning This was the baseline method. The model had only one LSTM for Japanese caption generation, and only the Japanese caption corpus was used for training.

Alternate learning In this scheme, a model had two LSTMs, one for English and one for Japanese. The training batches for captions contained either English or Japanese, and the batches were fed into the model alternating between English and Japanese.

Transfer learning A model with one LSTM was trained completely for the English dataset. The trained LSTM was then removed, and another LSTM was added for Japanese caption generation. W_{im} was shared between the English and Japanese training.

These models were implemented using the Chainer neural network framework (Tokui et al., 2015). We consulted NeuralTalk (Karpathy, 2014), an open source implemenation of neural network based image caption generation system, for training parameters and dataset preprocessing. Training took about one day using NVIDIA TITAN X/Tesla M40 GPUs.

5 Evaluation

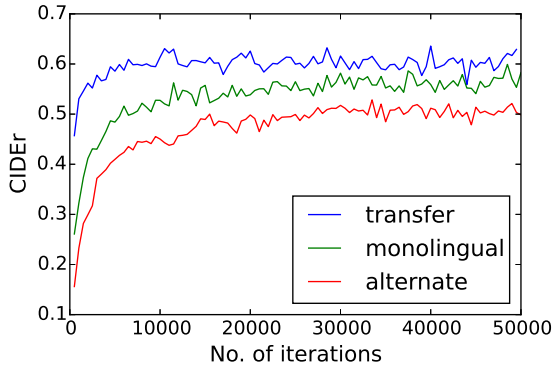

Figure 4: Learning Curve Represented by CIDEr Score

5.1 Evaluation Metrics

We used six standard metrics for evaluating the quality of the generated Japanese sentences: BLEU-1, BLEU-2, BLEU-3, BLEU-4 (Papineni et al., 2002), ROUGE-L (Lin, 2004), and CIDEr-D (Vedantam et al., 2014). We used the COCO caption evaluation tool (Chen et al., 2015b) to compute the metrics. BLEU (Papineni et al., 2002) was originally designed for automatic machine translation. By counting n-gram co-occurrences, it rates the quality of a translated sentence given several reference sentences. To apply BLEU, we considered that generating image captions is the same as translating images into sentences. ROUGE (Lin, 2004) is an evaluation metric designed by adapting BLEU to evaluate automatic text summarization algorithms. ROUGE is based on the longest common subsequences instead of n-grams. CIDEr (Vedantam et al., 2014) is a metric developed specifically for evaluating image captions. It measures consensus in image captions by performing a term-frequency inverse document frequency (TF-IDF) weighting for each n-gram. We used a robust variant of CIDEr called CIDEr-D. For all evaluation metrics, higher scores are better. In addition to these metrics, MS COCO caption evaluation (Chen et al., 2015b) uses METEOR (Lavie, 2014), another metric for evaluating automatic machine translation. Although METEOR is a good metric, it uses an English thesaurus. It was not used in our study due to the lack of a thesaurus for the Japanese language.

The CIDEr and METEOR metrics perform well in terms of correlation with human judgment (Bernardi et al., 2016). Although BLEU is unable to sufficiently discriminate between judgments, we report the BLEU figures as well since their use in literature is widespread. In the next section, we focus our analysis on CIDEr.

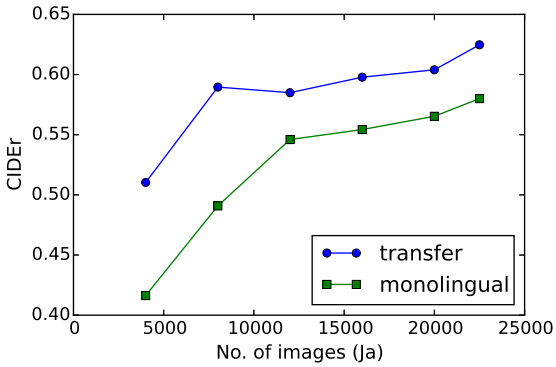

Figure 5: CIDEr Score vs. Japanese Data Set Size

5.2 Results

Table 2 shows the evaluation metrics for various settings of cross-lingual transfer learning. All values were calculated for Japanese captions gener-

	no. of images		metrics					
	En	Ja	BLEU-1	BLEU-2	BLEU-3	BLEU-4	ROUGE-L	CIDEr-D
monolingual	0	22,500	0.715	0.573	0.468	0.379	0.616	0.580
alternate	119,287	22,500	0.709	0.565	0.460	0.370	0.611	0.568
transfer	119,287	22,500	**0.717**	**0.574**	**0.469**	**0.380**	**0.619**	**0.625**

Table 2: Evaluation Metrics

ated for test set images. Our proposed model is labeled "transfer." As you can see, it outperformed the other two models for every metric. In particular, the CIDEr-D score was about 4% higher than that for the monolingual baseline. The performance of a model trained using the English and Japanese corpora alternately is shown on the line label "alternate." Surprisingly, this model had lower performance than the baseline model.

In Figure 4, we plot the learning curves represented by the CIDEr score for the Japanese captions generated for the validation set images. Transfer learning from English to Japanese converged faster than learning from the Japanese dataset or learning by training from both languages alternately. Figure 5 shows the relationship between the CIDEr score and the Japanese dataset size (number of images). The models pretrained using English captions (blue line) outperformed the ones trained using only Japanese captions for all training dataset sizes. As can be seen by comparing the case of 4,000 images with that of 20,000 images, the improvement due to cross-lingual transfer was larger when the Japanese dataset was smaller. These results show that pretraining the model with all available English captions is roughly equivalent to training the model with captions for 10,000 additional images in Japanese. This, in our case, nearly halves the cost of building the corpus.

Examples of machine-generated captions along with the crowd-written ground truth captions (English translations) are shown in Figure 6.

6 Discussion

Despite our initial belief, training by alternating English and Japanese input batch data for learning both languages did not work well for either language. As Japanese is a morphologically rich language and word ordering is subject-object-verb, it is one of most distant languages from English. We suspect that the alternating batch training interfered with learning the syntax of either language. Moreover, when we tried character-based models for both languages, the performance was significantly lower. This was not surprising because one word in English is roughly two characters in Japanese, and presumably differences in the language unit should affect performance. Perhaps not surprisingly, cross-lingual transfer was more effective when the resources in the target language are poor. Convergence was faster with the same amount of data in the target language when pretraining in the source language was done ahead of time. These two findings ease the burden of developing a large corpus in a resource poor language.

7 Conclusion

We have created an image caption dataset for the Japanese language by collecting 131,740 captions for 26,500 images using the Yahoo! Crowdsourcing service in Japan. We showed that pretraining a neural image caption model with the English portion of the corpus improves the performance of a Japanese caption generation model subsequently trained using Japanese data. Pretraining the model using the English captions of 119,287 images was roughly equivalent to training the model using the captions of 10,000 additional images in Japanese. This, in our case, nearly halves the cost of building a corpus. Since this performance gain is obtained without modifying the original monolingual image caption generator, the proposed model can serve as a strong baseline for future research in this area. We hope that our dataset and proposed method kick start studies on cross-lingual image caption generation and that many others follow our lead.

Abstract

We study the problem of automatically building hypernym taxonomies from textual and visual data. Previous works in taxonomy induction generally ignore the increasingly prominent visual data, which encode important perceptual semantics. Instead, we propose a probabilistic model for taxonomy induction by jointly leveraging text and images. To avoid hand-crafted feature engineering, we design end-to-end features based on distributed representations of images and words. The model is discriminatively trained given a small set of existing ontologies and is capable of building full taxonomies from scratch for a collection of unseen conceptual label items with associated images. We evaluate our model and features on the WordNet hierarchies, where our system outperforms previous approaches by a large gap.

1 Introduction

Human knowledge is naturally organized as semantic hierarchies. For example, in WordNet (Miller, 1995), specific concepts are categorized and assigned to more general ones, leading to a semantic hierarchical structure (a.k.a taxonomy). A variety of NLP tasks, such as question answering (Harabagiu et al., 2003), document clustering (Hotho et al., 2002) and text generation (Biran and McKeown, 2013) can benefit from the conceptual relationship present in these hierarchies.

Traditional methods of manually constructing taxonomies by experts (e.g. WordNet) and interest communities (e.g. Wikipedia) are either knowledge or time intensive, and the results have limited coverage. Therefore, automatic induction of taxonomies is drawing increasing attention in both

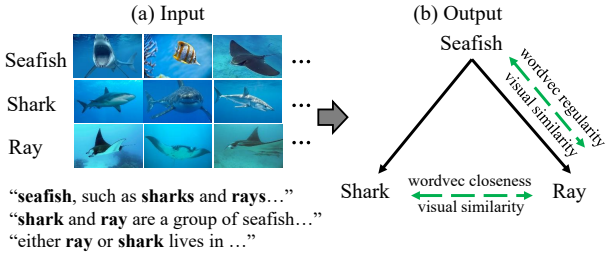

Figure 1: An overview of our system. (a) Input: a collection of label items, represented by text and images; (b) Output: we build a taxonomy from scratch by extracting features based on distributed representations of text and images.

NLP and computer vision. On one hand, a number of methods have been developed to build hierarchies based on lexical patterns in text (Yang and Callan, 2009; Snow et al., 2006; Kozareva and Hovy, 2010; Navigli et al., 2011; Fu et al., 2014; Bansal et al., 2014; Tuan et al., 2015). These works generally ignore the rich visual data which encode important perceptual semantics (Bruni et al., 2014) and have proven to be complementary to linguistic information and helpful for many tasks (Silberer and Lapata, 2014; Kiela and Bottou, 2014; Zhang et al., 2015; Chen et al., 2013). On the other hand, researchers have built visual hierarchies by utilizing only visual features (Griffin and Perona, 2008; Yan et al., 2015; Sivic et al., 2008). The resulting hierarchies are limited in interpretability and usability for knowledge transfer.

Hence, we propose to combine both visual and textual knowledge to automatically build taxonomies. We induce *is-a* taxonomies by supervised learning from existing entity ontologies where each concept category (entity) is associated with images, either from existing dataset (e.g. ImageNet (Deng et al., 2009)) or retrieved from the web using search engines, as illustrated in Fig 1. Such a scenario is realistic and can be extended to a variety of tasks; for example, in knowledge base

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1791–1801,
Berlin, Germany, August 7-12, 2016.

construction (Chen et al., 2013), text and image collections are readily available but label relations among categories are to be uncovered. In large-scale object recognition, automatically learning relations between labels can be quite useful (Deng et al., 2014; Zhao et al., 2011).

Both textual and visual information provide important cues for taxonomy induction. Fig 1 illustrates this via an example. The parent category *seafish* and its two child categories *shark* and *ray* are closely related as: (1) there is a hypernym-hyponym (*is-a*) relation between the words "seafish" and "shark"/"ray" through text descriptions like "...seafish, such as shark and ray...", "...shark and ray are a group of seafish..."; (2) images of the close neighbors, e.g., *shark* and *ray* are usually visually similar and images of the child, e.g. *shark/ray* are similar to a subset of images of *seafish*. To effectively capture these patterns, in contrast to previous works that rely on various hand-crafted features (Chen et al., 2013; Bansal et al., 2014), we extract features by leveraging the *distributed representations* that embed images (Simonyan and Zisserman, 2014) and words (Mikolov et al., 2013) as compact vectors, based on which the semantic closeness is directly measured in vector space. Further, we develop a probabilistic framework that integrates the rich multi-modal features to induce "is-a" relations between categories, encouraging *local semantic consistency* that each category should be visually and textually close to its parent and siblings.

In summary, this paper has the following contributions: (1) We propose a novel probabilistic Bayesian model (Section 3) for taxonomy induction by jointly leveraging textual and visual data. The model is discriminatively trained and can be directly applied to build a taxonomy from scratch for a collection of semantic labels. (2) We design novel features (Section 4) based on general-purpose distributed representations of text and images to capture both textual and visual relations between labels. (3) We evaluate our model and features on the ImageNet hierarchies with two different taxonomy induction tasks (Section 5). We achieve superior performance on both tasks and improve the F_1 score by 2x in the *taxonomy construction* task, compared to previous approaches. Extensive comparisons demonstrate the effectiveness of integrating visual features with language features for taxonomy induction. We also provide qualitative analysis on our features, the learned model, and the taxonomies induced to provide further insights (Section 5.3).

2 Related Work

Many approaches have been recently developed that build hierarchies purely by identifying either lexical patterns or statistical features in text corpora (Yang and Callan, 2009; Snow et al., 2006; Kozareva and Hovy, 2010; Navigli et al., 2011; Zhu et al., 2013; Fu et al., 2014; Bansal et al., 2014; Tuan et al., 2014; Tuan et al., 2015; Kiela et al., 2015). The approaches in Yang and Callan (2009) and Snow et al. (2006) assume a starting incomplete hierarchy and try to extend it by inserting new terms. Kozareva and Hovy (2010) and Navigli et al. (2011) first find leaf nodes and then use lexical patterns to find intermediate terms and all the attested hypernymy links between them. In (Tuan et al., 2014), syntactic contextual similarity is exploited to construct the taxonomy, while Tuan et al. (2015) go one step further to consider trustiness and collective synonym/contrastive evidence. Different from them, our model is discriminatively trained with multi-modal data. The works of Fu et al. (2014) and Bansal et al. (2014) use similar language-based features as ours. Specifically, in (Fu et al., 2014), linguistic regularities between pretrained word vectors (Mikolov et al., 2013) are modeled as projection mappings. The trained projection matrix is then used to induce pairwise hypernym-hyponym relations between words. Our features are partially motivated by Fu et al. (2014), but we jointly leverage both textual and visual information. In Kiela et al. (2015), both textual and visual evidences are exploited to detect pairwise lexical entailments. Our work is significantly different as our model is optimized over the whole taxonomy space rather than considering only word pairs separately. In (Bansal et al., 2014), a structural learning model is developed to induce a globally optimal hierarchy. Compared with this work, we exploit much richer features from both text and images, and leverage distributed representations instead of hand-crafted features.

Several approaches (Griffin and Perona, 2008; Bart et al., 2008; Marszałek and Schmid, 2008) have also been proposed to construct visual hierarchies from image collections. In (Bart et al., 2008), a nonparametric Bayesian model is developed to group images based on low-level features.

In (Griffin and Perona, 2008) and (Marszałek and Schmid, 2008), a visual taxonomy is built to accelerate image categorization. In (Chen et al., 2013), only binary object-object relations are extracted using co-detection matrices. Our work differs from all of these as we integrate textual with visual information to construct taxonomies.

Also of note are several works that integrate text and images as evidence for knowledge base autocompletion (Bordes et al., 2011) and zero-shot recognition (Gan et al., 2015; Gan et al., ; Socher et al., 2013). Our work is different because our task is to accurately construct multi-level hyponym-hypernym hierarchies from a set of (seen or unseen) categories.

3 Taxonomy Induction Model

Our model is motivated by the key observation that in a semantically meaningful taxonomy, a category tends to be closely related to its children as well as its siblings. For instance, there exists a hypernym-hyponym relation between the name of category *shark* and that of its parent *seafish*. Besides, images of *shark* tend to be visually similar to those of *ray*, both of which are seafishes. Our model is thus designed to encourage such local semantic consistency; and by jointly considering all categories in the inference, a globally optimal structure is achieved. A key advantage of the model is that we incorporate both visual and textual features induced from distributed representations of images and text (Section 4). These features capture the rich underlying semantics and facilitate taxonomy induction. We further distinguish the relative importance of visual and textual features that could vary in different layers of a taxonomy. Intuitively, visual features would be increasingly indicative in the deeper layers, as sub-categories under the same category of specific objects tend to be visually similar. In contrast, textual features would be more important when inducing hierarchical relations between the categories of general concepts (i.e. in the near-root layers) where visual characteristics are not necessarily similar.

3.1 The Problem

Assume a set of N categories $\boldsymbol{x} = \{x_1, x_2, \dots, x_N\}$, where each category x_n consists of a text term t_n as its name, as well as a set of images $\boldsymbol{i}_n = \{i_1, i_2, \dots\}$. Our goal is to construct a taxonomy tree T over these categories[1], such that categories of specific object types (e.g. shark) are grouped and assigned to those of general concepts (e.g. seafish). As the categories in $\boldsymbol{x}$ may be from multiple disjoint taxonomy trees, we add a *pseudo* category x_0 as the hyper-root so that the optimal taxonomy is ensured to be a single tree. Let $z_n \in \{1, \dots, N\}$ be the index of the parent of category x_n, i.e. x_{z_n} is the hypernymic category of x_n. Thus the problem of inducing a taxonomy structure is equivalent to inferring the conditional distribution $p(\boldsymbol{z}|\boldsymbol{x})$ over the set of (latent) indices $\boldsymbol{z} = \{z_1, \dots, z_n\}$, based on the images and text.

3.2 Model

We formulate the distribution $p(\boldsymbol{z}|\boldsymbol{x})$ through a model which leverages rich multi-modal features. Specifically, let $\boldsymbol{c}_n$ be the set of child nodes of category x_n in a taxonomy encoded by $\boldsymbol{z}$. Our model is defined as

$$p_w(\boldsymbol{z}, \boldsymbol{\pi}|\boldsymbol{x}, \boldsymbol{\alpha}) \propto p(\boldsymbol{\pi}|\boldsymbol{\alpha}) \prod_{n=1}^{N} \prod_{x_{n'} \in \boldsymbol{c}_n} \pi_n g_w(x_n, x_{n'}, \boldsymbol{c}_n \backslash x_{n'})$$

where $g_w(x_n, x_{n'}, \boldsymbol{c}_n \backslash x_{n'})$, defined as (1)

$$g_w(x_n, x_{n'}, \boldsymbol{c}_n \backslash x_{n'}) = \exp\{\boldsymbol{w}_{d(x_{n'})}^{\top} \boldsymbol{f}_{n,n',\boldsymbol{c}_n \backslash x_{n'}}\},$$

measures the semantic consistency between category $x_{n'}$, its parent x_n as well as its siblings indexed by $\boldsymbol{c}_n \backslash x_{n'}$. The function $g_w(\cdot)$ is loglinear with respect to $\boldsymbol{f}_{n,n',\boldsymbol{c}_n \backslash x_{n'}}$, which is the feature vector defined over the set of relevant categories $(x_n, x_{n'}, \boldsymbol{c}_n \backslash x_{n'})$, with $\boldsymbol{c}_n \backslash x_{n'}$ being the set of child categories excluding $x_{n'}$ (Section 4). The simple exponential formulation can effectively encourage close relations among nearby categories in the induced taxonomy. The function has combination weights $\boldsymbol{w} = \{\boldsymbol{w}_1, \dots, \boldsymbol{w}_L\}$, where L is the maximum depth of the taxonomy, to capture the importance of different features, and the function $d(x_{n'})$ to return the depth of $x_{n'}$ in the current taxonomy. Each layer l $(1 \le l \le L)$ of the taxonomy has a specific $\boldsymbol{w}_l$ thereby allowing varying weights of the same features in different layers. The parameters are learned in a *supervised* manner. In eq 1, we also introduce a weight π_n for each node x_n, in order to capture the varying popularity of different categories (in terms of being a parent category). For example, some categories like

[1] We assume T to be a tree. Most existing taxonomies are modeled as trees (Bansal et al., 2014), since a tree helps simplify the construction and ensures that the learned taxonomy is interpretable. With minor modifications, our model also works on non-tree structures.

plant can have a large number of sub-categories, while others such as *stone* have less. We model $\boldsymbol{\pi}$ as a multinomial distribution with Dirichlet prior $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_N)$ to encode any prior knowledge of the category popularity[2]; and the conjugacy allows us to marginalize out $\boldsymbol{\pi}$ analytically to get

$$p_w(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{\alpha}) \propto \int p(\boldsymbol{\pi}|\boldsymbol{\alpha}) \prod_{n=1}^{N} \prod_{x_{n'} \in \boldsymbol{c}_n} \pi_n g_w(x_n, x_{n'}, \boldsymbol{c}_n \backslash x_{n'}) d\boldsymbol{\pi}$$
$$\propto \prod_n \Gamma(q_n + \alpha_n) \prod_{x_{n'} \in \boldsymbol{c}_n} g_w(x_n, x_{n'}, \boldsymbol{c}_n \backslash x_{n'}) \tag{2}$$

where q_n is the number of children of category x_n.

Next, we describe our approach to infer the expectation for each z_n, and based on that select a particular taxonomy structure for the category nodes $\boldsymbol{x}$. As $\boldsymbol{z}$ is constrained to be a tree (i.e. cycle without loops), we include with eq 2, an indicator factor $\mathbf{1}(\boldsymbol{z})$ that takes 1 if $\boldsymbol{z}$ corresponds a tree and 0 otherwise. We modify the inference algorithm appropriately to incorporate this constraint.

Inference. Exact inference is computationally intractable due to the normalization constant of eq 2. We therefore use Gibbs Sampling, a procedure for approximate inference. Here we present the sampling formula for each z_n directly, and defer the details to the supplementary material. The sampling procedure is highly efficient because the normalization term and the factors that are irrelevant to z_n are cancelled out. The formula is

$$p(z_n = m|\boldsymbol{z} \backslash z_n, \cdot) \propto \mathbf{1}(z_n = m, \boldsymbol{z} \backslash z_n) \cdot \left(q_m^{-n} + \alpha_m\right) \cdot \frac{\prod_{x_{n'} \in \boldsymbol{c}_m \cup \{x_n\}} g_w(x_m, x_{n'}, \boldsymbol{c}_m \cup \{x_n\})}{\prod_{x_{n'} \in \boldsymbol{c}_m \backslash x_n} g_w(x_m, x_{n'}, \boldsymbol{c}_m \backslash x_n)}, \tag{3}$$

where q_m is the number of children of category m; the superscript $-n$ denotes the number excluding x_n. Examining the validity of the taxonomy structure (i.e. the tree indicator) in each sampling step can be computationally prohibitive. To handle this, we restrict the candidate value of z_n in eq 3, ensuring that the new z_n is always a tree. Specifically, given a tree T, we define a *structure operation* as the procedure of detaching one node x_n in T from its parent and appending it to another node x_m which is not a descendant of x_n.

Proposition 1. *(1) Applying a structure operation on a tree T will result in a structure that is still a tree. (2) Any tree structure over the node set $\boldsymbol{x}$ that has the same root node with tree T can be achieved by applying structure operation on T a finite number of times.*

[2] $\boldsymbol{\alpha}$ could be estimated using training data.

The proof is straightforward and we omit it due to space limitations. We also add a pseudo node x_0 as the fixed root of the taxonomy. Hence by initializing a tree-structured state rooted at x_0 and restricting each updating step as a structure operation, our sampling procedure is able to explore the whole valid tree space.

Output taxonomy selection. To apply the model to discover the underlying taxonomy from a given set of categories, we first obtain the marginals of $\boldsymbol{z}$ by averaging over the samples generated through eq 3, then output the optimal taxonomy $\boldsymbol{z}^*$ by finding the maximum spanning tree (MST) using the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Bansal et al., 2014).

Training. We need to learn the model parameters $\boldsymbol{w}_l$ of each layer l, which capture the relative importance of different features. The model is trained using the EM algorithm. Let $\ell(x_n)$ be the depth (layer) of category x_n; and $\tilde{\boldsymbol{z}}$ (siblings $\tilde{\boldsymbol{c}}_n$) denote the gold structure in training data. Our training algorithm updates $\boldsymbol{w}$ through maximum likelihood estimation, wherein the gradient of $\boldsymbol{w}_l$ is (see the supplementary materials for details):

$$\delta \boldsymbol{w}_l = \sum_{n:\ell(x_n)=l} \{\boldsymbol{f}(x_{\tilde{z}_n}, x_n, \tilde{\boldsymbol{c}}_n \backslash x_n) - \mathbb{E}_p[\boldsymbol{f}(x_{z_n}, x_n, \boldsymbol{c}_n \backslash x_n)]\},$$

which is the net difference between gold feature vectors and expected feature vectors as per the model. The expectation is approximated by collecting samples using the sampler described above and averaging them.

4 Features

In this section, we describe the feature vector $\boldsymbol{f}$ used in our model, and defer more details in the supplementary material. Compared to previous taxonomy induction works which rely purely on linguistic information, we exploit both perceptual and textual features to capture the rich spectrum of semantics encoded in images and text. Moreover, we leverage the *distributed representations* of images and words to construct compact and effective features. Specifically, each image i is represented as an embedding vector $\boldsymbol{v}_i \in \mathbb{R}^a$ extracted by deep convolutional neural networks. Such image representation has been successfully applied in various vision tasks. On the other hand, the category name t is represented by its word embedding $\boldsymbol{v}_t \in \mathbb{R}^b$, a low-dimensional dense vector induced by the Skip-gram model (Mikolov et

al., 2013) which is widely used in diverse NLP applications too. Then we design $\boldsymbol{f}(x_n, x_{n'}, \boldsymbol{c}_n \backslash x_{n'})$ based on the above image and text representations. The feature vector $\boldsymbol{f}$ is used to measure the local semantic consistency between category $x_{n'}$ and its parent category x_n as well as its siblings $\boldsymbol{c}_n \backslash x_{n'}$.

4.1 Image Features

Sibling similarity. As mentioned above, close neighbors in a taxonomy tend to be visually similar, indicating that the embedding of images of sibling categories should be close to each other in the vector space $\mathbb{R}^a$. For a category x_n and its image set $\boldsymbol{i}_n$, we fit a Gaussian distribution $\mathcal{N}(\overline{\boldsymbol{v}}_{\boldsymbol{i}_n}, \Sigma_n)$ to the image vectors, where $\overline{\boldsymbol{v}}_{\boldsymbol{i}_n} \in \mathbb{R}^a$ is the mean vector and $\Sigma_n \in \mathbb{R}^{a \times a}$ is the covariance matrix. For a sibling category x_m of x_n, we define the visual similarity between x_n and x_m as

$$vissim(x_n, x_m) = [\mathcal{N}(\overline{\boldsymbol{v}}_{\boldsymbol{i}_m}; \overline{\boldsymbol{v}}_{\boldsymbol{i}_n}, \Sigma_n) + \mathcal{N}(\overline{\boldsymbol{v}}_{\boldsymbol{i}_n}; \overline{\boldsymbol{v}}_{\boldsymbol{i}_m}, \Sigma_m)]/2$$

which is the average probability of the mean image vector of one category under the Gaussian distribution of the other. This takes into account not only the distance between the mean images, but also the closeness of the images of each category. Accordingly, we compute the visual similarity between $x_{n'}$ and the set $\boldsymbol{c}_n \backslash x_{n'}$ by averaging:

$$vissim(x_{n'}, \boldsymbol{c}_n \backslash x_{n'}) = \frac{\sum_{x_m \in \boldsymbol{c}_n \backslash x_{n'}} vissim(x_{n'}, x_m)}{|\boldsymbol{c}_n| - 1}.$$

We then bin the values of $vissim(x_{n'}, \boldsymbol{c}_n \backslash x_{n'})$ and represent it as an one-hot vector, which constitutes $\boldsymbol{f}$ as a component named as *siblings image-image relation feature* (denoted as *S-V1*[3]).

Parent prediction. Similar to feature S-V1, we also create the similarity feature between the image vectors of the parent and child, to measure their visual similarity. However, the parent node is usually a more general concept than the child, and it usually consists of images that are not necessarily similar to its child. Intuitively, by narrowing the set of images to those that are most similar to its child improves the feature. Therefore, different from S-V1, when estimating the Gaussian distribution of the parent node, we only use the top K images with highest probabilities under the Gaussian distribution of the child node. We empirically show in section 5.3 that choosing an appropriate K consistently boosts the performance. We name this feature as *parent-child image-image relation feature* (denoted as *PC-V1*).

[3]S: sibling, PC: parent-child, V: visual, T: textual.

Further, inspired by the linguistic regularities of word embedding, i.e. the hypernym-hyponym relationship between words can be approximated by a linear projection operator between word vectors (Mikolov et al., 2013; Fu et al., 2014), we design a similar strategy to (Fu et al., 2014) between images and words so that the parent can be "predicted" given the image embedding of its child category and the projection matrix. Specifically, let $(x_n, x_{n'})$ be a parent-child pair in the training data, we learn a projection matrix $\boldsymbol{\Phi}$ which minimizes the distance between $\boldsymbol{\Phi}\overline{\boldsymbol{v}}_{\boldsymbol{i}_{n'}}$ (i.e. the projected mean image vector $\overline{\boldsymbol{v}}_{\boldsymbol{i}_{n'}}$ of the child) and $\boldsymbol{v}_{t_n}$ (i.e. the word embedding of the parent):

$$\boldsymbol{\Phi}^* = \underset{\boldsymbol{\Phi}}{\operatorname{argmin}} \frac{1}{N} \sum_n \|\boldsymbol{\Phi}\overline{\boldsymbol{v}}_{\boldsymbol{i}_{n'}} - \boldsymbol{v}_{t_n}\|_2^2 + \lambda \|\boldsymbol{\Phi}\|_1,$$

where N is the number of parent-child pairs in the training data. Once the projection matrix has been learned, the similarity between a child node $x_{n'}$ and its parent x_n is computed as $\|\boldsymbol{\Phi}\overline{\boldsymbol{v}}_{\boldsymbol{i}_{n'}} - \boldsymbol{v}_{t_n}\|$, and we also create an one-hot vector by binning the feature value. We call this feature as *parent-child image-word relation feature* (*PC-V2*).

4.2 Word Features

We briefly introduce the text features employed. More details about the text feature extraction could be found in the supplementary material.

Word embedding features.d PC-V1, We induce features using word vectors to measure both sibling-sibling and parent-child closeness in text domain (Fu et al., 2014). One exception is that, as each category has only one word, the sibling similarity is computed as the cosine distance between two word vectors (instead of mean vectors). This will produce another two parts of features, *parent-child word-word relation feature* (*PC-T1*) and *siblings word-word relation feature* (*S-T1*).

Word surface features. In addition to the embedding-based features, we further leverage lexical features based on the surface forms of child/parent category names. Specifically, we employ the *Capitalization*, *Ends with*, *Contains*, *Suffix match*, *LCS* and *Length different* features, which are commonly used in previous works in taxonomy induction (Yang and Callan, 2009; Bansal et al., 2014).

5 Experiments

We first disclose our implementation details in section 5.1 and the supplementary material for bet-

ter reproducibility. We then compare our model with previous state-of-the-art methods (Fu et al., 2014; Bansal et al., 2014) with two taxonomy induction tasks. Finally, we provide analysis on the weights and taxonomies induced.

5.1 Implementation Details

Dataset. We conduct our experiments on the ImageNet2011 dataset (Deng et al., 2009), which provides a large collection of category items (synsets), with associated images and a label hierarchy (sampled from WordNet) over them. The original ImageNet taxonomy is preprocessed, resulting in a tree structure with 28231 nodes.

Word embedding training. We train word embedding for synsets by replacing each word/phrase in a synset with a unique token and then using Google's word2vec tool (Mikolov et al., 2013). We combine three public available corpora together, including the latest Wikipedia dump (Wikipedia, 2014), the One Billion Word Language Modeling Benchmark (Chelba et al., 2013) and the UMBC webbase corpus (Han et al., 2013), resulting in a corpus with total 6 billion tokens. The dimension of the embedding is set to 200.

Image processing. we employ the ILSVRC12 pre-trained convolutional neural networks (Simonyan and Zisserman, 2014) to embed each image into the vector space. Then, for each category x_n with images, we estimate a multivariate Gaussian parameterized by $\mathcal{N}_{x_n} = (\mu_{x_n}, \Sigma_{x_n})$, and constrain Σ_{x_n} to be diagonal to prevent overfitting. For categories with very few images, we only estimate a mean vector μ_{x_n}. For nodes that do not have images, we ignore the visual feature.

Training configuration. The feature vector is a concatenation of 6 parts, as detailed in section 4. All pairwise distances are precomputed and stored in memory to accelerate Gibbs sampling. The initial learning rate for gradient descent in the M step is set to 0.1, and is decreased by a fraction of 10 every 100 EM iterations.

5.2 Evaluation

5.2.1 Experimental Settings

We evaluate our model on three subtrees sampled from the ImageNet taxonomy. To collect the subtrees, we start from a given root (e.g. consumer goods) and traverse the full taxonomy using BFS, and collect all descendant nodes within a depth h (number of nodes in the longest path). We vary h to get a series of subtrees with increasing heights $h \in \{4, 5, 6, 7\}$ and various scales (maximally 1326 nodes) in different domains. The statistics of the evaluation sets are provided in Table 1. To avoid ambiguity, all nodes used in ILSVRC 2012 are removed as the CNN feature extractor is trained on them.

Trees	Tree A	Tree B	Tree C
Synset ID	12638	19919	23733
Name	consumer goods	animal	food, nutrient
$h = 4$	187	207	572
$h = 5$	362	415	890
$h = 6$	493	800	1166
$h = 7$	524	1386	1326

Table 1: Statistics of our evaluation set. The bottom 4 rows give the number of nodes within each height $h \in \{4, 5, 6, 7\}$. The scale of the threes range from small to large, and there is no overlapping among them.

We design two different tasks to evaluate our model. (1) In the *hierarchy completion* task, we randomly remove some nodes from a tree and use the remaining hierarchy for training. In the test phase, we infer the parent of each removed node and compare it with groundtruth. This task is designed to figure out whether our model can successfully induce hierarchical relations after learning from within-domain parent-child pairs. (2) Different from the previous one, the *hierarchy construction* task is designed to test the generalization ability of our model, i.e. whether our model can learn statistical patterns from one hierarchy and transfer the knowledge to build a taxonomy for another collection of out-of-domain labels. Specifically, we select two trees as the training set to learn $\boldsymbol{w}$. In the test phase, the model is required to build the full taxonomy from scratch for the third tree.

We use *Ancestor* F_1 as our evaluation metric (Kozareva and Hovy, 2010; Navigli et al., 2011; Bansal et al., 2014). Specifically, we measure $F_1 = 2PR/(P+R)$ values of predicted "is-a" relations where the precision (P) and recall (R) are:

$$P = \frac{|\text{isa}_{\text{predicted}} \cap \text{isa}_{\text{gold}}|}{|\text{isa}_{\text{predicted}}|}, R = \frac{|\text{isa}_{\text{predicted}} \cap \text{isa}_{\text{gold}}|}{|\text{isa}_{\text{gold}}|}.$$

We compare our method to two previously state-of-the-art models by Fu et al. (2014) and Bansal et al. (2014), which are closest to ours.

Method	$h = 4$	$h = 5$	$h = 6$	$h = 7$
Hierarchy Completion				
Fu2014	0.66	0.42	0.26	0.21
Ours (L)	0.70	0.49	0.45	0.37
Ours (LV)	**0.73**	**0.51**	**0.50**	**0.42**
Hierarchy Construction				
Fu2014	0.53	0.33	0.28	0.18
Bansal2014	0.67	0.53	0.43	0.37
Ours (L)	0.58	0.41	0.36	0.30
Ours (LB)	0.68	0.55	0.45	0.40
Ours (LV)	0.66	0.52	0.42	0.34
Ours (LVB - E)	0.68	0.55	0.44	0.39
Ours (LVB)	**0.70**	**0.57**	**0.49**	**0.43**

Table 2: Comparisons among different variants of our model, Fu et al. (2014) and Bansal et al. (2014) on two tasks. The ancestor-F_1 scores are reported.

5.2.2 Results

Hierarchy completion. In the *hierarchy completion* task, we split each tree into 70% nodes for training and 30% for test, and experiment with different h. We compare the following three systems: (1) *Fu2014*[4] (Fu et al., 2014); (2) *Ours (L)*: Our model with only language features enabled (i.e. surface features, parent-child word-word relation feature and siblings word-word relation feature); (3) *Ours (LV)*: Our model with both language features and visual features [5]. The average performance on three trees are reported at Table 2. We observe that the performance gradually drops when h increases, as more nodes are inserted when the tree grows higher, leading to a more complex and difficult taxonomy to be accurately constructed. Overall, our model outperforms Fu2014 in terms of the F_1 score, even without visual features. In the most difficult case with $h = 7$, our model still holds an F_1 score of 0.42 ($2\times$ of Fu2014), demonstrating the superiority of our model.

Hierarchy construction. The hierarchy construction task is much more difficult than hierarchy completion task because we need to build a taxonomy from scratch given only a hyper-root. For this task, we use a leave-one-out strategy, i.e. we train our model on every two trees and test on the third, and report the average performance in Table 2. We compare the following methods: (1) *Fu2014*, (2) *Ours (L)*, and (3) *Ours (LV)*, as described above; (4) *Bansal2014*: The model by Bansal et al. (2014) retrained using our dataset; (5) *Ours (LB)*: By excluding visual features, but including other language features from Bansal et al. (2014); (6) *Ours (LVB)*: Our full model further enhanced with all semantic features from Bansal et al. (2014); (7) *Ours (LVB - E)*: By excluding word embedding-based language features from *Ours (LVB)*.

As shown, on the hierarchy construction task, our model with only language features still outperforms Fu2014 with a large gap (0.30 compared to 0.18 when $h = 7$), which uses similar embedding-based features. The potential reasons are two-fold. First, we take into account not only parent-child relations but also siblings. Second, their method is designed to induce only pairwise relations. To build the full taxonomy, they first identify all possible pairwise relations using a simple thresholding strategy and then eliminate conflicted relations to obtain a legitimate tree hierarchy. In contrast, our model is optimized over the full space of all legitimate taxonomies by taking the *structure operation* in account during Gibbs sampling.

When comparing to Bansal2014, our model with only word embedding-based features underperforms theirs. However, when introducing visual features, our performance is comparable (p-value = 0.058).Furthermore, if we discard visual features but add semantic features from Bansal et al. (2014), we achieve a slight improvement of 0.02 over Bansal2014 (p-value = 0.016), which is largely attributed to the incorporation of word embedding-based features that encode high-level linguistic regularity. Finally, if we enhance our full model with all semantic features from Bansal et al. (2014), our model outperforms theirs by a gap of 0.04 (p-value < 0.01), which justifies our intuition that perceptual semantics underneath visual contents are quite helpful.

5.3 Qualitative Analysis

In this section, we conduct qualitative studies to investigate *how* and *when* the visual information helps the taxonomy induction task.

Contributions of visual features. To evaluate the contribution of each part of the visual features to the final performance, we train our model jointly with textual features and different combinations of visual features, and report the ancestor-F_1 scores. As shown in Table 3. When incorporating the feature S-V1, the performance is substantially boosted by a large gap at all heights, show-

[4]We tried different parameter settings for the number of clusters C and the identification threshold δ, and reported the best performance we achieved.

[5]In the comparisons to (Fu et al., 2014) and (Bansal et al., 2014), we simply set $K = \infty$, *i.e.* we use all available images of the parent category to estimate the PC-V1 feature.

S-V1	PC-V1	PC-V2	h = 4	h = 5	h = 6	h = 7
			0.58	0.41	0.36	0.30
✓			0.63	0.48	0.40	0.32
	✓		0.61	0.44	0.38	0.31
		✓	0.60	0.42	0.37	0.31
✓	✓		0.65	**0.52**	0.41	0.33
✓	✓	✓	**0.66**	**0.52**	**0.42**	**0.34**

Table 3: The performance when different combinations of visual features are enabled.

ing that visual similarity between sibling nodes is a strong evidence for taxonomy induction. It is intuitively plausible, as it is highly likely that two specific categories share a common (and more general) parent category if similar visual contents are observed between them. Further, adding the PC-V1 feature gains us a better improvement than adding PC-V2, but both minor than S-V1.

Compared to that of siblings, the visual similarity between parents and children does not strongly holds all the time. For example, images of *Terrestrial animal* are only partially similar to those of *Feline*, because the former one contains the later one as a subset. Our feature captures this type of "contain" relation between parents and children by considering only the top-K images from the parent category that have highest probabilities under the Gaussian distribution of the child category. To see this, we vary K while keep all other settings, and plot the F_1 scores in Fig 2. We observe a trend that when we gradually increase K, the performance goes up until reaching some maximal; It then slightly drops (or oscillates) even when more images are available, which confirms with our feature design that only top images should be considered in parent-child visual similarity.

Overall, the three visual features complement each other, and achieve the highest performance when combined.

Visual representations. To investigate how the image representations affect the final performance, we compare the ancestor-F1 score when different pre-trained CNNs are used for visual feature extraction. Specifically, we employ both the CNN-128 model (128 dimensional feature with 15.6% top-5 error on ILSVRC12) and the VGG-16 model (4096 dimensional feature with 7.5% top-5 error) by Simonyan and Zisserman (2014), but only observe a slight improvement of 0.01 on the ancestor-F1 score for the later one.

Relevance of textual and visual features v.s. depth of tree. Compared to Bansal et al. (2014),

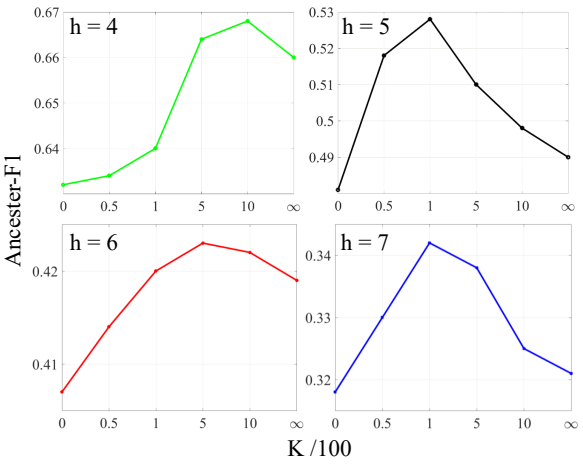

Figure 2: The Ancestor-F_1 scores changes over K (number of images used in the PC-V1 feature) at different heights. The values in the x-axis are $K/100$; $K = \infty$ means all images are used.

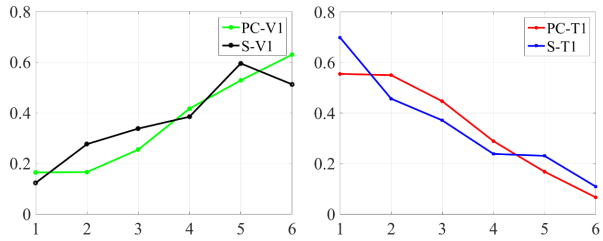

Figure 3: Normalized weights of each feature v.s. the layer depth.

a major difference of our model is that different layers of the taxonomy correspond to different weights $\boldsymbol{w}_l$, while in (Bansal et al., 2014) all layers share the same weights. Intuitively, introducing layer-wise $\boldsymbol{w}$ not only extends the model capacity, but also differentiates the importance of each feature at different layers. For example, the images of two specific categories, such as *shark* and *ray*, are very likely to be visually similar. However, when the taxonomy goes from bottom to up (specific to general), the visual similarity is gradually undermined — images of *fish* and *terrestrial animal* are not necessarily similar any more. Hence, it is necessary to privatize the weights $\boldsymbol{w}$ for different layers to capture such variations, i.e. the visual features become more and more evident from shallow to deep layers, while the textual counterparts, which capture more abstract concepts, relatively grow more indicative oppositely from specific to general.

To visualize the variations across layers, for each feature component, we fetch its correspond-

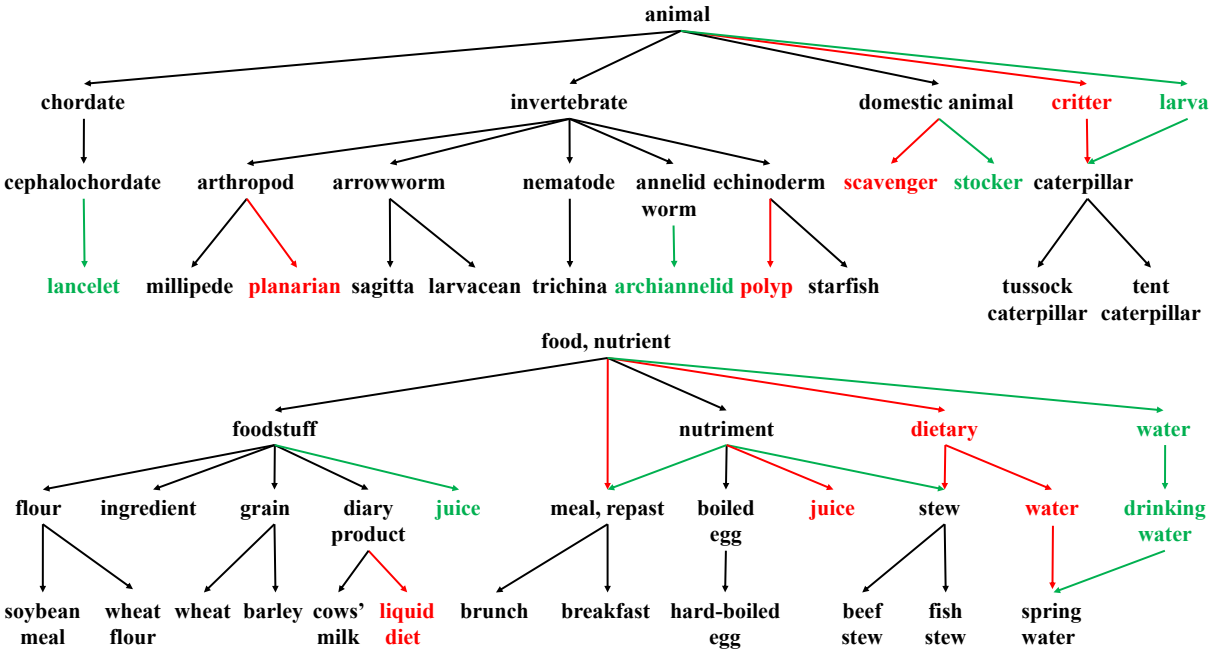

Figure 4: Excerpts of the prediction taxonomies, compared to the groundturth. Edges marked as red and green are false predictions and unpredicted groundtruth links, respectively.

ing block in $\boldsymbol{w}$ as V. Then, we average $|V|$ and observe how its values change with the layer depth h. For example, for the parent-child word-word relation feature, we first fetch its corresponding weights V from $\boldsymbol{w}$ as a 20×6 matrix, where 20 is the feature dimension and 6 is the number of layers. We then average its absolute values[6] in column and get a vector v with length 6. After ℓ_2 normalization, the magnitude of each entry in v directly reflects the relative importance of the feature as an evidence for taxonomy induction. Fig 3(b) plots how their magnitudes change with h for every feature component averaged on three train/test splits. It is noticeable that for both word-word relations (S-T1, PC-T1), their corresponding weights slightly decrease as h increases. On the contrary, the image-image relation features (S-V1, PC-V1) grows relatively more prominent. The results verify our conjecture that when the category hierarchy goes deeper into more specific classes, the visual similarity becomes relatively more indicative as an evidence for taxonomy induction.

Visualizing results. Finally, we visualize some excerpts of our predicted taxonomies, as compared to the groundtruth in Fig 4.

[6]We take the absolute value because we only care about the relevance of the feature as an evidence for taxonomy induction, but note that the weight can either encourage (positive) or discourage (negative) connections of two nodes.

6 Conclusion

In this paper, we study the problem of automatically inducing semantically meaningful concept taxonomies from multi-modal data. We propose a probabilistic Bayesian model which leverages distributed representations for images and words. We compare our model and features to previous ones on two different tasks using the ImageNet hierarchies, and demonstrate superior performance of our model, and the effectiveness of exploiting visual contents for taxonomy induction. We further conduct qualitative studies and distinguish the relative importance of visual and textual features in constructing various parts of a taxonomy.

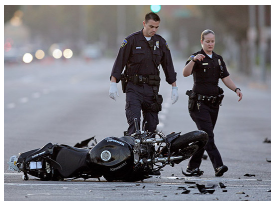
Abstract

There has been an explosion of work in the vision & language community during the past few years from image captioning to video transcription, and answering questions about images. These tasks have focused on literal descriptions of the image. To move beyond the literal, we choose to explore how questions about an image are often directed at commonsense inference and the abstract events evoked by objects in the image. In this paper, we introduce the novel task of **Visual Question Generation (VQG)**, where the system is tasked with asking a natural and engaging question when shown an image. We provide three datasets which cover a variety of images from object-centric to event-centric, with considerably more abstract training data than provided to state-of-the-art captioning systems thus far. We train and test several generative and retrieval models to tackle the task of VQG. Evaluation results show that while such models ask reasonable questions for a variety of images, there is still a wide gap with human performance which motivates further work on connecting images with commonsense knowledge and pragmatics. Our proposed task offers a new challenge to the community which we hope furthers interest in exploring deeper connections between vision & language.

1 Introduction

We are witnessing a renewed interest in interdisciplinary AI research in vision & language, from descriptions of the visual input such as image captioning (Chen et al., 2015; Fang et al., 2014; Donahue et al., 2014; Chen et al., 2015) and video transcription (Rohrbach et al., 2012; Venugopalan et al., 2015), to testing computer understanding of an image through question answering (Antol et al., 2015; Malinowski and Fritz, 2014). The most established work in the vision & language community is 'image captioning', where the task is to produce a literal description of the image. It has been shown (Devlin et al., 2015; Fang et al., 2014; Donahue et al., 2014) that a reasonable language modeling paired with deep visual features trained on large enough datasets promise a good performance on image captioning, making it a less challenging task from language learning perspective. Furthermore, although this task has a great value for communities of people who are low-sighted or cannot see in all or some environments, for others, the description does not add anything to what a person has already perceived.



Natural Questions:
- Was anyone injured in the crash?
- Is the motorcyclist alive?
- What caused this accident?

Generated Caption:
- A man standing next to a motorcycle.

Figure 1: Example image along with its natural questions and automatically generated caption.

The popularity of the image sharing applications in social media and user engagement around images is evidence that commenting on pictures is a very natural task. A person might respond to an image with a short comment such as 'cool', 'nice pic' or ask a question. Imagine someone has shared the image in Figure 1. What is the very first question that comes to mind? Your question is most probably very similar to the questions listed next to the image, expressing concern about the motorcyclist (who is not even present in the image). As you can tell, natural questions are not

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1802–1813,
Berlin, Germany, August 7-12, 2016.

about what is seen, the policemen or the motorcycle, but rather about what is inferred given these objects, e.g., an accident or injury. As such, questions are often about abstract concepts, i.e., events or states, in contrast to the concrete terms[1] used in image captioning. It is clear that the corresponding automatically generated caption[2] for Figure 1 presents only a literal description of objects.

To move beyond the literal description of image content, we introduce the novel task of Visual Question Generation (VQG), where given an image, the system should 'ask a natural and engaging question'. Asking a question that can be answered simply by looking at the image would be of interest to the Computer Vision community, but such questions are neither natural nor engaging for a person to answer and so are not of interest for the task of VQG.

Learning to ask questions is an important task in NLP and is more than a syntactic transformation of a declarative sentence (Vanderwende, 2008). Deciding what to ask about demonstrates understanding and as such, question generation provides an indication of machine understanding, just as some educational methods assess students' understanding by their ability to ask relevant questions[3]. Furthermore, training a system to ask a good question (not only answer a question) may imbue the system with what appears to be a cognitive ability unique to humans among other primates (Jordania, 2006). Developing the ability to ask relevant and to-the-point questions can be an essential component of any dynamic learner which seeks information. Such an ability can be an integral component of any conversational agent, either to engage the user in starting a conversation or to elicit task-specific information.

The contributions of this paper can be summarized as follows: (1) in order to enable the VQG research, we carefully created three datasets with a total of 75,000 questions, which range from object- to event-centric images, where we show that VQG covers a wide range of abstract terms including events and states (Section 3). (2) we collected 25,000 gold captions for our event-centric dataset and show that this dataset presents challenges to the state-of-the-art image captioning models (Section 3.3). (3) we perform analysis of various generative and retrieval approaches and conclude that end-to-end deep neural models outperform other approaches on our most-challenging dataset (Section 4). (4) we provide a systematic evaluation methodology for this task, where we show that the automatic metric ΔBLEU strongly correlates with human judgments (Section 5.3). The results show that while our models learn to generate promising questions, there is still a large gap to match human performance, making the generation of relevant and natural questions an interesting and promising new challenge to the community.

2 Related Work

For the task of image captioning, datasets have primarily focused on objects, e.g. Pascal VOC (Everingham et al., 2010) and Microsoft Common Objects in Context (MS COCO) (Lin et al., 2014). MS COCO, for example, includes complex everyday scenes with 91 basic objects in 328k images, each paired with 5 captions. Event detection is the focus in video processing and action detection, but these do not include a textual description of the event (Yao et al., 2011b; Andriluka et al., 2014; Chao et al., 2015; Xiong et al., 2015). The number of actions in each of these datasets is still relatively small, ranging from 40 (Yao et al., 2011a) to 600 (Chao et al., 2015) and all involve human-oriented activity (e.g. 'cooking', 'gardening', 'riding a bike'). In our work, we are focused on generating questions for static images of events, such as 'fire', 'explosion' or 'snowing', which have not yet been investigated in any of the above datasets.

Visual Question Answering is a relatively new task where the system provides an answer to a question about the image content. The most notable, Visual Question Answering (VQA) (Antol et al., 2015), is an open-ended (free-form) dataset, in which both the questions and the answers are crowd-sourced, with workers prompted to ask a visually verifiable question which will 'stump a smart robot'. Gao et al. (2015) used similar methodology to create a visual question answering dataset in Chinese. COCO-QA (CQA) (Ren et al., 2015), in contrast, does not use human-authored questions, but generates questions automatically from image captions of the MS COCO dataset by applying a set of transformation rules to generate the wh-question. The expected answers in CQA

[1] Concrete terms are the ones that can be experienced with five senses. Abstract terms refer to intangible things, such as feelings, concepts, and qualities

[2] Throughout this paper we use the state-of-the-art captioning system (Fang et al., 2014), henceforth MSR captioning system `https://www.captionbot.ai/`, to generate captions.

[3] `http://rightquestion.org/`

Figure 2: Example right and wrong questions for the task of VQG.

are by design limited to objects, numbers, colors, or locations. A more in- depth analysis of VQA and CQA datasets will be presented in Section 3.1.

In this work, we focus on questions which are interesting for a person to answer, not questions designed to evaluate computer vision. A recently published work on VQA, Visual7W (Zhu et al., 2016), establishes a grounding link on the object regions corresponding to the textual answer. This setup enables a system to answer a question with visual answers (in addition to textual answers). They collect a set of 327,939 7W multiple-choice QA pairs, where they point out that 'where', 'when' and 'why' questions often require high-level commonsense reasoning, going beyond spatial reasoning required for 'which' or 'who' questions. This is more in line with the type of questions that VQG captures, however, the majority of the questions in Visual7w are designed to be answerable by only the image, making them unnatural for asking a human. Thus, learning to generate the questions in VQA task is not a useful sub-task, as the intersection between VQG and any VQA questions is by definition minimal.

Previous work on question generation from textual input has focused on two aspects: the grammaticality (Wolfe, 1976; Mitkov and Ha, 2003; Heilman and Smith, 2010) and the content focus of question generation, i.e., "what to ask about". For the latter, several methods have been explored: (Becker et al., 2012) create fill-in-the-blank questions, (Mazidi and Nielsen, 2014) and (Lindberg et al., 2013) use manually constructed question templates, while (Labutov et al., 2015) use crowdsourcing to collect a set of templates and then rank the potentially relevant templates for the selected content. To our knowledge, neither a retrieval model nor a deep representation of textual input, presented in our work, have yet been used to generate questions.

3 Data Collection Methodology

Task Definition: Given an image, the task is to generate a natural question which can potentially engage a human in starting a conversation. Questions that are visually verifiable, i.e., that can be answered by looking at only the image, are outside the scope of this task. For instance, in Figure 2, a question about the number of horses (appearing in the VQA dataset) or the color of the field is not of interest. Although in this paper we focus on asking a question about an image in isolation, adding prior context or history of conversation is the natural next step in this project.

We collected the VQG questions by crowdsourcing the task on Amazon Mechanical Turk (AMT). We provide details on the prompt and the specific instructions for all the crowdsourcing tasks in this paper in the supplementary material. Our prompt was very successful at capturing non-literal questions, as the good question in Figure 2 demonstrates. In the following Sections, we describe our process for selecting the images to be included in the VQG dataset. We start with images from MS COCO, which enables meaningful comparison with VQA and CQA questions. Given that it is more natural for people to ask questions about event-centric images, we explore sourcing eventful images from Flickr and from querying an image search engine. Each data source is represented by 5,000 images, with 5 questions per image.

3.1 $VQG_{coco-5000}$ and $VQG_{Flickr-5000}$

As our first dataset, we collected VQG questions for a sample of images from the MS COCO dataset[4]. In order to enable comparisons with related datasets, we sampled 5,000 images of MS COCO which were also annotated by the CQA dataset (Ren et al., 2015) and by VQA (Antol et al., 2015). We name this dataset $VQG_{coco-5000}$. Table 1 shows a sample MS COCO image along with annotations in the various datasets. As the CQA questions are generated by rule application from captions, they are not always coherent. The VQA questions are written to evaluate the detailed visual understanding of a robot, so their questions are mainly visually grounded and literal. The table demonstrates how different VQG questions are from VQA and CQA questions.

In Figure 3 we provide statistics for the various annotations on that portion of the MS COCO images which are represented in the $VQG_{coco-5000}$

[4] http://mscoco.org/

Dataset	Annotations
COCO	- A man holding a box with a large chocolate covered donut.
CQA	- What is the man holding with a large chocolate-covered doughnut in it?
VQA	- Is this a large doughnut?
VQG	- Why is the donut so large? - Is that for a specific celebration? - Have you ever eaten a donut that large before? - Is that a big donut or a cake? - Where did you get that?

Table 1: Dataset annotations on the above image.

dataset. In Figure 3(a) we compare the percentage of object-mentions in each of the annotations. Object-mentions are words associated with the gold-annotated object boundary boxes[5] as provided with the MS COCO dataset. Naturally, COCO captions (green bars) have the highest percentage of these literal objects. Since object-mentions are often the answer to VQA and CQA questions, those questions naturally contain objects less frequently. Hence, we see that VQG questions include the mention of more of those literal objects. Figure 3(b) shows that COCO captions have a larger vocabulary size, which reflects their longer and more descriptive sentences. VQG shows a relatively large vocabulary size as well, indicating greater diversity in question formulation than VQA and CQA. Moreover, Figure 3(c) shows that the verb part of speech is represented with high frequency in our dataset.

Figure 3(d) depicts the percentage of abstract terms such as 'think' or 'win' in the vocabulary. Following Ferraro et al. (2015), we use a list of most common abstract terms in English (Vanderwende et al., 2015), and count all the other words except a set of function words as concrete. This figure supports our expectation that VQG covers more abstract concepts. Furthermore, Figure 3(e) shows inter-annotation textual similarity according to the BLEU metric (Papineni et al., 2002). Interestingly, VQG shows the highest inter-annotator textual similarity, which reflects on the existence of consensus among human for asking a natural question, even for object-centric images like the ones in MS COCO.

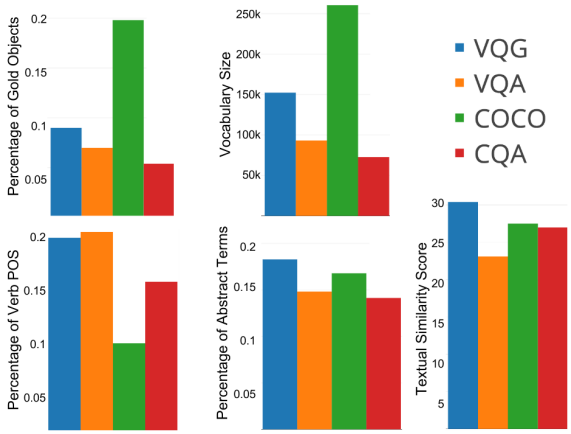


Figure 3: Comparison of various annotations on the MS COCO dataset. (a) Percentage of gold objects used in annotations. (b) Vocabulary size (c) Percentage of verb POS (d) Percentage of abstract terms (e) Inter-annotation textual similarity score.

The MS COCO dataset is limited in terms of the concepts it covers, due to its pre-specified set of object categories. Word frequency in $VQG_{coco-5000}$ dataset, as demonstrated in Figure 4, bears this out, with the words 'cat' and 'dog' the fourth and fifth most frequent words in the dataset. Not shown in the frequency graph is that words such as 'wedding', 'injured', or 'accident' are at the very bottom of frequency ranking list. This observation motivated the collection of the $VQG_{Flickr-5000}$ dataset, with images appearing as the middle photo in a story-full photo album (Huang et al., 2016) on Flickr[6]. The details about this dataset can be found in the supplementary material.

3.2 $VQG_{Bing-5000}$

To obtain a more representative visualization of specific event types, we queried a search engine[7] with 1,200 event-centric query terms which were obtained as follows: we aggregated all 'event' and 'process' hyponyms in WordNet (Miller, 1995), 1,000 most frequent TimeBank events (Pustejovsky et al., 2003) and a set of manually curated 30 stereotypical events, from which we selected the top 1,200 queries based on Project Gutenberg word frequencies. For each query, we collected the first four to five images retrieved, for a total

[5]Note that MS COCO annotates only 91 object categories.

[7]https://datamarket.azure.com/dataset/bing/search

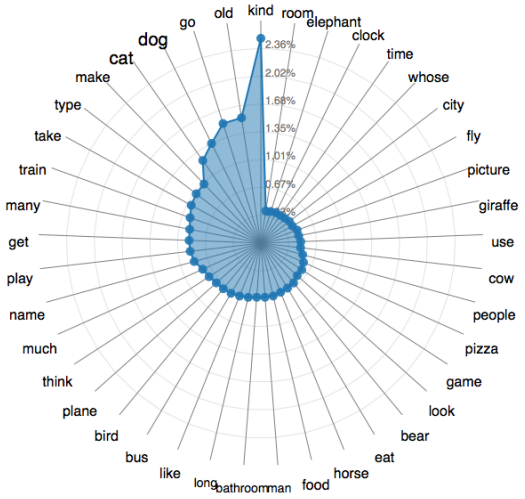

Figure 4: Frequency graph of top 40 words in $VQG_{coco-5000}$ dataset.

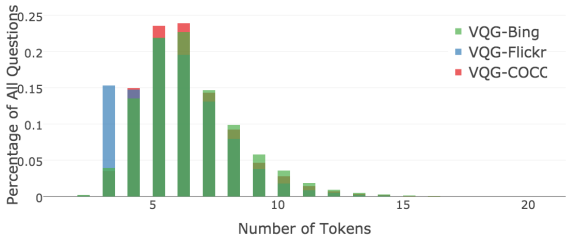

Figure 5: Average annotation length of the three VQG datasets.

of 5,000 images, having first used crowdsourcing to filter out images depicting graphics and cartoons. A similar word frequency analysis shows that the $VQG_{Bing-5000}$ dataset indeed contains more words asking about events: *happen*, *work*, *cause* appear in top 40 words, which was our aim in creating the Bing dataset.

Statistics: Our three datasets together cover a wide range of visual concepts and events, totaling 15,000 images with 75,000 questions. Figure 5 draws the histogram of number of tokens in VQG questions, where the average question length is 6 tokens. Figure 6 visualizes the n-gram distribution (with n=6) of questions in the three VQG datasets[8]. Table 2 shows the statistics of the crowdsourcing task.

3.3 $\boldsymbol{Captions_{Bing-5000}}$

The word frequencies of questions about the $\boldsymbol{VQG_{Bing-5000}}$ dataset indicate that this dataset

[8]Please refer to our web page on `http://research.microsoft.com/en-us/downloads` to get a link to a dynamic visualization and statistics of all n-gram sequences.

# all images	**15,000**
# questions per image	**5**
# all workers participated	308

Median work time per worker (sec)	23.0
Average payment per question (cents)	6.0

Table 2: Statistics of crowdsourcing task, aggregating all three datasets.

is substantially different from the MS COCO dataset. Human evaluation results of a recent work (Tran et al., 2016) further confirms the significant image captioning quality degradation on out-of-domain data. To further explore this difference, we crowdsourced 5 captions for each image in the $VQG_{Bing-5000}$ dataset using the same prompt as used to source the MS COCO captions. We call this new dataset $\boldsymbol{Captions_{Bing-5000}}$. Table 3 shows the results of testing the state-of-the-art MSR captioning system on the $\boldsymbol{Captions_{Bing-5000}}$ dataset as compared to the MS COCO dataset, measured by the standard BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014) metrics. The wide gap in the results further confirms that indeed the $\boldsymbol{VQG_{Bing-5000}}$ dataset covers a new class of images; we hope the availability of this new dataset will encourage including more diverse domains for image captioning.

BLEU		**METEOR**	
Bing	*MS COCO*	*Bing*	*MS COCO*
0.101	0.291	0.151	0.247

Table 3: Image captioning results

Together with this paper we are releasing an extended set of VQG dataset to the community. We hope that the availability of this dataset will encourage the research community to tackle more end-goal oriented vision & language tasks.

4 Models

In this Section we present several generative and retrieval models for tackling the task of VQG. For all the forthcoming models we use the VGGNet (Simonyan and Zisserman, 2014) architecture for computing deep convolutional image features. We primarily use the 4096-dimensional output the last fully connected layer ($fc7$) as the input to the generative models.

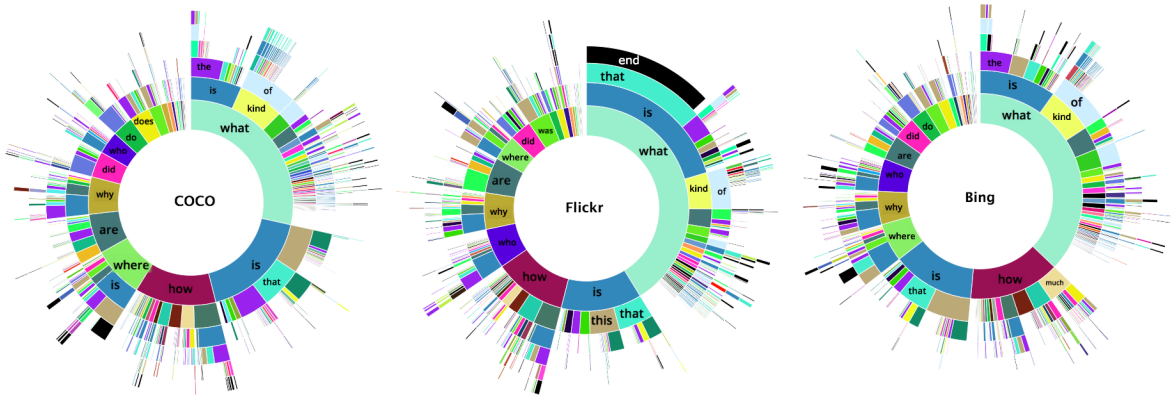

Figure 6: VQG N-gram sequences. 'End' token distinguishes natural ending with n-gram cut-off.

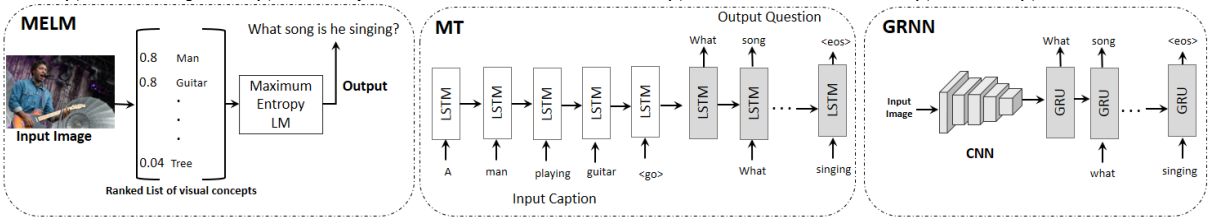

Figure 7: Three different generative models for tackling the task of VQG.

4.1 Generative Models

Figure 7 represents an overview of our three generative models. The MELM model (Fang et al., 2014) is a pipeline starting from a set of candidate word probabilities which are directly trained on images, which then goes through a maximum entropy (ME) language model. The MT model is a Sequence2Sequence translation model (Cho et al., 2014; Sutskever et al., 2014) which directly translates a description of an image into a question, where we used the MS COCO captions and $Captions_{Bing-5000}$ as the source of translation. These two models tended to generate less coherent sentences, details of which can be found in the supplementary material. We obtained the best results by using an end-to-end neural model, GRNN, as follows.

Gated Recurrent Neural Network (GRNN): This generation model is based on the state-of-the-art multimodal Recurrent Neural Network model used for image captioning (Devlin et al., 2015; Vinyals et al., 2015). First, we transform the $fc7$ vector to a 500-dimensional vector which serves as the initial recurrent state to a 500-dimensional Gated Recurrent Unit (GRU). We produce the output question one word at a time using the GRU, until we hit the end-of-sentence token. We train the GRU and the transformation matrix jointly, but we do not back-propagate the CNN due to the size of the training data. The neural network is trained using Stochastic Gradient Descent with early stopping, and decoded using a beam search of size 8. The vocabulary consists of all words seen 3 or more times in the training, which amounts to 1942 unique tokens in the full training set. Unknown words are mapped to to an `<unk>` token during training, but we do not allow the decoder to produce this token at test time.

4.2 Retrieval Methods

Retrieval models use the caption of a nearest neighbor training image to label the test image (Hodosh et al., 2013; Devlin et al., 2015; Farhadi et al., 2010; Ordonez et al., 2011). For the task of image captioning, it has been shown that up to 80% of the captions generated at test time by a near state-of-the-art generation approach (Vinyals et al., 2015) were exactly identical to the training set captions, which suggests that reusing training annotations can achieve good results. Moreover, basic nearest neighbor approaches to image captioning on the MS COCO dataset are shown to outperform generation models according to automatic metrics (Devlin et al., 2015). The performance of retrieval models of course depends on the diversity of the dataset.

We implemented several retrieval models customized for the task of VQG. As the first step, we compute K nearest neighbor images for each test image using the $fc7$ features to get a candidate pool. We obtained the most competitive results by setting K dynamically, as opposed to the earlier

				
Q.	Explosion	Hurricane	Rain Cloud	Car Accident
Human	- What caused this explosion? - Was this explosion an accident?	- What caused the damage to this city? - What happened to this place?	- Are those rain clouds? - Did it rain?	- Did the drivers of this accident live through it? - How fast were they going?
GRNN	- How much did the fire cost? - What is being burned here?	- What happened to the city? - What caused the fall?	- What kind of clouds are these? - Was there a bad storm?	- How did the car crash? - What happened to the trailer?
KNN	- What caused this fire?	- What state was this earthquake in?	- Did it rain?	- Was anybody hurt in this accident?
Caption	- A train with smoke coming from it.	- A pile of dirt.	- Some clouds in a cloudy day.	- A man standing next to a motorcycle.

Table 4: Sample generations by different systems on $VQG_{bing-5000}$, in order: Human$_{consensus}$ and Human$_{random}$, GRNN$_{bing}$ and GRNN$_{all}$, KNN+min$_{bleu-all}$, MSR captions. Q is the query-term.

works which fix K throughout the testing. We observed that candidate images beyond a certain distance made the pool noisy, hence, we establish a parameter called $max\text{-}distance$ which is an upper bound for including a neighbor image in the pool. Moreover, our experiments showed that if there exists a very similar image to the test image, the candidate pool can be ignored and that test image should become the only candidate[9]. For addressing this, we set a $min\text{-}distance$ parameter. All these parameters were tuned on the corresponding validation sets using the Smoothed-BLEU (Lin and Och, 2004) metric against the human reference questions.

Given that each image in the pool has five questions, we define the one-best question to be the question with the highest semantic similarity[10] to the other four questions. This results in a pool of K candidate questions. The following settings were used for our final retrieval models:

– **1-NN**: Set K=1, which retrieves the closest image and emits its one-best.

– **K-NN+min**: Set K=30 with $max\text{-}distance = 0.35$, and $min\text{-}distance = 0.1$. Among the 30 candidate questions (one-best of each image), find the question with the highest similarity to the rest of the pool and emit that: we compute the textual similarity according the two metrics, Smoothed-BLEU and Average-Word2Vec (gensim)[11].

Table 4 shows a few example images along with the generations of our best performing systems. For more examples please refer to the web page of the project.

5 Evaluation

While in VQG the set of possible questions is not limited, there is consensus among the natural questions (discussed in Section 3.1) which enables meaningful evaluation. Although human evaluation is the ideal form of evaluation, it is important to find an automatic metric that strongly correlates with human judgment in order to benchmark progress on the task.

5.1 Human Evaluation

The quality of the evaluation is in part determined by how the evaluation is presented. For instance,

[9] At test time, the frequency of finding a train set image with $distance \leq 0.1$ is 7.68%, 8.4% and 3.0% in COCO, Flickr and Bing datasets respectively.

[10] We use BLEU to compute textual similarity. This process eliminates outlier questions per image.

[11] Average-Word2Vec refers to the sentence-level textual similarity metric where we compute the cosine similarity between two sentences by averaging their word-level Word2Vec (Mikolov et al., 2013) vector representations. Here we use the GenSim software framework (Řehůřek and Sojka, 2010).

it is important for the human judges to see various system hypotheses at the same time in order to give a calibrated rating. We crowdsourced our human evaluation on AMT, asking three crowd workers to each rate the quality of candidate questions on a three-point semantic scale.

5.2 Automatic Evaluation

The goal of automatic evaluation is to measure the similarity of system-generated question hypotheses and the crowdsourced question references. To capture n-gram overlap and textual similarity between hypotheses and references, we use standard Machine Translation metrics, BLEU (Papineni et al., 2002) and METEOR (Denkowski and Lavie, 2014). We use BLEU with equal weights up to 4-grams and default setting of METEOR version 1.5. Additionally we use ΔBLEU (Galley et al., 2015) which is specifically tailored towards generation tasks with diverse references, such as conversations. ΔBLEU requires rating per reference, distinguishing between the quality of the references. For this purpose, we crowd-sourced three human ratings (on a scale of 1-3) per reference and used the majority rating.

The pairwise correlational analysis of human and automatic metrics is presented in Table 6, where we report on Pearson's r, Spearman's ρ and Kendall's τ correlation coefficients. As this table reveals, ΔBLEU strongly correlates with human judgment and we suggest it as the main evaluation metric for testing a VQG system. It is important to note that BLEU is also very competitive with ΔBLEU, showing strong correlations with human judgment. Hence, we recommend using BLEU for any further benchmarking and optimization purposes. BLEU can also be used as a proxy for ΔBLEU for evaluation purposes whenever rating per reference are not available.

5.3 Results

In this section, we present the human and automatic metric evaluation results of the models introduced earlier. We randomly divided each VQG-5000 dataset into train (50%), val (25%) and test (25%) sets. In order to shed some light on differences between our three datasets, we present the evaluation results separately on each dataset in Table 5. Each model (Section 4.2) is once trained on all train sets, and once trained only on its corresponding train set (represented as X in the results table). For quality control and further insight on the task, we include two human annotations among our models: 'Human$_{consensus}$' (the same as one-best) which indicates the consensus human annotation on the test image and 'Human$_{random}$' which is a randomly chosen annotation among the five human annotations.

It is quite interesting to see that among the human annotations, Human$_{consensus}$ achieves consistently higher scores than Human$_{random}$. This further verifies that there is indeed a common intuition about what is the most natural question to ask about a given image. As the results of human evaluation in Table 5 shows, GRNN$_{all}$ performs the best as compared with all the other models in 2/3 of runs. All the models achieve their best score on $VQG_{COCO-5000}$, which was expected given the less diverse set of images. Using automatic metrics, the GRNN$_X$ model outperforms other models according to all three metrics on the $VQG_{Bing-5000}$ dataset. Among retrieval models, the most competitive is K-NN+min_bleu_all, which performs the best on $VQG_{COCO-5000}$ and $VQG_{Flickr-5000}$ datasets according to BLEU and ΔBLEU score. This further confirms our effective retrieval methodology for including $min\text{-}distance$ and n-gram overlap similarity measures. Furthermore, the boost from 1-NN to K-NN models is considerable according to both human and automatic metrics. It is important to note that none of the retrieval models beat the GRNN model on the Bing dataset. This additionally shows that our Bing dataset is in fact more demanding, making it a meaningful challenge for the community.

6 Discussion

We introduced the novel task of 'Visual Question Generation', where given an image, the system is tasked with asking a natural question. We provide three distinct datasets, each covering a variety of images. The most challenging is the Bing dataset, requiring systems to generate questions with event-centric concepts such as 'cause', 'event', 'happen', etc., from the visual input. Furthermore, we show that our Bing dataset presents challenging images to the state-of-the-art captioning systems. We encourage the community to report their system results on the Bing test dataset and according to the ΔBLEU automatic metric. All the datasets will be released to the public[12].

This work focuses on developing the capabil-

ity to ask relevant and to-the-point questions, a key intelligent behavior that an AI system should demonstrate. We believe that VQG is one step towards building such a system, where an engaging question can naturally start a conversation. To continue progress on this task, it is possible to increase the size of the training data, but we also expect to develop models that will learn to generalize to unseen concepts. For instance, consider the examples of system errors in Table 7, where visual features can be enough for detecting the specific set of objects in each image, but the system cannot make sense of the combination of previously unseen concepts. Another natural future extension of this work is to include question generation within a conversational system (Sordoni et al., 2015; Li et al., 2016), where the context and conversation history affect the types of questions being asked.

		Human	- How long did it take to make that ice sculpture?	- Is the dog looking to take a shower?
GRNN	- How long has he been hiking?	- Is this in a hotel room?
KNN	- How deep was the snow?	- Do you enjoy the light in this bathroom?

Abstract

Linguistics studies have shown that action verbs often denote some *Change of State (CoS)* as the result of an action. However, the causality of action verbs and its potential connection with the physical world has not been systematically explored. To address this limitation, this paper presents a study on *physical causality* of action verbs and their implied changes in the physical world. We first conducted a crowdsourcing experiment and identified eighteen categories of physical causality for action verbs. For a subset of these categories, we then defined a set of detectors that detect the corresponding change from visual perception of the physical environment. We further incorporated physical causality modeling and state detection in grounded language understanding. Our empirical studies have demonstrated the effectiveness of causality modeling in grounding language to perception.

1 Introduction

Linguistics studies have shown that action verbs often denote some *change of state (CoS)* as the result of an action, where the *change of state* often involves an attribute of the direct object of the verb (Hovav and Levin, 2010). For example, the result of "slice a pizza" is that the state of the object (pizza) changes from one big piece to several smaller pieces. This change of state can be perceived from the physical world. In Artificial Intelligence (Russell and Norvig, 2010), decades of research on planning, for example, back to the early days of the STRIPS planner (Fikes and Nilsson, 1971), have defined action schemas to capture the change of state caused by a given action. Based on action schemas, planning algorithms can be applied to find a sequence of actions to achieve a goal state (Ghallab et al., 2004). The state of the physical world is a very important notion and changing the state becomes a driving force for agents' actions. Thus, motivated by linguistic literature on action verbs and AI literature on action representations, in our view, modeling change of physical state for action verbs, in other words, *physical causality*, can better connect language to the physical world.

Although this kind of physical causality has been described in linguistic studies (Hovav and Levin, 2010), a detailed account of potential causality that could be denoted by an action verb is lacking. For example, in VerbNet (Schuler, 2005) the semantic representation for various verbs may indicate that a change of state is involved, but it does not provide the specifics associated with the verb's meaning (e.g., to what attribute of its *patient* the changes might occur).

To address this limitation, we have conducted an empirical investigation on verb semantics from a new angle of how they may change the state of the physical world. As the first step in this investigation, we selected a set of action verbs from a cooking domain and conducted a crowd-sourcing study to examine the potential types of causality associated with these verbs. Motivated by linguistics studies on typology for gradable adjectives, which also have a notion of change along a scale (Dixon and Aikhenvald, 2006), we developed a set of eighteen main categories to characterize physical causality. We then defined a set of change-of-state detectors focusing on visual perception. We further applied two approaches, a knowledge-driven approach and a learning-based approach, to incorporate causality modeling in

Berlin, Germany, August 7-12, 2016.

grounded language understanding. Our empirical results have demonstrated that both of these approaches achieve significantly better performance in grounding language to perception compared to previous approaches (Yang et al., 2016).

2 Related Work

The notion of *causality* or *causation* has been explored in psychology, linguistics, and computational linguistics from a wide range of perspectives. For example, different types of causal relations such as causing, enabling, and preventing (Goldvarg and Johnson-Laird, 2001; Wolff and Song, 2003) have been studied extensively as well as their linguistic expressions (Wolff, 2003; Song and Wolff, 2003; Neeleman et al., 2012) and automated extraction of causal relations from text (Blanco et al., 2008; Mulkar-Mehta et al., 2011; Radinsky et al., 2012; Riaz and Girju, 2014). Different from these previous works, this paper focuses on the physical causality of action verbs, in other words, change of state in the physical world caused by action verbs as described in (Hovav and Levin, 2010). This is motivated by recent advances in computer vision, robotics, and grounding language to perception and action.

A recent trend in computer vision has started looking into intermediate representations beyond lower-level visual features for action recognition, for example, by incorporating object affordances (Koppula et al., 2013) and causality between actions and objects (Fathi and Rehg, 2013). Fathi and Rehg (2013) have borken down detection of actions to detection of state changes from video frames. Yang and colleagues (2013; 2014) have developed an object segmentation and tracking method to detect state changes (or, in their terms, consequences of actions) for action recognition. More recently, Fire and Zhu (2015) have developed a framework to learn perceptual causal structures between actions and object statuses in videos.

In the robotics community, as robots' low-level control systems are often pre-programmed to handle (and thus execute) only primitive actions, a high-level language command will need to be translated to a sequence of primitive actions in order for the corresponding action to take place. To make such translation possible, previous works (She et al., 2014a; She et al., 2014b; Misra et al., 2015; She and Chai, 2016) explicitly model verbs with predicates describing the resulting states of actions. Their empirical evaluations have demonstrated how incorporating resulting states into verb representations can link language with underlying planning modules for robotic systems. These results have motivated a systematic investigation on modeling physical causality for action verbs.

Although recent years have seen an increasing amount of work on grounding language to perception (Yu and Siskind, 2013; Walter et al., 2013; Liu et al., 2014; Naim et al., 2015; Liu and Chai, 2015), no previous work has investigated the link between physical causality denoted by action verbs and the change of state visually perceived. Our work here intends to address this limitation and examine whether the causality denoted by action verbs can provide top-down information to guide visual processing and improve grounded language understanding.

3 Modeling Physical Causality for Action Verbs

3.1 Linguistics Background on Action Verbs

Verb semantics have been studied extensively in linguistics (Pustejovsky, 1991; Levin, 1993; Baker et al., 1998; Kingsbury and Palmer, 2002). Particularly, for action verbs (such as *run*, *throw*, *cook*), Hovav and Levin (Hovav and Levin, 2010) propose that they can be divided into two types: ***manner verbs*** that "specify as part of their meaning a manner of carrying out an action" (e.g., *nibble, rub, scribble, sweep, flutter, laugh, run, swim*), and ***result verbs*** that "specify the coming about of a result state" (e.g., *clean, cover, empty, fill, chop, cut, melt, open, enter*). Result verbs can be further classified into three categories: *Change of State* verbs, which denote a change of state for a property of the verb's object (e.g. "to warm"); *Inherently Directed Motion* verbs, which denote movement along a path in relation to a landmark object (e.g. "to arrive"); and *Incremental Theme* verbs, which denote the incremental change of volume or area of the object (e.g. "to eat") (Levin and Hovav, 2010). In this work, we mainly focus on result verbs. Unlike Hovav and Levin's definition of *Change of State* verbs, we use the term *change of state* in a more general way such that the location, volume, and area of an object are part of its state.

Previous linguistic studies have also shown that result verbs often specify movement along a scale (Hovav and Levin, 2010), i.e., they are

verbs of scalar change. A scale is "a set of points on a particular dimension (e.g. height, temperature, cost)". In the case of verbs, the dimension is an attribute of the object of the verb. For example, "John cooled the coffee" means that the temperature attribute of the object *coffee* has decreased. Kennedy and McNally give a very detailed description of scale structure and its variations (Kennedy and McNally, 2005). Interestingly, gradable adjectives also have their semantics defined in terms of a scale structure. Dixon and Aikhenvald have defined a typology for adjectives which include categories such as Dimension, Color, Physical Property, Quantification, and Position (Dixon and Aikhenvald, 2006). The connection between gradable adjectives and result verbs through scale structure motivates us to use the Dixon typology as a basis to define our categorization of causality for verbs.

In summary, previous linguistic literature has provided abundant evidence and discussion on change of state for action verbs. It has also provided extensive knowledge on potential dimensions that can be used to categorize change of state as described in this paper.

3.2 A Crowd-sourcing Study

Motivated by the above linguistic insight, we have conducted a pilot study to examine the feasibility of causality modeling using a small set of verbs which appear in the TACoS corpus (Regneri et al., 2013). This corpus is a collection of natural language descriptions of actions that occur in a set of cooking videos. This is an ideal dataset to start with since it contains mainly descriptions of physical actions. Possibly because most actions in the cooking domain are goal-directed, a majority of the verbs in TACoS denote results of actions (changes of state) which can be observed in the world.

More specifically, we chose ten verbs (*clean, rinse, wipe, cut, chop, mix, stir, add, open, shake*)) based on the criteria that they occur relatively frequently in the corpus and take a variety of different objects as their *patient*. We paired each verb with three different objects in the role of *patient*. Nouns (e.g., *cutting board, dish, counter, knife, hand, cucumber, beans, leek, eggs, water, break, bowl, etc.*) were chosen based on the criteria that they represent objects dissimilar to each other, since we hypothesize that the change of state indicated by the verb will differ depending on the object's features.

Each verb-noun pair was presented to turkers via Amazon Mechanical Turk (AMT) and they were asked to describe (by text) the changes of state that occur to the object as a result of the verb. The descriptions were collected under two conditions: (1) without showing the corresponding video clips (so turkers would have to use their imagination of the physical situation) and (2) showing the corresponding video clips. For each condition and each verb-noun pair, we collected 30 turkers' responses, which resulted in a total of 1800 natural language responses describing change of state.

3.3 Categorization of Change of State

Based on Dixon and Aikhenvald's typology for adjectives (Dixon and Aikhenvald, 2006) and turkers' responses, we identified a categorization to characterize causality, as shown in Table 1. This categorization is also driven by the expectation that these attributes can be potentially recognized from the physical world by artificial agents. The first column specifies the type of state change and the second column specifies specific attributes related to the type. The third column specifies the particular value associated with the attribute, e.g., it could be a binary categorization on whether a change happens or not (i.e., *changes*), or a direction along a scale (i.e., *increase/decrease*), or a specific value (i.e., *specific* such as "five pieces"). In total, we have identified eighteen causality categories corresponding to eighteen attributes as shown in Table 1.

An important motivation of modeling physical causality is to provide guidance for visual processing. Our hypothesis is that once a language description is given together with its corresponding visual scene, potential causality of verbs or verb-noun pairs can trigger some visual detectors associated with the scene. This can potentially improve grounded language understanding (e.g., grounding nouns to objects in the scene). Next we give a detailed account on these visual detectors and their role in grounded language understanding.

4 Visual Detectors based on Physical Causality

The changes of state associated with the eighteen attributes can be detected from the physical world

Type	Attribute	Attribute Value
Dimension	Size, length, volume	Changes, increases, decreases, specific
	Shape	Changes, specific (cylindrical, flat, etc.)
Color/Texture	Color	Appear, disappear, changes, mix, separate, specific (green, red, etc.)
	Texture	Changes, specific (slippery, frothy, etc.)
Physical Property	Weight	Increase, decrease
	Flavor, smell	Changes, intensifies, specific
	Solidity	Liquefies, solidifies, specific
	Wetness	Becomes wet(ter), dry(er)
	Visibility	Appears, disappears
	Temperature	Increases, decreases
	Containment	Becomes filled, emptied, hollow
	Surface Integrity	A hole or opening appears
Quantification	Number of pieces	Increases, one becomes many, decreases, many become one
Position	Location	Changes, enter/exit container, specific
	Occlusion	Becomes covered, uncovered
	Attachment	Becomes detached
	Presence	No longer present, becomes present
	Orientation	Changes, specific

Table 1: Categorization of physical causality.

Attribute	Rule-based Detector	Refined Rule-based Detector
Attachment / NumberOfPieces	Multiple object tracks merge into one, or one object track breaks into multiple.	Multiple tracks merge into one.
		One track breaks into multiple.
Presence / Visibility	Object track appears or disappears.	Object track appears.
		Object track disappears.
Location	Object's final location is different from the initial location.	Location shifts upwards.
		Location shifts downwards.
		Location shifts rightwards.
		Location shifts leftwards.
Size	Object's x-axis length or y-axis length is different from the initial values.	Object's x-axis length increases.
		Object's x-axis length decreases.
		Object's y-axis length increases.
		Object's y-axis length decreases.

Table 2: Causality detectors applied to *patient* of a verb.

using various sensors. In this paper, we only focus on attributes that can be detected by visual perception. More specifically, we chose the subset: *Attachment*, *NumberOfPieces*, *Presence*, *Visibility*, *Location*, *Size*. They are chosen because: 1) according to the pilot study, they are highly correlated with our selected verbs; and 2) they are relatively easy to be detected from vision.

Corresponding to these causality attributes, we defined a set of rule-based detectors as shown in Table 2. These in fact are very simple detectors, which consist of four major detectors and a refined set that distinguishes directions of state change. These visual detectors are specifically applied to the potential objects that may serve as *patient* for a verb to identify whether certain changes of state occur to these objects in the visual scene.

5 Verb Causality in Grounded Language Understanding

In this section, we demonstrate how verb causality modeling and visual detectors can be used together for grounded language understanding. As shown in Figure 1, given a video clip V of human action and a parallel sentence S describing the action, our goal is to ground different semantic roles of the verb (e.g., *get*) to objects in the video. This is similar to the grounded semantic role labeling task (Yang et al., 2016). Here, we focus on a set of four semantic roles {*agent*, *patient*, *source*, *destination*}. We also assume that we have object and hand tracking results from video data. Each object in the video is represented by a track, which is a series of bounding boxes across video frames. Thus, given a video clip and a parallel sentence, the task is to ground semantic roles of the verb $\lambda_1, \lambda_2, \ldots, \lambda_k$ to object (or hand) tracks $\gamma_1, \gamma_2, \ldots, \gamma_n$, in the video.[1] We applied two approaches to this problem.

[1]For manipulation actions, the *agent* is almost always one of the human's hands (or both hands). So we constrain the grounding of the *agent* role to hand tracks, and constrain the grounding of the other roles to object tracks.

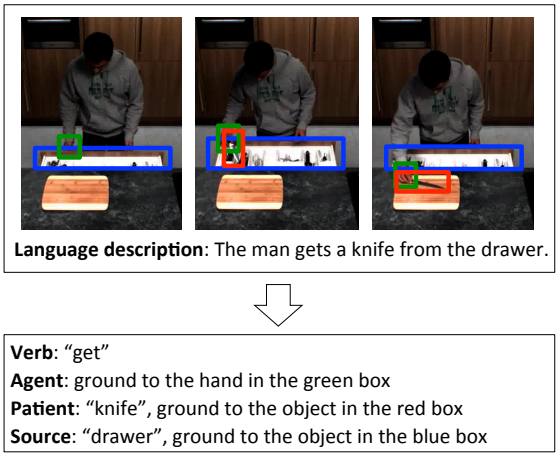

Figure 1: Grounding semantic roles of the verb *get* in the sentence: *the man gets a knife from the drawer*.

5.1 Knowledge-driven Approach

We intend to establish that the knowledge of physical causality for action verbs can be acquired directly from the crowd and such knowledge can be coupled with visual detectors for grounded language understanding.

Acquiring Knowledge. To acquire knowledge of verb causality, we collected a larger dataset of causality annotations based on sentences from the TACoS Multilevel corpus (Rohrbach et al., 2014), through crowd-sourcing on Amazon Mechanical Turk. Annotators were shown a sentence containing a verb-patient pair (e.g., "The person **chops** the **cucumber** into slices on the cutting board"). And they were asked to annotate the change of state that occurred to the *patient* as a result of the verb by choosing up to three options from the 18 causality attributes. Each sentence was annotated by three different annotators.

This dataset contains 4391 sentences, with 178 verbs, 260 nouns, and 1624 verb-noun pairs. After summarizing the annotations from three different annotators, each sentence is represented by a 18-dimension causality vector. In the vector, an element is 1 if at least two annotators labeled the corresponding causality attribute as true, 0 otherwise. For 83% of all the annotated sentences, at least one causality attribute was agreed on by at least two people.

From the causality annotation data, we can extract a *verb causality vector* $\mathbf{c}(\mathrm{v})$ for each verb by averaging all causality vectors of the sentences that contain this verb v.

Applying Knowledge. Since the collected causality knowledge was only for the *patient*, we first look at the grounding of *patient*. Given a sentence containing a verb v and its *patient*, we want to ground the *patient* to one of the object tracks in the video clip. Suppose we have the causality knowledge, i.e., $\mathbf{c}(\mathrm{v})$, for the verb. For each candidate track in the video, we can generate a causality detection vector $\mathbf{d}(\gamma_i)$, using the predefined causality detectors. A straightforward way is to ground the *patient* to the object track whose causality detection results has the best coherence with the causality knowledge of the verb. The coherence is measured by the cosine similarity between $\mathbf{c}(\mathrm{v})$ and $\mathbf{d}(\gamma_i)$.[2]

Since objects in other semantic roles often have relations with the *patient* during the action, once we have grounded the *patient*, we can use it as an anchor point to ground the other three semantic roles. To do this, we define two new detectors for grounding each role as shown in Table 3. These detectors are designed using some common sense knowledge, e.g., *source* is likely to be the initial location of the *patient*; *destination* is likely to be the final location of the *patient*; *agent* is likely to be the hand that touches the *patient*. With these new detectors, we simply ground a role to the object (or hand) track that has the largest number of positive detections from the corresponding detectors.

It is worth noting that although currently we only acquired knowledge for verbs that appear in the cooking domain, the same approach can be extended to verbs in other domains. The detectors associated with attributes are expected to remain the same. The significance of this knowledge-driven method is that, once you have the causality knowledge of a verb, it can be directly applied to any domain without additional training.

5.2 Learning-based Approach

Our second approach is based on learning from training data. A key requirement for this approach is the availability of annotated data where the arguments of a verb are already correctly grounded to the objects in the visual scene. Then we can learn the association between detected causality

[2] In the case that not every causality attribute has a corresponding detector, we need to first condense $\mathbf{c}(\mathrm{v})$ to the same dimensionality with $\mathbf{d}(\gamma_i)$.

Semantic Role	Rule-based Detector
Source	Patient track appears within its bounding box.
	Its track is overlapping with the patient track at the initial frame.
Destination	Patient track disappears within its bounding box.
	Its track is overlapping with the patient track at the final frame.
Agent	Its track is overlapping with the patient track when the patient track appears or disappears.
	Its track is overlapping with the patient track when the patient track starts moving or stops moving.

Table 3: Causality detectors for grounding *source*, *destination*, and *agent*.

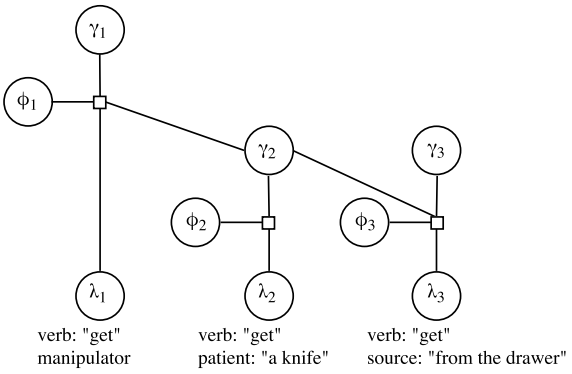

Figure 2: The CRF factor graph of the sentence: *the man gets a knife from the drawer*.

attributes and verbs. We use Conditional Random Field (CRF) to model the semantic role grounding problem. In this approach, causality detection results are used as features in the model.

An example CRF factor graph is shown in Figure 2. The structure of CRF graph is created based on the extracted semantic roles, which already abstracts away syntactic variations such as active/passive constructions. This CRF model is similar to the ones in (Tellex et al., 2011) and (Yang et al., 2016), where $\phi_1, \ldots, \phi_4$ are binary random variables, indicating whether the grounding is correct. In the learning stage, we use the following objective function:

$$p(\Phi|\lambda_1, \ldots, \lambda_k, \gamma_1, \ldots, \gamma_k, \mathrm{v}) = \frac{1}{Z} \prod_i \Psi_i(\phi_i, \lambda_i, \gamma_1, \ldots, \gamma_k, \mathrm{v}) \quad (1)$$

where Φ is the binary random vector $[\phi_1, \ldots, \phi_k]$, and v is the verb. Z is the normalization constant. Ψ_i is the potential function that takes the following log-linear form:

$$\Psi_i(\phi_i, \lambda_i, \Gamma, \mathrm{v}) = \exp\left(\sum_l w_l f_l(\phi_i, \lambda_i, \Gamma, \mathrm{v})\right) \quad (2)$$

where f_l is a feature function, w_l is feature weight to be learned, and $\Gamma = [\gamma_1, \ldots, \gamma_k]$ are the groundings. In our model, we use the following features:

1. Joint features between a track label of γ_i and a word occurrence in λ_i.

2. Joint features between each of the causality detection results and a verb v. Causality detection includes all the detectors in Table 2 and Table 3. Note that the causality detectors shown in Table 3 capture relations between groundings of different semantic roles.

During learning, gradient ascent with L2 regularization is used for parameter learning.

Compared to (Tellex et al., 2011) and (Yang et al., 2016), a key difference in our model is the incorporation of causality detectors. These previous works (Tellex et al., 2011; Yang et al., 2016) apply geometric features, for example, to capture relations, distance, and relative directions between grounding objects. These geometric features can be noisy. In our model, features based on causality detectors are motivated and informed by the underlying causality models for corresponding action verbs.

In the inference step, we want to find the most probable groundings. Given a video clip and its parallel sentence, we fix the Φ to be true, and search for groundings $\gamma_1, \ldots, \gamma_k$ that maximize the probability as in Equation 1. To reduce the search space we apply beam search to ground in the following order: *patient*, *source*, *destination*, *agent*.

5.3 Experiments and Results

We conducted our experiments using the dataset from (Yang et al., 2016). This dataset was developed from a subset of the TACoS corpus (Regneri et al., 2013). It contains a set of video clips paired with natural language descriptions related to two cooking tasks "cutting cucumber" and "cutting bread". Each task has 5 videos showing how different people perform the same task, and each of these videos was split into pairs of video clips and corresponding sentences. For each video clip, objects are annotated with bounding boxes, tracks,

Table 5: Grounding accuracy on four semantic roles

and labels (e.g. "cucumber, cutting board" etc). For each sentence, the semantic roles of a verb are extracted using Propbank (Kingsbury and Palmer, 2002) definitions and each of them is annotated with the ground truth groundings in terms of the object tracks in the corresponding video clip. We selected the 11 most frequent verbs (*get, take, wash, cut, rinse, slice, place, peel, put, remove, open*) and the 4 most frequent explicit semantic roles (*agent, patient, source, destination*) in this evaluation. In total, this dataset includes 977 pairs of video clips and corresponding sentences, and 1096 verb-patient occurrences.

We compare our knowledge-driven approach (*VC-Knowledge*) and learning-based approach (*VC-Learning*) with the following two baselines.

Label Matching. This method simply grounds the semantic role to the track whose label matches the word phrase. If there are multiple matching tracks, it will randomly choose one of them. If there is no matching track, it will randomly select one from all the tracks.

Yang et al., 2016. This work studies grounded semantic role labeling. The evaluation data from this work is used in this paper. It is a natural baseline for comparison.

To evaluate the learning-based approaches such as *VC-Learning* and *(Yang, et al., 2016)*, 75% of video clips with corresponding sentences were randomly sampled as the training set. The remaining 25% were used as the test set. For approaches which do not need training such as *Label Matching* and *VC-Knowledge*, we used the same test set to report their results.

The results of the *patient* role grounding for each verb are shown in Table 4. The results of grounding all four semantic roles are shown in Table 5. The scores in bold are statistically significant ($p < 0.05$) compared to the *Label Matching* method. The scores with an asterisk ($*$) are statistically significant ($p < 0.05$) compared to *(Yang et al., 2016)*.

As it can be difficult to obtain labels for the track, especially when the vision system encounters novel objects, we further conducted several experiments assuming we do not know the labels for the object tracks. In this case, only geometric information of tracked objects is available. Table 4 and Table 5 also include these results.

From the grounding results, we can see that the causality modeling has shown to be very effective in grounding semantic roles. First of all, both the knowledge-driven approach and the learning-based approach outperform the two baselines. In

	All	*take*	*put*	*get*	*cut*	*open*	*wash*	*slice*	*rinse*	*place*	*peel*	*remove*
VC-Knowledge	89.6	94.8	73.3	100	93.1	83.3	100	92.3	96.6	58.6	90.0	73.3
P-VC-Knowledge	89.9	96.6	73.3	100	96.6	66.7	100	92.3	96.6	65.5	90.0	60.0

Table 6: Grounding accuracy on *patient* role using predicted causality knowledge.

particular, our knowledge-driven approach (*VC-Knowledge*) even outperforms the trained model (*Yang et al., 2016*). Our learning-based approach (*VC-Learning*) achieves the best overall performance. In the learning-based approach, causality detection results can be seen as a set of intermediate visual features. The reason that our learning-based approach significantly outperforms the similar model in (*Yang et al., 2016*) is that the causality categorization provides a good guideline for designing intermediate visual features. These causality detectors focus on the changes of state of objects, which are more robust than the geometric features used in (*Yang et al., 2016*).

In the setting of no object recognition labels, *VC-Knowledge* and *VC-Learning* also generate significantly better grounding accuracy than the two baselines. This once again demonstrates the advantage of using causality detection results as intermediate visual features. All these results illustrate the potential of causality modeling for grounded language understanding.

The results in Table 5 also indicate that grounding *source* or *destination* is more difficult than grounding *patient* or *agent*. One reason could be that *source* and *destination* do not exhibit obvious change of state as a result of action, so their groundings usually depend on the correct grounding of other roles such as *patient*.

Since automated tracking for this TACoS dataset is notably difficult due to the complexity of the scene and the lack of depth information, our current results are based on annotated tracks. But object tracking algorithms have made significant progress in recent years (Yang et al., 2013; Milan et al., 2014). We intend to apply our algorithms with automated tracking on real scenes in the future.

6 Causality Prediction for New Verbs

While various methods can be used to acquire causality knowledge for verbs, it may be the case that during language grounding, we do not know the causality knowledge for every verb. Furthermore, manual annotation/acquisition of causality knowledge for all verbs can be time-consuming. In this section, we demonstrate that the existing causality knowledge for some seed verbs can be used to predict causality for new verbs of which we have no knowledge.

We formulate the problem as follows. Suppose we have causality knowledge for a set of seed verbs as training data. Given a new verb, whose causality knowledge is not known, our goal is to predict the causality attributes associated with this new verb. Although the causality knowledge is unknown, it is easy to compute Distributional Semantic Models (DSM) for this verb. Then our goal is to find the causality vector $\mathbf{c}'$ that maximizes

$$\arg\max_{\mathbf{c}'} p(\mathbf{c}'|\mathbf{v}), \tag{3}$$

where $\mathbf{v}$ is the DSM vector for the verb v. The usage of DSM vectors is based on our hypothesis that the textual context of a verb can reveal its possible causality information. For example, the contextual words "pieces" and "halves" may indicate the CoS attribute "NumberOfPieces" for the verb "cut".

We simplify the problem by assuming that the causality vector $\mathbf{c}'$ takes binary values, and also assuming the independence between different causality attributes. Thus, we can formulate this task as a group of binary classification problems: predicting whether a particular causality attribute is positive or negative given the DSM vector of a verb. We apply logistic regression to train a separate classifier for each attribute. Specifically, for the features of a verb, we use the Distributional Memory (*typeDM*) (Baroni and Lenci, 2010) vector. The class label indicates whether the corresponding attribute is associated with the verb.

In our experiment we chose six attributes to study: *Attachment*, *NumberOfPieces*, *Presence*, *Visibility*, *Location*, and *Size*. For each one of the eleven verbs in the grounding task, we predict its causality knowledge using classifiers trained on all other verbs (i.e., 177 verbs in training set). To evaluate the predicted causality vectors, we applied them in the knowledge-driven approach (*P-VC-Knowledge*). Grounding results were compared with the same method using the causality knowledge collected via crowd-sourcing. Ta-

ble 6 shows the grounding accuracy on the *patient* role for each verb. For most verbs, using the predicted knowledge achieves very similar performance compared to using the collected knowledge. The overall grounding accuracy of using the predicted knowledge on all four semantic roles is only 0.3% lower than using the collected knowledge. This result demonstrates that physical causality of action verbs, as part of verb semantics, can be learned through Distributional Semantics.

7 Conclusion

This paper presents, to the best of our knowledge, the first attempt that explicitly models the physical causality of action verbs. We have applied causality modeling to the task of grounding semantic roles to the environment using two approaches: a knowledge-based approach and a learning-based approach.

Our empirical evaluations have shown encouraging results for both approaches. When annotated data is available (in which semantic roles of verbs are grounded to physical objects), the learning-based approach, which learns the associations between verbs and causality detectors, achieves the best overall performance. On the other hand, the knowledge-based approach also achieves competitive performance (even better than previous learned models), without any training. The most exciting aspect about the knowledge-based approach is that causality knowledge for verbs can be acquired from humans (e.g., through crowd-sourcing) and generalized to novel verbs about which we have not yet acquired causality knowledge.

In the future, we plan to build a resource for modeling physical causality for action verbs. As object recognition and tracking are undergoing significant advancements in the computer vision field, such a resource together with causality detectors can be immediately applied for any applications that require grounded language understanding.

Optimizing an Approximation of ROUGE – a Problem-Reduction Approach to Extractive Multi-Document Summarization

Maxime Peyrard and **Judith Eckle-Kohler**

Abstract

This paper presents a problem-reduction approach to extractive multi-document summarization: we propose a reduction to the problem of scoring individual sentences with their ROUGE scores based on supervised learning. For the summarization, we solve an optimization problem where the ROUGE score of the selected summary sentences is maximized. To this end, we derive an approximation of the ROUGE-N score of a set of sentences, and define a principled discrete optimization problem for sentence selection. Mathematical and empirical evidence suggests that the sentence selection step is solved almost exactly, thus reducing the problem to the sentence scoring task. We perform a detailed experimental evaluation on two DUC datasets to demonstrate the validity of our approach.

1 Introduction

Multi-document summarization (MDS) is the task of constructing a summary from a topically related document collection. This paper focuses on the variant of extractive and generic MDS, which has been studied in detail for the news domain using available benchmark datasets from the Document Understanding Conference (DUC) (Over et al., 2007).

Extractive MDS can be cast as a budgeted subset selection problem (McDonald, 2007; Lin and Bilmes, 2011) where the document collection is considered as a set of sentences and the task is to select a subset of the sentences under a length constraint. State-of-the-art and recent works in extractive MDS solve this discrete optimization problem using integer linear programming (ILP) or submodular function maximization (Gillick and Favre, 2009; Mogren et al., 2015; Li et al., 2013b; Kulesza and Taskar, 2012; Hong and Nenkova, 2014). The objective function that is maximized in the optimization step varies considerably in previous work. For instance, Yih et al. (2007) maximize the number of informative words, Gillick and Favre (2009) the coverage of particular concepts, and others maximize a notion of "summary worthiness", while minimizing summary redundancy (Lin and Bilmes, 2011; Kågebäck et al., 2014).

There are also multiple approaches which maximize the evaluation metric for system summaries itself based on supervised Machine Learning (ML). System summaries are commonly evaluated using ROUGE (Lin, 2004), a recall oriented metric that measures the n-gram overlap between a system summary and a set of human-written reference summaries.

The benchmark datasets for MDS can be employed in two different ways for supervised learning of ROUGE scores: either by training a model that assigns ROUGE scores to individual textual units (e.g., sentences), or by performing structured output learning and directly maximizing the ROUGE scores of the created summaries (Nishikawa et al., 2014; Takamura and Okumura, 2010; Sipos et al., 2012). The latter approach suffers both from the limited amount of training data and from the higher complexity of the machine learning models.

In contrast, supervised learning of ROUGE scores for individual sentences can be performed with simple regression models using hundreds of sentences as training instances, taken from a single pair of documents and reference summaries. Extractive MDS can leverage the ROUGE scores of individual sentences in various ways, in particular, as part of an optimization step. In our work, we follow the previously successful approaches to

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1825–1836,
Berlin, Germany, August 7-12, 2016.

extractive MDS using discrete optimization, and make the following contributions:

We provide a theoretical justification and empirical validation for using ROUGE scores of individual sentences as an optimization objective. Assuming that ROUGE scores of individual sentences have been estimated by a supervised learner, we derive an approximation of the ROUGE-N score for a set of sentences from the ROUGE-N scores of the individual sentences in the general case of $N >= 1$.

We use our approximation to define a mathematically principled discrete optimization problem for sentence selection. We empirically evaluate our framework on two DUC datasets, demonstrating the validity of our approximation, as well as its ability to achieve competitive ROUGE scores in comparison to several strong baselines.

Most importantly, the resulting framework reduces the MDS task to the problem of scoring individual sentences with their ROUGE scores. The overall summarization task is converted to two sequential tasks: (i) scoring single sentences, and (ii) selecting summary sentences by solving an optimization problem where the ROUGE score of the selected sentences is maximized.

The optimization objective we propose almost exactly solves (ii), which we justify by providing both mathematical and empirical evidence. Hence, solving the whole problem of MDS is reduced to solving (i).

The rest of this paper is structured as follows: in Section 2, we discuss related work. Section 3 presents our subset selection framework consisting of an approximation of the ROUGE score of a set of sentences, and a mathematically principled discrete optimization problem for sentence selection. We evaluate our framework in Section 4 and discuss the results in Section 5. Section 6 concludes.

2 Related Work

Related to our approach is previous work in extractive MDS that (i) casts the summarization problem as budgeted subset selection, and (ii) employs supervised learning on MDS datasets to learn a scoring function for textual units.

Budgeted Subset Selection Extractive MDS can be formulated as the problem of selecting a subset of textual units from a document collection such that the overall score of the created summary is maximal and a given length constraint is observed. The selection of textual units for the summary relies on their individual scores, assigned by a scoring function which represents aspects of their relevance for a summary. Often, sentences are considered as textual units.

Simultaneously maximizing the relevance scores of the selected units and minimizing their pairwise redundancy given a length constraint is a global inference problem which can be solved using ILP (McDonald, 2007). Several state-of-the-art results in MDS have been obtained by using ILP to maximize the number of relevant concepts in the created summary while minimizing the pairwise similarity between the selected sentences (Gillick and Favre, 2009; Boudin et al., 2015; Woodsend and Lapata, 2012).

Another way to formulate the problem of finding the best subset of textual units is to maximize a submodular function. Maximizing submodular functions is a general technique that uses a greedy optimization algorithm with a mathematical guarantee on optimality (Nemhauser and Wolsey, 1978). Performing summarization in the framework of submodularity is natural because summaries try to maximize the coverage of relevant units while minimizing redundancy (Lin and Bilmes, 2011). However, several different coverage and redundancy functions have been proposed (Lin and Bilmes, 2011; Kågebäck et al., 2014; Yin and Pei, 2015) recently, and there is not yet a clear consensus on which coverage function to maximize.

Supervised Learning Supervised learning using datasets with reference summaries has already been employed in early work on summarization to classify sentences as summary-worthy or not (Kupiec et al., 1995; Aone et al., 1995).

Learning a scoring function for various kinds of textual units has become especially popular in the context of global optimization: scores of textual units, learned from data, are fed into an ILP problem solver to find the subset of sentences with maximal overall score. For example, Yih et al. (2007) score each word in the document cluster based on frequency and position, Li et al. (2013b) learn bigram frequency in the reference summaries, and Hong and Nenkova (2014) learn word importance from a rich set of features.

Closely related to our work are summarization approaches that include a supervised component

which assigns ROUGE scores to individual sentences. For example, Ng et al. (2012), Li et al. (2013a) and Li et al. (2015) all use a regression model to learn ROUGE-2 scores for individual sentences, but use it in different ways for the summarization. While Ng et al. (2012) use the ROUGE scores of sentences in combination with the Maximal Marginal Relevance algorithm as a baseline approach, Li et al. (2013a) use the scores to select the top-ranked sentences for sentence compression and subsequent summarization. Li et al. (2015), in contrast, use the ROUGE scores to re-rank a set of sentences that are output by an optimization step.

While learning ROUGE scores of textual units is widely used in summarization systems, the theoretical background on why this is useful has not been well studied yet. In our work, we present the mathematical and empirical justification for this common practice. In the next section, we start with the mathematical justification.

3 Content Selection Framework

3.1 Approximation of ROUGE-N

Notation: Let $S = \{s_i | i \leq m\}$ be a set of m sentences which constitute a system summary. We use $\rho_N(S)$ or simply $\rho(S)$ to denote the ROUGE-N score of S. ROUGE-N evaluates the n-gram overlap between S and a set of reference summaries (Lin, 2004). Let S^* denote the reference summary and R_N the number of n-gram tokens in S^*. R_N is a function of the summary length in words, in particular, R_1 is the target size of the summary in words. Finally, let $F_S(g)$ denote the number of times the n-gram type g occurs in S. For a single reference summary, ROUGE-N is computed as follows:

$$\rho(S) = \frac{1}{R_N} \sum_{g \in S^*} min(F_S(g), F_{S^*}(g)) \quad (1)$$

For compactness, we use the following notation for any set of sentences X:

$$C_{X,S^*}(g) = min(F_X(g), F_{S^*}(g)) \quad (2)$$

$C_{X,S^*}(g)$ can be understood as the contribution of the n-gram g.

ROUGE-N for a Pair of Sentences: Using this notation, the ROUGE-N score of a set of two sentences a and b can be written as:

$$\rho(a \cup b) = \frac{1}{R_N} \sum_{g \in S^*} min(C_{a \cup b,S^*}(g), F_{S^*}(g)) \quad (3)$$

We observe that $\rho(a \cup b)$ can be expressed as a function of the individual scores $\rho(a)$ and $\rho(b)$:

$$\rho(a \cup b) = \rho(a) + \rho(b) - \epsilon(a \cap b) \quad (4)$$

where $\epsilon(a \cap b)$ is an error correction term that discards overcounted n-grams from the sum of $\rho(a)$ and $\rho(b)$:

$$\epsilon(a \cap b) = \frac{1}{R_N} \sum_{g \in S^*} max(C_{a,S^*}(g) + C_{b,S^*}(g) - F_{S^*}(g), 0) \quad (5)$$

A proof that this error correction is correct is given in appendix A.1.

General Formulation of ROUGE-N: We can extend the previous formulation of ρ to sets of arbitrary cardinality using recursion. If $\rho(S)$ is given for a set of sentences S, and a is a sentence then:

$$\rho(S \cup a) = \rho(S) + \rho(a) - \epsilon(S \cap a) \quad (6)$$

We prove in appendix A.1 that this formula is the ROUGE-N score of $S \cup a$.

Another way to obtain ρ for an arbitrary set S is to adapt the principle of inclusion-exclusion:

$$\rho(S) = \sum_{i=1}^{m} \rho(s_i) + \sum_{k=2}^{m} (-1)^{k+1} \Big(\sum_{1 \leq i_1 \leq \cdots \leq i_k \leq m} \epsilon^{(k)}(s_{i_1} \cap \cdots \cap s_{i_k}) \Big) \quad (7)$$

This formula can be understood as adding up scores of individual sentences, but n-grams appearing in the intersection of two sentences might be overcounted. $\epsilon^{(2)}$ is used to account for these n-grams. But now, n-grams in the intersection of three sentences might be undercounted and $\epsilon^{(3)}$ is used to correct this. Each $\epsilon^{(k)}$ contributes to improving the accuracy by refining the errors made by $\epsilon^{(k-1)}$ for the n-grams appearing in the intersection of k sentences. When $k = |S|$, $\rho(S)$ is exactly the ROUGE-N of S. A rigorous proof and details about $\epsilon^{(k)}$ are provided in appendix A.2.

Approximation of ROUGE-N for a Pair of Sentences: To find a valid approximation of ρ as defined in (7), we first consider the $\rho(a \cup b)$ from equation (3) and then extend it to the general case. When maximizing ρ, scores for sentences are assumed to be given (e.g., estimated by a ML component). We still need to estimate $\epsilon(a \cap b)$, which means, according to (5), to estimate:

$$\sum_{g \in S^*} max(C_{a,S^*}(g) + C_{b,S^*}(g) - F_{S^*}(g), 0) \quad (8)$$

At inference time, neither S^* (the reference summary) nor F_{S^*} (number of occurrences of n-grams in the reference summary) is known.

At this point, we can observe that, similar as for sentence scoring, ϵ can be estimated via a supervised ML component. Such an ML model can easily be trained on the intersections of all sentence pairs in a given training dataset. Hence, we can assume that both the scores for individual sentences and the ϵ are learned empirically from data using ML. As a result, we have pushed all estimation steps into supervised ML components, which leaves the subset selection step fully principled.

However, we found in our experiments that even a simple heuristic yields a decent approximation of ϵ. The heuristic uses the frequency $freq(g)$ of an n-gram g observed in the source documents:

$$\sum_{g \in S^*} max(C_{a,S^*}(g) + C_{b,S^*}(g) - F_{S^*}(g), 0) \approx \sum_{g \in a \cap b} \mathbb{1}[freq(g) \geq \alpha] \quad (9)$$

The threshold α tells us which n-grams are likely to appear in the reference summary, and it is determined by grid-search on the training set. This is penalizing n-grams which appear twice and are likely to occur in the summary. It can be understood as a way of limiting redundancy. In practice, we used $\alpha = 0.3$. However, we experimented with various values of the hyper-parameter α and found that its value has no significant impact as long as it is fairly small (< 0.5). Higher values will ignore too many redundant n-grams and the summary will have a high redundancy.

R_N is known since it is simply the number of n-gram tokens in the summaries. We end up with the following approximation for the pairwise case:

$$\tilde{\rho}(a \cup b) = \rho(a) + \rho(b) - \tilde{\epsilon}(a \cup b), \text{ where}$$
$$\tilde{\epsilon}(a \cup b) = \frac{1}{R_N} \sum_{g \in a \cap b} \mathbb{1}[freq(g) \geq \alpha] \quad (10)$$

General Approximation of ROUGE-N: Now, we can approximate $\rho(S)$ for the general case defined by equation (7). We recall that $\rho(S)$ contains the sum of $\rho(s_i)$, the pairwise error terms $\epsilon^{(2)}(s_i \cap s_j)$, the error terms of three sentences $\epsilon^{(3)}$ and so on.

We can restrict ourselves to the individual sentences and the pairwise error corrections. Indeed, the intersection between more than two sentences is often empty, and accounting for it does not improve the accuracy significantly, but greatly increases the computational cost.

A formulation of ϵ in the case of two sentences has already been defined in (10). Thus, we have an approximation of the ROUGE-N function for any set of sentences that can be computed at inference time:

$$\tilde{\rho}(S) = \sum_{i=1}^{n} \rho(s_i) - \sum_{a,b \in S, a \neq b} \tilde{\epsilon}(a \cap b) \quad (11)$$

We empirically checked the validity of this approximation. For this, we sampled 1000 sets of sentences from source documents of DUC-2003 (sets of 2 to 5 sentences) and compared their $\tilde{\rho}$ score to the real ROUGE-N. We observe a pearson's r correlation ≥ 0.97, which validates $\tilde{\rho}$.

3.2 Discrete Optimization

$\tilde{\rho}$ from equation (11) defines a set function that scores a set of sentences. The task of summarization is now to select the set S^* with maximal $\tilde{\rho}(S^*)$ under a length constraint.

Submodularity: A submodular function is a set function obeying the diminishing returns property: $\forall S \subseteq T$ and a sentence a: $F(S \cup a) - F(S) \geq F(T \cup a) - F(T)$. Submodular functions are convenient because maximization under constraints can be done greedily with a guarantee of the optimality of the solution (Nemhauser et al., 1978).

It has been shown that ROUGE-N is submodular (Lin and Bilmes, 2011) and it is easy to verify that $\tilde{\rho}$ is submodular as well (the proof is given in the supplemental material).

We can therefore apply the greedy maximization algorithm to find a good set of sentences. This has the advantage of being straightforward and fast, however it does not necessarily find the optimal solution.

ILP: A common way to solve a discrete optimization problem is to formulate it as an ILP. It

maximizes (or minimizes) a linear objective function with some linear constraints where the variables are integers. ILP has been well studied and existing tools can efficiently retrieve the exact solution of an ILP problem.

We observe that it is possible to formulate the maximization of $\tilde{\rho}(S)$ as an ILP. Let x be the binary vector whose i-th entry indicates whether sentence i is in the summary or not, $\tilde{\rho}(s_i)$ the scores of sentences, and K the length constraint. We pre-compute the symmetric matrix $\tilde{P}$ where $\tilde{P}_{i,j} = \tilde{\epsilon}(s_i \cap s_j)$ and solve the following ILP:

$$max(\sum_{i=1}^{n} x_i * \tilde{\rho}(s_i) - d\frac{1}{R}\sum_{i \geq j} \alpha_{i,j} * \tilde{P}i, j)$$
$$\sum_{i=1}^{n} x_i * len(s_i) \leq K$$
$$\forall (i,j), \alpha_{i,j} - x_i \leq 0$$
$$\forall (i,j), \alpha_{i,j} - x_j \leq 0$$
$$\forall (i,j), x_i + x_j - \alpha_{i,j} \leq 1$$

d is a damping factor that allows to account for approximation errors. When $d = 0$, the problem becomes the maximization of "summary worthiness" under a length constraint, with "summary worthiness" being defined by $\rho(s_i)$.

In practice, we used a value $d = 0.9$ because we observed that the learner tends to slightly overestimate the ROUGE-N scores of sentences. The mathematical derivation implies $d = 1$, however we can easily adjust for shifts in average scores of sentences from the estimation step by adjusting d. Another option would be to post-process the scores after the estimation step to fix the average and let $d = 1$ in the optimization step. Indeed, if d moves away from 1, we move away from the mathematical framework of ROUGE-N maximization.

If $d \neq 0$, it seems intuitive to interpret the second term as minimizing the summary redundancy, which is in accordance to previous works.

However, in our framework, this term has a precise interpretation:

it maximizes ROUGE-N scores up to the second order of precision, and the ROUGE-N formula itself already induces a notion of "summary worthiness" and redundancy, which we can empirically infer from data via supervised ML for sentence scoring, and a simple heuristic for sentence intersections.

4 Evaluation

We perform three kinds of experiments in order to empirically evaluate our framework: first, we show that our proposed approximation is valid, then we analyze a basic supervised sentence scoring component, and finally we perform an extrinsic evaluation on end-to-end extractive MDS.

In our experiments, we use the DUC datasets from 2002 and 2003 (DUC-02 and DUC-03). We use the variants of ROUGE identified by Owczarzak et al. (2012) as strongly correlating with human evaluation methods: ROUGE-2 recall with stemming and stopwords not removed (giving the best agreement with human evaluation), and ROUGE-1 recall (as the measure with the highest ability to identify the better summary in a pair of system summaries). For DUC-03, summaries are truncated to 100 words, and to 200 words for DUC-02. [1] The truncation is done automatically by ROUGE. [2]

4.1 Framework Validity

Given that sentences receive scores close to their individual ROUGE-N, we presented a function that approximates the ROUGE-N of sets of these sentences and proposed an optimization to find the best scoring set under a length constraint.

To validate our framework empirically, we consider its upper-bound, which is obtained when our ILP/submodular optimizations use the real ROUGE-N scores of the individual sentences, calculated based on the reference summaries. We compare this upper bound to a greedy approach, which simply adds the best scoring sentences one by one to the subset until the length limit is reached, and to the real upper bound for extractive summarization which is determined by solving a maximum coverage problem for n-grams from the reference summary (as it was done by Takamura and Okumura (2010)).

Table 1 shows the results. We observe that ILP-R produces scores close to the reference, thus reducing the problem of extractive summarization to the task of sentence scoring, because the perfect scores induced near perfect extracted summaries in this framework. SBL-R seems less promising than ILP-R because it greedily maximizes a function which ILP-R exactly maximizes. Therefore, we continue our experiments in the following sec-

[1] In the official DUC-03 competitions, summaries of length 665 bytes were expected. Systems could produce different numbers of words. The variation in length has a noticeable impact on ROUGE recall scores.

[2] ROUGE-1.5.5 with the parameters: -n 2 -m -a -l 100 -x -c 95 -r 1000 -f A -p 0.5 -t 0. The length parameter becomes -l 200 for DUC-02.

tions with ILP-R only. However, SBL-R offers a nice trade-off between performance and computation cost. The greedy optimization of SBL-R is noticeably faster than ILP-R.

	DUC-02		DUC-03	
	R1	R2	R1	R2
Greedy	0.597	0.414	0.391	0.148
SBL-R	0.630	0.484	0.424	0.160
ILP-R	0.644	0.495	0.447	0.178
Upper Bound	0.648	0.497	0.452	0.181

Table 1: Upper bound of our framework compared to extractive upper bound.

In practice, the learner will not produce perfect scores. We experimentally validated that with learned scores converging to true scores, the extracted summary converges to the best extractive summary (w.r.t to ROUGE-N). To this end, we simulated approximate learners by artificially randomizing the true scores to end up with lists having various correlations with the true scores. We fed these scores to ILP-R and computed the ROUGE-1 of the generated summaries for an example topic from DUC-2003. Figure 1 displays the expected ROUGE-1 versus the performance of the artificial learner (correlation with true scores of sentences). We observe that, as the learner improves, the generated summaries approach the best ROUGE scoring summary.

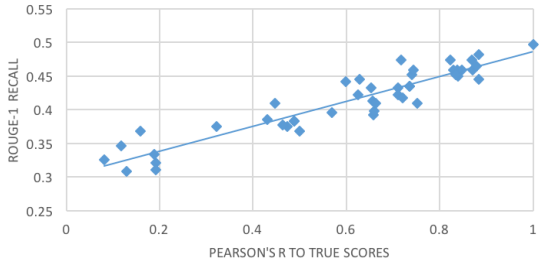

Figure 1: ROUGE-1 of summary against sentence scores correlation with true ROUGE-1 scores of sentences (d30003t from DUC-2003).

4.2 Sentence Scoring

Now we look at the supervised learning component which learns ROUGE-N scores for individual sentences. We know that we can achieve an overall summary ROUGE-N score close to the upper bound, if a learner would be able to learn the scores perfectly. For better understanding the difficulty of the task of sentence scoring, we look at the correlation of the scores produced by a basic learner and the true scores given in a reference dataset.

Model and Features From an existing summarization dataset (e.g. a DUC dataset), a training set can straightforwardly be extracted by annotating each sentence in the source documents with its ROUGE-N score. For each topic in the dataset, this yields a list of sentences and their target score.

To support the claim that learning ROUGE scores for individual sentences is easier than solving the whole summarization task, it is sufficient to choose a basic learner with simple features and little in-domain training data (models are trained on one DUC dataset and evaluated on another). Specifically, we employ a support vector regression (SVR).[3] We use only classical surface-level features to represent sentences (position, length, overlap with title) and combine them with frequency features. The latter include TF*IDF weighting of the terms (similar to Luhn (1958)), the sum of the frequency of the bi-grams in the sentence, as well as the sum of the document frequency (number of source documents in which the n-grams appear) of the terms and bi-grams in a sentence.

We trained two models, R1 and R2 on DUC-02 and DUC-03. For R1, the target score is the ROUGE-1 recall, while R2 learns ROUGE-2 recall.

Correlation Analysis We evaluated our sentence scoring models R1 and R2 by calculating the correlation of the scores produced by R1 and R2 and the true scores given in the DUC-03 data. We compare both models to the true ROUGE-1 and ROUGE-2 scores. In addition, we calculated the correlation of the TF*IDF and LexRank scores, in order to understand how well they would fit into our framework (TF*IDF and LexRank are described in section 4.3).

The results are displayed in Table 2. Even with a basic learner it is possible to learn scores that correlate well with the true ROUGE-N scores, which supports the claim that it is easier to learn scores for individual sentences than to solve the whole problem of summarization. This finding strongly supports our proposed reduction of the extractive MDS problem to the task of learning

[3] We use the implementation in scikit-learn (Pedregosa et al., 2011).

	with ROUGE-1			with ROUGE-2		
	Pearson's r	Kendall's tau	nDCG@15	Pearson's r	Kendall's tau	nDCG@15

Table 2: Correlation of different kinds of sentence scores and their true ROUGE-1 and ROUGE-2 scores.

scores for individual sentences, which correlate well with their true ROUGE-N scores.

We observe that TF*IDF correlates surprisingly well with the ROUGE-1 score, which indicates that we can expect a significant performance gain when feeding TF*IDF scores to our optimization framework. LexRank, on the other hand, orders sentences according to their centrality and does not look at individual sentences. Accordingly, we observe a low correlation with the true ROUGE-N scores, and thus LexRank may not benefit from the optimization (which we confirmed in our experiments).

Finally, we observe that there is significant room for improvement regarding ROUGE-2, as well as for Kendall's tau in ROUGE-1 where a more sophisticated learner could produce scores that correlate better with the true scores. The higher the correlation of the sentence scores assigned by a learner and the true scores, the better the summary produced by the subsequent subset selection.

4.3 End-to-End Evaluation

In our end-to-end evaluation on extractive MDS, we use the following baselines for comparison:

- **TF*IDF weighting**: This simple heuristic was introduced by Luhn (1958). Each sentence receives a score from the TF*IDF of its terms. We trained IDFs (Inverse Document Frequencies) on a background corpus [4] to improve the original algorithm.

- **LexRank**: Among other graph-based approaches to summarization (Mani and Bloedorn, 1997; Radev et al., 2000; Mihalcea, 2004), LexRank (Erkan and Radev, 2004) has become the most popular one. A similarity graph $G(V, E)$ is constructed where V is the set of sentences and an edge e_{ij} is drawn between sentences v_i and v_j if and only if the cosine similarity between them is above a given threshold. Sentences are scored according to their PageRank score in G. For our experiments, we use the implementation available in the sumy package.[5]

- **ICSI**: ICSI is a recent system that has been identified as one of the state-of-the-art systems by Hong et al. (2014). It is a global linear optimization framework that extracts a summary by solving a maximum coverage problem considering the most important concepts in the source documents. Concepts are identified as bi-grams and their importance is estimated via their frequency in the source documents. Boudin et al. (2015) released a Python implementation (ICSI sume) that we use in our experiments.

- **SFOUR**: SFOUR is a structured prediction approach that trains an end-to-end system with a large-margin method to optimize a convex relaxation of ROUGE (Sipos et al., 2012). We use the publicly available implementation. [6]

As described in the previous section, two models are trained: R1 and R2. We evaluate both of them in the end-to-end setup with and without our optimization. In the greedy version, sentences are added as long as the summary length is valid.

We apply the optimization for sentence scoring models trained on ROUGE-1 and ROUGE-2 as well. The scoring models are trained on one dataset and evaluated on the other. For the ILP optimization, the damping factor can vary and leads to different performance. We report the best results among few variations. In order to speed-up the ILP step, we propose to limit the search space by only looking at the top K sentences[7] (hence

[7] We used K=50 and observed that a range from K=25 to K=70 yields a good trade-off between computation cost and performance.

the importance of learning a correct ordering as well, like Kendall's tau). This results in a massive speed-up and can even lead to better results as it prunes parts of the noise. Finally, we perform significance testing with the t-test to compare differences between two means.[8]

Table 3: Impact of the optimization step on sentence subset selection.

Results Table 3 shows the results. The proposed optimization significantly and systematically improves TF*IDF performance as we expected from our analysis in the previous section. This result suggests that using only a frequency signal in source documents is enough to get high scoring summaries, which supports the common belief that frequency is one of the most useful features for generic news summarization. It also aligns well with the strong performance of ICSI, which combines an ILP step with frequency information as well.

The optimization also significantly and systematically improves upon the greedy approach combined with our scoring models. Combining a SVR learner (SVR-1 and SVR-2) and our ILP-R produces results on par with ICSI and sometimes significantly better. SFOUR maximizes ROUGE in an end-to-end fashion, but is outperformed by our framework when using the same training data. The framework is able to reach a competitive performance even with a basic learner. These results again suggest that investigating better learners for sentence scoring might be promising in order to improve the quality of the summaries.

We observe that the model trained on ROUGE-2 is performing better than the model trained on ROUGE-1, although learning the ROUGE-2 scores seems to be harder than learning ROUGE-1 scores (as shown in table 2). However, errors and approximations propagate less easily in ROUGE-2, because the number of bi-grams in the intersection of two given sentences is far less. Hence we conclude that learning ROUGE-2 scores should be put into the focus of future work on improving sentence scoring.

[8]The symbol * indicates that the difference compared to the previous best baseline is significant with $p \leq 0.05$.

5 Discussion

This section discusses our contributions in a broader context.

ROUGE Our subset selection framework performs the task of *content selection*, selecting an unordered set of textual units (sentences for now) for a system summary. The re-ordering of the sentences is left to a subsequent processing step, which accounts for aspects of discourse coherence and readability.

While we justified our choice of ROUGE-1 recall and ROUGE-2 recall as optimization objectives by their strong correlation with human evaluation methods, ROUGE-N has also various drawbacks. In particular, it does not take into account the overall discourse coherence of a system summary (see the supplemental material for examples of summaries generated by our framework).

From a broader perspective, systems that have high ROUGE scores can only be as good as ROUGE is, as a proxy for summary quality. However, as long as systems are evaluated with ROUGE, a natural approach is to develop systems that maximize it.

Should novel automatic evaluation metrics be developed, our approach can still be applied, provided that the new metrics can be expressed as a function of the scores of individual sentences.

Structured Learning Compared to MDS approaches using structured learning, our problem-reduction has the important advantage that it considerably scales-up the available training data by working on sentences instead of documents/summaries pairs. Moreover, the task of sentence scoring is not dependent on arbitrary parameters such as the summary length which are inherently abstracted from the "summary worthiness" of individual textual units.

Error Propagation The first step of the framework is left to a ML component which can only produce approximate scores. Empirical results (in Figure 1 and Table 2) suggest that even with an

imperfect first step, the subsequent optimization is able to produce high scoring summaries. However, it might be insightful to study rigorously and in greater detail the propagation of errors induced by the first step.

Other Metrics This work focused on maximizing ROUGE-N recall because it is a widely acknowledged automatic evaluation metric. ROUGE-N relies on reference summaries which forces us to perform an estimation step. In our framework, we use ML to estimate the individual scores of sentences without using reference summaries.

However, Louis and Nenkova (2013) proposed several alternative evaluation metrics for system summaries which do not need reference summaries. They are based on the properties of the system summary and the source documents alone, and correlate well with human evaluation. Some of them can even reach a correlation with human evaluation similar to the ROUGE-2 recall.

An example of such a metric is the Jensen-Shannon Divergence (JSD) which is a symmetric smoothed version of the Kullback-Leibler divergence. Maximizing JSD can not be solved exactly with an ILP because it can not be factorized into individual sentences. However, applying an efficient greedy algorithm or maximizing a factorizable relaxation might produce strong results as well (for example, a simple greedy maximization of Kullback-Leibler divergence already yields good results (Haghighi and Vanderwende, 2009)).

Future Work In this work, we developed a principled subset selection framework and empirically justified it. We focused on solving the second step of the framework while keeping the machine learning component as simple as possible. Essentially, our framework performs a modularization of the task of MDS, where all characteristics of the data and feature representations are pushed into a separate machine learning module – they should not affect the subsequent optimization step which remains fixed.

The promising results we obtained for summarization with a basic learner (see Section 4.3) encourage future work on plugging in more sophisticated supervised learners in our framework. For example, we plan to incorporate lexical-semantic information in the feature representation and leverage large-scale unsupervised pre-training. This direction is particularly promising because we have shown that we can expect significant performance gains for end-to-end MDS as the sentence scoring component improves.

6 Conclusion

We proposed a problem-reduction approach to extractive MDS, which performs a reduction to the problem of scoring individual sentences with their ROUGE scores based on supervised learning. We defined a principled discrete optimization problem for sentence selection which relies on an approximation of ROUGE. We empirically checked the validity of the approach on standard datasets and observed that even with a basic learner the framework produces promising results. The code for our optimizers is available at `github.com/UKPLab/acl2016-optimizing-rouge`.

A Supplemental Material

A.1 Recursive Expression of ROUGE-N

Let $S = \{s_i | i \leq m\}$ and $T = \{t_i | i \leq l\}$ be two sets of sentences, S^* the reference summary, and $\rho(X)$ denote the ROUGE-N score of the set of sentences X. Assuming that $\rho(S)$ and $\rho(T)$ are given, we prove the following recursive formula:

$$\rho(S \cup T) = \rho(S) + \rho(T) - \epsilon(S \cap T) \quad (12)$$

For compactness, we use the following notation as well:

$$C_{X,S^*}(g) = min(F_X(g), F_{S^*}(g)) \quad (13)$$

Proof: We have the following definitions:

$$\rho(S) = \frac{1}{R_N} \sum_{g \in S^*} \tilde{F}_{S,S^*}(g) \quad (14)$$

$$\rho(T) = \frac{1}{R_N} \sum_{g \in S^*} \tilde{F}_{T,S^*}(g) \quad (15)$$

$$\epsilon(S \cap T) = \frac{1}{R_N} \sum_{g \in S^*} max(C_{S,S^*}(g) + C_{T,S^*}(g) - F_{S^*}(g), 0) \quad (16)$$

And by definition of ROUGE, the formula of $S \cup T$:

$$\rho(S \cup T) = \frac{1}{R_N} \sum_{g \in S^*} min(F_{S \cup T}(g), F_{S^*}(g)) \quad (17)$$

In order to prove equation (12), we have to show that the following equation holds:

$$\sum_{g \in S^*} C_{S,S^*}(g) + \sum_{g \in S^*} C_{T,S^*}(g) - \sum_{g \in S^*} max(C_{S,S^*}(g) + C_{T,S^*}(g) - F_{S^*}(g), 0) = \sum_{g \in S^*} min(F_{S \cup T}(g), F_{S^*}(g)) \quad (18)$$

It is sufficient to show:

$$\forall g \in S^*, C_{S,S^*}(g) + C_{T,S^*}(g) - max(C_{S,S^*}(g) + C_{T,S^*}(g) - F_{S^*}(g), 0) = min(F_{S \cup T}(g), F_{S^*}(g)) \quad (19)$$

Let $g \in S^*$ be a n-gram. There are two possibilities:

- $F_S(g) + F_T(g) \leq F_{S^*}(g)$: g appears less times in $S \cup T$ than in the reference summary. It implies: $min(F_{S\cup T}(g), F_{S^*}(g)) = F_{S\cup T}(g) = F_S(g) + F_T(g)$. Moreover, all $F_X(g)$ are positive numbers by definition, and $F_S(g) \leq F_{S^*}(g)$ is equivalent to: $C_{S,S^*}(g) = min(F_S(g), F_{S^*}(g)) = F_S(g)$. Similarly, we have: $C_{T,S^*}(g) = min(F_T(g), F_{S^*}(g)) = F_T(g)$. Since $max(C_{S,S^*}(g) + C_{T,S^*}(g) - F_{S^*}(g), 0) = 0$, the equation (19) holds in this case.

- $F_S(g) + F_T(g) \geq F_{S^*}(g)$: g appears more frequently in $S \cup T$ than in the reference summary. It implies: $min(F_{S\cup T}(g), F_{S^*}(g)) = F_{S^*}(g)$. Here we have: $max(C_{S,S^*}(g) + C_{T,S^*}(g) - F_{S^*}(g), 0) = C_{S,S^*}(g) + C_{T,S^*}(g) - F_{S^*}(g)$, and it directly follows that equation (19) holds in this case as well.

Equation (19) has been proved, which proves (12) as well.

A.2 Expanded Expression of ROUGE-N

Let $S = \{s_i | i \leq m\}$ be a set of sentences and $\rho(S)$ its ROUGE-N score. We prove the following formula:

$$\rho(S) = \sum_{i=1}^{m} \rho(s_i) + \sum_{k=2}^{m} (-1)^{k+1} \Big(\sum_{1 \leq i_1 \leq \cdots \leq i_k \leq m} \epsilon^{(k)}(s_{i_1} \cap \cdots \cap s_{i_k}) \Big) \tag{20}$$

Proof: Let $g \in S^*$ be a n-gram in the reference summary, and $k \in [1, m]$ the number of sentences in which it appears. Specifically, $\exists \{s_{i_1}, \cdots, s_{i_k}\}, \forall s_{i_j} \in \{s_{i_1}, \ldots, s_{i_k}\}, g \in s_{i_j}$. In order to prove the formula (20), we have to find an expression for the $\epsilon^{(k)}$ that gives to g the correct contribution to the formula:

$$\frac{1}{R_N} min(F_S(g), F_{S^*}(g)) \tag{21}$$

First, we observe that g does not appear in the terms that contain the intersection of more than k sentences. Specifically, $\epsilon^{(t)}$ is not affected by g if $t \geq k$. However, g is affected by all the $\epsilon^{(t)}$ for which $t \leq k$.

Given that g appears in the sentences $\{s_{i_1}, \ldots, s_{i_j}\}$, we can determine the score attributed to g by the previous $\epsilon^{(t)}$ ($t \leq k$):

$$S^{(k-1)}(g) = \sum_{s \in \{s_{i_1}, \ldots, s_{i_k}\}} \rho(s) + \sum_{l=2}^{k} (-1)^{(l+1)} \sum_{1 \leq i_1 \leq \cdots \leq i_l \leq k} \epsilon^{(l)}(s_{i_1} \cap \cdots \cap s_{i_l})) \tag{22}$$

Now, g receives the correct contribution to the overall scores if $\epsilon^{(k)}$ is defined as follows:

$$\epsilon^{(k)}(s_{i_1} \cap \cdots \cap s_{i_j}) = \frac{1}{R} \sum_{g \in s_{i_1} \cap \cdots \cap s_{i_j}} min(C_{\{s_{i_1}, \ldots, s_{i_k}\}}(g), F_{S^*}(g)) - S^{(k-1)}(g) \tag{23}$$

Indeed, with this expression for $\epsilon^{(k)}$, the score of g is:

$$S^{(k-1)}(g) + \frac{1}{R_N} min(C_{\{s_{i_1}, \ldots, s_{i_k}\}}(g), F_{S^*}(g)) - S^{(k-1)}(g) \tag{24}$$

Which can be simplified to:

$$\frac{1}{R_N} min(C_{\{s_{i_1}, \ldots, s_{i_k}\}}(g), F_{S^*}(g)) \tag{25}$$

Since g appears only in the sentences $\{s_{i_1}, \ldots, s_{i_k}\}$, $\tilde{F}_{\{s_{i_1}, \ldots, s_{i_k}\}}(g) = F_S(g)$ and it follows that:

$$\frac{1}{R_N} min(C_{\{s_{i_1}, \ldots, s_{i_k}\}}(g), F_{S^*}(g)) = \frac{1}{R_N} min(F_S(g), F_{S^*}(g)) \tag{26}$$

This proves equation (20) because we observe that g will not be affected by any other terms. Every $\epsilon^{(t)}$ for $t \leq k$ including g is counted by $S^{(k-1)}$, and no other terms from $\epsilon^{(k)}$ will affect g because all the other terms $\epsilon^{(k)}$ should contain at least one sentence that is not in $\{s_{i_1}, \ldots, s_{i_k}\}$ and g would not belong to this intersection by definition.

Finally, it has been proved in the appendix A.1 that for $k = 2$, $\epsilon^{(2)}$ has a reduced form:

$$\epsilon^{(2)}(s_a \cap s_b) = \frac{1}{R_N} \sum_{g \in S^*} max(C_{s_a,S^*}(g) + C_{s_b,S^*}(g) - F_{S^*}(g), 0) \tag{27}$$

In the paper, we ignore the terms for $k \geq 2$, therefore we do not search for a reduced form for these terms.

Phrase Structure Annotation and Parsing for Learner English

Abstract

There has been almost no work on phrase structure annotation and parsing specially designed for learner English despite the fact that they are useful for representing the structural characteristics of learner English. To address this problem, in this paper, we first propose a phrase structure annotation scheme for learner English and annotate two different learner corpora using it. Second, we show their usefulness, reporting on (a) inter-annotator agreement rate, (b) characteristic CFG rules in the corpora, and (c) parsing performance on them. In addition, we explore methods to improve phrase structure parsing for learner English (achieving an F-measure of 0.878). Finally, we release the full annotation guidelines, the annotated data, and the improved parser model for learner English to the public.

1 Introduction

Learner corpora have been essential for NLP tasks related to learner language such as grammatical error correction. They are normally annotated with linguistic properties. In the beginning, attention was mainly focused on grammatical error annotation (Izumi et al., 2004; Díaz-Negrillo et al., 2009; Dale and Kilgarriff, 2011; Ng et al., 2013). Recently, it has been expanded to grammatical annotation — first, Part-Of-Speech (POS) tagging (Díaz-Negrillo et al., 2009; Nagata et al., 2011) and then syntactic annotation (Kepser et al., 2004; Dickinson and Ragheb, 2009; Ragheb and Dickinson, 2012; Ragheb and Dickinson, 2013); syntactic annotation for learner corpora is now intensively studied. Among a variety of studies, a series of work by Ragheb and Dickinson (Dickinson and Ragheb, 2009; Ragheb and Dickinson, 2012; Ragheb and Dickinson, 2013) is important in that they proposed a dependency annotation scheme, theoretically and empirically evaluated it, and revealed its theoretical problems, which gives a good starting point to those who wish to develop a new annotation scheme for learner corpora. Researchers including Foster (2004) and Ott and Ziai (2010) have even started using dependency-annotated learner corpora to develop dependency parsers for learner language.

Although research on syntactic analysis for learner corpora has been making great progress as noted above, it is not yet complete. There are at least three limitations in the previous work: (i) as far as we are aware, there has been almost no work on phrase structure annotation specially designed for learner corpora; (ii) there are no publicly available learner corpora annotated with syntax; (iii) phrase structure parsing performance on learner English has not yet been reported.

The first limitation is that there exists no phrase structure annotation scheme specially designed for learner English. As related work, Foster (2007a; 2007b) and Foster and Andersen (2009) propose a method for creating a pseudo-learner corpus by artificially generating errors in a native corpus with phrase structures. However, the resulting corpus does not capture various error patterns in learner English.

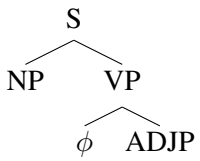
Concerning the second limitation, a corpus greatly increases in value when it is available to the public as has been seen in other domains. Nevertheless, whether dependency or phrase structure, there seems to be no publicly available learner corpora annotated with syntax.

The above two limitations cause the third one that phrase structure parsing performance on leaner English has not yet been reported. For this reason, Cahill (2015) demonstrates how ac-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1837–1847,
Berlin, Germany, August 7-12, 2016.

curately an existing parser performs on a pseudo-learner corpus (section 23 of WSJ with errors artificially generated by Foster and Andersen (2009)'s method). Cahill et al. (2014) show the performance of a phrase structure parser augmented by self-training on students' essays, many of which are presumably written by native speakers of English. Tetreault et al. (2010) partially show phrase structure parsing performance concerning preposition usage in learner English, concluding that it is effective in extracting features for preposition error correction. We need to reveal full parsing performance to be able to confirm that this is true for other syntactic categories and whether or not we should use phrase structure parsing to facilitate related tasks such as grammatical error correction and automated essay scoring.

Here, we emphasize that phrase structure annotation has at least two advantages over dependency annotation[1]. First of all, it can directly encode information about word order. This is particularly important because learner corpora often contain errors in word order. For example, phrase structure parsing will reveal in which phrases errors in word order tend to occur as we will partly do in Sect. 3. Second of all, phrase structure rather abstractly represents syntactic information in terms of phrase-to-phrase relations. This means that the characteristics of learner English are represented by means of phrase-to-phrase relations (e.g., context free grammar (CFG) rules) or even as trees. Take as an example, one of the characteristic trees we found in the corpora we have created:



As we will discuss in Sect. 3, this tree suggests the mother tongue interference that the copula is not necessary in adjective predicates in certain languages. It would be linguistically interesting to reveal what CFG rules we need to add to, or subtract from, the native CFG rule set to be able to generate learner English. This is our primary motivation for this work although our other motivations include developing a parser for learner English.

In view of this background, we address the above problems in this paper. Our contributions are three-fold. First, we present a phrase structure annotation scheme for dealing with learner English consistently and reliably. For this, we propose five principles which can be applied to creating a novel annotation scheme for learner corpora. Second, we evaluate the usefulness of the annotation scheme by annotating learner corpora using it. To be precise, we report on inter-annotator agreement rate and characteristic CFG rules in the corpora, and take the first step to revealing phrase structure parsing performance on learner English. In addition, we explore methods to improve phrase structure parsing for learner English. Finally, we release the full annotation guidelines, the annotated corpora, and the improved parser model to the public.

The rest of this paper is structured as follows. Sect. 2 describes the annotation scheme. Sect. 3 explores the annotated learner corpora. Sect. 4 evaluates parsing performance using it.

2 Phrase Structure Annotation Scheme

2.1 General Principles

The annotation scheme is designed to consistently retrieve the structure in the target text that is closest to the writer's intention. The following are the five principles we created to achieve it:

(P1) Consistency-first principle
(P2) Minimal rule set principle
(P3) Locally superficially-oriented principle
(P4) Minimum edit distance principle
(P5) Intuition principle

(P1) states that the most important thing in our annotation scheme is consistency. It is a trade-off between quality and quantity of information; detailed rules that are too complicated make annotation unmanageable yet they may bring out valuable information in learner corpora. Corpus annotation will be useless if it is inconsistent and unreliable no matter how precisely the rules can describe linguistic phenomena. Therefore, this principle favors consistency over completeness. Once we annotate a corpus consistently, we consider adding further detailed information to it.

(P2) also has to do with consistency. The smaller the number of rules is, the easier it becomes to practice the rules. Considering this, if we have several candidates for describing a new linguistic phenomenon particular to learner English, we will choose the one that minimizes the number of modifications to the existing rule set. Note that

[1]We are not arguing that phrase structure annotation is better than dependency annotation; they both have their own advantages, and thus both should be explored.

this applies to the entire rule set; an addition of a rule may change the existing rule set.

(P3) is used to determine the tag of a given token or phrase. As several researchers (Díaz-Negrillo et al., 2009; Dickinson and Ragheb, 2009; Nagata et al., 2011; Ragheb and Dickinson, 2012) point out, there are two ways of performing annotation, according to either superficial (morphological) or contextual (distributional) evidence. For example, in the sentence **My university life is enjoy.*, the word *enjoy* can be interpreted as a verb according to its morphological form or as an adjective (enjoyable) or a noun (enjoyment) according to its context. As the principle itself construes, our annotation scheme favors superficial evidence over distributional. This is because the interpretation of superficial evidence has much less ambiguity and (P3) can determine the tag of a given token by itself as seen in the above example. Distributional information is also partly encoded in our annotation scheme as we discuss in Subsect. 2.2.

(P4) regulates how to reconstruct a correct form of a given sentence containing errors, which helps to determine its phrase structure. The problem is that often one can think of several candidates as possible corrections, which can become a source of inconsistency. (P4) gives a clear solution to this problem. It selects the one that minimizes the edit distance from the original sentence. Note that the edit distances for deletion, addition, and replacement are one, one, and two (deletion and addition), respectively in our definition.

For the cases to which these four principles do not apply, the fifth and final principle (P5) allows annotators to use their intuition. It should be noted, however, that the five principles apply in the above order to avoid unnecessary inconsistency.

2.2 Annotation Rules

Our annotation scheme is based on the POS-tagging and shallow-parsing annotation guidelines for learner English (Nagata et al., 2011), which in turn are based on the Penn Treebank II-style bracketing guidelines (Bies et al., 1995) (which will be referred to as PTB-II, hereafter). This naturally leads us to adopt the PTB-II tag set in ours; an exception is that we exclude the function tags and null elements from our present annotation scheme for annotation efficiency[2]. Accordingly, we revise the above guidelines to be able to describe phrase structures characteristic of learner English.

The difficulties in syntactic annotation of learner English mainly lie in the fact that grammatical errors appear in learner English. Grammatical errors are often classified into three types as in Izumi et al. (2004): omission, insertion, and replacement type errors. In addition, we include other common error types (word order errors and fragments) in the error types to be able to describe learners' characteristics more precisely. The following discuss how to deal with these five error types based on the five principles.

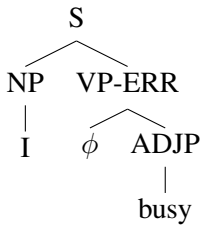
2.2.1 Omission Type Errors

This type of error is an error where a necessary word is missing. For example, some kind of determiner is missing in the sentence **I am student.*

The existing annotation rules in PTB-II can handle most omission type errors. For instance, the PTB-II rule set would parse the above example as "(S (NP I) (VP am (NP student).))." Note that syntactic tags for irrelevant parts are omitted in this example (and hereafter).

A missing head word may be more problematic. Take as an example the sentence **I busy.* where a verb is missing. The omission prevents the rule S $\rightarrow$ NP VP from applying to it. If we created a new rule for every head-omission with no limitation, it would undesirably increase the number of rules, which violates (P2).

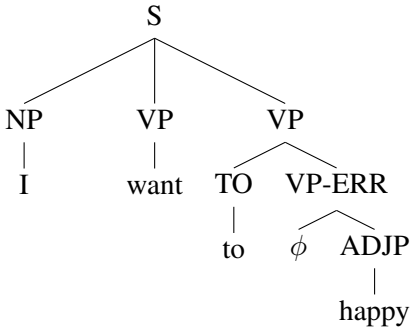
To handle head-omissions, we propose a function tag *-ERR*. It denotes that a head is missing in the phrase in question. The function tag makes it possible to apply the PTB-II rule set to sentences containing head-omissions as in:



We need to reconstruct a correct form of a given sentence to determine whether or not a head word is missing. We use Principle (P4) for solving the problem as discussed in Sect. 2.1. For instance, the sentence **I want to happy.* can be corrected as either *I want to be happy.* (edit distance is one; an addition of a word) or *I want happiness.* (three; two deletions and an addition). Following (P4), we select the first correction that minimizes the edit

[2]We will most likely include them in a future version.

distance, resulting in:



2.2.2 Insertion Type Errors

An insertion type error is an error where an extra word is used incorrectly. For example, the word *about* is an extra word in the sentence **She discussed about it.*

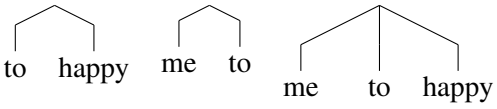
Insertion type errors are more problematic than omission type errors. It is not trivial how to annotate an erroneous extra word. On the one hand, one can argue that the extra word *about* is a preposition from its morphological form. On the other hand, one can also argue that it is not, because the verb *discuss* takes no preposition. As with this example, insertion type errors involve an ambiguity between superficial and distributional categories.

Principles (P2) and (P3) together solve the ambiguity. According to (P3), one should always stick to the superficial evidence. For example, the extra word *about* should be tagged as a preposition. After this, PTB-II applies to the rest of the sentence, which satisfies (P2). As a result, one would obtain the parse "(S (NP She) (VP discussed (PP (IN about) (NP it))))."

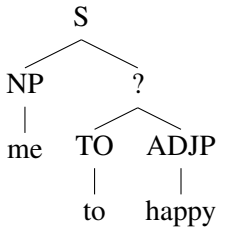
Insertion type errors pose a more vital problem in some cases. Take as an example the sentence **It makes me to happy.* where the word *to* is erroneous. As before, one can rather straightforwardly tag it as a preposition, giving the POS sequence:

**It/PRP makes/VBZ me/PRP to/TO happy/JJ ./.*

However, none of the PTB-II rules applies to the POS sequence *TO JJ* to make a phrase. This means that we have to create a new rule for such cases. There are at most three possibilities of grouping the words in question to make a phrase:



Intuitively, the first one seems to be the most acceptable. To be precise, the second one assumes a postposition, contrary to the English preposition system. The third one assumes a whole new rule generating a phrase from a personal pronoun, a preposition, and an adjective into a phrase. Thus, they cause significant modifications to PTB-II, which violates (P2). In contrast, a preposition normally constitutes a prepositional phrase with another phrase (although not normally with an adjective phrase). Moreover, the first grouping would produce for the rest of the words the perfect phrase structure corresponding to the correct sentence without the preposition *to*:



which satisfies (P2) unlike the second and third ones. Accordingly, we select the first one.

All we have to do now is to name the phrase *to happy*. There is an ambiguity between PP and ADJP, both of which can introduce the parent S. The fact that a preposition constitutes a prepositional phrase with another phrase leads us to select PP for the phrase. Furthermore, the tag of a phrase is normally determined by the POS of one of the immediate constituents, if any, that is entitled to be a head (i.e., the headedness). Considering this, we select PP in this case, which would give the parse to the entire sentence as follows:"(S (NP It) (VP makes (S (NP me) (PP (TO to) (ADJP happy))))).)"

In summary, for insertion errors to which PTB-II do not apply, we determine their phrase structures as follows: (i) intuitively group words into a phrase, minimizing the number of new rules added (it is often helpful to examine whether an existing rule is partially applicable to the words in question); (ii) name the resulting phrase by the POS of one of the immediate children that is entitled to be a head.

2.2.3 Replacement Type Errors

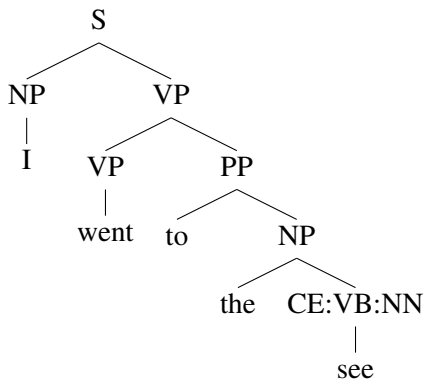
A replacement type error is an error where a word should be replaced with another word. For example, in the sentence: **I often study English conversation.*, the verb *study* should be replaced with a more appropriate verb such as *practice*.

To handle replacement type errors systematically, we introduce a concept called *POS class*, which is a grouping of POS categories defined as

Class	Members
Noun	NN, NNS, NNP, NNPS
Verb	VB, VBP, VBZ, VBD
Adjective	JJ, JJR, JJS
Adverb	RB, RBR, RBS
Participle	VBN, VBG

Table 1: POS class.

in Table 1; POS tags that are not shown in Table 1 form a POS class by itself. If the replacement in question is within the same POS class, it is annotated following Principles (P2) and (P3). Namely, the erroneous word is tagged according to its superficial form and the rest of the sentence is annotated by the original rule set, which avoids creating new rules[3]. If the replacement in question is from one POS class to another, we will need to take special care because of the ambiguity between superficial and distributional POS categories. For example, consider the sentence **I went to the see.* where the word *see* is used as a noun, which is not allowed in the standard English, and the intention of the learner is likely to be *sea* (from the surrounding context). Thus, the word *see* is ambiguous between a verb and a noun in the sentence. To avoid the ambiguity, we adopt a two layer-annotation scheme (Díaz-Negrillo et al., 2009; Nagata et al., 2011; Ragheb and Dickinson, 2012) to include both POSs. In our annotation scheme, we use a special tag (CE) for the replacement error and encode the two POSs as its attribute values as in *CE:VB:NN*. Then we can use the distributional POS tag to annotate the rest of the sentence. For example, the above example sentence would give a tree:

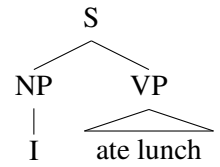


[3]This means that spelling and morphological errors are not directly coded in our annotation scheme as in *He/PRP has/VBZ a/DT books/NNS*.

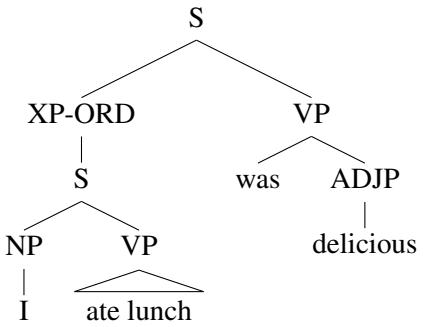
2.2.4 Errors in Word Order

Errors in word order often appear in learner English. A typical example would be the reverse of the subject-object order: **This place like my friends.* (correctly, *My friends like this place.*).

Principles (P2) and (P3) again play an important role in handling errors in word order. We first determine the POS tag of each word according to its morphological form. This is rather straightforward because errors in word order do not affect the morphological form. Then we determine the whole structure based on the resulting POS tags, following Principle (P2); if rules in PTB-II apply to the sentence in question, we parse it according to them just as in the above example sentence: "(S (NP This place) (VP like (NP my friends)).)" Even if any of the existing rules do not apply to a part of the sequence of the given POS tags, we stick to Principle (P3) as much as possible. In other words, we determine partial phrase structures according to the given POS sequence to which the existing rule set applies. Then we use the XP-ORD tag to put them together into a phrase. As an example, consider the sentence **I ate lunch was delicious.* (correctly, *The lunch I ate was delicious.*). According to the superficial forms and local contexts, the phrase *I ate lunch* would form an S:



However, the relations of the S to the rest of the constituents are not clear. Here, we use the XP-ORD tag to combine the S with the rest together:



2.2.5 Fragments

In learner corpora, sentences are sometimes incomplete. They are called fragments (e.g., missing main clause: *Because I like it.*).

Fortunately, there exists already a tag for fragments in PTB-II: FRAG. Accordingly, we use

it in our annotation scheme as well. For example, the above example would give the parse "(FRAG (SBAR Because (S (NP I (VP like (NP it))))).)" An exception is incomplete sentences which are defined as S in the bracketing guidelines for biomedical texts (Warner et al., 2012). We tag such incomplete sentences as S following the convention. For example, an adjective phrase can form an S (e.g., (S (ADVP Beautiful)!)).

2.2.6 Unknown Words and Phrases

There are cases where one cannot tell the tag of a given word. We use the UK tag for such words (e.g., *Everyone is don/UK)*.

Even if its tag is unknown, it is somehow clear in some cases that the unknown word is the head word of the phrase just as in the above example. In that case, we use the UP tag so that it satisfies the rule about the headedness of a phrase we have introduced in Subsect. 2.2.2. Based on this, the above example would give the parse "(S (NP everyone) (VP is (UP (UK don))).)"

For a phrase whose head word is unknown due to some error(s) in it, we use the XP tag instead of the UP tag. As a special case of XP, we use the XP-ORD tag to denote the information that we cannot determine the head of the phrase because of an error in word order.

3 Corpus Annotation

We selected the Konan-JIEM (KJ) learner corpus (Nagata et al., 2011) (beginning to intermediate levels) as our target data. It is manually annotated with POSs, chunks, and grammatical errors, which helps annotators to select correct tags. We also included in the target data a part of the essays in ICNALE (Ishikawa, 2011) consisting of a variety of learners (beginning to advanced levels[4]) in Asia (China, Indonesia, Japan, Korea, Taiwan, Thailand, Hong Kong, Singapore, Pakistan, Philippines). Table 2 shows the statistics on the two learner corpora.

Two professional annotators[5] participated in the annotation process. One of them first annotated the KJ data and double-checked the results. Between the first and second checks, we discussed the results with the annotator. We revised the annotation scheme based on the discussion which resulted in the present version. Then the second annotator annotated a part of the KJ data to evaluate the consistency between the two annotators. We took out 11 texts (955 tokens) as a development set. The second annotator annotated it using the revised annotation scheme where she consulted the first annotator if necessary. After this, we provided her with the differences between the results of the two annotators. Finally, the first annotator annotated the data in ICNALE while the second independently another part of the KJ data and a part of the ICNALE data (59 texts, 12,052 tokens in total), which were treated as a test set.

Table 3 shows inter-annotator agreement measured in recall, precision, F-measure, complete match rate, and chance-corrected measure (Skjærholt, 2014). We used the EVALB tool[6] with the Collins (1997)'s evaluation parameter where we regarded the annotation results of the first annotator as the gold standard set. We also used the syn-agreement tool[7] to calculate chance-corrected measure. It turns out that the agreement is very high. Even in the test set, they achieve an F-measure of 0.928 and a chance-corrected measure of 0.982. This shows that our annotation scheme enabled the annotators to consistently recognize the phrase structures in the learner corpora in which grammatical errors frequently appear. The comparison between the results of the two annotators shows the major sources of the disagreements. One of them is annotation concerning adverbial phrases. In PTB-II, an adverbial phrase between the subject NP and the main verb is allowed to be a constituent of the VP (e.g., (S (NP I) (VP (ADVP often) go))) and also of the S (e.g., (S (NP I) (ADVP often) (VP go))). Another major source is the tag FRAG (fragments); the annotators disagreed on distinguishing between FRAG and S in some cases.

The high agreement shows that the annotation scheme provides an effective way of consistently annotating learner corpora with phrase structures. However, one might argue that the annotation does not represent the characteristics of learner English well because it favors consistency (and rather simple annotation rules) over completeness.

To see if the annotation results represent the

[4]The details about the proficiency levels are available in http://language.sakura.ne.jp/icnale/about.html

[5]The annotators, whose mother tongue is Japanese, have a good command of English. They have engaged in corpus annotation including phrase structure annotation for around 20 years.

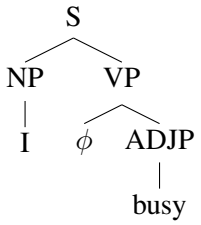
characteristics of learner English, we extracted characteristic CFG rules from them. The basic idea is that we compare the CFG rules obtained from them with those from a native corpus (the Penn Treebank-II)[8]; we select as characteristic CFG rules those that often appear in the learner corpora and not in the native corpus. To formalize the extraction procedures, we denote a CFG rule and its conditional probability as $A \rightarrow B$ and $p(B|A)$, respectively. Then we define the score for $A \rightarrow B$ by $s(A \rightarrow B) = \log \frac{p_L(B|A)}{p_N(B|A)}$ where we distinguish between learner and native corpora by the subscripts L and N, respectively. We estimate $p(B|A)$ by expected likelihood estimation. Note that we remove the function tags to reduce the differences in the syntactic tags in both corpora when we calculate the score.

Table 4 shows the top 10 characteristic CFG rules sorted in descending and ascending order according to their scores, which correspond to overused and underused rules in the learner corpora, respectively. Note that Table 4 excludes rules consisting of only terminal and/or preterminal symbols to focus on the structural characteristics. Also, it excludes rules containing a Quantifier Phrase (QP; e.g., (NP (QP 100 million) dollars)), which frequently appear and is one of the characteristics in the native corpus.

In the overused column, CFG rules often contain the ϕ element. At first sight, this does not seem so surprising because ϕ never appears in the native corpus. However, the rules actually show in which syntactic environment missing heads tend to occur. For example, the CFG rule *PP* $\rightarrow$ ϕ *S* shows that prepositions tend to be missing in the prepositional phrase governing an S as in **I am good _ doing this*, which we had not realized before this investigation. More interestingly, the CFG rule *VP* $\rightarrow$ ϕ *ADJP* reveals that an adjective phrase can form a verb phrase without a verb in learner English. Looking into the annotated data shows that the copula is missing in predicative adjectives as in the tree:



This suggests the transfer of the linguistic system that the copula is not necessary or may be omitted in predicate adjectives in certain languages such as Japanese and Chinese. Similarly, the rule *VP* $\rightarrow$ ϕ *NP* shows in which environment a verb taking the object tends to be missing. Out of the 28 instances, 18 (64%) are in a subordinate clause, which implies that learners tend to omit a verb when more than one verb appear in a sentence.

The second rule *S* $\rightarrow$ *XP VP* . implies that the subject NP cannot be recognized because of a combination of grammatical errors (c.f., *S* $\rightarrow$ *NP VP* .). The corpus data show that 21% of *XP* in *S* $\rightarrow$ *XP VP* . are actually *XP-ORD* concerning an error in a relative clause just as shown in the tree in Subsect. 2.2.4. Some of the learners apparently have problems in appropriately using relative clauses in the subject position. It seems that the structure of the relative clause containing another verb before the main verb confuses them.

Most of the underused CFG rules are those that introduce rather complex structures. For exam-

[8]To confirm that the extracted characteristics are not influenced by the differences in the domains of the two corpora, we also compared the learner data with the native speaker sub-corpus in ICNALE that is in the same domain. It turned out that the extracted CFG rules, were very similar to those shown in Table 4.

Overuse	Score	Underuse	Score
PP → ϕ NP	9.0	NP → NP , NP ,	-4.6
S → XP VP .	7.2	S → NP NP	-2.7
PP → IN IN S	6.7	S → NP VP . ”	-2.6
S → XP .	6.6	ADVP → NP RBR	-2.5
VP → ϕ ADJP	6.5	S → S , NP VP .	-2.4
VP → ϕ NP	6.3	NP → NP , SBAR	-2.4
SBAR → IN NN TO S	6.1	SBAR → WHPP S	-2.3
PP → ϕ S	6.1	VP → VBD SBAR	-2.2
S → ADVP NP ADVP VP .	5.8	S → NP PRN VP .	-2.2
PP → IN TO NP	5.7	S → PP , NP VP . ”	-2.1

Table 4: Characteristic CFG rules.

ple, the eighth rule *VP → VBD SBAR* implies a structure such as *He thought that* $\cdots$. The underused CFG rules are a piece of the evidence that this population of learners of English cannot use such complex structures as fluently as native speakers do. Considering this, it will be useful feedback to provide them with the rules (transformed into interpretable forms). As in this example, phrase structure annotation should be useful not only for second language acquisition research but also for language learning assistance.

4 Parsing Performance Evaluation

We tested the following two state-of-the-art parsers on the annotated data: Stanford Statistical Natural Language Parser (ver.2.0.3) (de Marneffe et al., 2006) and Charniak-Johnson parser (Charniak and Johnson, 2005). We gave the tokenized sentences to them as their inputs. We used again the EVALB tool with the Collins (1997)'s evaluation parameter.

Table 5 shows the results. To our surprise, both parsers perform very well on the learner corpora despite the fact that it contains a number of grammatical errors and also syntactic tags that are not defined in PTB-II. Their performance is comparable to, or even better than, that on the Penn Treebank (reported in Petrov (2010)).

To achieve further improvement, we augmented the Charniak-Johnson parser with the learner data. We first retrained its parser model using the 2-21 sections of Penn Treebank Wall Street Journal (hereafter, WSJ) as training data and its 24 section as development data, following the settings shown in Charniak and Johnson (2005). We then added the learner corpora to the training data using six-fold cross validation. We split it into six parts,

Parser	R	P	F	CMR
Stanford	0.812	0.832	0.822	0.398
Charniak-Johnson	0.845	0.865	0.855	0.465

Table 5: Parsing performance on learner English.

each of which approximately consisted of 61 essays, used one sixth as test data, another one sixth as development data instead of the 24 section, and retrained the parser model using the development data and the training data consisting of the remaining four-sixths part of the learner data and the 2-21 sections of WSJ. We also conducted experiments where we copied the four sixths of the learner data n times ($1 \leq n \leq 50$) and added them to the training data to increase its weight in retraining.

Figure 1 shows the results. The simple addition of the learner data ($n = 1$) already outperforms the parser trained only on the 2-21 sections of WSJ ($n = 0$) in both recall and precision, achieving an F-measure of 0.866 and a complete match rate of 0.515. The augmented parser model particularly works well on recognizing erroneous fragments in the learner data; F-measure improved to 0.796 ($n = 1$) from 0.683 ($n = 0$) in the sentences containing fragments (i.e., FRAG) (46 out of the 111 sentences that were originally erroneously parsed made even a complete match). It was also robust against spelling errors. The performance further improves as the weight n increases (up to $F = 0.878$ when $n = 24$), which shows the effectiveness of using learner corpus data as training data.

Figure 2 shows the parsing performance of the Charniak-Johnson parser in each sub-corpus of

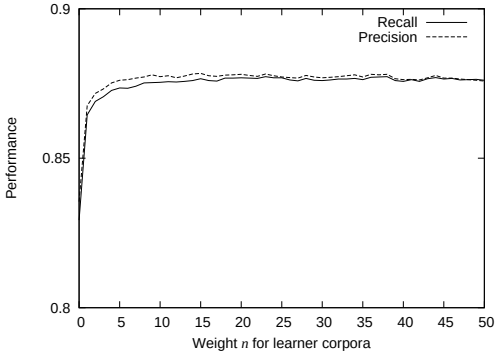


Figure 1: Relation between learner corpus size in training data and parsing performance.

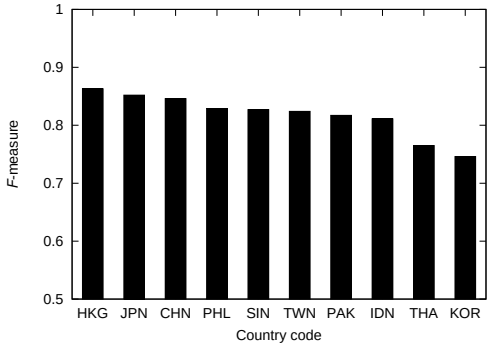

Figure 2: Parsing performance in each sub-corpus.

ICNALE (classified by country code[9]). In most of the sub-corpora, the parser achieves an F-measure of 0.800 or better. By contrast, it performs much worse on the Korean sub-corpus. The major reason for this is that it contains a number of word order errors (i.e., XP-ORD); to be precise, 27 instances compared to zero to two instances in the other sub-corpora. Similarly, FRAG is a source of parsing errors in the Thai sub-corpus. We need further investigation to determine whether the differences in parsing performance are due to the writers' mother tongue or other factors (e.g., proficiency).

We can summarize the findings as follows: (1) the state-of-the-art phrase structure parsers for native English are effective even in parsing learner English; (2) they are successfully augmented by learner corpus data; (3) the evaluation results support the previous report (Tetreault et al., 2010) that they are effective in extracting parse features for grammatical error correction (and probably for related NLP tasks such as automated essay scoring); (4) however, performance may vary depending on the writer's mother tongue and/or other factors, which we need further investigation to confirm.

5 Conclusions

This paper explored phrase structure annotation and parsing specially designed for learner English. Sect. 3 showed the usefulness of our phrase structure annotation scheme and the learner corpora annotated using it. The annotation results exhibited high consistency. They also shed light on (at least, part of) the characteristics of the learners of English. Sect. 4 further reported on the performance of the two state-of-the-art parsers on the annotated corpus, suggesting that they are accurate for providing NLP applications with phrase structures in learner English. All these findings support the effectiveness of our phrase structure annotation scheme for learner English. It would be much more difficult to conduct similar analyses and investigations without the phrase structure annotation scheme and a learner corpus annotated based on it. The annotation guidelines, the annotated data, and the parsing model for learner English created in this work are now available to the public[10].

In our future work, we will evaluate parsing performance on other learner corpora such as ICLE (Granger et al., 2009) consisting of a wide variety of learner Englishes. We will also extend phrase structure annotation, especially working on function tags.

Acknowledgments

We would like to thank Shin'ichiro Ishikawa, who created the ICNALE corpus, for providing us with the data and Arne Skærholt for the assistance to run the syn-agreement tool. We would also like to thank the three anonymous reviewers for their valuable feedback. This work was partly supported by Grant-in-Aid for Young Scientists (B) Grant Number JP26750091.

[9]Ideally, it would be better to use sub-corpora classified by their mother tongues. Unfortunately, however, only country codes are provided in ICNALE.

[10]We released the Konan-JIEM corpus with phrase structures on March 2015, which is available at `http://www.gsk.or.jp/en/catalog/gsk2015-a/`. We annotated the existing ICNALE, which was created by Dr. Ishikawa and his colleagues, with phrase structures. We released the data on Jun 2016, which is available at `http://language.sakura.ne.jp/icnale/`

Abstract

We present *half-life regression (HLR)*, a novel model for spaced repetition practice with applications to second language acquisition. HLR combines psycholinguistic theory with modern machine learning techniques, indirectly estimating the "half-life" of a word or concept in a student's long-term memory. We use data from Duolingo — a popular online language learning application — to fit HLR models, reducing error by 45%+ compared to several baselines at predicting student recall rates. HLR model weights also shed light on which linguistic concepts are systematically challenging for second language learners. Finally, HLR was able to improve Duolingo daily student engagement by 12% in an operational user study.

1 Introduction

The *spacing effect* is the observation that people tend to remember things more effectively if they use *spaced repetition practice* (short study periods spread out over time) as opposed to *massed practice* (i.e., "cramming"). The phenomenon was first documented by Ebbinghaus (1885), using himself as a subject in several experiments to memorize verbal utterances. In one study, after a day of cramming he could accurately recite 12-syllable sequences (of gibberish, apparently). However, he could achieve comparable results with half as many practices spread out over three days.

The *lag effect* (Melton, 1970) is the related observation that people learn even better if the spacing between practices gradually increases. For example, a learning schedule might begin with review sessions a few seconds apart, then minutes, then hours, days, months, and so on, with each successive review stretching out over a longer and longer time interval.

The effects of spacing and lag are well-established in second language acquisition research (Atkinson, 1972; Bloom and Shuell, 1981; Cepeda et al., 2006; Pavlik Jr and Anderson, 2008), and benefits have also been shown for gymnastics, baseball pitching, video games, and many other skills. See Ruth (1928), Dempster (1989), and Donovan and Radosevich (1999) for thorough meta-analyses spanning several decades.

Most practical algorithms for spaced repetition are simple functions with a few hand-picked parameters. This is reasonable, since they were largely developed during the 1960s–80s, when people would have had to manage practice schedules without the aid of computers. However, the recent popularity of large-scale online learning software makes it possible to collect vast amounts of parallel student data, which can be used to empirically train richer statistical models.

In this work, we propose *half-life regression (HLR)* as a trainable spaced repetition algorithm, marrying psycholinguistically-inspired models of memory with modern machine learning techniques. We apply this model to real student learning data from Duolingo, a popular language learning app, and use it to improve its large-scale, operational, personalized learning system.

2 Duolingo

Duolingo is a free, award-winning, online language learning platform. Since launching in 2012, more than 150 million students from all over the world have enrolled in a Duolingo course, either via the website[1] or mobile apps for Android, iOS,

and Windows devices. For comparison, that is more than the total number of students in U.S. elementary and secondary schools combined. At least 80 language courses are currently available or under development[2] for the Duolingo platform. The most popular courses are for learning English, Spanish, French, and German, although there are also courses for minority languages (Irish Gaelic), and even constructed languages (Esperanto).

More than half of Duolingo students live in developing countries, where Internet access has more than tripled in the past three years (ITU and UNESCO, 2015). The majority of these students are using Duolingo to learn English, which can significantly improve their job prospects and quality of life (Pinon and Haydon, 2010).

2.1 System Overview

Duolingo uses a playfully illustrated, gamified design that combines point-reward incentives with implicit instruction (DeKeyser, 2008), mastery learning (Block et al., 1971), explanations (Fahy, 2004), and other best practices. Early research suggests that 34 hours of Duolingo is equivalent to a full semester of university-level Spanish instruction (Vesselinov and Grego, 2012).

Figure 1(a) shows an example **skill tree** for English speakers learning French. This specifies the game-like curriculum: each icon represents a **skill**, which in turn teaches a set of thematically or grammatically related words or concepts. Students tap an icon to access lessons of new material, or to practice previously-learned material. Figure 1(b) shows a screen for the French skill *Gerund*, which teaches common gerund verb forms such as *faisant* (doing) and *étant* (being). This skill, as well as several others, have already been completed by the student. However, the *Measures* skill in the bottom right of Figure 1(a) has one lesson remaining. After completing each row of skills, students "unlock" the next row of more advanced skills. This is a gamelike implementation of *mastery learning*, whereby students must reach a certain level of prerequisite knowledge before moving on to new material.

[2]https://incubator.duolingo.com

Each language course also contains a **corpus** (large database of available exercises) and a **lexeme tagger** (statistical NLP pipeline for automatically tagging and indexing the corpus; see the Appendix for details and a lexeme tag reference). Figure 1(c,d) shows an example translation exercise that might appear in the *Gerund* skill, and Figure 2 shows the lexeme tagger output for this sentence. Since this exercise is indexed with a gerund lexeme tag (*être*.V.GER in this case), it is available for lessons or practices in this skill.

The lexeme tagger also helps to provide corrective feedback. Educational researchers maintain that incorrect answers should be accompanied by *explanations*, not simply a "wrong" mark (Fahy, 2004). In Figure 1(d), the student incorrectly used the 2nd-person verb form *es* (*être*.V.PRES.P2.SG) instead of the 3rd-person *est* (*être*.V.PRES.P3.SG). If Duolingo is able to parse the student response and detect a known grammatical mistake such as this, it provides an explanation[3] in plain language. Each lesson continues until the student masters all of the **target words** being taught in the session, as estimated by a mixture model of short-term learning curves (Streeter, 2015).

2.2 Spaced Repetition and Practice

Once a lesson is completed, all the target words being taught in the lesson are added to the **student model**. This model captures what the student has learned, and estimates how well she can recall this knowledge at any given time. Spaced repetition is a key component of the student model: over time, the strength of a skill will decay in the student's long-term memory, and this model helps the student manage her practice schedule.

Duolingo uses **strength meters** to visualize the student model, as seen beneath each of the completed skill icons in Figure 1(a). These meters represent the average probability that the student can, at any moment, correctly recall a random target word from the lessons in this skill (more on this probability estimate in §3.3). At four bars, the skill is "golden" and considered fresh in the student's memory. At fewer bars, the skill has grown stale and may need practice. A student can tap the skill icon to access practice sessions and target her weakest words. For example, Figure 1(b) shows some weak words from the *Gerund* skill. Practice sessions are identical to lessons, except that the exercises are taken from those indexed with words (lexeme tags) due for practice according to student model. As time passes, strength meters continuously update and decay until the student practices.

[3]If Duolingo cannot parse the precise nature of the mistake — e.g., because of a gross typographical error — it provides a "diff" of the student's response with the closest acceptable answer in the corpus (using Levenshtein distance).

3 Spaced Repetition Models

In this section, we describe several spaced repetition algorithms that might be incorporated into our student model. We begin with two common, established methods in language learning technology, and then present our half-life regression model which is a generalization of them.

3.1 The Pimsleur Method

Pimsleur (1967) was perhaps the first to make mainstream practical use of the spacing and lag effects, with his audio-based language learning program (now a franchise by Simon & Schuster). He referred to his method as *graduated-interval recall*, whereby new vocabulary is introduced and then tested at exponentially increasing intervals, interspersed with the introduction or review of other vocabulary. However, this approach is limited since the schedule is pre-recorded and cannot adapt to the learner's actual ability. Consider an English-speaking French student who easily learns a cognate like *pantalon* (pants), but struggles to remember *manteau* (coat). With the Pimsleur method, she is forced to practice both words at the same fixed, increasing schedule.

3.2 The Leitner System

Leitner (1972) proposed a different spaced repetition algorithm intended for use with flashcards. It is more adaptive than Pimsleur's, since the spacing intervals can increase or decrease depending on student performance. Figure 3 illustrates a popular variant of this method.

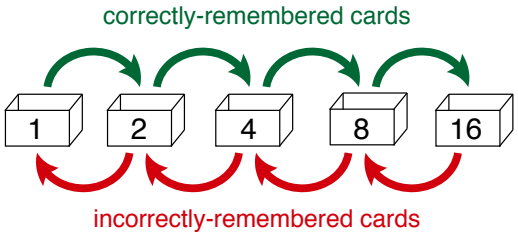

Figure 3: The Leitner System for flashcards.

The main idea is to have a few boxes that correspond to different practice intervals: 1-day, 2-day,

4-day, and so on. All cards start out in the 1-day box, and if the student can remember an item after one day, it gets "promoted" to the 2-day box. Two days later, if she remembers it again, it gets promoted to the 4-day box, etc. Conversely, if she is incorrect, the card gets "demoted" to a shorter interval box. Using this approach, the hypothetical French student from §3.1 would quickly promote *pantalon* to a less frequent practice schedule, but continue reviewing *manteau* often until she can regularly remember it.

Several electronic flashcard programs use the Leitner system to schedule practice, by organizing items into "virtual" boxes. In fact, when it first launched, Duolingo used a variant similar to Figure 3 to manage skill meter decay and practice. The present research was motivated by the need for a more accurate model, in response to student complaints that the Leitner-based skill meters did not adequately reflect what they had learned.

3.3 Half-Life Regression: A New Approach

We now describe half-life regression (HLR), starting from psychological theory and combining it with modern machine learning techniques.

Central to the theory of memory is the *Ebbinghaus model*, also known as the *forgetting curve* (Ebbinghaus, 1885). This posits that memory decays exponentially over time:

$$p = 2^{-\Delta/h} \ . \tag{1}$$

In this equation, p denotes the probability of correctly recalling an item (e.g., a word), which is a function of Δ, the *lag time* since the item was last practiced, and h, the *half-life* or measure of strength in the learner's long-term memory.

Figure 4(a) shows a forgetting curve (1) with half-life $h = 1$. Consider the following cases:

1. $\Delta = 0$. The word was just recently practiced, so $p = 2^0 = 1.0$, conforming to the idea that it is fresh in memory and should be recalled correctly regardless of half-life.

2. $\Delta = h$. The lag time is equal to the half-life, so $p = 2^{-1} = 0.5$, and the student is on the verge of being unable to remember.

3. $\Delta \gg h$. The word has not been practiced for a long time relative to its half-life, so it has probably been forgotten, e.g., $p \approx 0$.

Let $\mathbf{x}$ denote a feature vector that summarizes a student's previous exposure to a particular word, and let the parameter vector Θ contain weights that correspond to each feature variable in $\mathbf{x}$. Under the assumption that half-life should increase exponentially with each repeated exposure (a common practice in spacing and lag effect research), we let $\hat{h}_\Theta$ denote the estimated half-life, given by:

$$\hat{h}_\Theta = 2^{\Theta \cdot \mathbf{x}} \ . \tag{2}$$

In fact, the Pimsleur and Leitner algorithms can be interpreted as special cases of (2) using a few fixed, hand-picked weights. See the Appendix for the derivation of Θ for these two methods.

For our purposes, however, we want to fit Θ empirically to learning trace data, and accommodate an arbitrarily large set of interesting features (we discuss these features more in §3.4). Suppose we have a data set $\mathcal{D} = \{\langle p, \Delta, \mathbf{x} \rangle_i\}_{i=1}^{D}$ made up of student-word practice sessions. Each data instance consists of the observed recall rate p[4], lag time Δ since the word was last seen, and a feature vector $\mathbf{x}$ designed to help personalize the learning experience. Our goal is to find the best model weights Θ^* to minimize some loss function ℓ:

$$\Theta^* = \arg\min_{\Theta} \sum_{i=1}^{D} \ell(\langle p, \Delta, \mathbf{x} \rangle_i; \Theta) \ . \tag{3}$$

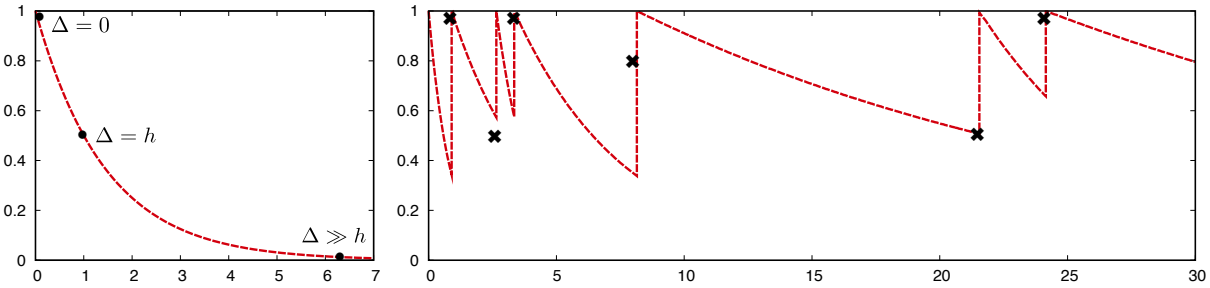
To illustrate, Figure 4(b) shows a student-word learning trace over the course of a month. Each ✖ indicates a data instance: the vertical position is the observed recall rate p for each practice session, and the horizontal distance between points is the lag time Δ between sessions. Combining (1) and (2), the model prediction $\hat{p}_\Theta = 2^{-\Delta/\hat{h}_\Theta}$ is plotted as a dashed line over time (which resets to 1.0 after each exposure, since $\Delta = 0$). The training loss function (3) aims to fit the predicted forgetting curves to observed data points for millions of student-word learning traces like this one.

We chose the L_2-regularized squared loss function, which in its basic form is given by:

$$\ell(✖; \Theta) = (p - \hat{p}_\Theta)^2 + \lambda \|\Theta\|_2^2 \ ,$$

where $✖ = \langle p, \Delta, \mathbf{x} \rangle$ is shorthand for the training data instance, and λ is a parameter to control the regularization term and help prevent overfitting.

[4] In our setting, each data instance represents a full lession or practice session, which may include multiple exercises reviewing the same word. Thus p represents the *proportion* of times a word was recalled correctly in a particular session.



(a) Ebbinghaus model ($h = 1$) (b) 30-day student-word learning trace and predicted forgetting curve

Figure 4: Forgetting curves. (a) Predicted recall rate as a function of lag time Δ and half-life $h = 1$. (b) Example student-word learning trace over 30 days: ✖ marks the observed recall rate p for each practice session, and half-life regression aims to fit model predictions $\hat{p}_\Theta$ (dashed lines) to these points.

In practice, we found it useful to optimize for the half-life h in addition to the observed recall rate p. Since we do not know the "true" half-life of a given word in the student's memory — this is a hypothetical construct — we approximate it algebraically from (1) using p and Δ. We solve for $h = \frac{-\Delta}{\log_2(p)}$ and use the final loss function:

$$\ell(\text{✖}; \Theta) = (p - \hat{p}_\Theta)^2 + \alpha(h - \hat{h}_\Theta)^2 + \lambda\|\Theta\|_2^2 \,,$$

where α is a parameter to control the relative importance of the half-life term in the overall training objective function. Since ℓ is smooth with respect to Θ, we can fit the weights to student-word learning traces using gradient descent. See the Appendix for more details on our training and optimization procedures.

3.4 Feature Sets

In this work, we focused on features that were easily instrumented and available in the production Duolingo system, without adding latency to the student's user experience. These features fall into two broad categories:

- *Interaction features*: a set of counters summarizing each student's practice history with each word (lexeme tag). These include the total number of times a student has seen the word x_n, the number of times it was correctly recalled $x_\oplus$, and the number of times incorrect $x_\ominus$. These are intended to help the model make more personalized predictions.

- *Lexeme tag features*: a large, sparse set of indicator variables, one for each lexeme tag in the system (about 20k in total). These are intended to capture the inherent difficulty of each particular word (lexeme tag).

recall rate		lag (days)	feature vector **x**			
p	($\oplus$/n)	Δ	x_n	$x_\oplus$	$x_\ominus$	$x_{\textit{être}.\text{V.GER}}$
1.0	(3/3)	0.6	3	2	1	1
0.5	(2/4)	1.7	6	5	1	1
1.0	(3/3)	0.7	10	7	3	1
0.8	(4/5)	4.7	13	10	3	1
0.5	(1/2)	13.5	18	14	4	1
1.0	(3/3)	2.6	20	15	5	1

Table 1: Example training instances. Each row corresponds to a data point in Figure 4(b) above, which is for a student learning the French word *étant* (lexeme tag *être*.V.GER).

To be more concrete, imagine that the trace in Figure 4(b) is for a student learning the French word *étant* (lexeme tag *être*.V.GER). Table 1 shows what $\langle p, \Delta, \mathbf{x} \rangle$ would look like for each session in the student's history with that word. The interaction features increase monotonically[5] over time, and $x_{\textit{être}.\text{V.GER}}$ is the only lexeme feature to "fire" for these instances (it has value 1, all other lexeme features have value 0). The model also includes a bias weight (intercept) not shown here.

4 Experiments

In this section, we compare variants of HLR with other spaced repetition algorithms in the context of Duolingo. First, we evaluate methods against historical log data, and analyze trained model weights for insight. We then describe two controlled user experiments where we deployed HLR as part of the student model in the production system.

[5]Note that in practice, we found that using the square root of interaction feature counts (e.g., $\sqrt{x_\oplus}$) yielded better results than the raw counts shown here.

Model	MAE↓	AUC↑	COR_h↑
HLR	**0.128***	0.538*	**0.201***
HLR -lex	**0.128***	0.537*	0.160*
HLR -h	0.350	0.528*	*-0.143**
HLR -lex-h	0.350	0.528*	*-0.142**
Leitner	0.235	**0.542***	*-0.098**
Pimsleur	0.445	0.510*	*-0.132**
LR	0.211	0.513*	n/a
LR -lex	0.212	0.514*	n/a
Constant $\bar{p} = 0.859$	0.175	n/a	n/a

Table 2: Evaluation results using historical log data (see text). Arrows indicate whether lower (↓) or higher (↑) scores are better. The best method for each metric is shown in bold, and statistically significant effects ($p < 0.001$) are marked with *.

4.1 Historical Log Data Evaluation

We collected two weeks of Duolingo log data, containing 12.9 million student-word lesson and practice session traces similar to Table 1 (for all students in all courses). We then compared three categories of spaced repetition algorithms:

- *Half-life regression (HLR)*, our model from §3.3. For ablation purposes, we consider four variants: with and without lexeme features (-lex), as well as with and without the half-life term in the loss function (-h).
- *Leitner and Pimsleur*, two established baselines that are special cases of HLR, using fixed weights. See the Appendix for a derivation of the model weights we used.
- *Logistic regression (LR)*, a standard machine learning[6] baseline. We evaluate two variants: with and without lexeme features (-lex).

We used the first 1 million instances of the data to tune the parameters for our training algorithm. After trying a handful of values, we settled on $\lambda = 0.1$, $\alpha = 0.01$, and learning rate $\eta = 0.001$. We used these same training parameters for HLR and LR experiments (the Leitner and Pimsleur models are fixed and do not require training).

[6]For LR models, we include the lag time x_Δ as an additional feature, since — unlike HLR — it isn't explicitly accounted for in the model. We experimented with polynomial and exponential transformations of this feature, as well, but found the raw lag time to work best.

Table 2 shows the evaluation results on the full data set of 12.9 million instances, using the first 90% for training and remaining 10% for testing. We consider several different evaluation measures for a comprehensive comparison:

- *Mean absolute error (MAE)* measures how closely predictions resemble their observed outcomes: $\frac{1}{D}\sum_{i=1}^{D}|p - \hat{p}_\Theta|_i$. Since the strength meters in Duolingo's interface are based on model predictions, we use MAE as a measure of prediction quality.
- *Area under the ROC curve (AUC)* — or the Wilcoxon rank-sum test — is a measure of ranking quality. Here, it represents the probability that a model ranks a random correctly-recalled word as more likely than a random incorrectly-recalled word. Since our model is used to prioritize words for practice, we use AUC to help evaluate these rankings.
- *Half-life correlation (COR_h)* is the Spearman rank correlation between $\hat{h}_\Theta$ and the algebraic estimate h described in §3.3. We use this as another measure of ranking quality.

For all three metrics, HLR with lexeme tag features is the best (or second best) approach, followed closely by HLR -lex (no lexeme tags). In fact, these are the only two approaches with MAE lower than a baseline constant prediction of the *average* recall rate in the training data (Table 2, bottom row). These HLR variants are also the only methods with positive COR_h, although this seems reasonable since they are the only two to directly optimize for it. While lexeme tag features made limited impact, the h term in the HLR loss function is clearly important: MAE more than doubles without it, and the -h variants are generally worse than the other baselines on at least one metric.

As stated in §3.2, Leitner was the spaced repetition algorithm used in Duolingo's production student model at the time of this study. The Leitner method did yield the highest AUC[7] values among the algorithms we tried. However, the top two HLR variants are not far behind, and they also reduce MAE compared to Leitner by least 45%.

[7]AUC of 0.5 implies random guessing (Fawcett, 2006), so the AUC values here may seem low. This is due in part to an inherently noisy prediction task, but also to a range restriction: $\bar{p} = 0.859$, so most words are recalled correctly and predictions tend to be high. Note that all reported AUC values are statistically significantly better than chance using a Wilcoxon rank sum test with continuity correction.

Table 3: Lexeme tag weights for English (EN), Spanish (ES), French (FR), and German (DE).

4.2 Model Weight Analysis

In addition to better predictions, HLR can capture the inherent difficulty of concepts that are encoded in the feature set. The "easier" concepts take on positive weights (less frequent practice resulting from longer half-lifes), while the "harder" concepts take on negative weights (more frequent practice resulting from shorter half-lifes).

Table 3 shows HLR model weights for several English, Spanish, French, and German lexeme tags. Positive weights are associated with cognates and words that are common, short, or morphologically simple to inflect; it is reasonable that these would be easier to recall correctly. Negative weights are associated with irregular forms, rare words, and grammatical constructs like past or present participles and imperfective aspect. These model weights can provide insight into the aspects of language that are more or less challenging for students of a second language.

	Daily Retention Activity		
Experiment	Any	Lesson	Practice
I. HLR (v. Leitner)	+0.3	+0.3	*-7.3**
II. HLR -lex (v. HLR)	+12.0*	+1.7*	+9.5*

Table 4: Change (%) in daily student retention for controlled user experiments. Statistically significant effects ($p < 0.001$) are marked with *.

4.3 User Experiment I

The evaluation in §4.1 suggests that HLR is a better approach than the Leitner algorithm originally used by Duolingo (cutting MAE nearly in half). To see what effect, if any, these gains have on actual student behavior, we ran controlled user experiments in the Duolingo production system.

We randomly assigned all students to one of two groups: HLR (experiment) or Leitner (control). The underlying spaced repetition algorithm determined strength meter values in the skill tree (e.g., Figure 1(a)) as well as the ranking of target words for practice sessions (e.g., Figure 1(b)), but otherwise the two conditions were identical. The experiment lasted six weeks and involved just under 1 million students.

For evaluation, we examined changes in *daily retention*: what percentage of students who engage in an activity return to do it again the following day? We used three retention metrics: any activity (including contributions to crowdsourced translations, online forum discussions, etc.), new lessons, and practice sessions.

Results are shown in the first row of Table 4. The HLR group showed a slight increase in overall activity and new lessons, but a significant decrease in practice. Prior to the experiment, many students claimed that they would practice instead of learning new material "just to keep the tree gold," but that practice sessions did not review what they thought they needed most. This drop in practice — plus positive anecdotal feedback about stength meter quality from the HLR group — led us to believe that HLR was actually better for student engagement, so we deployed it for all students.

4.4 User Experiment II

Several months later, active students pointed out that particular words or skills would decay rapidly, regardless of how often they practiced. Upon closer investigation, these complaints could be

traced to lexeme tag features with highly negative weights in the HLR model (e.g., Table 3). This implied that some feature-based overfitting had occurred, despite the L_2 regularization term in the training procedure. Duolingo was also preparing to launch several new language courses at the time, and no training data yet existed to fit lexeme tag feature weights for these new languages.

Since the top two HLR variants were virtually tied in our §4.1 experiments, we hypothesized that using interaction features alone might alleviate both student frustration and the "cold-start" problem of training a model for new languages. In a follow-up experiment, we randomly assigned all students to one of two groups: HLR -lex (experiment) and HLR (control). The experiment lasted two weeks and involved 3.3 million students.

Results are shown in the second row of Table 4. All three retention metrics were significantly higher for the HLR -lex group. The most substantial increase was for any activity, although recurring lessons and practice sessions also improved (possibly as a byproduct of the overall activity increase). Anecdotally, vocal students from the HLR -lex group who previously complained about rapid decay under the HLR model were also positive about the change.

We deployed HLR -lex for all students, and believe that its improvements are at least partially responsible for the consistent 5% month-on-month growth in active Duolingo users since the model was launched.

5 Other Related Work

Just as we drew upon the theories of Ebbinghaus to derive HLR as an empirical spaced repetition model, there has been other recent work drawing on other (but related) theories of memory.

ACT-R (Anderson et al., 2004) is a cognitive architecture whose declarative memory module[8] takes the form of a power function, in contrast to the exponential form of the Ebbinghaus model and HLR. Pavlik and Anderson (2008) used ACT-R predictions to optimize a practice schedule for second-language vocabulary, although their setting was quite different from ours. They assumed fixed intervals between practice exercises within the same laboratory session, and found that they could improve short-term learning within a session. In contrast, we were concerned with making accurate recall predictions between multiple sessions "in the wild" on longer time scales. Evidence also suggests that manipulation between sessions can have greater impact on long-term learning (Cepeda et al., 2006).

Motivated by long-term learning goals, the multiscale context model (MCM) has also been proposed (Mozer et al., 2009). MCM combines two modern theories of the spacing effect (Staddon et al., 2002; Raaijmakers, 2003), assuming that each time an item is practiced it creates an additional item-specific forgetting curve that decays at a different rate. Each of these forgetting curves is exponential in form (similar to HLR), but are combined via weighted average, which approximates a power law (similar to ACT-R). The authors were able to fit models to controlled laboratory data for second-language vocabulary and a few other memory tasks, on times scales up to several months. We were unaware of MCM at the time of our work, and it is unclear if the additional computational overhead would scale to Duolingo's production system. Nevertheless, comparing to and integrating with these ideas is a promising direction for future work.

There has also been work on more heuristic spaced repetition models, such as SuperMemo (Woźniak, 1990). Variants of this algorithm are popular alternatives to Leitner in some flashcard software, leveraging additional parameters with complex interactions to determine spacing intervals for practice. To our knowledge, these additional parameters are hand-picked as well, but one can easily imagine fitting them empirically to real student log data, as we do with HLR.

6 Conclusion

We have introduced *half-life regression (HLR)*, a novel spaced repetition algorithm with applications to second language acquisition. HLR combines a psycholinguistic model of human memory with modern machine learning techniques, and generalizes two popular algorithms used in language learning technology: Leitner and Pimsleur. We can do this by incorporating arbitrarily rich features and fitting their weights to data. This approach is significantly more accurate at predicting student recall rates than either of the previous methods, and is also better than a conventional machine learning approach like logistic regression.

[8] Declarative (specifically semantic) memory is widely regarded to govern language vocabulary (Ullman, 2005).

One result we found surprising was that lexeme tag features failed to improve predictions much, and in fact seemed to frustrate the student learning experience due to over-fitting. Instead of the sparse indicator variables used here, it may be better to decompose lexeme tags into denser and more generic features of tag *components*[9] (e.g., part of speech, tense, gender, case), and also use corpus frequency, word length, etc. This representation might be able to capture useful and interesting regularities without negative side-effects.

Finally, while we conducted a cursory analysis of model weights in §4.2, an interesting next step would be to study such weights for even deeper insight. (Note that using lexeme tag component features, as suggested above, should make this anaysis more robust since features would be less sparse.) For example, one could see whether the ranking of vocabulary and/or grammar components by feature weight is correlated with external standards such as the CEFR (Council of Europe, 2001). This and other uses of HLR hold the potential to transform data-driven curriculum design.

Data and Code

To faciliatate research in this area, we have publicly released our data set and code from §4.1: https://github.com/duolingo/halflife-regression.

Acknowledgments

Thanks to our collaborators at Duolingo, particularly Karin Tsai, Itai Hass, and André Horie for help gathering data from various parts of the system. We also thank the anonymous reviewers for suggestions that improved the final manuscript.

A Appendix

A.1 Lexeme Tagger Details

We use a lexeme tagger, introduced in §2, to analyze and index the learning corpus and student responses. Since Duolingo courses teach a moderate set of words and concepts, we do not necessarily need a complete, general-purpose, multi-lingual NLP stack. Instead, for each language we use a finite state transducer (FST) to efficiently parse candidate lexeme tags[10] for each word. We then use a hidden Markov model (HMM) to determine which tag is correct in a given context.

Consider the following two Spanish sentences: '*Yo como manzanas*' ('I eat apples') and '*Corro como el viento*' ('I run like the wind'). For both sentences, the FST parses the word *como* into the lexeme tag candidates *comer*.V.PRES.P1.SG ([I] eat) and *como*.ADV.CNJ (like/as). The HMM then disambiguates between the respective tags for each sentence. Table 5 contains a reference of the abbreviations used in this paper for lexeme tags.

Abbreviation	Meaning
ACC	accusative case
ADJ	adjective
ADV	adverb
DAT	dative case
DEF	definite
DET	determiner

P1/P2/P3	1st/2nd/3rd person
PL	plural
PN	pronoun
PP	past participle
PRESP	present participle
PRES	present tense
PST	past tense
SG	singular
V	verb

Table 5: Lexeme tag component abbreviations.

A.2 Pimsleur and Leitner Models

As mentioned in §3.3, the Pimsleur and Leitner algorithms are special cases of HLR using fixed, hand-picked weights. To see this, consider the original practice interval schedule used by Pimsleur (1967): 5 sec, 25 sec, 2 min, 10 min, 1 hr, 5 hr, 1 day, 5 days, 25 days, 4 months, and 2 years. If we interpret this as a sequence of $\hat{h}_\Theta$ half-lifes (i.e., students should practice when $\hat{p}_\Theta = 0.5$), we can rewrite (2) and solve for $\log_2(\hat{h}_\Theta)$ as a linear

[10] The lexeme tag set is based on a large morphology dictionary created by the Apertium project (Forcada et al., 2011), which we supplemented with entries from Wiktionary (Wikimedia Foundation, 2002) and other sources. Each Duolingo course teaches about 3,000–5,000 lexeme tags.

equation. This yields $\Theta = \{x_n : 2.4, x_b : \text{-}16.5\}$, where x_n and x_b are the number of practices and a bias weight (intercept), respectively. This model perfectly reconstructs Pimsleur's original schedule in days ($r^2 = 0.999$, $p \ll 0.001$). Analyzing the Leitner variant from Figure 3 is even simpler: this corresponds to $\Theta = \{x_\oplus : 1, x_\ominus : \text{-}1\}$, where $x_\oplus$ is the number of past correct responses (i.e., doubling the interval), and $x_\ominus$ is the number of incorrect responses (i.e., halving the interval).

A.3 Training and Optimization Details

The complete objective function given in §3.3 for half-life regression is:

$$\begin{aligned}\ell(\langle p, \Delta, \mathbf{x}\rangle; \Theta) &= (p - \hat{p}_\Theta)^2 \\ &\quad + \alpha(h - \hat{h}_\Theta)^2 + \lambda\|\Theta\|_2^2 \,.\end{aligned}$$

Substituting (1) and (2) into this equation produces the following more explicit formulation:

$$\begin{aligned}\ell(\langle p, \Delta, \mathbf{x}\rangle; \Theta) &= \left(p - 2^{-\frac{\Delta}{2^{\Theta\cdot\mathbf{x}}}}\right)^2 \\ &\quad + \alpha\left(\frac{-\Delta}{\log_2(p)} - 2^{\Theta\cdot\mathbf{x}}\right)^2 \\ &\quad + \lambda\|\Theta\|_2^2 \,.\end{aligned}$$

In general, the search for Θ^* weights to minimize ℓ cannot be solved in closed form, but since it is a smooth function, it can be optimized using gradient methods. The partial gradient of ℓ with respect to each θ_k weight is given by:

$$\begin{aligned}\frac{\partial\ell}{\partial\theta_k} &= 2(\hat{p}_\Theta - p)\ln^2(2)\hat{p}_\Theta\left(\frac{\Delta}{\hat{h}_\Theta}\right)x_k \\ &\quad + 2\alpha\left(\hat{h}_\Theta + \frac{\Delta}{\log_2(p)}\right)\ln(2)\hat{h}_\Theta x_k \\ &\quad + 2\lambda\theta_k \,.\end{aligned}$$

In order to fit Θ to a large amount of student log data, we use AdaGrad (Duchi et al., 2011), an online algorithm for stochastic gradient descent (SGD). AdaGrad is typically less sensitive to the learning rate parameter η than standard SGD, by dynamically scaling each weight update as a function of how often the corresponding feature appears in the training data:

$$\theta_k^{(+1)} := \theta_k - \eta\left[\mathrm{c}(x_k)^{-\frac{1}{2}}\right]\frac{\partial\ell}{\partial\theta_k} \,.$$

Here $\mathrm{c}(x_k)$ denotes the number of times feature x_k has had a nonzero value so far in the SGD pass through the training data. This is useful for training stability when using large, sparse feature sets (e.g., the lexeme tag features in this study). Note that to prevent computational overflow and underflow errors, we bound $\hat{p}_\Theta \in [0.0001, 0.9999]$ and $\hat{h}_\Theta \in [15 \text{ min}, 9 \text{ months}]$ in practice.

User Modeling in Language Learning with Macaronic Texts

Department of Computer Science
Johns Hopkins University
{adi.r,rknowles,phi,eisner}@jhu.edu

Abstract

Foreign language learners can acquire new vocabulary by using cognate and context clues when reading. To measure such incidental comprehension, we devise an experimental framework that involves reading mixed-language "macaronic" sentences. Using data collected via Amazon Mechanical Turk, we train a graphical model to simulate a human subject's comprehension of foreign words, based on cognate clues (edit distance to an English word), context clues (pointwise mutual information), and prior exposure. Our model does a reasonable job at predicting which words a user will be able to understand, which should facilitate the automatic construction of comprehensible text for personalized foreign language education.

1 Introduction

Second language (L2) learning requires the acquisition of vocabulary as well as knowledge of the language's constructions. One of the ways in which learners become familiar with novel vocabulary and constructions is through reading. According to Krashen's Input Hypothesis (Krashen, 1989), learners acquire language through incidental learning, which occurs when learners are exposed to comprehensible input. What constitutes "comprehensible input" for a learner varies as their knowledge of the L2 increases. For example, a student in their first month of German lessons would be hard-pressed to read German novels or even front-page news, but they might understand brief descriptions of daily routines. Comprehensible input need not be completely familiar to the learner; it could include novel vocabulary items or structures (whose meanings they can glean from context). Such input falls in the "zone of proximal development" (Vygotskiĭ, 2012), just outside of the learner's comfort zone. The related concept of "scaffolding" (Wood et al., 1976) consists of providing assistance to the learner at a level that is just sufficient for them to complete their task, which in our case is understanding a sentence.

Automatic selection or construction of comprehensible input—perhaps online and personalized—would be a useful educational technology. However, this requires modeling the student: what can an L2 learner understand in a given context? In this paper, we develop a model and train its parameters on data that we collect.

For the remainder of the paper we focus on native English speakers learning German. Our methodology is a novel solution to the problem of controlling for the learner's German skill level. We use subjects with *zero* previous knowledge of German, but we translate portions of the sentence into English. Thus, we can presume that they *do* already know the English words and *do not* already know the German words (except from seeing them in earlier trials *within* our experiment). We are interested in whether they can jointly infer the meanings of the remaining German words in the sentence, so we ask them to guess.

The resulting stimuli are sentences like "Der Polizist arrested the Bankräuber." Even a reader with no knowledge of German is likely to be able to understand this sentence reasonably well by using cognate and context clues. We refer to this as a *macaronic* sentence; so-called macaronic language is a pastiche of two or more languages (often intended for humorous effect).

Our experimental subjects are required to guess what "Polizist" and "Bankräuber" mean in this sentence. We train a featurized model to predict these guesses jointly within each sentence and thereby predict incidental comprehension on any macaronic sentence. Indeed, we hope our model design will generalize from predicting incidental comprehension on *macaronic* sentences (for our beginner subjects, who need some context words to be in English) to predicting incidental comprehension on *full German* sentences (for more ad-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1859–1869,
Berlin, Germany, August 7-12, 2016.

vanced students, who understand some of the context words *as if* they were in English). In addition, we are developing a user interface that uses macaronic sentences directly as a medium of language instruction: our companion paper (Renduchintala et al., 2016) gives an overview of that project.

We briefly review previous work, then describe our data collection setup and the data obtained. Finally, we discuss our model of learner comprehension and validate our model's predictions.

2 Previous Work

Natural language processing (NLP) has long been applied to education, but the majority of this work focuses on evaluation and assessment. Prominent recent examples include Heilman and Madnani (2012), Burstein et al. (2013) and Madnani et al. (2012). Other works fall more along the lines of intelligent and adaptive tutoring systems designed to improve learning outcomes. Most of those are outside of the area of NLP (typically focusing on math or science). An overview of NLP-based work in the education sphere can be found in Litman (2016). There has also been work specific to second language acquisition, such as Özbal et al. (2014), where the focus has been to build a system to help learners retain new vocabulary. However, much of the existing work on incidental learning is found in the education and cognitive science literature rather than NLP.

Our work is related to Labutov and Lipson (2014), which also tries to leverage incidental learning using mixed L1 and L2 language. Where their work uses surprisal to choose contexts in which to insert L2 vocabulary, we consider both context features and other factors such as cognate features (described in detail in 4.1). We collect data that gives direct evidence of the user's understanding of words (by asking them to provide English guesses) rather than indirectly (via questions about sentence validity, which runs the risk of overestimating their knowledge of a word, if, for instance, they've only learned whether it is animate or inanimate rather than the exact meaning). Furthermore, we are not only interested in whether a mixed L1 and L2 sentence is comprehensible; we are also interested in determining a distribution over the learner's belief state for each word in the sentence. We do this in an engaging, game-like setting, which provides the user with hints when the task is too difficult for them to complete.

3 Data Collection Setup

Our method of scaffolding is to replace certain foreign words and phrases with their English translations, yielding a macaronic sentence.[1] Simply presenting these to a learner would not give us feedback on the learner's belief state for each foreign word. Even assessing the learner's reading comprehension would give only weak indirect information about what was understood. Thus, we collect data where a learner explicitly guesses a foreign word's translation when seen in the macaronic context. These guesses are then treated as supervised labels to train our user model.

We used Amazon Mechanical Turk (MTurk) to collect data. Users qualified for tasks by completing a short quiz and survey about their language knowledge. Only users whose results indicated no knowledge of German and self-identified as native speakers of English were allowed to complete tasks. With German as the foreign language, we generated content by crawling a simplified-German news website, `nachrichtenleicht.de`. We chose simplified German in order to minimize translation errors and to make the task more suitable for novice learners. We translated each German sentence using the Moses Statistical Machine Translation (SMT) toolkit (Koehn et al., 2007). The SMT system was trained on the German-English Commoncrawl parallel text used in WMT 2015 (Bojar et al., 2015).

We used 200 German sentences, presenting each to 10 different users. In MTurk jargon, this yielded 2000 Human Intelligence Tasks (HITs). Each HIT required its user to participate in several rounds of guessing as the English translation was incrementally revealed. A user was paid US$0.12 per HIT, with a bonus of US$6 to any user who accumulated more than 2000 total points.

Our HIT user interface is shown in the video at `https://youtu.be/9PczEcnr4F8`.

3.1 HITs and Submissions

For each HIT, the user first sees a German sentence[2] (Figure 1). A text box is presented below each German word in the sentence, for the user

[1] Although the language distinction is indicated by italics and color, users were left to figure this out on their own.

[2] Except that we first "translate" any German words that have identical spelling in English (case-insensitive). This includes most proper names, numerals, and punctuation marks. Such translated words are displayed in English style (blue italics), and the user is not asked to guess their meanings.

Figure 1: After a user submits a set of guesses (top), the interface marks the correct guesses in green and also reveals a set of translation clues (bottom). The user now has the opportunity to guess again for the remaining German words.

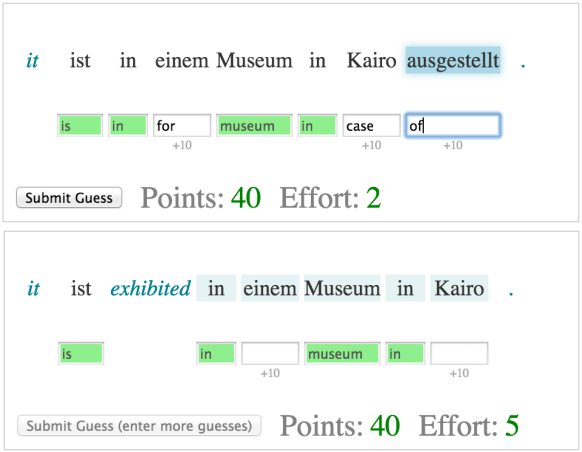

Figure 2: In this case, after the user submits a set of guesses (top), two clues are revealed (bottom): `ausgestellt` is moved into English order and then translated.

to type in their "best guess" of what each German word means. The user must fill in at least half of the text boxes before submitting this set of guesses. The resulting *submission*—i.e., the macaronic sentence together with the set of guesses—is logged in a database as a single training example, and the system displays feedback to the user about which guesses were correct.

After each submission, new *clues* are revealed (providing increased scaffolding) and the user is asked to guess again. The process continues, yielding multiple submissions, until all German words in the sentence have been translated. At this point, the entire HIT is considered completed and the user moves to a new HIT (i.e., a new sentence).

From our 2000 HITs, we obtained 9392 submissions (4.7 per HIT) from 79 distinct MTurk users.

3.2 Clues

Each update provides new clues to help the user make further guesses. There are 2 kinds of clues:

Translation Clue (Figure 1): A set of words that were originally in German are replaced with their English translations. The text boxes below these words disappear, since it is no longer necessary to guess them.

Reordering Clue (Figure 2): A German substring is moved into a more English-like position. The reordering positions are calculated using the word and phrase alignments obtained from Moses.

Each time the user submits a set of guesses, we reveal a sequence of $n = \max(1, \text{round}(N/3))$ clues, where N is the number of German words remaining in the sentence. For each clue, we sample a token that is currently in German. If the token is part of a movable phrase, we move that phrase; otherwise we translate the minimal phrase containing that token. These moves correspond exactly to clues that a user could request by clicking on the token in the macaronic reading interface of Renduchintala et al. (2016)—see that paper for details of how moves are constructed and animated. In our present experiments, the system is in control instead, and grants clues by "randomly clicking" on n tokens.

The system's probability of sampling a given token is proportional to its unigram type probability in the WMT corpus. Thus, rarer words tend to remain in German for longer, allowing the Turker to attempt more guesses for these difficult words.

3.3 Feedback

When a user submits a set of guesses, the system responds with feedback. Each guess is visibly "marked" in left-to-right order, momentarily shaded with green (for correct), yellow (for close) or red (for incorrect). Depending on whether a guess is correct, close, or wrong, users are awarded points as discussed below. Yellow and red shading then fades, to signal to the user that they may try entering a new guess. Correct guesses remain on the screen for the entire task.

3.4 Points

Adding points to the process (Figures 1–2) adds a game-like quality and lets us incentivize users by paying them for good performance (see section 3). We award 10 points for each exactly correct guess (case-insensitive). We give additional "effort points" for a guess that is close to the cor-

rect translation, as measured by cosine similarity in vector space. (We used pre-trained GLoVe word vectors (Pennington et al., 2014); when the guess or correct translation has multiple words, we take the average of the word vectors.) We deduct effort points for guesses that are careless or very poor. Our rubric for effort points is as follows:

$$e_p = \begin{cases} -1, & \text{if } \hat{e} \text{ is repeated or nonsense (red)} \\ -1, & \text{if } \mathrm{sim}(\hat{e}, e^*) < 0 \text{ (red)} \\ 0, & \text{if } 0 \leq \mathrm{sim}(\hat{e}, e^*) < 0.4 \text{ (red)} \\ 0, & \text{if } \hat{e} \text{ is blank} \\ 10 \times \mathrm{sim}(\hat{e}, e^*) & \text{otherwise (yellow)} \end{cases}$$

Here $\mathrm{sim}(\hat{e}, e^*)$ is cosine similarity between the vector embeddings of the user's guess $\hat{e}$ and our reference translation e^*. A "nonsense" guess contains a word that does not appear in the sentence bitext nor in the 20,000 most frequent word types in the GLoVe training corpus. A "repeated" guess is an incorrect guess that appears more than once in the set of guesses being submitted.

In some cases, $\hat{e}$ or e^* may itself consist of multiple words. In this case, our points and feedback are based on the best match between any word of $\hat{e}$ and any word of e^*. In alignments where multiple German words translate as a single phrase,[3] we take the phrasal translation to be the correct answer e^* for *each* of the German words.

3.5 Normalization

After collecting the data, we normalized the user guesses for further analysis. All guesses were lowercased. Multi-word guesses were crudely replaced by the longest word in the guess (breaking ties in favor of the earliest word).

The guesses included many spelling errors as well as some nonsense strings and direct copies of the input. We defined the *dictionary* to be the 100,000 most frequent word types (lowercased) from the WMT English data. If a user's guess $\hat{e}$ does not match e^* and is not in the dictionary, we replace it with

- the special symbol <COPY>, if $\hat{e}$ appears to be a copy of the German source word f (meaning that its Levenshtein distance from f is $< 0.2 \cdot \max(|\hat{e}|, |f|)$);
- else, the closest word in the dictionary[4] as measured by Levenshtein distance (breaking ties alphabetically), provided the dictionary has a word at distance ≤ 2;
- else <BLANK>, as if the user had not guessed.

4 User Model

In each submission, the user jointly guesses several English words, given spelling and context clues. One way that a *machine* could perform this task is via probabilistic inference in a factor graph—and we take this as our model of how the *human user* solves the problem.

The user observes a German sentence $\mathbf{f} = [f_1, f_2, \ldots, f_i, \ldots f_n]$. The translation of each word token f_i is E_i, which is from the user's point of view a random variable. Let Obs denote the set of indices i for which the user also observes that $E_i = e_i^*$, the aligned reference translation, because e_i^* has already been guessed correctly (green feedback) or shown as a clue. Thus, the user's posterior distribution over $\mathbf{E}$ is $P_{\boldsymbol{\theta}}(\mathbf{E} = \mathbf{e} \mid \mathbf{E}_{\text{Obs}} = \mathbf{e}^*_{\text{Obs}}, \mathbf{f}, \text{history})$, where "history" denotes the user's history of past interactions.

We assume that a user's submission $\hat{\mathbf{e}}$ is derived from this posterior distribution simply as a random sample. We try to fit the parameter vector $\boldsymbol{\theta}$ to maximize the log-probability of the submission. Note that our model is trained on the user guesses $\hat{\mathbf{e}}$, not the reference translations $\mathbf{e}^*$. That is, we seek parameters $\boldsymbol{\theta}$ that would explain why all users made their guesses.

Although we fit a single $\boldsymbol{\theta}$, this does not mean that we treat users as interchangeable (since $\boldsymbol{\theta}$ can include user-specific parameters) or unvarying (since our model conditions users' behavior on their history, which can capture some learning).

4.1 Factor Graph

We model the posterior distribution as a conditional random field (Figure 3) in which the value of E_i depends on the form of f_i as well as on the meanings e_j (which may be either observed or jointly guessed) of the context words at $j \neq i$:

$$P_{\boldsymbol{\theta}}(\mathbf{E} = \mathbf{e} \mid \mathbf{E}_{\text{Obs}} = \mathbf{e}^*_{\text{Obs}}, \mathbf{f}, \text{history}) \quad (1)$$
$$\propto \prod_{i \notin \text{Obs}} (\psi^{\text{ef}}(e_i, f_i) \cdot \prod_{j \neq i} \psi^{\text{ee}}(e_i, e_j, i-j))$$

We will define the factors ψ (the *potential functions*) in such a way that they do not "know German" but only have access to information that is available to an naive English speaker. In brief, the

[3] Our German-English alignments are constructed as in Renduchintala et al. (2016).

[4] Considering only words returned by the Pyenchant 'suggest' function (http://pythonhosted.org/pyenchant/).

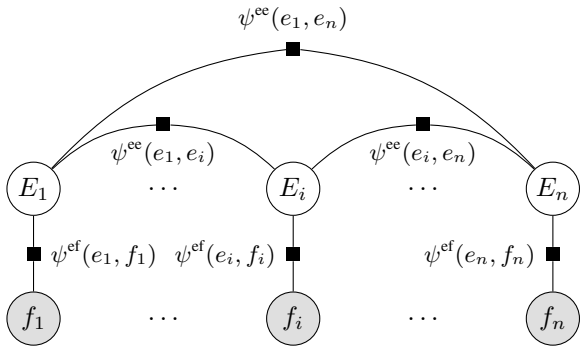

Figure 3: Model for user understanding of L2 words in sentential context. This figure shows an inference problem in which all the observed words in the sentence are in German (that is, Obs $= \emptyset$). As the user observes translations via clues or correctly-marked guesses, some of the E_i become shaded.

factor $\psi^{\text{ef}}(e_i, f_i)$ considers whether the hypothesized English word e_i "looks like" the observed German word f_i, and whether the user has previously observed during data collection that e_i is a correct or incorrect translation of f_i. Meanwhile, the factor $\psi^{\text{ee}}(e_i, e_j)$ considers whether e_i is commonly seen in the context of e_j in English text. For example, the user will elevate the probability that $E_i =$ `cake` if they are fairly certain that E_j is a related word like `eat` or `chocolate`.

The potential functions ψ are parameterized by $\boldsymbol{\theta}$, a vector of feature weights. For convenience, we define the features in such a way that we expect their weights to be positive. We rely on just 6 features at present (see section 6 for future work), although each is complex and real-valued. Thus, the weights $\boldsymbol{\theta}$ control the relative influence of these 6 different types of information on a user's guess. Our features broadly fall under the following categories: *Cognate*, *History*, and *Context*. We precomputed cognate and context features, while history features are computed on-the-fly for each training instance. All features are case-insensitive.

4.1.1 Cognate and History Features

For each German token f_i, the ψ^{ef} factor can score each possible guess e_i of its translation:

$$\psi^{\text{ef}}(e_i, f_i) = \exp(\boldsymbol{\theta}^{\text{ef}} \cdot \boldsymbol{\phi}^{\text{ef}}(e_i, f_i)) \quad (2)$$

The feature function $\boldsymbol{\phi}^{\text{ef}}$ returns a vector of 4 real numbers:

- *Orthographic Similarity*: The normalized Levenshtein distance between the 2 strings.

$$\phi^{\text{ef}}_{\text{orth}}(e_i, f_i) = 1 - \frac{\text{lev}(e_i, f_i)}{\max(|e_i|, |f_i|)} \quad (3)$$

  The weight on this feature encodes how much users pay attention to spelling.

- *Pronunciation Similarity*: This feature is similar to the previous one, except that it calculates the normalized distance between the *pronunciations* of the two words:

$$\phi^{\text{ef}}_{\text{pron}}(e_i, f_i) = \phi^{\text{ef}}_{\text{orth}}(\text{prn}(e_i), \text{prn}(f_i)) \quad (4)$$

  where the function $\text{prn}(x)$ maps a string x to its pronunciation. We obtained pronunciations for all words in the English and German vocabularies using the CMU pronunciation dictionary tool (Weide, 1998). Note that we use English pronunciation rules even for German words. This is because we are modeling a naive learner who may, in the absence of intuition about German pronunciation rules, apply English pronunciation rules to German.

- *Positive History Feature*: If a user has been rewarded in a previous HIT for guessing e_i as a translation of f_i, then they should be more likely to guess it again. We define $\boldsymbol{\phi}^{\text{ef}}_{\text{hist+}}(e_i, f_i)$ to be 1 in this case and 0 otherwise. The weight on this feature encodes whether users learn from positive feedback.

- *Negative History Feature*: If a user has already incorrectly guessed e_i as a translation of f_i in a previous submission during this HIT, then they should be less likely to guess it again. We define $\boldsymbol{\phi}^{\text{ef}}_{\text{hist-}}(e_i, f_i)$ to be -1 in this case and 0 otherwise. The weight on this feature encodes whether users remember negative feedback.[5]

4.1.2 Context Features

In the same way, the ψ^{ef} factor can score the compatibility of a guess e_i with a context word e_j, which may itself be a guess, or may be observed:

$$\psi^{\text{ee}}_{ij}(e_i, e_j) = \exp(\boldsymbol{\theta}^{\text{ee}} \cdot \boldsymbol{\phi}^{\text{ee}}(e_i, e_j, i-j)) \quad (5)$$

$\boldsymbol{\phi}^{\text{ee}}$ returns a vector of 2 real numbers:

$$\boldsymbol{\phi}^{\text{ee}}_{\text{pmi}}(e_i, e_j) = \begin{cases} \text{PMI}(e_i, e_j) \text{ if } |i-j| > 1 \\ 0 \text{ otherwise} \end{cases} \quad (6)$$

$$\boldsymbol{\phi}^{\text{ee}}_{\text{pmi1}}(e_i, e_j) = \begin{cases} \text{PMI}_1(e_i, e_j) \text{ if } |i-j| = 1 \\ 0 \text{ otherwise} \end{cases} \quad (7)$$

[5] At least in short-term memory—this feature currently omits to consider any negative feedback from previous HITs.

where the pointwise mutual information $\mathrm{PMI}(x, y)$ measures the degree to which the English words x, y tend to occur in the same English sentence, and $\mathrm{PMI}_1(x, y)$ measures how often they tend to occur in adjacent positions. These measurements are estimated from the English side of the WMT corpus, with smoothing performed as in Knowles et al. (2016).

For example, if $f_i =$ `Suppe`, the user's guess of E_i should be influenced by $f_j =$ `Brot` appearing in the same sentence, if the user suspects or observes that its translation is $E_j =$ `bread`. The PMI feature knows that `soup` and `bread` tend to appear in the same English sentences, whereas PMI_1 knows that they tend not to appear in the bigram `soup bread` or `bread soup`.

4.1.3 User-Specific Features

Apart from the basic 6-feature model, we also trained a version that includes user-specific copies of each feature (similar to the domain adaptation technique of Daumé III (2007)). For example, $\phi^{\text{ef}}_{\text{orth},32}(e_i, f_i)$ is defined to equal $\phi^{\text{ef}}_{\text{orth}}(e_i, f_i)$ for submissions by user 32, and defined to be 0 for submissions by other users.

Thus, with 79 users in our dataset, we learned 6×80 feature weights: a local weight vector for each user and a global vector of "backoff" weights. The global weight $\theta^{\text{ef}}_{\text{orth}}$ is large if users in general reward orthographic similarity, while $\theta^{\text{ef}}_{\text{orth},32}$ (which may be positive or negative) captures the degree to which user 32 rewards it more or less than is typical. The user-specific features are intended to capture individual differences in incidental comprehension.

4.2 Inference

According to our model, the probability that the user guesses $E_i = \hat{e}_i$ is given by a marginal probability from the CRF. Computing these marginals is a combinatorial optimization problem that involves reasoning jointly about the possible values of each E_i ($i \notin$ Obs), which range over the English vocabulary V^{e}.

We employ loopy belief propagation (Murphy et al., 1999) to obtain approximate marginals over the variables $\mathbf{E}$. A *tree-based* schedule for message passing was used (Dreyer and Eisner, 2009, footnote 22). We run 3 iterations with a new random root for each iteration.

We define the vocabulary V^{e} to consist of all reference translations e^*_i and normalized user guesses $\hat{e}_i$ from our entire dataset (see section 3.5), about 5K types altogether including `<BLANK>` and `<COPY>`. We define the cognate features to treat `<BLANK>` as the empty string and to treat `<COPY>` as f_i. We define the PMI of these special symbols with any e to be the mean PMI with e of all dictionary words, so that they are essentially uninformative.

4.3 Parameter Estimation

We learn our parameter vector $\boldsymbol{\theta}$ to approximately maximize the regularized log-likelihood of the users' guesses:

$$\left(\sum \log P_{\boldsymbol{\theta}}(\mathbf{E} = \hat{\mathbf{e}} \mid \mathbf{E}_{\text{Obs}} = \mathbf{e}^*_{\text{Obs}}, \mathbf{f}, \text{history})\right) - \lambda ||\boldsymbol{\theta}||^2 \quad (8)$$

where the summation is over all submissions in our dataset. The gradient of each summand reduces to a difference between observed and expected values of the feature vector $\boldsymbol{\phi} = (\boldsymbol{\phi}^{\text{ef}}, \boldsymbol{\phi}^{\text{ee}})$, summed over all factors in (1). The observed features are computed directly by setting $\mathbf{E} = \hat{\mathbf{e}}$. The expected features (which arise from the log of the normalization constant of (1)) are computed approximately by loopy belief propagation.

We trained $\boldsymbol{\theta}$ using stochastic gradient descent (SGD),[6] with a learning rate of 0.1 and regularization parameter of 0.2. The regularization parameter was tuned on our development set.

5 Experimental Results

We divided our data randomly into 5550 training instances, 1903 development instances, and 1939 test instances. Each instance was a single submission from one user, consisting of a batch of "simultaneous" guesses on a macaronic sentence.

We noted qualitatively that when a large number of English words have been revealed, particularly content words, the users tend to make better guesses. Conversely, when most context is German, we unsuprisingly see the user leave many guesses blank and make other guesses based on string similarity triggers. Such submissions are difficult to predict as different users will come up with a wide variety of guesses; our model therefore resorts to predicting similar-sounding words. For detailed examples of this see Appendix A.

[6] To speed up training, SGD was parallelized using Recht et al.'s (2011) Hogwild! algorithm. We trained for 8 epochs.

Model	Recall at k (dev)			Recall at k (test)		
	1	25	50	1	25	50
Basic	15.24	34.26	38.08	16.14	35.56	40.30
User-Adapted	15.33	34.40	38.67	16.45	35.71	40.57

Table 1: Percentage of foreign words for which the user's actual guess appears in our top-k list of predictions, for models with and without user-specific features ($k \in \{1, 25, 50\}$).

For each foreign word f_i in a submission with $i \notin$ Obs, our inference method (section 4.2) predicts a marginal probability distribution over a user's guesses $\hat{e}_i$. Table 1 shows our ability to predict user guesses.[7] Recall that this task is essentially a structured prediction task that does joint 4919-way classification of each German word. Roughly 1/3 of the time, our model's top 25 words include the user's exact guess.

However, the recall reported in Table 1 is too stringent for our educational application. We could give the model partial credit for predicting a synonym of the learner's guess $\hat{e}$. More precisely, we would like to give the model partial credit for predicting when the learner will make a poor guess of the truth e^*—even if the model does not predict the user's specific incorrect guess $\hat{e}$.

To get at this question, we use English word embeddings (as in section 3.4) as a proxy for the semantics and morphology of the words. We measure the *actual quality* of the learner's guess $\hat{e}$ as its cosine similarity to the truth, $\mathrm{sim}(\hat{e}, e^*)$. While quality of 1 is an exact match, and quality scores > 0.75 are consistently good matches, we found quality of ≈ 0.6 also reasonable. Pairs such as (`mosque`, `islamic`) and (`politics`, `government`) are examples from the collected data with quality ≈ 0.6. As quality becomes < 0.4, however, the relationship becomes tenuous, e.g., (`refugee`, `soil`).

Similarly, we measure the *predicted quality* as $\mathrm{sim}(e, e^*)$, where e is the model's 1-best prediction of the user's guess. Figure 4 plots predicted vs. actual quality (each point represents one of the learner's guesses on development data), obtaining a correlation of 0.38, which we call the "quality correlation" or QC. A clear diagonal band can be seen, corresponding to the instances where the model exactly predicts the user's guess. The cloud around the diagonal is formed by instances where the model's prediction was not identical to the user's guess but had similar quality.

[7] Throughout this section, we ignore the 5.2% of tokens on which the user did not guess (i.e., the guess was `<BLANK>` after the normalization of section 3.5). Our present model simply treats `<BLANK>` as an ordinary and very bland word (section 4.2), rather than truly attempting to predict when the user will not guess. Indeed, the model's posterior probability of `<BLANK>` in these cases is a paltry 0.0000267 on average (versus 0.0000106 when the user does guess). See section 6.

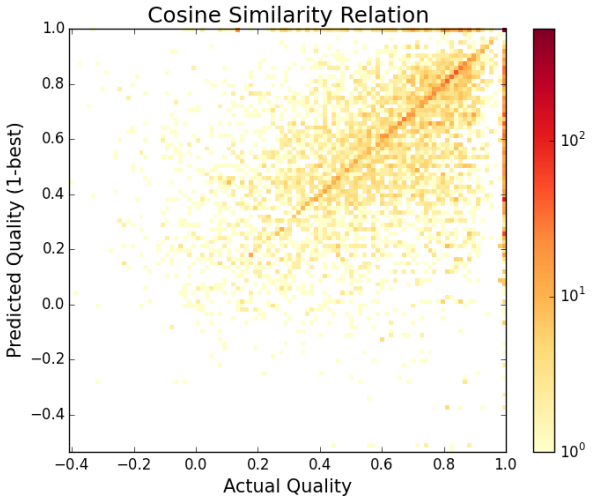

Figure 4: Actual quality $\mathrm{sim}(\hat{e}, e^*)$ of the learner's guess $\hat{e}$ on development data, versus predicted quality $\mathrm{sim}(e, e^*)$ where e is the basic model's 1-best prediction.

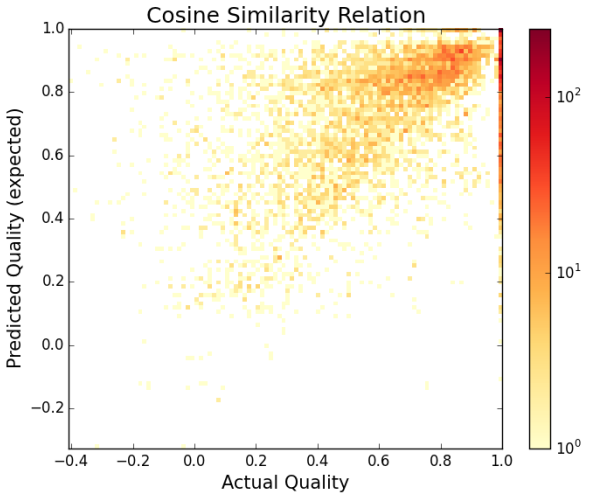

Figure 5: Actual quality $\mathrm{sim}(\hat{e}, e^*)$ of the learner's guess $\hat{e}$ on development data, versus the expectation of the predicted quality $\mathrm{sim}(e, e^*)$ where e is distributed according to the basic model's posterior.

We also consider the *expected* predicted quality, averaging over the model's predictions e of $\hat{e}$ (for all $e \in V^e$) in proportion to the probabilities that it assigns them. This allows the model to more smoothly assess whether the learner is likely to make a high-quality guess. Figure 5 shows this version, where the points tend to shift upward and the quality correlation (QC) rises to 0.53.

All QC values are given in Table 2. We used expected QC on the development set as the criterion for selecting the regularization coefficient λ and as the early stopping criterion during training.

Model	Dev		Test	
	Exp	1-Best	Exp	1-Best
Basic	0.525	0.379	0.543	0.411
User-Adapted	0.527	0.427	0.544	0.439

Table 2: Quality correlations: basic and user-adapted models.

Feature Removed	QC	
	Expected	1-Best
None	0.522	0.425
Cognate	0.516	0.366*
Context	0.510	0.366*
History	0.499*	0.259*

Table 3: Impact on quality correlation (QC) of removing features from the model. Ablated QC values marked with asterisk* differ significantly from the full-model QC values in the first row ($p < 0.05$, using the test of Preacher (2002)).

5.1 Feature Ablation

To test the usefulness of different features, we trained our model with various feature categories disabled. To speed up experimentation, we sampled 1000 instances from the training set and trained our model on those. The resulting QC values on dev data are shown in Table 3. We see that removing history-based features has the most significant impact on model performance: both QC measures drop relative to the full model. For cognate and context features, we see no significant impact on the expected QC, but a significant drop in the 1-best QC, especially for context features.

5.2 Analysis of User Adaptation

Table 2 shows that the user-specific features significantly improve the *1-best* QC of our model, although the much smaller improvement in *expected* QC is insignificant.

User adaptation allows us to discern different styles of incidental comprehension. A user-adapted model makes fine-grained predictions that could help to construct better macaronic sentences for a given user. Each user who completed at least 10 HITs has their user-specific weight vector shown as a row in Figure 6. Recall that the user-specific weights are not used in isolation, but are *added* to backoff weights shared by all users.

These user-specific weight vectors cluster into four groups. Furthermore, the average points per HIT differ by cluster (significantly between each cluster pair), reflecting the success of different strategies.[8] Users in group (a) employ a generalist

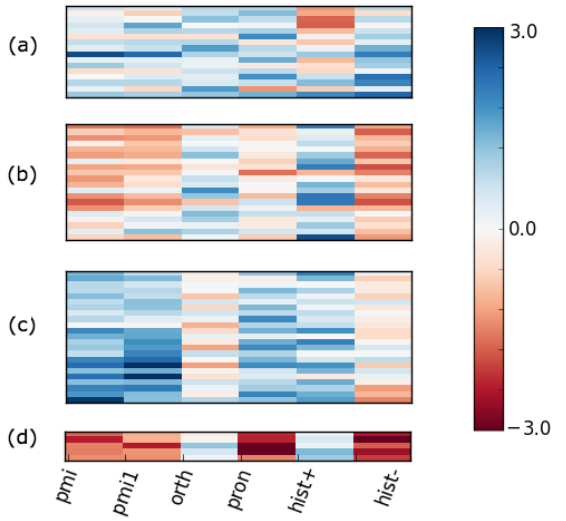

Figure 6: The user-specific weight vectors, clustered into groups. Average points per HIT for the HITs completed by each group: (a) 45, (b) 48, (c) 50 and (d) 42.

strategy for incidental comprehension. They pay typical or greater-than-typical attention to all features of the current HIT, but many of them have diminished memory for vocabulary learned during past HITs (the hist+ feature). Users in group (b) seem to use the opposite strategy, deriving their success from retaining common vocabulary across HITs (hist+) and falling back on orthography for new words. Group (c) users, who earned the most points per HIT, appear to make heavy use of context and pronunciation features *together* with hist+. We also see that pronunciation similarity seems to be a stronger feature for group (c) users, in contrast to the more superficial orthographic similarity. Group (d), which earned the fewest points per HIT, appears to be an "extreme" version of group (b): these users pay unusually little attention to any model features other than orthographic similarity and hist+. (More precisely, the model finds group (d)'s guesses harder to predict on the basis of the available features, and so gives a more uniform distribution over V^e.)

6 Future Improvements to the Model

Our model's feature set (section 4.1) could clearly be refined and extended. Indeed, in a separate paper (Knowles et al., 2016), we use a more tightly controlled experimental design to explore some simple feature variants. A cheap way to vet features would be to test whether they help on the task of modeling reference translations, which are

[8] Recall that in our data collection process, we award points for each HIT (section 3.4). While the points were designed more as a reward than as an evaluation of learner success, a higher score does reflect more guesses that were correct or close, while a lower score indicates that some words were never guessed before the system revealed them as clues.

more plentiful and less noisy than the user guesses.

For *Cognate* features, there exist many other good string similarity metrics (including trainable ones). We could also include $\boldsymbol{\phi}^{\text{ef}}$ features that consider whether e_i's part of speech, frequency, and length are plausible given f_i's burstiness, observed frequency, and length. (E.g., only short common words are plausibly translated as determiners.)

For *Context* features, we could design versions that are more sensitive to the position and status of the context word j. We speculate that the actual influence of e_j on a user's guess e_i is stronger when e_j is observed rather than itself guessed; when there are fewer intervening tokens (and particularly fewer observed ones); and when $j < i$. Orthogonally, $\boldsymbol{\phi}^{\text{ef}}(e_i, e_j)$ could go beyond PMI and windowed PMI to also consider cosine similarity, as well as variants of these metrics that are thresholded or nonlinearly transformed. Finally, we do not have to treat the context positions j as independent multiplicative influences as in equation (1) (cf. Naive Bayes): we could instead use a topic model or some form of language model to determine a conditional probability distribution over E_i given all other words in the context.

An obvious gap in our current feature set is that we have no $\boldsymbol{\phi}^{\text{e}}$ features to capture that some words $e_i \in V^{\text{e}}$ are more likely guesses *a priori*. By defining several versions of this feature, based on frequencies in corpora of different reading levels, we could learn user-specific weights modeling which users are unlikely to think of an obscure word. We should also include features that fire specifically on the reference translation e_i^* and the special symbols <BLANK> and <COPY>, as each is much more likely than the other features would suggest.

For *History* features, we could consider *negative* feedback from other HITs (not just the current HIT), as well as *positive* information provided by revealed clues (not just confirmed guesses). We could also devise non-binary versions in which more recent or more frequent feedback on a word has a stronger effect. More ambitiously, we could model generalization: after being shown that `Kind` means `child`, a learner might increase the probability that the similar word `Kinder` means `child` or something related (`children`, `childish`, ...), whether because of superficial orthographic similarity or a deeper understanding of the morphology. Similarly, a learner might gradually acquire a model of typical spelling changes in English-German cognate pairs.

A more significant extension would be to model a user's learning process. Instead of representing each user by a small vector of user-specific weights, we could recognize that the user's guessing strategy and knowledge can change over time.

A serious deficiency in our current model (not to mention our evaluation metrics!) is that we treat <BLANK> like any other word. A more attractive approach would be to learn a stochastic link from the posterior distribution to the user's guess or non-guess, instead of assuming that the user simply samples the guess from the posterior. As a simple example, we might say the user guesses $e \in V^{\text{e}}$ with probability $p(e)^\beta$—where $p(e)$ is the posterior probability and $\beta > 1$ is a learned parameter—with the remaining probability assigned to <BLANK>. This says that the user tends to avoid guessing except when there are relatively high-probability words to guess.

7 Conclusion

We have presented a methodology for collecting data and training a model to estimate a foreign language learner's understanding of L2 vocabulary in partially understood contexts. Both are novel contributions to the study of L2 acquisition.

Our current model is arguably crude, with only 6 features, yet it can already often do a reasonable job of predicting what a user might guess and whether the user's guess will be roughly correct. This opens the door to a number of future directions with applications to language acquisition using personalized content and learners' knowledge.

We plan a deeper investigation into how learners detect and combine cues for incidental comprehension. We also leave as future work the integration of this model into an adaptive system that tracks learner understanding and creates scaffolded content that falls in their zone of proximal development, keeping them engaged while stretching their understanding.

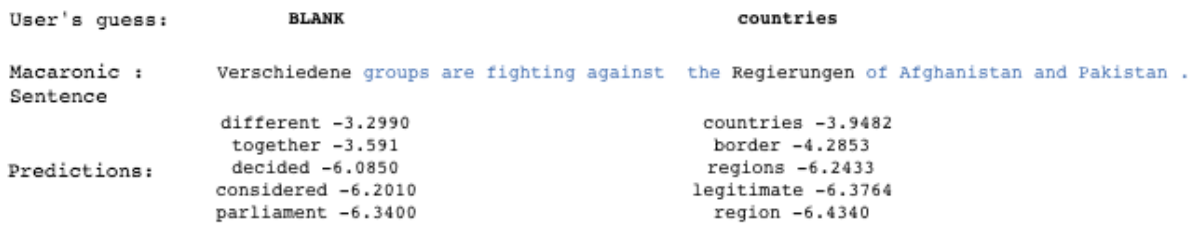
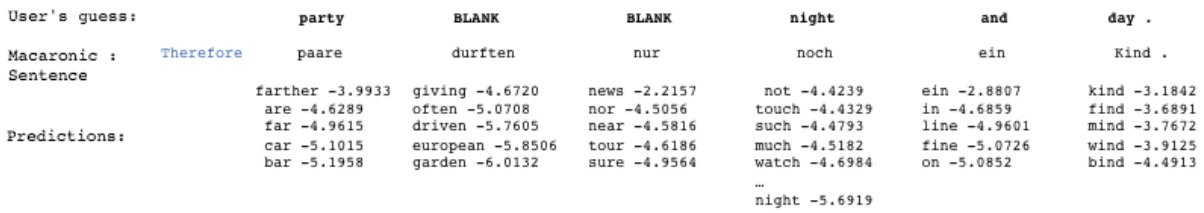
Appendices

A Example of Learner Guesses vs. Model Predictions

To give a sense of the problem difficulty, we have hand-picked and presented two training examples (submissions) along with the predictions of our basic model and their log-probabilities. In Figure 7a a large portion of the sentence has been revealed to the user in English (blue text) only 2 words are in German. The text in bold font is the user's guess. Our model expected both words to be guessed; the predictions are listed below the German words `Verschiedene` and `Regierungen`. The reference translation for the 2 words are `Various` and `governments`. In Figure 7b we see a much harder context where only one word is shown in English and this word is not particularly helpful as a contextual anchor.



(a)



(b)

Figure 7: Two examples of the system's predictions of what the user will guess on a single submission, contrasted with the user's actual guess. (The user's previous submissions on the same task instance are not shown.) In 7a, the model correctly expects that the substantial context will inform the user's guess. In 7b, the model predicts that the user will fall back on string similarity—although we can see that the user's actual guess of `and day` was likely informed by their guess of `night`, an influence that our CRF did consider. The numbers shown are log-probabilities. Both examples show the sentences in a macaronic state (after some reordering or translation has occurred). For example, the original text of the German sentence in 7b reads `Deshalb durften die Paare nur noch ein Kind bekommen .` The macaronic version has undergone some reordering, and has also erroneously dropped the verb due to an incorrect alignment.

On the Similarities Between Native, Non-native and Translated Texts

Abstract

We present a computational analysis of three language varieties: native, advanced non-native, and translation. Our goal is to investigate the similarities and differences between non-native language productions and translations, contrasting both with native language. Using a collection of computational methods we establish three main results: (1) the three types of texts are easily distinguishable; (2) non-native language and translations are closer to each other than each of them is to native language; and (3) some of these characteristics depend on the source or native language, while others do not, reflecting, perhaps, unified principles that similarly affect translations and non-native language.

1 Introduction

This paper addresses two linguistic phenomena: translation and non-native language. Our main goal is to investigate the similarities and differences between these two phenomena, and contrast them with native language. In particular, we are interested in the reasons for the differences between translations and originals, on one hand, and native and non-native language, on the other. Do they reflect "universal" principles, or are they dependent on the source/native language?

Much research in translation studies indicates that translated texts have unique characteristics. Translated texts (in any language) constitute a sublanguage of the target language, sometimes referred to as *translationese* (Gellerstam, 1986). The unique characteristics of translationese have been traditionally classified into two categories: properties that stem from *interference* of the source language (Toury, 1979), and universal traits resulting from the translation process itself, independently of the specific source and target languages (Baker, 1993; Toury, 1995). The latter so-called *translation universals* have triggered a continuous debate among translation studies researchers (Mauranen and Kujamäki, 2004; House, 2008; Becher, 2010).

Similarly, over half a century of research on second language acquisition (SLA) established the presence of *cross-linguistic influences* (CLI) in non-native utterances (Jarvis and Pavlenko, 2008). CLI is a cover term proposed by Kellerman and Sharwood-Smith (1986) to denote various phenomena that stem from language contact situations such as transfer, interference, avoidance, borrowing, etc.[1] In addition, universal traits resulting from the learning process itself have been noticed regardless of the native language, L1.[2] For example, similar developmental sequences have been observed for negation, question formation, and other sentence structures in English (Dulay and Burt, 1974; Odlin, 1989) for both Chinese and Spanish natives. Phenomena such as overgeneralization, strategies of learning (Selinker, 1972), psychological factors (Ellis, 1985), and cultural distance (Giles and Byrne, 1982) are also influential in the acquisition process.

There are clear similarities between translations and non-native language: both are affected by the simultaneous presence of (at least) two linguistic systems, which may result in a higher cognitive load (Shlesinger, 2003). The presence of the L1 may also cause similar CLI effects on the target language.

On the other hand, there are reasons to believe

[1]To avoid terminological conflicts, we shall henceforth use CLI to denote any influence of one linguistic system over another, w.r.t. both translations and non-native productions.

[2]For simplicity, we will use *L1* to refer both to the native language of a speaker and to the source language of a translated text. We use *target language* to refer to second and translation languages (English in this paper).

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1870–1881,
Berlin, Germany, August 7-12, 2016.

that translationese and non-native language should differ from each other. Translations are produced by *native* speakers of the target language. Non-natives, in contrast, arguably never attain native-like abilities (Coppieters, 1987; Johnson and Newport, 1991), however this hypothesis is strongly debated in the SLA community (Birdsong, 1992; Lardiere, 2006).

Our goal in this work is to investigate three language *varieties*: the language of native speakers (N), the language of advanced, highly fluent non-native speakers (NN), and translationese (T). We use the term *constrained language* to refer to the latter two varieties. We propose a unified computational umbrella for exploring two related areas of research on bilingualism: translation studies and second language acquisition. Specifically, we put forward three main hypotheses: (1) The three language varieties have unique characteristics that make them easily distinguishable. (2) Non-native language and translations are closer to each other than either of them is to native language. (3) Some of these characteristics are dependent on the specific L1, but many are not, and may reflect unified principles that similarly affect translations and non-native language.

We test these hypotheses using several corpus-based computational methods. We use supervised and unsupervised classification (Section 4) to show that the three language varieties are easily distinguishable. In particular, we show that native and advanced non-native productions can be accurately separated. More pertinently, we demonstrate that non-native utterances and translations comprise two distinct linguistic systems.

In Section 5, we use statistical analysis to explore the unique properties of each language variety. We show that the two varieties of constrained language are much closer to each other than they are to native language: they exhibit poorer lexical richness, a tendency to use more frequent words, a different distribution of idiomatic expressions and pronouns, and excessive use of cohesive devices. This is an unexpected finding, given that both natives and translators (in contrast to non-natives) produce texts in their mother tongue.

Finally, in Section 6 we use language modeling to show that translations and non-native language exhibit similar statistical properties that clearly reflect cross-linguistic influences: experiments with distinct language families reveal salient ties between the two varieties of constrained language.

The main contribution of this work is thus theoretical: it sheds light on some fundamental questions regarding bilingualism, and we expect it to motivate and drive future research in both SLA and translation studies. Moreover, a better understanding of constrained language may also have some practical import, as we briefly mention in the following section.

2 Related work

Corpus-based investigation of translationese has been a prolific field of recent research, laying out an empirical foundation for the theoretically motivated hypotheses on the characteristics of translationese. More specifically, identification of translated texts by means of automatic classification shed light on the manifestation of translation universals and cross-linguistic influences as markers of translated texts (Baroni and Bernardini, 2006; van Halteren, 2008; Gaspari and Bernardini, 2008; Kurokawa et al., 2009; Koppel and Ordan, 2011; Ilisei and Inkpen, 2011; Volansky et al., 2015; Rabinovich and Wintner, 2015; Nisioi, 2015b), while Gaspari and Bernardini (2008) introduced a dataset for investigation of potential common traits between translations and non-native texts. Such studies prove to be important for the development of parallel corpora (Resnik and Smith, 2003), the improvement in quality of plagiarism detection (Potthast et al., 2011), language modeling, and statistical machine translation (Lembersky et al., 2012, 2013).

Computational approaches also proved beneficial for theoretical research in second language acquisition (Jarvis and Pavlenko, 2008). Numerous studies address linguistic processes attributed to SLA, including automatic detection of highly competent non-native writers (Tomokiyo and Jones, 2001; Bergsma et al., 2012), identification of the mother tongue of English learners (Koppel et al., 2005; Tetreault et al., 2013; Tsvetkov et al., 2013; Nisioi, 2015a) and typology-driven error prediction in learners' speech (Berzak et al., 2015). These studies are instrumental for language teaching and student evaluation (Smith and Swan, 2001), and can improve NLP applications such as authorship profiling (Estival et al., 2007) or grammatical error correction (Chodorow et al., 2010). Most of these studies utilize techniques that are motivated by the same abstract principles associ-

ated with L1 influences on the target language.

To the best of our knowledge, our work is the first to address both translations and non-native language under a unifying computational framework, and in particular to compare both with native language.

3 Methodology and experimental setup

3.1 Dataset

Our dataset[3] is based on the highly homogeneous corpus of the European Parliament Proceedings (Koehn, 2005). Note that the proceedings are produced as follows: (1) the utterances of the speakers are transcribed; (2) the transcriptions are sent to the speaker who may suggest minimal editing without changing the content; (3) the edited version is then translated by native speakers. Note in particular that the texts are *not* a product of simultaneous interpretation.

In this work we utilize a subset of Europarl in which each sentence is manually annotated with speaker information, including the EU state represented and the original language in which the sentence was uttered (Nisioi et al., 2016). The texts in the corpus are uniform in terms of style, respecting the European Parliament's formal standards. Translations are produced by native English speakers and all non-native utterances are selected from members not representing UK or Ireland. Europarl N consists of texts delivered by native speakers from England.

Table 1 depicts statistics of the dataset.[4] In contrast to other learner corpora such as ICLE (Granger, 2003), EFCAMDAT (Geertzen et al., 2013) or TOEFL-11 (Blanchard et al., 2013), this corpus contains translations, native, and non-native English of high proficiency speakers. Members of the European Parliament have the right to use any of the EU's 24 official languages when speaking in Parliament, and the fact that some of them prefer to use English suggests a high degree of confidence in their language skills.

3.2 Preprocessing

All datasets were split by sentence, cleaned (text lowercased, punctuation and empty lines removed) and tokenized using the Stanford tools (Manning et al., 2014). For the classification experiments we randomly shuffled the sentences within each language variety to prevent interference of other artifacts (e.g., authorship, topic) into the classification procedure. We divided the data into chunks of approximately 2,000 tokens, respecting sentence boundaries, and normalized the values of lexical features by the number of tokens in each chunk. For classification we used Platt's sequential minimal optimization algorithm (Keerthi et al., 2001; Hall et al., 2009) to train support vector machine classifiers with the default linear kernel.

sub-corpus	sentences	tokens	types
native (N)	60,182	1,589,215	28,004
non-native (NN)	29,734	783,742	18,419
translated (T)	738,597	22,309,296	71,144
total	828,513	24,682,253	117,567

Table 1: Europarl corpus statistics: native, non-native and translated texts.

In all the experiments we used (the maximal) equal amount of data from each category, thus we always randomly down-sampled the datasets in order to have a comparable number of examples in each class; specifically, 354 chunks were used for each language variety: N, NN and T.

3.3 Features

The first feature set we utilized for the classification tasks comprises *function words* (FW), probably the most popular choice ever since Mosteller and Wallace (1963) used it successfully for the Federalist Papers. Function words proved to be suitable features for multiple reasons:(1) they abstract away from contents and are therefore less biased by topic; (2) their frequency is so high that by and large they are assumed to be selected unconsciously by authors; (3) although not easily interpretable, they are assumed to reflect grammar, and therefore facilitate the study of how structures are carried over from one language to another. We used the list of approximately 400 function words provided in Koppel and Ordan (2011).

A more informative way to capture (admittedly shallow) syntax is to use *part-of-speech (POS) trigrams*. Triplets such as PP (personal pronoun) + VHZ (*have*, 3sg present) + VBN (*be*, past participle) reflect a complex tense form, represented distinctively across languages. In Europarl, for example, this triplet is highly frequent in translations

[3] The dataset is available at `http://nlp.unibuc.ro/resources.html`

[4] Appendix A provides details on the distribution of NN and T texts by various L1s.

from Finnish and Danish and much rarer in translations from Portuguese and Greek. In this work we used the top-3,000 most frequent POS trigrams in each corpus.

We also used *positional token frequency* (Grieve, 2007). The feature is defined as counts of words occupying the first, second, third, penultimate and last positions in a sentence. The motivation behind this feature is that sentences open and close differently across languages, and it should be expected that these opening and closing devices will be transferred from L1 if they do not violate the grammaticality of the target language. Positional tokens were previously used for translationese identification (Volansky et al., 2015) and for native language detection (Nisioi, 2015a).

Translations are assumed to exhibit *explicitation*: the tendency to render implicit utterances in the source text more explicit in the translation product. For example, causality, even though not always explicitly expressed in the source, is expressed in the target by the introduction of cohesive markers such as *because*, *due to*, etc. (Blum-Kulka, 1986). Similarly, Hinkel (2001) conducted a comparative analysis of *explicit cohesive devices* in academic texts by non-native English students, and found that cohesive markers are distributed differently in non-native English productions, compared to their native counterparts. To study this phenomenon, we used the set of over 100 cohesive markers introduced in Hinkel (2001).

4 The status of constrained language

To establish the unique nature of each language variety in our dataset, we perform multiple pairwise binary classifications between N, NN, and T, as well as three-way classifications. Table 2 reports the results; the figures reflect average tenfold cross-validation accuracy (the best result in each column is boldfaced).

In line with previous works (see Section 2), classification of N–T, as well as N–NN, yields excellent results with most features and feature combinations. NN–T appears to be easily distinguishable as well; specifically, FW+POS-trigrams combination with/without positional tokens yields 99.57% accuracy. The word *maybe* is among the most discriminative feature for NN vs. T, being overused in NN, as opposed to *perhaps*, which exhibits a much higher frequency in T; this may indicate a certain degree of formality, typical of translated texts (Olohan, 2003). The words *or*, *which* and *too* are considerably more frequent in T, implying higher sentence complexity. This trait is also reflected by shorter NN sentences, compared to T: the average sentence length in Europarl is 26 tokens for NN vs. 30 for T. Certain decisiveness devices (*sure*, *very*) are underused in T, in accordance with Toury (1995)'s law of standardization (Vanderauwera, 1985). The three-way classification yields excellent results as well; the highest accuracy is obtained using FW+positional tokens with/without POS-trigrams.

feature / dataset	N-NN	N-T	NN-T	3-way
FW	98.72	98.72	96.89	96.60
POS (trigrams)	97.45	98.02	97.45	95.10
pos. tok	99.01	99.01	98.30	98.11
cohesive markers	85.59	87.14	82.06	74.19
FW+POS	99.43	99.57	**99.57**	99.34
FW+pos. tok	99.71	99.85	98.30	**99.52**
POS+pos. tok	99.57	99.57	99.01	99.15
FW+POS+pos. tok	**99.85**	**99.85**	**99.57**	**99.52**

Table 2: Pairwise and three-way classification results of N, NN and T texts.

A careful inspection of the results in Table 2 reveals that NN–T classification is a slightly yet systematically harder task than N–T or N–NN; this implies that NN and T texts are more similar to each other than either of them is to N.

To emphasize this last point, we analyze the separability of the three language varieties by applying unsupervised classification. We perform *bisecting KMeans* clustering procedure previously used for unsupervised identification of translationese by Rabinovich and Wintner (2015). Clustering of N, NN and T using function words into three clusters yields high accuracy, above 90%. For the sake of clusters' visualization in a bidimensional plane, we applied principal component analysis for dimensionality reduction.

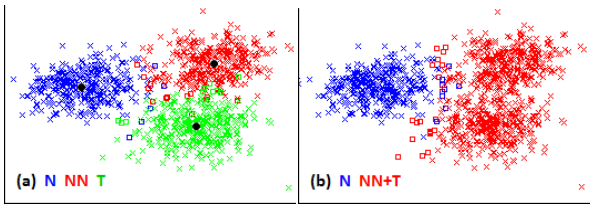

Figure 1: Clustering of N, NN and T into three (a) and two (b) clusters using function words. Clusters' centroids in (a) are marked by black circles; square sign stands for instances clustered wrongly.

The results are depicted in Figure 1 (a). Evidently, NN and T exhibit higher mutual proximity than either of them with N. Fixing the number of expected clusters to 2 further highlights this observation, as demonstrated in Figure 1 (b): both NN and T instances were assigned to a single cluster, distinctively separable from the N cluster.

We conclude that the three language varieties (N, NN, and T) constitute three different, distinguishable ontological categories, characterized by various lexical, syntactic and grammatical properties; in particular, the two varieties of constrained language (NN and T) represent two distinct linguistic systems. Nevertheless, we anticipate NN and T to share more common tendencies and regularities, when compared to N. In the following sections, we put this hypothesis to the test.

5 L1-independent similarities

In this section we address L1-independent similarities between NN and T, distinguishing them from N. We focus on characteristics which are theoretically motivated by translation studies and which are considered to be L1-independent, i.e., unrelated to cross-linguistic influences. We hypothesize that linguistic devices over- or under-represented in translation would behave similarly in highly competent non-native productions, compared to native texts.

To test this hypothesis, we realized various linguistic phenomena as properties that can be easily computed from N, NN and T texts. We refer to the computed characteristics as *metrics*. Our hypothesis is that NN metric values will be similar to T, and that both will differ from N. We used equally-sized texts of 780K tokens for N, NN and T; the exact computation is specified for each metric.

For the sake of visualization, the three values of each metric (for N, NN and T) were zero-one scaled by total-sum normalization. Figure 2 graphically depicts the normalized metric values. We now describe and motivate each metric. We analyze the results in Section 5.1 and establish their statistical significance in Section 5.2.

Lexical richness Translated texts tend to exhibit less lexical diversity (Al-Shabab, 1996). Blum-Kulka (1986) suggested that translated texts *make do with less words*, which is reflected by their lower type-to-token ratio (TTR) compared to that of native productions. We computed the TTR metric by dividing the number of unique (lemmatized) tokens by the total number of tokens.

Mean word rank Halverson (2003) claims that translators use more prototypical language, i.e., *they regress to the mean* (Shlesinger, 1989). We, therefore, hypothesize that rarer words are used more often in native texts than in non-native productions and translationese. To compute this metric we used a BNC-based ranked list of 50K English words[5], excluding the list of function words (see Section 3.3). The metric value was calculated by averaging the rank of all tokens in a text; tokens that do not appear in the list of 50K were excluded.

Collocations Collocations are distributed differently in translations and in originals (Toury, 1980; Kenny, 2001). Common and frequent collocations are used almost subconsciously by native speakers, but will be subjected to a more careful choice by translators and, presumably, by fluent non-native speakers (Erman et al., 2014). For example, the phrase *make sure* appears twice more often in native Europarl texts than in NN, and five times more than in T; *bear in mind* has almost double frequency in N, compared to NN and T. Expressions such as: *bring forward*, *figure out*, *in light of*, *food chain* and *red tape* appear dozens of times in N, as opposed to zero occurrences in NN and T Europarl texts. This metric is defined by computing the frequency of idiomatic expressions[6] in terms of types.

Cohesive markers Translations were proven to employ cohesion intensively (Blum-Kulka, 1986; Øverås, 1998; Koppel and Ordan, 2011). Non-native texts tend to use cohesive markers differently as well: *sentence transitions*, the major cohesion category, was shown to be overused by non-native speakers regardless of their native language (Hinkel, 2001). The metric is defined as the frequency of sentence transitions in the three language varieties.

Qualitative comparison of various markers between NN and T productions, compared to N in the Europarl texts, highlights this phenomenon: *in addition* is twice as frequent in NN and T than in N; *according*, *at the same time* and *thus* occur three times more frequently in NN and T, compared to N; *moreover* is used four times more fre-

[5] `https://www.kilgarriff.co.uk` we used the list extracted from both spoken and written text.

[6] Idioms were taken from `https://en.wiktionary.org/wiki/Category:English_idioms`. The list was minimally cleaned up.

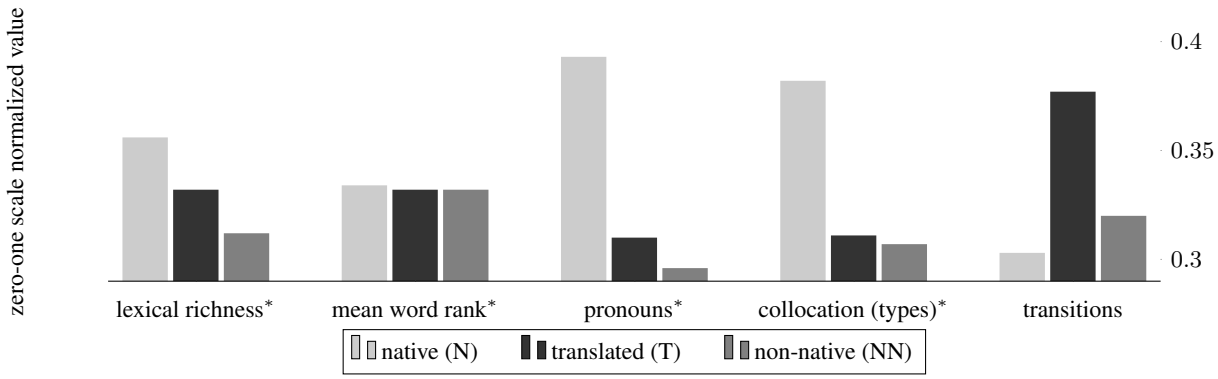

Figure 2: Metric values in N, NN and T. Tree-way differences are significant in all metric categories and "*" indicates metrics with higher pairwise similarity of NN and T, compared individually to N.

quently; and *to conclude* is almost six times more frequent.

Personal pronouns We expect both non-native speakers and translators to spell out entities (both nouns and proper nouns) more frequently, as a means of *explicitation* (Olohan, 2002), thus leading to under-use of personal pronouns, in contrast to native texts. As an example, *his* and *she* are twice more frequent in N than in NN and T.

We define this metric as the frequency of (all) personal and possessive pronouns used in the three language varieties. The over-use of personal pronouns in N utterances, is indeed balanced out by lower frequency of proper and regular nouns in these texts, compared to T and NN.[7]

5.1 Analysis

Evidently (see Figure 2), translationese and non-native productions exhibit a consistent pattern in both datasets, compared to native texts: NN and T systematically demonstrate lower metric values than N for all characteristics (except sentence transitions, where both NN and T expectedly share a higher value). All metrics except mean word rank exhibit substantial (sometimes dramatic) differences between N, on the one hand, and NN and T, on the other, thus corroborating our hypothesis. Mean word rank exhibits a more moderate variability in the three language varieties, yielding near identical value in NN and T; yet, it shows excessive usage in N.

The differences between metric values are statistically significant for all metrics (Section 5.2). Moreover, in all cases (except transitions), the difference between NN and T metrics is significantly lower than the difference between either of them and N, implying a higher proximity of NN and T distributions, compared individually to N. This finding further emphasizes the common tendencies between NN and T.

As shown in Figure 2, NN and T are systematically and significantly different from N. Additionally, we can see that T is consistently positioned between N and NN (except for sentence transitions), implying that translations produced by native speakers tend to resemble native utterances to a higher degree than non-native productions.

5.2 Statistical significance

Inspired by the results depicted in Figure 2, we now put to test two statistical hypotheses: (1) N, NN and T productions do not represent identical underlying distributions, i.e., at least one pair is distributed differently; and consequently, (2) NN and T productions exhibit higher similarity (in terms of *distance*) than either of them with N. We test these hypotheses by applying the *bootstrapping* statistical analysis.

Bootstrapping is a statistical technique involving random re-sampling (with replacement) from the original sample; it is often used to assign a measure of accuracy (e.g., a confidence interval) to an estimate. Specifically, let C_{N}, C_{NN} and C_{T} denote native, non-native and translated sub-corpora of equal size (780K tokens). Let C_{ALL} denote the concatenation of all three sub-corpora, resulting in a total of 2,340M tokens. We further denote a function computing a metric m by f^m; when applied to C, its value is $f^m(C)$. The sum of pair-

[7] Normalized frequencies of nouns and proper nouns are 0.323, 0.331 and 0.345 for N, T, and NN, respectively.

wise distances between the three individual dataset metrics is denoted by D_{total}:

$$D_{\text{total}} = |f^m(C_{\text{N}}) - f^m(C_{\text{NN}})| + |f^m(C_{\text{N}}) - f^m(C_{\text{T}})| + |f^m(C_{\text{NN}}) - f^m(C_{\text{T}})|$$

High values of D_{total} indicate a difference between the three language varieties. To examine whether the observed D_{total} is high beyond chance level, we use the bootstrap approach, and repeat the following process 1,000 times:[8] we sample C_{ALL} with replacement (at sentence granularity), generating in the j-th iteration equal-sized samples $\widehat{C_{\text{N}}}^j$, $\widehat{C_{\text{NN}}}^j$, $\widehat{C_{\text{T}}}^j$. The corresponding distance estimate, therefore, is:

$$\widehat{D_{\text{total}}}^j = |f^m(\widehat{C_{\text{N}}}^j) - f^m(\widehat{C_{\text{NN}}}^j)| + |f^m(\widehat{C_{\text{N}}}^j) - f^m(\widehat{C_{\text{T}}}^j)| + |f^m(\widehat{C_{\text{NN}}}^j) - f^m(\widehat{C_{\text{T}}}^j)|$$

We repeat random re-sampling and computation of $\widehat{D_{\text{total}}}^j$ 1,000 times, and estimate the p-value of $\widehat{D_{\text{total}}}$ by calculation of its percentile within the series of (sorted) $\widehat{D_{\text{total}}}^j$ values, where $j \in (1, \ldots, 1000)$. In all our experiments the original distance D_{total} exceeds the maximum estimate in the series of $\widehat{D_{\text{total}}}^j$, implying highly significant difference, with p-value<0.001 for all metrics.

In order to stress this outcome even further, we now test whether (the constrained) NN and T exhibit higher pairwise similarity, as opposed to N. We achieve this by assessment of the distance between NN and T productions, compared to the distance between N and its closest production (again, in terms of distance): either NN or T. We sample C_{N}, C_{NN} and C_{T} (with replacement) separately, constructing $\widetilde{C_{\text{N}}}$, $\widetilde{C_{\text{NN}}}$ and $\widetilde{C_{\text{T}}}$, respectively, and define the following distance function:

$$\widetilde{D_{\text{dif}}}^j = |f^m(\widetilde{C_{\text{N}}}^j) - f^m(\widetilde{C}_K^j)| - |f^m(\widetilde{C_{\text{NN}}}^j) - f^m(\widetilde{C_{\text{T}}}^j)|$$

where

$$K = \begin{cases} \text{NN} & \text{if } |f^m(C_{\text{N}}) - f^m(C_{\text{NN}})| < |f^m(C_{\text{N}}) - f^m(C_{\text{T}})| \\ \text{T} & \text{otherwise} \end{cases}$$

We repeat re-sampling and computation of $\widetilde{D_{\text{dif}}}^j$ 1,000 times for each metric value in both datasets and sort the results. The end points of the 95% confidence interval are defined by estimate values with 2.5% deviation from the minimum (*min-end-point*) and the maximum (*max-end-point*) estimates. We assess the p-value of the test by inspecting the estimate underlying the min-end-point; specifically, in case the min-end-point is greater than 0, we consider $p<0.05$. Metric categories exhibiting higher NN-T similarity than either N-NN or N-T are marked with "*" in Figure 2.

[8] This sample size is proven sufficient by the highly significant results (very low p-value).

6 L1-related similarities

We hypothesize that both varieties of constrained language exhibit similar (lexical, grammatical, and structural) patterns due to the influence of L1 over the target language. Consequently, we anticipate that non-native productions of speakers of a certain native language (L1) will be closer to translations from L1 than to translations from other languages.

Limited by the amount of text available for each individual language, we set out to test this hypothesis by inspection of two language *families*, Germanic and Romance. Specifically, the Germanic family consists of NN texts delivered by speakers from Austria, Germany, Netherlands and Sweden; and the Romance family includes NN speakers from Portugal, Italy, Spain, France and Romania. The respective T families comprise translations from Germanic and Romance originals, corresponding to the same countries. Table 3 provides details on the datasets.

	sentences	**tokens**	**types**
Germanic NN	5,384	132,880	7,841
Germanic T	269,222	7,145,930	43,931
Romance NN	6,384	180,416	9,838
Romance T	307,296	9,846,215	49,925

Table 3: Europarl Germanic and Romance families: NN and T.

We estimate L1-related traces in the two varieties of constrained language by the fitness of a translationese-based *language model* (LM) to utterances of non-native speakers from the same language family. Attempting to trace structural and grammatical, rather than content similarities, we compile five-gram *POS* language models from Germanic and Romance translationese (GerT and RomT, respectively).[9] We examine the predic-

[9] For building LMs we used the closed vocabulary of Penn

tion power of these models on non-native productions of speakers with Germanic and Romance native languages (GerNN and RomNN), hypothesizing that an LM compiled from Germanic translationese will better predict non-native productions of a Germanic speaker and vice versa. The fitness of a language model to a set of sentences is estimated in terms of *perplexity* (Jelinek et al., 1977).

For building and estimating language models we used the KenLM toolkit (Heafield, 2011), employing modified Kneser-Ney smoothing without pruning. Compilation of language-family-specific models was done using 7M tokens of Germanic and Romance translationese each; the test data consisted of 5350 sentences of Germanic and Romance non-native productions. Consequently, for perplexity experiments with individual languages we utilized 500 sentences from each language. We excluded OOVs from all perplexity computations.

Table 4 reports the results. Prediction of GerNN by the GerT language model yields a slightly lower perplexity (i.e., a better prediction) than prediction by RomT. Similarly, RomNN is much better predicted by RomT than by GerT. These differences are statistically significant: we divided the NN texts into 50 chunks of 100 sentences each, and computed perplexity values by the two LMs for each chunk. Significance was then computed by a two-tailed paired t-test, yielding p-values of 0.015 for GerNN and 6e-22 for RomNN.

LM / NN	GerNN	LM / NN	RomNN
GerT	8.77	GerT	8.64
RomT	8.79	RomT	8.43

Table 4: Perplexity: fitness of Germanic and Romance translationese LMs to Germanic and Romance NN test sets.

As a further corroboration of the above result, we computed the perplexity of the GerT and RomT language models with respect to the language of NN speakers, this time distinguishing speakers by their country of origin. We used the same language models and non-native test chunks of 500 sentences each. Inspired by the outcome of the previous experiment, we expect that NN productions by Germanic speakers will be better predicted by GerT LM, and vice versa. Figure 3 presents a scatter plot with the results.

A clear pattern, evident from the plot, reveals

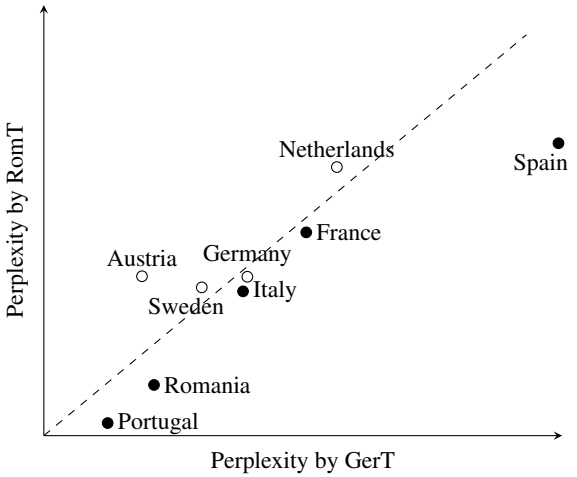

Figure 3: Perplexity of the GerT and RomT language models with respect to non-native utterances of speakers from various countries.

that all English texts with underlying Romance native languages (under the diagonal) are better predicted (i.e., obtain lower perplexity) by the RomT LM. All Germanic native languages (except German), on the other hand, are better predicted by the GerT LM. This finding further supports the hypothesis that non-native productions and translationese tend to exhibit similar L1-related traits.

7 Conclusion

We presented a unified computational approach for studying constrained language, where many of the features were theoretically motivated. We demonstrated that while translations and non-native productions are two distinct language varieties, they share similarities that stem from lower lexical richness, more careful choice of idiomatic expressions and pronouns, and (presumably) subconscious excessive usage of explicitation cohesive devices. More dramatically, the language modeling experiments reveal salient ties between the native language of non-native speakers and the source language of translationese, highlighting the unified L1-related traces of L1 in both scenarios. Our findings are intriguing: native speakers and translators, in contrast to non-native speakers, use their native language, yet translation seems to gravitate towards non-native language use.

The main contribution of this work is empirical, establishing the connection between these types of language production. While we believe that these common tendencies are not incidental, more research is needed in order to establish a theoretical

Treebank POS tag set.

explanation for the empirical findings, presumably (at least partially) on the basis of the cognitive load resulting from the simultaneous presence of two linguistic systems. We are interested in expanding the preliminary results of this work: we intend to replicate the experiments with more languages and more domains, investigate additional varieties of constrained language and employ more complex lexical, syntactic and discourse features. We also plan to investigate how the results vary when limited to specific L1s.

Acknowledgments

This research was supported by the Israeli Ministry of Science and Technology. We are immensely grateful to Yuval Nov for much advice and helpful suggestions. We are also indebted to Roy Bar-Haim, Anca Bucur, Liviu P. Dinu, and Yosi Mass for their support and guidance during the early stages of this work, and we thank our anonymous reviewers for their valuable insights.

Abstract

We present a *pairwise context-sensitive Autoencoder* for computing text pair similarity. Our model encodes input text into *context-sensitive* representations and uses them to compute similarity between text pairs. Our model outperforms the state-of-the-art models in two semantic retrieval tasks and a contextual word similarity task. For retrieval, our unsupervised approach that merely ranks inputs with respect to the cosine similarity between their hidden representations shows comparable performance with the state-of-the-art supervised models and in some cases outperforms them.

1 Introduction

Representation learning algorithms learn representations that reveal intrinsic low-dimensional structure in data (Bengio et al., 2013). Such representations can be used to induce similarity between textual contents by computing similarity between their respective vectors (Huang et al., 2012; Silberer and Lapata, 2014).

Recent research has made substantial progress on semantic similarity using neural networks (Rothe and Schütze, 2015; Dos Santos et al., 2015; Severyn and Moschitti, 2015). In this work, we focus our attention on deep autoencoders and extend these models to integrate sentential or document *context* information about their inputs. We represent context information as low dimensional vectors that will be injected to deep autoencoders. To the best of our knowledge, this is the first work that enables integrating context into autoencoders.

In representation learning, context may appear in various forms. For example, the context of a current sentence in a document could be either its neighboring sentences (Lin et al., 2015; Wang and Cho, 2015), topics associated with the sentence (Mikolov and Zweig, 2012; Le and Mikolov, 2014), the document that contains the sentence (Huang et al., 2012), as well as their combinations (Ji et al., 2016). It is important to integrate context into neural networks because these models are often trained with only local information about their individual inputs. For example, recurrent and recursive neural networks only use local information about previously seen words in a sentence to predict the next word or composition.[1] On the other hand, context information (such as topical information) often capture global information that can guide neural networks to generate more accurate representations.

We investigate the utility of context information in three semantic similarity tasks: *contextual word sense similarity* in which we aim to predict semantic similarity between given word pairs in their sentential context (Huang et al., 2012; Rothe and Schütze, 2015), *question ranking* in which we aim to retrieve semantically equivalent questions with respect to a given test question (Dos Santos et al., 2015), and *answer ranking* in which we aim to rank single-sentence answers with respect to a given question (Severyn and Moschitti, 2015).

The contributions of this paper are as follows: (1) integrating context information into deep autoencoders and (2) showing that such integration improves the representation performance of deep autoencoders across several different semantic similarity tasks.

Our model outperforms the state-of-the-art su-

[1]For example, RNNs can predict the word "sky" given the sentence "clouds are in the __," but they are less accurate when longer history or global context is required, e.g. predicting the word "french" given the paragraph "I grew up in France. ... I speak fluent __."

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1882–1892,
Berlin, Germany, August 7-12, 2016.

pervised baselines in three semantic similarity tasks. Furthermore, the unsupervised version of our autoencoder show comparable performance with the supervised baseline models and in some cases outperforms them.

2 Context-sensitive Autoencoders

2.1 Basic Autoencoders

We first provide a brief description of basic autoencoders and extend them to context-sensitive ones in the next Section. Autoencoders are trained using a local unsupervised criterion (Vincent et al., 2010; Hinton and Salakhutdinov, 2006; Vincent et al., 2008). Specifically, the basic autoencoder in Figure 1(a) locally optimizes the hidden representation $\mathbf{h}$ of its input $\mathbf{x}$ such that $\mathbf{h}$ can be used to accurately reconstruct $\mathbf{x}$,

$$\mathbf{h} = \mathbf{g}(\mathbf{W}\mathbf{x} + \mathbf{b}_{\mathbf{h}}) \quad (1)$$

$$\hat{\mathbf{x}} = \mathbf{g}(\mathbf{W}'\mathbf{h} + \mathbf{b}_{\hat{\mathbf{x}}}), \quad (2)$$

where $\hat{\mathbf{x}}$ is the reconstruction of $\mathbf{x}$, the learning parameters $\mathbf{W} \in \mathbb{R}^{d' \times d}$ and $\mathbf{W}' \in \mathbb{R}^{d \times d'}$ are weight matrices, $\mathbf{b}_{\mathbf{h}} \in \mathbb{R}^{d'}$ and $\mathbf{b}_{\hat{\mathbf{x}}} \in \mathbb{R}^{d}$ are bias vectors for the hidden and output layers respectively, and $\mathbf{g}$ is a nonlinear function such as $\tanh(.)$.[2] Equation (1) *encodes* the input into an intermediate representation and Equation (2) *decodes* the resulting representation.

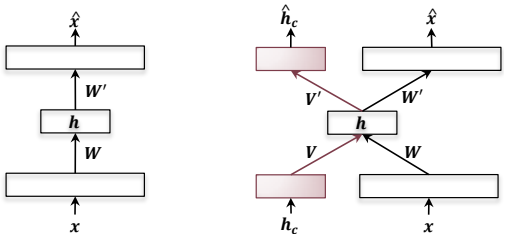
Training a single-layer autoencoder corresponds to optimizing the learning parameters to minimize the overall loss between inputs and their reconstructions. For real-valued $\mathbf{x}$, squared loss is often used, $l(\mathbf{x}) = ||\mathbf{x} - \hat{\mathbf{x}}||^2$, (Vincent et al., 2010):

$$\min_{\mathbf{\Theta}} \sum_{i=1}^{n} l(\mathbf{x}^{(i)}) \qquad \mathbf{\Theta} = \{\mathbf{W}, \mathbf{W}', \mathbf{b}_{\mathbf{h}}, \mathbf{b}_{\hat{\mathbf{x}}}\}. \quad (3)$$

This can be achieved using mini-batch stochastic gradient descent (Zeiler, 2012).

2.2 Integrating Context into Autoencoders

We extend the above basic autoencoder to integrate context information about inputs. We assume that—for each training example $\mathbf{x} \in \mathbb{R}^d$—we have a context vector $\mathbf{c}_{\mathbf{x}} \in \mathbb{R}^k$ that contains contextual information about the input.[3] The nature of this context vector depends on the input and target task. For example, neighboring words can be considered as the context of a target word in contextual word similarity task.



(a) Basic Autoencoder (b) Context Autoencoder

Figure 1: Schematic representation of basic and context-sensitive autoencoders: (a) Basic autoencoder maps its input $\mathbf{x}$ into the representation $\mathbf{h}$ such that it can reconstruct $\mathbf{x}$ with minimum loss, and (b) Context-sensitive autoencoder maps its inputs $\mathbf{x}$ and $\mathbf{h}_c$ into a context-sensitive representation $\mathbf{h}$ ($\mathbf{h}_c$ is the representation of the context information associated to $\mathbf{x}$).

We first learn the hidden representation $\mathbf{h}_c \in \mathbb{R}^{d'}$ for the given context vector $\mathbf{c}_{\mathbf{x}}$. For this, we use the same process as discussed above for the basic autoencoder where we use $\mathbf{c}_{\mathbf{x}}$ as the input in Equations (1) and (2) to obtain $\mathbf{h}_c$. We then use $\mathbf{h}_c$ to develop our context-sensitive autoencoder as depicted in Figure 1(b). This autoencoder maps its inputs $\mathbf{x}$ and $\mathbf{h}_c$ into a *context-sensitive* representation $\mathbf{h}$ as follows:

$$\mathbf{h} = \mathbf{g}(\mathbf{W}\mathbf{x} + \mathbf{V}\mathbf{h}_c + \mathbf{b}_{\mathbf{h}}) \quad (4)$$

$$\hat{\mathbf{x}} = \mathbf{g}(\mathbf{W}'\mathbf{h} + \mathbf{b}_{\hat{\mathbf{x}}}) \quad (5)$$

$$\hat{\mathbf{h}}_c = \mathbf{g}(\mathbf{V}'\mathbf{h} + \mathbf{b}_{\hat{\mathbf{h}}_c}). \quad (6)$$

Our intuition is that if $\mathbf{h}$ leads to a good reconstruction of its inputs, it has retained information available in the input. Therefore, it is a context-sensitive representation.

The loss function must then compute the loss between the input pair ($\mathbf{x}$, $\mathbf{h}_c$) and its reconstruction ($\hat{\mathbf{x}}$, $\hat{\mathbf{h}}_c$). For optimization, we can still use squared loss with a different set of parameters to minimize the overall loss on the training examples:

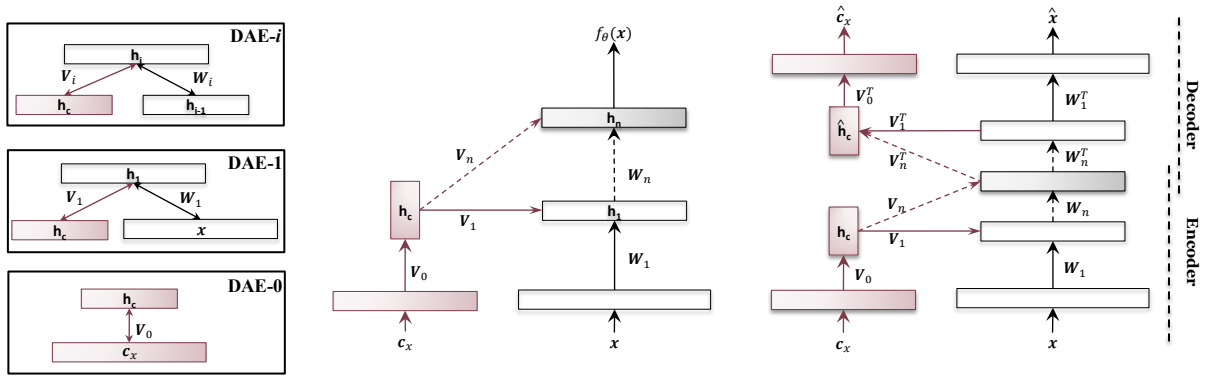
$$l(\mathbf{x}, \mathbf{h}_c) = ||\mathbf{x} - \hat{\mathbf{x}}||^2 + \lambda||\mathbf{h}_c - \hat{\mathbf{h}}_c||^2$$

$$\min_{\mathbf{\Theta}} \sum_{i=1}^{n} l(\mathbf{x}^{(i)}, \mathbf{h}_c^{(i)}) \quad (7)$$

$$\mathbf{\Theta} = \{\mathbf{W}, \mathbf{W}', \mathbf{V}, \mathbf{V}', \mathbf{b}_{\mathbf{h}}, \mathbf{b}_{\hat{\mathbf{x}}}, \mathbf{b}_{\hat{\mathbf{h}}_c}\},$$

[2] If the squared loss is used for optimization, as in Equation (3), nonlinearity is often not used in Equation (2) (Vincent et al., 2010).

[3] We slightly abuse the notation throughout this paper by referring to $\mathbf{c}_x$ or $\mathbf{h}_i$ as vectors, not elements of vectors.



(a) Network initialization (b) Stacking Denoising Autoencoders (c) Unrolling and Fine-tuning

Figure 2: Proposed framework for integrating context into deep autoencoders. Context layer ($\mathbf{c_x}$ and $\mathbf{h}_c$) and context-sensitive representation of input ($\mathbf{h}_n$) are shown in light red and gray respectively. (a) Pre-training properly initializes a stack of context-sensitive denoising autoencoders (DAE), (b) A context-sensitive deep autoencoder is created from properly initialized DAEs, (c) The network in (b) is unrolled and its parameters are fine-tuned for optimal reconstruction.

where $\lambda \in [0, 1]$ is a weight parameter that controls the effect of context information in the reconstruction process.

2.2.1 Denoising

Denoising autoencoders (DAEs) reconstruct an input from a *corrupted* version of it for more effective learning (Vincent et al., 2010). The corrupted input is then mapped to a hidden representation from which we obtain the reconstruction. However, the reconstruction loss is still computed with respect to the *uncorrupted* version of the input as before. Denoising autoencoders effectively learn representations by reversing the effect of the corruption process. We use *masking noise* to corrupt the inputs where a fraction η of input units are randomly selected and set to zero (Vincent et al., 2008).

2.2.2 Deep Context-Sensitive Autoencoders

Autoencoders can be stacked to create deep networks. A deep autoencoder is composed of multiple hidden layers that are stacked together. The initial weights in such networks need to be properly initialized through a greedy layer-wise training approach. Random initialization does not work because deep autoencoders converge to poor local minima with large initial weights and result in tiny gradients in the early layers with small initial weights (Hinton and Salakhutdinov, 2006).

Our deep context-sensitive autoencoder is composed of a stacked set of DAEs. As discussed above, we first need to properly initialize the learning parameters (weights and biases) associated to each DAE. As shown in Figure 2(a), we first train DAE-0, which initializes parameters associated to the context layer. The training procedure is exactly the same as training a basic autoencoder (Section 2.1 and Figure 1(a)).[4] We then treat $\mathbf{h}_c$ and $\mathbf{x}$ as "inputs" for DAE-1 and use the same approach as in training a context-sensitive autoencoder to initialize the parameters of DAE-1 (Section 2.2 and Figure 1(b)). Similarly, the i^{th} DAE is built on the output of the $(i-1)^{\text{th}}$ DAE and so on until the desired number of layers (e.g. n layers) are initialized. For denoising, the corruption is only applied on "inputs" of individual autoencoders. For example, when we are training DAE-i, $\mathbf{h}_{i-1}$ and $\mathbf{h}_c$ are first obtained from the original inputs of the network ($\mathbf{x}$ and $\mathbf{c_x}$) through a single forward pass and then their corrupted versions are computed to train DAE-i.

Figure 2(b) shows that the n properly initialized DAEs can be stacked to form a deep context-sensitive autoencoder. We *unroll* this network to fully optimize its weights through gradient descent and backpropagation (Vincent et al., 2010; Hinton and Salakhutdinov, 2006) .

2.2.3 Unrolling and Fine-tuning

We optimize the learning parameters of our initialized context-sensitive deep autoencoder by unfolding its n layers and making a $2n-1$ layer net-

[4] Figure 2(a) shows compact schematic diagrams of autoencoders used in Figures 1(a) and 1(b)

work whose lower layers form an "encoder" network and whose upper layers form a "decoder" network (Figure 2(c)). A global fine-tuning stage backpropagates through the entire network to fine-tune the weights for optimal reconstruction. In this stage, we update the network parameters again by training the network to minimize the loss between original inputs and their actual reconstruction. We backpropagate the error derivatives first through the decoder network and then through the encoder network. Each decoder layer tries to recover the input of its corresponding encoder layer. As such, the weights are initially symmetric and the decoder weights do need to be learned.

After the training is complete, the hidden layer $\mathbf{h}_n$ contains a context-sensitive representation of the inputs $\mathbf{x}$ and $\mathbf{c_x}$.

2.3 Context Information

Context is task and data dependent. For example, a sentence or document that contains a target word forms the word's context.

When context information is not readily available, we use topic models to determine such context for individual inputs (Blei et al., 2003; Stevens et al., 2012). In particular, we use Non-Negative Matrix Factorization (NMF) (Lin, 2007): Given a training set with n instances, i.e., $\mathbf{X} \in \mathbb{R}^{v \times n}$, where v is the size of a global vocabulary and the scalar k is the number of topics in the dataset, we learn the topic matrix $\mathbf{D} \in \mathbb{R}^{v \times k}$ and context matrix $\mathbf{C} \in \mathbb{R}^{k \times n}$ using the following sparse coding algorithm:

$$\begin{aligned} \min_{\mathbf{D},\mathbf{C}} \quad & \|\mathbf{X} - \mathbf{DC}\|_F^2 + \mu\|\mathbf{C}\|_1, \\ s.t. \quad & \mathbf{D} \geq 0,\ \mathbf{C} \geq 0, \end{aligned} \tag{8}$$

where each column in $\mathbf{C}$ is a sparse representation of an input over all topics and will be used as global context information in our model. We obtain context vectors for test instances by transforming them according to the fitted NMF model on training data. We also note that advanced topic modeling approaches, such as syntactic topic models (Boyd-Graber and Blei, 2009), can be more effective here as they generate linguistically rich context information.

3 Text Pair Similarity

We present unsupervised and supervised approaches for predicting semantic similarity scores

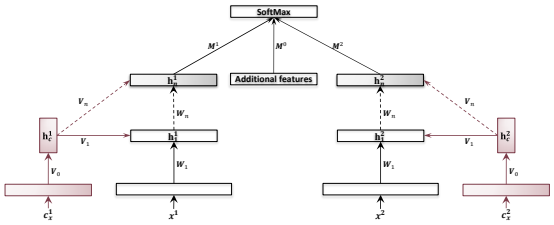


Figure 3: Pairwise context-sensitive autoencoder for computing text pair similarity.

for input texts (e.g., a pair of words) each with its corresponding context information. These scores will then be used to rank "documents" against "queries" (in retrieval tasks) or evaluate how predictions of a model correlate with human judgments (in contextual word sense similarity task).

In unsupervised settings, given a pair of input texts with their corresponding context vectors, ($\mathbf{x}^1$,$\mathbf{c}_{\mathbf{x}^1}$) and ($\mathbf{x}^2$,$\mathbf{c}_{\mathbf{x}^2}$), we determine their semantic similarity score by computing the cosine similarity between their hidden representations $\mathbf{h}_n^1$ and $\mathbf{h}_n^2$ respectively.

In supervised settings, we use a copy of our context-sensitive autoencoder to make a pairwise architecture as depicted in Figure 3. Given ($\mathbf{x}^1$,$\mathbf{c}_{\mathbf{x}^1}$), ($\mathbf{x}^2$,$\mathbf{c}_{\mathbf{x}^2}$), and their binary relevance score, we use $\mathbf{h}_n^1$ and $\mathbf{h}_n^2$ as well as additional features (see below) to train our pairwise network (i.e. further fine-tune the weights) to predict a similarity score for the input pair as follows:

$$rel(\mathbf{x}^1, \mathbf{x}^2) = softmax(\mathbf{M}^0\mathbf{a} + \mathbf{M}^1\mathbf{h}_n^1 + \mathbf{M}^2\mathbf{h}_n^2 + \mathbf{b}) \tag{9}$$

where $\mathbf{a}$ carries additional features, $\mathbf{M}$s are weight matrices, and $\mathbf{b}$ is the bias. We use the difference and similarity between the context-sensitive representations of inputs, $\mathbf{h}_n^1$ and $\mathbf{h}_n^2$, as additional features:

$$\begin{aligned} \mathbf{h}_{sub} &= |\mathbf{h}_n^1 - \mathbf{h}_n^2| \\ \mathbf{h}_{dot} &= \mathbf{h}_n^1 \odot \mathbf{h}_n^2, \end{aligned} \tag{10}$$

where $\mathbf{h}_{sub}$ and $\mathbf{h}_{dot}$ capture the element-wise difference and similarity (in terms of the sign of elements in each dimension) between $\mathbf{h}_n^1$ and $\mathbf{h}_n^2$, respectively. We expect elements in $\mathbf{h}_{sub}$ to be small for semantically similar and relevant inputs and large otherwise. Similarly, we expect elements in $\mathbf{h}_{dot}$ to be positive for relevant inputs and negative otherwise.

We can use any task-specific feature as additional features. This includes features from the

minimal edit sequences between parse trees of the input pairs (Heilman and Smith, 2010; Yao et al., 2013), lexical semantic features extracted from resources such as WordNet (Yih et al., 2013), or other features such as word overlap features (Severyn and Moschitti, 2015; Severyn and Moschitti, 2013). We can also use additional features (Equation 10), computed for BOW representations of the inputs $\mathbf{x}^1$ and $\mathbf{x}^2$. Such additional features improve the performance of our and baseline models.

4 Experiments

In this Section, we use t-test for significant testing and asterisk mark (*) to indicate significance at $\alpha = 0.05$.

4.1 Data and Context Information

We use three datasets: "SCWS" a word similarity dataset with ground-truth labels on similarity of pairs of target words in sentential context from Huang et al. (2012); "qAns" a TREC QA dataset with ground-truth labels for semantically relevant questions and (single-sentence) answers from Wang et al. (2007); and "qSim" a community QA dataset crawled from Stack Exchange with ground-truth labels for semantically equivalent questions from Dos Santos et al. (2015). Table 1 shows statistics of these datasets. To enable direct comparison with previous work, we use the same training, development, and test data provided by Dos Santos et al. (2015) and Wang et al. (2007) for qSim and qAns respectively and the entire data of SCWS (in unsupervised setting).

We consider local and global context for target words in SCWS. The local context of a target word is its ten neighboring words (five before and five after) (Huang et al., 2012), and its global context is a short paragraph that contains the target word (surrounding sentences). We compute average word embeddings to create context vectors for target words.

Also, we consider question title and body and answer text as input in qSim and qAns and use NMF to create global context vectors for questions and answers (Section 2.3).

4.2 Parameter Setting

We use pre-trained word vectors from GloVe (Pennington et al., 2014). However, because qSim questions are about specific technical topics, we only use GloVe as initialization.

Data	Split	#Pairs	%Rel
SCWS	All data	2003	100.0%
qAns	Train-All	53K	12.00%
	Train	4,718	7.400%
	Dev	1,148	19.30%
	Test	1,517	18.70%
qSim	Train	205K	0.048%
	Dev	43M	0.001%
	Test	82M	0.001%

Table 1: Data statistics. (#Pairs: number of word-word pairs in SCWS, question-answer pairs in qAns, and question-question pairs in qSim; %Rel: percentage of positive pairs.)

For the unsupervised SCWS task, following Huang et al. (2012), we use 100-dimensional word embeddings, $d = 100$, with hidden layers and context vectors of the same size, $d' = 100$, $k = 100$. In this unsupervised setting, we set the weight parameter $\lambda = .5$, masking noise $\eta = 0$, depth of our model $n = 3$. Tuning these parameters will further improve the performance of our model.

For qSim and qAns, we use 300-dimensional word embeddings, $d = 300$, with hidden layers of size $d' = 200$. We set the size of context vectors k (number of topics) using the reconstruction error of NMF on training data for different values of k. This leads to $k = 200$ for qAns and $k = 300$ for qSim. We tune the other hyper-parameters (η, n, and λ) using development data.

We set each input $\mathbf{x}$ (target words in SCWS, question titles and bodies in qSim, and question titles and single-sentence answers in qAns) to the average of word embeddings in the input. Input vectors could be initialized through more accurate approaches (Mikolov et al., 2013b; Li and Hovy, 2014); however, averaging leads to reasonable representations and is often used to initialize neural networks (Clinchant and Perronnin, 2013; Iyyer et al., 2015).

4.3 Contextual Word Similarity

We first consider the contextual word similarity task in which a model should predict the semantic similarity between words in their sentential context. For this evaluation, we compute Spearman's ρ correlation (Kokoska and Zwillinger, 2000) between the "relevance scores" predicted by different models and human judgments (Section 3).

The state-of-the-art model for this task is a semi-supervised approach (Rothe and Schütze, 2015). This model use resources like WordNet

to compute embeddings for different senses of words. Given a pair of target words and their context (neighboring words and sentences), this model represents each target word as the average of its sense embeddings weighted by cosine similarity to the context. The cosine similarity between the representations of words in a pair is then used to determine their semantic similarity. Also, the Skip-gram model (Mikolov et al., 2013a) is extended in (Neelakantan et al., 2014; Chen et al., 2014) to learn contextual word pair similarity in an unsupervised way.

Table 2 shows the performance of different models on the SCWS dataset. SAE, CSAE-LC, CSAE-LGC show the performance of our pairwise autoencoders without context, with local context, and with local and global context, respectively. In case of CSAE-LGC, we concatenate local and global context to create context vectors. CSAE-LGC performs significantly better than the baselines, including the semi-supervised approach in Rothe and Schütze (2015). It is also interesting that SAE (without any context information) outperforms the pre-trained word embeddings (Pre-trained embeds.).

Comparing the performance of CSAE-LC and CSAE-LGC indicates that global context is useful for accurate prediction of semantic similarity between word pairs. We further investigate these models to understand why global context is useful. Table 3 shows an example in which global context (words in neighboring sentences) effectively help to judge the semantic similarity between "Airport" and "Airfield." This is while local context (ten neighboring words) are less effective in helping the models to relate the two words.

Furthermore, we study the effect of global context in different POS tag categories. As Figure 4 shows global context has greater impact on A–A and N–N categories. We expect high improvement in the N–N category as noun senses are fairly self-contained and often refer to concrete things. Thus broader (not only local) context is needed to judge their semantic similarity. However, we don't know the reason for improvement on the A–A category as, in context, adjective interpretation is often affected by local context (e.g., the nouns that adjectives modify). One reason for improvement could be because adjectives are often interchangeable and this characteristic makes their meaning to be less sensitive to local context.

Model	**Context**	$\rho\times$**100**
Huang et al. (2012)	LGC	65.7

4.4 Answer Ranking Performance

We evaluate the performance of our model in the answer ranking task in which a model should retrieve correct answers from a set of candidates for test questions. For this evaluation, we rank answers with respect to each test question according to the "relevance score" between question and each answer (Section 3).

The state-of-the-art model for answer ranking on qAns is a pairwise convolutional neural network (PCNN) presented in (Severyn and Moschitti, 2015). PCNN is a supervised model that first maps input question-answer pairs to hidden representations through a standard convolutional neural network (CNN) and then utilizes these representations in a pairwise CNN to compute a relevance score for each pair. This model also utilizes external *word overlap* features for each question-answer pair.[5] PCNN outperforms other competing CNN models (Yu et al., 2014) and models that use

[5]Word overlap and IDF-weighted word overlap computed for (a): all words, and (b): only non-stop words for each question-answer pair (Severyn and Moschitti, 2015).

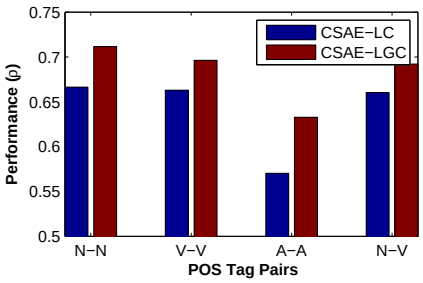

Figure 4: Effect of global context on contextual word similarity in different parts of speech (N: noun, V: verb, A: adjective). We only consider frequent categories.

Model	Train		Train-All	
	MAP	MRR	MAP	MRR
PCNN	62.58	65.91	67.09	72.80
SAE	65.69*	**71.70***	69.54*	75.47*
CSAE	**67.02***	70.99*	**72.29***	**77.29***
PCNN-WO	**73.29**	**79.62**	74.59	80.78
SAE-DST	72.53	76.97	76.38*	82.11*
CSAE-DST	71.26	76.88	**76.75***	**82.90***

Table 4: Answer ranking in *supervised* setting

Model	Train		Train-All	
	MAP	MRR	MAP	MRR
SAE	63.81	69.30	66.37	71.71
CSAE	**64.86***	**69.93***	**66.76***	**73.79***

Table 5: Answer ranking in *unsupervised* setting.

syntax and semantic features (Heilman and Smith, 2010; Yao et al., 2013).

Tables 4 and 5 show the performance of different models in terms of Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR) in supervised and unsupervised settings. PCNN-WO and PCNN show the baseline performance with and without word overlap features. SAE and CSAE show the performance of our pairwise autoencoders without and with context information respectively. Their "X-DST" versions show their performance when additional features (Equation 10) are used. These features are computed for the hidden and BOW representations of question-answer pairs. We also include word overlap features as additional features.

Table 4 shows that SAE and CSAE consistently outperform PCNN, and SAE-DST and CSAE-DST outperform PCNN-WO when the models are trained on the larger training dataset, "Train-All." But PCNN shows slightly better performance than our model on "Train," the smaller training dataset. We conjecture this is because PCNN's convolution filter is wider (n-grams, $n > 2$) (Severyn and Moschitti, 2015).

Table 5 shows that the performance of *unsupervised* SAE and CSAE are comparable and in some cases better than the performance of the *supervised* PCNN model. We attribute the high performance of our models to context information that leads to richer representations of inputs.

Furthermore, comparing the performance of CSAE and SAE in both supervised and unsupervised settings in Tables 4 and 5 shows that context information consistently improves the MAP and MRR performance at all settings except for MRR on "Train" (supervised setting) that leads to a comparable performance. Context-sensitive representations significantly improve the performance of our model and often lead to higher MAP than the models that ignore context information.

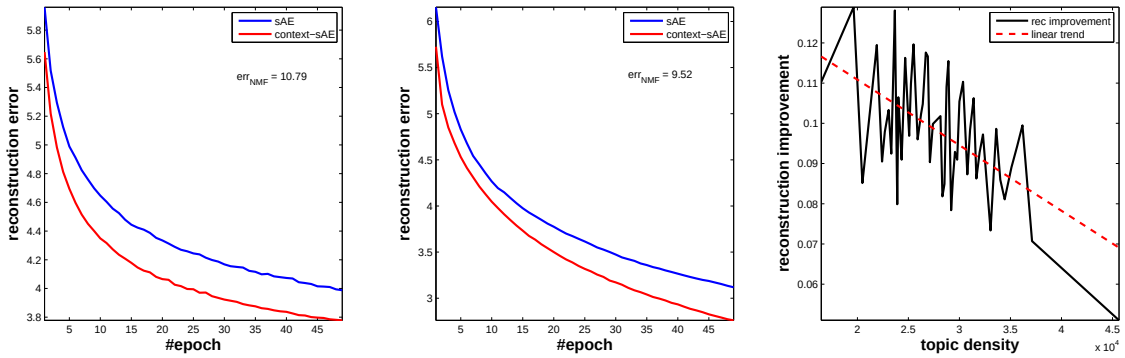
4.5 Question Ranking Performance

In the question ranking task, given a test question, a model should retrieve top-K questions that are semantically equivalent to the test question for $K = \{1, 5, 10\}$. We use qSim for this evaluation.

We compare our autoencoders against PCNN and PBOW-PCNN models presented in Dos Santos et al. (2015). PCNN is a pairwise convolutional neural network and PBOW-PCNN is a joint model that combines vector representations obtained from a pairwise bag-of-words (PBOW) network and a pairwise convolutional neural network (PCNN). Both models are supervised as they require similarity scores to train the network.

Table 6 shows the performance of different models in terms of Precision at Rank K, P@K. CSAE is more precise than the baseline; CSAE and CSAE-DST models consistently outperform the baselines on P@1, an important metric in search applications (CSAE also outperforms PCNN on P@5). Although context-sensitive models are more precise than the baselines at higher ranks, the PCNN and PBOW-PCNN models remain the best model for P@10.

Tables 6 and 7 show that context information consistently improves the results at all ranks in both supervised and unsupervised settings. The performance of the unsupervised SAE and CSAE models are comparable with the supervised PCNN model in higher ranks.



(a) qSim Dataset (b) qAns Dataset (c) qSim Dataset

Figure 5: Reconstruction Error and Improvement: (a) and (b) reconstruction error on qSim and qAns respectively. err_{NMF} shows the reconstruction error of NMF. Smaller error is better, (c) improvement in reconstruction error vs. topic density: greater improvement is obtained in topics with lower density.

5 Performance Analysis and Discussion

We investigate the effect of context information in reconstructing inputs and try to understand reasons for improvement in reconstruction error. We compute the average reconstruction error of SAE and CSAE (Equations (3) and (7)). For these experiments, we set $\lambda = 0$ in Equation (7) so that we can directly compare the resulting loss of the two models. CSAE will still use context information with $\lambda = 0$ but it *does not* backpropagate the reconstruction loss of context information.

Figures 5(a) and 5(b) show the average reconstruction error of SAE and CSAE on qSim and qAns datasets. Context information conistently improves reconstruction. The improvement is greater on qSim which contains smaller number of words per question as compared to qAns. Also, both models generate smaller reconstruction errors than NMF (Section 2.3). The lower performance of NMF is because it reconstructs inputs merely using global topics identified in datasets, while our models utilize both local and global information to reconstruct inputs.

5.1 Analysis of Context information

The improvement in reconstruction error mainly stems from areas in data where "topic density" is lower. We define topic density for a topic as the number of documents that are assigned to the topic by our topic model. We compute the average improvement in reconstruction error for each topic $\mathcal{T}_j$ using the loss functions for the basic and context-sensitive autoencoders:

$$\Delta_j = \frac{1}{|\mathcal{T}_j|} \sum_{\mathbf{x} \in \mathcal{T}_j} l(\mathbf{x}) - l(\mathbf{x}, \mathbf{h_x})$$

where we set $\lambda = 0$. Figure 5(c) shows improvement of reconstruction error versus topic density on qSim. Lower topic densities have greater improvement. This is because they have insufficient training data to train the networks. However, injecting context information improves the reconstruction power of our model by providing more information. The improvements in denser areas are smaller because neural networks can train effectively in these areas.[6]

5.2 Effect of Depth

The intuition behind deep autoencoders (and, generally, deep neural networks) is that each layer learns a more abstract representation of the input than the previous one (Hinton and Salakhutdinov, 2006; Bengio et al., 2013). We investigate

[6] We observed the same pattern in qAns.

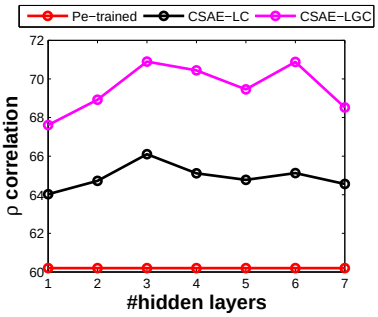

Figure 6: Effect of depth in contextual word similarity. Three hidden layers is optimal for this task.

if adding depth to our context-sensitive autoencoder will improve its performance in the contextual word similarity task.

Figure 6 shows that as we increase the depth of our autoencoders, their performances initially improve. The CSAE-LGC model that uses both local and global context benefits more from greater number of hidden layers than CSAE-LC that only uses local context. We attribute this to the use of global context in CSAE-LGC that leads to more accurate representations of words in their context. We also note that with just a single hidden layer, CSAE-LGC largely improves the performance as compared to CSAE-LC.

6 Related Work

Representation learning models have been effective in many tasks such as language modeling (Bengio et al., 2003; Mikolov et al., 2013b), topic modeling (Nguyen et al., 2015), paraphrase detection (Socher et al., 2011), and ranking tasks (Yih et al., 2013). We briefly review works that use context information for text representation.

Huang et al. (2012) presented an RNN model that uses document-level context information to construct more accurate word representations. In particular, given a sequence of words, the approach uses other words in the document as external (global) knowledge to predict the next word in the sequence. Other approaches have also modeled context at the document level (Lin et al., 2015; Wang and Cho, 2015; Ji et al., 2016).

Ji et al. (2016) presented a context-sensitive RNN-based language model that integrates representations of previous sentences into the language model of the current sentence. They showed that this approach outperforms several RNN language models on a text coherence task.

Liu et al. (2015) proposed a context-sensitive RNN model that uses Latent Dirichlet Allocation (Blei et al., 2003) to extract topic-specific word embeddings. Their best-performing model regards each topic that is associated to a word in a sentence as a pseudo word, learns topic and word embeddings, and then concatenates the embeddings to obtain topic-specific word embeddings.

Mikolov and Zweig (2012) extended a basic RNN language model (Mikolov et al., 2010) by an additional feature layer to integrate external information (such as topic information) about inputs into the model. They showed that such information improves the perplexity of language models.

In contrast to previous research, we integrate context into deep autoencoders. To the best of our knowledge, this is the first work to do so. Also, in this paper, we depart from most previous approaches by demonstrating the value of context information in *sentence-level* semantic similarity and ranking tasks such as QA ranking tasks. Our approach to the ranking problems, both for Answer Ranking and Question Ranking, is different from previous approaches in the sense that we judge the relevance between inputs based on their context information. We showed that adding sentential or document context information about questions (or answers) leads to better rankings.

7 Conclusion and Future Work

We introduce an effective approach to integrate sentential or document context into deep autoencoders and show that such integration is important in semantic similarity tasks. In the future, we aim to investigate other types of linguistic context (such as POS tag and word dependency information, word sense, and discourse relations) and develop a unified representation learning framework that integrates such linguistic context with representation learning models.

Abstract

Online news editors ask themselves the same question many times: *what is missing in this news article to go online?* This is not an easy question to be answered by computational linguistic methods. In this work, we address this important question and characterise the constituents of news article editorial quality. More specifically, we identify 14 aspects related to the content of news articles. Through a correlation analysis, we quantify their independence and relation to assessing an article's editorial quality. We also demonstrate that the identified aspects, when combined together, can be used effectively in quality control methods for online news.

1 Introduction

A recent study[1] found that online news is nowadays the main source of news for the population in the 18-29 age group (71%), and as popular as TV in the 30-39 age group (63%). The readers appetite for high-quality online news result in an offer of thousands of articles published every day in the whole of the Web. For instance, it is not uncommon to find the same facts reported by many different online news articles. However, only a few of them actually grab the attention of the readers. Journalists and editors follow standardised discourse rules and techniques aiming at engaging the reader in the article's narrative of article (Louis and Nenkova, 2013).

Analysing the discourse of such articles is central to properly assessing the quality of online news (van Dijk and Kintsch, 1983). Defining the variables that computational linguistics should quantify is a challenging task. Several questions arise from this exercise. For example, what does the quality refer to? What makes a new article perceived as high quality by the editors/users? What aspects of an article correlate better with its perceived quality? Can we predict the quality of an article using linguistic features extracted from its content? These are the kind of questions we address in this paper.

To this end, we propose a linguistic resource and assessment methodology to quantify the editorial quality of online news discourse. We argue that quality is too complex to be represented by a single number and should be instead decomposed into a set of simpler variables that capture the different linguistic and narrative aspects of online news. Thus, we depart from current literature and propose a multidimensional representation of quality. The first contribution of this paper is a taxonomy of 14 different content aspects that are associated with the editor-perceived quality of online news articles. The proposed 14 aspects are the result of an editorial study involving professional editors, journalists, and computational linguists.

The second contribution of this paper is an expert-annotated corpus of online news articles obtained from a major news portal. This corpus is curated by the editors and journalists who annotated the articles with respect to the 14 aspects and to the general editorial quality. To confirm the independence and relevance of the proposed aspects, we perform a correlation analysis on this ground-truth to determine the strength of the associations between different aspects and article editorial quality. Our analysis shows that the editor-perceived quality of an article exhibits a strong positive correlation with certain aspects, such as

*This work was done while the authors were at Yahoo!Research Barcelona.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1893–1902,
Berlin, Germany, August 7-12, 2016.

fluency and *completeness*, while it is weakly correlated with other aspects like *subjectivity* and *polarity*.

As a baseline benchmark, we investigate the feasibility of predicting the quality aspects of an article using features extracted from the article only. Our findings indicate that article editorial quality prediction is a challenging task and that article quality can be predicted to a varying degree, depending on the feature space. The proposed aspects can be used to control the editorial quality with a Root Mean Squared Error (RMSE) of 0.398 on a 5-point Likert-scale.

The rest of the paper is organised as follows. Next, we discuss existing literature in discourse analysis and text quality metrics. In Section 3, we present the aspects that we identified as potential indicators of article quality. Section 4 provides the details of our online news corpus targeting the aspects of editorial quality control. The results of the correlation analysis conducted between the identified aspects and article quality are presented in Section 4. In Section 5, we present a baseline benchmark to automatically infer individual aspects and editorial quality from online news.

2 Related Work

A very recent work related to ours is (Gao et al., 2014), where the authors try to predict the interestingness of a news article for a user who is currently reading another news article. In our work, however, we try to predict the perceived quality of an article without using any context information other than the content of the article itself. Moreover, while the authors of (Gao et al., 2014) take a quite pragmatic approach to handle the problem, we follow a more principled approach and model the quality of a news article according to five orthogonal dimensions: readability, informativeness, style, topic, and sentiment. Work has been done in each one of these dimensions, but none has tackled the problem of modelling overall article quality in a comprehensive and articulated manner as we do. Below, we provide a survey of the previous work on these dimensions.

The readability of a piece of text can be defined as the ease that the text can be processed and understood by a human reader (Richards and Schmidt, 2013; Zamanian and Heydari, 2012). The readability is usually associated with fluency and writing quality (Nenkova et al., 2010; Pitler and Nenkova, 2008). Even though there is a significant amount of research that targets readability, most work (Redish, 2000; Yan et al., 2006) were originally designed to measure the readability of school books and do not suit well to more complex reading materials, such as news articles, which form the focus of our work.

The informativeness of a news article has been tackled from several different angles. In (Tang et al., 2003), news information quality was characterised by a set of nine aspects that were shown to have a good correlation with textual features. Catchy titles were shown to often lead to frustration, as the reader does not get the content that she expects (Louis and Nenkova, 2011). The task of assessing a news title's descriptiveness is related to semantic text similarity and has been researched by the SemEval initiative (Agirre et al., 2013). Moreover, the completeness of a news article is an aspect that has been considered in the past by (Louis and Nenkova, 2014), which showed that reporting the news with adequate detail is key to provide the reader with enough information to grasp the entire story. The freshness of news information also sets the tone of the discourse: information can be novel to the average reader or it can be already known and be presented as a reference to the reader. The novelty of an article is essentially accomplished by either analysing previous articles (Gamon, 2006) or by relying on real-time data from social-media services (Phelan et al., 2009).

The characterisation of the style of text compositions has been an active topic of research in communication sciences and humanities. An excellent example of the research done in this area is the influential work in (McNamara et al., 2009), where the authors found the best predictors of writing quality to be the syntactic complexity (number of words before the main verb), the diversity of words used by the author, and some other shallow features. In NLP, the writing style has been investigated in several contexts. A problem relevant to the one we addressed is the characterisation of an author's writing style to predict the success of novels (Ashok et al., 2013). The authors investigated a wide range of complex linguistic features, ranging from simple unigrams to distribution of word categories, grammar rules, distribution of constituents, sentiment, and connotation. The comparison of novels and news articles revealed a great similar-

ity in the writing style of novels and informative articles.

The broadness of a news topic has an impact on the reader's perceived quality of the article. A technical article is usually targeting niche groups of users and a popular article targets the masses. One of the few corpus (Louis and Nenkova, 2013) addressing quality was limited to the domain of scientific journalism, thus more technical articles. This corpus only considered news from the New York Times, thus contained already very good quality news. Two recent work investigated the feasibility of predicting news articles' feature popularity in social media at cold start (Bandari et al., 2012; Arapakis et al., 2014a). In (Bandari et al., 2012), features extracted from the article's content as well as additional meta-data was used to predict the number of times an article will be shared in Twitter after it went online. In (Arapakis et al., 2014a), a similar study was repeated to predict the popularity of a news article in social media using additional features obtained from external sources.

Sentiment analysis concerns the subjectivity and the strength and sign of the opinions expressed in a given piece of text. In (Arapakis et al., 2014b), it was demonstrated that news articles exhibit considerable variation in terms of the sentimentality and polarity of their content. The work in (Phelan et al., 2009) has provided evidence that sentiment-related aspects are important to profile and assess the quality of news articles. Sentiment analysis has been applied to news articles in other contexts as well (Godbole et al., 2007; Balahur et al., 2010).

3 Modeling News Article Quality

The editorial control of news articles is an unsolved task that involves addressing a number of issues, such as identifying the characteristics of an effective text, determining what methods produce reliable and valid judgments for text quality, as well as selecting appropriate aspects of text evaluation that can be automated using machine learning methods. Underlying these tasks is a main theme: can we identify benchmarks for characterising news article quality? Therefore, there is a need for empirical work to identify the global and local textual features which will help us make an optimal evaluation of news articles.

By doing so, we achieve two goals. On one hand, we can offer valuable insights with respect to what constitutes an engaging, good quality news article. On the other hand, we can identify benchmarks for characterising news article quality in an automatic and scalable way and, thus, predict poor writing before a news article is even published. This can help reduce greatly the burden of manual evaluation which is currently performed by professional editors.

3.1 Methodology

The methodology described here provides a framework for characterising and modelling news article editorial quality. In our work, we follow a bottom-up approach and identify 14 different content aspects that are good predictors (as we demonstrate in Section 6.1) of news article quality. The aspects we identified are informed by input from news editors, journalists and computational linguists, and previous research in NLP and, particularly, the efforts in text summarisation (Bouayad-Agha et al., 2012), document understanding (Dang, 2005; Seki et al., 2006) and question answering (Surdeanu et al., 2008; Shtok et al., 2012).

After discussing the editorial quality control with professionals, we gathered a set of heuristics and examined the literature for ways of designing quantitative measures to achieve our goal. We group the aspects under five headings: readability, informativeness, style, topic, and sentiment (see Fig. 1). Below, we provide a brief description of each aspect.

3.2 Readability

High quality articles are written in a way that makes them easier to read. In our model, we include two different aspects related to readability (Pitler and Nenkova, 2008): fluency and conciseness.

Fluency: Fluent articles are built from sentence to sentence, forming a coherent body of information. Consecutive sentences are meaningfully connected. Similarly, paragraphs are written in a logical sequence.

Conciseness: Concise articles have a focus. Sentences contain information that is related to the main theme of the article. The same or similar information is tried to be not repeated.

3.3 Informativeness

As a main reason for reading online news is to remain well-informed (Tang et al., 2003), informativeness of articles have an effect on their per-

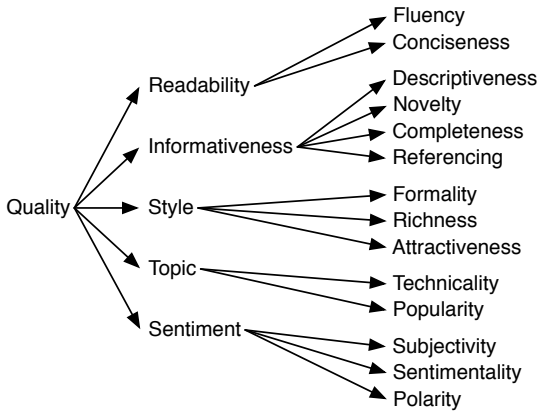

Figure 1: A taxonomy of the identified aspects.

ceived quality. In our model, we consider four different aspects related to informativeness: descriptiveness, novelty, completeness, and referencing.

Descriptiveness: Descriptiveness indicates how well the title of an article reflects its main body content. Titles with low descriptiveness are often click baits (e.g., "You won't believe what you will see"). Such titles may lead to dissatisfaction, as the provided news content usually does not meet the raised user expectation.

Novelty: Novel articles provide new and valuable information to the readers. The provided information is unlikely to be known to an average reader.

Completeness: Complete articles cover the topic in an adequate level of detail (Louis and Nenkova, 2014; Bouayad-Agha et al., 2012). A reader can satisfy her information need after reading such an article.

Referencing: Referencing is about the degree to which the article references external sources (including other people's opinions and related articles). Providing references allows the reader to access related information sources easily, (Gamon, 2006; van Dijk and Kintsch, 1983).

3.4 Style

The language and aesthetics is also related to the article quality (McNamara et al., 2009; Ashok et al., 2013; Pavlick and Tetreault, 2016; Peterson et al., 2011). We consider three style-related aspects: formality, richness, and attractiveness.

Formality: Formal articles are written by following certain writing guidelines. They are more likely to contain formal words and obey punctuation/grammar rules(Peterson et al., 2011).

Richness: The vocabulary of rich articles is perceived as diverse and interesting by the readers. Rich articles are not written in a plain and straightforward manner.

Attractiveness: Attractiveness measures the degree to which the title of an article raises curiosity in its readers. Attractive titles entice people to continue reading the main content of the article.

3.5 Topic

Editors consider the nature of the article with respect to its target audience, i.e., according to the target audience (technical or popular) the other aspects may play a different role. We investigate two topic-related aspects: technicality and popularity.

Technicality: Technical articles (Louis and Nenkova, 2013) usually require some effort to understand as well as previous knowledge on the topic. Examples of usually technical news topics include science and finance.

Popularity: The popularity refers to the size of the audience who would be interested in the topic of the article (Bandari et al., 2012; Arapakis et al., 2014b). For example, while many readers are interested in reading about celebrities, few readers are interested in articles about anthropology.

3.6 Sentiment

Finally, we consider the sentiments expressed in an article. Besides opinion articles (which are subjective by nature), many news may also convey a particular emotion. We evaluate three sentiment-related aspects: subjectivity, sentimentality, and polarity.

Subjectivity: Subjective articles tend to contain opinions, preferences, or possibilities. There are relatively few factual statements.

Sentimentality: Sentimentality is a measure of the total magnitude of positive or negative statements made in the article regarding an object or an event. Highly sentimental articles include relatively few neutral statements.

Polarity: Polarity indicates the overall sign of the sentiments expressed in the article (Arapakis et al., 2014a). Articles with positive (negative) polarity include relatively more statements with positive (negative) sentiment.

4 Corpus: Editorial Quality Control

Our goal is to identify proxies of news article quality that can be learned and predicted in an automatic and scalable manner. To identify these proxies, we rely on the domain knowledge and human intuition of expert judges, whom we employ in a rigorous, crowdsourcing-based evaluation for gen-

erating a ground-truth dataset. Through an editorial study we create an in-domain, annotated news corpus that allows us to learn predictive models which can estimate accurately the perceived quality of news articles.

4.1 Online News Articles

Our analysis was conducted on a dataset consisting of $13,319$ news articles taken from a major news portal[2]. We opted for a single news portal to be able to extract features that are consistent across all news articles. The dataset was constructed by crawling news articles over a period of two weeks. During the crawling period, we connected to the RSS news feed of the portal every 15 minutes and fetched newly published articles written in English. The content of the discovered articles was then downloaded from the portal.

Each article is identified by its unique URI and stored in a database, along with some meta-data, such as article's genre, its publication date, and its HTML content. We applied further filtering on the initial set of 13,319 news articles. The word count distribution of the articles followed a bimodal pattern, with the bulk of the articles located around a mean value of 447.5. Using this value as a reference point, we removed articles that contain less than 150 or more than 800 words. We then sampled a smaller set of articles such that each of the most frequent 15 genres have at least 65 articles in the sample. This left us with 1,043 new articles, out of which a randomly selected set of 561 articles were used in the editorial study.

The selected news articles were preprocessed before the editorial study. The preprocessing was performed in two steps. First, we removed the boilerplate of HTML pages and extracted the main body text of news articles, using Boilerpipe (Kohlschütter et al., 2010). Second, we segmented the body text into sentences and paragraphs. For sentence segmentation, we used the Stanford CoreNLP library, which includes a probabilistic parser (Klein and Manning, 2003; Mihalcea and Csomai, 2007). For each news article we generated a body- and sentence- level annotation form (see example in the supplementary notes).

4.2 Annotations of Editorial Quality Aspects

For our editorial study, we employed ten expert judges (male = 4, female = 6) who had a background in computational linguistics, journalism, or were media monitoring experts. The expert judges were either native English speakers or were proficient with the English language. The expert judges assessed a total of 561 news articles on 15 measures (14 aspects and the main quality measure), using a 5-point Likert scale, where low and high scores suggest weak or strong presence of the assessed measure, respectively.

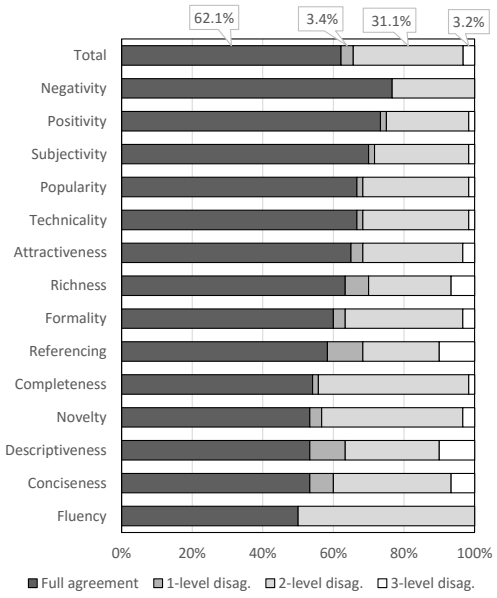

Figure 2: Annotators agreement.

The annotation took place remotely, and each expert judge could annotate up to ten news articles per day (this threshold was set to ensure a high quality of annotation), and each article was annotated by one expert judge and by one of the authors of this paper. Prior to that, there was a pilot session were each expert judge was asked to become familiar with the quality criteria and annotate three trial news articles. Next, a meeting (physical or online) was arranged and the authors discussed with the expert judge the rationale behind assigning the scores, and appropriate corrections and recommendations were made. This step ensured that we had disambiguated any questions prior to the editorial study and also assured that expert judges followed the same scoring procedure. The compensation for annotating was 10€per article. The annotated corpus is publicly available.[3]

Fig. 2 illustrates the details of the overall annotations agreement. We can see that annotations agree on 62.1% of the articles, on 65.5% they vary

[2]Yahoo! News at http://www.yahoo.com/news.

[3]`http://novasearch.org/datasets/`.

only 1-point and in 96.6% they vary 2 points in the 5-point Likert-scale. These results are quite satisfying and show a good level of agreement and consistency across all aspects.

4.3 Corpus Statistics

Table 1 shows the mean (M) and standard deviation (SD) values for five different distributions (number of characters, words, unique words, entities, and sentences) and four different subsets of the corpus. The subsets contain all articles, high-quality articles (labels 4 and 5), medium-quality articles (label 3), or low-quality articles (labels 1 and 2). The last three subsets contain 84, 298, and 179 news articles, respectively. According to these numbers, the article quality follows an unbalanced distribution: about half of the articles are labeled as medium quality, and there are about two times more low-quality articles than high-quality articles. According to Table 1, there is a clear difference between distributions for the high- and low- quality articles. In general, we observe that higher-quality articles are relatively longer (e.g., more words or sentences), on average.

5 Aspects Correlation Analysis

To identify which aspects of a news article are better discriminants of its quality, we perform a correlation analysis. Given that we are looking at ordinal data that violates parametric assumptions, we compute the Spearman's rank correlation coefficients (r_s) between the aspects' scores and the news article quality that we acquired from our ground truth. The motivation behind this analysis is to get a first intuition into the aspects' effectiveness to act as quality predictors, by understanding how they are associated to news article quality.

In Table 2, we report several statistically significant correlations between the different aspects. Given that our correlation analysis involves multiple pairwise comparisons, we need to correct the level of significance for each test such that the overall Type I error rate (α) across all comparisons remains at .05. Given that the Bonferroni correction is too conservative in the Type I error rate, we opt for the more liberal criterion proposed by Benjamini and Hochberg (Benjamini and Hochberg, 1995; Benjamini and Hochberg, 2000) and compute the critical p-value for every pairwise comparisons as

$$p_{\text{crit}} = \frac{j}{k}\alpha, \tag{1}$$

where j is the index of all pairwise comparison p-values, listed in an ascending order, and k is the number of comparisons. If we consider Cohen's conventions for the interpretation of effect size, we observe that most of the correlation coefficients shown in Table 2 represent sizeable effects, which range from small ($\pm.1$) to large ($\pm.5$). For example, *completeness* is highly correlated with quality ($r_s = .70$) while *polarity* is the least correlated with quality ($r_s = .05$). In addition, Table 2 does not provide any evidence of multicollinearity since none of the aspects (with the exception of quality) are significantly highly correlated ($r_s > .80$).

6 Predicting Editorial Quality

6.1 Predicting EQ with the Aspects

In this section, we demonstrate the predictive characteristics of the proposed aspects (Section 3) with respect to news article quality. We formulate the prediction problem as a regression problem, and conduct a 10-fold cross validation to estimate the regression model. For our regression task we use a Generalised Linear Model (`GLM`) via penalized maximum likelihood (Friedman et al., 2010). The regularisation path is computed for the lasso or elasticnet penalty at a grid of values for the regularisation parameter lambda. The `GLM` solves the following problem

$$\min_{\beta_0,\beta} \frac{1}{N}\sum_{i=1}^{N} w_i l(y_i, \beta_0+\beta^T x_i)+\lambda[(1-\alpha)\frac{\|\beta\|_2^2}{2}+\alpha\|\beta\|_1,], \tag{2}$$

over a grid of values of λ covering the entire range. Here $l(y, \eta)$ is the negative log-likelihood contribution for observation i. The elastic-net penalty is controlled by α, and bridges the gap between lasso ($\alpha = 1$, the default) and ridge ($\alpha = 0$). The tuning parameter λ controls the overall strength of the penalty. It is known that the ridge penalty shrinks the coefficients of correlated predictors towards each other while the lasso tends to pick one of them and discard the others, which makes it more robust against predictor collinearity and overfitting. We used the values that minimise RMSE, i.e., $\alpha = 0.95$ and $\lambda = 0.01$.

In Table 3, we see the coefficients of the final `GLM` model which are to be interpreted in the same manner as a Cox model. A positive regression coefficient for an explanatory variable means that the variable is associated with a higher risk of an event. In our case, all coefficients are positive, being *completeness*, *fluency* and *richness* the ones

Table 1: Statistics for the annotated news corpus (M $\pm$ SD values)

	All	High quality	Medium quality	Low quality

showing a higher relation to the overall editorial quality.

Next, we replicate our regression experiments for the GLM regression model, but this time we apply a leave-one-aspect-out method, to examine the relative importance of each aspect in explaining our predicted variable, i.e., the news article quality. To this end, we evaluate the 14 regression models, each one with out one of the aspects. The goal is to verify how prediction is affected by each individual quality aspect.

To compare the performance of our GLM regression model against the baseline method (with all quality aspects), we compute the Root Mean Squared Error (RMSE), given by

$$RMSE = \sqrt{\frac{\sum_{i=1}^{N} (\hat{y} - y_i)^2}{N}} \quad (3)$$

where $\hat{y}$ is the sample mean and y_i is the i-th estimate. However, while regression results give an idea of the prediction quality of the models they do

not quantify the size of the difference of their performance. We, therefore, also compute the Root Relative Squared Error (RRSE) metric as it provides a good indication of any relative improvement over the baseline methods, given by

$$RRSE = 1 - \frac{RMSE_{GLM}}{RMSE_{Baseline}}. \quad (4)$$

Table 4 shows the RMSE and RRSE, with respect to the GLM regression model trained on all the features. These results show that *completeness*, *fluency* and *richness* are the aspects that most affect RMSE when they are missing from the full model.

6.2 Automatic Prediction of EQ

We examined a baseline model (BaselineM) that always predicts the mean value and a baseline GLM model (BaselineShallow) trained on shallow features, to automatically predict the editorial quality. Shallow or lexical features are commonly used in traditional readability metrics, which are based on the analysis of superficial text properties. Flesh-Kincaid Grade Level (Flesch, 1979; François and Fairon, 2012), SMOG (McLaughlin, 1969), and Gunning Fog (Gunning, 1952) are some examples of readability metrics. The simplicity of these features makes them an attractive solution compared to computationally more expensive features, such as syntactic (Feng et al., 2010). However, as Shriver (Schriver, 1989) points out, the readability metrics can be useful when used as gross index of readability. For our baseline, we consider the Flesh Kincaid, Coleman Liau, ARI, RIX, Gunning Fog, SMOG, LIX features.

In Table 5, we report the average performance of the GLM regression model, BaselineM, and BaselineShallow across all folds. We note that our GLM regression model improves the RMSE by at least 40%, compared to both baselines.

Finally, as a reference for future research with the proposed corpus, we trained GLM regression models to predict each aspect individually. Table 6 presents the RMSE for each aspect, for two different sets of feature: a standard BoW and the shallow features described previously, as well as the BaselineM. Despite the simplicity of the features, we can see that the aspects can be inferred from the articles. In particular, the model trained on the BoW features achieves an RMSE that is very close to that of the BaselineM, whereas the model trained on the shallow features outperforms all other models.

Table 5: Average performance across all ten folds for the GLM, BaselineM and BaselineShallow.

Method	RMSE	RRSE
BaselineM	0.7048	43.47%
BaselineShallow	0.8937	55.41%

Sentimentality	.8170	.7668	.8046

7 Conclusions

In this paper, we proposed an annotated corpus for controlling the editorial quality of online news through 14 aspects related to editors perceived quality of news articles. To this end, we performed an editorial study with expert judges either in computational linguistics, journalism, or media monitoring experts. The judges assessed a total of 561 news articles with respect to 14 aspects. The study produced valuable insights. One important finding was that high quality articles share a significant amount of variability with several of the proposed aspects, which supports the claim that the proposed aspects may characterise news article quality in an automatic and scalable way. Another finding was that *fluency*, *completeness* and *richness* are the aspects that best correlate with quality, while *technicality*, *subjectivity* and *polarity* aspects show a poor correlation with quality. This shows that the text comprehension and writing style are aspects that are more relevant than sentiment. Later, we showed that using the entire

set of 14 aspects we could predict the text quality with an RMSE of only 0.400 in a 5-point Likert-scale. This renders a very effective decomposition of news article quality into the 14 aspects. As future work, we plan to investigate other linguistic representations that can improve the automated extraction of the proposed aspects to better predict the article's perceived quality.

Alleviating Poor Context with Background Knowledge for Named Entity Disambiguation

Abstract

Named Entity Disambiguation (NED) algorithms disambiguate mentions of named entities with respect to a knowledge-base, but sometimes the context might be poor or misleading. In this paper we introduce the acquisition of two kinds of background information to alleviate that problem: entity similarity and selectional preferences for syntactic positions. We show, using a generative Näive Bayes model for NED, that the additional sources of context are complementary, and improve results in the CoNLL 2003 and TAC KBP DEL 2014 datasets, yielding the third best and the best results, respectively. We provide examples and analysis which show the value of the acquired background information.

1 Introduction

The goal of Named Entity Disambiguation (NED) is to link each mention of named entities in a document to a knowledge-base of instances. The task is also known as Entity Linking or Entity Resolution (Bunescu and Pasca, 2006; McNamee and Dang, 2009; Hachey et al., 2012). NED is confounded by the ambiguity of named entity mentions. For instance, according to Wikipedia, *Liechtenstein* can refer to the micro-state, several towns, two castles or a national football team, among other instances. Another ambiguous entity is *Derbyshire* which can refer to a county in England or a cricket team. Most NED research use knowledge-bases derived or closely related to Wikipedia.

For a given mention in context, NED systems (Hachey et al., 2012; Lazic et al., 2015) typically rely on two models: (1) a mention module returns possible entities which can be referred to by the mention, ordered by prior probabilities; (2) a context model orders the entities according to the context of the mention, using features extracted from annotated training data. In addition, some systems check whether the entity is coherent with the rest of entities mentioned in the document, although (Lazic et al., 2015) shows that the coherence module is not required for top performance.

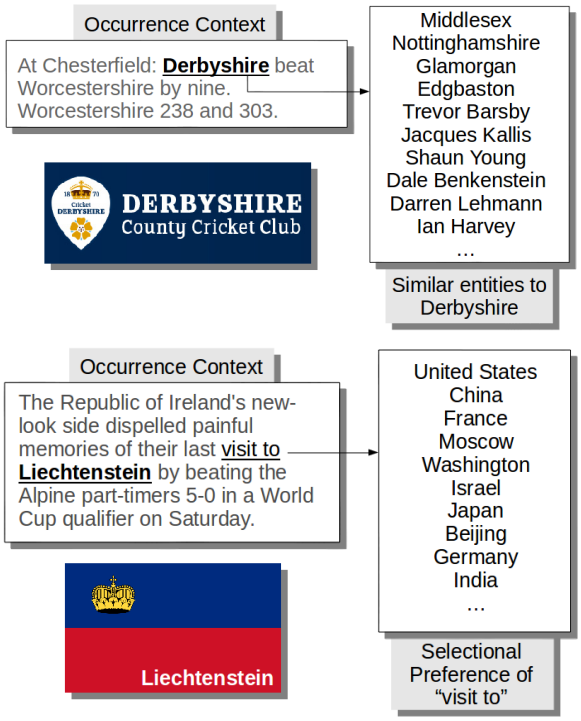

Figure 1: Two examples where NED systems fail, motivating our two background models: similar entities (top) and selectional preferences (bottom). The logos correspond to the gold label.

Figure 1 shows two real examples from the development dataset which contains text from News, where the clues in the context are too weak or misleading. In fact, two mentions in those examples (*Derbyshire* in the first and *Liechtenstein* in the second) are wrongly disambiguated by a bag-of-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1903–1912,
Berlin, Germany, August 7-12, 2016.

words context model.

In the first example, the context is very poor, and the system returns the *county* instead of the *cricket team*. In order to disambiguate it correctly one needs to be aware that *Derbyshire*, when occurring on News, is most notably associated with cricket. This background information can be acquired from large News corpora such as Reuters (Lewis et al., 2004), using distributional methods to construct a list of closely associated entities (Mikolov et al., 2013). Figure 1 shows entities which are distributionally similar to *Derbyshire*, ordered by similarity strength. Although the list might say nothing to someone not acquainted with cricket, all entities in the list are strongly related to cricket: Middlesex used to be a county in the UK that gives name to a cricket club, Nottinghamshire is a county hosting two powerful cricket and football teams, Edgbaston is a suburban area and a cricket ground, the most notable team to carry the name Glamorgan is Glamorgan County Cricket Club, Trevor Barsby is a cricketer, as are all other people in the distributional context. When using these similar entities as context, our system does return the correct entity for this mention.

In the second example, the words in the context lead the model to return the *football team* for *Liechtenstein*, instead of the *country*, without being aware that the nominal event "visit to" prefers locations arguments. This kind of background information, known as selections preferences, can be easily acquired from corpora (Erk, 2007). Figure 1 shows the most frequent entities found as arguments of "visit to" in the Reuters corpus. When using these filler entities as context, the context model does return the correct entity for this mention.

In this article we explore the addition of two kinds of background information induced from corpora to the usual context of occurrence: (1) given a mention we use distributionally similar entities as additional context; (2) given a mention and the syntactic dependencies in the context sentence, we use the selectional preferences of those syntactic dependencies as additional context. We test their contribution separately and combined, showing that they introduce complementary information.

Our contributions are the following: (1) we introduce novel background information to provide additional disambiguation context for NED; (2) we integrate this information in a Bayesian generative NED model; (3) we show that similar entities are useful when no textual context is present; (4) we show that selectional preferences are useful when limited context is present; (5) both kinds of background information help improve results of a NED system, yielding the state-of-the-art in the TAC KBP DEL 2014 dataset and getting the third best results in the CoNLL 2003 dataset; (6) we release both resources for free to facilitate reproducibility. [1]

The paper is structured as follows. We first introduce the method to acquire background information, followed by the NED system. Section 4 presents the evaluation datasets, Section 5 the development experiments and Section 6 the overall results. They are followed by related work, error analysis and the conclusions section.

2 Acquiring background information

We built our two background information resources from the Reuters corpus (Lewis et al., 2004), which comprises 250K documents. We chose this corpus because it is the one used to select the documents annotated in one of our gold standards (cf. Section 4). The documents in this corpus are tagged with categories, which we used to explore the influence of domains.

The documents were processed using a publicly available NLP pipeline, Ixa-pipes,[2] including tokenization, lematization, dependency tagging and NERC.

2.1 Similar entity mentions

Distributional similarity is known to provide useful information regarding words that have similar co-occurrences. We used the popular word2vec[3] tool to produce vector representations for named entities in the Reuters corpus. In order to build a resource that yields similar entity mentions, we took all entity-mentions detected by the NERC tool and, if they were multi word entities, joined them into a single token replacing spaces with underscores, and appended a tag to each of them. We run word2vec with default parameters on the preprocessed corpus. We only keep the vectors for named entities, but note that the corpus contains

[1] http://ixa2.si.ehu.es/anderbarrena/2016ACL_files.zip

[2] http://ixa2.si.ehu.es/ixa-pipes/

[3] https://code.google.com/archive/p/word2vec/

both named entities and other words, as they are needed to properly model co-occurrences.

Given a named entity mention, we are thus able to retrieve the named entity mentions which are most similar in the distributional vector space. All in all, we built vectors for 95K named entity mentions. Figure 1 shows the ten most similar named entities for *Derbyshire* according to the vectors learned from the Reuters corpus. These similar mentions can be seen as a way to encode some notion of a topic-related most frequent sense prior.

2.2 Selectional Preferences

Selectional preferences model the intuition that arguments of predicates impose semantic constraints (or preferences) on the possible fillers for that argument position (Resnik, 1996). In this work, we use the simplest model, where the selectional preference for an argument position is given by the frequency-weighted list of fillers (Erk, 2007).

We extract dependency patterns as follows. After we parse Reuters with the Mate dependency parser (Bohnet, 2010) integrated in IxaPipes, we extract ($H \xrightarrow{D} C$) dependency triples, where D is one of the Subject, Object or Modifier dependencies[4] (SBJ, OBJ, MOD, respectively), H is the head word and C the dependent word. We extract fillers in both directions, that is, the set of fillers in the dependent position $\{C : (H \xrightarrow{D} C)\}$, but also the fillers in the head position $\{H : (H \xrightarrow{D} C)\}$. Each such configuration forms a template, $(H \xrightarrow{D} *)$ and $(* \xrightarrow{D} C)$.

In addition to triples (single dependency relations) we also extracted tuples involving two dependency relations in two flavors: $(H \xrightarrow{D_1} C_1 \xrightarrow{D_2} C_2)$ and $(C_1 \xleftarrow{D_1} H \xrightarrow{D_2} C_2)$. Templates and fillers are defined as done for single dependencies, but, in this case, we extract fillers in any of the three positions and we thus have three different templates for each flavor.

As dependency parsers work at the word level, we had to post-process the output to identify whether the word involved in the dependency was part of a named entity identified by the NERC algorithm. We only keep tuples which involve at least one name entity. Some examples for the three kinds of tuples follow, including the frequency of occurrence, with entities shown in bold:

(beat $\xrightarrow{SBJ}$ **Australia**) 141
(refugee $\xrightarrow{MOD}$ **Hutu**) 1681
(visit $\xrightarrow{MOD}$ to $\xrightarrow{MOD}$ **United States**) 257
(match $\xrightarrow{MOD}$ against $\xrightarrow{MOD}$ **Manchester United**) 12
(Spokesman $\xleftarrow{SBJ}$ tell $\xrightarrow{OBJ}$ **Reuters**) 1378
(**The Middle East** $\xleftarrow{MOD}$ process $\xrightarrow{MOD}$ peace) 1126

When disambiguating a mention of a named entity, we check whether the mention occurs on a known dependency template, and we extract the most frequent fillers of that dependency template. For instance, the bottom example in Figure 1 shows how *Liechtenstein* occurs as a filler of the template (visit $\xrightarrow{MOD}$ to $\xrightarrow{MOD}$ *), and we thus extract the selectional preference for this template, which includes, in the figure 1, the ten most frequent filler entities.

We extracted more than 4.3M unique tuples from Reuters, producing 2M templates and their respective fillers. The most frequent dependency was MOD, followed by SUBJ and OBJ [5] The selectional preferences include 400K different named entities as fillers.

Note that selectional preferences are different from dependency path features. Dependency path features refer to features in the immediate context of the entity mention, and are sometimes added as additional features of supervised classifiers. Selectional preferences are learnt collecting fillers in the same dependency path, but the fillers occur elsewhere in the corpus.

3 NED system

Our disambiguation system is a Näive Bayes model as initially introduced by (Han and Sun, 2011a), but adapted to integrate the background information extracted from the Reuters corpus. The model is trained using Wikipedia,[6] which is also used to generate the entity candidates for each mention.

Following usual practice, candidate generation is performed off-line by constructing an association between strings and Wikipedia articles, which we call dictionary. The association is performed using article titles, redirections, disambiguation pages, and textual anchors. Each association is scored with the number of times the string was

[4] Labels are taken from the Penn Treebank https://www.ling.upenn.edu/courses/Fall_2003/ling001/penn_treebank_pos.html

[5] 1.5M, 0.8M and 0.7M respectively

[6] We used a dump from 25-5-2011. This dump is close in time to annotations of the datasets used in the evaluation (c.f. Section 4)

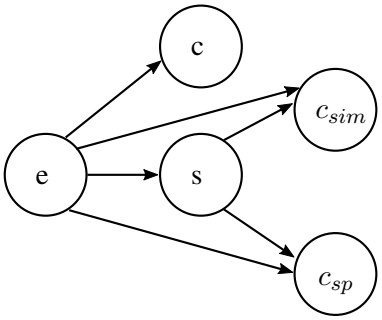

Figure 2: Dependencies among variables in our Bayesian network.

used to refer to the article (Agirre et al., 2015). We also use Wikipedia to extract training mention contexts for all possible candidate entities. Mention contexts for an entity are built by collecting a window of 50 words surrounding any hyper link pointing to that entity.

Both training and test instances are preprocessed the same way: occurrence context is tokenized, multi-words occurring in the dictionary are collapsed as a single token (longest matches are preferred). All occurrences of the same target mention in a document are disambiguated collectively, as we merge all contexts of the multiple mentions into one, following the one-entity-per-discourse hypothesis (Barrena et al., 2014).

The Näive Bayes model is depicted in Figure 2. The candidate entity e of a given mention s, which occurs within a context c, is selected according to the following formula:

$$e = \arg\max_e P(s, c, c_{\text{sp}}, c_{\text{sim}}, e) =$$
$$\arg\max_e P(e)P(s|e)P(c|e)P(c_{\text{sp}}|e, s)P(c_{\text{sim}}|e, s)$$

The formula combines evidences taken from five different probabilities: the entity prior $p(e)$, the mention probability $p(s|e)$, the textual context $p(c|s)$, the selectional preferences $P(c_{\text{sp}}|e, s)$ and the distributional similarity $P(c_{\text{sim}}|e, s)$. This formula is also referred to as the "**Full model**", as we also report results of partial models which use different combinations of the five probability estimations.

Entity prior $P(e)$ represents the popularity of entity e, and is estimated as follows:

$$P(e) \propto \frac{f(*, e) + 1}{f(*, *) + N}$$

where $f(*, e)$ is the number of times the entity e is referenced within Wikipedia, $f(*, *)$ is the total number of entity mentions and N is the number of distinct entities in Wikipedia. The estimation is smoothed using the *add-one* method.

Mention probability $P(s|e)$ represents the probability of generating the mention s given the entity e, and is estimated as follows:

$$P(s|e) \propto \theta\frac{f(s, e)}{f(*, e)} + (1 - \theta)\frac{f(s, *)}{f(*, *)}$$

where $f(s, e)$ is the number of times mention s is used to refer to entity e and $f(s, *)$ is the number of times mention s is used as anchor. We set the θ hyper-parameter to 0.9 according to developments experiments in the CoNLL testa dataset (cf. Section 5.5).

Textual context $P(c|e)$ is the probability of entity e generating the context $c = \{w_1, \ldots, w_n\}$, and is expressed as:

$$P(c|e) = \prod_{w \in c} P(w|e)^{\frac{1}{n}}$$

where $\frac{1}{n}$ is a correcting factor that compensates the effect of larger contexts having smaller probabilities. $P(w|e)$, the probability of entity e generating word w, is estimated following a bag-of-words approach:

$$P(w|e) \propto \lambda\frac{c(w, e)}{c(*, e)} + (1 - \lambda)\frac{f(w, *)}{f(*, *)}$$

where $c(w, e)$ is the number of times word w appears in the mention contexts of entity e, and $c(*, e)$ is the total number of words in the mention contexts. The term in the right is a smoothing term, calculated as the likelihood of word w being used as an anchor in Wikipedia. λ is set to 0.9 according to development experiments done in CoNLL testa.

Distributional Similarity $P(c_{\text{sim}}|e, s)$ is the probability of generating a set of similar entity mentions given an entity mention pair. This probability is calculated and estimated in exactly the same way as the textual context above, but replacing the mention context c with the mentions of the 30 most similar entities for s (cf. Section 2.1).

Selectional Preferences $P(c_{\text{sp}}|e, s)$ is the probability of generating a set of fillers c_{sp} given an entity and mention pair. The probability is again analogous to the previous ones, but using the filler entities of the selectional preferences of s instead of the context c (cf. Section 2.2). In our experiments, we select the 30 most frequent fillers for each selectional preferences, concatenating the filler list when more than one selectional preference is applied.

3.1 Ensemble model

In addition to the Full model, we created an ensemble system that combines the probabilities described above using a weighting schema, which we call "**Full weighted model**". In particular, we add an exponent coefficient to the probabilities, thus allowing to control the contribution of each model.

$$\arg\max_{e} P(e)^{\alpha} P(s|e)^{\beta}$$
$$P(c|e)^{\gamma} P(c_{\text{sp}}|e,s)^{\delta} P(c_{\text{sim}}|e,s)^{\omega}$$

We performed an exhaustive grid search in the interval $(0, 1)$ for each of the weights, using a step size of 0.05, and discarding the combinations whose sum is not one. Evaluation of each combination was performed in the CoNLL testa development set, and the best combination was applied in the test sets.[7]

4 Evaluation Datasets

The evaluation has been performed on one of the most popular datasets, the CoNLL 2003 named-entity disambiguation dataset, also know as the AIDA or CoNLL-Yago dataset (Hoffart et al., 2011). It is composed of 1393 news documents from Reuters Corpora where named entity mentions have been manually identified. It is divided in three main parts: *train*, *testa* and *testb*. We used *testa* for development experiments, and *testb* for the final results and comparison with the state-of-the-art. We ignored the training part.

In addition, we also report results in the Text Analysis Conference 2014 Diagnostic Entity Linking task dataset (TAC DEL 2014).[8] The gold standard for this task is very similar to the CoNLL dataset, where target named entity mentions have been detected by hand. Through the beginning of the task (2009 to 2013) the TAC datasets were query-driven, that is, the input included a document and a challenging and sometimes partial target-mention to disambiguate. As this task also involved mention detection and our techniques are sensitive to mention detection errors, we preferred to factor out that variation and focus on the 2014.

The evaluation measure used in this paper is micro-accuracy, that is, the percentage of linkable mentions that the system disambiguates correctly, as widely used in the CoNLL dataset. Note that TAC2014 EDL included several evaluation measures, including the aforementioned micro-accuracy of linkable mentions, but the official evaluation measure was Bcubed+ F1 score, involving also detection and clustering of mentions which refer to entities not in the target knowledge base. We decided to use the same evaluation measure for both datasets, for easier comparison. Table 1 summarizes the statistics of the datasets used in this paper where document and mention counts are presented.

Dataset	Documents	Mentions
CoNLL testa	216	4791
CoNLL testb	231	4485
TAC2014 DEL test	138	2817

Table 1: Document and linkable mention counts for CoNLL and TAC2014 DEL datasets.

5 Development experiments

We started to check the contribution of the acquired background information in the *testa* section of the CoNLL dataset. In fact, we decided to focus first on a subset of *testa* about sports,[9] and also acquired background information from the sports sub-collection of the Reuters corpus.[10] The rationale was that we wanted to start in a controlled setting, and having assumed that the domain of the test documents and the source of the background information could play a role, we decided to start focusing on the sports domain first. Another motivation is that we noticed that the ambiguity between locations and sport clubs (e.g. football, cricket, rugby, etc.) is challenging, as shown in Figure 1.

5.1 Entity similarity with no context

In our first controlled experiment, we wanted to test whether the entity similarity resource provided any added value for the cases where the target mentions had to be disambiguated out of context. Our hypothesis was that the background information from the unannotated Reuters collection, entity similarity in this case, should provide improved performance. We thus simulated a corpus where mentions have no context, extracting the named entity mentions in the sports subset that

[7] The best combination was $\alpha = 0.05$, $\beta = 0.1$, $\gamma = 0.55$ $\delta = 0.15$, $\omega = 0.15$

[8] http://www.nist.gov/tac/2014/KBP/

[9] Including 102 out of the 216 documents in *testa*, totaling 3319 mentions.

[10] Including approx. 35K documents out of the 250K documents in Reuters

Method	m-acc
$P(e)P(s\|e)$	63.83
$P(e)P(s\|e)P(c_{\text{sim}}\|e,s)$	70.98

Table 2: Results on mentions with no context on the sports subset of testa, limited to 85% of the mentions (cf. Section 5.1).

Method	m-acc
$P(e)P(s\|e)$	63.66
$P(e)P(s\|e)P(c\|e)$	66.18
$P(e)P(s\|e)P(c_{\text{sp}}\|e,s)$	67.33
$P(e)P(s\|e)P(c\|e)P(c_{\text{sp}}\|e,s)$	68.78

Table 3: Results on mentions with access to limited context on the sports subset of testa, limited to the 45% of mentions (cf. Section 5.2).

had an entry in the entity similarity resource (cf. Section 2.1), totaling 85% of the 3319 mentions.

Table 2 shows that the entity similarity resource improves the results of the model combining the entity prior and mention probability, similar to the so-called most frequent sense baseline (MFS). Note that the combination of both entity prior and mention probability is a hard-to-beat baseline, as we will see in Section 6. This experiment confirms that entity similarity information is useful when no context is present.

5.2 Selectional preferences with short context

In our second controlled experiment, we wanted to test whether the selectional preferences provided any added value for the cases where the target mentions had limited context, that of the dependency template. Our hypothesis was that the background information from the unannotated Reuters collection, selectional preferences in this case, should provide improved performance with respect to the baseline generative model of context. We thus simulated a corpus where mentions have only short context, exactly the same as the dependency templates which apply to the example, constructed extracting the named entity mentions in the sports subset that contained matching templates in the selectional preference resource (cf. Section 2.2), totaling 45% of the 3319 mentions.

Table 3 shows that the selectional preference resource (third row) allows to improve the results with respect to the no-context baseline (first row) and, more importantly, with respect to the baseline generative model (second row). The last row shows that the context model and the selectional preference model are complementary, as they produce the best result in the table. This experiment confirms that selectional preference information is effective when limited context is present.

Method	m-acc
$P(e)P(s\|e)P(c\|e)$	69.54
$P(e)P(s\|e)P(c\|e)P(c_{\text{sp}}\|e,s)$	71.25
$P(e)P(s\|e)P(c\|e)P(c_{\text{sim}}\|e,s)$	72.64
Full	73.94

Table 4: Results on mentions with limited context on the sports subset of testa, limited to the 41% of the mentions (cf. Section 5.3)

Models	Spor.	Reut.
$P(e)P(s\|e)$	65.52	65.52
$P(e)P(s\|e)P(c\|e)$	72.81	72.81
$P(e)P(s\|e)P(c\|e)P(c_{\text{sp}}\|e,s)$	73.56	73.06
$P(e)P(s\|e)P(c\|e)P(c_{\text{sim}}\|e,s)$	75.73	76.62
Full	76.30	76.87

Table 5: Results on the entire sports subset of testa: middle column uses the sports subset of Reuters to acquire background information, right column uses the full Reuters (cf. Section 5.4).

5.3 Combinations

In our third controlled experiments, we combine all three context and background models and evaluate them in the subset of the sports mentions that have entries in the similarity resource, and also contain matching templates in the selectional preference resource (41% of the sports subset). Note that, in this case, the context model has access to the entire context. Table 4 shows that, effectively, the background information adds up, with best results for the full combined model (cf. Section 3), confirming that both sources of background information are complementary to the baseline context model and between themselves.

5.4 Sports subsection of CoNLL testa

The previous experiments have been run on a controlled setting, limited to the subset where our constructed resources could be applied. In this section we report results for the entire sports subset of CoNLL testa. The middle column in Table 5 shows the results for the two baselines, and the improvements when adding the two background

models, separately, and in combination. The results show that the improvements reported in the controlled experiments carry over when evaluating to all mentions in the Sport subsection, with an accumulated improvement of 3.5 absolute points over the standard NED system (second row).

The experiments so far have tried to factor out domain variation, and thus the results have been produced using the background information acquired from the sports subset of the Reuters collection. In order to check whether this control of the target domain is necessary, reproduced the same experiment using the full Reuters collection to build the background information, as reported in the rightmost column in Table 5. The results are very similar,[11] with a small decrease for selectional preferences, a small increase for the similarity resource, and a small increase for the full system. In view of these results, we decided to use the full Reuters collection to acquire the background knowledge for the rest of the experiments, and did not perform further domain-related experiments.

5.5 Results on CoNLL testa

Finally, Table 6 reports the results on the full development dataset. The results show that the good results in the sports subsection carry over to the full dataset. The table reports results for the baseline systems (two top rows) and the addition of the background models, including the Full model, which yields the best results.

In addition, the two rows in the bottom report the results of the ensemble methods (cf. Section 3.1) which learn the weights on the same development dataset. These results are reported for completeness, as they are an over-estimation, and are over-fit. Note that all hyper-parameters have been tuned on this development dataset, including the ensemble weights, smoothing parameters λ and θ (cf. Section 3), as well as the number of similar entities and the number of fillers in the selectional preferences. The next section will show that the good results are confirmed in unseen test datasets.

6 Overall Results

In the previous sections we have seen that the background information is effective improving the results on development. In this section we report the result of our model in the popular CoNLL testb and TAC2014 DEL datasets, which allow to compare to the state-of-the-art in NED.

[11] The two first rows do not use background information, and are thus the same.

System	testa
$P(e)P(s\|e)$	73.76
$P(e)P(s\|e)P(c\|e)$	78.98
$P(e)P(s\|e)P(c\|e)P(c_{\text{sp}}\|e,s)$	79.32
$P(e)P(s\|e)P(c\|e)P(c_{\text{sim}}\|e,s)$	81.76
Full	81.90
$P(e)^{\alpha}P(s\|e)^{\beta}P(c\|e)^{\gamma}$	85.20
Full weighted	**86.62**

Table 6: Results on the full testa dataset (cf. Section 5.5).

System	CoNLL	TAC14
$P(e)P(s\|e)$	73.07	78.31
$P(e)P(s\|e)P(c\|e)$	79.98	82.11
$P(e)P(s\|e)P(c\|e)P(c_{\text{sp}}\|e,s)$	81.31	82.61
$P(e)P(s\|e)P(c\|e)P(c_{\text{sim}}\|e,s)$	82.72	83.24
Full	82.85	83.21
$P(e)^{\alpha}P(s\|e)^{\beta}P(c\|e)^{\gamma}$	86.44	81.61
Full weighted	**88.32**	**83.46**

Table 7: Overall micro accuracy results on the CoNLL testb and TAC 2014 DEL datasets.

Table 7 reports our results, confirming that both background information resources improve the results over the standard NED generative system, separately, and in combination, for both datasets (Full row). All differences with respect to the standard generative system are statistically significant according to the Wilcoxon test (p-value < 0.05).

In addition, we checked the contribution of learning the ensemble weights on the development dataset (testa). Both the generative system with and without background information improve considerably.

The error reduction between the weighted model using background information (Full weighted row) and the generative system without background information (previous row) exceeds 10% in both datasets, providing very strong results, and confirming that the improvement due to background information is consistent across both datasets, even when applied on a very strong system. The difference is statistically significant in both datasets.

System	CoNLL	TAC14
Full weighted	88.32	83.46
(Barrena et al., 2015)	83.61	80.69
(Lazic et al., 2015)	86.40	—
(Alhelbawy & Gaizauskas,14)	*87.60	—
(Chisholm and Hachey, 2015)	88.70	—
(Pershina et al., 2015)	*91.77	—
TAC14 best (Ji et al., 2014)	—	82.70

7 Related Work

Our generative model is based on (Han and Sun, 2011b), which is basically the core method used in later work (Barrena et al., 2015; Lazic et al., 2015) with good results. Although the first do not report results on our datasets the other two do. (Barrena et al., 2015) combines the generative model with a graph-based system yielding strong results in both datasets. (Lazic et al., 2015) adds a parameter estimation method which improved the results using unannotated data. Our work is complementary to those, as we could also introduce additional disambiguation probabilities (Barrena et al., 2015), or apply more sophisticated parameter estimation methods (Lazic et al., 2015).

Table 8 includes other high performing or well-known systems, which usually use complex methods to combine features coming from different sources, where our results are only second to those of (Chisholm and Hachey, 2015) in the CoNLL dataset and best in TAC 2014 DEL. The goal of this paper is not to provide the best performing system, but yet, the results show that our use of background information allows to obtain very good results.

Alhelbawy and Gaizauskas (2014) combines local and coherence features by means of a graph ranking scheme, obtaining very good results on the CONLL 2003 dataset. They evaluate on the full dataset, i.e. they test on train, testa and testb (20K, 4.8K and 4.4K mentions respectively). Our results on the same dataset are 84.25 (Full) and 88.07 (Full weighted), but note that we do tune the parameters on testa, so this might be slighly over-estimated. Our system does not use global coherence, and therefore their method is complementary to our NED system. In principle, our proposal for enriching context should improve the results of their system.

Pershina et al. (2015) propose a system closely resembling (Alhelbawy and Gaizauskas, 2014). They report the best known results on CONNL 2003 so far, but unfortunately, their results are not directly comparable to the rest of the state-of-the-art, as they artificially insert the gold standard entity in the candidate list.[12]

In (Chisholm and Hachey, 2015) the authors explore the use of links gathered from the web as an additional source of information for NED. They present a complex two-staged supervised system that incorporates global coherence features, with large amount of noisy training. Again, using additional training data seems an interesting future direction complementary to ours.

We are not aware of other works which try to use additional sources of context or background information as we do. (Cheng and Roth, 2013) use relational information from Wikipedia to add constraints to the coherence model, and is somehow reminiscent of our use dependency templates, although they focus on recognizing a fixed set of relations between entities (as in information extraction) and do not model selectional preferences. (Barrena et al., 2014) explored the use of syntactic collocations to ensure coherence, but did not model any selectional preferences.

Previous work on word sense disambiguation using selectional preference includes (McCarthy and Carroll, 2003) among others, but they report low results. (Brown et al., 2011) applied wordNet hypernyms for disambiguating verbs, but they did not test the improvement of this feature. (Taghipour and Ng, 2015) use embeddings as features which are fed into a supervised classifier, but our method is different, as we use embeddings to find similar words to be fed as additional context. None of the state-of-the-art systems, e.g. (Zhong and Ng, 2010), uses any model of selectional preferences.

8 Discussion
