We performed an analysis of the cases where our background models worsened the disambiguation performance. Both distributional similarity and selectional preferences rely on correct mention detection in the background corpus. We detected

[12] https://github.com/masha-p/PPRforNED/readme.txt

that mentions where missed, which caused some coverage issues. In addition, the small size of the background corpus sometimes produces arbitrary contexts. For instance, subject position fillers of "score" include mostly basketball players like Michael Jordan or Karl Malone. A similar issue was detected in the distributional similarity resource. A larger corpus would produce a broader range of entities, and thus use of larger background corpora (e.g. Gigaword) should alleviate those issues.

Another issue was that some dependencies do not provide any focused context, as for instance arguments of *say* or *tell*. We think that a more sophisticated combination model should be able to detect which selectional preferences and similarity lists provide a focused set of instances.

9 Conclusions and Future Work

In this article we introduced two novel kinds of background information induced from corpora to the usual context of occurrence in NED: (1) given a mention we used distributionally similar entities as additional context; (2) given a mention and the syntactic dependencies in the context sentence, we used the selectional preferences of those syntactic dependencies as additional context. We showed that similar entities are specially useful when no textual context is present, and that selectional preferences are useful when limited context is present.

We integrated them in a Bayesian generative NED model which provides very strong results. In fact, when integrating all knowledge resources we yield the state-of-the-art in the TAC KBP DEL 2014 dataset and get the third best results in the CoNLL 2003 dataset. Both resources are freely available for reproducibility.[13]

The analysis of the acquired information and the error analysis show several avenues for future work. First larger corpora should allow to increase the applicability of the similarity resource, and specially, that of the dependency templates, and also provide better quality resources.

Abstract

Finding paraphrases in text is an important task with implications for generation, summarization and question answering, among other applications. Of particular interest to those applications is the specific formulation of the task where the paraphrases are templated, which provides an easy way to lexicalize one message in multiple ways by simply plugging in the relevant entities. Previous work has focused on mining paraphrases from parallel and comparable corpora, or mining very short sub-sentence synonyms and paraphrases. In this paper we present an approach which combines distributional and KB-driven methods to allow robust mining of sentence-level paraphrasal templates, utilizing a rich type system for the slots, from a plain text corpus.

1 Introduction

One of the main difficulties in Natural Language Generation (NLG) is the *surface realization* of messages: transforming a message from its internal representation to a natural language phrase, sentence or larger structure expressing it. Often the simplest way to realize messages is though the use of templates. For example, any message about the birth year and place of any person can be expressed with the template "[Person] was born in [Place] in [Year]".

Templates have the advantage that the generation system does not have to deal with the internal syntax and coherence of each template, and can instead focus on document-level discourse coherence and on local coreference issues. On the other hand, templates have two major disadvantages. First, having a human manually compose a template for each possible message is costly, especially when a generation system is relatively open-ended or is expected to deal with many domains. In addition, a text generated using templates often lacks variation, which means the system's output will be repetitive, unlike natural text produced by a human.

In this paper, we are concerned with a task aimed at solving both problems: automatically mining paraphrasal templates, i.e. groups of templates which share the same slot types and which, if their slots are filled with the same entities, result in paraphrases. We introduce an unsupervised approach to paraphrasal template mining from the text of Wikipedia articles.

Most previous work on paraphrase detection focuses either on a corpus of aligned paraphrase candidates or on such candidates extracted from a parallel or comparable corpus. In contrast, we are concerned with a very large dataset of templates extracted from a single corpus, where any two templates are potential paraphrases. Specifically, paraphrasal templates can be extracted from sentences which are not in fact paraphrases; for example, the sentences "The population of Missouri includes more than 1 million African Americans" and "Roughly 185,000 Japanese Americans reside in Hawaii" can produce the templated paraphrases "The population of [american state] includes more than [number] [ethnic group]" and "Roughly [number] [ethnic group] reside in [american state]". Looking for paraphrases among templates, instead of among sentences, allows us to avoid using an aligned corpus.

Our approach consists of three stages. First, we process the entire corpus and determine slot locations, transforming the sentences to templates (Section 4). Next, we find most approriate *type* for each slot using a large taxonomy, and group together templates which share the same set of types

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1913–1923,
Berlin, Germany, August 7-12, 2016.

as potential paraphrases (Section 5). Finally, we cluster the templates in each group into sets of paraphrasal templates (Section 6).

We apply our approach to six corpora representing diverse subject domains, and show through a crowd-sourced evaluation that we can achieve a high precision of over 80% with a reasonable similarity threshold setting. We also show that our threshold parameter directly controls the trade-off between the number of paraphrases found and the precision, which makes it easy to adjust our approach to the needs of various applications.

2 Related Work

To our knowledge, although several works exist which utilize paraphrasal templates in some way, the task of extracting them has not been defined as such in the literature. The reason seems to be a difference in priorities. In the context of NLG, Angeli et al. (2010) as well as Kondadadi et al. (2013) used paraphrasal templates extracted from aligned corpora of text and data representations in specific domains, which were grouped by the data types they relate to. Duma and Klein (2013) extract templates from Wikipedia pages aligned with RDF information from DBPedia, and although they do not explicitly mention aligning multiple templates to the same set of RDF templates, the possibility seems to exist in their framework. In contrast, we are interested in extracting paraphrasal templates from non-aligned text for general NLG, as aligned corpora are difficult to obtain for most domains.

While template extraction has been a relatively small part of NLG research, it is very prominent in the field of Information Extraction (IE), beginning with Hearst (1992). There, however, the goal is to extract good data and not to extract templates that are good for generation. Many pattern extraction (as it is more commonly referred to in IE) approaches focus on semantic patterns that are not coherent lexically or syntactically, and the idea of paraphrasal templates is not important (Chambers and Jurafsky, 2011). One exception which expicitly contains a paraphrase detection component is (Sekine, 2006).

Meanwhile, independently of templates, detecting paraphrases is an important, difficult and well-researched problem of Natural Language Processing. It has implications for the general study of semantics as well as many specific applications such as Question Answering and Summarization. Research that focuses on mining paraphrases from large text corpora is especially relevant for our work. Typically, these approaches utilize a parallel (Barzilay and McKeown, 2001; Ibrahim et al., 2003; Pang et al., 2003; Quirk et al., 2004; Fujita et al., 2012; Regneri and Wang, 2012) or comparable corpus (Shinyama et al., 2002; Barzilay and Lee, 2003; Sekine, 2005; Shen et al., 2006; Zhao et al., 2009; Wang and Callison-Burch, 2011), and there have been approaches that leverage bilingual aligned corpora as well (Bannard and Callison-Burch, 2005; Madnani et al., 2008).

Of the above, two are particularly relevant. Barzilay and Lee (2003) produce *slotted lattices* that are in some ways similar to templates, and their work can be seen as the most closely related to ours. However, as they rely on a comparable corpus and produce untyped slots, it is not directly comparable. In our approach, it is precisely the fact that we use a rich type system that allows us to extract paraphrasal templates from sentences that are not, by themselves, paraphrases and avoid using a comparable corpus. Sekine (2005) produces typed phrase templates, but the approach does not allow learning non-trivial paraphrases (that is, paraphrases that do not share the exact same keywords) from sentences that do not share the same entities (thus remaining dependent on a comparable corpus), and the type system is not very rich. In addition, that approach is limited to learning short paraphrases of relations between two entities.

Another line of research is based on contextual similarity (Lin and Pantel, 2001; Paşca and Dienes, 2005; Bhagat and Ravichandran, 2008). Here, shorter (phrase-level) paraphrases are extracted from a single corpus when they appear in a similar lexical (and in later approaches, also syntactic) context. The main drawbacks of these methods are their inability to handle longer paraphrases and their tendency to find phrase pairs that are semantically related but not real paraphrases (e.g. antonyms or taxonomic siblings).

More recent work on paraphrase detection has, for the most part, focused on classifying provided sentence pairs as paraphrases or not, using the Microsoft Paraphrase Corpus (Dolan et al., 2004). Mihalcea et al. (2006) evaluated a wide range of lexical and semantic measures of similarity and introduced a combined metric that outperformed all previous measures. Madnani et al. (2012) showed that metrics from Machine Translation can be used

to find paraphrases with high accuracy. Another line of research uses the similarity of texts in a latent space created through matrix factorization (Guo and Diab, 2012; Ji and Eisenstein, 2013). Other approaches that have been explored are explicit alignment models (Das and Smith, 2009), distributional memory tensors (Baroni and Lenci, 2010) and syntax-aware representations of multi-word phrases using word embeddings (Socher et al., 2011). Word embeddings were also used by Milajevs et al. (2014). These approaches are not comparable to ours because they focus on classification, as opposed to mining, of paraphrases.

Detecting paraphrases is closely related to research on the mathematical representation of sentences and other short texts, which draws on a vast literature on semantics, including but not limited to lexical, distributional and knowledge-based semantics. Of particular interest to us is the work of Blacoe and Lapata (2012), which show that simple combination methods (e.g., vector multiplication) in classic vector space representations outperform more sophisticated alternatives which take into account syntax and which use deep representations (e.g. word embeddings, or the distributional memory approach). This finding is appealing since classic vector space representation (distributional vectors) are easy to obtain and are interpretable, making it possible to drill into errors.

3 Taxonomy

Our method relies on a type system which links entities to one another in a taxonomy. We use a combination of WordNet (Fellbaum, 1998) and DBPedia (Auer et al., 2007), which provides both a rich top-level type system with lexicalizations of multiple senses and a large database of entities linked through the type system (the top-level DBPedia categories all have cognates in WordNet, which make the two easy to combine). Leveraging the fact that DBPedia entities have corresponding Wikipedia pages, we also use the *redirect* terms for those pages as alternative lexicalizations of the entity (e.g., the Wikipedia article "United States" has "USA" as a redirect term, among others).

4 Creating Templates

The first step to creating the templates is to find entities, which are candidates to becoming slots in the templates. Since we are trying to find sentence-level paraphrasal templates, each sentence in the corpus is a potential template.

Entities are found in multiple ways. First, we use regular expressions to find dates, percentages, currencies, counters (e.g., "9th") and general numbers. Those special cases are immediately given their known type (e.g., "date" or "percentage"). Next, after POS-tagging the entire corpus, we look for candidate entities of the following kinds: terms that contain only NNP (including NNPS) tags; terms that begin and end with an NNP and contain only NNP, TO, IN and DT tags; and terms that contain only capitalized words, regardless of the POS tags. Of these candidates, we only keep ones that appear in the taxonomy. Unlike the special cases above, the type of the slots created from these general entities is not yet known and will be decided in the next step.

At the end of this step, we have a set of partially-typed templates: one made from each sentence in the corpus, with its slots (but not their types in most cases) defined by the location of entities. We remove from this set all templates which have less than two slots as these are not likely to be interesting, and all templates which have more than five slots to avoid excessively complicated templates.

We originally experimented with simply accepting any term that appears in the taxonomy as an entity. That method, however, resulted in a large number of both errors and entities that were too general to be useful (e.g, "table", "world" and similar terms are in the taxonomy). Note that NER approaches, even relatively fine-grained ones, would not give us the same richness of types that directly comparing to the taxonomy allows (and the next step requires that each entity we handle exist in the taxonomy, anyway).

5 Template Typing and Grouping

Determining the type of a slot in the template presents two difficulties. First, there is a sense disambiuation problem, as many lexical terms have more than one sense (that is, they can correspond to more than one entry in the taxonomy). Second, even if the sense is known, it is not clear which level of the taxonomy the type should be chosen from. For example, consider the sentence "[JFK] is [New York]'s largest airport" (the terms in square brackets will become slots once their types are determined). "JFK" is ambiguous: it can be an airport, a president, a school, etc. The first

step in this process is, then, to determine which of the possible senses of the term best fits the sentence. But once we determine that the sense of "JFK" here is of an airport, there are different types we can choose. JFK is a New York Airport, which is a type of Airport, which is a type of Air Field, which is a type of Facility and so on. The specificity of the type we choose will determine the correctness of the template, and also which other templates we can consider as potential paraphrases.

Our solution is a two-stage distributional approach: *choosing the sense*, and then *choosing the type level* that best fit the context of the slot. In each stage, we construct a $pseudo-sentence$ (a collection of words in arbitrary, non-grammatical order) from words used in the taxonomy to describe each option (a sense in the first stage, and a type level in the second stage), and then use their vector representations to find the option that best matches the context.

Following the observation of Blacoe and Lapata (2012) that simple similarity metrics in traditional vector representations match and even outperform more sophisticated representations in finding relations among short texts as long as multiplication is used in forming vector representations for the texts, we use traditional context vectors as the basis of our comparisons in both stages. We collect context vectors from the entire English Wikipedia corpus, with a token window of 5. To avoid noise from rarely occuring words and reduce the size of the vectors, we remove any feature with a count below a threshold of $log_{10}(\Sigma)$ where Σ is the sum of all feature counts in the vector. Finally, the vector features are weighted with (normalized) TF*IDF.[1]

For a multi-word collection (e.g. a pseudo-sentence) ψ, we define the features of the combined vector V_ψ using the vectors of member words V_w as:

$$V_{j\psi} = (\prod_{w \in \psi} V_{jw})^{\frac{1}{|S|}} \quad (1)$$

Where V_{jw} is the value of the jth feature of V_w.

To choose the sense of the slot (the first stage), we start with S, the set of all possible senses (in the taxonomy) for the entity in the slot. We create a pseudo-sentence ψ_s from the primary lexicalizations of all types in the hierarchy above each sense s - e.g., for the airport sense of JFK we create a single pseudo-sentence $\psi_{JFK-airport-sense}$ consisting of the terms "New York airport", "airport", "air field", "facility" and so on.[2] We create a vector representation V_{ψ_s} for each ψ_s using Equation 1. Then, we create a pseudo-sentence $\psi_{context}$ for the context of the slot, composed of the words in a 5-word window to the left and right of the slot in the original sentence, and create the vector $V_{\psi_{context}}$. We choose the sense $\hat{s}$ with the highest cosine similarity to the contex:

$$\hat{s} = \arg\max_{s \in S} \cos(V_{\psi_s}, V_{\psi_{context}})$$

Note that this is a deep similarity - the similarity of the (corpus) context of the sense and the (corpus) context of the slot context; the words in the sentence themselves are not used directly.

We use the lexicalizations of all types in the hierarchy to achieve a more robust vector representation that has higher values for features that co-occur with many levels in the sense's hierarchy. For example, we can imagine that "airplane" will co-occur with many of the types for the JFK airport sense, but "La Guardia" will not (helping to lower the score of the first, too-specific sense of "New York airport") and neither will features that co-occur with other senses of a particular type - e.g., "Apple" for the "airport" type.[3]

Once the sense is chosen, we choose the proper type level to use (the second stage). Here we create a pseudo-sentence for each type level separately, composed of all possible lexicalizations for the type. For example, the "air field" type contains the lexicalizations "air field", "landing field", and "flying field". These pseudo-sentences are then compared to the context in the same way as above, and the one with highest similarity is chosen. The reason for using all lexicalizations is similar to the one for using all types when determining the sense: to create a more robust representation that down-scores arbitrary co-occurences.

At the end of this step, the templates are fully typed. Before continuing to the next step of finding paraphrases, we group all *potential* paraphrases together. Potential paraphrases are simply

[1] A "term" being a single feature count, and a "document" being a vector

[2] But we exclude a fixed, small set of the most abstract types from the first few levels of the WordNet hierarchy, as these turn out to never be useful

[3] AirPort is the name of an Apple product

groups of templates which share exactly the same set of slot types (regardless of ordering).

6 Finding Paraphrases within Groups

Each group of potential paraphrases may contain multiple sub-groups such that each of the members of the subgroup is a paraphrase of all the others. In this last stage, we use a clustering algorithm to find these sub-groups.

We define the distance between any two templates in a group as the Euclidean distance between the vectors (created using Equation 1) of the two templates with the entity slots removed (that is, the pseudo-sentences created with all words in the template outside of the slots). We tried other distance metrics as well (for example, averaging the distances between the contexts surrounding each pair of corresponding slots in both templates) but the Euclidean distance seemed to work best.

Using this metric, we apply single-linkage agglomerative clustering, with the stopping criteria defined as a threshold τ for the maximum sum of squared errors (SSE) within any cluster. Specifically, the algorithm stops linking if the cluster C that would be created by the next link satisfies:

$$log(\sum_{v}^{C} d(v, \mu_C)^2) \geq \tau$$

Where μ_C is the centroid of C and d is the Euclidean distance. The logarithm is added for convenience, since the SSE can get quite large and we want to keep τ on a smaller scale.

The intuition behind this algorithm is that some paraphrases will be very similar (lexically or on a deeper level) and easy to find, while some will be more difficult to distinguish from template pairs that are related but not paraphrasal. The single-linkage approach is essentially transductive, allowing the most obvious clusters to emerge first and avoiding the creation of a central model that will become less precise over time. The threshold is a direct mechanism for controlling the trade-off between precision and recall.

At the end of this step, any pair of templates within the same cluster is considered a paraphrase. Clusters that contain only a single template are discarded (in groups that have high distances among their member templates, often the entire group is discarded since even a single link violates the threshold).

7 Evaluation

To evaluate our method, we applied it to the six domains described in Table 1. We tried to choose a set of domains that are diverse in topic, size and degree of repeated structure across documents. For each domain, we collected a corpus composed of relevant Wikipedia articles (as described in the table) and used the method described in Sections 4-6 to extract paraphrasal templates. We used Wikipedia for convenience, since it allows us to easily select domain corpora, but there is nothing in our approach that is specific to Wikipedia; it can be applied to any text corpus.

We sampled 400 pairs of paraphrases extracted from each domain and used this set of 2400 pairs to conduct a crowd-sourced human evaluation on CrowdFlower. For each template pair, we randomly selected one and used its original entities in both templates to create two sentences about the same set of entities. The annotators were presented with this pair and asked to score the extent to which they are paraphrases on a scale from 1 to 5. Table 2 shows the labels and a brief version of the explanations provided for each. To ensure the quality of annotations, we used a set of hidden test questions throughout the evaluation and rejected the contributions of annotators which did not get at least 70% of the test questions correctly. Of those that did perform well on the test questions, we had three annotators score each pair and used the average as the final score for the pair. In 39.4% of the cases, all three annotators agreed; two annotators agreed in another 47% of the cases, and in the remaining 13.6% there was complete disagreement. The inter-annotator agreement for the two annotators that had the highest overlap (27 annotated pairs), using Cohen's Kappa, was $\kappa = 0.35$.

The overall results are shown in Figure 1. Note that because of our clustering approach, we have a choice of similarity threshold. The results are shown across a range of thresholds from 8 to 11 - it is clear from the figure that the threshold provides a way to control the trade-off between the number of paraphrases generated and their precision. Table 3 shows the results with our preferred threshold of 9.5.

The number of paraphrase clusters found changes with the threshold. For the 9.5 threshold we find 512 clusters over all domains, a little over 60% of the number of paraphrases. The distribution of their sizes is Zipfian: a few very large clus-

Domain	Description	Size	Source article link
NBA	NBA teams	30	National_Basketball_Association
States	US states	50	N/A
AuMa	Automobile manufacturers	241	List_of_automobile_manufacturers
Metal	Heavy Metal bands (original movement, 1967-1981)	291	List_of_heavy_metal_bands
CWB	Battles of the American Civil War	446	List_of_American_Civil_War_battles
Marvel	Superheroes from the Marvel Comics universe	932	Category:Marvel_Comics_superheroes

Table 1: Evaluation domains. Source article links are preceded by https://en.wikipedia.org/wiki/

Score	Label	Explanation
5	Perfect Paraphrase	The two sentences are equivalent in meaning (but allow differences in e.g. tense, wordiness or sentiment)
4	Almost Paraphrase	The two sentences are equivalent in meaning with one minor difference (e.g., change or remove one word)
3	Somewhat Paraphrase	The two sentences are equivalent in meaning with a few minor differences, or are complex sentences with a part that is a paraphrase and a part that is not
2	Related	The sentences are related in meaning, but are not paraphrases
1	Unrelated	The meanings of the sentences are unrelated

Table 2: Annotation score labels and explanations

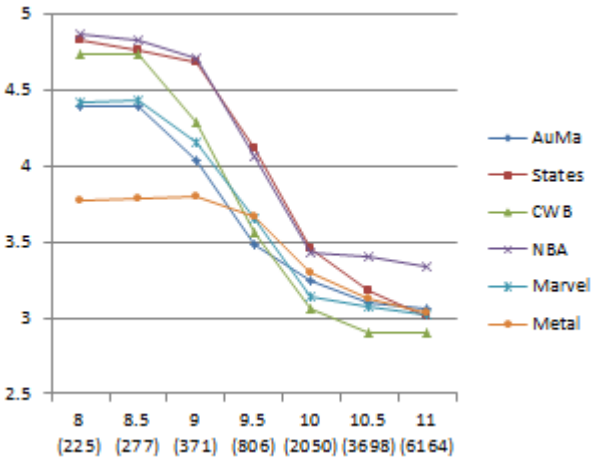

Figure 1: The average scores for each domain, for a range of threshold choices. The number in parentheses for each threshold is the number of paraphrases generated

Domain	# paraphrases	Avg.	%3+	%4+

CWB	81	3.6	75%	56%
Marvel	428	3.7	83%	63%

Table 3: Size, average score, % of pairs with a score above 3 (paraphrases), and % of pairs with a score above 4 (high quality paraphrases) for the different domains with a 9.5 threshold

ters, dozens of increasingly smaller medium-sized ones and a long tail of clusters that contain only two templates.

The vast majority of paraphrase pairs come from sentences that were not originally paraphrases (i.e, sentences that originally had different entities). With a 9.5 threshold, 86% of paraphrases answer that criteria. While that number varies somewhat across thresholds, it is always above 80% and does not consistently increase or decrease as the threshold increases.

* These papers do not report the number of sentences in the corpus, but do report enough for us to estimate it (e.g. the number of documents or the size in MB)

** These papers do not report the number of paraphrases extracted, or such a number does not exist in their approach

Table 4: Comparison with the precision and paraphrases generated per input sentence (PPS) of relevant prior work

While we wanted to show a meaningful comparison with another method from previous work, none of them do what we are doing here - extraction of sentence-size paraphrasal templates from a non-aligned corpus - and so a comparison using the same data would not be fair (and in most cases, not possible). While it seems that providing the results of human evaluation without comparison to prior methods is the norm in most relevant prior work (Ibrahim et al., 2003; Paşca and Dienes, 2005; Bannard and Callison-Burch, 2005; Fujita et al., 2012), we wanted to at least get some sense of where we stand in comparison to other methods, and so we provide a list of (not directly comparable) results reported by other authors in Table 4.[4] While it is impossible to meaningfully compare and rate such different methods, these numbers support the conclusion that our single-corpus, domain-agnostic approach achieves a precision that is similar to or better than other methods. We also include the *paraphrase per sentence (PPS)* value - the ratio of paraphrases extracted to the number of input sentences of the corpus - for each method in the table. We intend this figure as the closest thing to recall that we can conceive for mining paraphrases. However, keep in mind that it is not a comparable figure across the methods, since different corpora are used. In particular, it is expected to be significantly higher for parallel corpora, where the entire corpus consists of potential paraphrases (and that fact is reflected in Table 4, where some methods that use parallel corpora have a PPS that is an order of magnitude higher than other methods).

8 Discussion and Examples

The first thing to note about the results shown in Figure 1 is that even for the highest threshold considered, which gives us a $\times 21$ improvement in size over the smallest threshold considered, all domains except CWB achieve an average score higher than 3, meaning most of the pairs extracted are paraphrases (CWB is close - a little over 2.9 on average). For the lowest threshold considered, all domains are at a precision above 88%, and for three of them it is 100%. In general, across all domains, there seems to be a significant drop in precision (and a significant boost in size) for thresholds between 9 and 10, while the precisions and sizes are fairly stable for thresholds between 8 and 9 and between 10 and 11. This result is encouraging: since the method seems to behave fairly similarly for different domains with regard to changes in the threshold, we should be able to expect similar behavior for new domains as the threshold is

[4] We always show the results of the best system described. Where needed, if results were reported in a different way than simple percentages, we use averages and other appropriate measures. Some previous work defines related sentences (as opposed to paraphrases) as positives and some does not; we do not change their numbers to fit a single definition, but we use the harsher measure for our own results

adjusted.

The magnitude of precision across domains is another matter. It is clear from the results that some domains are more difficult than others. The Metal domain seems to be the hardest: it never achieves an average score higher than 3.8. For the highest threshold, however, Metal is not different from most of the others, while CWB is significantly lower in precision. The reason seems to be the styles of the domain articles: some domains tend to have a more structured form. For example, each article in the States domain will discuss the economy, demographics, formation etc. of the state, and we are more likely to find paraphrases there (simply by virtue of there being 50×49 candidates). Articles in the Metal domain are much less structured, and there are fewer obvious paraphrase candidates. In CWB articles, there are a few repetitive themes: the outcome of the battle, the casualties, the generals involved etc., but beyond that it is fairly unstructured. This "structurality" of the domain also affects the number of paraphrases that can be found, as evident from the number of paraphrases found in the states domain in Table 3 as compared with the (much larger) Metal and CWB domains.

Table 5 shows a number of examples from each domain, along with the score given to each by the annotators. In an informal error analysis, we saw a few scenarios recurring in low-scored pairs. The Metal example at the bottom of Table 5 is a double case of bad sense disambiguation: the *album* in the second sentence ("Pyromania" in the original) happened to have a name that is also a pathological state. In addition, the *number* in the second sentence really was a date ("1980"). If we had correctly assigned the senses, these two templates would not be paraphrase candidates. The process of grouping by type is an important part of improving precision: two sentences can be misleadingly similar in the vector space, but it is less likely to have two sentences with the exact same entity types and a high vector similarity that are not close in meaning.

Another scenario is the one seen in the NBA example that was scored as 1. Here the senses were chosen correctly, but the level of the hierarchy chosen for the *person* slot was too high. If instead we had chosen *basketball coach* and *basketball player* for the two sentences respectively, they would not be considered as paraphrase candidates (and note that both meanings are implied by the templates). This sort of error does not create a problem (in our evaluation, at least) if the more accurate sense is the same in both sentences - for example, in the other NBA example (which scored 4), the *place* slot could be more accurately replaced with *sports arena* in both templates.

Cases where the types are chosen correctly do not always result in perfect paraphrases, but are typically at least related (e.g. in the examples that scored 2, and to a lesser extent those that scored 3). That scenario can be controlled using a lower threshold, with the downside that the number of paraphrases found decreases.

9 Conclusion and Future Work

We presented a method for extracting paraphrasal templates from a plain text corpus in three steps: templatizing the sentences of the corpus; finding the most appropriate type for each slot; and clustering groups of templates that share the same set of types into paraphrasal sub-groups. We conducted a crowd-sourced human evaluation and showed that our method performs similarly to or better than prior work on mining paraphrases, with three major improvements. First, we do not rely on a parallel or comparable corpus, which are not as easily obtained; second, we produce typed templates that utilize a rich, fine-grained type system, which can make them more suitable for generation; and third, by using such a type system we are able to find paraphrases from sentence pairs that are not, before templatization, really paraphrases.

Many, if not most, of the worst misidentifications seem to be the result of errors in the second stage of the approach - disambiguating the sense and specificity of the slot types. In this paper we focused on a traditional distributional approach that has the advantage of being explainable, but it would be interesting and useful to explore other options such as word embeddings, matrix factorization and semantic similarity metrics. We leave these to future work.

Another task for future work is semantic alignment. Our approach discovers paraphrasal templates without aligning them to a semantic meaning representation; while these are perfectly usable by summarization, question answering, and other text-to-text generation applications, it would be useful for concept-to-text generation and other applications to have each cluster of templates aligned

Score	Domain	Templates
5	States	Per dollar of federal tax collected in [date 1], [american state 1] citizens received approximately [money 1] in the way of federal spending.
		In [date) 1] the federal government spent [money 1] on [american state 1] for every dollar of tax revenue collected from the state.
	AuMa	Designed as a competitor to the [car 1], [car 2] and [car 3].
		It is expected to rival the [car 1], [car 2], and [car 3].
4	CWB	Federal casualties were heavy with at least [number 1] killed or mortally wounded, [number 2] wounded , and [number 3] made prisoner.
		Federal losses were [number 1] killed, [number 2] wounded, and [number 3] unaccounted for – primarily prisoners.
	NBA	For the [date 1] season, the [basketball team 1] moved into their new arena , the [place 1], with a seating capacity of [number 1].
		As a result of their success on the court, the [basketball team 1] moved into the [place 1] in [date 1], which seats over [number 1] fans.
3	Marvel	[imaginary being 1] approached [imaginary being 2], hunting for leads about the whereabouts of the X-Men.
		[imaginary being 1] and [imaginary being 2] eventually found the X-Men and became full time members.
	Metal	In [date 1], [band) 1] recorded their third studio album, "[album 1]", which was produced by Kornelije Kovač.
		[band 1] released their next full-length studio album, "[album 1]" in [date 1].
2	Auma	[company 1] and its subsidiaries created a variety of initiatives in the social sphere, initially in [country 1] and then internationally as the company expanded.
		[company 1] participated in [country 1]'s unprecedented economic growth of the 1950s and 1960s.
	Marvel	Using her powers of psychological deduction, she picked up on [first name 1]'s attraction towards her, and then [first name 2] admits she is attracted to him as well.
		While [first name 1] became shy, reserved and bookish, [first name 2] became athletically inclined, aggressive, and arrogant.
1	NBA	Though the [date 1] 76ers exceeded many on-court expectations, there was a great deal of behind-the-scenes tension between [person 1], his players, and the front office.
		After an [date 1] start, with [person 1] already hurt, these critics seemed to have been proven right.
	Metal	Within [number 1] hours of the statement, he died of bronchial pneumonia, which was brought on as a complication of [pathological state 1].
		With the album's massive success, "[pathological state 1]" was the catalyst for the [number 1] pop-metal movement.

Table 5: Examples of template pairs and their scores

to a semantic representation of the meaning expressed. Since we already discover all the entity types involved, all that is missing is the proposition (or frame, or set of propositions); this seems to be a straightforward, though not necessarily easy, task to tackle in the near future.

How to Train Dependency Parsers with Inexact Search for Joint Sentence Boundary Detection and Parsing of Entire Documents

Anders Björkelund and **Agnieszka Faleńska** and **Wolfgang Seeker** and **Jonas Kuhn**
Institut für Maschinelle Sprachverarbeitung
University of Stuttgart

Abstract

We cast sentence boundary detection and syntactic parsing as a joint problem, so an entire text document forms a training instance for transition-based dependency parsing. When trained with an early update or max-violation strategy for inexact search, we observe that only a tiny part of these very long training instances is ever exploited. We demonstrate this effect by extending the ArcStandard transition system with swap for the joint prediction task. When we use an alternative update strategy, our models are considerably better on both tasks and train in substantially less time compared to models trained with early update/max-violation. A comparison between a standard pipeline and our joint model furthermore empirically shows the usefulness of syntactic information on the task of sentence boundary detection.

1 Introduction

Although punctuation mostly provides reliable cues for segmenting longer texts into sentence units, human readers are able to exploit their understanding of the syntactic and semantic structure to (re-)segment input in the absence of such cues.

When working with carefully copy-edited text documents, sentence boundary detection can be viewed as a minor preprocessing task in Natural Language Processing, solvable with very high accuracy. However, when dealing with the output of automatic speech recognition or "noisier" texts such as blogs and emails, non-trivial sentence segmentation issues do occur. Dridan and Oepen (2013), for example, show how much impact fully automatic preprocessing can have on parsing quality for well-edited and less-edited text.

Two possible strategies to approach this problem are (i) to exploit other cues for sentence boundaries, such as prosodic phrasing and intonation in speech (e.g., Kolář et al. (2006)) or formatting cues in text documents (Read et al., 2012), and (ii) to emulate the human ability to exploit syntactic competence for segmentation. We focus here on the latter, which has received little attention, and propose to cast sentence boundary detection and syntactic (dependency) parsing as a joint problem, such that segmentations that would give rise to suboptimal syntactic structures can be discarded early on.

A joint model for parsing and sentence boundary detection by definition operates on documents rather than single sentences, as is the standard case for parsing. The task is illustrated in Figure 1, which shows the beginning of a document in the Switchboard corpus, a collection of transcribed telephone dialogues. The parser must predict the syntactic structure of the three sentences as well as the start points of each sentence.[1]

The simple fact that documents are considerably longer than sentences, often by orders of magnitude, creates some interesting challenges for a joint system. First of all, the decoder needs to handle long inputs efficiently. This problem is easily solved by using transition-based decoders, which excel in this kind of setting due to their incremental approach and their low theoretical complexity. Specifically, we use a transition-based decoder that extends the Swap transition system of Nivre (2009) in order to introduce sentence boundaries during the parsing process. The parser performs inexact search for the optimal structure by

[1] We chose this example for its brevity. For this particular example, the task of sentence boundary prediction could be solved easily with speaker information since the second sentence is from another speaker's turn. The interesting cases involve sentence segmentation within syntactically complex turns of a single speaker.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1924–1934,
Berlin, Germany, August 7-12, 2016.

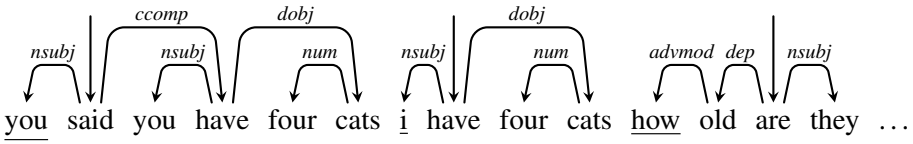

Figure 1: The beginning of a sample document from the Switchboard corpus. Tokens that start a sentence are underlined. The task is to predict syntactic structure and sentence boundaries jointly.

maintaining a beam of several candidate derivations throughout the parsing process.

We will show in this paper that, besides efficient decoding, a second, equally significant challenge lies in the way such a parser is trained. Normally, beam-search transition-based parsers are trained with structured perceptrons using either *early update* (Zhang and Clark, 2008; Collins and Roark, 2004) or *max-violation updates* (Huang et al., 2012). Yet our analysis demonstrates that neither of these update strategies is appropriate for training on very long input sequences as they discard a large portion of the training data.[2] A significant part of the training data is therefore never used to train the model. As a remedy to this problem, we instead use an adaptation of the update strategy in Björkelund and Kuhn (2014). They apply early update in a coreference resolution system and observe that the task is inherently so difficult that the correct item practically never stays in the beam. So early updates are unable to exploit the full instances during training. They propose to apply the updates iteratively on the same document until the full document has been observed. In our case, i.e. when parsing entire documents, the problem is similar in that early updates do not reach the point where the learning algorithm exploits the full training data within reasonable time. Training instead with the iterative update strategy gives us significantly better models in substantially less training time.

The second contribution in this paper is to demonstrate empirically that syntactic information can make up to a large extent for missing or unreliable cues from punctuation. The joint system implements this hypothesis and allows us to test the influence of syntactic information on the prediction of sentence boundaries as compared to a pipeline baseline where both tasks are performed independently of each other. For our analysis, we use the Wall Street Journal as the standard benchmark set and as a representative for copy-edited text. We also use the Switchboard corpus of transcribed dialogues as a representative for data where punctuation cannot give clues to a sentence boundary predictor (other types of data that may show this property to varying degrees are web content data, e.g. forum posts or chat protocols, or (especially historical) manuscripts). While the Switchboard corpus gives us a realistic scenario for a setting with unreliable punctuation, the syntactic complexity of telephone conversations is rather low compared to the Wall Street Journal. Therefore, as a controlled experiment for assessing how far syntactic competence alone can take us if we stop trusting punctuation and capitalization entirely, we perform joint sentence boundary detection/parsing on a lower-cased, no-punctuation version of the Wall Street Journal. In this setting, where the parser must rely on syntactic information alone to predict sentence boundaries, syntactic information makes a difference of 10 percentage point absolute for the sentence boundary detection task, and two points for labeled parsing accuracy.

2 Transition system

We start from the ArcStandard system extended with a swap transition to handle non-projective arcs (Nivre, 2009). We add a transition SB (for sentence boundary) that flags the front of the buffer as the beginning of a new sentence. SB blocks the SHIFT transition until the stack has been reduced and a tree has been constructed, which prevents the system from introducing arcs between separate sentences. To track the predicted sentence boundaries, we augment the configurations with a set S to hold the predicted sentence boundaries. Conceptually this leads to a representation where a document has a single artificial root

[2] We make one simplifying assumption in our experimental setup by assuming gold tokenization. Tokenization is often taken for granted, mostly because it is a fairly easy task in English. For a realistic setting, tokenization would have to be predicted as well, but since we are interested in the effect of long sequences on training, we do not complicate our setting by including tokenization.

Transition				Preconditions
LEFTARC	$(\sigma\|s_1\|s_0, \beta, A, S)$	$\Rightarrow$	$(\sigma\|s_0, \beta, A \cup \{s_0 \rightarrow s_1\}, S)$	$s_1 \neq 0$
RIGHTARC	$(\sigma\|s_1\|s_0, \beta, A, S)$	$\Rightarrow$	$(\sigma\|s_1, \beta, A \cup \{s_1 \rightarrow s_0\}, S)$	
SHIFT	$(\sigma, b_0\|\beta, A, S)$	$\Rightarrow$	$(\sigma\|b_0, \beta, A, S)$	$b_0 \neq \text{LAST}(S) \vee \|\sigma\| = 1 \vee \text{SWAPPED}(\beta)$
SWAP	$(\sigma\|s_1\|s_0, \beta, A, S)$	$\Rightarrow$	$(\sigma\|s_0, s_1\|\beta, A, S)$	$s_1 < s_0$
SB	$(\sigma, b_0\|\beta, A, S)$	$\Rightarrow$	$(\sigma, b_0\|\beta, A, S \cup \{b_0\})$	$\text{LAST}(S) < b_0 \wedge \neg\text{SWAPPED}(\beta)$

Figure 2: Transition system. $\sigma|s_1|s_0$ denotes the stack with s_0 and s_1 on top, $b_0|\beta$ denotes the buffer with b_0 in front. $\text{LAST}(S)$ denotes the most recent sentence boundary, and $\text{SWAPPED}(\beta)$ is true iff the buffer contains swapped items.

node that replaces the artificial root nodes for individual sentences.

The transition types of the system are shown in Figure 2. The configurations consist of four data structures: the stack σ, the input buffer β, the set of constructed arcs A, and the set of sentence boundaries S. LEFTARC, RIGHTARC, and SWAP have the same semantics and preconditions as in Nivre (2009). We modify the preconditions of SHIFT in order to block shifts when necessary. Whether shift is allowed can be categorized into three cases subject to the most recently predicted sentence boundary:

- If $\text{LAST}(S) < b_0$: The last predicted sentence boundary has already been shifted onto the stack. At this point, the system is building a new sentence and has not yet decided where it ends. SHIFT is therefore allowed.
- If $\text{LAST}(S) > b_0$: This situation can only occur if the system predicted a sentence boundary and subsequently made a SWAP. $\text{LAST}(S)$ then denotes the end of the current sentence and is deeper in the buffer than b_0. Thus SHIFT is allowed since b_0 belongs to the current sentence.
- If $\text{LAST}(S) = b_0$: The system must complete the current sentence by reducing the stack before it can continue shifting and SHIFT is generally not allowed, with two exceptions. (1) If the stack consists only of the root (i.e., $|\sigma| = 1$), the current sentence has been completed and the system is ready to begin parsing the next one. (2) If b_0 denotes the beginning of a new sentence, but it has been swapped back onto the buffer, then it belongs to the same sentence as the tokens currently on the stack.

The preconditions for SB are straightforward. It is only allowed if the current b_0 is ahead of the most recently predicted sentence boundary. Additionally, the transition is not allowed if b_0 has been swapped out from the stack. If it were, then b_0 would be part of the following sentence and sentences would no longer be continuous.

Extending the transition system to also handle sentence boundaries does not affect the computational complexity. While the swap transition system has worst case $O(n^2)$ complexity, Nivre (2009) shows that swaps are rare enough that the system maintains a linear time complexity on average. A naive implementation of the configurations that make the arc set A and the sentence boundary set S explicit could result in configurations that require linear time for copying during beam search. Goldberg et al. (2013) show how this problem can be circumvented in the case of a sentence-based parser. Instead of making the arc set explicit, the arcs are reconstructed after parsing by following back-pointers to previous states. Only a small set of arcs required for feature extraction are saved in the states. We note that the same trick can be applied to avoid keeping an explicit representation of S since the system only needs to know the last predicted sentence boundary.

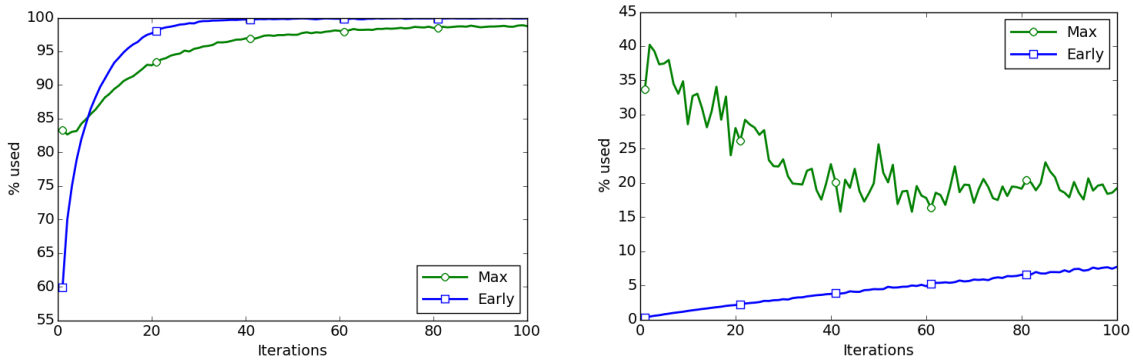
Table 1: Transition sequences including sentence boundary transitions for the example in Figure 1.

Oracle. Since each sentence constitutes its own subtree under the root node, a regular sentence-based oracle can be used to derive the oracle transition sequence for complete documents. Specifically, we apply the sentence-based oracle to each sentence, and then join the sequences with a SB transition in between. In the oracle sequences derived this way we can either apply the SB transition as *late* as possible, requiring the system to completely reduce the stack before introducing a sentence boundary. Alternatively, sentence boundaries can be introduced as *early* as possible, i.e., applying the SB transition as soon as b_0 starts a new sentence. Table 1 shows this difference in the



(a) sentences (b) documents

Figure 3: Average length of training sequences used during training for early update and max violation.

oracle transitions of each sentence from Figure 1. During preliminary experiments we compared the two alternatives and found that the early version performed better than the late.[3]

3 Learning

We focus on training structured perceptrons for search-based dependency parsing. Here, the score of a parse is defined as the scalar product of a weight vector w and a global feature vector Φ. The feature vector in turn is defined as the sum of *local* feature vectors ϕ, corresponding to the features extracted for a single transition t given a configuration c. During prediction we thus aim to obtain

$$\begin{aligned}\hat{y} &= \arg\max_{y \in \mathcal{Y}} \Phi(y) \cdot w \\ &= \arg\max_{y \in \mathcal{Y}} \sum_{(t,c) \in \textsc{TrSeq}(y)} \phi(t,c) \cdot w \end{aligned} \quad (1)$$

where TRSEQ represents the sequence of configurations and transitions executed to obtain the tree y. As the space of possible transition sequences is too large to search exhaustively, we use beam search for approximate search.

Early Update. Using approximate search while training structured perceptrons is complicated by the fact that the correct solution may actually obtain the highest score given the current model, but it was pruned off by the search procedure and therefore never considered. Collins and Roark (2004) solve this by halting search as soon as the correct solution is pruned and then making an *early update* on the partial sequences. Intuitively this makes sense, since once the correct solution is no longer reachable, it makes no sense to continue searching.

Max-violation updates. Huang et al. (2012) note that early updates require a considerable number of training iterations as it often discards a big portion of the training data. Moreover, they show that updates covering a greater subsequence can also be valid and define the *max-violation* update. Specifically, max-violation updates extend the beam beyond early updates and apply updates where the maximum difference in scores as defined by Equation (1) between the correct solution and the best prediction (i.e., the maximal violation) is used for update. They show that this leads to faster convergence compared to early update.

The curse of long sequences. Neither early nor max-violation updates commit to using the full training sequence for updates. In standard sentence-level tasks such as part-of-speech tagging or sentence-based dependency parsing these updates suffice and reasonably quickly reach a level where all or almost all of the training sequences are used for training. An entire document, however, may be composed of tens or hundreds of sentences, leading to transition sequences that are orders of magnitude longer.

To illustrate the difference between sentence-level and document-level parsing Figure 3 shows plots of the average percentage of the gold training sequences that are being used as training progresses on the Switchboard training set.

The left plot shows the parser trained on sen-

[3] One could also imagine leaving the decision of when to apply SB latent and let the machine learning decide. However, preliminary experiments again suggested that this strategy was inferior to the earliest possible point.

tences, the right one when it is trained on documents (where it also has to predict sentence boundaries). On the sentence level we see that both update strategies quite quickly reach close to 100%, i.e., they see more or less complete transition sequences during training. On the document level the picture is considerably different. The average length of seen transition sequences never even goes above 50%. In other words, more than half of the training data is never used. Early update shows a slow increase over time, presumably because the parser sees a bit more of every training instance at every iteration and therefore advances. However, max violation starts off using much more training data than early update, but then drops and settles around 20%. This illustrates the fact that max violation does not commit to exploiting more training data, but rather selects the update which constitutes the maximum violation irrespective of how much of the instance is being used. Empirically, even though the percentage of used training data decreases over iterations, max violation is still profiting from more iterations in the document-level task (cf. Figure 4 in Section 4).

Delayed LaSO. To solve the problem with the discarded training data, we follow Björkelund and Kuhn (2014) and apply the DLaSO[4] update. This idea builds on early update, but crucially differs in the sense that the remainder of a training sequence is not discarded when a mistake is made. Rather, the corresponding update is stored and the beam is reseeded with the correct solution. This enables the learning algorithm to exploit the full training data while still making sound updates (or, using the terminology of Huang et al. (2012), a number of updates that are all *violations*).

Pseudocode for DLaSO is shown in Algorithm 1. Similar to early update it performs beam search until the correct item falls off the beam (lines 9-12). Here, early update would halt, update the weights w and move on to the next instance. Instead, DLaSO computes the corresponding update, i.e., a change in the w, and stores it away. It then resets the beam to the correct solution c_i, and continues beam search. This procedure is repeated until the end of a sequence, with a final check for correctness after search has finished (line 15). After a complete pass-through of the training instance an update is made if any updates were recorded during beam search (lines 17-18).

[4] *Delayed Learning as Search Optimization*

Algorithm 1 DLaSO

Input: Training data $D = \{(x_i, y_i)\}_{i=1}^{n}$, epochs T, beam size B.
Output: Weight vector w.

```
 1: w = 0
 2: for t ∈ 1..T do
 3:     for (x, y) ∈ D do
 4:         c_{0..n} = ORACLE(y)
 5:         Beam = {c_0}
 6:         Updates = {}
 7:         for i ∈ 1 .. (n − 1) do
 8:             Beam = EXPANDANDFILTER(Beam, B)
 9:             if c_i ∉ Beam then
10:                 ŷ = BEST(Beam)
11:                 Updates = Updates ∪ CALCUPDATE(c_i, ŷ)
12:                 Beam = {c_i}
13:         Beam = EXPANDANDFILTER(Beam, B)
14:         ŷ = BEST(Beam)
15:         if c_n ≠ ŷ then
16:             Updates = Updates ∪ CALCUPDATE(c_n, ŷ)
17:         if |Updates| > 0 then
18:             w = APPLYUPDATES(w, Updates)
19: return w
```

The DLaSO update is closely related to LaSO (Daumé III and Marcu, 2005), but differs in that it delays the updates until the full instance has been decoded. Björkelund and Kuhn (2014) show that the difference is important, as it prevents the learning algorithm from getting feedback within instances. Without the delay the learner can bias the weights for rare (e.g., lexicalized) features that occur within a single instance which renders the learning setting quite different from test time inference where no such feedback is available.

4 Experimental setup

Data sets. We experiment with two parts of the English Penn Treebank (Marcus et al., 1993). We use the Wall Street Journal (WSJ) as an example of copy-edited newspaper-quality texts with proper punctuation and capitalized sentences. We also use the Switchboard portion which consists of (transcribed) telephone conversations between strangers. Following previous work on Switchboard we lowercase all text and remove punctuation and disfluency markups.

We use sections 2-21 of the WSJ for training, 24 as development set and 23 as test set. For Switchboard we follow Charniak and Johnson (2001). We convert both data sets to Stanford dependencies with the Stanford dependency converter (de Marneffe et al., 2006). We predict part-of-speech tags with the CRF tagger MarMoT (Müller et al., 2013) and annotate the training sets via 10-fold jackknifing. Depending on the experimental sce-

nario we use MARMOT in two different settings – standard sentence-level where we train and apply it on sentences, and document-level where a whole document is fed to the tagger, implicitly treating it as a single very long sentence.

Sentence boundary detection. We work with two well-established sentence boundary detection baselines. Following (Read et al., 2012) we use the tokenizer from the Stanford CoreNLP (Manning et al., 2014) and the sentence boundary detector from OpenNLP[5] which has been shown to achieve state-of-the-art results on WSJ. We evaluate the performance of sentence boundary detection on the token level using F-measure (F_1).[6]

Typical sentence boundary detectors such as CORENLP or OPENNLP focus on punctuation marks and are therefore inapplicable to data like Switchboard that does not originally include punctuation. In such cases CRF taggers are commonly selected as baselines, e.g. for punctuation prediction experiments (Zhang et al., 2013a). We therefore introduce a third baseline using MARMOT. For this, we augment the POS tags with information to indicate if a token starts a new sentence or not. We prepare the training data accordingly and train the document-level sequence labeler on them. Table 2 shows the accuracies of all baseline systems on the development sets. For WSJ all three algorithms achieve similar results which shows that MARMOT is a competitive baseline. As can be seen, predicting sentence boundaries for the Switchboard dataset is a more difficult task than for well-formatted text like the WSJ.

	WSJ	Switchboard
OPENNLP	98.09	–
CORENLP	98.60	–
MARMOT	98.21	71.78

Table 2: Results (F_1) for baselines for sentence boundary detection on dev sets.

Parser implementation. Our parser implements the labeled version of the transition system described in Section 2 with a default beam size of 20. We use the oracle by Nivre et al. (2009) to create transition sequences for each sentence of a document, and then concatenate them with SB transitions that occur as early as possible (cf. Section 2). The feature set is based on previous work (Zhang and Nivre, 2011; Bohnet and Kuhn, 2012; Bohnet et al., 2013) and was developed for a sentence-based parser for the WSJ. We made initial experiments trying to introduce new features aimed at capturing sentence boundaries such as trying to model verb subcategorization or sentence length, however none of these proved useful compared to the baseline feature set. Following the line of work by Bohnet et al., we use the passive-aggressive algorithm (Crammer et al., 2006) instead of the vanilla perceptron, parameter averaging (Collins, 2002), and a hash function to map features (Bohnet, 2010).[7]

5 Analysis

Comparison of training methods. Figure 4 shows learning curves of the different training algorithms where sentence boundary F_1 and parsing accuracy LAS are plotted as a function of training iterations. The plots show performance for early update, max-violation, and DLASO updates. In addition, a greedy version of the parser is also included. The greedy parser uses a plain averaged perceptron classifier that is trained on all the training data. The straight dashed line corresponds to the MARMOT baseline.

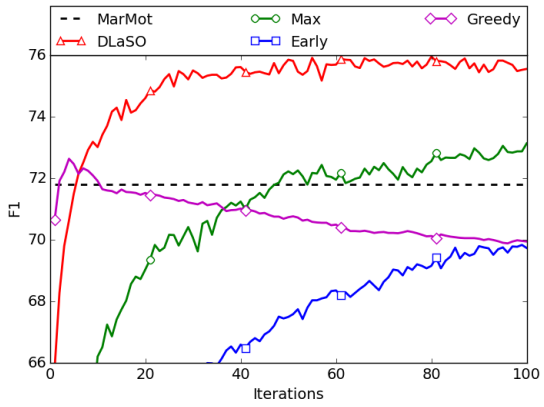
While the greedy parser, DLASO, and the MARMOT baseline all exploit the full training data during training, early update and max-violation do not (as shown in Section 3). This fact has a direct impact on the performance of these systems. DLASO reaches a plateau rather quickly, whereas even after 100 iterations, early update and max-violation perform considerably worse.[8] We also see that the greedy parser quickly reaches an optimum and then starts degrading, presumably due to overfitting. It is noteworthy, however, that max-violation needs something between 40 to 60 iterations until it reaches a level similar to the greedy parsers optimal value. This effect is quite different from single sentence parsing scenarios, where it is known that beam search parsers easily outperform the greedy counterparts, requiring not nearly as many training iterations.

[5] http://opennlp.apache.org

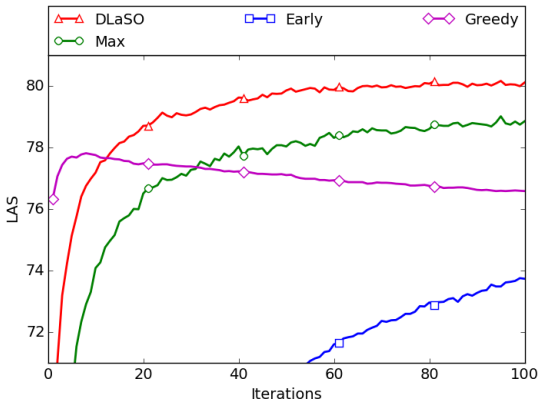
[6] A true positive is defined as a token that was correctly predicted to begin a new sentence.

[7] We make the source code of the parser available on the first author's website.

[8] The x-axis is cut at 100 iterations for simplicity. Although early update and max-violation still are growing at this point, the overall effect does not change – even after 200 iterations the DLASO update outperforms the other two by at least two points absolute.



(a) sentence boundary detection



(b) parsing

Figure 4: Performance of different update strategies on the Switchboard development set.

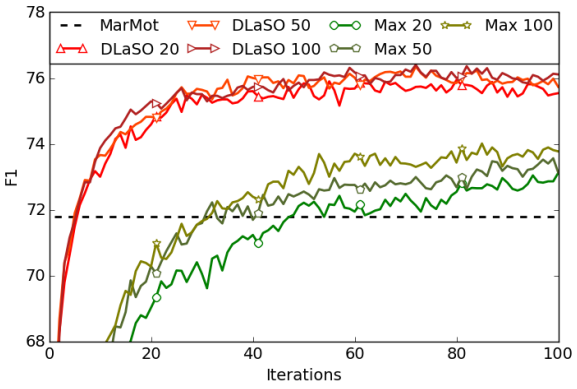


Figure 5: The effect of increasing beam size.

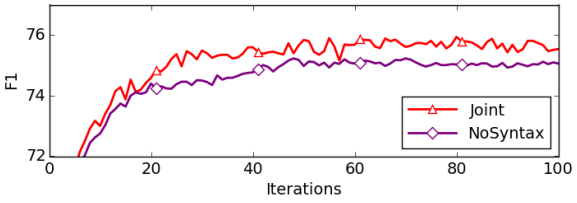
Increasing the beam size. Intuitively, using a bigger beam size might alleviate the problem of discarded training data and enable max-violation to exploit more training data. Figure 5 shows the sentence boundary F_1 as a function of training iterations for different beam sizes for DLaSO and max-violation. For DLaSO, we see that a bigger beam provides a slight improvement. Max-violation shows a greater correlation between greater beam size and improved F_1. However, even with a beam of size 100 max-violation is nowhere near DLaSO. In theory a beam size orders of magnitude greater may rival DLaSO but as the beam size directly influences the time complexity of the parser, this is not a viable option.

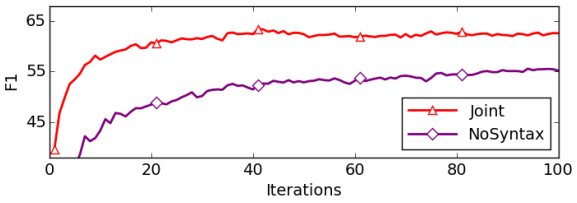
Does syntax help? One of the underlying assumptions of the joint model is our expectation that access to syntactic information should support the model in finding the sentence boundaries. We have already seen that the joint parser outperforms the MarMoT baseline by a big margin in terms of sentence boundary F_1 (Figure 4). However, the comparison is not entirely fair as the two systems use different feature sets and learning algorithms.

To properly measure the effect of syntactic information on the sentence boundary detection task, we therefore trained another model for the joint system on a treebank where we replaced the gold-standard trees with trivial trees that connect the last token of each sentence to the root node, and everything in between as a left-branching chain. We dub this setting NoSyntax and it allows us to use exactly the same machine learning for a fair comparison between a system that has access to syntax and one without.

As the syntactic complexity in Switchboard is rather low, we compare these two systems also on a version of the WSJ where we removed all punctuation and lower-cased all words, effectively making it identical to the Switchboard setting (henceforth WSJ*). Figure 6 shows sentence boundary F_1 over training iterations when training with and without access to syntax. On both data sets, the system with access to syntax stays consistently above the other system. The striking difference between the data sets is that syntactic information has a much bigger impact on WSJ* than on Switchboard, which we attribute to the higher syntactic complexity of newswire text. Overall the comparison shows clearly that syntactic structure provides useful information to the task of sentence boundary detection.



(a) Switchboard



(b) WSJ*

Figure 6: The effect of syntactic information on sentence boundary prediction, on dev sets.

6 Final results

Sentence boundary detection. We optimize the number of iterations on the dev sets: for the joint model we take the iteration with the highest average between F_1 and LAS, NOSYNTAX is tuned according to F_1. Table 3 gives the performance of the sentence boundary detectors on test sets.[9]

On WSJ all systems are close to 98 and this high number once again affirms that the task of segmenting newspaper-quality text does not leave much space for improvement. Although the parsing models outperform MARMOT, the improvements in F_1 are not significant.

In contrast, all systems fare considerably worse on WSJ* which confirms that the orthographic clues in newspaper text suffice to segment the sentences properly. Although NOSYNTAX outperforms MARMOT, the difference is not significant. However, when real syntax is used (JOINT) we see a huge improvement in F_1 – 10 points absolute – which is significantly better than both NOSYNTAX and MARMOT.

On Switchboard MARMOT is much lower and both parsing models outperform it significantly. Surprisingly the NOSYNTAX system achieves a very high result beating the baseline significantly by almost 4.5 points. The usage of syntax in the JOINT model raises this gain to 4.8 points.

[9]We test for significance using the Wilcoxon signed-rank test with $p < 0.01$. † and ‡ denote significant increases over MARMOT and NOSYNTAX, respectively. * denotes significant increases over JOINT (Table 4).

	WSJ	Switchboard	WSJ*
MARMOT	97.64	71.87	53.02
NOSYNTAX	98.21	76.31†	55.15
JOINT	98.21	76.65†	65.34†‡

Table 3: Sentence boundary detection results (F_1) on test sets.

Parsing. In order to evaluate the joint model on the parsing task separately we compare it to pipeline setups. We train a basic parser on single sentences using gold standard sentence boundaries, predicted POS tags and max-violation updates (GOLD). The number of training iterations is tuned to optimize LAS on the dev set. This parser is used as the second stage in the pipeline models. Additionally, we also build a pipeline where we use JOINT only as a sentence segmenter and then parse once again (denoted JOINT-REPARSED).

Table 4 shows the results on the test sets. For WSJ, where sentence segmentation is almost trivial, we see only minor drops in LAS between GOLD and the systems that use predicted sentence boundaries. Among the systems that use predicted boundaries, no differences are significant.

	WSJ	Switchboard	WSJ*
GOLD	90.22	84.99	88.71
MARMOT	89.81	78.93	83.37
NOSYNTAX	89.95	80.30†	83.61
JOINT	89.71	79.97†	85.66†‡
JOINT-REPARSED	89.93	80.61†‡*	85.38†‡

Table 4: Parsing results (LAS) on test sets for different sentence boundaries.

For WSJ* and Switchboard the picture is much different. Compared to GOLD, all systems show considerable drops in accuracy which asserts that errors from the sentence boundary detection task propagate to the parser and worsen the parser accuracy. On Switchboard the parsers yield significantly better results than MARMOT. The best result is obtained after reparsing and this is also significantly better than any other system. Although there is a slight drop in accuracy between NOSYNTAX and JOINT, this difference is not significant.

The results on WSJ* show that not only does syntax help to improve sentence segmentation, it does so to a degree that parsing results deteriorate when simpler sentence boundary detectors are used. Here, both JOINT and JOINT-REPARSED

obtain significantly better parsing accuracies than the systems that do not have access to syntax during sentence boundary prediction. Although JOINT-REPARSED performs a bit worse, the difference compared to JOINT is not significant.

7 Related work

Zhang and Clark (2008) first showed how to train transition-based parsers with the structured perceptron (Collins, 2002) using beam search and early update (Collins and Roark, 2004). It has since become the de facto standard way of training search-based transition-based dependency parsers (Huang and Sagae, 2010; Zhang and Nivre, 2011; Bohnet et al., 2013). Huang et al. (2012) showed how max-violation leads to faster convergence for transition-based parsers and max-violation updates have subsequently been applied to other tasks such as machine translation (Yu et al., 2013) and semantic parsing (Zhao and Huang, 2015).

Sentence Boundary Detection. Sentence boundary detection has attracted only modest attention by the research community even though it is a component in every real-world NLP application. Previous work is divided into rule-based, e.g., CoreNLP (Manning et al., 2014), and machine learning approaches (e.g., OpenNLP, a re-implementation of Reynar and Ratnaparkhi (1997)'s MxTerminator). The task is often simplified to the task of period disambiguation (Kiss and Strunk, 2006), which only works on text that uses punctuation consistently. The current state of the art uses sequence labelers, e.g., a CRF (Evang et al., 2013; Dridan and Oepen, 2013). For a broad survey of methodology and tools, we refer the reader to Read et al. (2012).

Joint models. Solving several tasks jointly has lately been popular in transition-based parsing, e.g., combining parsing with POS tagging (Hatori et al., 2011; Bohnet and Nivre, 2012) and tokenization (Zhang et al., 2013b; Zhang et al., 2014). Joint approaches avoid error propagation between the subtasks and often lead to overall better models, especially for the lower level tasks that suddenly have access to syntactic information.

Our transition system is inspired by the work of Zhang et al. (2013a). They present a projective transition-based parser that jointly predicts punctuation and syntax. Their ArcEager transition system (Nivre, 2003) includes an additional transition that introduces punctuation similar to our SB transition. They also use beam search and circumvent the problem of long training sequences by chopping up the training data into pseudo-documents of at most 10 sentences. As we have shown, this solution works because the training instances are not long enough to hurt the performance. However, while this is possible for parsing, other tasks may not be able to chop up their training data.

8 Conclusion

We have demonstrated that training a structured perceptron for inexact search on very long input sequences ignores significant portions of the training data when using early update or max-violation. We then showed how this effect can be avoided by applying a different update strategy, DLASO, which leads to considerably better models in significantly less time. This effect only occurs when the training instances are very long, e.g., on whole documents, but not when training on single sentences. We also showed that the lower performance of early update and max-violation cannot be compensated for by increasing beam size or number of iterations. We compared our system for joint sentence boundary detection and dependency parsing to competitive pipeline systems showing that syntax can provide valuable information to sentence boundary prediction when punctuation and capitalization is not available.

Abstract

Precise evaluation metrics are important for assessing progress in high-level language generation tasks such as machine translation or image captioning. Historically, these metrics have been evaluated using correlation with human judgment. However, human-derived scores are often alarmingly inconsistent and are also limited in their ability to identify precise areas of weakness. In this paper, we perform a case study for metric evaluation by measuring the effect that systematic sentence transformations (e.g. active to passive voice) have on the automatic metric scores. These sentence "corruptions" serve as unit tests for precisely measuring the strengths and weaknesses of a given metric. We find that not only are human annotations heavily inconsistent in this study, but that the Metric Unit TesT analysis is able to capture precise shortcomings of particular metrics (e.g. comparing passive and active sentences) better than a simple correlation with human judgment can.

1 Introduction

The success of high-level language generation tasks such as machine translation (MT), paraphrasing and image/video captioning depends on the existence of reliable and precise automatic evaluation metrics.

A man is holding a frog	There is no man holding a frog	2.1
The man is playing with a skull	There is no man playing with a skull	2.3
A man is driving a car	There is no man driving the car	3.6
A woman is combing her hair	There is no woman combing her hair	3.6
A man is walking outside	There is no man walking outside	4.6
A man is playing soccer	There is no man playing soccer	4.8

Figure 1: A few select entries from the SICK dataset. All of these entries follow the same "Negated Subject" transformation between sentence 1 and sentence 2, yet humans annotated them with an inconsistently wide range of scores (from 1 to 5). Regardless of whether the gold labels for this particular transformation should score this high or low, they *should* score be scored consistently.

Efforts have been made to create standard metrics (Papineni et al., 2001; Lin, 2004; Denkowski and Lavie, 2014; Vedantam et al., 2014) to help advance the state-of-the-art. However, most such popular metrics, despite their wide use, have serious deficiencies. Many rely on ngram matching and assume that annotators generate all reasonable reference sentences, which is infeasible for many tasks. Furthermore, metrics designed for one task, e.g., MT, can be a poor fit for other tasks, e.g., video captioning.

To design better metrics, we need a principled approach to evaluating their performance. Historically, MT metrics have been evaluated by how well they correlate with human annotations (Callison-Burch et al., 2010; Machacek and Bojar, 2014). However, as we demonstrate in Sec. 5, human judgment can result in inconsistent scoring. This presents a serious problem for determining whether

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1935–1943,
Berlin, Germany, August 7-12, 2016.

a metric is "good" based on correlation with inconsistent human scores. When "gold" target data is unreliable, even good metrics can appear to be inaccurate.

Furthermore, correlation of system output with human-derived scores typically provides an overall score but fails to isolate specific errors that metrics tend to miss. This makes it difficult to discover system-specific weaknesses to improve their performance. For instance, an ngram-based metric might effectively detect non-fluent, syntactic errors, but could also be fooled by legitimate paraphrases whose ngrams simply did not appear in the training set. Although there has been some recent work on paraphrasing that provided detailed error analysis of system outputs (Socher et al., 2011; Madnani et al., 2012), more often than not such investigations are seen as above-and-beyond when assessing metrics.

The goal of this paper is to propose a process for consistent and informative automated analysis of evaluation metrics. This method is demonstrably more consistent and interpretable than correlation with human annotations. In addition, we extend the SICK dataset to include un-scored fluency-focused sentence comparisons and we propose a toy metric for evaluation.

The rest of the paper is as follows: Section 2 introduces the corruption-based metric unit testing process, Section 3 lists the existing metrics we use in our experiments as well as the toy metric we propose, Section 4 describes the SICK dataset we used for our experiments, Section 5 motivates the need for corruption-based evaluation instead of correlation with human judgment, Section 6 describes the experimental procedure for analyzing the metric unit tests, Section 7 analyzes the results of our experiments, and in Section 8 we offer concluding remarks.

2 Metric Unit TesTs

We introduce metric unit tests based on *sentence corruptions* as a new method for automatically evaluating metrics developed for language generation tasks. Instead of obtaining human ranking for system output and comparing it with the metric-based ranking, the idea is to modify existing references with specific transformations, and examine the scores assigned by various metrics to such corruptions. In this paper, we analyze three broad categories of transformations – meaning-altering, meaning-preserving, and fluency-disrupting sentence corruptions – and we evaluate how successfully several common metrics can detect them.

As an example, the original sentence "A man is playing a guitar." can be corrupted as follows:

> *Meaning-Altering*: A man is not playing guitar.
> *Meaning-Preserving*: A guitar is being played by a man.
> *Fluency-Disrupting*: A man a guitar is playing.

Examples for each corruption type we consider are shown in Tables 1 and 2.

2.1 Meaning-altering corruptions

Meaning-altering corruptions modify the semantics of a sentence, resulting in a new sentence that has a different meaning. Corruptions (1–2) check whether a metric can detect small lexical changes that cause the sentence's semantics to entirely change. Corruption (3) is designed to fool distributed and distributional representations of words, whose vectors often confuse synonyms and antonyms.

2.2 Meaning-preserving corruptions

Meaning-preserving corruptions change the lexical presentation of a sentence while still preserving meaning and fluency. For such transformations, the "corruption" is actually logically equivalent to the original sentence, and we would expect that consistent annotators would assign roughly the same score to each. These transformations include changes such as rephrasing a sentence from active voice to passive voice (4) or paraphrasing within a sentence (5).

2.3 Fluency disruptions

Beyond understanding semantics, metrics must also recognize when a sentence lacks fluency and grammar. Corruptions (7–9) were created for this reason, and do so by generating ungrammatical sentences.

Meaning Altering			
1	*negated subject* (337)	"A man is playing a harp"	"There is no man playing a harp"
2	*negated action* (202)	"A jet is flying"	"A jet is not flying"
3	*antonym replacement* (246)	"a dog with short hair"	"a dog with long hair"
Meaning Preserving			
4	*active-to-passive* (238)	"A man is cutting a potato"	"A potato is being cut by a man"
5	*synonymous phrases* (240)	"A dog is eating a doll"	"A dog is biting a doll"
6	*determiner substitution* (65)	"A cat is eating food"	"The cat is eating food"

Table 1: Corruptions from the SICK dataset. The left column lists the number of instances for each corruption type.

Fluency disruptions			
7	*double PP* (500)	"A boy walks at night"	"A boy walks at night at night"
8	*remove head from PP* (500)	"A man danced in costume"	"A man danced costume"
9	*re-order chunked phrases* (500)	"A woman is slicing garlics"	"Is slicing garlics a woman"

Table 2: Generated corruptions. The first column gives the total number of generated corruptions in parentheses.

3 Metrics Overview

3.1 Existing Metrics

Many existing metrics work by identifying lexical similarities, such as n-gram matches, between the candidate and reference sentences. Commonly-used metrics include BLEU, CIDEr, and TER:

- BLEU, an early MT metric, is a precision-based metric that rewards candidates whose words can be found in the reference but penalizes short sentences and ones which overuse popular n-grams (Papineni et al., 2001).
- CIDEr, an image captioning metric, uses a consensus-based voting of tf-idf weighted ngrams to emphasize the most unique segments of a sentence in comparison (Vedantam et al., 2014).
- TER (Translation Edit Rate) counts the changes needed so the surface forms of the output and reference match (Snover et al., 2006).

Other metrics have attempted to capture similarity beyond surface-level pattern matching:

- METEOR, rather than strictly measuring ngram matches, accounts for soft similarities between sentences by computing synonym and paraphrase scores between sentence alignments (Denkowski and Lavie, 2014).
- BADGER takes into account the contexts over the entire set of reference sentences by using a simple compression distance calculation after performing a series of normalization steps (Parker, 2008).
- TERp (TER-plus) minimizes the edit distance by stem matches, synonym matches, and phrase substitutions before calculating the TER score, similar to BADGER's normalization step (Snover et al., 2009).

We evaluate the strengths and weaknesses of these existing metrics in Section 7.

3.2 Toy Metric: W2V-AVG

To demonstrate how this paper's techniques can also be applied to measure a new evaluation metric, we create a toy metric, W2V-AVG, using the cosine of the centroid of a sentence's word2vec embeddings (Mikolov et al., 2013). The goal for this true bag-of-words metric is to serve as a sanity check for how corruption unit tests can identify metrics that capture soft word-level similarities, but cannot handle directed relationships between entities.

4 Datasets

4.1 SICK

All of our experiments are run on the Sentences Involving Compositional Knowledge (SICK) dataset,

which contains entries consisting of a pair of sentences and a human-estimated semantic relatedness score to indicate the similarity of the sentence pair (Marelli et al., 2014). The reason we use this data is twofold:

1. it is a well-known and standard dataset within semantic textual similarity community.

2. it contains many common sentence transformation patterns, such as those described in Table 1.

The SICK dataset was built from the 8K ImageFlickr dataset[1] and the SemEval 2012 STS MSR-Video Description corpus[2]. Each of these original datasets contain human-generated descriptions of images/videos – a given video often has 20-50 reference sentences describing it. These reference sets prove very useful because they are more-or-less paraphrases of one another; they all describe the same thing. The creators of SICK selected sentence pairs and instructed human annotators to ensure that all sentences obeyed proper grammar. The creators of SICK ensured that two of the corruption types – meaning-altering and meaning-preserving – were generated in the annotated sentence pairs. We then filtered through SICK using simple rule-based templates[3] to identify each of the six corruption types listed in Table 1. Finally, we matched the sentences in the pair back to their original reference sets in the Flickr8 and MSR-Video Description corpora to obtain reference sentences for our evaluation metrics experiments.

4.2 SICK+

Since all of the entries in the SICK dataset were created for compositional semantics, every sentence was manually checked by annotators to ensure fluency. For our study, we also wanted to measure the effects of bad grammar between sentences, so we automatically generated our own corruptions to the SICK dataset to create SICK+, a set of fluency-disrupting corruptions. The rules to generate these corruptions were simple operations involving chunking and POS-tagging. Fortunately, these corruptions were, by design, meant to be ungrammatical, so there was no need for (difficult) automatic correctness checking for fluency.

5 Inconsistencies in Human Judgment

A major issue with comparing metrics against human judgment is that human judgments are often inconsistent. One reason for this is that high-level semantic tasks are difficult to pose to annotators. Consider SICK's semantic relatedness annotation as a case study for human judgment. Annotators were shown two sentences, were asked "To what extent are the two sentences expressing related meaning?", and were instructed to select an integer from 1 (completely unrelated) to 5 (very related). We can see the difficulty annotators faced when estimating semantic relatedness, especially because the task description was intentionally vague to avoid biasing annotator judgments with strict definitions. In the end, "the instructions described the task only through [a handful of] examples of relatedness" (Marelli et al., 2014).

As a result of this hands-off annotation guideline, the SICK dataset contains glaring inconsistencies in semantic relatedness scores, even for sentence pairs where the only difference between two sentences is due to the same known transformation. Figure 1 demonstrates the wide range of human-given scores for the pairs from SICK that were created with the *Negated Subject* transformation. Since the guidelines did not establish how to handle the effect of this transformation, some annotators rated it high for describing the same actions, while others rated it low for having completely opposite subjects.

To better appreciate the scope of these annotation discrepancies, Figure 2 displays the distribution of "gold" human scores for every instance of the "Negated Subject" transformation. We actually find that the relatedness score approximately follows a normal distribution centered at 3.6 with a standard

[1] http://nlp.cs.illinois.edu/HockenmaierGroup/data.html

[2] http://www.cs.york.ac.uk/semeval-2012/task6/index.php?id=data

[3] For instance, the "Antonym Replacement" template checked to see if the two sentences were one word apart, and if so whether they had a SICK-annotated NOT_ENTAILMENT relationsip.

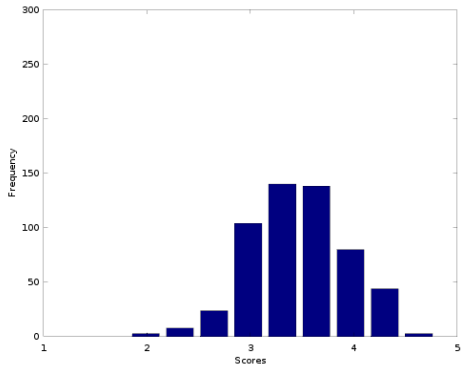

Figure 2: Human annotations for the *Negated Subject* corruption.

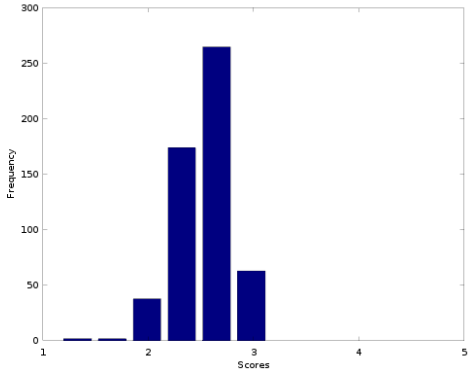

Figure 3: Metric predictions for the *Negated Subject* corruption.

deviation of about .45. The issue with this distribution is that regardless of whether the annotators rank this specific transformation as low or high, they *should* be ranking it consistently. Instead, we see that their annotations span all the way from 2.5 to 4.5 with no reasonable justification as to why.

Further, a natural question to ask is whether all sentence pairs within this common *Negated Subject* transformation do, in fact, share a structure of how similar their relatedness scores "should" be. To answer this question, we computed the similarity between the sentences in an automated manner using three substantially different evaluation metrics: METEOR, BADGER, and TERp. These three metrics were chosen because they present three very different approaches for quantifying semantic similarity, namely: sentence alignments, compression redundancies, and edit rates. We felt that these different approaches for processing the sentence pairs would allow for different views of their underlying relatedness.

To better understand how similar an automatic metric would rate these sentence pairs, Figure 3 shows the distribution over scores predicted by the METEOR metric. The first observation is that the metric produces scores that are far more peaky than the gold scores in Figure 2, which indicates that they have a significantly more consistent structure about them.

In order to see how each metric's scores compare, Table 3 lists all pairwise correlations between the gold and the three metrics. As a sanity check, we can see that the 1.0s along the diagonal indicate perfect correlation between a prediction and itself. More interestingly, we can see that the three metrics have alarmingly low correlations with the gold scores: 0.09, 0.03, and 0.07. However, we also see that the three metrics all have significantly higher correlations amongst one another: 0.80, 0.80, and 0.91. This is a very strong indication that the three metrics all have approximate agreement about how the various sentences should be scored, but this consensus is not at all reflected by the human judgments.

6 MUTT Experiments

In our Metric Unit TesTing experiments, we wanted to measure the fraction of times that a given metric is able to appropriately handle a particular corruption type. Each (original,corruption) pair is considered a trial, which the metric either gets correct or

	gold	METEOR	BADGER	TERp
gold	1.00	0.09	0.03	0.07
METEOR	0.09	1.00	0.91	0.80
BADGER	0.03	0.91	1.00	0.80
TERp	0.07	0.80	0.80	1.00

Table 3: Pairwise correlation between the predictions of three evaluation metrics and the gold standard.

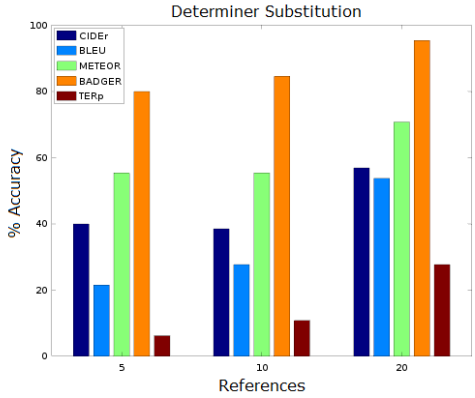

Figure 4: Results for the *Determiner Substitution* corruption (using *Difference formula* scores).

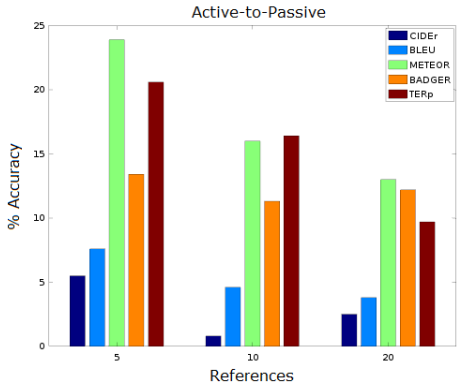

Figure 5: Results for the *Active-to-Passive* corruption (using *Difference formula* scores).

incorrect. We report the percent of successful trials for each metric in Tables 4, 5, and 6. Experiments were run using 5, 10, and 20 reference sentences to understand which metrics are able perform well without much data and also which metrics are able to effectively use more data to improve. An accuracy of 75% would indicate that the metric is able to assign appropriate scores 3 out of 4 times.[4]

For Meaning-altering and Fleuncy-disrupting corruptions, the corrupted sentence will be truly different from the original and reference sentences. A trial would be successful when the score of the original s_{orig} is rated higher than the score of the corruption s_{corr}:

$$s_{orig} > s_{corr}$$

Alternatively, Meaning-preserving transformations create a "corruption" sentence which is just as correct as the original. To reflect this, we consider a trial to be successful when the score of the corruption s_{corr} is within 15% of the score of the original s_{orig}:

$$\left| \frac{s_{orig} - s_{corr}}{s_{orig} + \epsilon} \right| \leq 0.15$$

where ϵ is a small constant (10^{-9}) to prevent division by zero. We refer to this alternative trial formulation as the *Difference formula*.

7 Discussion

7.1 Meaning-altering corruptions

As shown by the middle figure in Table 4, it is CIDEr which performs the best for Antonym Replacement. Even with only a few reference sentences, it is already able to score significantly higher than the other metrics. We believe that a large contributing factor for this is CIDEr's use of tf-idf weights to emphasize the important aspects of each sentence, thus highlighting the modified when compared against the reference sentences.

The success of these metrics reiterates the earlier point about metrics being able to perform more consistently and reliably than human judgment.

7.2 Meaning-preserving corruptions

The graph in Figure 4 of the determiner substitution corruption shows an interesting trend: as the number of references increase, all of the metrics increase in accuracy. This corruption replaces "a" in the candidate with a "the', or vice versa. As the references increase, there we tend to see more examples which use these determiners interchanagably while keeping the rest of the sentence's meaning the same. Since a large number of references results in far more for the pair to agree on, the two scores are very close.

Conversely, the decrease in accuracy in the

TERp	91.0	93.4	93.4

Table 6: **Fluency-disrupting corruptions**. These % accuracies represent the number of times that a given metric was able to correctly score the original sentence higher than the corrupted sentence. Numbers referenced in the prose analysis are highlighted in bold.

Active-to-Passive table reflects how adding more (mostly active) references makes the system more (incorrectly) confident in choosing the active original. As the graph in Figure 5 shows, METEOR performed the best, likely due to its sentence alignment approach to computing scores.

7.3 Fluency disruptions

All of the metrics perform well at identifying the duplicate prepositional phrase corruption, except for BADGER which has noticeably lower accuracy scores than the rest. These lower scores may be attributed to the compression algorithm that it uses to compute similarity. Because BADGER's algorithm works by compressing the candidate and references jointly, we can see why a repeated phrase would be of little effort to encode – it is a compression algorithm, after all. The result of easy-to-compress redundancies is that the original sentence and its corruption have very similar scores, and BADGER gets fooled.

Unlike the other two fluency-disruptions, none of

the accuracy scores of the "Remove Head from PP" corruption reach 90%, so this corruption could be seen as one that metrics could use improvement on. BLEU performed the best on this task. This is likely due to its ngram-based approach, which is able to identify that deleting a word breaks the fluency of a sentence.

All of the metrics perform well on the "Re-order Chunks" corruption. METEOR, however, does slightly worse than the other metrics. We believe this to be due to its method of generating an alignment between the words in the candidate and reference sentences. This alignment is computed while minimizing the number of chunks of contiguous and identically ordered tokens in each sentence pair (Chen et al., 2015). Both the original sentence and the corruption contain the same chunks, so it makes sense that METEOR would have more trouble distinguishing between the two than the n-gram based approaches.

7.4 W2V-AVG

The results for the W2V-AVG metric's success on each corruption are shown in Table 7. "Shuffled Chunks" is one of the most interesting corruptions for this metric, because it achieves an accuracy of 0% across the board. The reason for this is that W2V-AVG is a pure bag-of-words model, meaning that word order is entirely ignored, and as a result the model cannot distinguish between the original sentence and its corruption, and so it can never rank the original greater than the corruption.

Surprisingly, we find that W2V-AVG is far less fooled by active-to-passive than most other metrics. Again, we believe that this can be attributed to its bag-of-words approach, which ignores the word order imposed by active and passive voices. Because each version of the sentence will contain nearly all of the same tokens (with the exception of a few "is" and "being" tokens), the two sentence representations are very similar. In a sense, W2V-AVG does well on passive sentences for the wrong reasons - rather than understanding that the semantics are unchanged, it simply observes that most of the words are the same. However, we still see the trend that performance goes down as the number of reference sentences increases.

average word2vec metric			
num references	5	10	20

8. Remove Head From PP	78.4	82.5	82.5
9. Shuffle Chunks	**00.0**	**00.0**	**00.0**
1. Negated Action*	**100.0**	**100.0**	**100.0**
3. Negated Subject*	**82.8**	**87.3**	**87.1**

Table 7: **Performance of the AVG-W2V metric**. These % accuracies represent the number of successful trials. Numbers referenced in the prose analysis are highlighted in bold. * indicates the scores computed with the *Difference formula*.

Interestingly, we can see that although W2V-AVG achieved 98% accuracy on "Negated Subject", it scored only 75% on "Negated Action". This initially seems quite counter intuitive - either the model should be good at the insertion of a negation word, or it should be bad. The explanation for this reveals a bias in the data itself: in every instance where the "Negated Subject" corruption was applied, the sentence was transformed from "A/The [subject] is" to "There is no [subject]". This is differs from the change in "Negated Action", which is simply the insertion of "not" into the sentence before an action. Because one of these corruptions resulted in 3x more word replacements, the model is able to identify it fairly well.

To confirm this, we added two final entries to Table 7 where we applied the *Difference formula* to the "Negated Subject" and "Negated Action" corruptions to see the fraction of sentence pairs whose scores are within 15% of one another. We found that, indeed, the "Negated Action" corruption scored 100% (meaning that the corruption embeddings were very similar to the original embeddings), while the "Negated Subject" corruption pairs were only similar about 85% of the time. By analyzing these interpretable errors, we can see that stop

words play a larger role than we'd want in our toy metric. To develop a stronger metric, we might change W2V-AVG so that it considers only the content words when computing the centroid embeddings.

8 Conclusion

The main contribution of this work is a novel approach for analyzing evaluation metrics for language generation tasks using Metric Unit TesTs. Not only is this evaluation procedure able to highlight particular metric weaknesses, it also demonstrates results which are far more consistent than correlation with human judgment; a good metric will be able to score well regardless of how noisy the human-derived scores are. Finally, we demonstrate the process of how this analysis can guide the development and strengthening of newly created metrics that are developed.

N-gram language models for massively parallel devices

Nikolay Bogoychev and **Adam Lopez**
University of Edinburgh
Edinburgh, United Kingdom

Abstract

For many applications, the query speed of N-gram language models is a computational bottleneck. Although massively parallel hardware like GPUs offer a potential solution to this bottleneck, exploiting this hardware requires a careful rethinking of basic algorithms and data structures. We present the first language model designed for such hardware, using B-trees to maximize data parallelism and minimize memory footprint and latency. Compared with a single-threaded instance of KenLM (Heafield, 2011), a highly optimized CPU-based language model, our GPU implementation produces identical results with a smaller memory footprint and a sixfold increase in throughput on a batch query task. When we saturate both devices, the GPU delivers nearly twice the throughput per hardware dollar even when the CPU implementation uses faster data structures.

Our implementation is freely available at `https://github.com/XapaJIaMnu/gLM`

1 Introduction

N-gram language models are ubiquitous in speech and language processing applications such as machine translation, speech recognition, optical character recognition, and predictive text. Because they operate over large vocabularies, they are often a computational bottleneck. For example, in machine translation, Heafield (2013) estimates that decoding a single sentence requires a million language model queries, and Green et al. (2014) estimate that this accounts for more than 50% of decoding CPU time.

To address this problem, we turn to massively parallel hardware architectures, exemplified by general purpose graphics processing units (GPUs), whose memory bandwidth and computational throughput has rapidly outpaced that of CPUs over the last decade (Figure 1). Exploiting this increased power is a tantalizing prospect for any computation-bound problem, so GPUs have begun to attract attention in natural language processing, in problems such as parsing (Canny et al., 2013; Hall et al., 2014), speech recognition (Chong et al., 2009; Chong et al., 2008), and phrase extraction for machine translation (He et al., 2015). As these efforts have shown, it is not trivial to exploit this computational power, because the GPU computational model rewards data parallelism, minimal branching, and minimal access to global memory, patterns ignored by many classic NLP algorithms (Section 2).

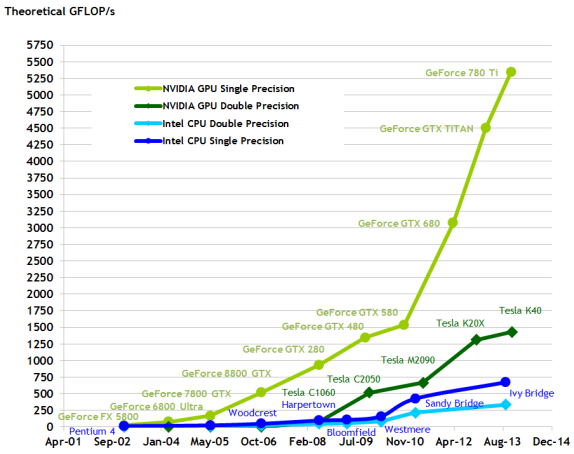

Figure 1: Theoretical floating point performance of CPU and GPU hardware over time (Nvidia Corporation, 2015).

We present the first language model data structure designed for this computational model. Our data structure is a trie in which individual nodes are represented by B-trees, which are searched in parallel (Section 3) and arranged compactly in

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1944–1953,
Berlin, Germany, August 7-12, 2016.

memory (Section 4). Our experiments across a range of parameters in a batch query setting show that this design achieves a throughput six times higher than KenLM (Heafield, 2011), a highly efficient CPU implementation (Section 5). They also show the effects of device saturation and of data structure design decisions.

2 GPU computational model

GPUs and other parallel hardware devices have a different computational profile from widely-used x86 CPUs, so data structures designed for serial models of computation are not appropriate. To produce efficient software for a GPU we must be familiar with its design (Figure 2).

2.1 GPU design

A GPU consists of many simple computational *cores*, which have neither complex caches nor branch predictors to hide latencies. Because they have far fewer circuits than CPU cores, GPU cores are much smaller, and many more of them can fit on a device. So the higher throughput of a GPU is due to the sheer number of cores, each executing a single *thread* of computation (Figure 2). Each core belongs to a *Streaming Multiprocessor (SM)*, and all cores belonging to a SM must execute the same instruction at each time step, with exceptions for branching described below. This execution model is very similar to single instruction, multiple data (SIMD) parallelism.[1]

Computation on a GPU is performed by an inherently parallel function or *kernel*, which defines a *grid* of data elements to which it will be applied, each processed by a *block* of parallel threads. Once scheduled, the kernel executes in parallel on all cores allocated to blocks in the grid. At minimum, it is allocated to a single *warp*—32 cores on our experimental GPU. If fewer cores are requested, a full warp is still allocated, and the unused cores idle.

A GPU offers several memory types, which differ in size and latency (Table 1). Unlike a CPU program, which can treat memory abstractly, a GPU program must explicitly specify in which physical memory each data element resides. This choice has important implications for efficiency that entail design tradeoffs, since memory closer to a core is small and fast, while memory further away is large and slow (Table 1).

[1]Due to differences in register usage and exceptions for branching, this model is not pure SIMD. Nvidia calls it SIMT (single instruction, multiple threads).

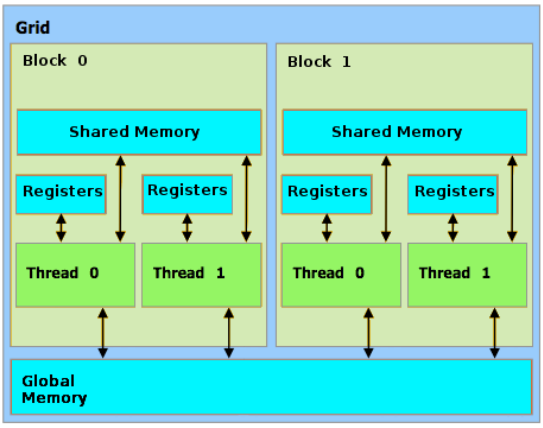

Figure 2: GPU memory hierarchy and computational model (Nvidia Corporation, 2015).

Memory type	Latency	Size
Register	0	4B
Shared	4–8	16KB–96KB
Global GPU	200–800	2GB–12GB
CPU	10K+	16GB–1TB

Table 1: Latency (in clock cycles) and size of different GPU memory types. Estimates are adapted from Nvidia Corporation (2015) and depend on several aspects of hardware configuration.

2.2 Designing efficient GPU algorithms

To design an efficient GPU application we must observe the constraints imposed by the hardware, which dictate several important design principles.

Avoid branching instructions. If a branching instruction occurs, threads that meet the branch condition run while the remainder idle (a *warp divergence*). When the branch completes, threads that don't meet the condition run while the first group idles. So, to maximize performance, code must be designed with little or no branching.

Use small data structures. Total memory on a state-of-the-art GPU is 12GB, expected to rise to 24GB in the next generation. Language models that run on CPU frequently exceed these sizes, so our data structures must have the smallest possible memory footprint.

Minimize global memory accesses. Data in the CPU memory must first be transferred to the device. This is very slow, so data structures must reside in GPU memory. But even when they

Data structure	Size	Query speed	Ease of backoff	Construction time	Lossless
Trie (Heafield, 2011)	Small	Fast	Yes	Fast	Yes
Probing hash table (Heafield, 2011)	Larger	Faster	Yes	Fast	Yes
Double array (Yasuhara et al., 2013)	Larger	Fastest	Yes	Very slow	Yes
Bloom filter (Talbot and Osborne, 2007)	Small	Slow	No	Fast	No

Table 2: A survey of language model data structures and their computational properties.

reside in global GPU memory, latency is high, so wherever possible, data should be accessed from shared or register memory.

Access memory with coalesced reads. When a thread requests a byte from global memory, it is copied to shared memory along with many surrounding bytes (between 32 and 128 depending on the architecture). So, if consecutive threads request consecutive data elements, the data is copied in a single operation (a *coalesced read*), and the delay due to latency is incurred only once for all threads, increasing throughput.

3 A massively parallel language model

Let w be a sentence, w_i its ith word, and N the order of our model. An N-gram language model defines the probability of w as:

$$P(w) = \prod_{i=1}^{|w|} P(w_i|w_{i-1}...w_{i-N+1}) \quad (1)$$

A backoff language model (Chen and Goodman, 1999) is defined in terms of n-gram probabilities $P(w_i|w_{i-1}...w_{i-n+1})$ for all n from 1 to N, which are in turn defined by n-gram parameters $\hat{P}(w_i...w_{i-n+1})$ and backoff parameters $\beta(w_{i-1}...w_{i-n+1})$. Usually $\hat{P}(w_i...w_{i-n+1})$ and $\beta(w_{i-1}...w_{i-n+1})$ are probabilities conditioned on $w_{i-1}...w_{i-n+1}$, but to simplify the following exposition, we will simply treat them as numeric parameters, each indexed by a reversed n-gram. If parameter $\hat{P}(w_i...w_{i-n+1})$ is nonzero, then:

$$P(w_i|w_{i-1}...w_{i-n+1}) = \hat{P}(w_i...w_{i-n+1})$$

Otherwise:

$$P(w_i|w_{i-1}...w_{i-n+1}) = P(w_i|w_{i-1}...w_{i-n+2}) \times \beta(w_{i-1}...w_{i-n+1})$$

This recursive definition means that the probability $P(w_i|w_{i-1}...w_{i-N+1})$ required for Equation 1 may depend on multiple parameters. If r ($< N$) is the largest value for which $\hat{P}(w_i|w_{i-1}...w_{i-r+1})$ is nonzero, then we have:

$$P(w_i|w_{i-1}...w_{i-N+1}) = \hat{P}(w_i...w_{i-r+1}) \prod_{n=r+1}^{N} \beta(w_{i-1}...w_{i-n+1}) \quad (2)$$

Our data structure must be able to efficiently access these parameters.

3.1 Trie language models

With this computation in mind, we surveyed several popular data structures that have been used to implement N-gram language models on CPU, considering their suitability for adaptation to GPU (Table 2). Since a small memory footprint is crucial, we implemented a variant of the trie data structure of Heafield (2011). We hypothesized that its slower query speed compared to a probing hash table would be compensated for by the throughput of the GPU, a question we return to in Section 5.

A trie language model exploits two important guarantees of backoff estimators: first, if $\hat{P}(w_i...w_{i-n+1})$ is nonzero, then $\hat{P}(w_i...w_{i-m+1})$ is also nonzero, for all $m < n$; second, if $\beta(w_{i-1}...w_{i-n+1})$ is one, then $\beta(w_{i-1}...w_{i-p+1})$ is one, for all $p > n$. Zero-valued n-gram parameters and one-valued backoff parameters are not explicitly stored. To compute $P(w_i|w_{i-1}...w_{i-N+1})$, we iteratively retrieve $\hat{P}(w_i...w_{i-m+1})$ for increasing values of m until we fail to find a match, with the final nonzero value becoming $\hat{P}(w_i...w_{i-r+1})$ in Equation 2. We then iteratively retrieve $\beta(w_{i-1}...w_{i-n+1})$ for increasing values of n starting from $r+1$ and continuing until $n = N$ or we fail to find a match, multiplying all retrieved terms to compute $P(w_i|w_{i-1}...w_{i-N+1})$ (Equation 2). The trie is designed to execute these iterative parameter retrievals efficiently.

Let Σ be a our vocabulary, Σ^n the set of all n-grams over the vocabulary, and $\Sigma^{[N]}$ the

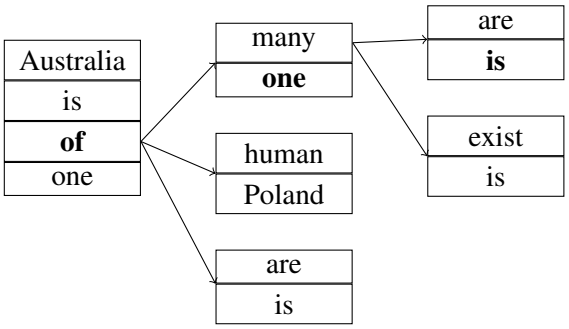

Figure 3: Fragment of a trie showing the path of N-gram **is one of** in bold. A query for the N-gram **every one of** traverses the same path, but since **every** is not among the keys in the final node, it returns the n-gram parameter $\hat{P}$(**of**|**one**) and returns to the root to seek the backoff parameter β(**every one**). Based on image from Federico et al. (2008).

set $\Sigma^1 \cup ... \cup \Sigma^N$. Given an n-gram *key* $w_i...w_{i-n+1} \in \Sigma^{[N]}$, our goal is to retrieve *value* $\langle \hat{P}(w_i...w_{i-n+1}), \beta(w_i...w_{i-n+1}) \rangle$. We assume a bijection from Σ to integers in the range $1, ..., |\Sigma|$, so in practice all keys are sequences of integers.

When $n = 1$, the set of all possible keys is just Σ. For this case, we can store keys with nontrivial values in a sorted array A and their associated values in an array V of equal length so that $V[j]$ is the value associated with key $A[j]$. To retrieve the value associated with key k, we seek j for which $A[j] = k$ and return $V[j]$. Since A is sorted, j can be found efficiently with binary or interpolated search (Figure 4).

When $n > 1$, queries are recursive. For $n < N$, for every $w_i...w_{i-n+1}$ for which $\hat{P}(w_i...w_{i-n+1}) > 0$ or $\beta(w_i...w_{i-n+1}) < 1$, our data structure contains associated arrays $K_{w_i...w_{i-n+1}}$ and $V_{w_i...w_{i-n+1}}$. When key k is located in $A_{w_i...w_{i-n+1}}[j]$, the value stored at $V_{w_i...w_{i-n+1}}[j]$ includes the address of arrays $A_{w_i...w_{i-n+1}k}$ and $V_{w_i...w_{i-n+1}k}$. To find the values associated with an n-gram $w_i...w_{i-n+1}$, we first search the root array A for j_1 such that $A[j_1] = w_i$. We retrieve the address of A_{w_i} from $V[j_1]$, and we then search for j_2 such that $A_{w_i}[j_2] = w_{i-1}$. We continue to iterate this process until we find the value associated with the longest suffix of our n-gram stored in the trie. We therefore iteratively retrieve the parameters needed to compute Equation 2, returning to the root exactly once if backoff parameters are required.

3.1.1 K-ary search and B-trees

On a GPU, the trie search algorithm described above is not efficient because it makes extensive use of binary search, an inherently serial algorithm. However, there is a natural extension of binary search that is well-suited to GPU: K-ary search (Hwu, 2011). Rather than divide an array in two as in binary search, K-ary search divides it into K equal parts and performs $K - 1$ comparisons simultaneously (Figure 5).

To accommodate large language models, the complete trie must reside in global memory, and in this setting, K-ary search on an array is inefficient, since the parallel threads will access non-consecutive memory locations. To avoid this, we require a data structure that places the K elements compared by K-ary search in consecutive memory locations so that they can be copied from global to shared memory with a coalesced read. This data structure is a B-tree (Bayer and McCreight, 1970), which is widely used in databases, filesystems and information retrieval.

Informally, a B-tree generalizes binary trees in exactly the same way that K-ary search generalizes binary search (Figure 6). More formally, a B-tree is a recursive data structure that replaces arrays A and V at each node of the trie. A B-tree node of size K consists of three arrays: a 1-indexed array B of $K - 1$ keys; a 1-indexed array V of $K - 1$ associated values so that $V[j]$ is the value associated with key $B[j]$; and, if the node is not a leaf, a 0-indexed array C of K addresses to child B-trees. The keys in B are sorted, and the subtree at address pointed to by child $C[j]$ represents only key-value pairs for keys between $B[j]$ and $B[j + 1]$ when $1 \leq j < K$, keys less than $B[1]$ when $j = 0$, or keys greater than $B[K]$ when $j = K$.

To find a key k in a B-tree, we start at the root node, and we seek j such that $B[j] \leq k < B[j + 1]$. If $B[j] = k$ we return $V[j]$, otherwise if the node is not a leaf node we return the result of recursively querying the B-tree node at the address $C[j]$ ($C[0]$ if $k < B[1]$ or $C[K]$ if $k > B[K]$). If the key is not found in array B of a leaf, the query fails.

Our complete data structure is a trie in which each node except the root is a B-tree (Figure 7). Since the root contains all possible keys, its keys are simply represented by an array A, which can be indexed in constant time without any search.

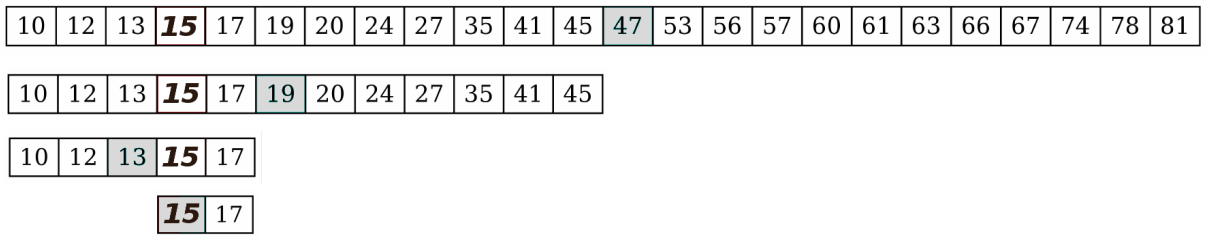

Figure 4: Execution of a binary search for key 15. Each row represents a time step and highlights the element compared to the key. Finding key 15 requires four time steps and four comparisons.

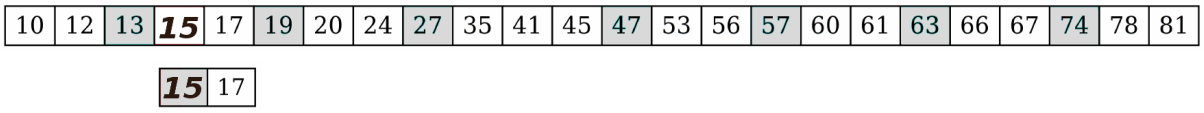

Figure 5: Execution of K-ary search with the same input as Figure 4, for $K = 8$. The first time step executes seven comparisons in parallel, and the query is recovered in two time steps.

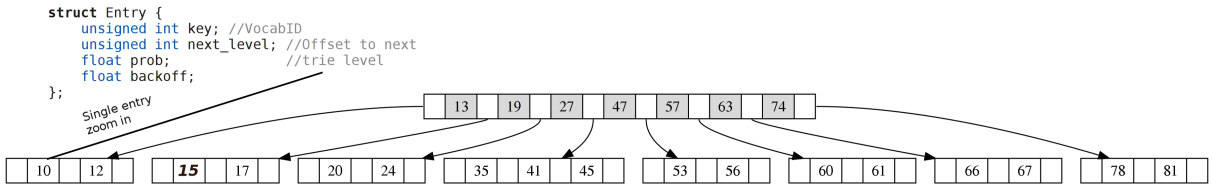

Figure 6: In a B-tree, the elements compared in K-ary search are consecutive in memory. We also show the layout of an individual entry.

4 Memory layout and implementation

Each trie node represents a unique n-gram $w_i...w_{i-n+1}$, and if a B-tree node within the trie node contains key w_{i-n}, then it must also contain the associated values $\hat{P}(w_i...w_{i-n})$, $\beta(w_i...w_{i-n})$, and the address of the trie node representing $w_i...w_{i-n}$ (Figure 6, Figure 3). The entire language model is laid out in memory as a single byte array in which trie nodes are visited in breadth-first order and the B-tree representation of each node is also visited in breadth-first order (Figure 7).

Since our device has a 64-bit architecture, pointers can address 18.1 exabytes of memory, far more than available. To save space, our data structure does not store global addresses; it instead stores the difference in addresses between the parent node and each child. Since the array is aligned to four bytes, these relative addresses are divided by four in the representation, and multiplied by four at runtime to obtain the true offset. This enables us to encode relative addresses of 16GB, still larger than the actual device memory. We estimate that relative addresses of this size allow us to store a model containing around one billion n-grams.[2] Unlike CPU language model implementations such as those of Heafield (2011) and Watanabe et al. (2009), we do not employ further compression techniques such as variable-byte encoding or LOUDS, because their runtime decompression algorithms require branching code, which our implementation must avoid.

We optimize the node representation for coalesced reads by storing the keys of each B-tree consecutively in memory, followed by the corresponding values, also stored consecutively (Figure 6). When the data structure is traversed, only key arrays are iteratively copied to shared memory until a value array is needed. This design minimizes the number of reads from global memory.

4.1 Construction

The canonical B-tree construction algorithm (Cormen et al., 2009) produces nodes that are not fully saturated, which is desirable for B-trees that

[2] We estimate this by observing that a model containing 423M n-grams takes 3.8Gb of memory, and assuming an approximately linear scaling, though there is some variance depending on the distribution of the n-grams.

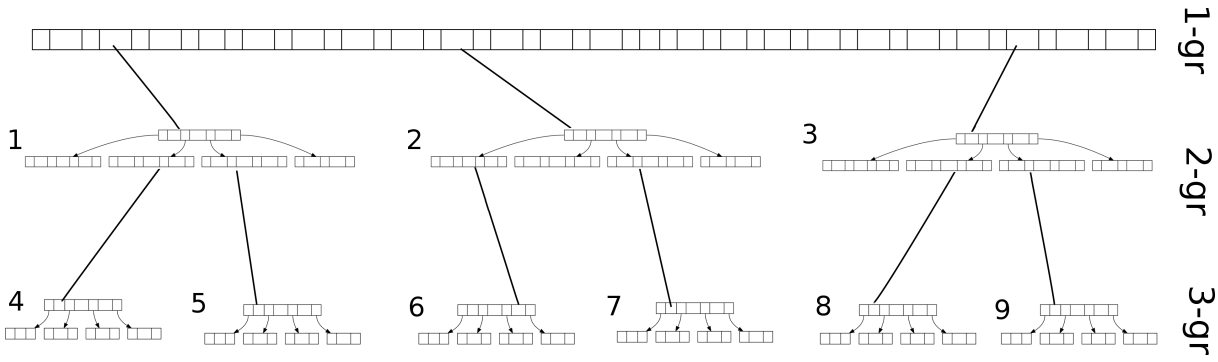

Figure 7: Illustration of the complete data structure, showing a root trie node as an array representing unigrams, and nine B-trees, each representing a single trie node. The trie nodes are numbered according to the order in which they are laid out in memory.

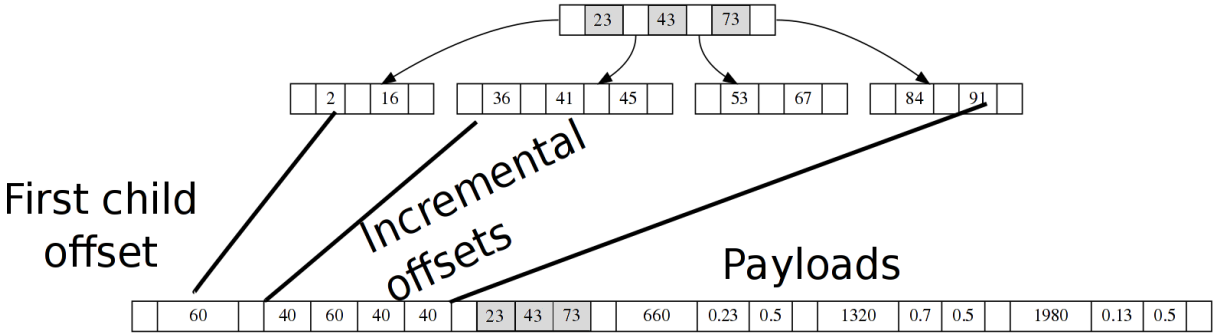

Figure 8: Layout of a single B-tree node for $K = 4$. Relative addresses of the four child B-tree nodes (array C) are followed by three keys (array B), and three values (array V), each consisting of an n-gram probability, backoff, and address of the child trie node.

support insertion. However, our B-trees are immutable, and unsaturated nodes of unpredictable size lead to underutilization of threads, warp divergence, and deeper trees that require more iterations to query. So, we use a construction algorithm inspired by Cesarini and Soda (1983) and Rosenberg and Snyder (1981). It is implemented on CPU, and the resulting array is copied to GPU memory to perform queries.

Since the entire set of keys and values is known in advance for each n-gram, our construction algorithm receives them in sorted order as the array A described in Section 3.1. The procedure then splits this array into K consecutive subarrays of equal size, leaving $K-1$ individual keys between each subarray.[3] These $K-1$ keys become the keys of the root B-tree. The procedure is then applied recursively to each subarray. When applied to an array whose size is less than K, the algorithm returns a leaf node. When applied to an array whose size is greater than or equal to K but less than $2K$, it splits the array into a node containing the first $K-1$ keys, and a single leaf node containing the remaining keys, which becomes a child of the first.

4.2 Batch queries

To fully saturate our GPU we execute many queries simultaneously. A grid receives the complete set of N-gram queries and each block processes a single query by performing a sequence of K-ary searches on B-tree nodes.

5 Experiments

We compared our open-source GPU language model **gLM** with the CPU language model KenLM (Heafield, 2011).[4][5] KenLM can use two quite different language model data structures: a fast probing hash table, and a more compact but slower trie, which inspired our own language model design. Except where noted, our B-tree

[3] Since the size of the array may not be exactly divisible by K, some subarrays may differ in length by one.

[4] https://github.com/XapaJIaMnu/gLM

[5] https://github.com/kpu/kenlm/commit/9495443

node size $K = 31$, and we measure throughput in terms of query speed, which does not include the cost of initializing or copying data structures, or the cost of moving data to or from the GPU.

We performed our GPU experiments on an Nvidia Geforce GTX, a state-of-the-art GPU, released in the first quarter of 2015 and costing 1000 USD. Our CPU experiments were performed on two different devices: one for single-threaded tests and one for multi-threaded tests. For the single-threaded CPU tests, we used an Intel Quad Core i7 4720HQ CPU released in the first quarter of 2015, costing 280 USD, and achieving 85% of the speed of a state-of-the-art consumer-grade CPU when single-threaded. For the multi-threaded CPU tests we used two Intel Xeon E5-2680 CPUs, offering a combined 16 cores and 32 threads, costing at the time of their release 3,500 USD together. Together, their performance specifications are similar to the recently released Intel Xeon E5-2698 v3 (16 cores, 32 threads, costing 3,500USD). The different CPU configurations are favorable to the CPU implementation in their tested condition: the consumer-grade CPU has higher clock speeds in single-threaded mode than the professional-grade CPU; while the professional-grade CPUs provide many more cores (though at lower clock speeds) when fully saturated. Except where noted, CPU throughput is reported for the single-threaded condition.

Except where noted, our language model is the Moses 3.0 release English 5-gram language model, containing 88 million n-grams.[6] Our benchmark task computes perplexity on data extracted from the Common Crawl dataset used for the 2013 Workshop on Machine Translation, which contains 74 million words across 3.2 million sentences.[7] Both gLM and KenLM produce identical perplexities, so we are certain that our implementation is correct. Except where noted, the faster KenLM Probing backend is used. The perplexity task has been used as a basic test of other language model implementations (Osborne et al., 2014; Heafield et al., 2015).

5.1 Query speed

When compared to single-threaded KenLM, our results (Table 3) show that gLM is just over six times faster than the fast probing hash table, and nearly fifteen times faster than the trie data structure, which is quite similar to our own, though slightly smaller due to the use of compression. The raw speed of the GPU is apparent, since we were able to obtain our results with a relatively short engineering effort when compared to that of KenLM, which has been optimized over several years.

LM (threads)	Throughput	Size (GB)
KenLM probing (1)	10.3M	1.8
KenLM probing (16)	49.8M	1.8
KenLM probing (32)	**120.4M**	1.8
KenLM trie (1)	4.5M	**0.8**
gLM	65.5M	1.2

Table 3: Comparison of gLM and KenLM on throughput (N-gram queries per second) and data structure size.

When we fully saturate our professional-grade CPU, using all sixteen cores and sixteen hyper-threads, KenLM is about twice as fast as gLM. However, our CPU costs nearly four times as much as our GPU, so economically, this comparison favors the GPU.

On first glance, the scaling from one to sixteen threads is surprisingly sublinear. This is not due to vastly different computational power of the individual cores, which are actually very similar. It is instead due to scheduling, cache contention, and—most importantly—the fact that our CPUs implement *dynamic overclocking*: the base clock rate of 2.7 GHz at full saturation increases to 3.5 GHz when the professional CPU is underutilized, as when single-threaded; the rates for the consumer-grade CPU similarly increase from 2.6 to 3.6 GHz.[8]

5.2 Effect of B-tree node size

What is the optimal K for our B-tree node size? We hypothesized that the optimal size would be one that approaches the size of a coalesced memory read, which should allow us to maximize parallelism while minimizing global memory accesses and B-tree depth. Since the size of a coalesced read is 128 bytes and keys are four bytes, we hypothesized that the optimal node size would be around $K = 32$, which is also the size of a warp. We tested this by running experiments

[8] Intel calls this Intel Turbo Boost.

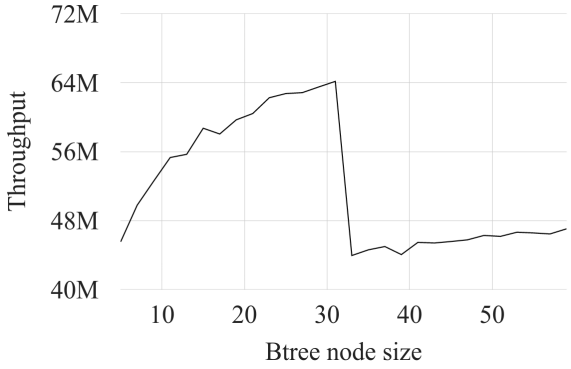

Figure 9: Effect of BTree node size on throughput (ngram queries per second)

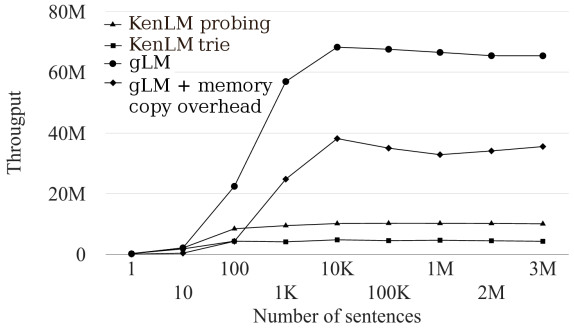

Figure 10: Throughput (N-gram queries per second) vs. batch size for gLM, KenLM probing, and KenLM trie.

	Regular LM	Big LM
KenLM	10.2M	8.2M
KenLM Trie	4.5M	3.0M
gLM	**65.5M**	**55M**

Table 4: Throughput comparison (ngram queries per second) between **gLM** and **KenLM** with a 5 times larger model and a regular language model.

that varied K from 5 to 59, and the results (Figure 9) confirmed our hypothesis. As the node size increases, throughput increases until we reach a node size of 33, where it steeply drops. This result highlights the importance of designing data structures that minimize global memory access and maximize parallelism.

We were curious about what effect this node size had on the depth of the B-trees representing each trie node. Measuring this, we discovered that for bigrams, 88% of the trie nodes have a depth of one—we call these *B-stumps*, and they can be exhaustively searched in a single parallel operation. For trigrams, 97% of trie nodes are B-stumps, and for higher order n-grams the percentage exceeds 99%.

5.3 Saturating the GPU

A limitation of our approach is that it is only effective in high-throughput situations that continually saturate the GPU. In situations where a language model is queried only intermittently or only in short bursts, a GPU implementation may not be useful. We wanted to understand the point at which this saturation occurs, so we ran experiments varying the batch size sent to our language model, comparing its behavior with that of KenLM. To understand situations in which the GPU hosts the language model for query by an external GPU, we measure query speed with and without the cost of copying queries to the device.

Our results (Figure 10) suggest that the device is nearly saturated once the batch size reaches a thousand queries, and fully saturated by ten thousand queries. Throughput remains steady as batch size increases beyond this point. Even with the cost of copying batch queries to GPU memory, throughput is more than three times higher than that of single threaded KenLM. We have not included results of multi-threaded KenLM scaling on Figure 10 but they are similar to the single-threaded case: throughput (as shown on Table 3) plateaus at around one hundred sentences per thread.

5.4 Effect of model size

To understand the effect of model size on query speed, we built a language model with 423 million n-grams, five times larger than our basic model. The results (Table 4) show an 18% slowdown for gLM and 20% slowdown for KenLM, showing that model size affects both implementations similarly.

5.5 Effect of N-gram order on performance

All experiments so far use an N-gram order of five. We hypothesized that lowering the ngram order of the model would lead to faster query time (Table 5). We observe that N-gram order affects throughput of the GPU language model much more than the CPU one. This is likely due to effects of backoff queries, which are more optimized in KenLM. At higher orders, more backoff queries occur, which reduces throughput for gLM.

	5-gram	4-gram	3-gram
KenLM	10.2M	9.8M	11.5M
KenLM Trie	4.5M	4.5M	5.2M
gLM	**65.5M**	**71.9M**	**93.7M**

Table 5: Throughput comparison (ngram queries per second) achieved using lower order ngram models.

5.6 Effect of templated code

Our implementation initially relied on hard-coded values for parameters such as B-tree node size and N-gram order, which we later replaced with parameters. Surprisingly, we observed that this led to a reduction in throughput from 65.6 million queries per second to 59.0 million, which we traced back to the use of dynamically allocated shared memory, as well as compiler optimizations that only apply to compile-time constants. To remove this effect, we heavily templated our code, using as many compile-time constants as possible, which improves throughput but enables us to change parameters through recompilation.

5.7 Bottlenecks: computation or memory?

On CPU, language models are typically memory-bound: most cycles are spent in random memory accesses, with little computation between accesses. To see if this is true in gLM we experimented with two variants of the benchmark in Figure 3: one in which the GPU core was underclocked, and one in which the memory was underclocked. This effectively simulates two variations in our hardware: A GPU with slower cores but identical memory, and one with slower memory, but identical processing speed. We found that throughput decreases by about 10% when underclocking the cores by 10%. On the other hand, underclocking memory by 25% reduced throughput by 1%. We therefore conclude that gLM is computation-bound. We expect that gLM will continue to improve on parallel devices offering higher theoretical floating point performance.

6 Conclusion

Our language model is implemented on a GPU, but its general design (and much of the actual code) is likely to be useful to other hardware that supports SIMD parallelism, such as the Xeon Phi. Because it uses batch processing, our on-chip language model could be integrated into a machine translation decoder using strategies similar to those used to integrate an on-network language model nearly a decade ago (Brants et al., 2007). An alternative method of integration would be to move the decoder itself to GPU. For phrase-based translation, this would require a translation model and dynamic programming search algorithm on GPU. Translation models have been implemented on GPU by He et al. (2015), while related search algorithms for (Chong et al., 2009; Chong et al., 2008) and parsing (Canny et al., 2013; Hall et al., 2014) have been developed for GPU. We intend to explore these possibilities in future work.

Abstract

Morphologically rich languages often lack the annotated linguistic resources required to develop accurate natural language processing tools. We propose models suitable for training morphological taggers with rich tagsets for low-resource languages without using direct supervision. Our approach extends existing approaches of projecting part-of-speech tags across languages, using bitext to infer constraints on the possible tags for a given word type or token. We propose a tagging model using Wsabie, a discriminative embedding-based model with rank-based learning. In our evaluation on 11 languages, on average this model performs on par with a baseline weakly-supervised HMM, while being more scalable. Multilingual experiments show that the method performs best when projecting between related language pairs. Despite the inherently lossy projection, we show that the morphological tags predicted by our models improve the downstream performance of a parser by +0.6 LAS on average.

1 Introduction

Morphologically rich languages pose significant challenges for Natural Language Processing (NLP) due to data-sparseness caused by large vocabularies. Intermediate processing is often required to address the limitations of only using surface forms, especially for small datasets. Common morphological processing tasks include segmentation (Creutz and Lagus, 2007; Snyder and Barzilay, 2008), paradigm learning (Durrett and DeNero, 2013; Ahlberg et al., 2015) and morphological tagging (Müller and Schuetze, 2015). In this paper we focus on the latter.

Parts-of-speech (POS) tagging is the most common form of syntactic annotation. However, the granularity of POS varies across languages and annotation-schemas, and tagsets have often been extended to include tags for morphologically-marked properties such as number, case or degree. To enable cross-lingual learning, a small set of universal (coarse-grained) POS tags have been proposed (Petrov et al., 2012). For morphological processing this can be complemented with a set of attribute-feature values that makes the annotation more fine-grained (Zeman, 2008; Sylak-Glassman et al., 2015b).

Tagging text with morphologically-enriched labels has been shown to benefit downstream tasks such as parsing (Tsarfaty et al., 2010) and semantic role labelling (Hajič et al., 2009). In generation tasks such as machine translation these tags can help to generate the right form of a word and to model agreement (Toutanova et al., 2008). Morphological information can also benefit automatic speech recognition for low-resource languages (Besacier et al., 2014).

However, annotating sufficient data to learn accurate morphological taggers is expensive and relies on linguistic expertise, and is therefore currently only feasible for the world's most widely-used languages. In this paper we are interested in learning morphological taggers without the availability of supervised data. A successful paradigm for learning without direct supervision is to make use of word-aligned parallel text, with a resource-rich language on one side and a resource-poor language on the other side (Yarowsky et al., 2001; Fossum and Abney, 2005; Das and Petrov, 2011; Täckström et al., 2013).

In this paper we extend these methods, that have mostly been proposed for universal POS-taggers, to learn weakly-supervised morphological taggers.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1954–1964,
Berlin, Germany, August 7-12, 2016.

Our approach is based on projecting token and type constraints across parallel text, learning a tagger in a weakly-supervised manner from the projected constraints (Täckström et al., 2013). We propose an embedding-based model trained with the Wsabie algorithm (Weston et al., 2011), and compare this approach against a baseline HMM model.

We evaluate the projected tags for a set of languages for which morphological tags are available in the Universal Dependency corpora. To show the feasibility of our approach, and to compare the performance of different models, we use English as source language. Then we perform an evaluation on all language pairs in the set of target languages which shows that the best performance is obtained when projecting between genealogically related languages.

As an extrinsic evaluation of our approach, we show that NLP models can benefit from using these induced tags even if they are not as accurate as tags produced by supervised models, by evaluating the effect of features obtained from tags predicted by the induced morphological taggers in dependency parsing.

2 Universal Morphological Tags

In order to do cross-lingual learning we require a common morphological tagset. To evaluate these models we require datasets in multiple languages which have been annotated with such a consistent schema. The treebanks annotated in the Universal Dependencies (UD) project (de Marneffe et al., 2014) are suitable for this purpose.

All the data is annotated with universal POS tags, a set of 17 tags[1]. We use UD v1.2 (Nivre et al., 2015), which contain 25 languages annotated with morphological attributes (called features). In addition to POS, there are 17 universal *attributes*, which each takes one of a set of *values* when annotated. The morphological tag of a token denotes the union of its morphological attribute-value pairs, including its POS.

Although the schema is consistent across languages, there are language-specific phenomena and considerations that result in some mismatches for a given pair of languages. One source of this is that the UD treebanks were mostly constructed by fully or semi-automatic conversion of existing treebanks which had used different annotation schemes. Furthermore, not all the attributes and values appear in all languages (e.g. additional cases in morphologically-rich languages such as Finnish), and there are still a number of language-specific tags not in the universal schema. Finally, in some instances properties that are not realised in the surface word form are absent from the annotation (e.g. in English the person and number of verbs are only annotated for third-person singular, as there are no distinct morphological forms for their other values).

An example of the morphological annotation employed is given in Figure 1. Note that the annotations for aligned word-pairs are not fully consistent. Some attributes appear only in the English treebank (e.g. Voice), while others appear only in the Dutch treebank (e.g. Aspect, Subcat).

3 Tag Projection across Bitext

Our approach to train morphological taggers is based on the paradigm of projecting token and type constraints as proposed by Täckström et al. (2013). The training data consist of parallel text with the resource-rich language on the source-side and the low-resource language on the target side. The source-side text is tagged with a supervised morphological tagger. For every target-side sentence, the type and token constraints are used to construct a set of permitted tags for each token in the sentence. These constraints will then be used to train morphological taggers.

3.1 Type and token constraints

To extract constraints from the parallel text, we first obtain bidirectional word alignments. To ensure high quality alignments, alignment pairs with a confidence below a fixed threshold α are removed. The motivation for using only high-confidence alignments is that incorrect alignments will hurt the performance of the model, while it is easier to use more parallel text to obtain a sufficient number of alignments for training.

The first class of constraints that we extract from the parallel text is type constraints. For each word type, we construct a distribution over tags for the word by accumulating counts of the morphological tags of source-side tokens that are aligned to instances of the word type. The set of tags with probability above some threshold β is taken as the tag dictionary entry for that word type. To

[1]This extends, but is not fully consistent with, the set of 12 tags proposed by Petrov et al. (2012).

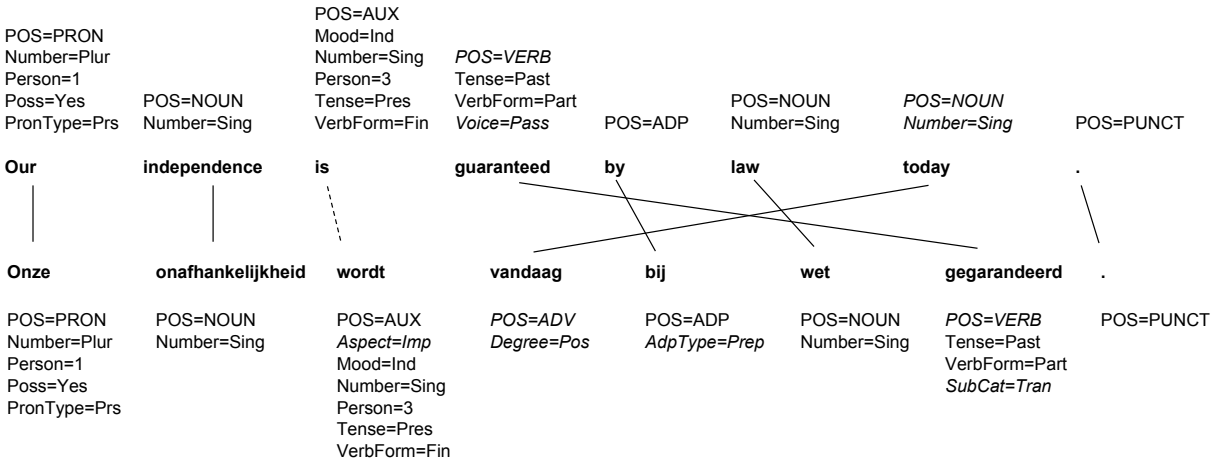

Figure 1: A parallel sentence in English and Dutch annotated with universal morphological tags, showing high-confidence automatic word-alignments. Attribute-value pairs that occur only on one side of an aligned pair of tokens are indicated in *italics*. The dashed line indicates a low-confidence alignment point, which is ignored in our projection method.

construct the training examples, each token whose type occurs in the tag dictionary is restricted to the set of tags in the dictionary entry. For tokens for which the dictionary entry is empty, all the tags are included in the set of permitted tags (this happens when the tag distribution is too flat and all the probabilities are below the threshold). In principle, type constraints can also be obtained from an external dictionary, but in this paper we assume we do not have such a resource.

The second class of constraints places restrictions on word tokens. Every target token is constrained to the tag of its aligned source token, while unaligned tokens can take any tag.

Token constraints are combined with type constraints as proposed by Täckström et al. (2013): If a token is unaligned, its type constraints are used. If the token is aligned, and there is no dictionary entry for the token type, the token constraint is used. If there is a dictionary entry for the token type, and the token constraint tag is in the dictionary, the token constraint is used. If the token constraint tag is not in the dictionary entry, the type constraints are used.

4 Learning from Projected Tags

Next we propose models to learn a morphological tagger from cross-lingually projected constraints.

4.1 Related work

HMMs have previously been used for weakly-supervised learning from token or type constraints (Das and Petrov, 2011; Li et al., 2012; Täckström et al., 2013). HMMs are generative models, and in this setting the words in the target sentence form the observed sequence and the morphological tags the hidden sequence. The projected constraints are used as partially observed training data for the hidden sequence.

Täckström et al. (2013) proposed a discriminative CRF model that relies on incorporating two sets of constraints, of which one is a subset of the other. Ganchev and Das (2013) used a similar CRF model, but instead of using the projected tags as hard constraints, they were employed as soft constraints with posterior regularization.

The model of Wisniewski et al. (2014) makes greedy predictions with a history-based model, that includes previously predicted tags in the sequence, during training and testing. The model is trained with a variant of the perceptron algorithm that allows a set of positive labels. When an incorrect prediction is made during training, the parameters are updated in the direction of all the positive labels.

4.2 HMM model

As a baseline model we use an HMM where the transition and emission distributions are parameterized by log-linear models (a feature-HMM). Training is performed with L-BFGS rather than with the EM algorithm. This parameterization was proposed by Berg-Kirkpatrick et al. (2010) and applied to cross-lingual POS induction by Das and

Petrov (2011) and Täckström et al. (2013).

Let $\mathbf{w}$ be the target sentence and $\mathbf{t}$ the sequence of tags for the sentence. The marginal probability of a sequence during training is

$$p(\mathbf{w}_{1:n}) = \sum_{\mathbf{t}_{1:n} \in \mathcal{T}} \prod_{i=1}^{n} p(t_i|t_{i-1})p(w_i|t_i),$$

where $\mathcal{T}$ is the set of tag sequences allowed by the type and token constraints. The probability of all other tag sequences are assumed to be 0.

The features in our model are similar to those used by Täckström et al. (2013), including features based on word and tag identity, suffixes up to length 3, punctuation and word clusters. Word clusters are obtained by clustering frequent words into 256 clusters with the Exchange algorithm (Uszkoreit and Brants, 2008), using the data and methodology detailed in Täckström et al. (2012).

4.3 Wsabie model

We propose a discriminative model based on Wsabie (Weston et al., 2011), a shallow neural network that learns to optimize precision at the top of a ranked list of labels. In our application, the goal is to learn to rank the set of tags allowed by the projected constraints in the training data above all other tags. In contrast to the HMM, which performs inference over the entire sequence, Wsabie makes the predictions at each token independently, based on a large context-size. Therefore, Wsabie inference is linear in the number of tags, while for an HMM it is quadratic, making the Wsabie model much faster during training and decoding.

Wsabie maps the input features and output labels into a low-dimensional joint space. The input vector x for a word w consists of the concatenation of word embeddings and sparse features extracted from w and the surrounding context. A mapping

$$\Theta_I(x) = Vx$$

maps $x \in \mathbb{R}^d$ into $\mathbb{R}^D$, with matrix $V \in \mathbb{R}^{D \times d}$ of parameters. The output tag t is mapped into the same space by

$$\Theta_O(t) = W_t,$$

where $W \in \mathbb{R}^{D \times L}$ is a matrix of output tag embeddings and W_t selects the column embedding of tag t. The model score for tag t given input token with feature vector x is the dot product

$$f_t(x) = \Theta_O(t)^T \Theta_I(x),$$

where the tags are ranked by the magnitude of $f_t(x)$. The norms of the columns of V and W are constrained, which acts as a regularizer.

The loss function is a margin-based hinge loss based on the rank of a tag given by $f_t(x)$. The rank is estimated by sampling an incorrect tag uniformly with replacement until the sampled tag violates the margin with a correct tag. Training is performed with stochastic gradient descent by performing a gradient step against the violating tag.

The word embedding features for the Wsabie models consist of 64-dimensional word vectors of the 5 words on either side of a token and of the token itself. The embeddings are trained with word2vec (Mikolov et al., 2013) on large corpora of newswire text.

Sparse features are based on prefixes and suffixes up to length 3 as well as word cluster features for a window size 3 around the token, using the clusters described in the previous section.

5 Experiments

We evaluate our model in two settings. The first evaluation measures the accuracy of the cross-lingual taggers on language pairs where annotated data is available for both languages. The annotated target language data is used only during evaluation and not for training. Second, we perform a downstream evaluation by including the morphological attributes predicted by the tagger as features in a dependency parser to guage the effectiveness of our approach in a setting where one does not have access to gold morphological annotations.

5.1 Experimental setup

As source of parallel training data we use Europarl[2] (Koehn, 2005) version 7. Sentences are tokenized but not lower-cased, and sentences longer than 80 words are excluded. In our experiments we learn taggers for a set of 11 European languages that have both UD training data with morphological features, and parallel data in Europarl: Bulgarian, Czech, Danish, Dutch, Finnish, Italian, Polish, Portuguese, Slovene, Spanish and Swedish. We train cross-lingual models in two setups: The first uses English as source language; in the second we train models with different source languages for each target language.

Word alignments over the parallel data are obtained using FastAlign (Dyer et al., 2013). High-

[2] http://www.statmt.org/europarl/

confidence bidirectional word alignments are constructed by intersecting the alignments in the two directions and including alignment points only if the posterior probabilities in both directions are above the alignment threshold α. For each language pair all the word-aligned parallel data available (between 10 and 50 million target-side tokens per language) are used to extract the type constraints, and the models are trained on a subset of 2 million target-side tokens (optionally with their token constraints).

The number of distinct attribute-value pairs appearing in the tagsets depends on the language pair and ranges between 35 and 79, with 54 on average (including POS tags). The number of distinct composite morphological tags is 423 on average, with a much larger range, between 81 and 1483. The English UD data has 116 tags composed out of 51 distinct attribute-value pairs. Therefore, we can project a reasonable number of morpho-syntactic attributes from English, although the number of attribute combinations that occur in the data is less than for morphologically richer languages.

The source text is tagged with supervised taggers, trained with Wsabie on the UD training data for each of the source languages used. For each language pair, we train a distinct source-side model covering only the attribute types appearing in both languages. This is meant to obtain a maximally accurate source-side tagger, while accepting that our approach cannot predict target-side attributes that are absent from the source language. The average accuracy of the English taggers on the UD test data is 94.96%. The source-side taggers over all the language pairs we experiment on have an average accuracy of 95.75%, with a minimum of 89.14% and a maximum of 98.59%.

5.2 Tuning

The hyperparameters of the Wsabie taggers are tuned on the English development set, and the same parameters are used for the Wsabie target-side models trained on the projected tags. The optimal setting is a learning rate of 0.01, embedding dimension size $D = 50$, margin 0.1, and 25 training iterations.

Hyperparameters for the projection models are set by tuning on the UD dev set accuracy for English to Danish. English was chosen as it is the language with the most available data and the most likely to be used when projecting to other languages; Danish simply because its corpus size is typical of the larger languages in Europarl. Using a small grid search, we choose the parameters that give the best average accuracy across all four projection model instances we consider. This allows using the same hyperparameters for all these models, an important factor in making them comparable in the evaluation, since the hyperparameters determine the effective training data. The parameters tuned in this manner are the alignment threshold α, which is set to 0.8, and the type distribution threshold β, set to 0.3.

5.3 Tagging evaluation setup

In order to evaluate the induced taggers on the annotated UD data for the target languages, we define two settings that circumvent mismatches between source and target language annotations to different degrees.

The STANDARD setting involves first making minor corrections to certain predicted POS values to account for inconsistencies in the original annotated data. When predicted by the model, the POS tag values absent from the target language training corpus are deterministically mapped to the most-related value present in the target language in the following way: `PROPN` to `NOUN`; `SYM` and `INTJ` to `X`; `SYM` and `X` to `PUNCT`. Besides POS, the evaluation considers only those attribute *types* that appear in both languages' training corpora, i.e., the set of attributes for which the model was trained. Note that this leaves cases intact where the model predicts certain attribute *values* that appear only in one of the two languages; it is thus penalised for making mistakes on values that it cannot learn under our projection approach.

The second evaluation setting, INTERSECTED, relaxes the latter aspect: it only considers attribute-value pairs appearing in the training corpora of both languages. The motivation for this is to get a better measurement of the accuracy of our method, assuming that the tagsets are consistent.

In both settings we report macro-averaged F1 scores over all the considered attribute types. Results for Wsabie are averaged over 3 random restarts because it uses stochastic optimization during training.

5.4 Tagging results projecting from English

Following previous work on projecting POS tags and the assumption that it is easier to obtain paral-

Model	STANDARD		INTERSECTED		POS

supervised 1K	62.44	(1.52)	61.74	(1.55)	72.51	(0.82)
supervised type	75.55	(1.88)	74.72	(1.95)	75.91	(1.16)

Table 1: Cross-lingual morphological tagging from English: Macro F1 scores averaged across 11 languages. All the results except for the first two rows are for Wsabie models. The standard deviation over 3 runs is given in brackets.

lel data between a low-resource language and English than with another language, we start by training cross-lingual taggers using English as source language.

The overall tagging results are given in Table 1. In addition to evaluating the morphological tags in the two settings described above, we also report accuracies for POS tags only, projected jointly with the morphological attributes.

We find that for both the HMM and Wsabie models the performance with type and token constraints is worse than when only using type constraints. Täckström et al. (2013) similarly found that for HMMs for POS projection, models with joint constraints do not perform better than those using only type constraints. They postulated that this is due to the type dictionaries having the same biases as token projections, and therefore the model with joint constraints not being able to filter out systematic errors in the projections.

For both sets of constraints the performance of the Wsabie model is close to that of the corresponding HMM, despite the Wsabie model having a linear runtime against the quadratic runtime of the HMM.

As another baseline we train a Wsabie model on unambiguous type constraints, i.e., we only extract training examples for words which only have a single tag in the tag dictionary. Including ambiguous type constraints gives an average improvement of 2.2%.

As a target ceiling on performance we train a Wsabie model with supervised type constraints. This model uses type constraints based on an oracle morphological tag dictionary extracted from the gold training data of the target language. It is trained on the same training data as the projected models (without token constraints). The model scores higher on STANDARD than on INTERSECTED, as it has access to annotations for the full set of tags used in the target language, not just the restricted set that can be projected. This oracle performs on average 17% better than the projected type constraints model on INTERSECTED. Therefore, despite the promising results of our approach, there is still a considerable amount of noise in the type constraints extracted from the aligned data.

We also compare the performance of the model to that of a supervised model trained on a small annotated corpus. Average performance when training on 1000 annotated tokens is only a few points higher than that of the best projected model for INTERSECTED. Given that is it expensive to let annotators learn to annotate a large set of attributes, even for a small corpus, it shows that our model can bring considerable benefits in practice to the development of NLP models for low-resource languages. It is possible to obtain further improvements in performance by learning jointly from a small annotated dataset and parallel data (Duong et al., 2014), but we leave that for future work.

The results when evaluating only the POS tags follow the same pattern, except that the overall level of accuracy is much higher than when considering all morphological attributes. For POS, the models with projected constraints actually perform better than those with supervised type constraints. In this case the benefits from learning constraints from a larger set of word types seem to outweigh the noise in the projections. The projected models are also more accurate than the supervised model trained on 1000 tokens.

5.5 Multilingual tagging results

Results for cross-lingual experiments on all pairs of the target languages under consideration are

Table 2: Cross-lingual morphological tagging results (STANDARD F1 scores) per source and target language, Wsabie projected model with type constraints. Rows indicate source language and columns target language.

given in Table 2, using the STANDARD evaluation setup. We make use of Wsabie for these experiments, as it is a more efficient model, which is especially significant when training models with large tagsets.

We see that there is large variance in the morphological tagging accuracies across language pairs. In most cases the source language for which we learn the most accurate model for morphological tagging on the target language is a related language. The Romance languages we consider (Spanish, Italian and Portuguese) seem to transfer particularly well across each other. Swedish and Danish also transfer well to each other, while English transfers best to Dutch, which the former is most closely related to among the languages compared here. However, there are also some cases of unrelated source languages performing best: Using Danish as source language gives the highest performing models for both Bulgarian and Czech. When comparing these results, however, one should keep in mind that the attribute type sets used to train taggers from different source languages for the same target language is not always the same (due to our definition of the STANDARD evaluation), therefore these results should not be interpreted directly as indicating which source language gives the best target language performance on a particular tagset.

We compare the results of the STANDARD and INTERSECTED evaluations, both when using English as source language, and when using the source language which gives the highest accuracy on STANDARD for each target language (Table 3). We see that the gap in performance between the two evaluations tends to be larger when projecting from English than when projecting from the source language which performs best for each target language.

Table 3: Comparison of the performance of the most accurate cross-lingual taggers for each target language, compared to having English as source language.

One of the main causes of variation in performance is annotation differences. Languages that are morphologically rich tend to have lower performance, but we also see variation between similar languages: There is a 10% performance gap between Danish and Swedish when projecting from English, even though they are closely related.

We also investigate the effect of the choice of source language on the accuracy of the projected POS tags (Table 4). Again, we compare the performance with English as source (which is standard for previous work on POS projection) to that of the best source language for each target. Although the gap in performance is smaller than for

the full evaluation, we see that for most target languages we can still do better by projecting from a language other than English.

Detailed per attribute results for the STANDARD evaluation are given in Table 5, again comparing the results of projecting from English to that of the most accurate model for each target language. We see that there are large differences in accuracy across attributes and across languages. In some cases, the transfer is unsuccessful. For example, degree accuracy in Italian is 2% F1 when projecting from English and 14% F1 projecting from Portuguese. Some of the cases can be explained by differences in where an attribute is marked: For example, for definiteness the performance is 1% from English to Bulgarian, as Bulgarian marks definiteness on nouns and adjectives rather than on determiners. Other attributes are very language-dependent. Gender transfers well between Romance languages, but poorly when transferring from English.

5.6 Parsing evaluation

To evaluate the effect of our models on a downstream task, we apply the cross-lingual taggers induced using English as source language to dependency parsing. This is applicable to a scenario where a language might have a corpus annotated with dependency trees and universal POS, but not morphological attributes. We want to determine how much of the performance gain from features based on supervised morphological tags we can recover with the tags predicted by our model.

As baseline we use a reimplementation of Zhang and Nivre (2011), an arc-eager transition-based dependency parser with a rich feature-set, with beam-size 8, trained for 10 epochs with a structured perceptron. We assume that universal POS tags are available, using a supervised SVM POS tagger for training and evaluation.

To include the morphology, we add features based on the predicted tags of the word on top of the stack and the first two words on the buffer.

Parsing results are given in Table 6. We report labelled attachment scores (LAS) for the baseline with no morphological tags, the model with features predicted by Wsabie with projected type constraints, and the model with features predicted by the supervised morphological tagger.

We obtain improvements in parsing accuracies for all languages except Bulgarian when adding the induced morphological tags. Using the projected tags as features recovers 24.67% (0.6 LAS absolute) of the average gain that supervised morphology features delivers over the baseline parser. The parser with features from the supervised tagger trained on 1000 tokens obtains 73.63 LAS on average. This improvement of $+0.15$ LAS over the baseline versus the $+0.6$ of our method shows that the tags predicted by our projected models are more useful as features than those predicted by a small supervised model.

To investigate the effect of source language choice for the projected models in this evaluation, we trained a model for Swedish using Danish as source language. The parsing performance is insignificantly different from using English as source, despite the accuracy of the tags projected

from Danish being higher.

Faruqui et al. (2016) show that features from induced morpho-syntactic lexicons can also improve dependency parsing accuracy. However, their method relies on having a seed lexicon of 1000 annotated word types, while our method does not require any morphological annotations in the target language.

6 Future Work

A big challenge in cross-lingual morphology is that of relatedness between source and target languages. Although we evaluate our models on multiple source-target language pairs, more work is required to investigate strategies for choosing which source language to use for a low-resource target language. A related direction is to constructing models from multiple source languages, as our results show that the overall best-performing source language for a given target language may not always have the best performance on all attributes.

Another direction is to make use of dictionaries such as Wiktionary to obtain type constraints, similar to previous work on weakly-supervised POS tagging (Li et al., 2012; Täckström et al., 2013). Sylak-Glassman et al. (2015b) and Sylak-Glassman et al. (2015a) proposed a morphological schema and method to extract annotations in that schema from Wiktionary. Although different from the schema used in this paper, their method can be used to extract type dictionaries for morphological tags that can be used to complement constraints extracted from parallel data.

Finally, greater use can be made of syntactic information: There is a close relation between the syntactic structure expressed in dependency parses and inflections in morphologically rich languages; by including this syntactic structure in our models we can induce morphological tags, e.g. related to case, that is also expressed in dependency parses.

7 Conclusion

In this paper we proposed a method that can successfully induce morphological taggers for resource-scarce languages using tags projected across bitext. It relies on access to a morphological tagger for a source-language and a moderate amount of bitext. The method obtains strong performance on a range of language pairs. We showed that downstream tasks such as dependency parsing can be improved by using the predictions from the tagger as features. Our results provide a strong baseline for future work in weakly-supervised morphological tagging.

Abstract

While end-to-end neural machine translation (NMT) has made remarkable progress recently, NMT systems only rely on parallel corpora for parameter estimation. Since parallel corpora are usually limited in quantity, quality, and coverage, especially for low-resource languages, it is appealing to exploit monolingual corpora to improve NMT. We propose a semi-supervised approach for training NMT models on the concatenation of labeled (parallel corpora) and unlabeled (monolingual corpora) data. The central idea is to reconstruct the monolingual corpora using an autoencoder, in which the source-to-target and target-to-source translation models serve as the encoder and decoder, respectively. Our approach can not only exploit the monolingual corpora of the target language, but also of the source language. Experiments on the Chinese-English dataset show that our approach achieves significant improvements over state-of-the-art SMT and NMT systems.

1 Introduction

End-to-end neural machine translation (NMT), which leverages a single, large neural network to directly transform a source-language sentence into a target-language sentence, has attracted increasing attention in recent several years (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015). Free of latent structure design and feature engineering that are critical in conventional statistical machine translation (SMT) (Brown et al., 1993; Koehn et al., 2003; Chiang, 2005), NMT has proven to excel in modeling long-distance dependencies by enhancing recurrent neural networks (RNNs) with the gating (Hochreiter and Schmidhuber, 1993; Cho et al., 2014; Sutskever et al., 2014) and attention mechanisms (Bahdanau et al., 2015).

However, most existing NMT approaches suffer from a major drawback: they heavily rely on parallel corpora for training translation models. This is because NMT directly models the probability of a target-language sentence given a source-language sentence and does not have a separate language model like SMT (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015). Unfortunately, parallel corpora are usually only available for a handful of research-rich languages and restricted to limited domains such as government documents and news reports. In contrast, SMT is capable of exploiting abundant target-side monolingual corpora to boost fluency of translations. Therefore, the unavailability of large-scale, high-quality, and wide-coverage parallel corpora hinders the applicability of NMT.

As a result, several authors have tried to use abundant monolingual corpora to improve NMT. Gulccehre et al. (2015) propose two methods, which are referred to as shallow fusion and deep fusion, to integrate a language model into NMT. The basic idea is to use the language model to score the candidate words proposed by the translation model at each time step or concatenating the hidden states of the language model and the decoder. Although their approach leads to significant improvements, one possible downside is that the network architecture has to be modified to integrate the language model.

Alternatively, Sennrich et al. (2015) propose two approaches to exploiting monolingual corpora that is transparent to network architectures. The first approach pairs monolingual sentences with dummy input. Then, the parameters of encoder

Berlin, Germany, August 7-12, 2016.

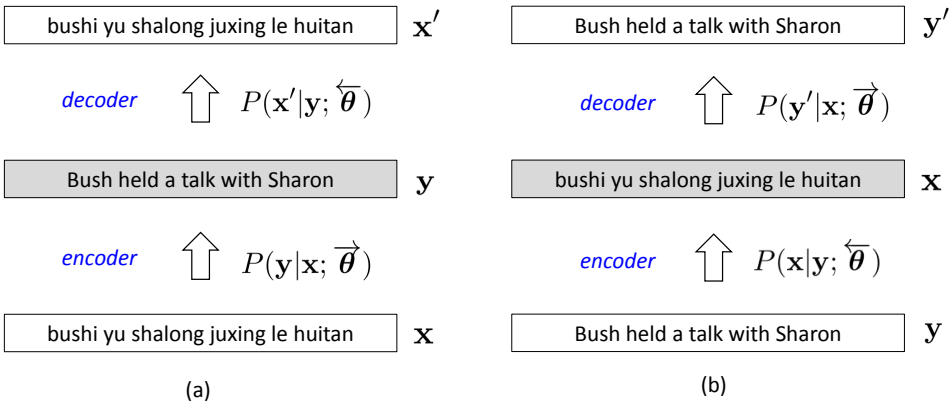

Figure 1: Examples of (a) source autoencoder and (b) target autoencoder on monolingual corpora. Our idea is to leverage autoencoders to exploit monolingual corpora for NMT. In a source autoencoder, the source-to-target model $P(\mathbf{y}|\mathbf{x};\overrightarrow{\boldsymbol{\theta}})$ serves as an encoder to transform the observed source sentence $\mathbf{x}$ into a latent target sentence $\mathbf{y}$ (highlighted in grey), from which the target-to-source model $P(\mathbf{x}'|\mathbf{y};\overleftarrow{\boldsymbol{\theta}})$ reconstructs a copy of the observed source sentence $\mathbf{x}'$ from the latent target sentence. As a result, monolingual corpora can be combined with parallel corpora to train bidirectional NMT models in a semi-supervised setting.

and attention model are fixed when training on these pseudo parallel sentence pairs. In the second approach, they first train a nerual translation model on the parallel corpus and then use the learned model to translate a monolingual corpus. The monolingual corpus and its translations constitute an additional pseudo parallel corpus. Similar ideas have also been suggested in conventional SMT (Ueffing et al., 2007; Bertoldi and Federico, 2009). Sennrich et al. (2015) report that their approach significantly improves translation quality across a variety of language pairs.

In this paper, we propose semi-supervised learning for neural machine translation. Given labeled (i.e., parallel corpora) and unlabeled (i.e., monolingual corpora) data, our approach jointly trains source-to-target and target-to-source translation models. The key idea is to append a reconstruction term to the training objective, which aims to reconstruct the observed monolingual corpora using an autoencoder. In the autoencoder, the source-to-target and target-to-source models serve as the encoder and decoder, respectively. As the inference is intractable, we propose to sample the full search space to improve the efficiency. Specifically, our approach has the following advantages:

1. *Transparent to network architectures*: our approach does not depend on specific architectures and can be easily applied to arbitrary end-to-end NMT systems.
2. *Both the source and target monolingual corpora can be used*: our approach can benefit NMT not only using target monolingual corpora in a conventional way, but also the monolingual corpora of the source language.

Experiments on Chinese-English NIST datasets show that our approach results in significant improvements in both directions over state-of-the-art SMT and NMT systems.

2 Semi-Supervised Learning for Neural Machine Translation

2.1 Supervised Learning

Given a parallel corpus $\mathcal{D} = \{\langle \mathbf{x}^{(n)}, \mathbf{y}^{(n)} \rangle\}_{n=1}^{N}$, the standard training objective in NMT is to maximize the likelihood of the training data:

$$L(\boldsymbol{\theta}) = \sum_{n=1}^{N} \log P(\mathbf{y}^{(n)}|\mathbf{x}^{(n)};\boldsymbol{\theta}), \quad (1)$$

where $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta})$ is a neural translation model and $\boldsymbol{\theta}$ is a set of model parameters. $\mathcal{D}$ can be seen as *labeled* data for the task of predicting a target sentence $\mathbf{y}$ given a source sentence $\mathbf{x}$.

As $P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta})$ is modeled by a single, large neural network, there does not exist a separate target language model $P(\mathbf{y};\boldsymbol{\theta})$ in NMT. Therefore, parallel corpora have been the only resource for parameter estimation in most existing NMT systems. Unfortunately, even for a handful of resource-rich

languages, the available domains are unbalanced and restricted to government documents and news reports. Therefore, the availability of large-scale, high-quality, and wide-coverage parallel corpora becomes a major obstacle for NMT.

2.2 Autoencoders on Monolingual Corpora

It is appealing to explore the more readily available, abundant monolingual corpora to improve NMT. Let us first consider an *unsupervised* setting: how to train NMT models on a monolingual corpus $\mathcal{T} = \{\mathbf{y}^{(t)}\}_{t=1}^{T}$?

Our idea is to leverage *autoencoders* (Vincent et al., 2010; Socher et al., 2011): (1) *encoding* an observed target sentence into a latent source sentence using a target-to-source translation model and (2) *decoding* the source sentence to reconstruct the observed target sentence using a source-to-target model. For example, as shown in Figure 1(b), given an observed English sentence "Bush held a talk with Sharon", a target-to-source translation model (i.e., encoder) transforms it into a Chinese translation "bushi yu shalong juxing le huitan" that is unobserved on the training data (highlighted in grey). Then, a source-to-target translation model (i.e., decoder) reconstructs the observed English sentence from the Chinese translation.

More formally, let $P(\mathbf{y}|\mathbf{x};\overrightarrow{\boldsymbol{\theta}})$ and $P(\mathbf{x}|\mathbf{y};\overleftarrow{\boldsymbol{\theta}})$ be *source-to-target* and *target-to-source* translation models respectively, where $\overrightarrow{\boldsymbol{\theta}}$ and $\overleftarrow{\boldsymbol{\theta}}$ are corresponding model parameters. An autoencoder aims to reconstruct the observed target sentence via a latent source sentence:

$$\begin{aligned} & P(\mathbf{y}'|\mathbf{y};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}}) \\ = & \sum_{\mathbf{x}} P(\mathbf{y}',\mathbf{x}|\mathbf{y};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}}) \\ = & \sum_{\mathbf{x}} \underbrace{P(\mathbf{x}|\mathbf{y};\overleftarrow{\boldsymbol{\theta}})}_{encoder} \underbrace{P(\mathbf{y}'|\mathbf{x};\overrightarrow{\boldsymbol{\theta}})}_{decoder}, \end{aligned} \quad (2)$$

where $\mathbf{y}$ is an observed target sentence, $\mathbf{y}'$ is a copy of $\mathbf{y}$ to be reconstructed, and $\mathbf{x}$ is a latent source sentence.

We refer to Eq. (2) as a *target autoencoder*. [1] Likewise, given a monolingual corpus of source language $\mathcal{S} = \{\mathbf{x}^{(s)}\}_{s=1}^{S}$, it is natural to introduce a *source autoencoder* that aims at reconstructing the observed source sentence via a latent target sentence:

$$\begin{aligned} & P(\mathbf{x}'|\mathbf{x};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}}) \\ = & \sum_{\mathbf{y}} P(\mathbf{x}',\mathbf{y}|\mathbf{x};\overleftarrow{\boldsymbol{\theta}}) \\ = & \sum_{\mathbf{y}} \underbrace{P(\mathbf{y}|\mathbf{x};\overrightarrow{\boldsymbol{\theta}})}_{encoder} \underbrace{P(\mathbf{x}'|\mathbf{y};\overleftarrow{\boldsymbol{\theta}})}_{decoder}. \end{aligned} \quad (3)$$

Please see Figure 1(a) for illustration.

2.3 Semi-Supervised Learning

As the autoencoders involve both source-to-target and target-to-source models, it is natural to combine parallel corpora and monolingual corpora to learn birectional NMT translation models in a semi-supervised setting.

Formally, given a parallel corpus $\mathcal{D} = \{\langle \mathbf{x}^{(n)}, \mathbf{y}^{(n)} \rangle\}_{n=1}^{N}$, a monolingual corpus of target language $\mathcal{T} = \{\mathbf{y}^{(t)}\}_{t=1}^{T}$, and a monolingual corpus of source language $\mathcal{S} = \{\mathbf{x}^{(s)}\}_{s=1}^{S}$, we introduce our new semi-supervised training objective as follows:

$$\begin{aligned} & J(\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}}) \\ = & \underbrace{\sum_{n=1}^{N} \log P(\mathbf{y}^{(n)}|\mathbf{x}^{(n)};\overrightarrow{\boldsymbol{\theta}})}_{source\text{-}to\text{-}target\ likelihood} \\ & + \underbrace{\sum_{n=1}^{N} \log P(\mathbf{x}^{(n)}|\mathbf{y}^{(n)};\overleftarrow{\boldsymbol{\theta}})}_{target\text{-}to\text{-}source\ likelihood} \\ & + \lambda_1 \underbrace{\sum_{t=1}^{T} \log P(\mathbf{y}'|\mathbf{y}^{(t)};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}})}_{target\ autoencoder} \\ & + \lambda_2 \underbrace{\sum_{s=1}^{S} \log P(\mathbf{x}'|\mathbf{x}^{(s)};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}})}_{source\ autoencoder}, \end{aligned} \quad (4)$$

where λ_1 and λ_2 are hyper-parameters for balancing the preference between likelihood and autoencoders.

Note that the objective consists of four parts: source-to-target likelihood, target-to-source likelihood, target autoencoder, and source autoencoder. In this way, our approach is capable of exploiting abundant monolingual corpora of both source and target languages.

[1] Our definition of auotoencoders is inspired by Ammar et al. (2014). Note that our autoencoders inherit the same spirit from conventional autoencoders (Vincent et al., 2010; Socher et al., 2011) except that the hidden layer is denoted by a latent sentence instead of real-valued vectors.

The optimal model parameters are given by

$$\overrightarrow{\boldsymbol{\theta}}^* = \text{argmax}\left\{\sum_{n=1}^{N}\log P(\mathbf{y}^{(n)}|\mathbf{x}^{(n)};\overrightarrow{\boldsymbol{\theta}}) + \lambda_1\sum_{t=1}^{T}\log P(\mathbf{y}'|\mathbf{y}^{(t)};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}}) + \lambda_2\sum_{s=1}^{S}\log P(\mathbf{x}'|\mathbf{x}^{(s)};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}})\right\} \quad (5)$$

$$\overleftarrow{\boldsymbol{\theta}}^* = \text{argmax}\left\{\sum_{n=1}^{N}\log P(\mathbf{x}^{(n)}|\mathbf{y}^{(n)};\overleftarrow{\boldsymbol{\theta}}) + \lambda_1\sum_{t=1}^{T}\log P(\mathbf{y}'|\mathbf{y}^{(t)};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}}) + \lambda_2\sum_{s=1}^{S}\log P(\mathbf{x}'|\mathbf{x}^{(s)};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}})\right\} \quad (6)$$

It is clear that the source-to-target and target-to-source models are connected via the autoencoder and can hopefully benefit each other in joint training.

2.4 Training

We use mini-batch stochastic gradient descent to train our joint model. For each iteration, besides the mini-batch from the parallel corpus, we also construct two additional mini-batches by randomly selecting sentences from the source and target monolingual corpora. Then, gradients are collected from these mini-batches to update model parameters.

The partial derivative of $J(\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}})$ with respect to the source-to-target model $\overrightarrow{\boldsymbol{\theta}}$ is given by

$$\begin{aligned}&\frac{\partial J(\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}})}{\partial\overrightarrow{\boldsymbol{\theta}}}\\ =&\sum_{n=1}^{N}\frac{\partial\log P(\mathbf{y}^{(n)}|\mathbf{x}^{(n)};\overrightarrow{\boldsymbol{\theta}})}{\partial\overrightarrow{\boldsymbol{\theta}}}\\ &+\lambda_1\sum_{t=1}^{T}\frac{\partial\log P(\mathbf{y}'|\mathbf{y}^{(t)};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}})}{\partial\overrightarrow{\boldsymbol{\theta}}}\\ &+\lambda_2\sum_{s=1}^{S}\frac{\partial\log P(\mathbf{x}'|\mathbf{x}^{(s)};\overrightarrow{\boldsymbol{\theta}},\overleftarrow{\boldsymbol{\theta}})}{\partial\overrightarrow{\boldsymbol{\theta}}}. \quad (7)\end{aligned}$$

The partial derivative with respect to $\overleftarrow{\boldsymbol{\theta}}$ can be calculated similarly.

Unfortunately, the second and third terms in Eq. (7) are intractable to calculate due to the exponential search space. For example, the derivative in the third term in Eq. (7) is given by

$$\frac{\sum_{\mathbf{x}\in\mathcal{X}(\mathbf{y})}P(\mathbf{x}|\mathbf{y};\overleftarrow{\boldsymbol{\theta}})P(\mathbf{y}'|\mathbf{x};\overrightarrow{\boldsymbol{\theta}})\frac{\partial\log P(\mathbf{y}'|\mathbf{x};\overrightarrow{\boldsymbol{\theta}})}{\partial\overrightarrow{\boldsymbol{\theta}}}}{\sum_{\mathbf{x}\in\mathcal{X}(\mathbf{y})}P(\mathbf{x}|\mathbf{y};\overleftarrow{\boldsymbol{\theta}})P(\mathbf{y}'|\mathbf{x};\overrightarrow{\boldsymbol{\theta}})}. \quad (8)$$

It is prohibitively expensive to compute the sums due to the exponential search space of $\mathcal{X}(\mathbf{y})$.

Alternatively, we propose to use a subset of the full space $\tilde{\mathcal{X}}(\mathbf{y}) \subset \mathcal{X}(\mathbf{y})$ to approximate Eq. (8):

$$\frac{\sum_{\mathbf{x}\in\tilde{\mathcal{X}}(\mathbf{y})}P(\mathbf{x}|\mathbf{y};\overleftarrow{\boldsymbol{\theta}})P(\mathbf{y}'|\mathbf{x};\overrightarrow{\boldsymbol{\theta}})\frac{\partial\log P(\mathbf{y}'|\mathbf{x};\overrightarrow{\boldsymbol{\theta}})}{\partial\overrightarrow{\boldsymbol{\theta}}}}{\sum_{\mathbf{x}\in\tilde{\mathcal{X}}(\mathbf{y})}P(\mathbf{x}|\mathbf{y};\overleftarrow{\boldsymbol{\theta}})P(\mathbf{y}'|\mathbf{x};\overrightarrow{\boldsymbol{\theta}})}. \quad (9)$$

In practice, we use the top-k list of candidate translations of $\mathbf{y}$ as $\tilde{\mathcal{X}}(\mathbf{y})$. As $|\tilde{\mathcal{X}}(\mathbf{y})| \ll \mathcal{X}|(\mathbf{y})|$, it is possible to calculate Eq. (9) efficiently by enumerating all candidates in $\tilde{\mathcal{X}}(\mathbf{y})$. In practice, we find this approximation results in significant improvements and $k = 10$ seems to suffice to keep the balance between efficiency and translation quality.

		Chinese	English
Parallel	# Sent.	2.56M	
	# Word	67.54M	74.82M
	Vocab.	0.21M	0.16M
Monolingual	# Sent.	18.75M	22.32M
	# Word	451.94M	399.83M
	Vocab.	0.97M	1.34M

Table 1: Characteristics of parallel and monolingual corpora.

3 Experiments

3.1 Setup

We evaluated our approach on the Chinese-English dataset.

As shown in Table 1, we use both a parallel corpus and two monolingual corpora as the training set. The parallel corpus from LDC consists of 2.56M sentence pairs with 67.53M Chinese words and 74.81M English words. The vocabulary sizes of Chinese and English are 0.21M and 0.16M, respectively. We use the Chinese and English parts of the Xinhua portion of the GIGAWORD corpus as the monolingual corpora. The Chinese monolingual corpus contains 18.75M sentences with 451.94M words. The English corpus contains 22.32M sentences with 399.83M words. The vocabulary sizes of Chinese and English are 0.97M and 1.34M, respectively.

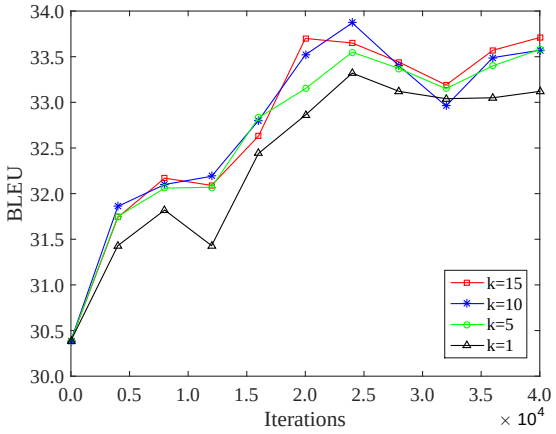

Figure 2: Effect of sample size k on the Chinese-to-English validation set.

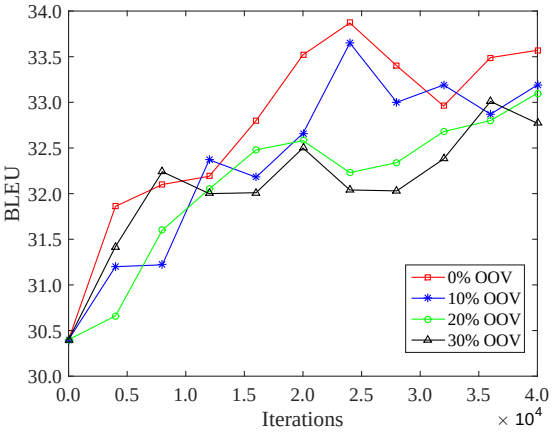

Figure 4: Effect of OOV ratio on the Chinese-to-English validation set.

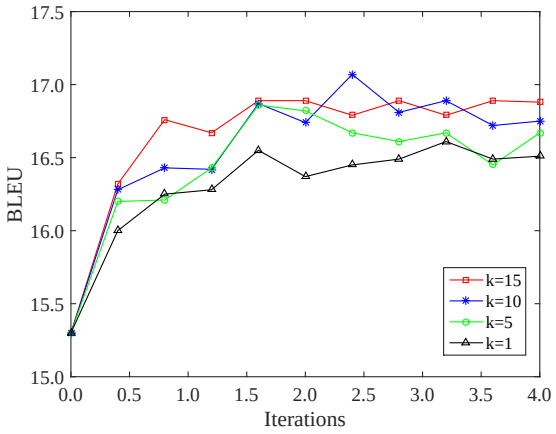

Figure 3: Effect of sample size k on the English-to-Chinese validation set.

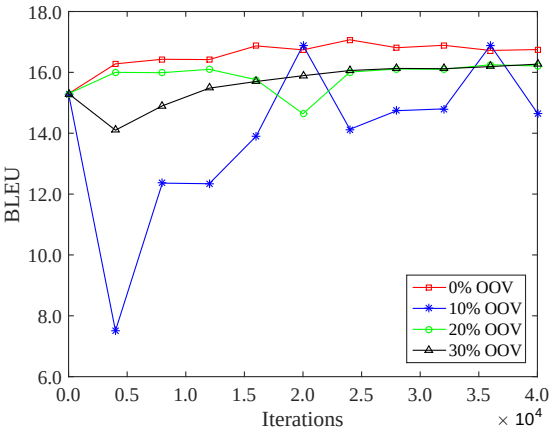

Figure 5: Effect of OOV ratio on the English-to-Chinese validation set.

For Chinese-to-English translation, we use the NIST 2006 Chinese-English dataset as the validation set for hyper-parameter optimization and model selection. The NIST 2002, 2003, 2004, and 2005 datasets serve as test sets. Each Chinese sentence has four reference translations. For English-to-Chinese translation, we use the NIST datasets in a reverse direction: treating the first English sentence in the four reference translations as a source sentence and the original input Chinese sentence as the single reference translation. The evaluation metric is case-insensitive BLEU (Papineni et al., 2002) as calculated by the `multi-bleu.perl` script.

We compared our approach with two state-of-the-art SMT and NMT systems:

1. MOSES (Koehn et al., 2007): a phrase-based SMT system;
2. RNNSEARCH (Bahdanau et al., 2015): an attention-based NMT system.

For MOSES, we use the default setting to train the phrase-based translation on the parallel corpus and optimize the parameters of log-linear models using the minimum error rate training algorithm (Och, 2003). We use the SRILM toolkit (Stolcke, 2002) to train 4-gram language models.

For RNNSEARCH, we use the parallel corpus to train the attention-based neural translation models. We set the vocabulary size of word embeddings to 30K for both Chinese and English. We follow Luong et al. (2015) to address rare words.

On top of RNNSEARCH, our approach is capable of training bidirectional attention-based neural translation models on the concatenation of parallel and monolingual corpora. The sample size k is set to 10. We set the hyper-parameter $\lambda_1 = 0.1$ and

$\lambda_2 = 0$ when we add the target monolingual corpus, and $\lambda_1 = 0$ and $\lambda_2 = 0.1$ for source monolingual corpus incorporation. The threshold of gradient clipping is set to 0.05. The parameters of our model are initialized by the model trained on parallel corpus.

3.2 Effect of Sample Size k

As the inference of our approach is intractable, we propose to approximate the full search space with the top-k list of candidate translations to improve efficiency (see Eq. (9)).

Figure 2 shows the BLEU scores of various settings of k over time. Only the English monolingual corpus is appended to the training data. We observe that increasing the size of the approximate search space generally leads to improved BLEU scores. There are significant gaps between $k = 1$ and $k = 5$. However, keeping increasing k does not result in significant improvements and decreases the training efficiency. We find that $k = 10$ achieves a balance between training efficiency and translation quality. As shown in Figure 3, similar findings are also observed on the English-to-Chinese validation set. Therefore, we set $k = 10$ in the following experiments.

3.3 Effect of OOV Ratio

Given a parallel corpus, what kind of monolingual corpus is most beneficial for improving translation quality? To answer this question, we investigate the effect of *OOV ratio* on translation quality, which is defined as

$$\text{ratio} = \frac{\sum_{y \in \mathbf{y}} [\![y \notin \mathcal{V}_{D_t}]\!]}{|\mathbf{y}|}, \quad (10)$$

where $\mathbf{y}$ is a target-language sentence in the monolingual corpus $\mathcal{T}$, y is a target-language word in $\mathbf{y}$, $\mathcal{V}_{D_t}$ is the vocabulary of the target side of the parallel corpus D.

Intuitively, the OOV ratio indicates how a sentence in the monolingual resembles the parallel corpus. If the ratio is 0, all words in the monolingual sentence also occur in the parallel corpus.

Figure 4 shows the effect of OOV ratio on the Chinese-to-English validation set. Only English monolingual corpus is appended to the parallel corpus during training. We constructed four monolingual corpora of the same size in terms of sentence pairs. "0% OOV" means the OOV ratio is 0% for all sentences in the monolingual corpus. "10% OOV" suggests that the OOV ratio is no greater 10% for each sentence in the monolingual corpus. We find that using a monolingual corpus with a lower OOV ratio generally leads to higher BLEU scores. One possible reason is that low-OOV monolingual corpus is relatively easier to reconstruct than its high-OOV counterpart and results in better estimation of model parameters.

Figure 5 shows the effect of OOV ratio on the English-to-Chinese validation set. Only English monolingual corpus is appended to the parallel corpus during training. We find that "0% OOV" still achieves the highest BLEU scores.

3.4 Comparison with SMT

Table 2 shows the comparison between MOSES and our work. MOSES used the monolingual corpora as shown in Table 1: 18.75M Chinese sentences and 22.32M English sentences. We find that exploiting monolingual corpora dramatically improves translation performance in both Chinese-to-English and English-to-Chinese directions.

Relying only on parallel corpus, RNNSEARCH outperforms MOSES trained also only on parallel corpus. But the capability of making use of abundant monolingual corpora enables MOSES to achieve much higher BLEU scores than RNNSEARCH only using parallel corpus.

Instead of using all sentences in the monolingual corpora, we constructed smaller monolingual corpora with zero OOV ratio: 2.56M Chinese sentences with 47.51M words and 2.56M English English sentences with 37.47M words. In other words, the monolingual corpora we used in the experiments are much smaller than those used by MOSES.

By adding English monolingual corpus, our approach achieves substantial improvements over RNNSEARCH using only parallel corpus (up to +4.7 BLEU points). In addition, significant improvements are also obtained over MOSES using both parallel and monolingual corpora (up to +3.5 BLEU points).

An interesting finding is that adding English monolingual corpora helps to improve English-to-Chinese translation over RNNSEARCH using only parallel corpus (up to +3.2 BLEU points), suggesting that our approach is capable of improving NMT using source-side monolingual corpora.

In the English-to-Chinese direction, we obtain similar findings. In particular, adding Chi-

System	Training Data			Direction	NIST06	NIST02	NIST03	NIST04	NIST05

				E →C	21.12^{**}	29.52^{**}	20.49	21.59^{**}	19.97^{**}

Table 3: Comparison with Sennrich et al. (2015). Both Sennrich et al. (2015) and our approach build on top of RNNSEARCH to exploit monolingual corpora. The BLEU scores are case-insensitive. "*": significantly better than Sennrich et al. (2015) ($p < 0.05$); "**": significantly better than Sennrich et al. (2015) ($p < 0.01$).

nese monolingual corpus leads to more benefits to English-to-Chinese translation than adding English monolingual corpus. We also tried to use both Chinese and English monolingual corpora through simply setting all the λ to 0.1 but failed to obtain further significant improvements.

Therefore, our findings can be summarized as follows:

1. Adding target monolingual corpus improves over using only parallel corpus for source-to-target translation;
2. Adding source monolingual corpus also improves over using only parallel corpus for source-to-target translation, but the improvements are smaller than adding target monolingual corpus;
3. Adding both source and target monolingual corpora does not lead to further significant improvements.

3.5 Comparison with Previous Work

We re-implemented Sennrich et al. (2015)'s method on top of RNNSEARCH as follows:

1. Train the target-to-source neural translation model $P(\mathbf{x}|\mathbf{y}; \overleftarrow{\boldsymbol{\theta}})$ on the parallel corpus $D = \{\langle \mathbf{x}^{(n)}, \mathbf{y}^{(n)} \rangle\}_{n=1}^{N}$.
2. The trained target-to-source model $\overleftarrow{\boldsymbol{\theta}}^{*}$ is used to translate a target monolingual corpus $\mathcal{T} = \{\mathbf{y}^{(t)}\}_{t=1}^{T}$ into a source monolingual corpus $\tilde{\mathcal{S}} = \{\tilde{\mathbf{x}}^{(t)}\}_{t=1}^{T}$.
3. The target monolingual corpus is paired with its translations to form a pseudo parallel corpus, which is then appended to the original parallel corpus to obtain a larger parallel corpus: $\tilde{\mathcal{D}} = \mathcal{D} \cup \langle \tilde{\mathcal{S}}, \mathcal{T} \rangle$.
4. Re-train the the source-to-target neural translation model on $\tilde{\mathcal{D}}$ to obtain the final model parameters $\overrightarrow{\boldsymbol{\theta}}^{*}$.

Table 4: Example translations of sentences in the monolingual corpus during semi-supervised learning. We find our approach is capable of generating better translations of the monolingual corpus over time.

Table 3 shows the comparison results. Both the two approaches use the same parallel and monolingual corpora. Our approach achieves significant improvements over Sennrich et al. (2015) in both Chinese-to-English and English-to-Chinese directions (up to +1.8 and +1.0 BLEU points). One possible reason is that Sennrich et al. (2015) only use the pesudo parallel corpus for parameter estimation for once (see Step 4 above) while our approach enables source-to-target and target-to-source models to interact with each other iteratively on both parallel and monolingual corpora.

To some extent, our approach can be seen as an iterative extension of Sennrich et al. (2015)'s approach: after estimating model parameters on the pseudo parallel corpus, the learned model parameters are used to produce a better pseudo parallel corpus. Table 4 shows example Viterbi translations on the Chinese monolingual corpus over iterations:

$$\mathbf{x}^* = \arg\max_{\mathbf{x}} \left\{ P(\mathbf{y}'|\mathbf{x}; \overrightarrow{\boldsymbol{\theta}}) P(\mathbf{x}|\mathbf{y}; \overleftarrow{\boldsymbol{\theta}}) \right\}. \quad (11)$$

We observe that the quality of Viterbi translations generally improves over time.

4 Related Work

Our work is inspired by two lines of research: (1) exploiting monolingual corpora for machine translation and (2) autoencoders in unsupervised and semi-supervised learning.

4.1 Exploiting Monolingual Corpora for Machine Translation

Exploiting monolingual corpora for conventional SMT has attracted intensive attention in recent years. Several authors have introduced transductive learning to make full use of monolingual corpora (Ueffing et al., 2007; Bertoldi and Federico, 2009). They use an existing translation model to translate unseen source text, which can be paired with its translations to form a pseudo parallel corpus. This process iterates until convergence. While Klementiev et al. (2012) propose an approach to estimating phrase translation probabilities from monolingual corpora, Zhang and Zong (2013) directly extract parallel phrases from monolingual corpora using retrieval techniques. Another important line of research is to treat translation on monolingual corpora as a decipherment problem (Ravi and Knight, 2011; Dou et al., 2014).

Closely related to Gulccehre et al. (2015) and Sennrich et al. (2015), our approach focuses on learning birectional NMT models via autoencoders on monolingual corpora. The major advantages of our approach are the transparency to network architectures and the capability to exploit both source and target monolingual corpora.

4.2 Autoencoders in Unsupervised and Semi-Supervised Learning

Autoencoders and their variants have been widely used in unsupervised deep learning ((Vincent et al., 2010; Socher et al., 2011; Ammar et al., 2014), just to name a few). Among them, Socher et al. (2011)'s approach bears close resemblance to our approach as they introduce semi-supervised recursive autoencoders for sentiment analysis. The difference is that we are interested in making a better use of parallel and monolingual corpora while they concentrate on injecting partial supervision to conventional unsupervised autoencoders. Dai and Le (2015) introduce a sequence autoencoder to reconstruct an observed sequence via RNNs. Our approach differs from sequence autoencoders in that we use bidirectional translation models as encoders and decoders to enable them to interact within the autoencoders.

5 Conclusion

We have presented a semi-supervised approach to training bidirectional neural machine translation models. The central idea is to introduce autoencoders on the monolingual corpora with source-to-target and target-to-source translation models as encoders and decoders. Experiments on Chinese-English NIST datasets show that our approach leads to significant improvements.

As our method is sensitive to the OOVs present in monolingual corpora, we plan to integrate Jean et al. (2015)'s technique on using very large vocabulary into our approach. It is also necessary to further validate the effectiveness of our approach on more language pairs and NMT architectures. Another interesting direction is to enhance the connection between source-to-target and target-to-source models (e.g., letting the two models share the same word embeddings) to help them benefit more from interacting with each other.

Strategies for Training Large Vocabulary Neural Language Models

Wenlin Chen **David Grangier** **Michael Auli**
Facebook, Menlo Park, CA

Abstract

Training neural network language models over large vocabularies is computationally costly compared to count-based models such as Kneser-Ney. We present a systematic comparison of neural strategies to represent and train large vocabularies, including softmax, hierarchical softmax, target sampling, noise contrastive estimation and self normalization. We extend self normalization to be a proper estimator of likelihood and introduce an efficient variant of softmax. We evaluate each method on three popular benchmarks, examining performance on rare words, the speed/accuracy trade-off and complementarity to Kneser-Ney.

1 Introduction

Neural network language models (Bengio et al., 2003; Mikolov et al., 2010) have gained popularity for tasks such as automatic speech recognition (Arisoy et al., 2012) and statistical machine translation (Schwenk et al., 2012; Vaswani et al., 2013; Baltescu and Blunsom, 2014). Similar models are also developed for translation (Le et al., 2012; Devlin et al., 2014; Bahdanau et al., 2015), summarization (Chopra et al., 2015) and language generation (Sordoni et al., 2015).

Language models assign a probability to a word given a context of preceding, and possibly subsequent, words. The model architecture determines how the context is represented and there are several choices including recurrent neural networks (Mikolov et al., 2010; Jozefowicz et al., 2016), or log-bilinear models (Mnih and Hinton, 2010). This paper does not focus on architecture or context representation but rather on how to efficiently deal with large output vocabularies, a problem common to all approaches to neural language modeling and related tasks (machine translation, language generation). We therefore experiment with a classical feed-forward neural network model similar to Bengio et al. (2003).

Practical training speed for these models quickly decreases as the vocabulary grows. This is due to three combined factors: (i) model evaluation and gradient computation become more time consuming, mainly due to the need of computing normalized probabilities over a large vocabulary; (ii) large vocabularies require more training data in order to observe enough instances of infrequent words which increases training times; (iii) a larger training set often allows for larger models which requires more training iterations.

This paper provides an overview of popular strategies to model large vocabularies for language modeling. This includes the classical *softmax* over all output classes, *hierarchical softmax* which introduces latent variables, or clusters, to simplify normalization, target sampling which only considers a random subset of classes for normalization, *noise contrastive estimation* which discriminates between genuine data points and samples from a noise distribution, and *infrequent normalization*, also referred as self-normalization, which computes the partition function at an infrequent rate. We also extend self-normalization to be a proper estimator of likelihood. Furthermore, we introduce *differentiated softmax*, a novel variation of softmax which assigns more parameters, or capacity, to frequent words and which we show to be faster and more accurate than softmax (§2).

Our comparison assumes a reasonable budget of one week for training models on a high end GPU (Nvidia K40). We evaluate on three benchmarks differing in the amount of training data and vocabulary size, that is Penn Treebank, Gigaword and the Billion Word benchmark (§3).

Our results show that conclusions drawn from small datasets do not always generalize to larger settings. For instance, hierarchical softmax is less accurate than softmax on the small vocabulary Penn Treebank task but performs best on the very large vocabulary Billion Word benchmark. This is because hierarchical softmax is the fastest method for training and can perform more training updates in the same period of time. Furthermore, our re-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1975–1985,
Berlin, Germany, August 7-12, 2016.

sults with differentiated softmax demonstrate that assigning capacity where it has the most impact allows to train better models in our time budget (§4). Our analysis also shows clearly that traditional Kneser-Ney models are competitive on rare words, contrary to the common belief that neural models are better on infrequent words (§5).

2 Modeling Large Vocabularies

We first introduce our model architecture with a classical softmax and then describe various other methods including a novel variation of softmax.

2.1 Softmax Neural Language Model

Our feed-forward neural network implements an n-gram language model, i.e., it is a parametric function estimating the probability of the next word w^t given $n-1$ previous context words, $w^{t-1}, \ldots, w^{t-n+1}$. Formally, we take as input a sequence of discrete indexes representing the $n-1$ previous words and output a vocabulary-sized vector of probability estimates, i.e.,

$$f : \{1, \ldots, V\}^{n-1} \rightarrow [0,1]^V,$$

where V is the vocabulary size. This function results from the composition of simple differentiable functions or *layers*.

Specifically, f composes an input mapping from discrete word indexes to continuous vectors, a succession of linear operations followed by hyperbolic tangent non-linearities, plus one final linear operation, followed by a softmax normalization.

The input layer maps each context word index to a continuous d'_0-dimensional vector. It relies on a matrix $W^0 \in \mathbb{R}^{V \times d'_0}$ to convert the input

$$x = [w^{t-1}, \ldots, w^{t-n+1}] \in \{1, \ldots, V\}^{n-1}$$

to $n-1$ vectors of dimension d'_0. These vectors are concatenated into a single $(n-1) \times d'_0$ matrix,

$$h^0 = [W^0_{w^{t-1}}; \ldots; W^0_{w^{t-n+1}}] \in \mathbb{R}^{n-1 \times d'_0}.$$

This state h^0 is considered as a $d_0 = (n-1) \times d'_0$ vector by the next layer. The subsequent states are computed through k layers of linear mappings followed by hyperbolic tangents, i.e.

$$\forall i = 1, \ldots, k, \quad h^i = \tanh(W^i h^{i-1} + b^i) \in \mathbb{R}^{d_i}$$

where $W^i \in \mathbb{R}^{d_i \times d_{i-1}}, b \in \mathbb{R}^{d_i}$ are learnable weights and biases and $\tanh$ denotes the component-wise hyperbolic tangent.

Finally, the last layer performs a linear operation followed by a softmax normalization, i.e.,

$$\begin{aligned} & h^{k+1} = W^{k+1} h^k + b^{k+1} \in \mathbb{R}^V \\ \text{and} \quad & y = \tfrac{1}{Z} \exp(h^{k+1}) \in [0,1]^V \end{aligned} \tag{1}$$

where $Z = \sum_{j=1}^{V} \exp(h^{k+1}_j)$ and $\exp$ denotes the component-wise exponential. The network output y is therefore a vocabulary-sized vector of probability estimates. We use the standard cross-entropy loss with respect to the computed log probabilities

$$\frac{\partial \log y_i}{\partial h^{k+1}_j} = \delta_{ij} - y_j$$

where $\delta_{ij} = 1$ if $i = j$ and 0 otherwise The gradient update therefore increases the score of the correct output h^{k+1}_i and decreases the score of all other outputs h^{k+1}_j for $j \neq i$.

A downside of the classical softmax formulation is that it requires computation of the activations for *all output words*, Eq. (1). The output layer with V activations is much larger than any other layer in the network and its matrix multiplication dominates the complexity of the entire network.

2.2 Hierarchical Softmax

Hierarchical Softmax (HSM) organizes the output vocabulary into a tree where the leaves are the words and the intermediate nodes are latent variables, or *classes* (Morin and Bengio, 2005). The tree has potentially many levels and there is a unique path from the root to each word. The probability of a word is the product of the probabilities of the latent variables along the path from the root to the leaf, including the probability of the leaf.

We follow Goodman (2001) and Mikolov et al. (2011b) and model a two-level tree. Given context x, HSM predicts the *class* of the next word c^t and the actual word w^t

$$p(w^t|x) = p(c^t|x)\, p(w^t|c^t, x) \tag{2}$$

If the number of classes is $\mathcal{O}(\sqrt{V})$ and classes are balanced, then we only need to compute $\mathcal{O}(2\sqrt{V})$ outputs. In practice, this strategy results in weight matrices whose largest dimension is $< 1,000$, a setting for which GPU hardware is fast.

A popular strategy is *frequency* clustering. It sorts the vocabulary by frequency and then forms clusters of words with similar frequency. Each cluster contains an equal share of the total unigram probability. We compare this strategy to random class assignment and to clustering based on word

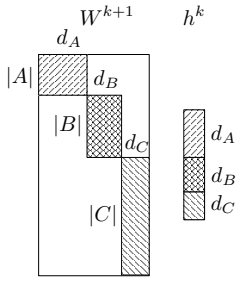

Figure 1: Output weight matrix W^{k+1} and hidden layer h^k for differentiated softmax for vocabulary partitions A, B, C with embedding dimensions d_A, d_B, d_C; non-shaded areas are zero.

contexts, relying on PCA (Lebret and Collobert, 2014). A full comparison of context-based clustering is beyond the scope of this work (Brown et al., 1992; Mikolov et al., 2013).

2.3 Differentiated Softmax

This section introduces a novel variation of softmax that assigns a variable number of parameters to each word in the output layer. The weight matrix of the final layer $W^{k+1} \in \mathbb{R}^{d_k \times V}$ stores *output embeddings* of size d_k for the V words the language model may predict: $W_1^{k+1}; \ldots; W_V^{k+1}$. Differentiated softmax (D-Softmax) varies the dimension of the output embeddings d_k across words depending on how much model capacity, or parameters, are deemed suitable for a given word. We assign more parameters to frequent words than to rare words since more training occurrences allow for fitting more parameters.

We partition the output vocabulary based on word frequency and the words in each partition share the same embedding size. Partitioning the vocabulary in this way results in a sparse final weight matrix W^{k+1} which arranges the embeddings of the output words in blocks, each block corresponding to a separate partition (Figure 1). The size of the final hidden layer h^k is the sum of the embedding sizes of the partitions. The final hidden layer is effectively a concatenation of separate features for each partition which are used to compute the dot product with the corresponding embedding type in W^{k+1}. In practice, we efficiently compute separate matrix-vector products, or in batched form, matrix-matrix products, for each partition in W^{k+1} and h^k.

Overall, differentiated softmax can lead to large speed-ups as well as accuracy gains since we can greatly reduce the complexity of computing the output layer. Most significantly, this strategy speeds up *both* training and inference. This is in contrast to hierarchical softmax which is fast during training but requires even more effort than softmax for computing the most likely next word.

2.4 Target Sampling

Sampling-based methods approximate the softmax normalization, Eq. (1), by summing over a sub-sample of impostor classes. This can significantly speed-up each training iteration, depending on the size of the impostor set. Target sampling builds upon the importance sampling work of Bengio and Senécal (2008). We follow Jean et al. (2014) who choose as impostors all positive examples in a mini-batch as well as a subset of the remaining words. This subset is sampled uniformly and its size is chosen by validation.

2.5 Noise Contrastive Estimation

Noise contrastive estimation (NCE) is another sampling-based technique (Hyvärinen, 2010; Mnih and Teh, 2012; Chen et al., 2015). Contrary to target sampling, it does not maximize the training data likelihood directly. Instead, it solves a two-class problem of distinguishing genuine data from noise samples. The training algorithm samples a word w given the preceding context x from a mixture

$$p(w|x) = \frac{1}{k+1} p_{\text{train}}(w|x) + \frac{k}{k+1} p_{\text{noise}}(w|x)$$

where p_{train} is the empirical distribution of the training set and p_{noise} is a known noise distribution which is typically a context-independent unigram distribution. The training algorithm fits the model $\hat{p}(w|x)$ to recover whether a mixture sample came from the data or the noise distribution, this amounts to minimizing the binary cross-entropy $-y \log \hat{p}(y=1|w,x) - (1-y) \log \hat{p}(y=0|w,x)$ where y is a binary variable indicating where the current sample originates from

$$\begin{cases} \hat{p}(y=1|w,x) = \frac{\hat{p}(w|x)}{\hat{p}(w|x) + k p_{\text{noise}}(w|x)} & \text{(data)} \\ \hat{p}(y=0|w,x) = 1 - \hat{p}(y=1|w,x) & \text{(noise).} \end{cases}$$

This formulation still involves a softmax over the vocabulary to compute $\hat{p}(w|x)$. However, Mnih and Teh (2012) suggest to forego normalization and replace $\hat{p}(w|x)$ with unnormalized exponentiated scores. This makes the training complexity independent of the vocabulary size. At test time, softmax normalization is reintroduced to get a proper distribution. We also follow Mnih and Teh (2012) recommendations for p_{noise} and rely on a unigram distribution of the training set.

2.6 Infrequent Normalization

Devlin et al. (2014), followed by Andreas and Klein (2015), proposed to relax score normalization. Their strategy (here referred to as WeaknormSQ) associates unnormalized likelihood maximization with a penalty term that favors normalized predictions. This yields the following loss over the training set T

$$L_{\alpha}^{(2)} = -\sum_{(w,x)\in T} s(w|x) + \alpha \sum_{(w,x)\in T} (\log Z(x))^2$$

where $s(w|x)$ refers to the unnormalized score of word w given context x and $Z(x) = \sum_w \exp(s(w|x))$ refers to the partition function for context x. This strategy therefore pushes the log partition towards zero. For efficient training, the second term can be down-sampled

$$L_{\alpha,\gamma}^{(2)} = -\sum_{(w,x)\in T} s(w|x) + \frac{\alpha}{\gamma} \sum_{(w,x)\in T_\gamma} (\log Z(x))^2$$

where T_γ is the training set sampled at rate γ. A small rate implies computing the partition function only for a small fraction of the training data.

We extend this strategy to the case where the log partition term is not squared (Weaknorm), i.e.,

$$L_{\alpha,\gamma}^{(1)} = -\sum_{(w,x)\in T} s(w|x) + \frac{\alpha}{\gamma} \sum_{(w,x)\in T_\gamma} \log Z(x)$$

For $\alpha = 1$, this loss is an unbiased estimator of the negative log-likelihood of the training data $L_1^{(2)} = -\sum_{(w,x)\in T} s(w|x) + \log Z(x)$.

3 Experimental Setup

Datasets We run experiments over three news datasets of different sizes: Penn Treebank (PTB), WMT11-lm (billionW) and English Gigaword, version 5 (gigaword). Penn Treebank (Marcus et al., 1993) is the smallest corpus with 1M tokens and we use a vocabulary size of 10k (Mikolov et al., 2011a). The billion word benchmark (Chelba et al., 2013) comprises almost one billion tokens and a vocabulary of about 800k words[1]. Gigaword (Parker et al., 2011) is even larger with 5 billion tokens and was previously used for language modeling (Heafield, 2011) but there is no standard train/test split or vocabulary for this set. We split according to time: training covers 1994–2009 and test covers 2010. The vocabulary comprises the 100k most frequent words in train. Table 1 summarizes the data statistics.

[1]T. Robinson version `http://tiny.cc/1billionLM`.

Dataset	Train	Test	Vocab	OOV
PTB	1M	0.08M	10k	5.8%
gigaword	4,631M	279M	100k	5.6%
billionW	799M	8.1M	793k	0.3%

Table 1: Dataset statistics. Number of tokens for train and test, vocabulary size, fraction of OOV.

Evaluation We measure perplexity on the test set. For PTB and billionW, we report results on a per sentence basis, i.e., models do not use context words across sentence boundaries and we score end-of-sentence markers. This is the standard setting for these benchmarks and allows comparison with other work. On gigaword, we use contexts across sentence boundaries and evaluation does not include end-of-sentence markers.

Our baseline is an interpolated Kneser-Ney (KN) model. We use KenLM (Heafield, 2011) to train 5-gram models without pruning. For neural models, we train 11-gram models for gigaword and billionW; for PTB we train a 6-gram model. The model parameters (weights W^i and biases b^i for $i = 0, \ldots, k+1$) are learned to maximize the training log-likelihood relying on stochastic gradient descent (SGD; LeCun et al.. 1998).

Validation Hyper-parameters are the number of layers k and the dimension of each layer $d_i, \forall i = 0, \ldots, k$. We tune the following settings for each technique on the validation set: the number of clusters, the clustering technique for hierarchical softmax, the number of frequency bands and their allocated capacity for differentiated softmax, the number of distractors for target sampling, the noise/data ratio for NCE, as well as the regularization rate and strength for infrequent normalization. Similarly, SGD parameters (learning rate and mini-batch size) are set to maximize validation likelihood. We also tune the dropout rate (Srivastava et al., 2014); dropout is employed after each tanh non-linearity.[2]

Training Time We train for 168 hours (one week) on the large datasets (billionW, gigaword) and 24 hours (one day) for Penn Treebank. All experiments are performed on the same hardware, a single K40 GPU. We select the hyper-parameters which yield the best validation perplexity after the allocated time and report the perplexity of the resulting model on the test set. This training time

[2]More parameter settings are available in an extended version of the paper at `http://arxiv.org/abs/1512.04906`.

is a trade-off between being able to do a comprehensive exploration of the various settings for each method and good accuracy. The chosen training times are not long enough to observe over-fitting, i.e. validation performance is still improving – albeit very slowly – at the end of the training session. As a general observation, even on the small PTB where 24 hours is rather long, we always found better results using the full training time, possibly increasing the dropout rate.

A concern may be that a fixing the training time favors models with better implementations. However, all models are very similar and their core computations are always matrix/matrix products. Training differs mostly in the size and frequency of large matrix/matrix products. Matrix products rely on CuBLAS[3], using torch[4]. For the matrix sizes involved ($> 500 \times 1,000$), the time complexity of matrix product is linear in each dimension, both on CPU (Intel MKL[5]) and GPU (CuBLAS), with a $10X$ speedup for GPU (Nvidia K40) compared to CPU (Intel Xeon E5-2680). Therefore, the speed trade-off applies to both CPU and GPU hardware, albeit with a different time scale.

4 Results

The test perplexities (Table 2) and validation learning curves (Figures 2, 3, and 4) show that the competitiveness of softmax diminishes with larger vocabularies. Softmax does well on the small vocabulary PTB but poorly on the large vocabulary billionW corpus. Faster methods such as sampling, hierarchical softmax, and infrequent normalization (Weaknorm, WeaknormSQ) are much better in the large vocabulary setting of billionW.

D-Softmax is performing well on all sets and shows that assigning higher capacity where it benefits most results in better models. Target sampling performs worse than softmax on gigaword but better on billionW. Hierarchical softmax performs poorly on Penn Treebank which is in stark contrast to billionW where it does well. Noise contrastive estimation has good accuracy on billionW, where speed is essential to achieving good accuracy.

Of all the methods, hierarchical softmax processes most training examples in a given time frame (Table 3). Our test time speed comparison assumes that we would like to find the highest scoring next word rather than rescoring an existing string. This scenario requires scoring all output words and D-Softmax can process nearly twice as many tokens per second than the other methods whose complexity is similar to softmax.

4.1 Softmax

Despite being our baseline, softmax ranks among the most accurate methods on PTB and it is second best on gigaword after D-Softmax (with WeaknormSQ performing similarly). For billionW, the extremely large vocabulary makes softmax training too slow to compete with faster alterna-

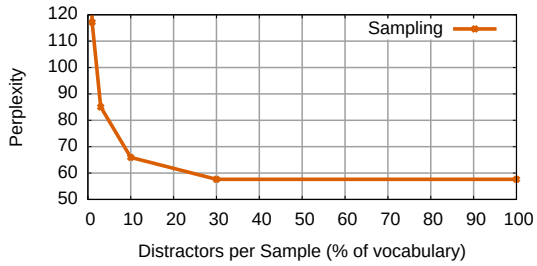

Figure 5: Number of Distractors versus Perplexity for Target Sampling over Gigaword

tives. However, of all the methods softmax has the simplest implementation and it has no additional hyper-parameters compared to other methods.

4.2 Target Sampling

Figure 5 shows that target sampling is most accurate for distractor sets that amount to a large fraction of the vocabulary, i.e. $> 30\%$ on gigaword (billionW best setting $> 50\%$ is even higher). Target sampling is faster and performs more iterations than softmax in the same time. However, its perplexity reduction per iteration is less than softmax. Overall, it is not much better than softmax. A reason might be that sampling chooses distractors independently from context and current model performance. This does not favor distractors the model incorrectly considers likely for the current context. These distractors would yield higher gradients that could update the model faster.

4.3 Hierarchical Softmax

Hierarchical softmax is very efficient for large vocabularies and it is the best method on billionW. On the other hand, HSM does poorly on small vocabularies as seen on PTB. We found that a good word clustering structure is crucial: when clusters gather words occurring in similar contexts, cluster likelihoods are easier to learn; when the cluster structure is uninformative, cluster likelihoods converge to the uniform distribution. This affects accuracy since words cannot have higher probability than their clusters, Eq. (2).

Our experiments organize words into a two level hierarchy and compare four clustering strategies on billionW and gigaword (§2.2). Random clustering shuffles the vocabulary and splits it into equally sized partitions. Frequency-based clustering first orders words based on their frequency and assigns words to clusters such that each cluster represents an equal share of the total frequency (Mikolov et al., 2011b). K-means runs the well-known clustering algorithm on Hellinger PCA word embeddings. Weighted k-means weights each word by its frequency.[7]

Random clusters perform worst (Table 4) followed by frequency-based clustering but k-means does best; weighted k-means performs similarly to its unweighted version. In earlier experiments, plain k-means performed very poorly since the most frequent cluster captured up to 40% of the

[7]The time to compute the clustering (multi-threaded word co-occurrence counts, PCA and k-means) is under one hour, which is negligible given a one week training budget.

	billionW	gigaword
random	98.51	62,27
frequency-based	92.02	59.47
k-means	85.70	57.52
weighted k-means	85.24	57.09

Table 4: HSM with different clustering.

token occurrences. We then explicitly capped the frequency budget of each cluster to 10% which brought k-means on par with weighted k-means.

4.4 Differentiated Softmax

D-Softmax is the best technique on gigaword and second best on billionW after HSM. On PTB it ranks among the best techniques whose perplexities cannot be reliably distinguished. The variable-capacity scheme of D-Softmax can assign large embeddings to frequent words, while keeping computational complexity manageable through small embeddings for rare words.

Unlike for hierarchical softmax, NCE or Weaknorm, the computational advantage of D-Softmax is preserved at test time (Table 3). D-Softmax is the fastest technique at test time, while ranking among the most accurate methods. This speed advantage is due to the low dimensional representation of rare words which negatively affects the model accuracy on these words (Table 5).

4.5 Noise Contrastive Estimation

Although we report better perplexities than the original NCE paper on PTB (Mnih and Teh, 2012), we found NCE difficult to use for large vocabularies. In order to work in this setting where models are larger, we had to dissociate the number of noise samples from the data to noise ratio in the modeled mixture. For instance, a data/noise ratio of $1/50$ gives good performance in our experiments but estimating only 50 noise sample posteriors per data point is wasteful given the cost of network evaluation. Moreover, 50 samples do not allow frequent sampling of every word in a large vocabulary. Our setting considers more noise samples and up-weights the data sample. This allows to set the data/noise ratio independently from the number of noise samples.

Overall, NCE results are better than softmax only for billionW, a setting for which softmax is very slow due to the very large vocabulary. Why does NCE perform so poorly? Figure 6 shows entropy on the validation set versus the NCE loss for several models. The results clearly show that similar NCE loss values can result in very different validation entropy. Although NCE might make sense for other metrics such as BLEU (Baltescu and Blunsom, 2014), it is not among the best techniques for minimizing perplexity. Jozefowicz et al. (2016) recently drew similar conclusions.

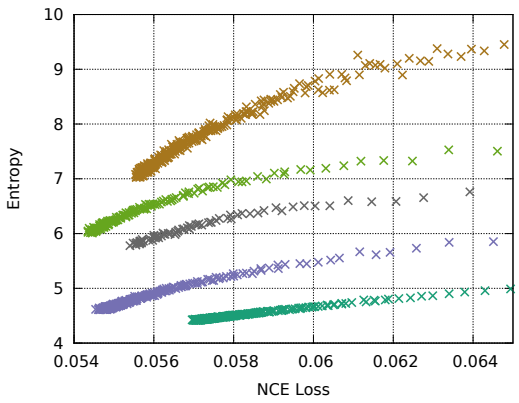

Figure 6: Validation entropy versus NCE loss on gigaword for experiments differing only in learning rates and initial weights. Each color corresponds to one experiment, with one point per hour.

4.6 Infrequent Normalization

Infrequent normalization (Weaknorm and WeaknormSQ) performs better than softmax on billionW and comparably to softmax on Penn Treebank and gigaword (Table 2). The speedup from skipping partition function computations is substantial. For instance, WeaknormSQ on billionW evaluates the partition only on 10% of the examples. In one week, the model is evaluated and updated on 868M tokens (with 86.8M partition evaluations) compared to 156M tokens for softmax.

Although referred to as self-normalizing (Andreas and Klein, 2015), the trained models still need normalization after training. The partition varies greatly between data samples. On billionW, the partition ranges between 9.4 to 10.3 in log scale for 10th to 90th percentile, i.e. a ratio of 2.5.

We observed the squared version (WeaknormSQ) to be unstable at times. Regularization strength could be found too low (collapse) or too high (blow-up) after a few days of training. We added an extra unit to bound unnormalized predictions $x \rightarrow 10 \tanh(x/5)$, which yields stable training and better generalization. For the non-squared Weaknorm, stability was not an issue. A regularization strength of 1 was the best setting for Weaknorm. This choice makes the loss an unbiased estimator of the data likelihood.

	1-4K	4-20K	20-40K	40-70K	70-100K

5 Analysis

5.1 Model Capacity

Training neural language models over large corpora highlights that training time, not training data, is the main factor limiting performance. The learning curves on gigaword and billionW indicate that most models are still making progress after one week. Training time has therefore to be taken into account when considering increasing capacity. Figure 7 shows validation perplexity versus the number of iterations for a week of training. This figure shows that a softmax model with 1024 hidden units in the last layer could perform better than the 512-hidden unit model with a longer training horizon. However, in the allocated time, 512 hidden units yield the best validation performance. D-softmax shows that it is possible to *selectively* increase capacity, i.e., to allocate more hidden units to the most frequent words at the expense of rarer words. This captures most of the benefit of a larger softmax model while staying within a reasonable training budget.

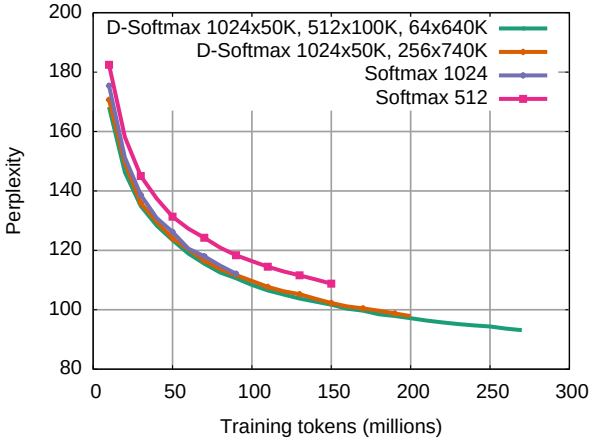

Figure 7: Validation perplexity per iteration on billionW for softmax and D-softmax. Softmax uses the same number of units for all words. The first D-Softmax experiment uses 1024 units for the 50K most frequent words, 512 for the next 100K, and 64 units for the rest; similarly for the second experiment. All experiments end after one week.

5.2 Effect of Initialization

We consider initializing both the input word embeddings and the output matrix from Hellinger PCA embeddings. Several alternative techniques for pre-training embeddings have been proposed (Mikolov et al., 2013; Lebret and Collobert, 2014; Pennington et al., 2014). Our experiment highlights the advantage of initialization and do not aim to compare embedding techniques.

Figure 8 shows that PCA is better than random for initializing both input and output word representations; initializing both from PCA is even better. We see that even after long training sessions, the initial conditions still impact the validation perplexity. We observed this trend also with other strategies than softmax. After one week of training, HSM is the only method which can reach comparable accuracy to PCA initialization when the output matrix is randomly initialized.

5.3 Training Set Size

Large training sets and a fixed training time introduce competition between slower models with more capacity and observing more training data. This trade-off only applies to iterative SGD optimization and does not apply to classical count-based models, which visit the training set once and then solve training in closed form.

We compare Kneser-Ney and softmax, trained for one week, with gigaword on differently sized subsets of the training data. For each setting we take care to include all data from the smaller subsets. Figure 9 shows that the performance of the neural model improves very little on more than

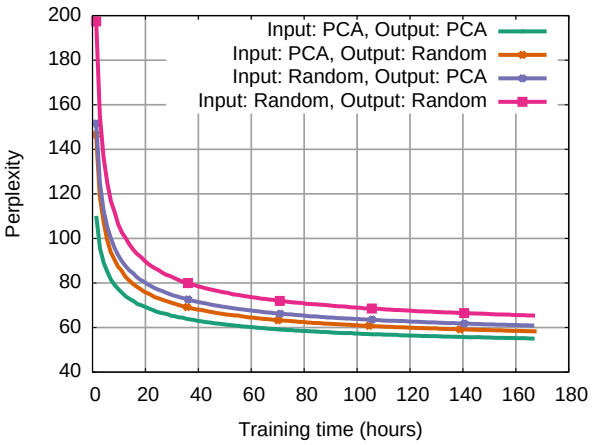

Figure 8: Effect of random initialization and with Hellinger PCA on gigaword for softmax.

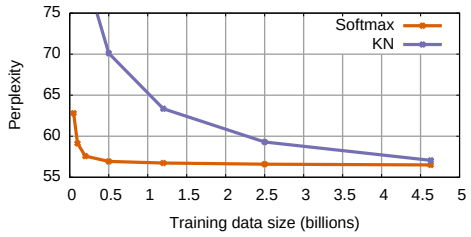

Figure 9: Effect of training set size measured on test of gigaword for Softmax and Kneser-Ney.

500M tokens. In order to benefit from the full training set we would require a much higher training budget, faster hardware, or parallelization.

Scaling training to large datasets can have a significant impact on perplexity, even when data from the distribution of interest is limited. As an illustration, we adapted a softmax model trained on billionW to Penn Treebank and achieved a perplexity of 96 - a far better result than with any model we trained from scratch on PTB (cf. Table 2).

5.4 Rare Words

How well do neural models perform on rare words? To answer this question, we computed entropy across word frequency bands for Kneser-Ney and neural models. Table 5 reports entropy for the $4,000$ most frequent words, then the next most frequent $16,000$ words, etc. For frequent words, neural models are on par or better than Kneser-Ney. For rare words, Kneser-Ney is very competitive. Although neural models might eventually close this gap with much longer training, one should consider that Kneser-Ney trains on gigaword in only 8 hours on CPU which contrasts with 168 hours of training for neural models on high end GPUs. This result highlights the complementarity of both approaches, as observed in our interpolation experiments (Table 2).

For neural models, D-Softmax excels on frequent words but performs poorly on rare ones. This is because D-Softmax assigns more capacity to frequent words at the expense of rare words. Overall, hierarchical softmax is the best neural technique for rare words. HSM does more iterations than any other technique and so it can observe every rare word more often.

6 Conclusions

This paper presents a comprehensive analysis of strategies to train neural language models with large vocabularies. This setting is very challenging for neural networks as they need to compute the partition function over the entire vocabulary at each evaluation.

We compared classical softmax to hierarchical softmax, target sampling, noise contrastive estimation and infrequent normalization, commonly referred to as self-normalization. Furthermore, we extend infrequent normalization to be a proper estimator of likelihood and we introduce differentiated softmax, a novel variant of softmax assigning less capacity to rare words to reduce computation.

Our results show that methods which are effective on small vocabularies are not necessarily equally so on large vocabularies. In our setting, target sampling and noise contrastive estimation failed to outperform the softmax baseline. Overall, differentiated softmax and hierarchical softmax are the best strategies for large vocabularies. Compared to classical Kneser-Ney models, neural models are better at modeling frequent words, but are less effective for rare words. A combination of the two is therefore very effective.

We conclude that there is a lot to explore in training from a combination of normalized and unnormalized objectives. An interesting future direction is to combine complementary approaches, either through combined parameterization (e.g. hierarchical softmax with differentiated capacity per word) or through a curriculum (e.g. transitioning from target sampling to regular softmax as training progresses). Further promising areas are parallel training as well as better rare word modeling.

Abstract

Distributional semantic models (DSMs) are often evaluated on artificial similarity datasets containing single words or fully compositional phrases. We present a large-scale multilingual evaluation of DSMs for predicting the degree of semantic compositionality of nominal compounds on 4 datasets for English and French. We build a total of 816 DSMs and perform 2,856 evaluations using *word2vec*, *GloVe*, and PPMI-based models. In addition to the DSMs, we compare the impact of different parameters, such as level of corpus preprocessing, context window size and number of dimensions. The results obtained have a high correlation with human judgments, being comparable to or outperforming the state of the art for some datasets (Spearman's ρ=.82 for the *Reddy* dataset).

1 Introduction

Distributional semantic models (DSMs) use context information to represent the meaning of lexical units as vectors. They normally focus on the accurate semantic representation of single words. It is based on single words that many optimizations for these models have been proposed (Lin, 1999; Erk and Padó, 2010; Baroni and Lenci, 2010). This is particularly true for *word embeddings*, that is, a type of DSM where distributional vectors are obtained as a by-product of training a neural network to learn a function between words and their contexts (Mikolov et al., 2013a).

Simultaneously, there has been intensive research on models to compose individual word vectors in order to create representations for larger units such as phrases, sentences and even whole documents (Mitchell and Lapata, 2010; Mikolov et al., 2013a). Larger units can often be assumed to have their meanings derived from their parts according to the language's grammar, but this is not always the case (Sag et al., 2002). Many multiword units are associated with idiomatic interpretations, unrelated to the meaning of the component words (e.g. *silver bullet, eager beaver*).

Precision-oriented NLP applications need to be able to identify partly-compositional and idiomatic cases and ensure meaning preservation during processing. Compositionality identification is a first step towards complete semantic interpretation in tasks such as machine translation (to translate non-compositional compounds as a unit), word sense disambiguation (to avoid assigning a sense to parts of non-compositional compounds), and semantic parsing (to identify complex predicates and their arguments).

Even when larger units are explicitly represented in DSMs (McCarthy et al., 2003; Reddy et al., 2011; Mikolov et al., 2013c; Ferret, 2014), it is not clear whether the quality of these representations is comparable to the representations of single words. In particular, when building vectors for larger units, their generally lower frequencies in corpora (Kim and Baldwin, 2006) may combine with morphosyntactic phenomena to increase sparsity even further, often requiring non-trivial preprocessing (lemmatization and word reordering) to conflate variants.

This paper presents a large-scale multilingual evaluation of DSMs and their parameters for the task of compositionality prediction of nominal compounds in French and English. We examine parameters like the level of corpus preprocessing, the size of the context window and the number of dimensions for context representation. Additionally, we compare standard DSMs based on positive pointwise mutual information (PPMI)

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1986–1997,
Berlin, Germany, August 7-12, 2016.

against widely used word embedding tools such as *word2vec*, henceforth *w2v* (Mikolov et al., 2013c), and *GloVe* (Pennington et al., 2014). We start with a discussion of related work (§2) and the materials and methods used (§3). We report on the evaluations performed (§4) and finish with conclusions and future work (§5).

2 Related Work

We define *nominal compounds* as conventional noun phrases composed by two or more words, such as *science fiction* (Nakov, 2013). In English, they are often expressed as *noun compounds* but their syntactic realization may vary for different languages. For instance, one of the equivalent forms in French involves a denominal adjective used as modifier (e.g. *cell death* and the corresponding *mort cellulaire*).[1] In this paper, we focus on 2-word nominal compounds involving modifiers that are nouns (e.g. *word embedding*) or adjectives (e.g. *hard time*).

Semantically, nominal compounds may display a wide range of idiomaticity, from compositional cases like *access road* to idiomatic or non-compositional cases like *gravy train*, whose meaning is unrelated to its parts.[2] Even when there is a level of compositionality in the compound, the contribution of each word may vary considerably, independently from its status as a syntactic head or modifier, as *cash* in *cash cow* versus *tears* in *crocodile tears*. Indeed, various annotation scales have been proposed as means to collect human judgments about compositionality. Particularly for nominal compounds, Reddy et al. (2011) used a 6-point scale to collect judgments on the literal or figurative use of nominal compounds and its components in English. Similar judgments have also been collected for 244 German compounds, for which an average of 30 judgments on a scale from 1 to 7 were gathered through crowdsourcing (Roller et al., 2013). An alternative to multi-point scales is the binary judgment adopted by Farahmand et al. (2015), for a dataset of English nominal compounds.

There has been much interest in creating semantic representations of larger units, such as phrases (Mikolov et al., 2013b), sentences and documents (Le and Mikolov, 2014), and in examining whether it is possible to accurately derive the semantics of a compound or multiword expression from its parts (McCarthy et al., 2003; Baldwin et al., 2003; Tratz and Hovy, 2010; Reddy et al., 2011). For the latter, proposals include using additive and multiplicative functions to combine vector representations of component words (Mitchell and Lapata, 2008; Reddy et al., 2011), calculating the overlap between the components and the expression (McCarthy et al., 2003) and looking at the literality of translations into multiple languages (Salehi et al., 2014). Other proposals to explicitly represent the semantics of nominal compounds include the use of paraphrases (Lauer, 1995; Nakov, 2008; Hendrickx et al., 2013), and inventories of semantic relations (Girju et al., 2005).

The ability of DSMs for accurately capturing semantic information may be affected by a number of factors involved in constructing the models, such as the source *corpus*, *context* representation, and parameters of the *model*. Relevant corpus parameters include size (Ferret, 2013; Mikolov et al., 2013c) and quality (Lapesa and Evert, 2014). Factors related to context representation include the context window size and the number of context dimensions adopted for a model (Lapesa and Evert, 2014); the choice of contexts to be used with targets (syntactic dependencies vs. bag-of-words) (Agirre et al., 2009); the use of morphosyntactic information (Padó and Lapata, 2003; Padó and Lapata, 2007); context filtering (Riedl and Biemann, 2012; Padró et al., 2014a); and dimensionality reduction methods (van de Cruys et al., 2012). Important model parameters that have been studied include the choice of association and similarity measures (Curran and Moens, 2002) and the use of subsampling and negative sampling techniques (Mikolov et al., 2013c). However, the particular effects may be heterogeneous and depend on the task and model (Lapesa and Evert, 2014). In this paper, we examine the impact of both corpus and context parameters for a variety of models, for the task of nominal compound compositionality prediction in English and French.

For the choice of particular DSM, contradictory results have been published showing the superiority of neural models (Baroni et al., 2014) and of more traditional but carefully designed models (Levy et al., 2015). The former were also reported as a better fit to behavioral data on semantic prim-

[1] In French, one can also use a preposition and optional determiner, like *cancer du poumon* (*lung cancer*).

[2] It refers to an initiative that provides money to many people without much effort.

ing tasks (Mandera et al., 2016). Moreover, these evaluations are often performed on single-word similarity tasks (Freitag et al., 2005; Camacho-Collados et al., 2015) and little has been said about the use of word embeddings for the compositionality prediction of multiword expressions. Two notable exceptions are the recent works of Salehi et al. (2015) and Yazdani et al. (2015). Salehi et al. (2015) show that word embeddings are more accurate in predicting compositionality than a simplistic count-based DSM. Yazdani et al. (2015) focus on the composition function, using a lightly supervised neural network to learn the best combination strategy for individual word vectors. In order to consolidate previous punctual results, we present a large-scale and systematic evaluation, comparing DSMs and their parameters, on several compositionality datasets.

3 Materials and Methods

We examine the impact of corpus parameters related to the target language and the degree of corpus preprocessing adopted. We also investigate context parameters related to the size of the context window and the number of dimensions used to represent context.

3.1 Corpora Preprocessing

We use the lemmatized and POS-tagged versions of the ukWaC for English (∼2 billion tokens) and frWaC (∼1.6 billion tokens) for French (Baroni et al., 2009) to train the models and build vector representations of words and compounds. For each corpus, we re-tokenize all target compounds as a single word with a separator (e.g. *monkey business* → *monkey_business*) and re-tag them using a single manually selected tag per compound to handle POS-tagging errors.[3] All forms are then lowercased (surface forms, lemmas and POS-tags); and noisy tokens, with special characters, numbers or punctuation, are removed. Additionally, ligatures are normalized for French (e.g. *œ* → *oe*) and a spellchecker[4] is applied to normalize words across English spelling variants (e.g. *color* → *colour*).

To test the influence of preprocessing in model accuracy, for each corpus, we generate four variants with different degrees of abstraction:

1. *surface*$^+$: the original corpus with no preprocessing, containing surface forms.
2. *surface*: stopword removal; generating a corpus of surface forms of content words.
3. *lemma*: stopword removal and lemmatization; generating a corpus of lemmas of content words.
4. *lemmaPOS*: stopword removal, lemmatization and POS-tagging; generating a corpus of content words, represented as lemma/tag.

The operation of stopword removal eliminates from the corpus all function words, leaving only nouns, adjectives, adverbs and verbs. In lemmatized corpora, the lemmas of proper names are replaced by placeholders.

3.2 Compositionality Datasets

For evaluation, we use nominal compound compositionality datasets for English (*Reddy*, *Reddy++* and *Farahmand*) and for French (*FR-comp*). They provide annotations as to whether a given compound is more idiomatic or more compositional.

Reddy contains compositionality judgments for 90 compounds and their individual word components, in a scale of literality from 0 (idiomatic) to 5 (literal), collected with Mechanical Turk (Reddy et al., 2011). For each compound, compositionality scores are averaged over its annotators. Compounds included in the dataset were selected to balance frequency range and degree of compositionality (low, middle and high). We use only the global compositionality score, ignoring individual word judgments. With a few exceptions (e.g. *sacred cow*), most compounds are formed exclusively by nouns.

Reddy++ is a new resource created for this evaluation (Ramisch et al., 2016). It extends the *Reddy* set with an additional 90 English nominal compounds, in a total of 180 entries. Scores also range from 0 to 5 and were collected through Mechanical Turk and averaged over the annotators. The extra 90 entries include some adjective-noun compounds and are balanced with respect to frequency and compositionality. We focus our evaluation on this combined dataset, since it includes *Reddy*. However, to allow comparison with state of the art, we also report results individually for *Reddy*.

Farahmand contains 1042 English compounds extracted from Wikipedia with binary non-compositionality judgments by four experts (Farahmand et al., 2015). We consider a compound as non-compositional if at least two judges agree that it is non-compositional, following Yaz-

[3] We use a simplified tag set (e.g. `v` instead of `vvz`).

[4] `https://hunspell.github.io`

dani et al. (2015). In our evaluations, we use the sum of all judgments in order to have a single numeral compositionality score, ranging from 0 (compositional) to 4 (idiomatic).

FR-comp is also a new resource created for this evaluation (Ramisch et al., 2016). It contains 180 adjective-noun and noun-adjective compounds in French, such as *belle-mère* (*mother-in-law*, lit. *beautiful-mother*) and *carte bleue* (*credit card*, lit. *blue card*). This dataset was constructed in the same manner as the extension to *Reddy*, that is, using crowdsourcing and average numerical scores. Special care was taken to guarantee that annotators were native speakers by asking them to provide paraphrases along with compositionality scores.

The new datasets *Reddy++* and *FR-comp* are similar to *Reddy*. For instance, the average standard deviation of compound scores given by different annotators is $\sigma = 1.17$ for the new compounds in *Reddy++*, $\sigma = 1.15$ for *FR-comp* and $\sigma = 0.99$ for *Reddy*. Their detailed evaluation is presented by Ramisch et al. (2016).

3.3 DSM Models

We build three types of DSMs: models based on sparse PPMI cooccurrence vectors, as well as those constructed with *word2vec* and *GloVe*.

PPMI For each target word or compound, we extract from the corpus its neighboring nouns and verbs in a symmetric sliding window of w words to the left/right[5], using a linear decay weighting scheme with respect to its distance d to the target (Levy et al., 2015). In other words, each cooccurrence count of target-context pairs is incremented by $w + 1 - d$ instead of 1. The representation of a target is a vector containing the positive pointwise mutual information (PPMI) association scores between the target and its contexts.[6]

In *PPMI-thresh*, we follow Padró et al. (2014b) to select the top k most relevant contexts (highest PPMI) for each target. No further dimensionality reduction is applied.

In *PPMI-TopK*, we use a fixed global list of 1000 contexts, built by looking at the most frequent words in the corpus: the top 50 are skipped, and the next 1000 are taken (Salehi et al., 2015). No further dimensionality reduction is applied.

In *PPMI-SVD*, for each target, contexts that appear less than 1000 times are discarded.[7] We then use the Dissect toolkit[8] (Dinu et al., 2013) in order to build a PPMI matrix and reduce its dimensionality using singular value decomposition (SVD) to factorize the matrix.

w2v Uses the *word2vec* toolkit based on neural networks to predict target/context cooccurrence (Mikolov et al., 2013a). We build models from two variants of word2vec: CBOW (*w2v-cbow*) and skipgram (*w2v-sg*). In both cases, the configurations are the default ones, except for the following: no hierarchical softmax; negative sampling of 25; frequent-word downsampling weight of 10^{-6}; runs 15 training iterations. We use the default minimum word count threshold of 5.

glove We use the count-based DSM of Pennington et al. (2014), which implements a factorization of the co-occurrence count matrix. The configurations are the default ones, except for the following: internal cutoff parameter $x_{max} = 75$; builds co-occurrence matrix in 15 iterations. Due to the large vocabulary size, we use a minimum word count threshold of 5 for lemma-based models, 15 for *surface* and 20 for *surface*$^+$.

For each DSM, we evaluate the influence of a set of parameters. By varying the values of these parameters, we build a total of 408 models per language. The parameters are:

- WORDFORM: Refers to one of the four variants of each corpus: *surface*$^+$, *surface*, *lemma*, and *lemmaPOS*.
- WINDOWSIZE: Indicates within how many words to the left/right we are searching for target-context co-occurrence pairs. In this work we explore windows of sizes of 1, 4 and 8.
- DIMENSION: Each model is constructed to have a maximum number of final dimensions for each vector. We generate models with 250, 500 and 750 dimensions.

3.4 Compositionality Prediction

To predict the compositionality of a nominal compound w_1w_2 using the DSMs, we use as a measure the cosine similarity between the compound

[5] Syntactic context definition is planned as future work.

[6] *PPMI* vectors are built using minimantics `https://github.com/ceramisch/minimantics`.

[7] Aggressive filtering was required because SVD seems quite sensitive to low-frequency contexts.

[8] `http://clic.cimec.unitn.it/composes/toolkit/index.html`

vector representation $v(w_1w_2)$ and the sum of the vector representations of the component words:

$$\cos(\ v(w_1w_2),\ v(w_1 + w_2)\ )$$

where for $v(w_1 + w_2)$ we use the normalized sum

$$v(w_1 + w_2) = \frac{v(w_1)}{||v(w_1)||} + \frac{v(w_2)}{||v(w_2)||}.$$

In this framework, a compound is compositional if the compound representation is close to the sum of its components representations (cosine is close to 1), and it is idiomatic otherwise.

One possible improvement of the predictive model would consist in using more sophisticated composition functions instead of sum, such as the multiplicative model of Mitchell and Lapata (2008). However, we want to first assess the performance of a simple additive function. Other optimized functions like the ones proposed by Yazdani et al. (2015) could also be verified, but are out of the scope of this paper, since they are based on supervised learning.

3.5 Evaluation Setup

We evaluate the compositionality models and their parameters on the datasets described in Section 3.2. For *Reddy*, *Reddy++* and *FR-comp*, we report Spearman's ρ correlation between the ranking provided by humans and those calculated from the models. We follow Yazdani et al. (2015) and report the best F1 score (BF1) obtained for the *Farahmand* dataset, by calculating the F1 score for the top k compounds classified as positive (non-compositional), for all possible values of k.

Given the high number of experiments we performed, we report the best performance of each model type. For instance, the performances reported for *w2v-cbow* using different values of WINDOWSIZE are the best configurations across all possible values of other parameters such as DIMENSION and WORDFORM. This avoids reporting local maxima that can arise if one fixes all other parameters when evaluating a given one (Lapesa and Evert, 2014).

For *Reddy++* and *Farahmand*, we distinguish between *strict* evaluation, reported in the form of wider bars in the figures, and *loose* evaluation, shown as narrow blue bars in the figures. Strict evaluation corresponds to the performance of the model only on those compounds that have a vector representation in all underlying DSMs, 175 out of 180 for *Reddy++* and 913 out of 1042 for *Farahmand*. Loose evaluation considers the full dataset, using a fallback strategy for the imputation of missing values, assigning the average compositionality score to absent compounds (Salehi et al., 2015). This is particularly important for *Farahmand*, which contains more rare compounds such as *universe human* and *mankind instruction* so that 129 compounds are missing in the corpus. Only strict evaluation is reported for *FR-comp*, as all compounds are frequent enough in FRWaC.

The vectors generated by *w2v* and *glove* have some non-determinism due to random initialization. To assess its impact on results, we report the average of 3 runs using identical configurations and use error bars in the graphics.[9]

4 Results

We report results on each dataset separately and then discuss findings that hold for all datasets.

4.1 *Reddy++* and *Reddy* Datasets

Figure 1 summarizes the results for *Reddy++* dataset.[10] Overall, *w2v-cbow* ($\rho = 0.73$), *w2v-sg* ($\rho = 0.73$), *PPMI-SVD* ($\rho = 0.72$) and *PPMI-thresh* ($\rho = 0.71$) obtain similar results. In spite of this, except for the two best *w2v* models, all differences were deemed statistically significant (Wilcoxon rank correlation test, $p < 0.05$).

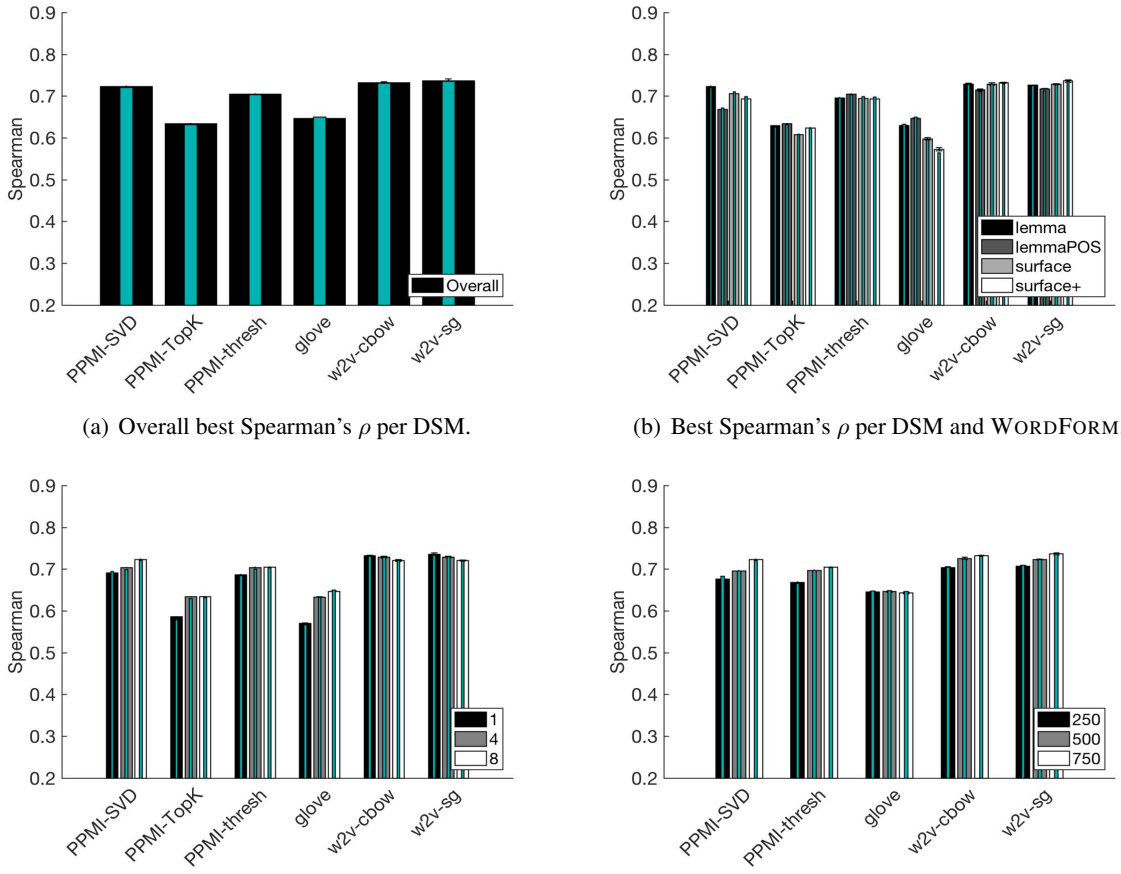
Figure 1(b) shows the influence of the degree of corpus preprocessing (shown as WORDFORM in these figures). The results are heterogeneous, as the best *w2v* models seem to profit from the presence of stopwords, unlike the other models for which more preprocessing (*lemma* and *lemma-POS*) leads to better results. One exception is *PPMI-SVD* for which the use of *lemmaPOS* drastically reduces performance.[11]

For WINDOWSIZE, Figure 1(c), although increasing context size seems to help DSMs (at least up to 4), for the best *w2v* models, a better result is obtained with limited context of 1 word left/right. Probably the interaction between the subsampling strategy and randomized window size explains why increasing this value does not improve the

[9] Error bars are barely visible because results are stable.

[10] In the remainder of this section, we will discuss strict evaluation results (outer bars).

[11] Further investigation must be done to determine the cause of this reduction as an increase in vocabulary size alone is insufficient to explain the effect, given that both surface forms outperform it.



(a) Overall best Spearman's ρ per DSM.

(b) Best Spearman's ρ per DSM and WORDFORM.

(c) Best Spearman's ρ per DSM and WINDOWSIZE.

(d) Best Spearman's ρ per DSM and DIMENSION.

Figure 1: Spearman's ρ for different DSM parameters on *Reddy++* dataset.

results. *PPMI-SVD* can use extra information from larger window sizes (WINDOWSIZE=8) better than models based on context filtering. This is probably related to the aggressive context filter, which keeps only very salient cooccurrences even in large windows.

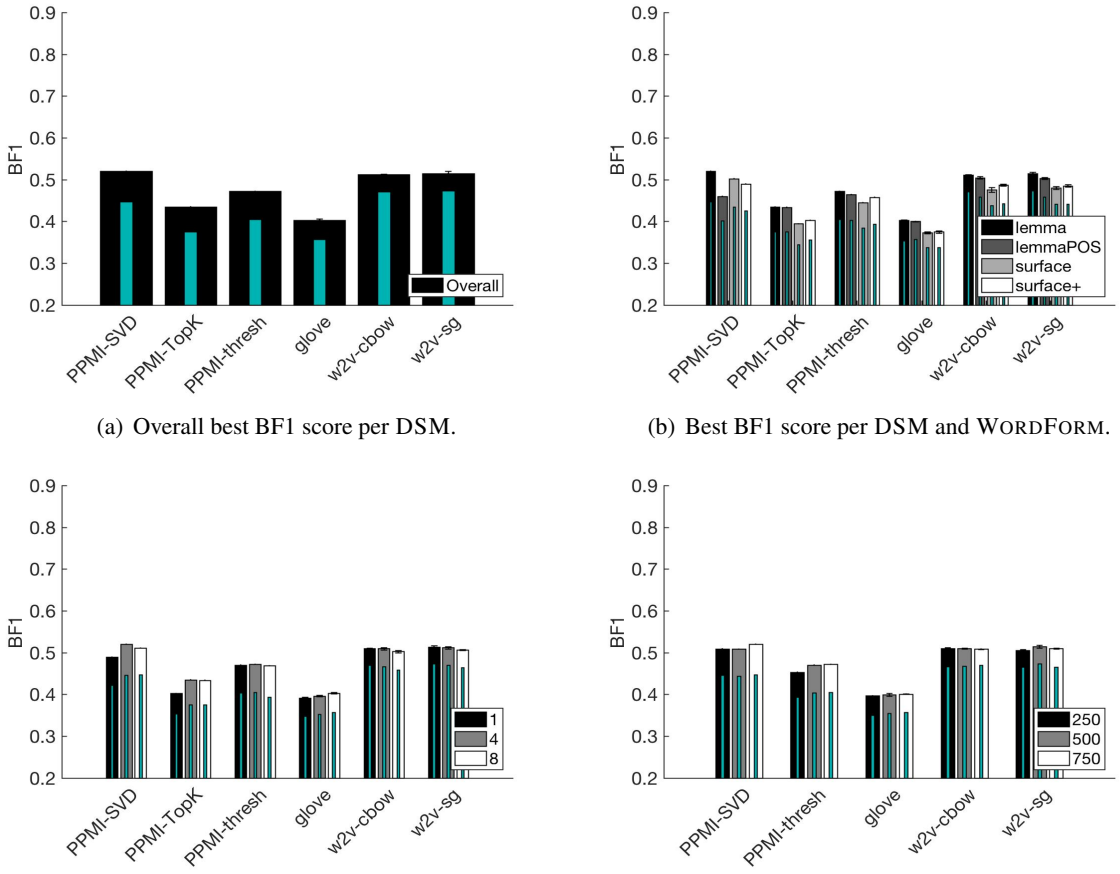
The results for context vector dimensionality, Figure 1(d), show, as expected, that the best results are obtained with larger dimensions (DIMENSION=750) for all models, except for *glove*, which displays very similar results independently of the number of dimensions.

Examining the *Reddy* dataset alone, the same trends for all parameters were found, but with higher results. The overall best performances on *Reddy* were quite similar: *w2v-cbow* ($\rho = 0.82$), *w2v-sg* ($\rho = 0.81$), *PPMI-SVD* ($\rho = 0.80$) and *PPMI-thresh* ($\rho = 0.79$), and the differences are significant except for the two best *w2v* models. The 90 compounds added to *Reddy++* seem to be more difficult to assess than the original ones, probably because they include many adjectives, which have been found harder to judge for compositionality than nouns (Ramisch et al., 2016).

4.2 *Farahmand* Dataset

Figure 2(a) shows the overall best model for the *Farahmand* dataset. *PPMI-SVD* reached a BF1 score of 0.52, with DIMENSION=750, WINDOWSIZE=4, using *lemma*, and both *w2v* (BF1=0.51) obtain comparable results with similar configurations.

These results show a marked difference between the loose (the narrower bars in the figures) and the strict evaluation (wider bars). The former uses a fallback strategy for the imputation of missing values that does not accurately reflect how the compositionality scores vary. Indeed, we observed that compounds that do not appear very often in our corpora tend to be non-compositional, whereas most of the compound occurrences are compositional, increasing average compositionality. For instance, the 10 most compositional compounds in *Reddy++* occur an average of 26551



(a) Overall best BF1 score per DSM.

(b) Best BF1 score per DSM and WORDFORM.

(c) Best BF1 score per DSM and WINDOWSIZE.

(d) Best BF1 score per DSM and DIMENSION.

Figure 2: BF1 scores for different DSM parameters on *Farahmand* dataset.

times in the UKWaC vs 1096 times for the 10 least compositional ones. Spearman rank correlation between frequency and compositionality in *Reddy++* is $\rho = 0.43$.[12] In short, even if a fallback strategy is adopted as the means to obtain a lower-bound for performance, it may be unrelated to the real performance for the missing compounds.

For most models, corpus preprocessing resulted in better scores, with WORDFORM=*lemma* outperforming all other forms of preprocessing, especially for French. Concatenating lemmas and POS tags does not seem to help, probably due to decreasing word frequencies without substantial gain in informativeness (Figure 2(b)).

The impact of WINDOWSIZE has a similar trend to the one found for the *Reddy++* and *Reddy* datasets (Figure 2(c)). That is, the larger window was preferred by most models, but the average difference between the best and the worst size for each DSM is only 0.01. For DIMENSION, a larger number resulted in better scores, as expected, with 750 being the best for all models in Figure 2(d). Nonetheless, here too the average difference in scores between DIMENSION=750 and 250 is 0.01.

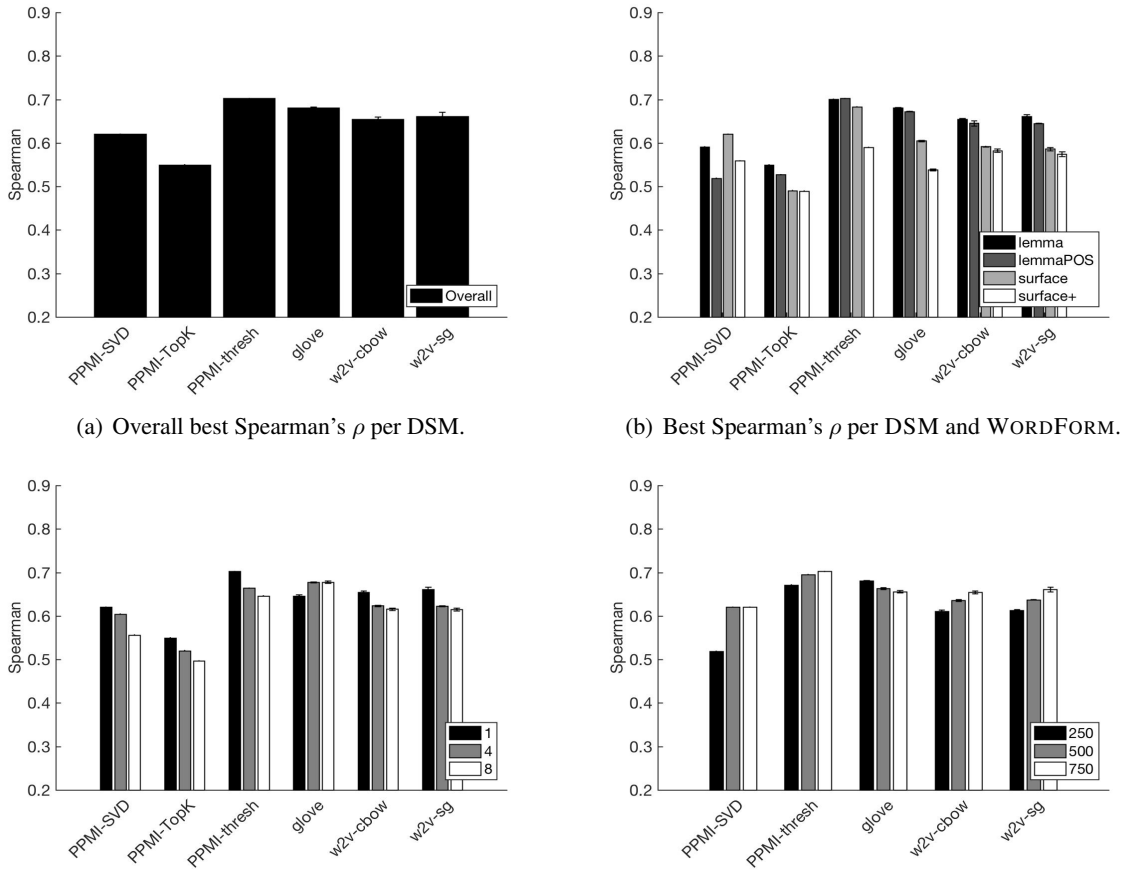
4.3 *FR-comp* Dataset

Globally, for the *FR-comp* dataset, *PPMI-thresh* ($\rho = 0.70$) outperforms *glove* ($\rho = 0.68$) and *w2v* ($\rho = 0.66$), as can be seen in Figure 3(a).[13]

For morphologically rich languages like French, Figure 3(b) indicates that working on lemmatized data often yields better results than working on surface forms. Lemmas conflate the frequencies for all the many morphologically inflected variants which would otherwise be dispersed in different surface forms. Therefore, it is not surprising that the best results concerning WORDFORM are achieved by *lemma*. These results differ from English, where a corpus without any preprocess-

[12] We report these figures for *Reddy++* because *Farahmand* has many ties, given the binary nature of compositionality annotations.

[13] As all compounds in the dataset occur in the corpus, only strict evaluation results are reported.



(a) Overall best Spearman's ρ per DSM.

(b) Best Spearman's ρ per DSM and WORDFORM.

(c) Best Spearman's ρ per DSM and WINDOWSIZE.

(d) Best Spearman's ρ per DSM and DIMENSION.

Figure 3: Spearman's ρ for different DSM parameters on *FR-comp* dataset.

ing yields more accurate results. Moreover, a smaller WINDOWSIZE leads to better results for most models, as shown in Figure 3(c). But just as in English, all models except *glove* benefit from an increase in dimension, as shown in Figure 3(d).[14]

4.4 Discussion

When comparing DIMENSION across languages and datasets, larger values often bring better performance. Likewise, the *lemma* is usually the better WORDFORM. The recommended WINDOWSIZE depends on the model and language, but for the best models in all datasets, a window of 1 outperforms the others. This may be a consequence of the linear decay context weighting process, which assigns higher weights to closer words as window size increases. As an overall conclusion, in combination with a large dimension and a small window size, investing in preprocessing provides a good balance of a small vocabulary (of lemmas) and good accuracy. This is especially clear for a morphologically richer language like French, where lemmatization is homogeneously better for all models, even in *w2v*, for which surface forms were better for English.

In terms of models, the *w2v* models performed better than *PPMI* for *Reddy++*, both were in a tie for *Farahmand*, and *w2v* was outperformed by *PPMI-thresh* for French. The performance of *glove* for English was underwhelming, probably because we did not perform parameter tuning. As shown by (Salehi et al., 2015), *PPMI-TopK* is not an appropriate DSM for this task, as it does not model relevant cooccurrence very well.

The average Spearman's ρ for *Reddy* over all tested parameter configurations was 0.71 for both *w2v* models and 0.67 for *PPMI-SVD* and *PPMI-*

[14]For *w2v*, the same parameters used for English were adopted also for French. As a sanity check, we tested a range of negative sampling values [5, 15, 25, 35, 50], as well as subsampling rates for powers of 10 in [10^{-3} to 10^{-7}]. Variations in ρ are minor and do not show any clear trend.

thresh, and this was also observed for the other datasets. In short, both types of models can obtain good results. While *PPMI-thresh* is a simple, fast and inexpensive model to build, *w2v* has a free and push-button implementation, and requires less hyper-parameter tuning, as is it seems more robust to parameter variation. More generally, the best results obtained for *Reddy* and *Farahmand* are comparable and even outperform the state of the art, as shown in Tables 1 and 2, when strict evaluation is adopted (that is, when not using a fallback strategy for missing compounds).

5 Conclusions

In this paper we presented a multilingual, large-scale evaluation of DSMs for compound compositionality prediction. We have built 816 DSMs and performed 2,856 evaluations, examining the impact of corpus and context parameters, namely the level of corpus preprocessing, the context window size and the number of dimensions. Evaluation on 3 English datasets and a French one revealed that a large dimension is consistently better, and corpus preprocessing is usually beneficial. The choice of window size varies according to language and dataset, but a small window can often provide a good performance. The DSMs *w2v* and *PPMI* alternated in providing the best results. Moreover, the results obtained were comparable and even outperformed the state-of-the-art.

As future work, we plan to examine the use of a voting scheme for combining the output of complementary DSMs. Moreover, we also plan to combine additional sources of information for building the models, such as multilingual resources or translation data, to improve even further the compositionality prediction. We would also like to propose and evaluate more sophisticated compositionality functions that take into account the unbalanced contribution of individual words to the global meaning of a compound.

Abstract

We present a discriminative model for single-document summarization that integrally combines compression and anaphoricity constraints. Our model selects textual units to include in the summary based on a rich set of sparse features whose weights are learned on a large corpus. We allow for the deletion of content within a sentence when that deletion is licensed by compression rules; in our framework, these are implemented as dependencies between subsentential units of text. Anaphoricity constraints then improve cross-sentence coherence by guaranteeing that, for each pronoun included in the summary, the pronoun's antecedent is included as well or the pronoun is rewritten as a full mention. When trained end-to-end, our final system[1] outperforms prior work on both ROUGE as well as on human judgments of linguistic quality.

1 Introduction

While multi-document summarization is well-studied in the NLP literature (Carbonell and Goldstein, 1998; Gillick and Favre, 2009; Lin and Bilmes, 2011; Nenkova and McKeown, 2011), single-document summarization (McKeown et al., 1995; Marcu, 1998; Mani, 2001; Hirao et al., 2013) has received less attention in recent years and is generally viewed as more difficult. Content selection is tricky without redundancy across multiple input documents as a guide and simple positional information is often hard to beat (Penn and Zhu, 2008). In this work, we tackle the single-document problem by training an expressive summarization model on a large naturally occurring corpus—the New York Times Annotated Corpus (Sandhaus, 2008) which contains around 100,000 news articles with abstractive summaries—learning to select important content with lexical features. This corpus has been explored in related contexts (Dunietz and Gillick, 2014; Hong and Nenkova, 2014), but to our knowledge it has not been directly used for single-document summarization.

To increase the expressive capacity of our model we allow more aggressive compression of individual sentences by combining two different formalisms—one syntactic and the other discursive. Additionally, we incorporate a model of anaphora resolution and give our system the ability rewrite pronominal mentions, further increasing expressivity. In order to guide the model, we incorporate (1) constraints from coreference ensuring that critical pronoun references are clear in the final summary and (2) constraints from syntactic and discourse parsers ensuring that sentence realizations are well-formed. Despite the complexity of these additional constraints, we demonstrate an efficient inference procedure using an ILP-based approach. By training our full system end-to-end on a large-scale dataset, we are able to learn a high-capacity structured model of the summarization process, contrasting with past approaches to the single-document task which have typically been heuristic in nature (Daumé and Marcu, 2002; Hirao et al., 2013).

We focus our evaluation on the New York Times Annotated corpus (Sandhaus, 2008). According to ROUGE, our system outperforms a document prefix baseline, a bigram coverage baseline adapted from a strong multi-document system (Gillick and Favre, 2009), and a discourse-informed method from prior work (Yoshida et al., 2014). Imposing discursive and referential constraints improves human judgments of linguistic clarity and referential structure—outperforming the method of

Berlin, Germany, August 7-12, 2016.

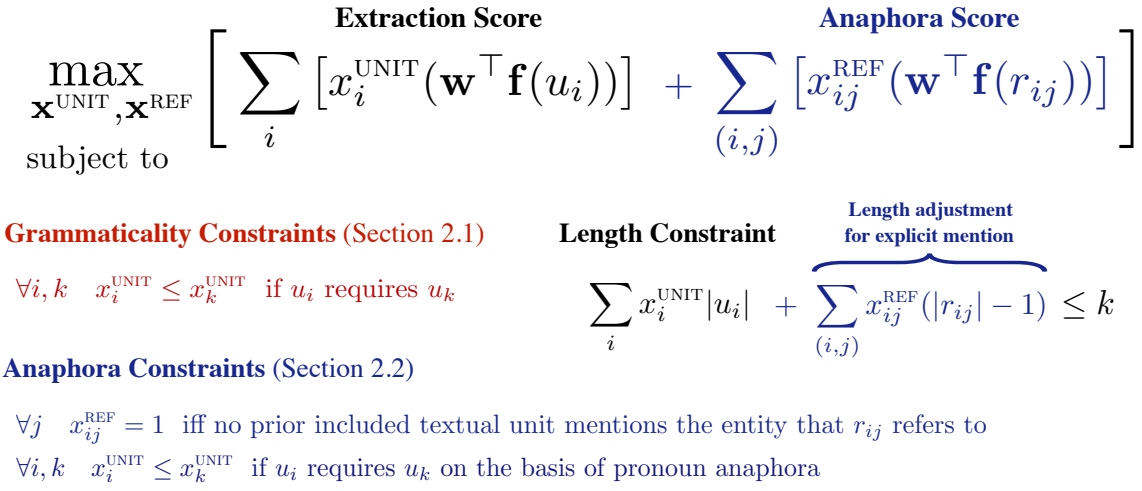

Figure 1: ILP formulation of our single-document summarization model. The basic model extracts a set of textual units with binary variables $\mathbf{x}^{\text{UNIT}}$ subject to a length constraint. These textual units $\mathbf{u}$ are scored with weights $\mathbf{w}$ and features $\mathbf{f}$. Next, we add constraints derived from both syntactic parses and Rhetorical Structure Theory (RST) to enforce grammaticality. Finally, we add anaphora constraints derived from coreference in order to improve summary coherence. We introduce additional binary variables $\mathbf{x}^{\text{REF}}$ that control whether each pronoun is replaced with its antecedent using a candidate replacement r_{ij}. These are also scored in the objective and are incorporated into the length constraint.

Yoshida et al. (2014) and approaching the clarity of a sentence-extractive baseline—and still achieves substantially higher ROUGE score than either method. These results indicate that our model has the expressive capacity to extract important content, but is sufficiently constrained to ensure fluency is not sacrificed as a result.

Past work has explored various kinds of structure for summarization. Some work has focused on improving content selection using discourse structure (Louis et al., 2010; Hirao et al., 2013), topical structure (Barzilay and Lee, 2004), or related techniques (Mithun and Kosseim, 2011). Other work has used structure primarily to reorder summaries and ensure coherence (Barzilay et al., 2001; Barzilay and Lapata, 2008; Louis and Nenkova, 2012; Christensen et al., 2013) or to represent content for sentence fusion or abstraction (Thadani and McKeown, 2013; Pighin et al., 2014). Similar to these approaches, we appeal to structures from upstream NLP tasks (syntactic parsing, RST parsing, and coreference) to restrict our model's capacity to generate. However, we go further by optimizing for ROUGE subject to these constraints with end-to-end learning.

2 Model

Our model is shown in Figure 1. Broadly, our ILP takes a set of textual units $\mathbf{u} = (u_1, \ldots, u_n)$ from a document and finds the highest-scoring extractive summary by optimizing over variables $\mathbf{x}^{\text{UNIT}} = x_1^{\text{UNIT}}, \ldots, x_n^{\text{UNIT}}$, which are binary indicators of whether each unit is included. Textual units are contiguous parts of sentences that serve as the fundamental units of extraction in our model. For a sentence-extractive model, these would be entire sentences, but for our compressive models we will have more fine-grained units, as shown in Figure 2 and described in Section 2.1. Textual units are scored according to features $\mathbf{f}$ and model parameters $\mathbf{w}$ learned on training data. Finally, the extraction process is subject to a length constraint of k words. This approach is similar in spirit to ILP formulations of multi-document summarization systems, though in those systems content is typically modeled in terms of bigrams (Gillick and Favre, 2009; Berg-Kirkpatrick et al., 2011; Hong and Nenkova, 2014; Li et al., 2015). For our model, type-level n-gram scoring only arises when we compute our loss function in max-margin training (see Section 3).

In Section 2.1, we discuss grammaticality constraints, which take the form of introducing dependencies between textual units, as shown in Figure 2. If one textual unit *requires* another, it cannot be included unless its prerequisite is. We will show that different sets of requirements can capture both syntactic and discourse-based compression schemes.

Furthermore, we introduce anaphora constraints (Section 2.2) via a new set of variables that capture the process of rewriting pronouns to make them

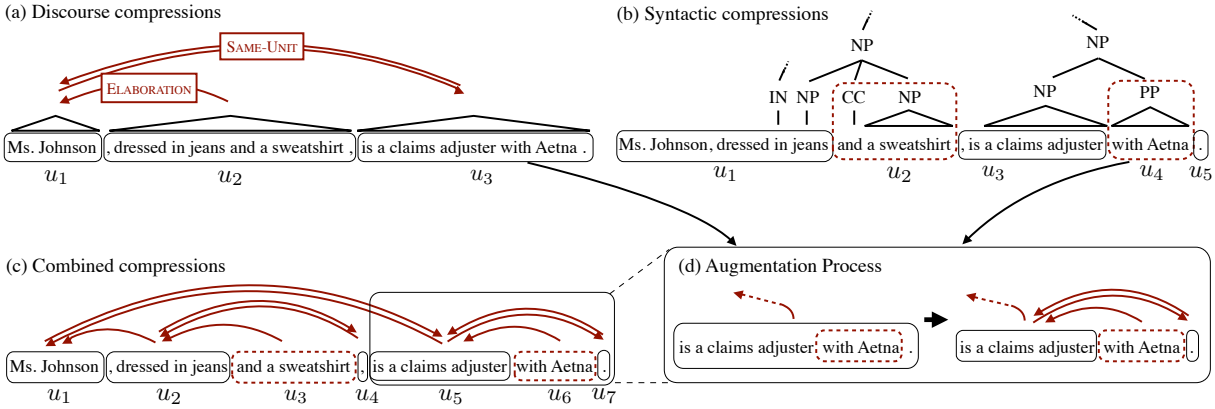

Figure 2: Compression constraints on an example sentence. (a) RST-based compression structure like that in Hirao et al. (2013), where we can delete the ELABORATION clause. (b) Two syntactic compression options from Berg-Kirkpatrick et al. (2011), namely deletion of a coordinate and deletion of a PP modifier. (c) Textual units and requirement relations (arrows) after merging all of the available compressions. (d) Process of augmenting a textual unit with syntactic compressions.

explicit mentions. That is, $x_{ij}^{\text{REF}} = 1$ if we should rewrite the jth pronoun in the ith unit with its antecedent. These pronoun rewrites are scored in the objective and introduced into the length constraint to make sure they do not cause our summary to be too long. Finally, constraints on these variables control when they are used and also require the model to include antecedents of pronouns when the model is not confident enough to rewrite them.

2.1 Grammaticality Constraints

Following work on isolated sentence compression (McDonald, 2006; Clarke and Lapata, 2008) and compressive summarization (Lin, 2003; Martins and Smith, 2009; Berg-Kirkpatrick et al., 2011; Woodsend and Lapata, 2012; Almeida and Martins, 2013), we wish to be able to compress sentences so we can pack more information into a summary. During training, our model learns how to take advantage of available compression options and select content to match human generated summaries as closely possible.[2] We explore two ways of deriving units for compression: the RST-based compressions of Hirao et al. (2013) and the syntactic compressions of Berg-Kirkpatrick et al. (2011).

RST compressions Figure 2a shows how to derive compressions from Rhetorical Structure Theory (Mann and Thompson, 1988; Carlson et al., 2001). We show a sentence broken into elementary discourse units (EDUs) with RST relations between them. Units marked as SAME-UNIT must both be kept or both be deleted, but other nodes in the tree structure can be deleted as long as we do not delete the parent of an included node. For example, we can delete the ELABORATION clause, but we can delete neither the first nor last EDU. Arrows depict the constraints this gives rise to in the ILP (see Figure 1): u_2 requires u_1, and u_1 and u_3 mutually require each other. This is a more constrained form of compression than was used in past work (Hirao et al., 2013), but we find that it improves human judgments of fluency (Section 4.3).

Syntactic compressions Figure 2b shows two examples of compressions arising from syntactic patterns (Berg-Kirkpatrick et al., 2011): deletion of the second part of a coordinated NP and deletion of a PP modifier to an NP. These patterns were curated to leave sentences as grammatical after being compressed, though perhaps with damaged semantic content.

Combined compressions Figure 2c shows the textual units and requirement relations yielded by combining these two types of compression. On this example, the two schemes capture orthogonal compressions, and more generally we find that they stack to give better results for our final system (see Section 4.3). To actually synthesize textual units and the constraints between them, we start from the set of RST textual units and introduce syntactic compressions as new children when they don't cross existing brackets; because syntactic compressions are typically narrower in scope, they are usually completely contained in EDUs.

[2]The features in our model are actually rich enough to learn a sophisticated compression model, but the data we have (abstractive summaries) does not directly provide examples of correct compressions; past work has gotten around this with multi-task learning (Almeida and Martins, 2013), but we simply treat grammaticality as a constraint from upstream models.

Figure 2d shows an example of this process: the possible deletion of *with Aetna* is grafted onto the textual unit and appropriate requirement relations are introduced. The net effect is that the textual unit is wholly included, partially included (*with Aetna* removed), or not at all.

Formally, we define an RST tree as $T_{\text{rst}} = (S_{\text{rst}}, \pi_{\text{rst}})$ where S_{rst} is a set of EDU spans (i, j) and $\pi : S \rightarrow 2^S$ is a mapping from each EDU span to EDU spans it depends on. Syntactic compressions can be expressed in a similar way with trees T_{syn}. These compressions are typically smaller-scale than EDU-based compressions, so we use the following modification scheme. Denote by $T_{\text{syn}(kl)}$ a nontrivial (supports some compression) subtree of T_{syn} that is completely contained in an EDU (i, j). We build the following combined compression tree, which we refer to as the *augmentation* of T_{rst} with $T_{\text{syn}(kl)}$:

$$T_{\text{comb}} = (S \cup S_{\text{syn}}(kl) \cup \{(i,k),(l,j)\}, \pi_{\text{rst}} \cup \pi_{\text{syn}(kl)} \cup \{(i,k) \rightarrow (l,j), (l,j) \rightarrow (i,k), (k,l) \rightarrow (i,k)\})$$

That is, we maintain the existing tree structure except for the EDU (i, j), which is broken into three parts: the outer two depend on each other (*is a claims adjuster* and . from Figure 2d) and the inner one depends on the others and preserves the tree structure from T_{syn}. We augment T_{rst} with all maximal subtrees of T_{syn}, i.e. all trees that are not contained in other trees that are used in the augmentation process.

This is broadly similar to the combined compression scheme in Kikuchi et al. (2014) but we use a different set of constraints that more strictly enforce grammaticality.[3]

2.2 Anaphora Constraints

What kind of cross-sentential coherence do we need to ensure for the kinds of summaries our system produces? Many notions of coherence are useful, including centering theory (Grosz et al., 1995) and lexical cohesion (Nishikawa et al., 2014), but one of the most pressing phenomena to deal with is pronoun anaphora (Clarke and Lapata, 2010). Cases of pronouns being "orphaned" during extraction (their antecedents are deleted) are relatively common: they occur in roughly 60% of examples produced by our summarizer when no anaphora constraints are enforced. This kind of error is particularly concerning for summary interpretation and impedes the ability of summaries to convey information effectively (Grice, 1975). Our solution is to explicitly impose constraints on the model based on pronoun anaphora resolution.[4]

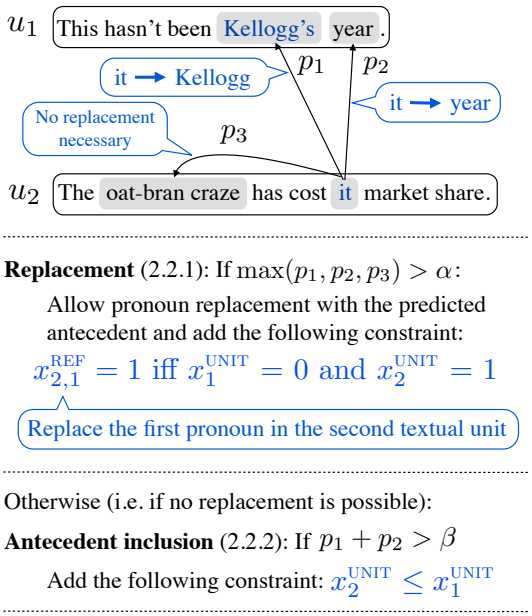

Figure 3: Modifications to the ILP to capture pronoun coherence. *It*, which refers to *Kellogg*, has several possible antecedents from the standpoint of an automatic coreference system (Durrett and Klein, 2014). If the coreference system is confident about its selection (above a threshold α on the posterior probability), we allow for the model to explicitly replace the pronoun if its antecedent would be deleted (Section 2.2.1). Otherwise, we merely constrain one or more probable antecedents to be included (Section 2.2.2); even if the coreference system is incorrect, a human can often correctly interpret the pronoun with this additional context.

Figure 3 shows an example of a problem case. If we extract only the second textual unit shown, the pronoun *it* will lose its antecedent, which in this case is *Kellogg*. We explore two types of constraints for dealing with this: rewriting the pronoun explicitly, or constraining the summary to include the pronoun's antecedent.

2.2.1 Pronoun Replacement

One way of dealing with these pronoun reference issues is to explicitly replace the pronoun with what it refers to. This replacement allows us to maintain maximal extraction flexibility, since we

[3] We also differ from past work in that we do not use cross-sentential RST constraints (Hirao et al., 2013; Yoshida et al., 2014). We experimented with these and found no improvement from using them, possibly because we have a feature-based model rather than a heuristic content selection procedure, and possibly because automatic discourse parsers are less good at recovering cross-sentence relations.

[4] We focus on pronoun coreference because it is the most pressing manifestation of this problem and because existing coreference systems perform well on pronouns compared to harder instances of coreference (Durrett and Klein, 2013).

can make an isolated textual unit meaningful even if it contains a pronoun. Figure 3 shows how this process works. We run the Berkeley Entity Resolution System (Durrett and Klein, 2014) and compute posteriors over possible links for the pronoun. If the coreference system is sufficiently confident in its prediction (i.e. $\max_i p_i > \alpha$ for a specified threshold $\alpha > \frac{1}{2}$), we allow ourselves to replace the pronoun with the first mention of the entity corresponding to the pronoun's most likely antecedent. In Figure 3, if the system correctly determines that *Kellogg* is the correct antecedent with high probability, we enable the first replacement shown there, which is used if u_2 is included the summary without u_1.[5]

As shown in the ILP in Figure 1, we instantiate corresponding pronoun replacement variables $\mathbf{x}^{\text{REF}}$ where $x_{ij}^{\text{REF}} = 1$ implies that the jth pronoun in the ith sentence should be replaced in the summary. We use a candidate pronoun replacement if and only if the pronoun's corresponding (predicted) entity hasn't been mentioned previously in the summary.[6] Because we are generally replacing pronouns with longer mentions, we also need to modify the length constraint to take this into account. Finally, we incorporate features on pronoun replacements in the objective, which helps the model learn to prefer pronoun replacements that help it to more closely match the human summaries.

2.2.2 Pronoun Antecedent Constraints

Explicitly replacing pronouns is risky: if the coreference system makes an incorrect prediction, the intended meaning of the summary may be damaged. Fortunately, the coreference model's posterior probabilities have been shown to be well-calibrated (Nguyen and O'Connor, 2015), meaning that cases where it is likely to make errors are signaled by flatter posterior distributions. In this case, we enable a more conservative set of constraints that include additional content in the summary to make the pronoun reference clear without explicitly replacing it. This is done by requiring the inclusion of any textual unit which contains possible pronoun references whose posteriors sum to at least a threshold parameter β. Figure 3 shows that this constraint can force the inclusion of u_1 to provide additional context. Although this could still lead to unclear pronouns if text is stitched together in an ambiguous or even misleading way, in practice we observe that the textual units we force to be added almost always occur very recently before the pronoun, giving enough additional context for a human reader to figure out the pronoun's antecedent unambiguously.

[5] If the proposed replacement is a proper mention, we replace the pronoun just with the subset of the mention that constitutes a named entity (rather than the whole noun phrase). We control for possessive pronouns by deleting or adding *'s* as appropriate.

[6] Such a previous mention may be a pronoun; however, note that that pronoun would then be targeted for replacement unless its antecedent were included somehow.

2.3 Features

The features in our model (see Figure 1) consist of a set of surface indicators capturing mostly lexical and configurational information. Their primary role is to identify important document content. The first three types of features fire over textual units, the last over pronoun replacements.

Lexical These include indicator features on non-stopwords in the textual unit that appear at least five times in the training set and analogous POS features. We also use lexical features on the first, last, preceding, and following words for each textual unit. Finally, we conjoin each of these features with an indicator of bucketed position in the document (the index of the sentence containing the textual unit).

Structural These features include various conjunctions of the position of the textual unit in the document, its length, the length of its corresponding sentence, the index of the paragraph it occurs in, and whether it starts a new paragraph (all values are bucketed).

Centrality These features capture rough information about the centrality of content: they consist of bucketed word counts conjoined with bucketed sentence index in the document. We also fire features on the number of times of each entity mentioned in the sentence is mentioned in the rest of the document (according to a coreference system), the number of entities mentioned in the sentence, and surface properties of mentions including type and length

Pronoun replacement These target properties of the pronoun replacement such as its length, its sentence distance from the current mention, its type (nominal or proper), and the identity of the pronoun being replaced.

3 Learning

We learn weights $\mathbf{w}$ for our model by training on a large corpus of documents $\mathbf{u}$ paired with reference summaries $\mathbf{y}$. We formulate our learning problem as a standard instance of structured SVM (see Smith (2011) for an introduction). Because we want to optimize explicitly for ROUGE-1,[7] we define a ROUGE-based loss function that accommodates the nature of our supervision, which is in terms of abstractive summaries $\mathbf{y}$ that in general cannot be produced by our model. Specifically, we take:

$$\ell(\mathbf{x}^{\text{NGRAM}}, \mathbf{y}) = \max_{\mathbf{x}^*} \text{ROUGE-1}(\mathbf{x}^*, \mathbf{y}) - \text{ROUGE-1}(\mathbf{x}^{\text{NGRAM}}, \mathbf{y})$$

i.e. the gap between the hypothesis's ROUGE score and the oracle ROUGE score achievable under the model (including constraints). Here $\mathbf{x}^{\text{NGRAM}}$ are indicator variables that track, for each n-gram type in the reference summary, whether that n-gram is present in the system summary. These are the sufficient statistics for computing ROUGE.

We train the model via stochastic subgradient descent on the primal form of the structured SVM objective (Ratliff et al., 2007; Kummerfeld et al., 2015). In order to compute the subgradient for a given training example, we need to find the most violated constraint on the given instance through a loss-augmented decode, which for a linear model takes the form $\arg\max_{\mathbf{x}} \mathbf{w}^\top \mathbf{f}(\mathbf{x}) + \ell(\mathbf{x}, \mathbf{y})$. To do this decode at training time in the context of our model, we use an extended version of our ILP in Figure 1 that is augmented to explicitly track type-level n-grams:

$$\max_{\mathbf{x}^{\text{UNIT}}, \mathbf{x}^{\text{REF}}, \mathbf{x}^{\text{NGRAM}}} \left[\sum_i \left[x_i^{\text{UNIT}} (\mathbf{w}^\top \mathbf{f}(u_i)) \right] + \sum_{(i,j)} \left[x_{ij}^{\text{REF}} (\mathbf{w}^\top \mathbf{f}(r_{ij})) \right] - \ell(\mathbf{x}^{\text{NGRAM}}, \mathbf{y}) \right]$$

subject to all constraints from Figure 1, and

$x_i^{\text{NGRAM}} = 1$ iff an included textual unit or replacement contains the ith reference n-gram

These kinds of variables and constraints are common in multi-document summarization systems that score bigrams (Gillick and Favre, 2009 *inter alia*). Note that since ROUGE is only computed over non-stopword n-grams and pronoun replacements only replace pronouns, pronoun replacement can never remove an n-gram that would otherwise be included.

For all experiments, we optimize our objective using AdaGrad (Duchi et al., 2011) with ℓ_1 regularization ($\lambda = 10^{-8}$, chosen by grid search), with a step size of 0.1 and a minibatch size of 1. We train for 10 iterations on the training data, at which point held-out model performance no longer improves. Finally, we set the anaphora thresholds $\alpha = 0.8$ and $\beta = 0.6$ (see Section 2.2). The values of these and other hyperparameters were determined on a held-out development set from our New York Times training data. All ILPs are solved using GLPK version 4.55.

4 Experiments

We primarily evaluate our model on a roughly 3000-document evaluation set from the New York Times Annotated Corpus (Sandhaus, 2008). We also investigate its performance on the RST Discourse Treebank (Carlson et al., 2001), but because this dataset is only 30 documents it provides much less robust estimates of performance.[8] Throughout this section, when we decode a document, we set the word budget for our summarizer to be the same as the number of words in the corresponding reference summary, following previous work (Hirao et al., 2013; Yoshida et al., 2014).

4.1 Preprocessing

We preprocess all data using the Berkeley Parser (Petrov et al., 2006), specifically the GPU-accelerated version of the parser from Hall et al. (2014), and the Berkeley Entity Resolution System (Durrett and Klein, 2014). For RST discourse analysis, we segment text into EDUs using a semi-Markov CRF trained on the RST treebank with features on boundaries similar to those of Hernault et al. (2010), plus novel features on spans including span length and span identity for short spans.

To follow the conditions of Yoshida et al. (2014) as closely as possible, we also build a discourse parser in the style of Hirao et al. (2013), since their parser is not publicly available. Specifically,

[7] We found that optimizing for ROUGE-1 actually resulted in a model with better performance on both ROUGE-1 and ROUGE-2. We hypothesize that this is because framing our optimization in terms of ROUGE-2 would lead to a less nuanced set of constraints: bigram matches are relatively rare when the reference is a short, abstractive summary, so a loss function based on ROUGE-2 will express a flatter preference structure among possible outputs.

[8] Tasks like DUC and TAC have focused on multi-document summarization since around 2003, hence the lack of more standard datasets for single-document summarization.

NYT50 article:

Federal officials reported yesterday that students in 4th, 8th and 12th grades had scored modestly higher on an American history test than five years earlier, although more than half of high school seniors still showed poor command of basic facts like the effect of the cotton gin on the slave economy or the causes of the Korean War. Federal officials said they considered the results encouraging because at each level tested, student performance had improved since the last time the exam was administered, in 2001. "In U.S. history there were higher scores in 2006 for all three grades," said Mark Schneider, commissioner of the National Center for Education Statistics, which administers the test, at a Boston news conference that the Education Department carried by Webcast. **The results were less encouraging on a national civics test, on which only fourth graders made any progress.** The best results in the history test were also in fourth grade, where 70 percent of students attained the basic level of achievement or better. **The test results in the two subjects are likely to be closely studied, because Congress is considering the renewal of President Bush's signature education law, the No Child Left Behind Act.** A number of studies have shown that because No Child Left Behind requires states…

Summary:

National Center for Education Statistics reports students in 4th, 8th and 12th grades scored modestly higher on American history test than five years earlier. Says more than half of high school seniors still show poor command of basic facts. Only 4th graders made any progress in civics test. New exam results are another ingredient in debate over renewing Pres Bush's signature No Child Left Behind Act.

Filtered article:

Long before President Bush's proposal to rethink Social Security became part of the national conversation, Westchester County came up with its own dialogue to bring issues of aging to the forefront. Before the White House Conference on Aging scheduled in October, **the county's Office for the Aging a year ago started Speak-Up,** which stands for Student Participants Embrace Aging Issues of Key Concern, to reach students in the county's 13 colleges and universities. Through a variety of events **to bring together the elderly and college students,** organizers said they hoped to have by this spring a series of recommendations that could be given to Washington…

Summary:

Article on Speak-Up, program begun by Westchester County Office for the Aging to bring together elderly and college students.

Figure 4: Examples of an article kept in the NYT50 dataset (top) and an article removed because the summary is too short. The top summary has a rich structure to it, corresponding to various parts of the document (bolded) and including some text that is essentially a direct extraction.

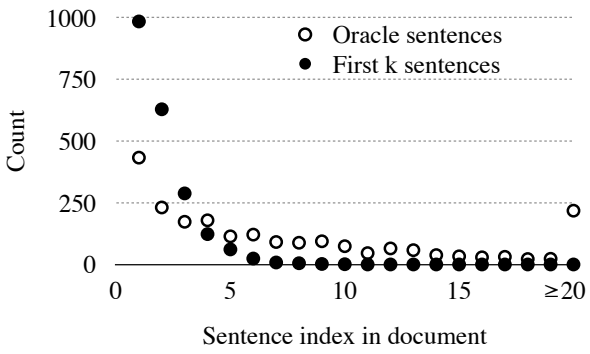

Figure 5: Counts on a 1000-document sample of how frequently both a document prefix baseline and a ROUGE oracle summary contain sentences at various indices in the document. There is a long tail of useful sentences later in the document, as seen by the fact that the oracle sentence counts drop off relatively slowly. Smart selection of content therefore has room to improve over taking a prefix of the document.

we use the first-order projective parsing model of McDonald et al. (2005) and features from Soricut and Marcu (2003), Hernault et al. (2010), and Joty et al. (2013). When using the same head annotation scheme as Yoshida et al. (2014), we outperform their discourse dependency parser on unlabeled dependency accuracy, getting 56% as opposed to 53%.

4.2 New York Times Corpus

We now provide some details about the New York Times Annotated corpus. This dataset contains 110,540 articles with abstractive summaries; we split these into 100,834 training and 9706 test examples, based on date of publication (test is all articles published on January 1, 2007 or later). Examples of two documents from this dataset are shown in Figure 4. The bottom example demonstrates that some summaries are extremely short and formulaic (especially those for obituaries and editorials). To counter this, we filter the raw dataset by removing all documents with summaries that are shorter than 50 words. One benefit of filtering is that the length distribution of our resulting dataset is more in line with standard summarization evaluations like DUC; it also ensures a sufficient number of tokens in the budget to produce nontrivial summaries. The filtered test set, which we call NYT50, includes 3,452 test examples out of the original 9,706.

Interestingly, this dataset is one where the classic document prefix baseline can be substantially outperformed, unlike in some other summarization settings (Penn and Zhu, 2008). We show this fact explicitly in Section 4.3, but Figure 5 provides additional analysis in this regard. We compute oracle ROUGE-1 sentence-extractive summaries on a 1000-document subset of the training set and look at where the extracted sentences lie in the document. While they certainly skew earlier in the document, they do not all fall within the doc-

Table 1: Results on the NYT50 test set (documents with summaries of at least 50 tokens) from the New York Times Annotated Corpus (Sandhaus, 2008). We report ROUGE-1 (R-1), ROUGE-2 (R-2), clarity/grammaticality (CG), and number of unclear pronouns (UP) (lower is better). On content selection, our system substantially outperforms all baselines, our implementation of the tree knapsack system (Yoshida et al., 2014), and learned extractive systems with less compression, even an EDU-extractive system that sacrifices grammaticality. On clarity metrics, our final system performs nearly as well as sentence-extractive systems. The symbols * and † indicate statistically significant gains compared to No Anaphoricity and Tree Knapsack (respectively) with $p < 0.05$ according to a bootstrap resampling test. We also see that removing either syntactic or EDU-based compressions decreases ROUGE.

ument prefix summary. One reason for this is that many of the articles are longer-form pieces that begin with a relatively content-free lede of several sentences, which should be identifiable with lexicosyntactic indicators as are used in our discriminative model.

4.3 New York Times Results

We evaluate our system along two axes: first, on content selection, using ROUGE[9] (Lin and Hovy, 2003), and second, on clarity of language and referential structure, using annotators from Amazon Mechanical Turk. We follow the method of Gillick and Liu (2010) for this evaluation and ask Turkers to rate a summary on how grammatical it is using a 10-point Likert scale. Furthermore, we ask how many unclear pronouns references there were in the text. The Turkers do not see the original document or the reference summary, and rate each summary in isolation. Gillick and Liu (2010) showed that for linguistic quality judgments (as opposed to content judgments), Turkers reproduced the ranking of systems according to expert judgments.

To speed up preprocessing and training time on this corpus, we further restrict our training set to only contain documents with fewer than 100 EDUs. All told, the final system takes roughly 20 hours to make 10 passes through the subsampled training data (22,000 documents) on a single core of an Amazon EC2 r3.4xlarge instance.

Table 1 shows the results on the NYT50 corpus. We compare several variants of our system and baselines. For baselines, we use two variants of first k: one which must stop on a sentence boundary (which gives better linguistic quality) and one which always consumes k tokens (which gives better ROUGE). We also use a heuristic sentence-extractive baseline that maximizes the document counts (term frequency) of bigrams covered by the summary, similar in spirit to the multi-document method of Gillick and Favre (2009).[10] We also compare to our implementation of the Tree Knapsack method of Yoshida et al. (2014), which matches their results very closely on the RST Discourse Treebank when discourse trees are controlled for. Finally, we compare several variants of our system: purely extractive systems operating over sentences and EDUs respectively, our full system, and ablations removing either the anaphoricity component or parts of the compression module.

In terms of content selection, we see that all of the systems that incorporate end-to-end learning (under "This work") substantially outperform our various heuristic baselines. Our full system using the full compression scheme is substantially better on ROUGE than ablations where the syntactic or discourse compressions are removed. These improvements reflect the fact that more compression options give the system more flexibility to include key content words. Removing the anaphora resolution constraints actually causes ROUGE to increase slightly (as a result of granting the model flexibility), but has a negative impact on the linguistic quality metrics.

On our linguistic quality metrics, it is no surprise that the sentence prefix baseline performs the best. Our sentence-extractive system also does well on these metrics. Compared to the EDU-extractive system with no constraints, our constrained compression method improves substantially on both linguistic quality and reduces the

[9] We use the ROUGE 1.5.5 script with the following command line arguments: `-n 2 -x -m -s`. All given results are macro-averaged recall values over the test set.

[10] Other heuristic multi-document approaches could be compared to, e.g. He et al. (2012), but a simple term frequency method suffices to illustrate how these approaches can underperform in the single-document setting.

Table 2: Results for RST Discourse Treebank (Carlson et al., 2001). Differences between our system and the Tree Knapsack system of Yoshida et al. (2014) are not statistically significant, reflecting the high variance in this small (20 document) test set.

number of unclear pronouns, and adding the pronoun anaphora constraints gives further improvement. Our final system is approaches the sentence-extractive baseline, particularly on unclear pronouns, and achieves substantially higher ROUGE score.

4.4 RST Treebank

We also evaluate on the RST Discourse Treebank, of which 30 documents have abstractive summaries. Following Hirao et al. (2013), we use the gold EDU segmentation from the RST corpus but automatic RST trees. We break this into a 10-document development set and a 20-document test set. Table 2 shows the results on the RST corpus. Our system is roughly comparable to Tree Knapsack here, and we note that none of the differences in the table are statistically significant. We also observed significant variation between multiple runs on this corpus, with scores changing by 1-2 ROUGE points for slightly different system variants.[11]

5 Conclusion

We presented a single-document summarization system trained end-to-end on a large corpus. We integrate a compression model that enforces grammaticality as well as pronoun anaphoricity constraints that enforce coherence. Our system improves substantially over baseline systems on ROUGE while still maintaining good linguistic quality.

Our system and models are publicly available at `http://nlp.cs.berkeley.edu`

[11] The system of Yoshida et al. (2014) is unavailable, so we use a reimplementation. Our results differ from theirs due to having slightly different discourse trees, which cause large changes in metrics due to high variance on the test set.

Acknowledgments

This work was partially supported by NSF Grant CNS-1237265 and a Google Faculty Research Award. Thanks to Tsutomu Hirao for providing assistance with our reimplementation of the Tree Knapsack model, and thanks the anonymous reviewers for their helpful comments.

Abstract

We describe and evaluate a simple method to extract parallel sentences from comparable corpora. The approach, termed STACC, is based on expanded lexical sets and the Jaccard similarity coefficient. We evaluate our system against state-of-the-art methods on a large range of datasets in different domains, for ten language pairs, showing that it either matches or outperforms current methods across the board and gives significantly better results on the noisiest datasets. STACC is a portable method, requiring no particular adaptation for new domains or language pairs, thus enabling the efficient mining of parallel sentences in comparable corpora.

1 Introduction

With the rise of data-driven machine translation, be it statistical (Brown et al., 1990), example-based (Nagao, 1984), or rooted in neural networks (Bahdanau et al., 2014), the need for large parallel corpora has increased accordingly. Although quality bitexts have been made available over the years (Tiedemann, 2012), creating parallel corpora is a resource-consuming effort involving professional human translation of large volumes of texts in multiple languages. As a consequence, there is still a lack of parallel data to properly model translation across languages and domains.

To overcome this limitation, special emphasis has been placed in the last two decades on the exploitation of comparable corpora, with the development of a range of methods to mine parallel sentences from texts addressing similar topics in different languages. The work we present follows this line of research, describing and evaluating a simple method that allows parallel sentences to be efficiently mined in different languages and domains with minimal adaptation effort.

The method we describe, termed STACC, is based on expanded lexical sets and the Jaccard similarity coefficient (Jaccard, 1901), which is computed as the ratio of set intersection over union. We evaluate this simple approach against state-of-the-art methods for comparable sentence alignment on a variety of datasets for ten different language pairs, showing that STACC either matches or outperforms competing approaches.

The paper is organised as follows: Section 2 describes related work on parallel sentence mining in comparable corpora; Section 3 presents the STACC method; Section 4 describes the experiments in comparable sentence alignment, including the description of test corpora and systems, and an analysis of the results; Section 5 presents results obtained with an optimised version of the alignment process, beyond system comparison; finally, Section 6 draws conclusions from the work described in the paper.

2 Related work

A large variety of techniques have been proposed to mine parallel sentences in comparable corpora. One of the first approaches was proposed by (Zhao and Vogel, 2002), who combined sentence length and bilingual lexicon models under a maximum likelihood criterion. (Munteanu and Marcu, 2002) explored the use of suffix trees, later opting for maximum entropy-based binary classification using a modified version of IBM Model 1 word translation probabilities (Brown et al., 1993)

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2009–2018,
Berlin, Germany, August 7-12, 2016.

and both general and alignment-specific features (Munteanu and Marcu, 2005). (Fung and Cheung, 2004) describe the first approach to tackle parallel sentence mining in very non-parallel corpora, using cosine similarity as their sentence selection criterion.

Several approaches have employed full statistical machine translation models instead of relying only on lexical tables. (Abdul-Rauf and Schwenk, 2009), for instance, apply the TER metric (Snover et al., 2006) on fully machine translated output to identify parallel sentences; (Sarikaya et al., 2009) use a similar approach but with BLEU (Papineni et al., 2002) as their similarity metric. One of the noted advantages of including full machine translation is the ability to better model the complex factors found in translation, e.g. fertility and contextual information, as compared to lexicon-based approaches. The latter enable, in principle, the capture of a larger set of lexical translation variants, and do not require the training of complete translation models.

Sophisticated feature-based approaches have been developed in recent years in order to provide a method that may apply to larger sets of language pairs and domains. (Stefănescu et al., 2012) report improvements over previous methods with a feature-based sentence similarity measure, an approach which is described in more detail in Section 4.2.1. Another feature-rich approach is described in (Smith et al., 2010), showing improvements over standard and improved binary classifiers; we describe their model in more details in Section 4.2.2.

Jaccard similarity, a core component of the approach we describe, has been standardly used as a text similarity measure in information retrieval and text summarisation tasks, or to compute semantic similarity (Pilehvar et al., 2013). For comparable corpora, it has been notably employed by (Paramita et al., 2013), who estimate document comparability by computing the coefficient on a subset of translated source sentences, discarding those containing large amounts of named entities or numbers, and taking the average of these sentence-level scores. The method we present in the next section builds on a related similarity measure as a direct indicator of comparable sentence similarity.

3 STACC

STACC is an approach to sentence similarity based on expanded lexical sets, whose main goal is to provide a simple yet effective procedure that can be applied across domains and corpora with minimal adaptation and deployment costs.

We start with the minimal set of bilingual information that can be automatically extracted from a seed parallel corpus, using lexical translations determined and ranked according to IBM models; word translations are computed in both directions using the GIZA++ toolkit (Och and Ney, 2003).

STACC relies on the Jaccard index, which defines set similarity as the ratio of set intersection over union. We base our comparable sentence similarity measure strictly on this index, applying it to expanded lexical sets as described below.

Let s_i and s_j be two tokenised and truecased sentences in languages l_1 and l_2, respectively, S_i the set of tokens in s_i, S_j the set of tokens in s_j, T_{ij} the set of expanded translations into l_2 for all tokens in S_i, and T_{ji} the set of expanded translations into l_1 for all tokens in S_j. The STACC similarity score is then computed as in Equation 1:

$$sim_{stacc} = \frac{\frac{|T_{ij} \cap S_j|}{|T_{ij} \cup S_j|} + \frac{|T_{ji} \cap S_i|}{|T_{ji} \cup S_i|}}{2} \quad (1)$$

That is, the score is defined as the average of the Jaccard similarity coefficients obtained between sentence token sets and expanded lexical translations in both directions.

The translation sets T_{ij} and T_{ji} are initially computed from sentences s_i and s_j by retaining the k-best lexical translations found in GIZA tables, if any. Lexical translations are selected according to the ranking provided by the precomputed lexical probabilities but the specific probability values are not used any further to compute similarity:[1] all potential translations are members of the translation set as tokens. Discarding this source of potentially exploitable information is mostly motivated by the relative reliability of lexical translation probabilities across domains. Lexical translations are usually extracted from a different domain than that of the comparable corpora at hand, typically using professionally created institutional corpora such as Europarl (Koehn, 2005), and lexical distributions across

[1] This differs from (Skadiņa et al., 2012), who include a lexical translation feature where actual probabilities are used to compute the final score.

domains can be expected to be quite different. This casts doubt on the usefulness of using precomputed translation probabilities and simple set membership was favoured in our approach.

The initial lexical translation sets undergo a first expansion step to capture morphological variation, using longest common prefix matching (hereafter, LCP). To apply prefix matching to the minimal set of elements necessary, we compute the following two set differences:

- Set of elements in the source to target translation set that are not members of the target token set: $T'_{ij} = T_{ij} - S_j$
- Set of elements in the target to source translation set that are not members of the source token set: $T'_{ji} = T_{ji} - S_i$

For each element in T'_{ij} (respectively T'_{ji}) and each element in S_j (respectively S_i), if a common prefix is found with a minimal length of more than n characters, the prefix is added to both translation sets.[2]

This simplified approach to stemming removes the need to rely on manually constructed endings lists to compute similarity or on a complete morphological analyser, which might not be available at all for under-resourced languages. It is also computationally more efficient as it exploits the nature of the alignment problem to reduce the search space: instead of matching each source and target word against every potential ending, with hundreds of possible endings in some languages, only the prefixes of word pairs within the subsets created through set difference need to be compared using LCP.

Another set expansion operation is defined to handle named entities, which are strong indicators of potential alignment, given their low relative frequency, and are likely to be missing from translation tables trained on a different domain. While creating the previously defined lexical translation sets from truecased sentences, capitalised tokens that are not found in the translation tables are added to the translation sets. Numbers are similarly handled and added to the expanded sets, as they can also act as alignment indicators, in particular when they denote dates.

These two expansions steps are essential to a successful use of Jaccard similarity for comparable sentence alignment. For instance, LCP gives a 2.9 points improvement in F1 measure on the initial Basque-Spanish test set described in Section 4.1, whereas the NE/Number expansion resulted in a 1.3 points gain; the two expansions combined gave a 4.3 points increase in terms of F1 measure. For the English-Bulgarian pair on the initial Wikipedia test set, the gains were 3.7, 2.6 and 5.5, respectively. Combining the two operations thus contributed to the improvements over the state of the art described in Section 4.3.

No additional operations are performed on the created sets, and in particular no filtering is applied, with punctuation and functional words kept alongside content words in the final sets. This notably eliminates the use of stop word lists from the computation of similarity.

Although it builds on fairly standard ideas, such as the use of GIZA tables or the Jaccard index, the approach is original in its conjoined use of these elements with surface-based information and simple set-theoretic operations to form a similarity assessment mechanism that proved efficient on comparable corpora, as shown in the next section.

4 Comparable sentence alignment

We performed a systematic comparison between different approaches to comparable sentence alignment on a variety of comparable corpora and language pairs. This section describes the components of the experimental setup.

4.1 Corpora

Three core sets of corpora were used in the evaluation, which we describe in turn. The selected test sets, all manually aligned, were used in different settings with gradual amounts of alignment noise added to the original sets. The goal of noisification is to assess the behavior of each approach in different scenarios and evaluate their ability to properly align data from ideal conditions to gradually noisier environments, the latter being a more realistic case when dealing with comparable corpora.

The first corpus consists in the public datasets created within the Accurat project.[3] The corpus covers 7 language pairs, each one composed of English and an under-resourced language. The datasets contain manually verified alignments that were created from news articles. We noisified these datasets by adding sentences from the

[2] Throughout the experiments we describe, n was set to 3.

Table 3: EITB evaluation sets

original comparable corpora collected within the project, creating the following additional variants: (i) a 2:1 noisified version, where for each sentence in the original sets, 2 additional sentences without corresponding alignments were added; and (ii) a 100:1 noisified version with 100 sentences added for each sentence in the test sets. For each language pair, the additional sentences were taken from the initial portion of the selected additional corpora in one language and the final portion in the other language. For the 2:1 datasets, and the 100:1 variants in some language pairs, the original comparable corpora were used as additional data. For other language pairs, creating the 100:1 variant required adding sentences from different corpora to reach the required amount of data. Table 1 describes the final datasets used in the evaluation.[4]

As a second corpus, we used the data described in (Smith et al., 2010).[5] The texts were extracted from Wikipedia articles in 3 language pairs (English-German, English-Spanish and English-Bulgarian) and manually annotated for parallelism. We used the provided test sets (hereafter, WTS) and added a 100:1 noisified variant using sentences from the News Crawl corpus[6] for English-German and English-Spanish, and from Europarl for the English-Bulgarian pair. Table 2 describes these datasets, to which we will refer collectively as the Wikipedia corpus.

Finally, we used the EITB corpus, composed of news generated by the Basque Country's public broadcasting service.[7] The news are written independently in Basque and Spanish but refer to the same specific events and the corpus can thus be categorized as strongly comparable. We defined initial test sets of 500 manually aligned sentences in each language, and created two noisified variants: (i) a test set with 500 additional sentences in both languages, and (ii) a test set with 500 additional sentences in Spanish and 1000 in Basque. All additional sentences were taken from unaligned portions of the same EITB corpus. Table 3 summarises the EITB test sets.

The selected corpora thus cover 10 different language pairs and different domains, with varying degrees of noisification, and provide for a large and diverse comparison set.

4.2 Systems

Three approaches were evaluated against the previously described corpora: LEXACC (Stefănescu et al., 2012), the STACC method described in Section 3, and the approach based on Conditional Random Fields described in (Smith et al., 2010), to which we will refer as CRF. The latter was only evaluated on the Wikipedia corpus, using the re-

[4]In the table, ATS refers to the Accurat test sets, AOC to the Accurat original corpora, and EUP to the Europarl corpus.

sults reported in the aforementioned article, as the tools to apply this method were not available to us; both LEXACC and STACC were evaluated on all test sets.

LEXACC was selected given its reported performance and its aim at portability across domains and language pairs; the system is also available as part of the Accurat toolkit,[8] which allowed for a direct comparison with STACC on all datasets.

The CRF approach has proven more effective than standard classifier-based methods on the Wikipedia datasets, with published results on publically available test sets, and was thus selected as an alternative approach to comparable sentence alignment.

Both approaches are based on sophisticated methods with demonstrated improvements over the state-of-the-art, thus providing strong baselines for system comparison.

4.2.1 LEXACC

LEXACC is a fast parallel sentence mining system based on a cross-linguistic information retrieval (CLIR) approach. It uses the Lucene search engine[9] in two major steps: target sentences are first indexed by the search engine, and a search query is built from a translation of content words in the source sentence to retrieve alignment candidates. The query is constructed using IBM Model 1 lexical translation tables, extracted from seed parallel corpora

The alignment metric in LEXACC is a translation similarity measure based on 5 feature functions briefly described here (see (Ștefănescu et al., 2012) for a detailed description):

- f_1 measures source-target candidate pairs strength in terms of content word translation and string similarity;
- f_2 is similar to f_1 but applies to functional words, as identified in manually created stop word lists;
- f_3 measures content word alignment obliqueness defined as a discounted correlation measure;
- f_4 is a binary feature that compares the number of initial/final aligned word translations over a pre-defined threshold;
- f_5 is a second binary feature which evaluates if the source and target sentences end with the same punctuation.

The similarity measure is then computed according to the sum of weighted feature functions, with optimal weights determined by means of logistic regression. We used the optimal feature weights described in (Ștefănescu et al., 2012) for the language pairs in the Accurat corpus and the provided default weights for English-Spanish and English-Bulgarian; for Basque-Spanish, optimal weights were estimated through logistic regression on a training set formed with 9500 positive parallel examples from the IVAP corpus[10] and an equal amount of non-parallel negative examples.

For the experiments, all lexical translation tables were created with GIZA++ on the JRC-Acquis Communautaire corpus.[11] Lucene searches were set to return a maximum of 100 candidates for each source sentence. We used the default setup for LEXACC, except for two minor changes. First, we removed the initial Lucene search constraint which was set to discard identical source and target sentences, a setting which prevented the retrieval of valid news candidates such as sports results. Secondly, we increased the length ratio filter from 1.5 to 7.5, as the initial value was too restrictive for the Basque-Spanish corpus. Both changes were thus meant to retrieve the most accurate set of alignment candidates, in order to get meaningful results on the test sets with both methods.

4.2.2 Conditional Random Fields

The model we refer to as CRF (Smith et al., 2010) is a first order linear chain Conditional Random Field (Lafferty et al., 2001), where for each source sentence a hidden variable indicates the corresponding target sentence to which it is aligned, or null if there is no such target sentence. This system was compared to the standard binary classifier of (Munteanu and Marcu, 2005) and to a ranking variant designed by the authors to avoid class imbalance issues that arise with binary classification. On the Wikipedia test sets, the CRF approach gave

[8] http://www.accurat-project.eu/index.php?p=accurat-toolkit

[9] http://lucenenet.apache.org/

[10] Extracted from the translation memories released by the Basque Public Administration Institute (http://opendata.euskadi.eus/catalogo/-/memorias-de-traduccion-del-servicio-oficial-de-traductores-del-ivap/), which consist of professional translations of public administration texts.

[11] We used the latest available version of the corpus, as of November 2015, in the OPUS repository: http://opus.lingfil.uu.se/JRC-Acquis.php.

the best results overall and was thus selected for our system comparison.

The sequence model comprises the following features:

- A word alignment feature set, based on IBM Model 1 and HMM alignments, which includes: log probability of the alignment; number of aligned/unaligned words; longest aligned/unaligned sequence of words; and number of words for different degrees of fertility.
- Two sentence-related features: source and target length ratio modeled through a Poisson distribution (Moore, 2002), and relative position of source and target sentences in the document.
- A set of distortion features measuring the difference in position between the previous and current aligned sentences.
- A set of features based on Wikipedia markup, including matching and non-matching links for alignment candidates.
- A set of lexicon features based on a probabilistic model of word pair alignments, trained on a set of annotated Wikipedia articles. The lexicon-based feature set includes the HMM translation probability, word-based positional differences, orthographic similarity, context translation similarity and distributional similarity.

The seed parallel data were based on the Europarl corpus for Spanish and German and the JRC-Aquis corpus for Bulgarian. The authors also included article titles of parallel Wikipedia documents and Wiktionary translations as additional seed data.

4.2.3 STACC

In order to establish a fair comparison between LEXACC and STACC, all shared settings were identical. Thus, lexical translations were based on the same previously described GIZA tables extracted from the JRC corpus, and STACC alignment was performed on the same sets of candidates retrieved from the Lucene searches by LEXACC for each language pair.

As described in Section 3, STACC is based on the k-best translations provided by lexical translation tables. For the experiments, k was set to 5, a value arbitrarily determined to be an optimal compromise between overcrowding the sets with unlikely translations and limiting translation candidates to minimal translation variants. Experimenting with different values on the test sets showed that this value for k was not actually the optimal one for some language pairs, with e.g. a 2.9 point gain in F1 measure when setting k to 2 for English-Greek on the initial Accurat test set.[12]

The results we present in the next section are thus not the best achievable ones using the STACC approach. Nonetheless, we maintained the use of a default value because of the lack of in-domain development sets on which an optimal value could be fairly computed.

4.3 Results

To evaluate the accuracy of the tested methods, precision was taken as the ratio of correct alignments over predicted alignments, and recall as the ratio of correct alignments over true alignments. We present results in terms of F1 measure, as we seek an optimal balance between alignment precision and recall.

Table 4 presents the results on the Accurat test sets for LEXACC and STACC using their respective optimal similarity thresholds.[13] On the 21 test sets, the two systems were tied on two occasions, with STACC obtaining better results in 89.5% of the remaining cases. On the noisiest datasets, STACC was consistently and markedly better across language pairs.

The results on the Wikipedia test sets are shown in Table 5. For English-Spanish and English-German, both approaches performed quite similarily on the initial test sets, with STACC obtaining the best results on the noisier sets.

The results for English-Bulgarian are interesting, as this is the only case where LEXACC outperforms STACC on both the clean and noisy datasets. The data used for noisification in this case may have had an effect on the results. Data extracted from Europarl, which compose the entire noisifi-

[12] Note that similar issues would arise if the selected translations were determined based on thresholds over translation probabilities, as the thresholds would need to be empirically set as well.

[13] The optimal thresholds were determined as the values providing the best results on the test sets. This would obviously not be an available threshold selection method when mining comparable corpora, where a default value would have to be used instead. Such a default value would however not allow for a fair comparison of the systems.

cation set for this language pair, is closer to the JRC vocabulary than the original comparable data on which the alignment process would take place in real-world conditions. Although we have not thoroughly tested the impact of this variable, it is possible that those datasets are more confusing for an approach such as STACC, which is based mostly on lexical information extracted from seed parallel data, than for a feature-based approach where some features, like the boolean punctuation-based ones in LEXACC, may compensate for erroneous alignments due to artificial domain vocabulary overlap. Determining if this hypothesis is indeed correct would require further experiments beyond the scope of this paper

To include the CRF approach in the comparison, we used two of the provided measures, namely recall obtained at precisions of 80 and 90 percent on the 1:1 test sets.[14] We report results obtained with the best variant of CRF, namely the model which includes Wikipedia and lexicon features, with intersected results from both directions. Results are reported in Table 6. Although the comparison was limited in this case, results were in favour of LEXACC and STACC on targeted recall measures for the Wikipedia datasets.

Finally, both LEXACC and STACC were compared against the EITB test sets, with results shown in Table 7. For this language pair, STACC performed markedly better with differences of up to 25 points. A likely explanation for these results is the nature of the features that compose the LEXACC model. In particular the features related to alignment obliqueness and number of initial/final aligned words might be detrimental in the case of Basque, which exhibits free word order. Given the poor results obtained with feature weights optimised on the IVAP corpus, we also checked the results using the provided default weights. This resulted in slightly better performance, as shown in the rows named LEXACC_DF in Table 7, though still far from the results achieved with STACC.

4.4 Discussion

Overall, STACC provided the best results across domains and language pairs, in particular for noisier datasets. Additionally, the approach has several advantages over existing methods and systems for comparable segment alignment.

First, it is undoubtedly simpler, as it requires but minimal information to reach optimal results. Lexical tables and simple set expansion operations based on surface properties of the tokens are the only components of the approach, as compared to the more sophisticated feature-based approaches which rely on larger sets of components for which optimal weights need to be computed prior to applying the models.

Secondly, because of its simplicity, STACC is a more portable method, as is it is not necessary to perform any type of adaptation for new domains and language pairs, nor to rely on domain-specific information such as link structure in Wikipedia. In actual practice, portability is an important issue which hinders on the exploitation of comparable corpora. An efficient yet easily deployable method is therefore a welcome addition to the toolset for parallel data extraction.

Finally, STACC results in fewer computational steps when compared to more complex feature-based methods. First, it involves simple binary set intersection and union operations for the computation of similarity, instead of conjoined feature computation on larger component sets. Secondly, the approach relies on tractable set differences for its most computationally expensive operation of longest common prefix matching, compared to matching all tokens against lists of word endings which can be quite large, notably in the case of agglutinative languages.

Although promising, the approach could be further evaluated, and potentially improved, along two main lines.

It might be worth exploring for instance the impact of filtering alignment candidates according to the relative position of sentence pairs in the original source and target documents, a document-level property notably exploited by (Smith et al., 2010). As the STACC approach is featureless, and meant to remain as such in order to maintain its portability and ease of deployment, filtering distant sentence pairs would need to take place prior to the computation of alignment scores. A simple approach compatible with STACC would consist in constraining candidate sets by including sentence position information when performing indexing and candidate querying in a CLIR approach. This would provide an additional evalua-

[14] Note that, for both LEXACC and STACC, in some scenarios even the lowest thresholds gave precisions higher than 90, rendering the comparison moot. We indicate these cases with a ↑ sign next to the highest recall obtained at the closest precision to the arbitrary 80 and 90 precision points.

tion of the accuracy of the approach in scenarios where document-level information is exploitable.

Additionally, given the importance of k-best lexical translations in computing STACC similarity, variations in lexical coverage obtained with different translation tables can be expected to impact alignment accuracy. Although mining comparable corpora usually requires the use of seed translation knowledge extracted from a domain that differs from the one being mined, default tables with wide lexical coverage can be built from existing parallel corpora in different domains. Thus, improvements might be obtained with larger and more diverse tables than the ones used in the experiments reported here, which were based on translations extracted from a single domain. A precise assessment of the evolution of alignment accuracy given variations in lexical translation coverage is left for future research.

5 Alignment optimisation

As previously mentioned, for both LEXACC and STACC, alignments were computed for every source sentence against candidate translations retrieved by Lucene and all cases where a given target sentence has more than one source alignment were left as is.

Although this methodology enabled a fair comparison between the two systems, it evidently impacts alignment accuracy. One simple optimisation is to retain only the best overall source-target alignments, discarding all alignments established between a given source sentence and a target sentence if the latter is linked to better scoring source sentences.

The net effect of this procedure is the promotion of better alignments, as some correct alignments would not be hidden anymore by other better scoring shared alignments. This is most likely to occur with source-target pairs that are close variants of each other, with close similarity scores.

We applied this simple optimisation to the Accurat test sets and observed improvements across the board, as shown in Figure 1. Depending on actual usage, this optimised version of STACC alignment can constitute the best alternative for the extraction of parallel sentences from comparable corpora.

6 Conclusions

We described a simple approach to comparable sentence alignment, termed STACC, which is based on automatically extracted seed lexical translations, the Jaccard similarity coefficient, and simple set expansion operations that target named entities, numbers, and morphological variation using longest common prefixes. Building on fairly standard components for the computation of similarity, this method is shown to perform better than current alternatives.

The approach was evaluated on a large range of datasets from various domains for ten language pairs, giving the best results overall when compared to sophisticated state-of-the-art methods. STACC also performed better than competing approaches on noisier corpora, showing promises for the exploitation of the typically noisy data found when mining comparable corpora.

STACC is a highly portable method which requires no adaptation for its application to new domains and language pairs. It thus allows for the fast deployment of a crucial component in comparable corpora alignment, which opens the path for an increase in the amount of such corpora that can be exploited in the future.

Abstract

We propose a joint formulation for learning task-specific cross-lingual word embeddings, along with classifiers for that task. Unlike prior work, which first learns the embeddings from parallel data and then plugs them in a supervised learning problem, our approach is one-shot: a single optimization problem combines a co-regularizer for the multilingual embeddings with a task-specific loss. We present theoretical results showing the limitation of Euclidean co-regularizers to increase the embedding dimension, a limitation which does not exist for other co-regularizers (such as the ℓ_1-distance). Despite its simplicity, our method achieves state-of-the-art accuracies on the RCV1/RCV2 dataset when transferring from English to German, with training times below 1 minute. On the TED Corpus, we obtain the highest reported scores on 10 out of 11 languages.

1 Introduction

Distributed representations of text (embeddings) have been the target of much research in natural language processing (Collobert and Weston, 2008; Mikolov et al., 2013; Pennington et al., 2014; Levy et al., 2015). Word embeddings partially capture semantic and syntactic properties of text in the form of dense real vectors, making them apt for a wide variety of tasks, such as language modeling (Bengio et al., 2003), sentence tagging (Turian et al., 2010; Collobert et al., 2011), sentiment analysis (Socher et al., 2011), parsing (Chen and Manning, 2014), and machine translation (Zou et al., 2013).

At the same time, there has been a consistent progress in devising "universal" multilingual models via cross-lingual transfer techniques of various kinds (Hwa et al., 2005; Zeman and Resnik, 2008; McDonald et al., 2011; Ganchev and Das, 2013; Martins, 2015). This line of research seeks ways of using data from resource-rich languages to solve tasks in resource-poor languages. Given the difficulty of handcrafting language-independent features, it is highly appealing to obtain rich, delexicalized, multilingual representations embedded in a shared space.

A string of work started with Klementiev et al. (2012) on learning bilingual embeddings for text classification. Hermann and Blunsom (2014) proposed a noise-contrastive objective to push the embeddings of parallel sentences to be close in space. A bilingual auto-encoder was proposed by Chandar et al. (2014), while Faruqui and Dyer (2014) applied canonical correlation analysis to parallel data to improve monolingual embeddings. Other works optimize a sum of monolingual and cross-lingual terms (Gouws et al., 2015; Soyer et al., 2015), or introduce bilingual variants of skip-gram (Luong et al., 2015; Coulmance et al., 2015). Recently, Pham et al. (2015) extended the non-compositional paragraph vectors of Le and Mikolov (2014) to a bilingual setting, achieving a new state of the art at the cost of more expensive (and non-deterministic) prediction.

In this paper, we propose an alternative joint formulation that learns embeddings suited to a particular task, together with the corresponding classifier for that task. We do this by minimizing a combination of a supervised loss function and a multilingual regularization term. Our approach leads to a convex optimization problem and makes a bridge between classical co-regularization approaches for semi-supervised learning (Sindhwani et al., 2005; Altun et al., 2005; Ganchev et al.,

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2019–2028,
Berlin, Germany, August 7-12, 2016.

2008) and modern representation learning. In addition, we show that Euclidean co-regularizers have serious limitations to learn rich embeddings, when the number of task labels is small. We establish this by proving that the resulting embedding matrices have their rank upper bounded by the number of labels. This limitation does not exist for other regularizers (convex or not), such as the ℓ_1-distance and noise-contrastive distances.

Our experiments in the RCV1/RCV2 dataset yield state-of-the-art accuracy (92.7%) with this simple convex formulation, when transferring from English to German, without the need of negative sampling, extra monolingual data, or non-additive representations. For the reverse direction, our best number (79.3%), while far behind the recent `para_doc` approach (Pham et al., 2015), is on par with current compositional methods.

On the TED corpus, we obtained general purpose multilingual embeddings for 11 target languages, by considering the (auxiliary) task of reconstructing pre-trained English word vectors. The resulting embeddings led to cross-lingual multi-label classifiers that achieved the highest reported scores on 10 out of these 11 languages.[1]

2 Cross-Lingual Text Classification

We consider a **cross-lingual classification** framework, where a classifier is trained on a dataset from a source language (such as English) and applied to a target language (such as German). Later, we generalize this setting to multiple target languages and to other tasks besides classification.

The following data are assumed available:

1. A **labeled dataset** $\mathcal{D}_l := \{\langle \boldsymbol{x}^{(m)}, y^{(m)}\rangle\}_{m=1}^{M}$, consisting of text documents $\boldsymbol{x}$ in the source language categorized with a label $y \in \{1, \ldots, L\}$.
2. An **unlabeled parallel corpus** $\mathcal{D}_u := \{(\boldsymbol{s}^{(n)}, \boldsymbol{t}^{(n)})\}_{n=1}^{N}$, containing sentences $\boldsymbol{s}$ in the source language paired with their translations $\boldsymbol{t}$ in the target language (but no information about their categories).

Let V_{S} and V_{T} be the vocabulary size of the source and target languages, respectively. Throughout, we represent sentences $\boldsymbol{s} \in \mathbb{R}^{V_{\text{S}}}$ and $\boldsymbol{t} \in \mathbb{R}^{V_{\text{T}}}$ as vectors of word counts, and documents $\boldsymbol{x}$ as an average of sentence vectors. We assume that the unlabeled sentences largely outnumber the labeled documents, $N \gg M$, and that the number of labels L is relatively small. The goal is to use the data above to learn a classifier $h : \mathbb{R}^{V_{\text{T}}} \to \{1, \ldots, L\}$ for the target language.

This problem is usually tackled with a two-stage approach: in the first step, bilingual word embeddings $\boldsymbol{P} \in \mathbb{R}^{V_{\text{S}} \times K}$ and $\boldsymbol{Q} \in \mathbb{R}^{V_{\text{T}} \times K}$ are learned from $\mathcal{D}_u$, where each row of these matrices contains a Kth dimensional word representation in a shared vector space. In the second step, a standard classifier is trained on $\mathcal{D}_l$, using the source embeddings $\boldsymbol{P} \in \mathbb{R}^{V_{\text{S}} \times K}$. Since the embeddings are in a shared space, the trained model can be applied directly to classify documents in the target language. We describe next these two steps in more detail. We assume throughout an additive representation for sentences and documents (denoted ADD by Hermann and Blunsom (2014)). These representations can be expressed algebraically as $\boldsymbol{P}^\top \boldsymbol{x}, \boldsymbol{P}^\top \boldsymbol{s}, \boldsymbol{Q}^\top \boldsymbol{t} \in \mathbb{R}^K$, respectively.

Step 1: Learning the Embeddings. The cross-lingual embeddings $\boldsymbol{P}$ and $\boldsymbol{Q}$ are trained so that the representations of paired sentences $(\boldsymbol{s}, \boldsymbol{t}) \in \mathcal{D}_u$ have a small (squared) Euclidean distance

$$d_{\ell_2}(\boldsymbol{s}, \boldsymbol{t}) = \frac{1}{2}\|\boldsymbol{P}^\top \boldsymbol{s} - \boldsymbol{Q}^\top \boldsymbol{t}\|^2. \quad (1)$$

Since a direct minimization of Eq. 1 leads to a degenerate solution ($\boldsymbol{P} = \boldsymbol{0}, \boldsymbol{Q} = \boldsymbol{0}$), Hermann and Blunsom (2014) use instead a noise-contrastive large-margin distance obtained via negative sampling,

$$d_{\text{ns}}(\boldsymbol{s}, \boldsymbol{t}, \boldsymbol{n}) = [m + d_{\ell_2}(\boldsymbol{s}, \boldsymbol{t}) - d_{\ell_2}(\boldsymbol{s}, \boldsymbol{n})]_+, \quad (2)$$

where $\boldsymbol{n}$ is a random (unpaired) target sentence, m is a "margin" parameter, and $[x]_+ := \max\{0, x\}$. Letting J be the number of negative examples in each sample, they arrive at the following objective function to be minimized:

$$\mathcal{R}_{\text{ns}}(\boldsymbol{P}, \boldsymbol{Q}) := \frac{1}{N}\sum_{n=1}^{N}\sum_{j=1}^{J} d_{\text{ns}}(\boldsymbol{s}^{(n)}, \boldsymbol{t}^{(n)}, \boldsymbol{n}^{(n,j)}). \quad (3)$$

This minimization can be carried out efficiently with gradient-based methods, such as stochastic gradient descent or AdaGrad (Duchi et al., 2011). Note however that the objective function in Eq. 3 is not convex. Therefore, one may land at different local minima, depending on the initialization.

[1] We provide the trained embeddings at `http://www.cs.cmu.edu/~afm/projects/multilingual_embeddings.html`.

Step 2: Training the Classifier. Once we have the bilingual embeddings $\boldsymbol{P}$ and $\boldsymbol{Q}$, we can compute the representation $\boldsymbol{P}^\top \boldsymbol{x} \in \mathbb{R}^K$ of each document $\boldsymbol{x}$ in the labeled dataset $\mathcal{D}_l$. Let $\boldsymbol{V} \in \mathbb{R}^{K \times L}$ be a matrix of parameters (weights), with one column $\boldsymbol{v}_y$ per label. A linear model is used to make predictions, according to

$$\begin{aligned} \widehat{y} &= \text{argmax}_{y \in \{1,\ldots,L\}} \boldsymbol{v}_y^\top \boldsymbol{P}^\top \boldsymbol{x} \\ &= \text{argmax}_{y \in \{1,\ldots,L\}} \boldsymbol{w}_y^\top \boldsymbol{x}, \end{aligned} \quad (4)$$

where $\boldsymbol{w}_y$ is a column of the matrix $\boldsymbol{W} := \boldsymbol{PV} \in \mathbb{R}^{V_\text{S} \times L}$. In prior work, the perceptron algorithm was used to learn the weights $\boldsymbol{V}$ from the labeled examples in $\mathcal{D}_l$ (Klementiev et al., 2012; Hermann and Blunsom, 2014). Note that, at test time, it is not necessary to store the full embeddings: if $L \ll K$, we may simply precompute $\boldsymbol{W} := \boldsymbol{PV}$ (one weight per word and label) if the input is in the source language—or $\boldsymbol{QV}$, if the input is in the target language—and treat this as a regular bag-of-words linear model.

3 Jointly Learning to Embed and Classify

Instead of a two-stage approach, we propose to learn the bilingual embeddings and the classifier *jointly* on $\mathcal{D}_l \cup \mathcal{D}_u$, as described next.

Our formulation optimizes a combination of a **co-regularization function** $\mathcal{R}$, whose goal is to push the embeddings of paired sentences in $\mathcal{D}_u$ to stay close, and a **loss function** $\mathcal{L}$, which fits the model to the labeled data in $\mathcal{D}_l$.

The simplest choice for $\mathcal{R}$ is a simple Euclidean co-regularization function:

$$\begin{aligned} \mathcal{R}_{\ell_2}(\boldsymbol{P}, \boldsymbol{Q}) &= \frac{1}{N} \sum_{n=1}^{N} d_{\ell_2}(\boldsymbol{s}^{(n)}, \boldsymbol{t}^{(n)}) \\ &= \frac{1}{2N} \sum_{n=1}^{N} \|\boldsymbol{P}^\top \boldsymbol{s}^{(n)} - \boldsymbol{Q}^\top \boldsymbol{t}^{(n)}\|^2. \end{aligned} \quad (5)$$

An alternative is the ℓ_1-distance:

$$\mathcal{R}_{\ell_1}(\boldsymbol{P}, \boldsymbol{Q}) = \frac{1}{N} \sum_{n=1}^{N} \|\boldsymbol{P}^\top \boldsymbol{s}^{(n)} - \boldsymbol{Q}^\top \boldsymbol{t}^{(n)}\|_1. \quad (6)$$

One possible advantage of $\mathcal{R}_{\ell_1}(\boldsymbol{P}, \boldsymbol{Q})$ over $\mathcal{R}_{\ell_2}(\boldsymbol{P}, \boldsymbol{Q})$ is that the ℓ_1-distance is more robust to outliers, hence it is less sensitive to differences in the parallel sentences. Note that both functions in Eqs. 5–6 are jointly convex on $\boldsymbol{P}$ and $\boldsymbol{Q}$, unlike the one in Eq. 3. They are also simpler and do not require negative sampling. While these functions have a degenerate behavior in isolation (since they are both minimized by $\boldsymbol{P} = \boldsymbol{0}$ and $\boldsymbol{Q} = \boldsymbol{0}$), we will see that they become useful when plugged into a joint optimization framework.

The next step is to define the loss function $\mathcal{L}$ to leverage the labeled data in $\mathcal{D}_l$. We consider a log-linear model $P(y \mid \boldsymbol{x}; \boldsymbol{W}) \propto \exp(\boldsymbol{w}_y^\top \boldsymbol{x})$, which leads to the following logistic loss function:

$$\mathcal{L}_{LL}(\boldsymbol{W}) = -\frac{1}{M} \sum_{m=1}^{M} \log P(y^{(m)} \mid \boldsymbol{x}^{(m)}; \boldsymbol{W}). \quad (7)$$

We impose that $\boldsymbol{W}$ is of the form $\boldsymbol{W} = \boldsymbol{PV}$ for a fixed $\boldsymbol{V} \in \mathbb{R}^{K \times L}$, whose choice we discuss below.

Putting the pieces together and adding some extra regularization terms, we formulate our joint objective function as follows:

$$\begin{aligned} \mathcal{F}(\boldsymbol{P}, \boldsymbol{Q}) &= \mu \mathcal{R}(\boldsymbol{P}, \boldsymbol{Q}) + \mathcal{L}(\boldsymbol{PV}) \\ &\quad + \frac{\mu_\text{S}}{2} \|\boldsymbol{P}\|_\text{F}^2 + \frac{\mu_\text{T}}{2} \|\boldsymbol{Q}\|_\text{F}^2, \end{aligned} \quad (8)$$

where $\mu, \mu_\text{S}, \mu_\text{T} \geq 0$ are regularization constants. By minimizing a combination of $\mathcal{L}(\boldsymbol{PV})$ and $\mathcal{R}(\boldsymbol{P}, \boldsymbol{Q})$, we expect to obtain embeddings $\boldsymbol{Q}^*$ that lead to an accurate classifier h for the target language. Note that $\boldsymbol{P} = \boldsymbol{0}$ and $\boldsymbol{Q} = \boldsymbol{0}$ is no longer a solution, due to the presence of the loss term $\mathcal{L}(\boldsymbol{PV})$ in the objective.

Choice of $\boldsymbol{V}$. In Eq. 8, we chose to keep $\boldsymbol{V}$ fixed rather than optimize it. The rationale is that there are many more degrees of freedom in the embedding matrices $\boldsymbol{P}$ and $\boldsymbol{Q}$ than in $\boldsymbol{V}$ (concretely, $\mathcal{O}(K(V_\text{S} + V_\text{T}))$ versus $\mathcal{O}(KL)$, where we are assuming a small number of labels, $L \ll V_\text{S} + V_\text{T}$). Our assumption is that we have enough degrees of freedom to obtain an accurate model, regardless of the choice of $\boldsymbol{V}$. These claims will be backed in §4 by a more rigorous theoretical result. Keeping $\boldsymbol{V}$ fixed has another important advantage: it allows to minimize $\mathcal{F}$ with respect to $\boldsymbol{P}$ and $\boldsymbol{Q}$ only, which makes it a convex optimization problem if we choose $\mathcal{R}$ and $\mathcal{L}$ to be both convex—*e.g.*, setting $\mathcal{R} \in \{\mathcal{R}_{\ell_2}, \mathcal{R}_{\ell_1}\}$ and $\mathcal{L} := \mathcal{L}_{LL}$.

Relation to Multi-View Learning. An interesting particular case of this formulation arises if $K = L$ and $\boldsymbol{V} = \boldsymbol{I}_L$ (the identity matrix). In that case, we have $\boldsymbol{W} = \boldsymbol{P}$ and the embedding matrices $\boldsymbol{P}$ and $\boldsymbol{Q}$ are in fact weights for every pair of word and label, as in standard bag-of-word

models. In this case, we may interpret the co-regularizer $\mathcal{R}(\boldsymbol{P}, \boldsymbol{Q})$ in Eq. 8 as a term that pushes the *label scores* of paired sentences $\boldsymbol{P}^\top \boldsymbol{s}^{(n)}$ and $\boldsymbol{Q}^\top \boldsymbol{t}^{(n)}$ to be similar, while the source-based log-linear model is fit via $\mathcal{L}(\boldsymbol{W})$. The same idea underlies various semi-supervised co-regularization methods that seek agreement between multiple views (Sindhwani et al., 2005; Altun et al., 2005; Ganchev et al., 2008). In fact, we may regard the joint optimization in Eq. 8 as a generalization of those methods, making a bridge between those methods and representation learning.

Multilingual Embeddings. It is straightforward to extend the framework herein presented to the case where there are *multiple* target languages (say R of them), and we want to learn one embedding matrix for each, $\{\boldsymbol{Q}_1, \ldots, \boldsymbol{Q}_R\}$. The simplest way is to consider a sum of pairwise co-regularizers,

$$\mathcal{R}'(\boldsymbol{P}, \{\boldsymbol{Q}_1, \ldots, \boldsymbol{Q}_R\}) := \sum_{r=1}^{R} \mathcal{R}(\boldsymbol{P}, \boldsymbol{Q}_r). \quad (9)$$

If $\mathcal{R}$ is additive over the parallel sentences (which is the case for $\mathcal{R}_{\ell_2}$, $\mathcal{R}_{\ell_1}$ and $\mathcal{R}_{\text{ns}}$), then this procedure is equivalent to concatenating all the parallel sentences (regardless of the target language) and adding a language suffix to the words to distinguish them. This reduces directly to a problem in the same form as Eq. 8.

Pre-Trained Source Embeddings. In practice, it is often the case that pre-trained embeddings for the source language are already available (let $\bar{\boldsymbol{P}}$ be the available embedding matrix). It would be foolish not to exploit those resources. In this scenario, the goal is to use $\bar{\boldsymbol{P}}$ and the dataset $\mathcal{D}_u$ to obtain "good" embeddings for the target languages (possibly tweaking the source embeddings too, $\boldsymbol{P} \approx \bar{\boldsymbol{P}}$). Our joint formulation in Eq. 8 can also be used to address this problem. It suffices to set $K = L$ and $\boldsymbol{V} = \boldsymbol{I}_L$ (as in the multi-view learning case discussed above) and to define an auxiliary task that pushes $\boldsymbol{P}$ and $\bar{\boldsymbol{P}}$ to be similar. The simplest way is to use a reconstruction loss:

$$\mathcal{L}_{\ell_2}(\boldsymbol{P}, \bar{\boldsymbol{P}}) := \frac{1}{2}\|\boldsymbol{P} - \bar{\boldsymbol{P}}\|_{\text{F}}^2. \quad (10)$$

The resulting optimization problem has resemblances with the retrofitting approach of Faruqui et al. (2015), except that the goal here is to extend the embeddings to other languages, instead of pushing monolingual embeddings to agree with a semantic lexicon. We will present some experiments in §5.2 using this framework.

4 Limitations of the Euclidean Co-Regularizer

One may wonder how much the embedding dimension K influences the learned classifier. The next proposition shows the (surprising) result that, with the formulation in Eq. 8 with $\mathcal{R} = \mathcal{R}_{\ell_2}$, it makes absolutely no difference to increase K past the number of labels L. Below, $\boldsymbol{T} \in \mathbb{R}^{V_{\text{T}} \times N}$ denotes the matrix with columns $\boldsymbol{t}^{(1)}, \ldots, \boldsymbol{t}^{(N)}$.

Proposition 1. *Let $\mathcal{R} = \mathcal{R}_{\ell_2}$ and assume $\boldsymbol{T}$ has full row rank.*[2] *Then, for any choice of $\boldsymbol{V} \in \mathbb{R}^{K \times L}$, possibly with $K > L$, the following holds:*

1. *There is an alternative, low-dimensional, $\boldsymbol{V}' \in \mathbb{R}^{K' \times L}$ with $K' \leq L$ such that the classifier obtained (for both languages) by optimizing Eq. 8 using $\boldsymbol{V}'$ is the same as if using $\boldsymbol{V}$.*[3]
2. *This classifier depends on $\boldsymbol{V}$ only via the L-by-L matrix $\boldsymbol{V}^\top \boldsymbol{V}$.*
3. *If $\boldsymbol{P}^*, \boldsymbol{Q}^*$ are the optimal embeddings obtained with $\boldsymbol{V}$, then we always have $\text{rank}(\boldsymbol{P}^*) \leq L$ and $\text{rank}(\boldsymbol{Q}^*) \leq L$ regardless of K.*

Proof. See App. A.1 in the supplemental material. □

Let us reflect for a moment on the practical impact of Prop. 1. This result shows the limitation of the Euclidean co-regularizer $\mathcal{R}_{\ell_2}$ in a very concrete manner: when $\mathcal{R} = \mathcal{R}_{\ell_2}$, we only need to consider representations of dimension $K \leq L$.

Note also that a corollary of Prop. 1 arises when $\boldsymbol{V}^\top \boldsymbol{V} = \boldsymbol{I}_L$, i.e., when $\boldsymbol{V}$ is chosen to have orthonormal columns (a sensible choice, since it corresponds to seeking embeddings that leave the label weights "uncorrelated"). Then, the second statement of Prop. 1 tells us that the resulting classifier will be the same as if we had simply set $\boldsymbol{V} = \boldsymbol{I}_L$ (the particular case discussed in §3). We will see in §5.1 that, despite this limitation, this classifier is actually a very strong baseline. Of course, if the number of labels L is large enough,

[2] This assumption is not too restrictive: it holds if $N \geq V_{\text{T}}$ and if no target sentence can be written as a linear combination of the others (this can be accomplished if we remove redundant parallel sentences).

[3] Let $\boldsymbol{P}^*, \boldsymbol{Q}^*$ and $\boldsymbol{P}'^*, \boldsymbol{Q}'^*$ be the optimal embeddings obtained with $\boldsymbol{V}$ and $\boldsymbol{V}'$, respectively. Since we are working with linear classifiers, the two classifiers are the same in the sense that $\boldsymbol{P}^*\boldsymbol{V} = \boldsymbol{P}'^*\boldsymbol{V}'$ and $\boldsymbol{Q}^*\boldsymbol{V} = \boldsymbol{Q}'^*\boldsymbol{V}'$.

this limitation might not be a reason for concern.[4] An instance will be presented in §5.2, where we will see that the Euclidean co-regularizer excels.

Finally, one might wonder whether Prop. 1 applies only to the (Euclidean) ℓ_2 norm or if it holds for arbitrary regularizers. In fact, we show in App. A.2 that this limitation applies more generally to Mahalanobis-Frobenius norms, which are essentially Euclidean norms after a linear transformation of the vector space. However, it turns out that for general norms such limitation does *not* exist, as shown below.

Proposition 2. *If $\mathcal{R} = \mathcal{R}_{\ell_1}$ in Eq. 8, then the analogous to Proposition 1 does not hold. It also does not hold for the ℓ_∞-norm and the ℓ_0-"norm."*

Proof. See App. A.3 in the supplemental material. □

This result suggests that, for other regularizers $\mathcal{R} \neq \mathcal{R}_{\ell_2}$, we may eventually obtain better classifiers by increasing K past L. As such, in the next section, we experiment with $\mathcal{R} \in \{\mathcal{R}_{\ell_2}, \mathcal{R}_{\ell_1}, \mathcal{R}_{\text{ns}}\}$, where $\mathcal{R}_{\text{ns}}$ is the (non-convex) noise-contrastive regularizer of Eq. 3.

5 Experiments

We report results on two experiments: one on cross-lingual classification on the Reuters RCV1/RCV2 dataset, and another on multi-label classification with multilingual embeddings on the TED Corpus.[5]

5.1 Reuters RCV1/RCV2

We evaluate our framework on the cross-lingual document classification task introduced by Klementiev et al. (2012). Following prior work, our dataset $\mathcal{D}_u$ consists of 500,000 parallel sentences from the Europarl v7 English-German corpus (Koehn, 2005); and our labeled dataset $\mathcal{D}_l$ consists of English and German documents from the RCV1/RCV2 corpora (Lewis et al., 2004), each categorized with one out of $L = 4$ labels. We used the same split as Klementiev et al. (2012): 1,000 documents for training, of which 200 are held out as validation data, and 5,000 for testing.

Note that, in this dataset, we are classifying documents based on their bag-of-word representations, and learning word embeddings by bringing the bag-of-word representations of parallel sentences to be close together. In this sense, we are bringing together these multiple levels of representations (document, sentence and word).

We experimented with the joint formulation in Eq. 8, with $\mathcal{L} := \mathcal{L}_{LL}$ and $\mathcal{R} \in \{\mathcal{R}_{\ell_2}, \mathcal{R}_{\ell_1}, \mathcal{R}_{\text{ns}}\}$. We optimized with AdaGrad (Duchi et al., 2011) with a stepsize of 1.0, using mini-batches of 100 Reuters RCV1/RCV2 documents and 50,000 Europarl v7 parallel sentences. We found no need to run more than 100 iterations, with most of our runs converging under 50. Our vocabulary has 69,714 and 175,650 words for English and German, respectively, when training on the English portion of the Reuters RCV1/RCV2 corpus, and 61,120 and 183,888 words for English and German, when training in the German portion of the corpus. This difference is due to the inclusion of words in the training data into the vocabulary. We do not remove any words from the vocabulary, for simplicity. We used the validation set to tune the hyperparameters $\{\mu, \mu_{\text{S}}, \mu_{\text{T}}\}$ and to choose the iteration number. When using $K = L$, we chose $\boldsymbol{V} = \boldsymbol{I}_L$; otherwise, we chose $\boldsymbol{V}$ randomly, sampling its entries from a Gaussian $\mathcal{N}(0, 0.1)$.

Table 1 shows the results. We include for comparison the most competitive systems published to date. The first thing to note is that our joint system with Euclidean co-regularization performs very well for this task, despite the theoretical limitations shown in §4. Although its embedding size is only $K = 4$ (one dimension per label), it outperformed all the two-stage systems trained on the same data, in both directions.

For the EN→DE direction, our joint system with ℓ_1 co-regularization achieved state-of-the-art results (92.7%), matching two-stage systems that use extra monolingual data, negative sampling, or non-additive document representations. It is conceivable that the better results of $\mathcal{R}_{\ell_1}$ over $\mathcal{R}_{\ell_2}$ come from its higher robustness to differences in the parallel sentences.

For the DE→EN direction, our best result (79%) was obtained with the noise-contrastive co-regularizer, which outperformed all systems except `para_doc` (Pham et al., 2015). While the accuracy of `para_doc` is quite impressive, note that it requires 500-dimensional embeddings

[4] For regression tasks (such as the one presented in the last paragraph of 3), instead of the "number of labels," L should be regarded as the number of output variables to regress.

[5] Our code is available at `https://github.com/dcferreira/multilingual-joint-embeddings`.

Table 1: Accuracies in the RCV1/RCV2 dataset. Shown for comparison are Klementiev et al. (2012) [KTB12], Hermann and Blunsom (2014) [HB14], Gouws et al. (2015) [GBC15], Soyer et al. (2015) [SSA15], Shi et al. (2015) [SLLS15], and Pham et al. (2015) [PLM15]. Systems marked with (†) used the full 1.8M parallel sentences in Europarl. The one with (‡) used additional target monolingual data from RCV1/RCV2. The bottom rows refer to our joint method, with Euclidean (ℓ_2), ℓ_1, and noise-contrastive co-regularization.

(hence many more parameters), was trained on more parallel sentences, and requires more expensive (and non-deterministic) computation at test time to compute a document's embedding. Our method has the advantage of being simple and very fast to train: it took less than 1 minute to train the joint-$\mathcal{R}_{\ell_1}$ system for EN→DE, using a single core on an Intel Xeon @2.5 GHz. This can be compared with Klementiev et al. (2012), who took 10 days on a single core, or Coulmance et al. (2015), who took 10 minutes with 6 cores.[6]

Although our theoretical results suggest that increasing K when using the ℓ_1 norm may increase the expressiveness of our embeddings, our results do not support this claim (the improvements in DE→EN from $K = 4$ to $K = 40$ were tiny). However, it led to a gain of 2.5 points when using negative sampling. For $K = 40$, this system is much more accurate than Hermann and Blunsom (2014), which confirms that learning the embeddings together with the task is highly beneficial.

[6]Coulmance et al. (2015) reports accuracies of 87.8% (EN→DE) and 78.7% (DE→EN), when using 10,000 training documents from the RCV1/RCV2 corpora.

5.2 TED Corpus

To assess the ability of our framework to handle multiple target languages, we ran a second set of experiments on the TED corpus (Cettolo et al., 2012), using the training and test partitions created by Hermann and Blunsom (2014), downloaded from `http://www.clg.ox.ac.uk/tedcorpus`. The corpus contains English transcriptions and multilingual, sentence-aligned translations of talks from the TED conference in 12 different languages, with 12,078 parallel documents in the training partition (totalling 1,641,985 parallel sentences). Following their prior work, we used this corpus both as parallel data ($\mathcal{D}_u$) and as the task dataset ($\mathcal{D}_l$). There are $L = 15$ labels and documents can have multiple labels.

We experimented with two different strategies:

- A one-stage system (*Joint*), which jointly trains the multilingual embeddings and the multi-label classifier (similarly as in §5.1). To cope with multiple target languages, we used a sum of pairwise co-regularizers as described in Eq. 9. For classification, we use multinomial logistic regression, where we select those labels with a posterior probability above 0.18 (tuned on vali-

dation data).

- A two-stage approach (*Joint w/ Aux*), where we first obtain multilingual embeddings by applying our framework with an auxiliary task with pre-trained English embeddings (as described in Eq. 10 and in the last paragraph of §3), and then use the resulting multilingual representations to train the multi-label classifier. We address this multi-label classification problem with independent binary logistic regressors (one per label), trained by running 100 iterations of L-BFGS (Liu and Nocedal, 1989). At test time, we select those labels whose posterior probability are above 0.5.

For the *Joint w/ Aux* strategy, we used the 300-dimensional GloVe-840B vectors (Pennington et al., 2014), downloaded from `http://nlp.stanford.edu/projects/glove/`.

Table 2 shows the results for cross-lingual classification, where we use English as source and each of the other 11 languages as target. We compare our two strategies above with the strong Machine Translation (MT) baseline used by Hermann and Blunsom (2014) (which translates the input documents to English with a state-of-the-art MT system) and with their two strongest systems, which build document-level representations from embeddings trained bilingually or multilingually (called DOC/ADD *single* and DOC/ADD *joint*, respectively).[7] Overall, our *Joint* system with ℓ_2 regularization outperforms both Hermann and Blunsom (2014)'s systems (but not the MT baseline) for 8 out of 11 languages, performing generally better than our ℓ_1-regularized system. However, the clear winner is our ℓ_2-regularized *Joint w/ Aux* system, which wins over all systems (including the MT baseline) by a substantial margin, for all languages. This shows that pre-trained source embeddings can be extremely helpful in bootstrapping multilingual ones.[8] On the other hand, the performance of the *Joint w/ Aux* system with ℓ_1 regularization is rather disappointing. Note that the limitations of $\mathcal{R}_{\ell_2}$ shown in §4 are not a concern here, since the auxiliary task has $L = 300$ dimensions (the dimension of the pre-trained embeddings). A small sample of the multilingual embeddings produced by the winner system is shown in Table 4.

Finally, we did a last experiment in which we use our multilingual embeddings obtained with *Joint w/ Aux* to train monolingual systems for each language. This time, we compare with a bag-of-words naïve Bayes system (reported by Hermann and Blunsom (2014)), a system trained on the Polyglot embeddings from Al-Rfou et al. (2013) (which are multilingual, but not in a shared representation space), and the two systems developed by Hermann and Blunsom (2014). The results are shown in Table 3. We observe that, with the exception of Turkish, our systems consistently outperform all the competitors. Comparing the bottom two rows of Tables 2 and 3 we also observe that, for the ℓ_2-regularized system, there is not much degradation caused by cross-lingual training versus training on the target language directly (in fact, for Spanish, Polish, and Brazilian Portuguese, the former scores are even higher). This suggests that the multilingual embeddings have high quality.

6 Conclusions

We proposed a new formulation which jointly minimizes a combination of a supervised loss function with a multilingual co-regularization term using unlabeled parallel data. This allows learning task-specific multilingual embeddings together with a classifier for the task. Our method achieved state-of-the-art accuracy on the Reuters RCV1/RCV2 cross-lingual classification task in the English to German direction, while being extremely simple and computationally efficient. Our results in the Reuters RCV1/RCV2 task, obtained using Europarl v7 as parallel data, show that our method has no trouble handling different levels of representations simutaneously (document, sentence and word). On the TED Corpus, we obtained the highest reported scores for 10 out of 11 languages, using an auxiliary task with pre-trained English embeddings.

Acknowledgments

We would like to thank the three anonymous reviewers. This work was partially supported by the European Union under H2020 project SUMMA, grant 688139, and by Fundação para a Ciência e Tecnologia (FCT),

[7] Note that, despite the name, the Hermann and Blunsom (2014)'s *joint* systems are not doing joint training as we are.

[8] Note however that, overall, our *Joint w/ Aux* systems have access to more data than our *Joint* systems and also than Hermann and Blunsom (2014)'s systems, since the pre-trained embeddings were trained on a large amount of English monolingual data. Yet, the amount of target language data is the same.

Abstract

Coarse-grained semantic categories such as supersenses have proven useful for a range of downstream tasks such as question answering or machine translation. To date, no effort has been put into integrating the supersenses into distributional word representations. We present a novel joint embedding model of words and supersenses, providing insights into the relationship between words and supersenses in the same vector space. Using these embeddings in a deep neural network model, we demonstrate that the supersense enrichment leads to a significant improvement in a range of downstream classification tasks.

1 Introduction

The effort of understanding the meaning of words is central to the NLP community. The word sense disambiguation (WSD) task has therefore received a substantial amount of attention (see Navigli (2009) or Pal and Saha (2015) for an overview). Words in training and evaluation data are usually annotated with senses taken from a particular lexical semantic resource, most commonly WordNet (Miller, 1995). However, WordNet has been criticized to provide too fine-grained distinctions for end level applications. e.g. in machine translation or information retrieval (Izquierdo et al., 2009). Although some researchers report an improvement in sentiment prediction using WSD (Rentoumi et al., 2009; Akkaya et al., 2011; Sumanth and Inkpen, 2015), the publication bias toward positive results (Plank et al., 2014) impedes the comparison to experiments with the opposite conclusion, and the contribution of WSD to downstream document classification tasks remains "mostly speculative"(Ciaramita and Altun, 2006), which can be attributed to the too subtle sense distinctions (Navigli, 2009). This is why *supersenses*, the coarse-grained word labels based on WordNet's (Fellbaum, 1998) lexicographer files, have recently gained attention for text classification tasks. Supersenses contain 26 labels for nouns, such as ANIMAL, PERSON or FEELING and 15 labels for verbs, such as COMMUNICATION, MOTION or COGNITION. Usage of supersense labels has been shown to improve dependency parsing (Agirre et al., 2011), named entity recognition (Marrero et al., 2009; Rüd et al., 2011), non-factoid question answering (Surdeanu et al., 2011), question generation (Heilman, 2011), semantic role labeling (Laparra and Rigau, 2013), personality profiling (Flekova and Gurevych, 2015), semantic similarity (Severyn et al., 2013) and metaphor detection (Tsvetkov et al., 2013).

An alternative path to semantic interpretation follows the distributional hypothesis (Harris, 1954). Recently, word vector representations learned with neural-network based language models have contributed to state-of-the-art results on various linguistic tasks (Bordes et al., 2011; Mikolov et al., 2013b; Pennington et al., 2014; Levy et al., 2015).

In this work, we present a novel approach for incorporating the supersense information into the word embedding space and propose a new methodology for utilizing these to label the text with supersenses and to exploit these joint word and supersense embeddings in a range of applied text classification tasks. Our contributions in this work include the following:

- We are the first to provide a joint word- and supersense-embedding model, which we make publicly available[1] for the research community. This provides an insight into the word and supersense positions in the vector space

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2029–2041,
Berlin, Germany, August 7-12, 2016.

through similarity queries and visualizations, and can be readily used in any word embedding application.

- Using this information, we propose a supersense tagging model which achieves competitive performance on recently published social media datasets.
- We demonstrate how these predicted supersenses and their embeddings can be used in a range of text classification tasks. Using a deep neural network architecture, we achieve an improvement of 2-6% in accuracy for the tasks of sentiment polarity classification, subjectivity classification and metaphor prediction.

2 Related Work

2.1 Semantically Enhanced Word Embeddings

An idea of combining the distributional information with the expert knowledge is attractive and has been newly pursued in multiple directions. One of them is creating the word sense or synset embeddings (Iacobacci et al., 2015; Chen et al., 2014; Rothe and Schütze, 2015; Bovi et al., 2015). While the authors demonstrate the utility of these embeddings in tasks such as WSD, knowledge base unification or semantic similarity, the contribution of such vectors to downstream document classification problems can be challenging, given the fine granularity of the WordNet senses (cf. the discussion in Navigli (2009)). As discussed above, supersenses have been shown to be better suited for carrying the relevant amount of semantic information. An alternative approach focuses on altering the objective of the learning mechanism to capture relational and similarity information from knowledge bases (Bordes et al., 2011; Bordes et al., 2012; Yu and Dredze, 2014; Bian et al., 2014; Faruqui and Dyer, 2014; Goikoetxea et al., 2015). While, in principle, supersenses could be seen as a relation between a word and its hypernym, to our knowledge they have not been explicitly employed in these works. Moreover, an important advantage of our explicit supersense embeddings compared to the retrained vectors is their direct interpretability.

2.2 Supersense Tagging

Supersenses, also known as lexicographer files or semantic fields, were originally used to organize lexical-semantic resources (Fellbaum, 1990). The supersense tagging task was introduced by Ciaramita and Johnson (2003) for nouns and later expanded for verbs (Ciaramita and Altun, 2006). Their state-of-the-art system is trained and evaluated on the SemCor data (Miller et al., 1994) with an F-score of 77.18%, using a hidden Markov model. Since then, the system, resp. its reimplementation by Heilman[2], was widely used in applied tasks (Agirre et al., 2011; Surdeanu et al., 2011; Laparra and Rigau, 2013). Supersense taggers have then been built also for Italian (Picca et al., 2008), Chinese (Qiu et al., 2011) and Arabic (Schneider et al., 2013). Tsvetkov et al. (2015) proposes the usage of SemCor supersense frequencies as a way to evaluate word embedding models, showing that a good alignment of embedding dimensions to supersenses correlates with performance of the vectors in word similarity and text classification tasks. Recently, Johannsen et al. (2014) introduced a task of multiword supersense tagging on Twitter. On their newly constructed dataset, they show poor domain adaptation performance of previous systems, achieving a maximum performance with a search-based structured prediction model (Daumé III et al., 2009) trained on both Twitter and SemCor data. In parallel, Schneider and Smith (2015) expanded a multiword expression (MWE) annotated corpus of online reviews with supersense information, following an alternative annotation scheme focused on MWE. Similarly to Johannsen et al. (2014), they find that SemCor may not be a sufficient resource for supersense tagging adaption to different domains. Therefore, in our work, we explore the potential of using an automatically annotated Babelfied Wikipedia corpus (Scozzafava et al., 2015) for this task.

3 Building Supersense Embeddings

To learn our embeddings, we adapt the freely available sample of 500k articles of Babelfied English Wikipedia (Scozzafava et al., 2015). To our knowledge, this is one of the largest published and evaluated sense-annotated corpora, containing over 500 million words, of which over 100 million are annotated with Babel synsets, with an estimated synset annotation accuracy of 77.8%. Few other automatically sense-annotated Wikipedia corpora are available (Jordi Atserias and Attardi, 2008; Reese et

[2] https://github.com/kutschkem/SmithHeilmann_fork/tree/master/MIRATagger

2	*About 10.9% of* N.GROUP *were below the* N.POSSESSION V.CHANGE *13.6% of those under* N.ATTRIBUTE *18.*
3	*About 10.9% of* FAMILIES_N.GROUP *were below the* POVERTY_LINE_N.POSSESSION INCLUDING_V.CHANGE *13.6% of those under* AGE_N.ATTRIBUTE *18.*

Table 1: Example of plain (1), generalized (2) and disambiguated (3) Wikipedia

al., 2010). However, their annotation quality was assessed only on the training domain and as Atserias et al. state (p.2316): *"Wikipedia text differs significantly ... from the corpora used to train the taggers ... Therefore the quality of these NLP processors is considerably lower than the results of the evaluation in-domain."*

We map the Babel synsets to WordNet 3.0 synsets (Miller, 1995) using the BabelNet API (Navigli and Ponzetto, 2012), and map these synsets to their corresponding WordNet's supersense categories (Miller, 1990; Fellbaum, 1990). For the nested named entities, only the largest BabelNet span is considered, hence there are no nested supersense labels in our data. In this manner we obtain an alternative Wikipedia corpus, where each word is replaced by its corresponding supersense (see Table 1, second row) and another alternative corpus where each word has its supersense appended (Table 1, third row). Using the Gensim (Řehůřek and Sojka, 2010) implementation of Word2vec (Mikolov et al., 2013a), we applied the skip-gram model with negative sampling on these three Wikipedia corpora jointly (i.e., on the rows 1, 2 and 3 in Table 1) to produce continuous representations of words, supersense-disambiguated words and standalone supersenses in one vector space based on the distributional information obtained from the data. [3] The benefits of learning this information jointly are threefold:

1. Vectorial representations of the original words are altered (compared to training on text only), taking into account the similarity to supersenses in the vector space
2. Standalone supersenses are positioned in the vector space, enabling insightful similarity queries between words and supersenses, esp. for unannotated words
3. Disambiguated word+supersense vectors of annotated words can be employed similarly to sense embeddings (Iacobacci et al., 2015; Chen et al., 2014) to improve downstream tasks and serve as input for supersense disambiguation or contextual similarity systems

In the following, the designation WORDS denotes the experiments with the word embeddings learned on plain Wikipedia text (as in row 1 of Table 1) while the designation SUPER denotes the experiments with the word embeddings learned jointly on the supersense-enriched Wikipedia (i.e., rows 1, 2 and 3 in Table 1 together).

4 Qualitative Analysis

4.1 Verb Supersenses

Table 2 shows the most similar word vectors to each of the verb supersense vectors using cosine similarity. Note that while no explicit part-of-speech information is specified, the most similar words hold both the semantic and syntactic information - most of the assigned words are verbs.

VERBS	
BODY	wearing, injured, worn, wear, wounded, bitten, soaked, healed, cuffed, dressed
CHANGE	changed, started, added, dramatically, expanded drastically, begun, altered, shifted, transformed
COGNITION	known, thought, consider, regarded, remembered attributed, considers, accepted, believed, read
COMMUNICATION	stated, said, argued, jokingly, called, noted, suggested, described, claimed, referred
COMPETITION	won, played, lost, beat, scored defeated, win, competed, winning, playing
CONSUMPTION	feed, fed, employed, based, hosted feeds, utilized, applied, provided, consumed
CONTACT	thrown, set, carried, opened, laid pulled, placed, cut, dragged, broken
CREATION	produced, written, created, designed, developed directed, built, published, penned, constructed
EMOTION	want, felt, loved, wanted, delighted disappointed, feel, like, saddened, thrilled
MOTION	brought, led, headed, returned, followed left, turned, sent, travelled, entered
PERCEPTION	seen, shown, revealed, appeared, appears shows, noticed, see, showing, presented
POSSESSION	received, obtained, awarded, acquired, provided donated, gained, bought, found, sold
SOCIAL	appointed, established, elected, joined, assisted led, succeeded, encouraged, initiated, organized
STATIVE	included, held, includes, featured, served, represented, referred, holds, continued, related
WEATHER	glow, emitted, ignited, flare, emitting smoke, fumes, sunlight, lit, darkened

Table 2: Top 10 most similar word embeddings for verb supersense vectors

[3] The embeddings are learned using skip-gram as training algorithm with downsampling of 0.001 higher-frequency words, negative sampling of 5 noise words, minimal word frequency of 100, window of size 2 and alpha of 0.025, using 10 epochs to produce 300-dimensional vectors. Our experiments with less dimensions and with the CBOW model performed worse.

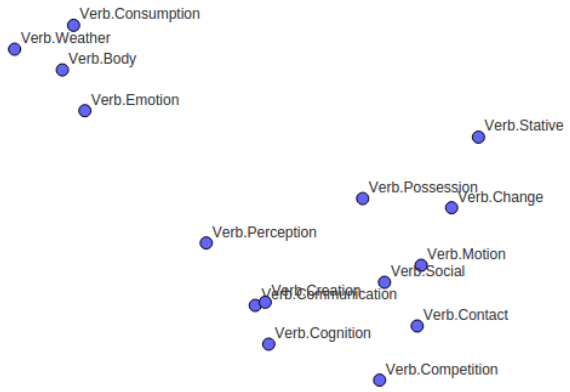

Figure 1: Verb supersense embeddings visualized in the vector space (t-SNE)

Furthermore, using a large corpus such as Wikipedia conveniently reduces the current need of lemmatization for supersense tagging, as the words are sufficiently represented in all their forms. The most frequent error originates from assigning the adverbs to their related verb categories, e.g. *jokingly* to COMMUNICATION and *drastically* to CHANGE. Such information, however, can be beneficial for context analysis in supersense tagging.

Figure 1 displays the verb supersenses using the t-distributed Stochastic Neighbor Embedding (Van der Maaten and Hinton, 2008), a technique designed to visualize structures in high-dimensional data. While many of the distances are probable to be dataset-agnostic, such as the proximity of BODY, CONSUMPTION and EMOTION, other appear emphasized by the nature of Wikipedia corpus, e.g. the proximity of supersenses COMMUNICATION and CREATION or SOCIAL and MOTION, as can be explained by table 2 (see e.g. *led* and *followed*).

Figure 2: Noun supersense embeddings (t-SNE)

4.2 Noun Supersenses

Table 3 displays the most similar word embeddings for noun supersenses. In accordance with previous work on suppersense tagging (Ciaramita and Altun, 2006; Schneider et al., 2012; Johannsen et al., 2014), the assignments of more specific supersenses such as FOOD, PLANT, TIME or PERSON are in general more plausible than those for abstract concepts such as ACT, ARTIFACT or COGNITION. The same is visible in Figure 2, where these supersense embeddings are more central, with closer neighbors. In contrast to the observations by Schneider et al. (2012) and Johannsen et al. (2014), the COMMUNICATION supersense appears well defined, likely due to the character of Wikipedia.

NOUNS	
ACT	participation, activities, involvement, undertaken ongoing, conduct, efforts, large-scale, success
ANIMAL	peccaries, capybaras, frogs, echidnas, birds marmosets, rabits, hatchling, ciconiidae, species
ARTIFACT	wooden, two-floor, purpose-built, installed, wall fittings, turntable, racks, wrought-iron, ceramic, stone
ATTRIBUTE	height, strength, age, versatility, hardness power, fluidity, mastery, brilliance, inherent
BODY	abdomen, bone, femur, anterior, forearm femoral, skin, neck, muscles, thigh
COGNITION	ideas, concepts, empirical, philosophy, knowledge, epistemology, analysis, atomistic, principles
COMMUNICATION	written, excerpts, text, music, excerpted, translation, lyrics, subtitle, transcription, words
EVENT	sudden, death, occurred, event, catastrophic unexpected, accident, victory, final, race
FEELING	sadness, love, sorrow, frustration, disgust anger, affection, feelings, grief, fear
FOOD	cheese, butter, coffee, milk, yogurt dessert, meat, bread, vegetables, sauce
GROUP	members, school, phtheochroa, ypsolophidae pitcairnia, cryptanthus, group, division, schools
LOCATION	northern, southern, northeastern, area, south capital, town, west, region, city
MOTIVE	motivation, reasons, rationale, justification, motive justifications, motives, incentive, desire, why
OBJECT	river, valley, lake, hills, floodplain lakes, rivers, mountain, estuary, ocean
PERSON	greatgrandfather, son, nephew, son-in-law, father halfbrother, brother, who, mentor, fellow
PHENOMENON	wind, forces, self-focusing, radiation, ionizing result, intensity, gravitational, dissipation, energy
PLANT	fruit, fruits, magnifera, sativum, flowers caesalpinia, shrubs, trifoliate, vines, berries
POSSESSION	property, payment, money, payments, taxes tax, cash, fund, pay, $100
PROCESS	growth, decomposition, oxidative, mechanism rapid, reaction, hydrolysis, inhibition, development
QUANTITY	miles, square, meters, kilometer, cubic, ton, number, megabits, volume, kilowatthours
RELATION	southeast, southwest, northeast, northwest, east portion, link, correlation, south, west
SHAPE	semicircles, right-angled, concave, parabola, ellipse, angle, circumcircle, semicircle, lines
STATE	chronic, condition, debilitating, problems, health worsening, illness, illnesses, exacerbation, disease
SUBSTANCE	magnesium, zinc, silica, manganese, sulfur oxide, sulphate, phosphate, salts, phosphorus
TIME	september, december, november, july, april january, august, february, year, days
TOPS	time, group, event, person, groups individuals, events, animals, individual, plant

Table 3: Top 10 most similar word embeddings for noun supersense vectors

4.3 Word Analogy and Word Similarity Tasks

We also assess the changes between the individual word embeddings learned on plain Wikipedia text (WORDS) and jointly with the supersense-enriched Wikipedia (SUPER). With this aim we perform two standard embedding evaluation tasks: word similarity and word analogy.

Mikolov et al. (2013b) introduce a word analogy dataset containing 19544 analogy questions that can be answered with word vector operations (*Paris is to France as Athens are to...?*). The questions are grouped into 13 categories. Table 4 presents our results. Word vectors trained in the SUPER setup achieve better results on groups related to entities, e.g. Family Relations and Citizen to State questions, where the PERSON and LOCATION supersenses can provide additional information to reduce noise. At the same time, performance on questions such as Opposites or Plurals drops, as this information is pushed to the background. Enriching our data with the recently proposed adjective supersenses (Tsvetkov et al., 2014) could be of interest for these categories.

Group/Vectors:	WORDS	SUPER
Capitals - common	91.1	94.7±0.99
Capitals - world	87.6	89.5±0.69
City in state	65.2	65.7±1.03
Nationality to state	94.5	95.2±0.58
Family relations	93.0	94.4±1.28
Opposites	56.7	54.6±3.21
Plurals	89.4	86.4±1.08
Comparatives	90.6	90.4±0.85
Superlatives	79.4	79.6±1.83
Adjective to adverb	20.2	22.2±1.53
Present to participle	64.2	64.6±1.57
Present to past	60.0	59.2±1.30
3rd person verbs	84.3	82.1±1.44
Total	75.0	76.0±0.28

Table 4: Accuracy and standard error on analogy tasks. Tasks related to noun supersense distinctions show the tendency to improve, while syntax-related information is pushed to the background. In most cases, however, the difference is not significant.

Without explicitly exploiting the sense infromation, we compare the performance of our text-trained (WORDS) to our jointly trained (SUPER) word vectors on the following word similarity datasets: WordSim353-Similarity (353-S) and WordSim353-Relatedness (353-R) (Agirre et al., 2009), MEN dataset (Bruni et al., 2014), RG-65 dataset (Rubenstein and Goodenough, 1965) and MC-30 (Miller and Charles, 1991).

Data:	MEN	353-S	353-R	RG-65	MC-30
WORDS	73.18	76.93	62.11	79.13	79.49
SUPER	74.26	78.63	61.22	79.75	80.94

Table 5: Performance of our vectors (Spearman's ρ) on five similarity datasets. Results indicate a trend of better performance of vectors trained jointly with supersenses.

The word embeddings for words trained jointly with supersenses achieve higher performance than those trained solely on the same text without supersenses on 4 out of 5 tasks (Table 5). In addition, the explicit supersense information could be further exploited, similarly to previous sense embedding works (Iacobacci et al., 2015; Rothe and Schütze, 2015; Chen et al., 2014). Furthermore, note that while we report the performance of our embeddings on the word similarity tasks for completeness, there has been a substantial discussion on seeking alternative ways to quantify embedding quality with the focus on their purpose in downstream applications (Li and Jurafsky, 2015; Faruqui et al., 2016). Therefore, in the remainder of this paper we explore the usefulness of supersense embeddings in text classification tasks.

5 Building a Supersense Tagger

The task of predicting supersenses has recently regained its popularity (Johannsen et al., 2014; Schneider and Smith, 2015), since supersenses provide disambiguating information, useful for numerous downstream NLP tasks, without the need of tedious fine-grained WSD. Exploiting our joint embeddings, we build a deep neural network model to predict supersenses on the Twitter supersense corpus created by Johannsen et al. (2014), based on the Twitter NER task (Ritter et al., 2011), using the same training data as the authors. [4] [5] The datasets follow the token-level annotation which combines the B-I-O flags (Ramshaw and Marcus, 1995) with the supersense class labels to represent the multiword expression segmentation and supersense labeling in a sentence.

5.1 Experimental Setup

We implement a window-based approach with a multi-channel multi-layer perceptron model using

[4] https://github.com/kutschkem/SmithHeilmann_fork/tree/master/MIRATagger/data

[5] https://github.com/coastalcph/supersense-data-twitter

the Theano framework (Bastien et al., 2012). With a sliding window of size 5 for the sequence learning setup we extract for each word the following seven feature vectors:

1. 300-dimensional word embedding,
2. 41 cosine similarities of the word to each standalone supersense embedding,
3. 41 cosine similarities of the word to each of its *word*_SUPERSENSE embeddings,
4. fixed vector of frequencies of each supersense in Wikipedia, in order to simulate the MFS backoff strategy,
5. for the given word, the frequency of each *word*_SUPERSENSE in our Wikipedia corpus,
6. part-of-speech information as a unit vector,
7. casing information as a 3-dimensional (upper/lower/mixed) unit vector

After a dropout regularization, the embedding sets are flattened, concatenated and fed into fully connected dense layers with a rectified linear unit (ReLU) activation function and a final softmax.

5.2 Supersense Prediction

We evaluate our system on the same Twitter dataset with provided training and development (`Tw-R-dev`) set and two test sets: `Tw-R-eval`, reported by Johannsen et al. as *RITTER*, and `Tw-J-eval`, reported by Johannsen et al. as *INHOUSE*. Our results are shown in table 6 and compared to results reported in previous work by Johannsen et al. (2014), with two additional baselines: The SemCor system of Ciaramita and Altun (2006) and the most frequent sense. Our system achieves comparable performance to the best previously used supervised systems, without using any explicit gazetteers.

To get an intuition.[6] of how the individual feature vectors contribute to the prediction, we perform an ablation test by removing one feature group at a time. The biggest performance drop in the F-score (2.7–5.4) occurs when removing the the part of speech information, followed by the supersense similarity features and supersense frequency priors (0.2–3.0). The casing information has only a minor contribution to Twitter supersense tagging (0–0.9).

System/Data:	Tw-R-dev	Tw-R-eval	Tw-J-eval
Baseline and upper bound			
Most frequent sense	47.54	44.98	38.65
Inter-annotator agreement		69.15	61.15
SemCor-trained systems			
(Ciaramita and Altun, 2006)†	48.96	45.03	39.65
Searn (Johannsen et al., 2014)	56.59	50.89	40.50

6 Using Supersense Embeddings in Document Classification Tasks

Word sense disambiguation is to some extent an artificial stand-alone task. Despite its popularity, its contribution to downstream document classification tasks remains rather limited, which might be attributed to the complexity of document preprocessing and the errors cumulated along the pipeline. In this section, we demonstrate an alternative, deep learning approach, in which we process the original text in parallel to the supersense information. The model can then flexibly learn the usefulness of provided input. We demonstrate that the model extended with supersense embeddings outperforms the same model using only word-based features on a range of classification tasks.

6.1 Experimental Setup

Both Convolutional Neural Networks (CNNs) and Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) are state-of-the-art semantic composition models for a variety of text classification tasks (Kim, 2014; Li et al., 2015; Johnson and Zhang, 2014). Recently, their combinations have been proposed, achieving an unprecedented performance (Sainath et al., 2015). We extend the CNN-LSTM approach from the publicly available

[6] Intuition, since there are many additional aspects that may affect the performance. For example, we keep the network parameters fixed for the ablation, although the feature vectors are of different lengths. Furthermore, our model performs a concatenation of the feature vectors, hence only the ablation extended to all possible permutations would verify the feature order effect.

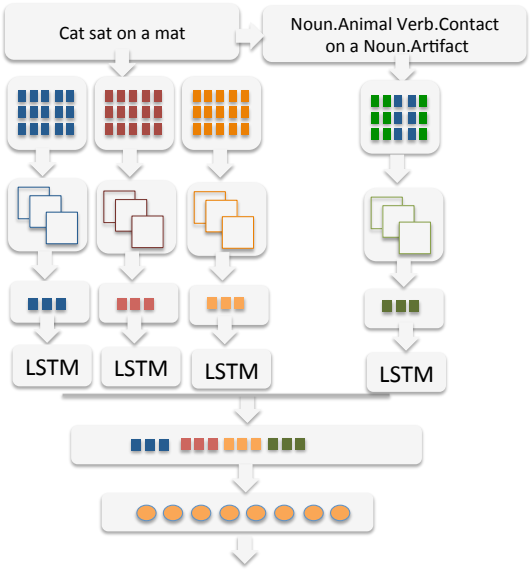

Figure 3: Network architecture. Each of the four different embedding channels serves as input to its CNN layer, followed by an LSTM layer. Afterwards, the outputs are concatenated and fed into a dense layer.

Keras demo[7], into which we incorporate the supersense information. Figure 3 displays our network architecture. First, we use three channels of word embeddings on the plain textual input. The first channel are the 300-dimensional word embeddings obtained from our enriched Wikipedia corpus. The second embedding channel consists of 41-dimensional vectors capturing the cosine similarity of the word to each supersense embedding. The third channel contains the vector of relative frequencies of the word occurring in the enriched Wikipedia together with its supersense, i.e. providing the background supersense distribution for the word. Each of the document embeddings is then convoluted with the filter size of 3, followed by a pooling layer of length 2 and fed into a long-short-term-memory (LSTM) layer. In parallel, we feed as input a processed document text, where the words are replaced by their predicted supersenses. Given that we have the Wikipedia-based supersense embeddings in the same vector space as the word embeddings, we can now proceed to creating the 300-dimensional embedding channel also for the supersense text. As in the plain text channels, we feed also these embeddings into the convolutional and LSTM layers in a similar fashion. Afterwards, we concatenate all LSTM outputs and feed them into a standard fully connected neural network layer, followed by the sigmoid for the binary output. The following subsections discuss our results on a range of classification tasks: subjectivity prediction, sentiment polarity classification and metaphor detection.

6.2 Sentiment Polarity Classification

Sentiment classification has been a widely explored task which received a lot of attention. The Movie Review dataset, published by Pang and Lee (2005)[8], has become a standard machine learning benchmark task for binary sentence classification. Socher et al. (2011) address this task with recursive autoencoders and Wikipedia word embeddings, later improving their score using recursive neural network with parse trees (Socher et al., 2012). Competitive results were achieved also by a sentiment-analysis-specific parser (Dong et al., 2015), with a fast dropout logistic regression (Wang and Manning, 2013), and with convolutional neural networks (Kim, 2014). Table 7 compares these approaches to our results for a 10-fold crossvalidation with 10% of the data withheld for parameter tuning. The line *WORDS* displays the performance using only the leftmost part of our architecture, i.e. only the text input with our word embeddings. The line *SUPER* shows the result of using the full supersense architecture. As it can be seen from the table, the supersense features improve the accuracy by about 2%. Both systems are significantly different ($p < 0.01$), using the McNemar's test.

Table 8: Example of documents classified incorrectly with word embeddings and correctly with word and supersense embeddings on Pang and Lee (2005) movie review data.

concepts such as GROUP, LOCATION, TIME and PERSON appear somewhat more frequently in positive reviews while certain verb supersenses such as PERCEPTION, SOCIAL and COMMUNICATION are more frequent in the negative ones. On the other hand, the supersense tagging introduces additional errors too - for example the director's *cut* is persistently classified into FOOD.

Table 8 shows an example of positive and negative reviews which were consistently (5x in repeated experiments with different random seeds) classified incorrectly with word embeddings and classified correctly with supersense embeddings. Often the wit of unusual expressions is lost for the benefit of generalization. Some improvements appear to be a result of replacing proper names by NOUN.PERSON.

6.3 Subjectivity Classification

Pang and Lee (2004) demonstrate that the subjectivity detection can be a useful input for a sentiment classifier. They compose a publicly available dataset[9] of 5000 subjective and 5000 objective sentences, classifying them with a reported accuracy of 90-92% and further show that predicting this information improves the end-level sentiment classification on a movie review dataset. Kim (2014) and Wang and Manning (2013) further improve the performance through different machine learning methods. Supersenses are a natural candidate for subjectivity prediction, as we hypothesize that the nouns and verbs in the subjective and objective sentences often come from different semantic classes (e.g. VERB.FEELING vs. VERB.COGNITION). We employ the same architecture as in previous task, automatically annotating the words in the documents with their supersenses. Our results are reported in Table 9. The supersenses (SUPER) provide an additional information, improving the model performance by up to 2% over word embeddings (WORDS). The difference between both systems is significant. Based on a manual error analysis, the supersense information contributes here in a similar manner as in the previous case. Subjective sentences contain more verbs of supersense PERCEPTION, while objective ones more frequently feature the supersenses POSSESSION and SOCIAL. Nouns in the subjective category are characterized by supersenses COMMUNICATION and ATTRIBUTE, while in objective ones the PERSON and POSSESSION are more frequent.

6.4 Metaphor Identification

Supersenses have recently been shown to provide improvements in metaphor prediction tasks (Gershman et al., 2014), as they hold the information of coarse semantic concepts. Turney et al. (2011) explore the task of discriminating literal and metaphoric adjective-noun expressions. They report an accuracy of 79% on a small dataset rated by five annotators. Tsvetkov et al. (2013) pursue this work further by constructing and publishing a dataset of 985 literal and 985 methaphorical adjective-noun pairs[10] and classify them. Gershman et al. (2014) further expand on this work using 64-dimensional vector-space word representations constructed by Faruqui and Dyer (2014) for classification. They report a state-of-the-art F-score of 85% with random decision forests, including also abstractness and imageability features (Wilson, 1988) and supersenses from WordNet, averaged across senses.

System	F1-score on test set
(Gershman et al., 2014)	85
WORDS	81.91±2.81
SUPER	**87.23**±2.36

Table 10: F1-score and a standard error on a provided test set for the adjective-noun metaphor prediction task Gershman et al. (2014). WORDS: word embeddings only, SUPER: multi-channel word embeddings with the supersense similarity and frequency vectors added

Since this setup is simpler than the sentence classification tasks, we use only a subset of our architecture, specifically the left half of Figure 3, i.e. our word embeddings, similarity vectors and supersense frequency vectors. Since there are only two words in each document, we leave out the LSTM layer. We merge the similarity and frequency layers by multiplication and concatenate the result to the word embedding convolution, feeding the output of the concatenation directly to the dense layer. Table 10 shows our results on a provided test set. Based on McNemar's test, there is a significant difference ($p < 0.01$) between our system based on words only and the one with supersenses.

7 Discussion

Unlike previous research on supersenses, our work is not based on a manually produced gold standard, but on an automatically annotated large corpus. While Scozzafava et al. (2015) report a high accuracy estimate of 77.8% on sense level, the performance and possible bias on tagged supersenses are yet to be evaluated. We are also aware that some of the previously proposed approaches for building word sense embeddings (Rothe and Schütze, 2015; Chen et al., 2014; Iacobacci et al., 2015) could be eventually extended to supersenses. We strongly encourage the authors to do so and perform a contrastive evaluation comparing these methods. Additionaly, a different level of granularity of the concepts, such as WordNet Domains (Magnini and Cavaglia, 2000) could be explored.

8 Conclusions and Future Work

We have presented a novel joint embedding set of words and supersenses, which provides a new insight into the word and supersense positions in the vector space. We demonstrated the utility of these embeddings for predicting supersenses and manifested that the supersense enrichment can lead to a significant improvement in a range of downstream classification tasks, using our embeddings in a neural network model. The outcomes of this work are available to the research community.[11]. In follow-up work, we aim to apply our embedding method on smaller, yet gold-standard corpora such as SemCor (Miller et al., 1994) and STREUSLE (Schneider and Smith, 2015) to examine the impact of the corpus choice in detail and extend the training data beyond WordNet vocabulary. Moreover, the coarse semantic categorization contained in supersenses was shown to be preserved in translation (Schneider et al., 2013), making them a perfect candidate for a multilingual adaptation of the vector space, e.g. extending Faruqui and Dyer (2014).

Acknowledgments

This work has been supported by the Volkswagen Foundation as part of the Lichtenberg Professorship Program under grant No. I/82806 and by the German Research Foundation under grant No. GU 798/14-1. Additional support was provided by the German Federal Ministry of Education and Research (BMBF) as a part of the Software Campus program under the reference 01-S12054 and by the German Institute for Educational Research (DIPF). Abstract

Parsing for a wide variety of grammar formalisms can be performed by intersecting finite tree automata. However, naive implementations of parsing by intersection are very inefficient. We present techniques that speed up tree-automata-based parsing, to the point that it becomes practically feasible on realistic data when applied to context-free, TAG, and graph parsing. For graph parsing, we obtain the best runtimes in the literature.

1 Introduction

Grammar formalisms that go beyond context-free grammars have recently enjoyed renewed attention throughout computational linguistics. Classical grammar formalisms such as TAG (Joshi and Schabes, 1997) and CCG (Steedman, 2001) have been equipped with expressive statistical models, and high-performance parsers have become available (Clark and Curran, 2007; Lewis and Steedman, 2014; Kallmeyer and Maier, 2013). Synchronous grammar formalisms such as synchronous context-free grammars (Chiang, 2007) and tree-to-string transducers (Galley et al., 2004; Graehl et al., 2008; Seemann et al., 2015) are being used as models that incorporate syntactic information in statistical machine translation. Synchronous string-to-tree (Wong and Mooney, 2006) and string-to-graph grammars (Chiang et al., 2013) have been applied to semantic parsing; and so forth.

Each of these grammar formalisms requires its users to develop new algorithms for parsing and training. This comes with challenges that are both practical and theoretical. From a theoretical perspective, many of these algorithms are basically the same, in that they rest upon a CKY-style parsing algorithm which recursively explores substructures of the input object and assigns them nonterminal symbols, but their exact relationship is rarely made explicit. On the practical side, this parsing algorithm and its extensions (e.g. to EM training) have to be implemented and optimized from scratch for each new grammar formalism. Thus, development time is spent on reinventing wheels that are slightly different from previous ones, and the resulting implementations still tend to underperform.

Koller and Kuhlmann (2011) introduced *Interpreted Regular Tree Grammars (IRTGs)* in order to address this situation. An IRTG represents a language by describing a regular language of derivation trees, each of which is mapped to a term over some algebra and evaluated there. Grammars from a wide range of monolingual and synchronous formalisms can be mapped into IRTGs by using different algebras: Context-free and tree-adjoining grammars use string algebras of different kinds, graph grammars can be captured by using graph algebras, and so on. In addition, IRTGs come with a universal parsing algorithm based on closure results for tree automata. Implementing and optimizing this parsing algorithm once, one could apply it to all grammar formalisms that can be mapped to IRTG. However, while Koller and Kuhlmann show that asymptotically optimal parsing is possible in theory, it is non-trivial to implement their algorithm optimally.

In this paper, we introduce practical algorithms for the two key operations underlying IRTG parsing: computing the intersection of two tree automata and applying an inverse tree homomorphism to a tree automaton. After defining IRTGs (Section 2), we will first illustrate that a naive bottom-up implementation of the intersection algorithm yields asymptotic parsing complexities that are too high (Section 3). We will then

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2042–2051,
Berlin, Germany, August 7-12, 2016.

show how the parsing complexity can be improved by combining algebra-specific index data structures with a generic parsing algorithm (Section 4), and by replacing bottom-up with top-down queries (Section 5). In contrast to the naive algorithm, both of these methods achieve the expected asymptotic complexities, e.g. $O(n^3)$ for context-free parsing, $O(n^6)$ for TAG parsing, etc. Furthermore, an evaluation with realistic grammars shows that our algorithms improve practical parsing times with IRTG grammars encoding context-free grammars, tree-adjoining grammars, and graph grammars by orders of magnitude (Section 6). Thus our algorithms make IRTG parsing practically feasible for the first time; for graph parsing, we obtain the fastest reported runtimes.

2 Interpreted Regular Tree Grammars

We will first define IRTGs and explain how the universal parsing algorithm for IRTGs works.

2.1 Formal foundations

First, we introduce some fundamental theoretical concepts and notation.

A *signature* Σ is a finite set of symbols $r, f, \ldots$, each of which has an *arity* $\mathsf{ar}(r) \geq 0$. A *tree* t over the signature Σ is a term of the form $r(t_1, \ldots, t_n)$, where the t_i are trees and $r \in \Sigma$ has arity n. We identify the nodes of t by their Gorn addresses, i.e. paths $\pi \in \mathbb{N}^*$ from the root to the node, and write $t(\pi)$ for the label of π. We write T_Σ for the set of all trees over Σ, and $T_\Sigma(\mathcal{X}_k)$ for the trees in which each node either has a label from Σ, or is a leaf labeled with one of the variables $\{x_1, \ldots, x_k\}$.

A *(linear, nondeleting) tree homomorphism* h from a signature Σ to a signature Δ is a mapping $h : T_\Sigma \to T_\Delta$. It is defined by specifying, for each symbol $r \in \Sigma$ of arity k, a term $h(r) \in T_\Delta(\mathcal{X}_k)$ in which each variable occurs exactly once. This symbol-wise mapping is lifted to entire trees by letting $h(r(t_1, \ldots, t_k)) = h(r)[h(t_1), \ldots, h(t_k)]$, i.e. by replacing the variable x_i in $h(r)$ by the recursively computed value $h(t_i)$.

Let Δ be a signature. A Δ-*algebra* $\mathcal{A}$ consists of a nonempty set A, called the *domain*, and for each symbol $f \in \Delta$ with arity k, a function $f^{\mathcal{A}} : A^k \to A$, the *operation* associated with f. We can *evaluate* any term $t \in T_\Delta$ to a value $t^{\mathcal{A}} \in A$, by evaluating the operation symbols bottom-up. In this paper, we will be particularly interested in the *string algebra* E^* over the finite alphabet E. Its domain is the set of all strings over E. For each symbol $a \in E$, it has a nullary operation symbol a with $\mathsf{a}^{E^*} = a$. It also has a single binary operation symbol $*$, such that $*^{E^*}(w_1, w_2)$ is the concatenation of the strings w_1 and w_2. Thus the term $*(\mathsf{John}, *(\mathsf{walks}, *(\mathsf{on}, \mathsf{Mars})))$ in Fig. 2b evaluates to the string "John walks on Mars".

automaton rule	homomorphism
$\mathsf{S} \to \mathsf{r}_1(\mathsf{NP}, \mathsf{VP})$	$*(x_1, x_2)$
$\mathsf{NP} \to \mathsf{r}_2$	John
$\mathsf{VP} \to \mathsf{r}_3$	walks
$\mathsf{VP} \to \mathsf{r}_4(\mathsf{VP}, \mathsf{NP})$	$*(x_1, *(\mathsf{on}, x_2))$
$\mathsf{NP} \to \mathsf{r}_5$	Mars

Figure 1: An example IRTG.

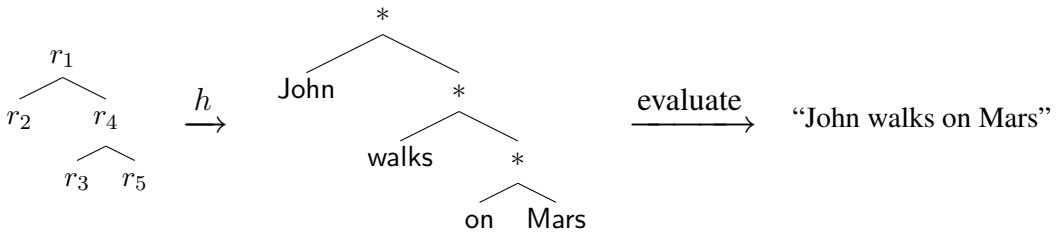
A *finite tree automaton* M over the signature Σ is a structure $M = (\Sigma, Q, R, X_F)$, where Q is a finite set of *states* and $X_F \in Q$ is a *final state*. R is a finite set of *transition rules* of the form $X \to r(X_1, \ldots, X_k)$, where the *terminal symbol* $r \in \Sigma$ is of arity k and $X, X_1, \ldots, X_k \in Q$. A tree automaton can *run* non-deterministically on a tree $t \in T_\Sigma$ by assigning states to the nodes of t bottom-up. If we have $t = r(t_1, \ldots, t_n)$ and M can assign the state X_i to each t_i, written $X_i \to^* t_i$, then we also have $X \to^* t$. We say that M *accepts* t if $X_F \to^* t$, and define the *language* $L(M) \subseteq T_\Sigma$ of M as the (possibly infinite) set of all trees that M accepts. An example of a tree automaton (with states S, NP, etc.) is shown in the "automaton rule" column of Fig. 1. It accepts, among others, the tree τ_1 in Fig. 2a.

Tree automata can be defined top-down or bottom-up, and are equivalent to *regular tree grammars*. The languages that can be accepted by finite tree automata are called the *regular tree languages*. See e.g. Comon et al. (2008) for details.

2.2 Interpreted regular tree grammars

We can combine tree automata, homomorphisms, and algebras into grammars that can describe languages of arbitrary objects, as well as relations between such objects – in a way that inherits many technical properties from context-free grammars, while extending the expressive capacity.

An *interpreted regular tree grammar* (IRTG, Koller and Kuhlmann (2011)) $\mathcal{G} = (M, (h_1, \mathcal{A}_1), \ldots, (h_n, \mathcal{A}_n))$ consists of a tree automaton M over some signature Σ, together with an arbitrary number n of *inter-*



(a) Tree τ_1. (b) Term $h(\tau_1)$. (c) $h(\tau_1)$ evaluated in E^*.

Figure 2: The tree τ_1, evaluated by the homomorphism h and the algebra E^*

pretations $(h_i, \mathcal{A}_i)$, where each $\mathcal{A}_i$ is an algebra over some signature Δ_i and each h_i is a tree homomorphism from Σ to Δ_i. The automaton M describes a language $L(M)$ of *derivation trees* which represent abstract syntactic structures. Each derivation tree τ is then interpreted n ways: we map it to a term $h_i(\tau) \in T_{\Delta_i}$, and then we evaluate $h_i(\tau)$ to a value $a_i = h_i(\tau)^{\mathcal{A}_i} \in A_i$ of the algebra $\mathcal{A}_i$. Thus, the IRTG $\mathcal{G}$ defines a language $L(\mathcal{G}) = \{(h_1(\tau)^{\mathcal{A}_1}, \ldots, h_n(\tau)^{\mathcal{A}_n}) \mid \tau \in L(M)\}$, which is an n-place relation between the domains of the algebras.

Consider the IRTG $\mathcal{G}$ shown in Fig. 1. The "automaton rule" column indicates the five rules of M; the final state is S. We already saw the derivation tree $\tau_1 \in L(M)$. $\mathcal{G}$ has a single interpretation, into a string algebra E^*, and with a homomorphism that is specified by the "homomorphism" column; for instance, $h(\mathsf{r}_1) = *(x_1, x_2)$ and $h(\mathsf{r}_2) = \mathsf{John}$. Applying this homomorphism to τ_1, we obtain the term $h(\tau_1)$ in Fig. 2b. As we saw earlier, this term evaluates in the string algebra to the string "John walks on Mars" (Fig. 2c). Thus this string is an element of $L(\mathcal{G})$.

We assume that no two rules of M use the same terminal symbol; this is generally not required in tree automata, but every IRTG can be brought into this convenient form. Furthermore, we focus (but only for simplicity of presentation) on IRTGs that use a single string-algebra interpretation, as in Fig. 1. Such grammars capture context-free grammars. However, IRTGs can capture a wide variety of grammar formalisms by using different algebras. For instance, an interpretation that uses a TAG string algebra (or TAG derived-tree algebra) models a tree-adjoining grammar (Koller and Kuhlmann, 2012), and an interpretation into an s-graph algebra models a hyperedge replacement graph grammar (HRG, Groschwitz et al. (2015)). By using multiple algebras, IRTGs can also represent synchronous grammars and (bottom-up) tree-to-tree and tree-to-string transducers. In general, any grammar formalism whose grammars describe derivations in terms of a finite set of states can typically be converted into IRTG.

2.3 Parsing IRTGs

Koller and Kuhlmann (2011) present a uniform parsing algorithm for IRTGs based on tree automata. The (monolingual) *parsing problem* of IRTG consists in determining, for an IRTG $\mathcal{G}$ and an input object $a \in A$, a representation of the set $\mathsf{parses}(a) = \{\tau \in L(M) \mid h(\tau)^{\mathcal{A}} = a\}$, i.e. of the derivation trees that are grammatically correct and are mapped to a by the interpretation. In the example, we have $\mathsf{parses}(\text{"John walks on Mars"}) = \{\tau_1\}$, where τ_1 is as above. In general, $\mathsf{parses}(a)$ may be infinite, and thus we aim to represent it using a tree automaton Ch_a with $L(\mathrm{Ch}_a) = \mathsf{parses}(a)$, the *parse chart* of a.

We can compute Ch_a as follows. First, observe that $\mathsf{parses}(a) = L(M) \cap h^{-1}(\mathsf{terms}(a))$, where $h^{-1}(L) = \{\tau \in T_\Sigma \mid h(\tau) \in L\}$ (the *inverse homomorphic image*, or *invhom*, of L) and $\mathsf{terms}(a) = \{t \in T_\Delta \mid t^{\mathcal{A}} = a\}$, i.e. the set of all terms that evaluate to a. Now assume that the algebra $\mathcal{A}$ is *regularly decomposable*, which means that every $a \in A$ has a *decomposition automaton* D_a, i.e. there is a tree automaton D_a such that $L(D_a) = \mathsf{terms}(a)$. Because regular tree languages are closed under invhom and intersection, we can then compute a tree automaton Ch_a by intersecting M with the invhom of D_a.

To illustrate the IRTG parsing algorithm, let us compute a chart for the sentence $s =$ "John walks on Mars" with the example grammar $\mathcal{G}$ of Fig. 1. The states of the decomposition automaton D_s are spans $[i, k]$ of s; the final state is $X_F = [1, 5]$. The automaton contains fourteen rules, including the ones shown in Fig. 3a.

$[1,5] \to *([1,2],[2,5])$
$[2,5] \to *([2,3],[3,5])$
$[3,5] \to *([3,4],[4,5])$
$[3,4] \to \mathsf{on}$
$[4,5] \to \mathsf{Mars}$

(a) Some rules of D_s.

$[1,5] \to \mathsf{r}_1([1,2],[2,5])$
$[2,5] \to \mathsf{r}_4([2,3],[4,5])$
$[2,4] \to \mathsf{r}_1([2,3],[3,4])$
$[1,2] \to \mathsf{r}_2$
$[2,3] \to \mathsf{r}_3$

(b) Some rules of $I = h^{-1}(D_s)$.

$\mathsf{S}[1,5] \to \mathsf{r}_1(\mathsf{NP}[1,2],\mathsf{VP}[2,5])$
$\mathsf{VP}[2,5] \to \mathsf{r}_4(\mathsf{VP}[2,3],\mathsf{NP}[4,5])$
$\mathsf{NP}[1,2] \to \mathsf{r}_2$
$\mathsf{VP}[2,3] \to \mathsf{r}_3$
$\mathsf{NP}[4,5] \to \mathsf{r}_5$

(c) The parse chart Ch_s.

Figure 3: Example rules for the sentence $s =$ "John walks on Mars"

Algorithm 1 Naive bottom-up intersection

```
1: initialize agenda with state pairs for constants
2: initialize P as empty
3: while agenda is not empty do
4:    T'X' ← pop(agenda)
5:    add T'X' to P
6:    for T''X'' ∈ P do
7:       for {T1X1, T2X2} = {T'X', T''X''} do
8:          for T → r(T1, T2) in M_L do
9:             for X → r(X1, X2) in M_R do
10:               store TX → r(T1X1, T2X2)
11:               add TX to agenda if new
```

We can then compute the invhom automaton I, such that $L(I) = h^{-1}(L(D_s))$. I uses the same states as D_s, but uses terminal symbols from Σ instead of Δ. Some rules of the invhom automaton I in the example are shown in Fig. 3b. Notice that I also contains rules that are not consistent with M, i.e. that would not occur in a grammatical parse of the sentence, such as $[2,4] \to \mathsf{r}_1([2,3],[3,4])$. Finally, the chart Ch_s is computed by intersecting M with I (see Fig. 3c). The states of Ch_s are pairs of states from M and states from I. It accepts τ_1, because $\tau_1 \in \mathsf{parses}(s)$. Observe the similarity to a traditional context-free parse chart.

3 Bottom-up intersection

Both the practical efficiency of this algorithm and its asymptotic complexity depend crucially on how we compute intersection and invhom. We illustrate this using an overly naive intersection algorithm as a strawman, and then analyze the problem to lay the foundations for the improved algorithms in Sections 4 and 5.

Let's say that we want to compute a tree automaton C for the intersection of a "left" automaton M_L and a "right" automaton M_R both over the same signature Σ. In the application to IRTG parsing, M_L is typically the derivation tree automaton (called M above) and M_R is the invhom of a decomposition automaton. As in the product construction for finite string automata, the states of C will be pairs TX of states T of M_L and states X of M_R, and the rules of C will all have the form $TX \to r(T_1X_1, \ldots, T_nX_n)$, where $T \to r(T_1, \ldots, T_n)$ is a rule in M_L, and $X \to r(X_1, \ldots, X_n)$ is a rule in M_R.

3.1 Naive intersection

A naive bottom-up algorithm is shown in Alg. 1.[1] This algorithm maintains an agenda of state pairs that have been discovered, but not explored as children of bottom-up rule applications; and a chart-like set P of all state pairs that have ever been popped off the agenda. The algorithm maintains the invariant that if TX is on the agenda or in P, then T and X are *partners* (written $T \approx X$), i.e. there is a tree $t \in T_\Sigma$ such that $T \to^* t$ in M_L and $X \to^* t$ in M_R.

The agenda is initialized with all state pairs TX, for which M_L has a rule $T \to r$ and M_R has a rule $X \to r$ for some nullary symbol $r \in \Sigma$. Then, while there are state pairs left on the agenda, Alg. 1 pops a state pair $T'X'$ off the agenda and adds it to P; iterates over all state pairs $T''X''$ in P; and queries M_L and M_R bottom-up for rules in which these states appear as children.[2] The iteration in line 7 allows T' and X' to be either left or right children in these rules. For each pair of left and right rules, the rules are combined into a rule of C, and the pair of the parent states T and X is added to the agenda.

This naive intersection algorithm yields an asymptotic complexity for IRTG parsing that is higher than expected. Assume, for example,

[1] We assume binary symbols for simplicity; all algorithms generalize to arbitrary arities.

[2] For the invhom automaton this can be done by substituting the variables in the homomorphic image $h(r)$ with the corresponding states X' and X'', and running the decomposition automaton on the resulting tree.

Algorithm 2 Bottom-up intersection with BU

```
1: initialize agenda with state pairs for constants
2: generate new S_r = S(M_R, r) for every r ∈ Σ
3: while agenda is not empty do
4:    T'X' ← pop(agenda)
5:    for T → r(T_1, T_2) in M_L s.t. T_i = T' do
6:       for X → r(X_1, X_2) ∈ BU(S_r, i, X') do
7:          store rule TX → r(T_1X_1, T_2X_2)
8:          add TX to agenda if new
```

that we are parsing with an IRTG encoding of a context-free grammar, i.e. with a string algebra (as in Fig. 1). Then the states of M_R are spans $[i, k]$, i.e. M_R has $O(n^2)$ states. Once line 4 has picked a span $X' = [i, j]$, line 6 iterates over all spans $X'' = [k, l]$ that have been discovered so far – including ones in which $j \neq k$ and $i \neq l$. Thus the bottom-up lookup in line 9 is executed $O(n^4)$ times, most of which will yield no rules. The overall runtime of Alg. 1 is therefore higher than the asymptotic runtime of $O(n^3)$ expected for context-free parsing. Similar problems arise for other algebras; for instance, the runtime of Alg. 1 for TAG parsing is $O(n^8)$ rather than $O(n^6)$.

3.2 Indexing

In context-free parsing algorithms, such as CKY or Earley, this issue is addressed through appropriate index datastructures, which organize P such that the lookup in line 5 only returns state pairs where X'' is of the form $[j, k]$ or $[k, i]$. This reduces the runtime to cubic.

The idea of obtaining optimal asymptotic complexities in IRTG parsing through appropriate indexing was already mentioned from a theoretical perspective by Koller and Kuhlmann (2011). However, they assumed an optimal indexing data structure as given. In practice, indexing requires algebra-specific knowledge about X'': A CKY-style index only works if we assume that the states of the decomposition automaton are spans (this is not the case in other algebras), and that the only binary operation in the string algebra is $*$, which composes spans in a certain way. Furthermore, in IRTG parsing the rules of the invhom automaton do not directly correspond to algebra operations, but to *terms* of operations, which further complicates indexing.

In this paper, we incorporate indexing into the intersection algorithm through *sibling-finders*. A sibling-finder $S = S(M, r)$ for an automaton M and a label r in M's signature is a data structure that supports a single operation, $\mathsf{BU}(S, i, X')$. We require that a call to $\mathsf{BU}(S, i, X')$ returns the set of rules $X \to r(X_1, \ldots, X_n)$ of M such that X' is the i-th child state, and for every $j \neq i$, X_j must be a state for which we previously called $\mathsf{BU}(S, j, X_j)$. Thus a sibling-finder performs a bottom-up rule lookup, changing its state after each call by caching the state and position.

Assume that we have sibling-finders for M_R. Then we can modify the naive Alg. 1 to the closely related algorithm shown as Alg. 2. This algorithm maintains the same agenda as Alg. 1, but instead of iterating over all explored partner states $T''X''$, it first iterates over all rules in M_L that have T' as a child (line 5). In line 6, Alg. 2 then queries M_R sibling-finders – we maintain one for each rule label – for right rules with matching rule label and child positions. Note that because there is only one rule with label r in M_L, the sibling-finders implicitly keep track of the partners of T_2 we have seen so far. Thus they play the role of a more structured variant of P.

There are a number of ways in which sibling-finders can be implemented. First, they could simply maintain sets $\mathsf{chi}(S_r, i)$ where a call to $\mathsf{BU}(S_r, i, X')$ first adds X' to $\mathsf{chi}(S_r, i)$. The query can then iterate over the set $\mathsf{chi}(S_r, 3-i)$, to check for each state X'' in that set whether M_R actually contains a rule with terminal symbol r and children X' and X'' (in the right order). This essentially reimplements the behavior of Alg. 1, and comes with the same complexity issues.

Second, we could theoretically iterate over all rules of M_R to implement the sibling finders via a bottom-up index (e.g., a trie) that supports efficient BU queries. However, in IRTG parsing M_R is the invhom of a decomposition automaton. Because the decomposition automaton represents all the ways in which the input object can be built recursively out of smaller structures, including ones which will later be rejected by the grammar, such automata can be very large in practice. Thus we would like to work with a lazy representation of M_R and avoid iterating over all rules.

4 Efficient bottom-up lookup

Finally, we can exploit the fact that in IRTG parsing, M_R is the invhom of a decomposition automaton. Below, we first show how to define algebra-specific sibling-finders for decompo-

Algorithm 3 passUpwards(Y, π, i, r)

```
rules ← BU(S_{r,π}, i, Y)
if π = π'k ≠ ϵ then
    for X → f(X_1, ..., X_n) ∈ rules do
        passUpwards(X, π', k, r)
```

sition automata. Then we develop an algebra-independent way to generate invhom sibling-finders out of those for the decomposition automata. These can be plugged into Alg. 2 to achieve the expected parsing complexity.

4.1 Sibling-finders for decomposition automata

First, consider the special case of sibling-finders for a decomposition automaton D. The terminal symbols f of D are the operation symbols of an algebra. If we have information about the operations of this algebra, and how they operate on the states of D, a sibling-finder $S = S(D, f)$ can use indexing specific to the operation f to look up potential siblings, and only for them query D to answer $\mathsf{BU}(S, i, X)$

For instance, a sibling-finder for the '$*$' operation of the string algebra may store all states $[k, l]$ for $i = 1$ under the index l. Thus a lookup $\mathsf{BU}(S, 2, [l, m])$ can directly retrieve siblings from the l-bin, just as a traditional parse chart would. Spans which do not end at l are never considered. Different algebras require different index structures. For instance, sibling-finders for the string-wrapping operation in the TAG string algebra might retrieve all pairs of substrings $[k, l, m, o]$ that wrap around $[l, m]$ instead. Analogous data structures can be defined for the s-graph algebra.

4.2 Sibling-finders for invhom

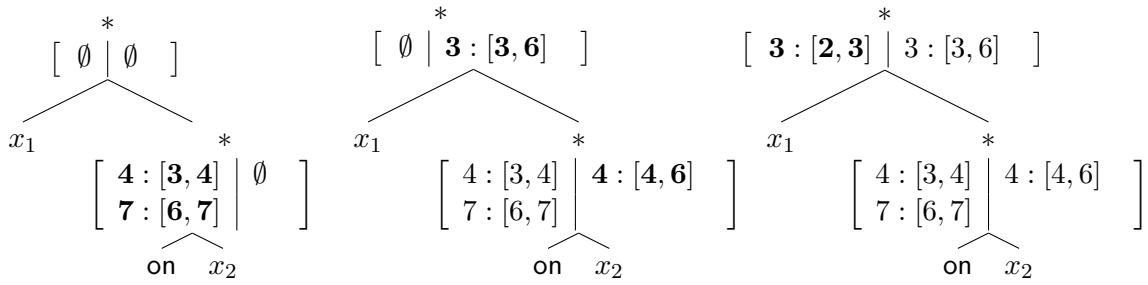
We can build upon the D-sibling-finders to construct sibling-finders for the invhom I of D. The basic idea is as follows. Consider the term $h(\mathsf{r}_1) = *(x_1, x_2)$ from Fig. 1. It contains a single operation symbol $*$ (plus variables); the homomorphism only replaces one symbol with another. Thus a sibling-finder $S(D, *)$ from the decomposition automaton can directly serve as a sibling-finder $S(I, \mathsf{r}_1)$. We only need to replace the $*$ label on the returned rules with r_1.

In general, the situation is more complicated, because $t = h(r)$ may be a complex term consisting of many algebra operations. In such a case, we construct a separate sibling-finder $S_{r,\pi} =$ new $S(D, t(\pi))$ for each node π with at least two children. For instance, consider the term $t = h(\mathsf{r}_4)$ in Fig. 1. It contains three nodes which are labeled by algebra operations, two of which are the concatenation. We decorate these with the sibling-finders $S_{\mathsf{r}_4,\epsilon}$ and $S_{\mathsf{r}_4,1}$. Each of these is a sibling-finder for the algebra's concatenation operation; but they may have different state because they received different queries.

We can then construct an invhom sibling-finder $S_r = S(I, r)$, which answers a query $\mathsf{BU}(S_r, i, X')$ in two steps. First, we substitute the variable x_i by the state X' and percolate it upward through t using the D-sibling-finders on the path from x_i to the root. If $\pi = \pi' k$ is the path to x_i, we do this by calling passUpwards(X', π', k, r), as defined in Alg. 3. If the local sibling-finder returns rules and we are not at the root yet, we recursively call passUpwards at the parent node π' with each parent state of these rules.

As we do this, we let each sibling-finder maintain the set of rules it found, indexed by their parent state. This allows us to perform the second step: we traverse t top-down from the root to extract the rules of the invhom automaton that answer the BU query. Recall that $\mathsf{BU}(S_r, i, X')$ should return only rules $X \to r(X_1, X_2)$ where $\mathsf{BU}(S_r, 3 - i, X_{3-i})$ was called before. Here, this is guaranteed by having distinct D-sibling-finders $S_{\pi,r}$ for every node π at every tree $h(r)$. A final detail is that before the first query to r, we initialize the sibling-finders by calling passUpwards for all the leaves that are labeled by constants.

This process is illustrated in Fig. 4, on the sibling-finder $S = S(I, \mathsf{r}_4)$ and the input string "John walks on a hill on Mars", parsed with a suitable extension of the IRTG in Fig. 1. The decomposition automaton can accept the word "on" from states $[3, 4]$ and $[6, 7]$, which during initialization are entered into position 1 of the lower D-sibling-finder $S_{\mathsf{r}_4,2}$, indexed by their end positions (a). Alg. 2 may then generate the query $\mathsf{BU}(S, 2, [4, 6])$. This enters $[4, 6]$ into the lower D-sibling-finder, and because there is a state with end position 4 on the left side of this sibling-finder, $\mathsf{BU}(S_{\mathsf{r}_4,2}, 2, [4, 6])$ returns a rule with parent $[3, 6]$. The parent is subsequently entered into the upper sibling-finder (b). Finally, the query $\mathsf{BU}(S, 1, [2, 3])$ enters $[2, 3]$ into the upper D-sibling-finder and discovers its sibling $[3, 6]$ (c). This yields a state $X = [2, 6]$ for the whole phrase



(a) After initialization. (b) After $\mathsf{BU}(S, 2, [4, 6])$. (c) After $\mathsf{BU}(S, 1, [2, 3])$.

Figure 4: Three stages of BU on $S(I, \mathsf{r}_4)$ for the sentence "John walks on a hill on Mars".

Algorithm 4 Top-down intersection

```
1: function expand(X):
2: if X ∉ visited then
3:     add X to visited
4:     for X → r(X1, X2) in M_R do
5:         call expand(X_i) for i = 1, 2
6:         for T→r(T1, T2) s.t. T_i ∈ prt(X_i) do
7:             store rule TX→r(T1X1, T2X2)
8:             add T to prt(X)
```

"walks on a hill". The top-down traversal of the sibling-finders reveals that this state is reached by combining $x_1 = [2, 3]$, for which this BU query asked, with $x_2 = [4, 6]$, and thus the BU query yields the rule $[2, 6] \to \mathsf{r}_4([2, 3], [4, 6])$. A subsequent query for $\mathsf{BU}(S, 2, [4, 8])$ would yield the rule $[2, 8] \to \mathsf{r}_4([2, 3], [4, 8])$, and so on.

The overall construction allows us to answer BU queries on invhom automata while making use of algebra-specific index structures. Given suitable index structures, the asymptotic complexity drops down to the expected levels, e.g. $O(n^3)$ for IRTGs using the string algebra, $O(n^6)$ for the TAG string algebra, and so on. This yields a practical algorithm that can be flexibly adapted to new algebras by implementing their sibling-finders.

5 Top-down intersection

Instead of investing into efficient bottom-up queries, we can also explore the use of top-down queries instead. These ask for all rules with parent state X and terminal symbol r. Such queries completely avoid the problem of finding siblings in M_R. An invhom automaton can answer top-down queries for r efficiently by running the decomposition automaton top-down on $h(r)$, collecting child states at the variable nodes. For instance, if we query I from Section 2 top-down for rules with the parent $[1, 5]$ and symbol r_1, it will enumerate the rules $[1, 5] \to \mathsf{r}_1([1, 2], [2, 5])$, $[1, 5] \to \mathsf{r}_1([1, 3], [3, 5])$, and $[1, 5] \to \mathsf{r}_1([1, 4], [4, 5])$, without ever considering any other combination of child states.

This is the idea underlying the intersection algorithm in Alg. 4. It recursively visits states X of M_R, collecting for each X a set $\mathsf{prt}(X)$ of states T of M_L such that $T \approx X$. Line 5 ensures that the prt sets have been computed for both child states of the rule $X \to r(X_1, X_2)$. Line 6 then does a bottom-up lookup of M_L rules with the terminal symbol r and with child states that are partners of X_1 and X_2. Applied to our running example, Alg. 4 parses "John walks on Mars" by recursive calls on $\mathrm{expand}([1, 5])$ and $\mathrm{expand}([2, 5])$, following the rules of I top-down. Recursive calls for $[2, 3]$ and $[4, 5]$ establish $\mathsf{VP} \in \mathsf{prt}([2, 3])$ and $\mathsf{NP} \in \mathsf{prt}([4, 5])$, which enables the recursive call for $[2, 5]$ to apply r_4 in line 6 and consequently add VP to $\mathsf{prt}([2, 5])$ in line 8.

The algorithm mixes top-down queries to M_R with bottom-up queries to M_L. Line 6 implements the core idea of the CKY parser, in that it performs bottom-up queries on sets of nonterminals that are partners of adjacent spans – but generalized to arbitrary IRTGs instead of just the string algebra. The top-down query to M_R in line 4 is bounded by the number of rules that actually exist in M_R, which is $O(n^3)$ for the string algebra, $O(n^6)$ in the TAG string algebra, and $O\left(n^s \cdot 3^{ds} ds\right)$ for graphs of degree d and treewidth $s - 1$ in the graph algebra. Thus Alg. 4 achieves the same asymptotic complexity as native parsing algorithms.

Condensed top-down intersection. One weakness of Alg. 4 is that it iterates over all rules $X \to r(X_1, X_2)$ of M_R individually. This can be extremely wasteful when M_R is the invhom of a decomposition automaton, because it may contain

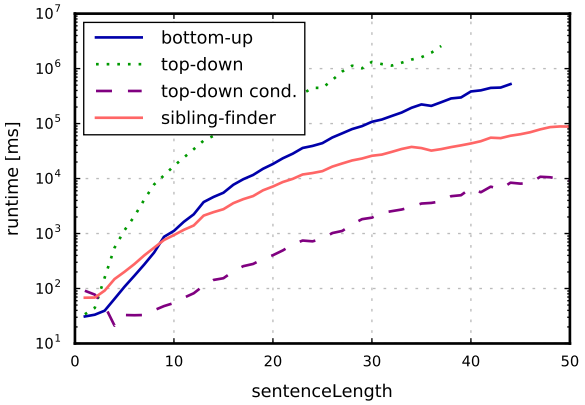


Figure 5: Runtimes for context-free parsing.

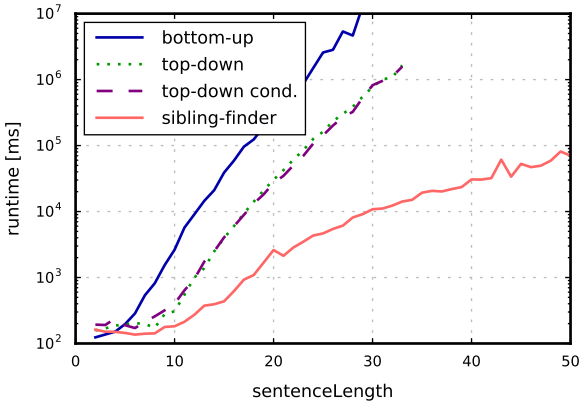

Figure 6: Runtimes for TAG parsing.

a great number of rules that have the same states and only differ in the terminal symbol r. For instance, when we encode a context-free grammar as an IRTG, for every rule r of the form $\mathsf{A} \to \mathsf{B}\ \mathsf{C}$ we have $h(\mathsf{r}) = *(x_1, x_2)$. The rules of the invhom automaton are the same for all terminal symbols r with the same term $h(\mathsf{r})$. But Alg. 4 iterates over rules r and not over different terms $h(\mathsf{r})$, repeating the exact same computation for every binary rule of the context-free grammar.

To solve this, we define *condensed* tree automata, which have rules of the form $X \to \rho(X_1, \ldots, X_n)$, where $\rho \subseteq \Sigma$ is a nonempty set of symbols with arity n. A condensed automaton represents the tree automaton which for all condensed rules $X \to \rho(X_1, \ldots, X_n)$ and all $r \in \rho$ has the rule $X \to r(X_1, \ldots, X_n)$. It is straightforward to represent an invhom automaton as a condensed condensed automaton, by determining for each distinct homomorphic image t the set $\rho_t = \{r_1, \ldots, r_k\}$ of symbols with $h(r_i) = t$.

We can modify Alg. 4 to iterate over condensed rules in line 4, and to iterate in line 6 over the rules $T \to r(T_1, T_2)$ for which $T_i \in \mathsf{prt}(X_i)$ and $r \in \rho$. This bottom-up query to M_L can be answered efficiently from an appropriate index on the rules of M_L. Altogether, this condensed intersection algorithm can be dramatically faster than the original version, if the grammar contains many symbols with the same homomorphic image.

6 Evaluation

We compare the runtime performance of the proposed algorithms on practical grammars and inputs, from three very different grammar formalisms: context-free grammars, TAG, and HRG graph grammars. In each setting, we measure the runtime of four algorithms: the naive bottom-up baseline of Section 3; the sibling-finder algorithm from Section 4; and the non-condensed and the condensed version of the top-down algorithm from Section 5. The results are shown in Figures 5, 6 and 7. We measure the runtimes for computing the complete chart, and plot the geometric mean of runtimes for each input size on a log scale.

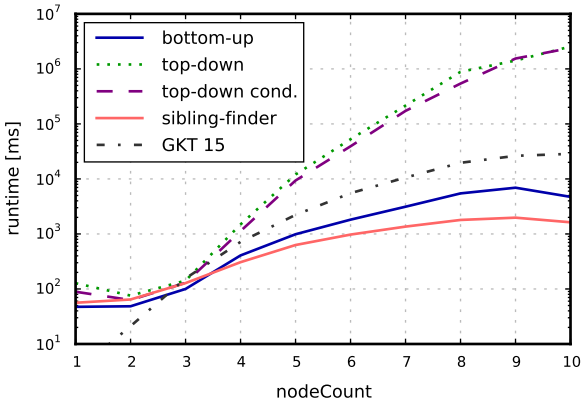

Figure 7: Runtimes for graph parsing.

We measured all runtimes on an Intel Xeon E7-8857 CPU at 3 GHz using Java 8. The JVM was warmed up before the measurements. The parser filtered each grammar automatically, removing all rules whose homomorphic image contained a constant that could not be used for a given input (e.g., a word that did not occur in the sentence).

PCFG. We extracted a binarized context-free grammar with 6929 rules from Section 00 of the Penn Treebank, and parsed the sentences of Section 00 with it. The homorphism in the corresponding IRTG assigns every terminal symbol a constant or the term $*(x_1, x_2)$, as in Fig. 1. As a consequence, the condensed automaton optimization from Section 5 outperforms all other algo-

rithms, achieving a 100x speedup over the naive bottom-up algorithm when it was cancelled.

TAG. We also extracted a tree-adjoining grammar from Section 00 of the PTB as described by Chen and Vijay-Shanker (2000), converted it to an IRTG as described by Koller and Kuhlmann (2012), and binarized it, yielding an IRTG with 26652 rules. Each term $h(r)$ in this grammar represents an entire TAG elementary tree, which means the terms are much more complex than for the PCFG and there are much fewer terminal symbols with the same homomorphic term. As a consequence, condensing the invhom is much less helpful. However, the sibling-finder algorithm excels at maintaining state information within each elementary tree, yielding a 1000x speedup over the naive bottom-up algorithm when it was cancelled.

Graphs. Finally, we parsed a corpus of graphs instead of strings, using the 13681-rule graph grammar of Groschwitz et al. (2015) to parse the 1258 graphs with up to 10 nodes from the "Little Prince" AMR-Bank (Banarescu et al., 2013). The top-down algorithms are slow in this experiment, confirming Groschwitz et al.'s findings. Again, the sibling-finder algorithm outperforms all other algorithms. Note that Groschwitz et al.'s parser ("GKT 15" in Fig. 7) shares much code with our system. It uses the same decomposition automata, but a less mature version of the sibling-finder method which fully computes the invhom automaton. Our new system achieves a 9x speedup for parsing the whole corpus, compared to GKT 15.

7 Related Work

Describing parsing algorithms at a high level of abstraction has a long tradition in computational linguistics, e.g. in deductive parsing with parsing schemata (Shieber et al., 1995). A key challenge under this view is to index chart entries so they can be retrieved efficiently, which parallels the situation in automata intersection discussed here. Gómez-Rodríguez et al. (2009) present an algorithm that automatically establishes index structures that guarantee optimal asymptotic runtime, but also requires algebra-specific extensions for grammar formalisms that go beyond context-free string grammars.

Efficient parsing has also been studied in other generalized grammar formalisms beyond IRTG. Kanazawa (to appear) shows how the parsing problem of Abstract Categorial Grammars (de Groote, 2001) can be translated into Datalog, which enables the use of generic indexing strategies for Datalog to achieve optimal asymptotic complexity. Ranta (2004) discusses parsing for his Grammatical Framework formalism in terms of partial evaluation techniques from functional programming, which are related to the step-by-step evaluation of sibling-finders in Figure 4. Like the approach of Gomez-Rodriguez et al., these methods have not been evaluated for large-scale grammars and realistic evaluation data, which makes it hard to judge their relative practical merits.

Most work in the tree automata community has a theoretical slant, and there is less research on the efficient implementation of algorithms for tree automata than one would expect; Cleophas (2009) and Lengal et al. (2012) are notable exceptions. Even these tend to be motivated by applications such as specification and verification, where the tree automata are much smaller and much less ambiguous than in computational linguistics. This makes these systems hard to apply directly.

8 Conclusion

We have presented novel algorithms for computing the intersection and the inverse homomorphic image of finite tree automata. These can be used to implement a generic algorithm for IRTG parsing, and apply directly to any grammar formalism that can be represented as an IRTG. An evaluation on practical data from three different grammar formalisms shows consistent speed improvements of several orders of magnitude, and our graph parser has the fastest published runtimes.

A Java implementation of our algorithms is available as part of the Alto parser, `http://bitbucket.org/tclup/alto`.

We focused here purely on symbolic parsing, and on computing complete parse charts. In the presence of a probability model (e.g. for IRTG encodings of PCFGs), our algorithms could be made faster through the use of appropriate pruning techniques. It would also be interesting to combine the strengths of the condensed and sibling-finder algorithms for further efficiency gains.

A Vector Space for Distributional Semantics for Entailment *

James Henderson and **Diana Nicoleta Popa**
Xerox Research Centre Europe
james.henderson@xrce.xerox.com and diana.popa@xrce.xerox.com

Abstract

Distributional semantics creates vector-space representations that capture many forms of semantic similarity, but their relation to semantic entailment has been less clear. We propose a vector-space model which provides a formal foundation for a distributional semantics of entailment. Using a mean-field approximation, we develop approximate inference procedures and entailment operators over vectors of probabilities of features being known (versus unknown). We use this framework to reinterpret an existing distributional-semantic model (Word2Vec) as approximating an entailment-based model of the distributions of words in contexts, thereby predicting lexical entailment relations. In both unsupervised and semi-supervised experiments on hyponymy detection, we get substantial improvements over previous results.

1 Introduction

Modelling entailment is a fundamental issue in computational semantics. It is also important for many applications, for example to produce abstract summaries or to answer questions from text, where we need to ensure that the input text entails the output text. There has been a lot of interest in modelling entailment in a vector-space, but most of this work takes an empirical, often ad-hoc, approach to this problem, and achieving good results has been difficult (Levy et al., 2015). In this work, we propose a new framework for modelling entailment in a vector-space, and illustrate its effectiveness with a distributional-semantic model of hyponymy detection.

$\Rightarrow$	*unk*	f	g	$\neg f$
unk	1	0	0	0
f	1	1	0	0
g	1	0	1	0
$\neg f$	1	0	0	1

Table 1: Pattern of logical entailment between nothing known (*unk*), two different features f and g known, and the complement of f ($\neg f$) known.

Unlike previous vector-space models of entailment, the proposed framework explicitly models what information is unknown. This is a crucial property, because entailment reflects what information is and is not known; a representation y entails a representation x if and only if everything that is known given x is also known given y. Thus, we model entailment in a vector space where each dimension represents something we might know. As illustrated in Table 1, knowing that a feature f is true always entails knowing that same feature, but never entails knowing that a different feature g is true. Also, knowing that a feature is true always entails not knowing anything (*unk*), since strictly less information is still entailment, but the reverse is never true. Table 1 also illustrates that knowing that a feature f is false ($\neg f$) patterns exactly the same way as knowing that an unrelated feature g is true. This illustrates that the relevant dichotomy for entailment is known versus unknown, and not true versus false.

Previous vector-space models have been very successful at modelling semantic similarity, in particular using distributional semantic models (e.g. (Deerwester et al., 1990; Schütze, 1993; Mikolov et al., 2013a)). Distributional semantics uses the distributions of words in contexts to induce vector-space embeddings of words, which have been

*This work was partially supported by French ANR grant CIFRE N 1324/2014.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2052–2062,
Berlin, Germany, August 7-12, 2016.

shown to be useful for a wide variety of tasks. Two words are predicted to be similar if the dot product between their vectors is high. But the dot product is an anti-symmetric operator, which makes it more natural to interpret these vectors as representing whether features are true or false, whereas the dichotomy known versus unknown is asymmetric. We surmise that this is why distributional semantic models have had difficulty modelling lexical entailment (Levy et al., 2015).

To develop a vector-space model of whether features are known or unknown, we start with discrete binary vectors, where 1 means known and 0 means unknown. Entailment between these discrete binary vectors can be calculated by independently checking each dimension. But as soon as we try to do calculations with *distributions* over these vectors, we need to deal with the case where the features are not independent. For example, if feature f has a 50% chance of being true and a 50% chance of being false, we can't assume that there is a 25% chance that both f and $\neg f$ are known. This simple case of mutual exclusion is just one example of a wide range of constraints between features which we need to handle in semantic models. These constraints mean that the different dimensions of our vector space are not independent, and therefore exact models are not factorised. Because the models are not factorised, exact calculations of entailment and exact inference of vectors are intractable.

Mean-field approximations are a popular approach to efficient inference for intractable models. In a mean-field approximation, distributions over binary vectors are represented using a single probability for each dimension. These vectors of real values are the basis of our proposed vector space for entailment.

In this work, we propose a vector-space model which provides a formal foundation for a distributional semantics of entailment. This framework is derived from a mean-field approximation to entailment between binary vectors, and includes operators for measuring entailment between vectors, and procedures for inferring vectors in an entailment graph. We validate this framework by using it to reinterpret existing Word2Vec (Mikolov et al., 2013a) word embedding vectors as approximating an entailment-based model of the distribution of words in contexts. This reinterpretation allows us to use existing word embeddings as an unsupervised model of lexical entailment, successfully predicting hyponymy relations using the proposed entailment operators in both unsupervised and semi-supervised experiments.

2 Modelling Entailment in a Vector Space

To develop a model of entailment in a vector space, we start with the logical definition of entailment in terms of vectors of discrete known features: y entails x if and only if all the known features in x are also included in y. We formalise this relation with binary vectors x, y where 1 means known and 0 means unknown, so this discrete entailment relation $(y \Rightarrow x)$ can be defined with the binary formula:

$$P((y \Rightarrow x) \mid x, y) = \prod_k (1 - (1 - y_k)x_k)$$

Given prior probability distributions $P(x), P(y)$ over these vectors, the exact joint and marginal probabilities for an entailment relation are:

$$P(x, y, (y \Rightarrow x)) = P(x)\ P(y) \prod_k (1 - (1 - y_k)x_k)$$

$$P((y \Rightarrow x)) = E_{P(x)} E_{P(y)} \prod_k (1 - (1 - y_k)x_k) \quad (1)$$

We cannot assume that the priors $P(x)$ and $P(y)$ are factorised, because there are many important correlations between features and therefore we cannot assume that the features are independent. As discussed in Section 1, even just representing both a feature f and its negation $\neg f$ requires two different dimensions k and k' in the vector space, because 0 represents unknown and not false. Given valid feature vectors, calculating entailment can consider these two dimensions separately, but to reason with distributions over vectors we need the prior $P(x)$ to enforce the constraint that x_k and $x_{k'}$ are mutually exclusive. In general, such correlations and anti-correlations exist between many semantic features, which makes inference and calculating the probability of entailment intractable.

To allow for efficient inference in such a model, we propose a mean-field approximation. This in effect assumes that the posterior distribution over vectors is factorised, but in practice this is a much weaker assumption than assuming the prior is factorised. The posterior distribution has less uncertainty and therefore is influenced less by non-factorised prior constraints. By assuming a factorised posterior, we can then represent distributions over feature vectors with simple vectors of

probabilities of individual features (or as below, with their log-odds). These real-valued vectors are the basis of the proposed vector-space model of entailment.

In the next two subsections, we derive a mean-field approximation for inference of real-valued vectors in entailment graphs. This derivation leads to three proposed vector-space operators for approximating the log-probability of entailment, summarised in Table 2. These operators will be used in the evaluation in Section 5. This inference framework will also be used in Section 3 to model how existing word embeddings can be mapped to vectors to which the entailment operators can be applied.

2.1 A Mean-Field Approximation

A mean-field approximation approximates the posterior P using a factorised distribution Q. First of all, this gives us a concise description of the posterior $P(x|\ldots)$ as a vector of continuous values $Q(x{=}1)$, where $Q(x{=}1)_k = Q(x_k{=}1) \approx E_{P(x|\ldots)}x_k = P(x_k{=}1|\ldots)$ (i.e. the marginal probabilities of each bit). Secondly, as is shown below, this gives us efficient methods for doing approximate inference of vectors in a model.

First we consider the simple case where we want to approximate the posterior distribution $P(x, y|y{\Rightarrow}x)$. In a mean-field approximation, we want to find a factorised distribution $Q(x, y)$ which minimises the KL-divergence $D_{KL}(Q(x, y)||P(x, y|y{\Rightarrow}x))$ with the true distribution $P(x, y|y{\Rightarrow}x)$.

$$\begin{aligned}
L &= D_{KL}(Q(x,y)||P(x,y|(y{\Rightarrow}x))) \\
&\propto \sum_x Q(x) \log \frac{Q(x,y)}{P(x,y,(y{\Rightarrow}x))} \\
&= \sum_k E_{Q(x_k)} \log Q(x_k) + \sum_k E_{Q(y_k)} \log Q(y_k) \\
&\quad - E_{Q(x)} \log P(x) - E_{Q(y)} \log P(y) \\
&\quad - \sum_k E_{Q(x_k)} E_{Q(y_k)} \log(1{-}(1{-}y_k)x_k)
\end{aligned}$$

In the final equation, the first two terms are the negative entropy of Q, $-H(Q)$, which acts as a maximum entropy regulariser, the final term enforces the entailment constraint, and the middle two terms represent the prior for x and y. One approach (generalised further in the next subsection) to the prior terms $-E_{Q(x)} \log P(x)$ is to bound them by assuming $P(x)$ is a function in the exponential family, giving us:

$$\begin{aligned}
E_{Q(x)} \log P(x) &\geq E_{Q(x)} \log \frac{\exp(\sum_k \theta^x_k x_k)}{\mathcal{Z}_\theta} \\
&= \sum_k E_{Q(x_k)} \theta^x_k x_k - \log \mathcal{Z}_\theta
\end{aligned}$$

where the $\log \mathcal{Z}_\theta$ is not relevant in any of our inference problems and thus will be dropped below.

As typically in mean-field approximations, inference of $Q(x)$ and $Q(y)$ can't be done efficiently with this exact objective L, because of the non-linear interdependence between x_k and y_k in the last term. Thus, we introduce two approximations to L, one for use in inferring $Q(x)$ given $Q(y)$ (forward inference), and one for the reverse inference problem (backward inference). In both cases, the approximation is done with an application of Jensen's inequality to the log function, which gives us an upper bound on L, as is standard practice in mean-field approximations. For forward inference:

$$\begin{aligned}
L \leq & -H(Q) - Q(x_k{=}1)\theta^x_k - E_{Q(y_k)}\theta^y_k y_k \\
& - Q(x_k{=}1) \log Q(y_k{=}1)\ )
\end{aligned} \quad (2)$$

which we can optimise for $Q(x_k{=}1)$:

$$Q(x_k{=}1) = \sigma(\ \theta^x_k + \log Q(y_k{=}1)\ ) \quad (3)$$

where $\sigma()$ is the sigmoid function. The sigmoid function arises from the entropy regulariser, making this a specific form of maximum entropy model. And for backward inference:

$$\begin{aligned}
L \leq & -H(Q) - E_{Q(x_k)}\theta^x_k x_k - Q(y_k{=}1)\theta^y_k \\
& - (1{-}Q(y_k{=}1)) \log(1{-}Q(x_k{=}1))\ )
\end{aligned} \quad (4)$$

which we can optimise for $Q(y_k{=}1)$:

$$Q(y_k{=}1) = \sigma(\ \theta^y_k - \log(1{-}Q(x_k{=}1))\ ) \quad (5)$$

Note that in equations (2) and (4) the final terms, $Q(x_k{=}1) \log Q(y_k{=}1)$ and $(1{-}Q(y_k{=}1)) \log(1{-}Q(x_k{=}1))$ respectively, are approximations to the log-probability of the entailment. We define two vector-space operators, $\circledcirc$ and $\oslash$, to be these same approximations.

$$\begin{aligned}
&\log Q(y{\Rightarrow}x) \\
&\quad \approx \sum_k E_{Q(x_k)} \log(E_{Q(y_k)}(1 - (1{-}y_k)x_k)) \\
&\quad = Q(x{=}1) \cdot \log Q(y{=}1) \ \equiv X \circledcirc Y
\end{aligned}$$

$$\begin{aligned}
&\log Q(y{\Rightarrow}x) \\
&\quad \approx \sum_k E_{Q(y_k)} \log(E_{Q(x_k)}(1 - (1{-}y_k)x_k)) \\
&\quad = (1{-}Q(y{=}1)) \cdot \log(1{-}Q(x{=}1)) \ \equiv Y \oslash X
\end{aligned}$$

$$
\begin{aligned}
X \circledcirc Y &\equiv \sigma(X) \cdot \log \sigma(Y) \\
Y \circledS X &\equiv \sigma(-Y) \cdot \log \sigma(-X) \\
Y \barwedge X &\equiv \sum_k \log(1 - \sigma(-Y_k)\sigma(X_k))
\end{aligned}
$$

Table 2: The proposed entailment operators, approximating $\log P(y \Rightarrow x)$.

We parametrise these operators with the vectors X, Y of log-odds of $Q(x), Q(y)$, namely $X = \log \frac{Q(x=1)}{Q(x=0)} = \sigma^{-1}(Q(x=1))$. The resulting operator definitions are summarised in Table 2.

Also note that the probability of entailment given in equation (1) becomes factorised when we replace P with Q. We define a third vector-space operator, $\barwedge$, to be this factorised approximation, also shown in Table 2.

2.2 Inference in Entailment Graphs

In general, doing inference for one entailment is not enough; we want to do inference in a graph of entailments between variables. In this section we generalise the above mean-field approximation to entailment graphs.

To represent information about variables that comes from outside the entailment graph, we assume we are given a prior $P(x)$ over all variables x_i in the graph. As above, we do not assume that this prior is factorised. Instead we assume that the prior $P(x)$ is itself a graphical model which can be approximated with a mean-field approximation.

Given a set of variables x_i each representing vectors of binary variables x_{ik}, a set of entailment relations $r = \{(i,j)|(x_i \Rightarrow x_j)\}$, and a set of negated entailment relations $\bar{r} = \{(i,j)|(x_i \not\Rightarrow x_j)\}$, we can write the joint posterior probability as:

$$
\begin{aligned}
P(x, r, \bar{r}) = \frac{1}{\mathcal{Z}} P(x) \prod_i \Big(& \\
& \Big(\prod_{j:r(i,j)} \prod_k P(x_{ik} \Rightarrow x_{jk} | x_{ik}, x_{jk}) \Big) \\
& \Big(\prod_{j:\bar{r}(i,j)} (1 - \prod_k P(x_{ik} \Rightarrow x_{jk} | x_{ik}, x_{jk})) \Big) \Big)
\end{aligned}
$$

We want to find a factorised distribution Q that minimises $L = D_{KL}(Q(x)||P(x|r,\bar{r}))$. As above, we bound this loss for each element $X_{ik} = \sigma^{-1}(Q(x_{ik}=1))$ of each vector we want to infer, using analogous Jensen's inequalities for the terms involving nodes i and j such that $r(i,j)$ or $r(j,i)$. For completeness, we also propose similar inequalities for nodes i and j such that $\bar{r}(i,j)$ or $\bar{r}(j,i)$, and bound them using the constants

$$C_{ijk} \geq \prod_{k' \neq k} (1 - \sigma(-X_{ik'})\sigma(X_{jk'})).$$

To represent the prior $P(x)$, we use the terms

$$\theta_{ik}(X_{\bar{ik}}) \leq \log \frac{E_{Q(x_{\bar{ik}})} P(x_{\bar{ik}}, x_{ik}=1)}{1 - E_{Q(x_{\bar{ik}})} P(x_{\bar{ik}}, x_{ik}=1)}$$

where $x_{\bar{ik}}$ is the set of all $x_{i'k'}$ such that either $i' \neq i$ or $k' \neq k$. These terms can be thought of as the log-odds terms that would be contributed to the loss function by including the prior's graphical model in the mean-field approximation.

Now we can infer the optimal X_{ik} as:

$$
\begin{aligned}
X_{ik} \;=\; & \theta_{ik}(X_{\bar{ik}}) + \sum_{j:r(i,j)} -\log \sigma(-X_{jk}) \qquad (6) \\
& + \sum_{j:r(j,i)} \log \sigma(X_{jk}) + \sum_{j:\bar{r}(j,i)} \log \frac{1 - C_{ijk}\sigma(X_{jk})}{1 - C_{ijk}} \\
& + \sum_{j:\bar{r}(i,j)} -\log \frac{1 - C_{ijk}\sigma(-X_{jk})}{1 - C_{ijk}}
\end{aligned}
$$

In summary, the proposed mean-field approximation does inference in entailment graphs by iteratively re-estimating each X_i as the sum of: the prior log-odds, $-\log \sigma(-X_j)$ for each entailed variable j, and $\log \sigma(X_j)$ for each entailing variable j.[1] This inference optimises $X_i \circledcirc X_j$ for each entailing j plus $X_i \circledS X_j$ for each entailed j, plus a maximum entropy regulariser on X_i. Negative entailment relations, if they exist, can also be incorporated with some additional approximations. Complex priors can also be incorporated through their log-odds, simulating the inclusion of the prior within the mean-field approximation.

Given its dependence on mean-field approximations, it is an empirical question to what extent we should view this model as computing real entailment probabilities and to what extent we should view it as a well-motivated non-linear mapping for which we simply optimise the input-output behaviour (as for neural networks (Henderson and Titov, 2010)). In Sections 3 and 5 we argue for the former (stronger) view.

3 Interpreting Word2Vec Vectors

To evaluate how well the proposed framework provides a formal foundation for the distributional semantics of entailment, we use it to re-interpret an

[1] It is interesting to note that $-\log \sigma(-X_j)$ is a non-negative transform of X_j, similar to the ReLU nonlinearity which is popular in deep neural networks (Glorot et al., 2011). $\log \sigma(X_j)$ is the analogous non-positive transform.

existing model of distributional semantics in terms of semantic entailment. There has been a lot of work on how to use the distribution of contexts in which a word occurs to induce a vector representation of the semantics of words. In this paper, we leverage this previous work on distributional semantics by re-interpreting a previous distributional semantic model and using this understanding to map its vector-space word embeddings to vectors in the proposed framework. We then use the proposed operators to predict entailment between words using these vectors. In Section 5 below, we evaluate these predictions on the task of hyponymy detection. In this section we motivate three different ways to interpret the Word2Vec (Mikolov et al., 2013a; Mikolov et al., 2013b) distributional semantic model as an approximation to an entailment-based model of the semantic relationship between a word and its context.

Distributional semantics learns the semantics of words by looking at the distribution of contexts in which they occur. To model this relationship, we assume that the semantic features of a word are (statistically speaking) redundant with those of its context words, and consistent with those of its context words. We model these properties using a hidden vector which is the consistent unification of the features of the middle word and the context. In other words, there must exist a hidden vector which entails both of these vectors, and is consistent with prior constraints on vectors. We split this into two steps, inference of the hidden vector Y from the middle vector X_m, context vectors X_c and prior, and computing the log-probability (7) that this hidden vector entails the middle and context vectors:

$$\max_{Y}(\log P(y, y{\Rightarrow}x_m, y{\Rightarrow}x_c)) \tag{7}$$

We interpret Word2Vec's Skip-Gram model as learning its context and middle word vectors so that the log-probability of this entailment is high for the observed context words and low for other (sampled) context words. The word embeddings produced by Word2Vec are only related to the vectors X_m assigned to the middle words; context vectors are computed but not output. We model the context vectors X'_c as combining (as in equation (5)) information about a context word itself with information which can be inferred from this word given the prior, $X'_c = \theta_c - \log\sigma(-X_c)$.

The numbers in the vectors output by Word2Vec are real numbers between negative infinity and infinity, so the simplest interpretation of them is as the log-odds of a feature being known. In this case we can treat these vectors directly as the X_m in the model. The inferred hidden vector Y can then be calculated using the model of backward inference from the previous section.

$$\begin{aligned} Y &= \theta_c - \log\sigma(-X_c) - \log\sigma(-X_m) \\ &= X'_c - \log\sigma(-X_m) \end{aligned}$$

Since the unification Y of context and middle word features is computed using backward inference, we use the backward-inference operator $\circledcirc$ to calculate how successful that unification was. This gives us the final score:

$$\begin{aligned} &\log P(y, y{\Rightarrow}x_m, y{\Rightarrow}x_c) \\ &\quad\approx\ Y{\circledcirc}X_m + Y{\circledcirc}X_c + -\sigma(-Y){\cdot}\theta_c \\ &\quad=\ Y{\circledcirc}X_m + -\sigma(-Y){\cdot}X'_c \end{aligned}$$

This is a natural interpretation, but it ignores the equivalence in Word2Vec between pairs of positive values and pairs of negative values, due to its use of the dot product. As a more accurate interpretation, we interpret each Word2Vec dimension as specifying whether its feature is known to be true or known to be false. Translating this Word2Vec vector into a vector in our entailment vector space, we get one copy Y^+ of the vector representing known-to-be-true features and a second negated duplicate Y^- of the vector representing known-to-be-false features, which we concatenate to get our representation Y.

$$\begin{aligned} Y^+ &= X'_c - \log\sigma(-X_m) \\ Y^- &= -X'_c - \log\sigma(X_m) \\ &\log P(y, y{\Rightarrow}x_m, y{\Rightarrow}x_c) \\ &\quad\approx\ Y^+{\circledcirc}X_m + -\sigma(-Y^+){\cdot}X'_c \\ &\qquad + Y^-{\circledcirc}(-X_m) + -\sigma(-Y^-){\cdot}(-X'_c) \end{aligned}$$

As a third alternative, we modify this latter interpretation with some probability mass reserved for unknown in the vicinity of zero. By subtracting 1 from both the original and negated copies of each dimension, we get a probability of unknown of $1{-}\sigma(X_m{-}1) - \sigma(-X_m{-}1)$. This gives us:

$$\begin{aligned} Y^+ &= X'_c - \log\sigma(-(X_m{-}1)) \\ Y^- &= -X'_c - \log\sigma(-(-X_m{-}1)) \\ &\log P(y, y{\Rightarrow}x_m, y{\Rightarrow}x_c) \\ &\quad\approx\ Y^+{\circledcirc}(X_m{-}1) + -\sigma(-Y^+){\cdot}X'_c \\ &\qquad + Y^-{\circledcirc}(-X_m{-}1)) + -\sigma(-Y^-){\cdot}(-X'_c) \end{aligned}$$

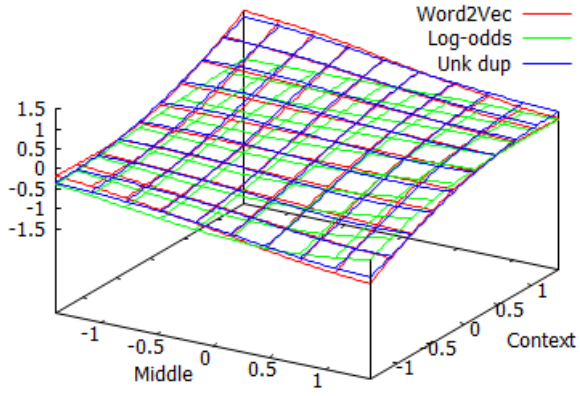

Figure 1: The learning gradients for Word2Vec, the *log-odds* ⊘, and the *unk dup* ⊘ interpretation of its vectors.

To understand better the relative accuracy of these three interpretations, we compared the training gradient which Word2Vec uses to train its middle-word vectors to the training gradient for each of these interpretations. We plotted these gradients for the range of values typically found in Word2Vec vectors for both the middle vector and the context vector. Figure 1 shows three of these plots. As expected, the second interpretation is more accurate than the first because its plot is anti-symmetric around the diagonal, like the Word2Vec gradient. In the third alternative, the constant 1 was chosen to optimise this match, producing a close match to the Word2Vec training gradient, as shown in Figure 1 (*Word2Vec* versus *Unk dup*).

Thus, Word2Vec can be seen as a good approximation to the third model, and a progressively worse approximation to the second and first models. Therefore, if the entailment-based distributional semantic model we propose is accurate, then we would expect the best accuracy in hyponymy detection using the third interpretation of Word2Vec vectors, and progressively worse accuracy for the other two interpretations. As we will see in Section 5, this prediction holds.

4 Related Work

There has been a significant amount of work on using distributional-semantic vectors for hyponymy detection, using supervised, semi-supervised or unsupervised methods (e.g. (Yu et al., 2015; Necsulescu et al., 2015; Vylomova et al., 2015; Weeds et al., 2014; Fu et al., 2015; Rei and Briscoe, 2014)). Because our main concern is modelling entailment within a vector space, we do not do a thorough comparison to models which use measures computed outside the vector space (e.g. symmetric measures (LIN (Lin, 1998)), asymmetric measures (WeedsPrec (Weeds and Weir, 2003; Weeds et al., 2004), balAPinc (Kotlerman et al., 2010), invCL (Lenci and Benotto, 2012)) and entropy-based measures (SLQS (Santus et al., 2014))), nor to models which encode hyponymy in the parameters of a vector-space operator or classifier (Fu et al., 2015; Roller et al., 2014; Baroni et al., 2012)). We also limit our evaluation of lexical entailment to hyponymy, not including other related lexical relations (cf. (Weeds et al., 2014; Vylomova et al., 2015; Turney and Mohammad, 2014; Levy et al., 2014)), leaving more complex cases to future work on compositional semantics. We are also not concerned with models or evaluations which require supervised learning about individual words, instead limiting ourselves to semi-supervised learning where the words in the training and test sets are disjoint.

For these reasons, in our evaluations we replicate the experimental setup of Weeds et al. (2014), for both unsupervised and semi-supervised models. Within this setup, we compare to the results of the models evaluated by Weeds et al. (2014) and to previously proposed vector-space operators. This includes one vector space operator for hyponymy which doesn't have trained parameters, proposed by Rei and Briscoe (2014), called *weighted cosine*. The dimensions of the dot product (normalised to make it a cosine measure) are weighted to put more weight on the larger values in the entailed (hypernym) vector.

We base this evaluation on the Word2Vec (Mikolov et al., 2013a; Mikolov et al., 2013b) distributional semantic model and its publicly available word embeddings. We choose it because it is popular, simple, fast, and its embeddings have been derived from a very large corpus. Levy and Goldberg (2014) showed that it is closely related to the previous PMI-based distributional semantic models (e.g. (Turney and Pantel, 2010)).

The most similar previous work, in terms of motivation and aims, is that of Vilnis and McCallum (2015). They also model entailment directly using a vector space, without training a classifier. But instead of representing words as a point in a vector space (as in this work), they represent words as a Gaussian distribution over points in a vector space. This allows them to represent the extent to which a feature is known versus unknown as the

amount of variance in the distribution for that feature's dimension. While nicely motivated theoretically, the model appears to be more computationally expensive than the one proposed here, particularly for inferring vectors. They do make unsupervised predictions of hyponymy relations with their learned vector distributions, using KL-divergence between the distributions for the two words. They evaluate their models on the hyponymy data from (Baroni et al., 2012). As discussed further in section 5.2, our best models achieve non-significantly better average precision than their best models.

The semi-supervised model of Kruszewski et al. (2015) also models entailment in a vector space, but they use a discrete vector space. They train a mapping from distributional semantic vectors to Boolean vectors such that feature inclusion respects a training set of entailment relations. They then use feature inclusion to predict hyponymy, and other lexical entailment relations. This approach is similar to the one used in our semi-supervised experiments, except that their discrete entailment prediction operator is very different from our proposed entailment operators.

5 Evaluation

To evaluate whether the proposed framework is an effective model of entailment in vector spaces, we apply the interpretations from Section 3 to publicly available word embeddings and use them to predict the hyponymy relations in a benchmark dataset. This framework predicts that the more accurate interpretations of Word2Vec result in more accurate unsupervised models of hyponymy. We evaluate on detecting hyponymy relations between words because hyponymy is the canonical type of lexical entailment; most of the semantic features of a hypernym (e.g. "animal") must be included in the semantic features of the hyponym (e.g. "dog"). We evaluate in both a fully unsupervised setup and a semi-supervised setup.

5.1 Hyponymy with Word2Vec Vectors

For our evaluation on hyponymy detection, we replicate the experimental setup of Weeds et al. (2014), using their selection of word pairs[2] from the BLESS dataset (Baroni and Lenci, 2011).[3] These noun-noun word pairs include positive hyponymy pairs, plus negative pairs consisting of some other hyponymy pairs reversed, some pairs in other semantic relations, and some random pairs. Their selection is balanced between positive and negative examples, so that accuracy can be used as the performance measure. For their semi-supervised experiments, ten-fold cross validation is used, where for each test set, items are removed from the associated training set if they contain any word from the test set. Thus, the vocabulary of the training and testing sets are always disjoint, thereby requiring that the models learn about the vector space and not about the words themselves. We had to perform our own 10-fold split, but apply the same procedure to filter the training set.

We could not replicate the word embeddings used in Weeds et al. (2014), so instead we use publicly available word embeddings.[4] These vectors were trained with the Word2Vec software applied to about 100 billion words of the Google-News dataset, and have 300 dimensions.

The hyponymy detection results are given in Table 3, including both unsupervised (upper box) and semi-supervised (lower box) experiments. We report two measures of performance, hyponymy detection accuracy (*50% Acc*) and direction classification accuracy (*Dir Acc*). Since all the operators only determine a score, we need to choose a threshold to get detection accuracies. Given that the proportion of positive examples in the dataset has been artificially set at 50%, we threshold each model's score at the point where the proportion of positive examples output is 50%, which we call "*50% Acc*". Thus the threshold is set after seeing the testing inputs but not their target labels.

Direction classification accuracy (*Dir Acc*) indicates how well the method distinguishes the relative abstractness of two nouns. Given a pair of nouns which are in a hyponymy relation, it classifies which word is the hypernym and which is the hyponym. This measure only considers positive examples and chooses one of two directions, so it is inherently a balanced binary classification task. Classification is performed by simply comparing the scores in both directions. If both directions produce the same score, the expected random accuracy (50%) is used.

As representative of previous work, we report

Table 3: Accuracies on the BLESS data from Weeds et al. (2014), for hyponymy detection (*50% Acc*) and hyponymy direction classification (*Dir Acc*), in the unsupervised (upper box) and semi-supervised (lower box) experiments. For unsupervised accuracies, * marks a significant difference with the previous row.

the best results from Weeds et al. (2014), who try a number of unsupervised and semi-supervised models, and use the same testing methodology and hyponymy data. However, note that their word embeddings are different. For the semi-supervised models, Weeds et al. (2014) trains classifiers, which are potentially more powerful than our linear vector mappings. We also compare the proposed operators to the dot product (*dot*),[5] vector differences (*dif*), and the weighted cosine of Rei and Briscoe (2014) (*weighted cos*), all computed with the same word embeddings as for the proposed operators.

In Section 3 we argued for three progressively more accurate interpretations of Word2Vec vectors in the proposed framework, the log-odds interpretation (*log-odds* $\oslash$), the negated duplicate interpretation (*dup* $\oslash$), and the negated duplicate interpretation with unknown around zero (*unk dup* $\oslash$). We also evaluate using the factorised calculation of entailment (*log-odds* $\vec{\Rightarrow}$, *unk dup* $\vec{\Rightarrow}$), and the backward-inference entailment operator (*log-odds* $\oslash$), neither of which match the proposed interpretations. For the semi-supervised case, we train a linear vector-space mapping into a new vector space, in which we apply the operators (*mapped* operators). All these results are discussed in the next two subsections.

[5]We also tested the cosine measure, but results were very slightly worse than *dot*.

5.2 Unsupervised Hyponymy Detection

The first set of experiments evaluate the vector-space operators in unsupervised models of hyponymy detection. The proposed models are compared to the dot product, because this is the standard vector-space operator and has been shown to capture semantic similarity very well. However, because the dot product is a symmetric operator, it always performs at chance for direction classification. Another vector-space operator which has received much attention recently is vector differences. This is used (with vector sum) to perform semantic transforms, such as "king - male + female = queen", and has previously been used for modelling hyponymy (Vylomova et al., 2015; Weeds et al., 2014). For our purposes, we sum the pairwise differences to get a score which we use for hyponymy detection.

For the unsupervised results in the upper box of table 3, the best unsupervised model of Weeds et al. (2014), and the operators *dot*, *dif* and *weighted cos* all perform similarly on accuracy, as does the log-odds factorised entailment calculation (*log-odds* $\vec{\Rightarrow}$). The forward-inference entailment operator (*log-odds* $\oslash$) performs above chance but not well, as expected given the backward-inference-based interpretation of Word2Vec vectors. By definition, *dot* is at chance for direction classification, but the other models all perform better, indicating that all these operators are able to measure relative abstractness. As predicted, the $\oslash$ operator performs significantly better than all these results on accuracy, as well as on direction classification, even assuming the log-odds interpretation of Word2Vec vectors.

When we move to the more accurate interpretation of Word2Vec vectors as specifying both original and negated features (*dup* $\oslash$), we improve (non-significantly) on the log-odds interpretation. Finally, the third and most accurate interpretation, where values around zero can be unknown (*unk dup* $\oslash$), achieves the best results in unsupervised hyponymy detection, as well as for direction classification. Changing to the factorised entailment operator (*unk dup* $\vec{\Rightarrow}$) is worse but also signifi-

cantly better than the other accuracies.

To allow a direct comparison to the model of Vilnis and McCallum (2015), we also evaluated the unsupervised models on the hyponymy data from (Baroni et al., 2012). Our best model achieved 81% average precision on this dataset, non-significantly better than the 80% achieved by the best model of Vilnis and McCallum (2015).

5.3 Semi-supervised Hyponymy Detection

Since the unsupervised learning of word embeddings may reflect many context-word correlations which have nothing to do with hyponymy, we also consider a semi-supervised setting. Adding some supervision helps distinguish features that capture semantic properties from other features which are not relevant to hyponymy detection. But even with supervision, we still want the resulting model to be captured in a vector space, and not in a parametrised scoring function. Thus, we train mappings from the Word2Vec word vectors to new word vectors, and then apply the entailment operators in this new vector space to predict hyponymy. Because the words in the testing set are always disjoint from the words in the training set, this experiment measures how well the original unsupervised vector space captures features that generalise entailment across words, and not how well the mapping can learn about individual words.

Our objective is to learn a mapping to a new vector space in which an operator can be applied to predict hyponymy. We train linear mappings for the $\oslash$ operator (*mapped* $\oslash$) and for vector differences (*mapped dif*), since these were the best performing proposed operator and baseline operator, respectively, in the unsupervised experiments. We do not use the duplicated interpretations because these transforms are subsumed by the ability to learn a linear mapping.[6] Previous work on using vector differences for semi-supervised hyponymy detection has used a linear SVM (Vylomova et al., 2015; Weeds et al., 2014), which is mathematically equivalent to our vector-differences model, except that we use cross entropy loss and they use a large-margin loss and SVM training.

The semi-supervised results in the bottom box of table 3 show a similar pattern to the unsupervised results.[7] The $\oslash$ operator achieves the best generalisation from training word vectors to testing word vectors. The *mapped* $\oslash$ model has the best accuracy, followed by the factorised entailment operator *mapped* $\vec{\Rightarrow}$ and Weeds et al. (2014). Direction accuracies of all the proposed operators (*mapped* $\oslash$, *mapped* $\vec{\Rightarrow}$, *mapped* $\oslash$) reach into the 90's. The *dif* operator performs particularly poorly in this *mapped* setting, perhaps because both the mapping and the operator are linear. These semi-supervised results again support our distributional-semantic interpretations of Word2Vec vectors and their associated entailment operator $\oslash$.

6 Conclusion

In this work, we propose a vector-space model which provides a formal foundation for a distributional semantics of entailment. We developed a mean-field approximation to probabilistic entailment between vectors which represent known versus unknown features. And we used this framework to derive vector operators for entailment and vector inference equations for entailment graphs. This framework allows us to reinterpret Word2Vec as approximating an entailment-based distributional semantic model of words in context, and show that more accurate interpretations result in more accurate unsupervised models of lexical entailment, achieving better accuracies than previous models. Semi-supervised evaluations confirm these results.

A crucial distinction between the semi-supervised models here and much previous work is that they learn a mapping into a vector space which represents entailment, rather than learning a parametrised entailment classifier. Within this new vector space, the entailment operators and inference equations apply, thereby generalising naturally from these lexical representations to the compositional semantics of multi-word expressions and sentences. Further work is needed to explore the full power of these abilities to extract information about entailment from both unlabelled text and labelled entailment data, encode it all in a single vector space, and efficiently perform complex inferences about vectors and entailments. This future work on compositional distributional semantics should further demonstrate the full power of the proposed framework for modelling entailment in a vector space.

[6] Empirical results confirm that this is in practice the case, so we do not include these results in the table.

[7] It is not clear how to measure significance for cross-validation results, so we do not attempt to do so.

Abstract

We propose a new unsupervised learning model, hidden softmax sequence model (HSSM), based on Boltzmann machine for dialogue structure analysis. The model employs three types of units in the hidden layer to discovery dialogue latent structures: softmax units which represent latent states of utterances; binary units which represent latent topics specified by dialogues; and a binary unit that represents the global general topic shared across the whole dialogue corpus. In addition, the model contains extra connections between adjacent hidden softmax units to formulate the dependency between latent states. Two different kinds of real world dialogue corpora, Twitter-Post and AirTicketBooking, are utilized for extensive comparing experiments, and the results illustrate that the proposed model outperforms sate-of-the-art popular approaches.

1 Introduction

Dialogue structure analysis is an important and fundamental task in the natural language processing domain. The technology provides essential clues for solving real-world problems, such as producing dialogue summaries (Murray et al., 2006; Liu et al., 2010), controlling conversational agents (Wilks, 2006), and designing interactive dialogue systems (Young, 2006; Allen et al., 2007) etc. The study of modeling dialogues always assumes that for each dialogue there exists an unique latent structure (namely dialogue structure), which consists of a series of latent states.[1]

[1]Also called dialogue acts or speech acts in some past work. In this paper, for simplicity we will only use the term "latent state" to describe the sequential dialogue structure.

Some past works mainly rely on supervised or semi-supervised learning, which always involve extensive human efforts to manually construct latent state inventory and to label training samples. Cohen et al. (2004) developed an inventory of latent states specific to E-mail in an office domain by inspecting a large corpus of e-mail. Jeong et al. (2009) employed semi-supervised learning to transfer latent states from labeled speech corpora to the Internet media and e-mail. Involving extensive human efforts constrains scaling the training sample size (which is essential to supervised learning) and application domains.

In recent years, there has been some work on modeling dialogues with unsupervised learning methods which operate only on unlabeled observed data. Crook et al. (2009) employed Dirichlet process mixture clustering models to recognize latent states for each utterance in dialogues from a travel-planning domain, but they do not inspect dialogues' sequential structure. Chotimongkol (2008) proposed a hidden Markov model (HMM) based dialogue analysis model to study structures of task-oriented conversations from in-domain dialogue corpus. More recently, Ritter et al. (2010) extended the HMM based conversation model by introducing additional word sources for topic learning process. Zhai et al. (2014) assumed words in an utterance are emitted from topic models under HMM framework, and topics were shared across all latent states. All these dialogue structure analysis models are directed generative models, in which the HMMs, language models and topic models are combined together.

In this study, we attempt to develop a Boltzmann machine based **undirected generative model** for dialogue structure analysis. As for the document modeling using undirected generative model, Hinton and Salakhutdinov (2009) proposed a general framework, replicated soft-

Berlin, Germany, August 7-12, 2016.

max model (RSM), for topic modeling based on restricted Boltzmann machine (RBM). The model focuses on the document-level topic analysis, it cannot be applied for the structure analysis. We propose a hidden softmax sequence model (HSSM) for the dialogue modeling and structure analysis. HSSM is a two-layer special Boltzmann machine. The visible layer contains softmax units used to model words in a dialogue, which are the same with the visible layer in RSM (Hinton and Salakhutdinov, 2009). However, the hidden layer has completely different design. There are three kinds of hidden units: softmax hidden units, which is utilized for representing latent states of dialogues; binary units used for representing dialogue specific topics; and a special binary unit used for representing the general topic of the dialogue corpus. Moreover, unlike RSM whose hidden binary units are conditionally independent when visible units are given, HSSM has extra connections utilized to formulate the dependency between adjacent softmax units in the hidden layer. The connections are the latent states of two adjacent utterances. Therefore, HSSM can be considered as a special Boltzmann machine.

The remainder of this paper is organized as follows. Section 2 introduces two real world dialogue corpora utilized in our experiments. Section 3 describes the proposed hidden softmax sequence model. Experimental results and discussions are presented in Section 4. Finally, Section 5 presents our conclusions.

2 Data Set

Two different datasets are utilized to test the effectiveness of our proposed model: a corpus of post conversations drawn from Twitter (Twitter-Post), and a corpus of task-oriented human-human dialogues in the airline ticket booking domain (AirTicketBooking).

2.1 Twitter-Post

Conversations in Twitter are carried out by replying or responding to specific posts with short 140-character messages. The post length restriction makes Twitter keep more chat-like interactions than blog posts. The style of writing used on Twitter is widely varied, highly ungrammatical, and often with spelling errors. For example, the terms "be4", "b4", and "bef4" are always appeared in the Twitter posts to represent the word "before". Here, we totally collected about 900, 000 raw Twitter dialogue sessions. The majority of conversation sessions are very short; and the frequencies of conversation session lengths follow a power law relationship as described in (Ritter et al., 2010). For simplicity , in the data preprocessing stage non-English sentences were dropped; and non-English characters, punctuation marks, and some non-meaning tokens (such as "&") were also filtered from dialogues. We filtered short Twitter dialogue sessions and randomly sampled 5,000 dialogues (the numbers of utterances in dialogues rang from 5 to 25) to build the Twitter-Post dataset.

2.2 AirTicketBooking

The AirTicketBooking corpus consists of a set of task-oriented human-human mandarin dialogues from an airline ticket booking service center. The manual transcripts of the speech dialogues are utilized in our experiments. In the dataset, there is always a relative clear structure underlying each dialogue. A dialogue often begins with a customer's request about airline ticket issues. And the service agent always firstly checks the client's personal information, such as name, phone number and credit card numberm, etc. Then the agent starts to deal with the client's request. We totally collected 1,890 text-based dialogue sessions obtaining about 40,000 conversation utterances with length ranging from 15 to 100.

3 Dialogue Structure Analysis

3.1 Model Design

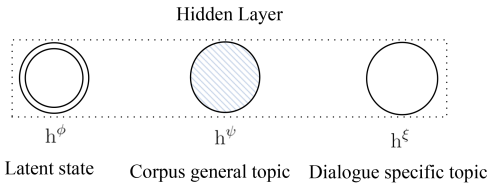

Figure 1: Hidden layer that consists of different types of latent variables

We design an undirected generative model based on Boltzmann machine. As we known, dialogue structure analysis models are always based on an underlying assumption: each utterance in the dialogues is generated from one latent state, which has a causal effect on the words. For instance, an utterance in AirTicketBooking dataset, "Tomorrow afternoon, about 3 o'clock" corre-

sponds to the latent state "Time Information". However, by carefully examining words in dialogues we can observe that not all words are generated from the latent states (Ritter et al., 2010; Zhai and Williams, 2014). There are some words relevant to a global or background topic shared across dialogues. For example, "about" and "that" belong to a global (general English) topic. Some other words in a dialogue may be strongly related to the dialogue specific topic. For example, "cake", "toast" and "pizza" may appear in a Twitter dialogue with respect to a specific topic, "food". From the perspective of generative model, we can also consider that words in a dialogue are generated by the mixture model of latent states, a global/background topic, and a dialogue specific topic. Therefore, there are three kinds of units in the hidden layer of our proposed model, which are displayed in Figure 1. $\mathbf{h}^{\phi}$ is a softmax unit, which indicates the latent state for a utterance. $\mathbf{h}^{\psi}$ and $\mathbf{h}^{\xi}$ represent the general topic, and the dialogue specific topic, respectively. For the visible layer, we utilize the softmax units to model words in each utterance, which is the same with the approach in RSM (Hinton and Salakhutdinov, 2009). In Section 3.2, We propose a basic model based on Boltzmann machine to formulate each word in utterances of dialogues.

A dialogue can be abstractly viewed as a sequence of latent states in a certain reasonable order. Therefore, formulating the dependency between latent states is another import issue for dialogue structure analysis. In our model, we assume that each utterance's latent state is dependent on its two neighbours. So there exist connections between each pair of adjacent hidden softmax units in the hidden layer. The details of the model will be presented in Section 3.3.

3.2 HSM: Hidden Softmax Model

Notation	Explanation
K	dictionary size
J	number of latent states
$\mathbf{V}$	observed visibles representing words in dialogues
$\mathbf{b}$	bias term of $\mathbf{V}$
$\mathbf{h}^{\phi}$	latent variables representing latent states
$\mathbf{h}^{\psi}$	latent variable representing corpus general topic
$\mathbf{h}^{\xi}$	latent variables representing dialogue specific topics
$\mathbf{a}^{\phi}$	bias terms of $\mathbf{h}^{\phi}$
$\mathbf{a}^{\psi}$	bias term of $\mathbf{h}^{\psi}$
$\mathbf{a}^{\xi}$	bias terms of $\mathbf{h}^{\xi}$
$\mathbf{W}^{\phi}$	weights connecting $\mathbf{h}^{\phi}$ to $\mathbf{V}$
$\mathbf{W}^{\psi}$	weights connecting $\mathbf{h}^{\psi}$ to $\mathbf{V}$
$\mathbf{W}^{\xi}$	weights connecting $\mathbf{h}^{\xi}$ to $\mathbf{V}$
$\mathbf{F}, \mathbf{F}^{s}, \mathbf{F}^{e}$	weights between hidden softmax units

Table 1: Definition of notations.

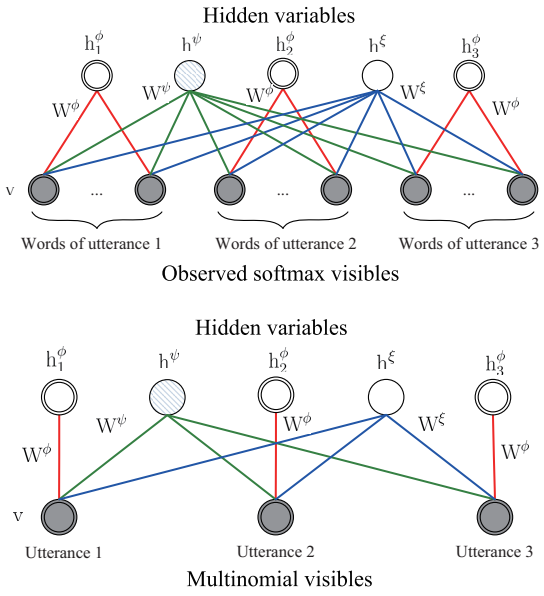

Figure 2: Hidden Softmax Model. The bottom layer are softmax visible units and the top layer consists of three types of hidden units: softmax hidden units used for representing latent states, a binary stochastic hidden unit used for representing the dialogue specific topic, and a special binary stochastic hidden unit used for representing corpus general topic. **Upper**: The model for a dialogue session containing three utterances. Connection lines in the same color related to a latent state represent the same weight matrix. **Lower**: A different interpretation of the Hidden Softmax Model, in which D_r visible softmax units in the r^{th} utterance are replaced by one single multinomial unit which is sampled D_r times.

Table 1 summarizes important notations utilized in this paper. Before introducing the ultimate learning model for dialogue structure analysis, we firstly discuss a simplified version, Hidden Softmax Model (HSM), which is based on Boltzmann machine and assumes that the latent variables are independent given visible units. HSM has a two-layer architecture as shown in Figure 2. The energy of the state $\{\mathbf{V}, \mathbf{h}^{\phi}, \mathbf{h}^{\psi}, \mathbf{h}^{\xi}\}$ is defined as follows:

$$E(\mathbf{V}, \mathbf{h}^{\phi}, \mathbf{h}^{\psi}, \mathbf{h}^{\xi}) = \bar{E}_{\phi}(\mathbf{V}, \mathbf{h}^{\phi}) + \bar{E}_{\psi}(\mathbf{V}, \mathbf{h}^{\psi}) + \bar{E}_{\xi}(\mathbf{V}, \mathbf{h}^{\xi}) + C(\mathbf{V}), \quad (1)$$

where $\bar{E}_{\phi}(\mathbf{V}, \mathbf{h}^{\phi})$, $\bar{E}_{\psi}(\mathbf{V}, \mathbf{h}^{\psi})$ and $\bar{E}_{\xi}(\mathbf{V}, \mathbf{h}^{\xi})$ are sub-energy functions related to hidden variables $\mathbf{h}^{\phi}$, $\mathbf{h}^{\psi}$, and $\mathbf{h}^{\xi}$, respectively. $C(\mathbf{V})$ is the shared visible units bias term. Suppose K is the dictionary size, D_r is the r^{th} utterance size (i.e. the

number of words in the r^{th} utterance), and R is the number of utterances in the a dialogue.

For each utterance $v_r(r = 1, .., R)$ in the dialogue session we have a hidden variable vector h_r^ϕ (with size of J) as a latent state of the utterance, the sub-energy function $\bar{E}_\phi(\mathbf{V}, \mathbf{h}^\phi)$ is defined by

$$\begin{aligned}\bar{E}_\phi(\mathbf{V}, \mathbf{h}^\phi) = &- \sum_{r=1}^{R}\sum_{j=1}^{J}\sum_{i=1}^{D_r}\sum_{k=1}^{K} h_{rj}^\phi W_{rjik}^\phi v_{rik} \\ &- \sum_{r=1}^{R}\sum_{j=1}^{J} h_{rj}^\phi a_{rj}^\phi,\end{aligned} \tag{2}$$

where $v_{rik} = 1$ means the i^{th} visible unit v_{ri} in the r^{th} utterance takes on k^{th} value, $h_{rj}^\phi = 1$ means the r^{th} softmax hidden units takes on j^{th} value, and a_{rj}^ϕ is the corresponding bias. W_{rjik}^ϕ is a symmetric interaction term between visible unit v_{ri} that takes on k^{th} value and hidden variable h_r^ϕ that takes on j^{th} value.

The sub-energy function $\bar{E}_\psi(\mathbf{V}, \mathbf{h}^\psi)$, related to the global general topic of the corpus, is defined by

$$\bar{E}_\psi(\mathbf{V}, \mathbf{h}^\psi) = -\sum_{r=1}^{R}\sum_{i=1}^{D_r}\sum_{k=1}^{K} h^\psi W_{rik}^\psi v_{rik} - h^\psi a^\psi. \tag{3}$$

The sub-energy function $\bar{E}_\xi(\mathbf{V}, \mathbf{h}^\xi)$ corresponds to the dialogue specific topic, and is defined by

$$\bar{E}_\xi(\mathbf{V}, \mathbf{h}^\xi) = -\sum_{r=1}^{R}\sum_{i=1}^{D_r}\sum_{k=1}^{K} h^\xi W_{rik}^\xi v_{rik} - h^\xi a^\xi. \tag{4}$$

W_{rik}^ψ in Eq. (3) and W_{rik}^ξ in Eq. (4) are two symmetric interaction terms between visible units and the corresponding hidden units, which are similar to W_{rjik}^ϕ in (2); a^ψ and a^ξ are the corresponding biases. $C(\mathbf{V})$ is defined by

$$C(\mathbf{V}) = -\sum_{r=1}^{R}\sum_{i=1}^{D_r}\sum_{k=1}^{K} v_{rik} b_{rik}, \tag{5}$$

where b_{rik} is the corresponding bias.

The probability that the model assigns to a visible binary matrix $\mathbf{V} = \{v_1, v_2, ..., v_D\}$ (where $D = \sum_{r=1}^{R} D_r$ is the dialogue session size) is

$$\begin{aligned}P(\mathbf{V}) &= \frac{1}{\mathcal{Z}} \sum_{\mathbf{h}^\phi,\, \mathbf{h}^\psi, \mathbf{h}^\xi} \exp(-E(\mathbf{V}, \mathbf{h}^\phi,\, \mathbf{h}^\psi, \mathbf{h}^\xi)) \\ \mathcal{Z} &= \sum_{\mathbf{V}} \sum_{\mathbf{h}^\phi,\, \mathbf{h}^\psi, \mathbf{h}^\xi} \exp(-E(\mathbf{V}, \mathbf{h}^\phi,\, \mathbf{h}^\psi,\, \mathbf{h}^\xi),\end{aligned} \tag{6}$$

where $\mathcal{Z}$ is known as the partition function or normalizing constant.

In our proposed model, for each word in the document we use a softmax unit to represent it. For the sake of simplicity, assume that the order of words in an utterance is ignored. Therefore, all of these softmax units can share the same set of weights that connect them to hidden units, thus the visible bias term $C(\mathbf{V})$ and the sub-energy functions $\bar{E}_\phi(\mathbf{V}, \mathbf{h}^\phi)$, $\bar{E}_\psi(\mathbf{V}, \mathbf{h}^\psi)$ and $\bar{E}_\xi(\mathbf{V}, \mathbf{h}^\xi)$ in Eq. (1) can be redefined as follows:

$$\begin{aligned}\bar{E}_\phi(\mathbf{V}, \mathbf{h}^\phi) = &- \sum_{r=1}^{R}\sum_{j=1}^{J}\sum_{k=1}^{K} h_{rj}^\phi W_{jk}^\phi \hat{v}_{rk} \\ &- \sum_{r=1}^{R}(D_r \sum_{j=1}^{J} h_{rj}^\phi a_j^\phi)\end{aligned} \tag{7}$$

$$\bar{E}_\psi(\mathbf{V}, \mathbf{h}^\psi) = -\sum_{k=1}^{K} h^\psi W_k^\psi \hat{v}_k - D h^\psi a^\psi \tag{8}$$

$$\bar{E}_\xi(\mathbf{V}, \mathbf{h}^\xi) = -\sum_{k=1}^{K} h^\xi W_k^\xi \hat{v}_k - D h^\xi a^\xi \tag{9}$$

$$C(\mathbf{V}) = -\sum_{k=1}^{K} \hat{v}_k b_k, \tag{10}$$

where $\hat{v}_{rk} = \sum_{i=1}^{D_r} v_{rik}$ denotes the count for the k^{th} word in the r^{th} utterance of the dialogue, $\hat{v}_k = \sum_{r=1}^{R} \hat{v}_{rk}$ is the count for the k^{th} word in whole dialogue session. D_r and D ($D = \sum_{r=1}^{R} D_r$) are employed as the scaling parameters, which can make hidden units behave sensibly when dealing with dialogues of different lengths (Hinton and Salakhutdinov, 2009).

The conditional distributions are given by softmax and logistic functions:

$$P(h_{rj}^\phi = 1|\mathbf{V}) = \frac{exp(\sum_{k=1}^{K} W_{jk}^\phi \hat{v}_{rk} + D_r a_j^\phi)}{\sum_{j'=1}^{J} exp(\sum_{k=1}^{K} W_{j'k}^\phi \hat{v}_{rk} + D_r a_{j'}^\phi)} \tag{11}$$

$$P(h^\psi = 1|\mathbf{V}) = \sigma(\sum_{k=1}^{K} W_k^\psi \hat{v}_k + D a^\psi) \tag{12}$$

$$P(h^\xi = 1|\mathbf{V}) = \sigma(\sum_{k=1}^{K} W_k^\xi \hat{v}_k + D a^\xi) \tag{13}$$

$$\begin{aligned}&P(v_{rik} = 1|\mathbf{h}^\phi, \mathbf{h}^\psi, \mathbf{h}^\xi) = \\ &\frac{exp(\sum_{j=1}^{J} h_{rj}^\phi W_{jk}^\phi + h^\psi W_k^\psi + h^\xi W_k^\xi + b_k)}{\sum_{k'=1}^{K} exp(\sum_{j=1}^{J} h_{rj}^\phi W_{jk'}^\phi + h^\psi W_{k'}^\psi + h^\xi W_{k'}^\xi + b_{k'})},\end{aligned} \tag{14}$$

where $\sigma(x) = 1/(1 + exp(-x))$ is the logistic function.

3.3 HSSM: Hidden Softmax Sequence Model

In this section, we consider the dependency between the adjacent latent states of utterances, and extend the HSM to hidden softmax sequence model (HSSM), which is displayed in Figure 3. We define the energy of the state $\{\mathbf{V}, \mathbf{h}^\phi, \mathbf{h}^\psi, \mathbf{h}^\xi\}$ in HSSM as follows:

$$\begin{aligned} E(\mathbf{V}, \mathbf{h}^\phi, \mathbf{h}^\psi, \mathbf{h}^\xi) =& \bar{E}_\phi(\mathbf{V}, \mathbf{h}^\phi) + \bar{E}_\psi(\mathbf{V}, \mathbf{h}^\psi) + \bar{E}_\xi(\mathbf{V}, \mathbf{h}^\xi) \\ &+ C(\mathbf{V}) + \bar{E}_\Phi(\mathbf{h}^\phi, \mathbf{h}^\phi), \end{aligned} \tag{15}$$

where $C(\mathbf{V})$, $\bar{E}_\phi(\mathbf{V}, \mathbf{h}^\phi)$, $\bar{E}_\psi(\mathbf{V}, \mathbf{h}^\psi)$ and $\bar{E}_\xi(\mathbf{V}, \mathbf{h}^\xi)$ are the same with that in HSM. The last term $\bar{E}_\Phi(\mathbf{h}^\phi, \mathbf{h}^\phi)$ is utilized to formulate the dependency between latent variables $\mathbf{h}^\phi$, which is defined as follows:

$$\begin{aligned} \bar{E}_\Phi(\mathbf{h}^\phi, \mathbf{h}^\phi) = &- \sum_{q=1}^{J} h_s^\phi F_q^s h_{1q}^\phi - \sum_{q=1}^{J} h_{Rq}^\phi F_q^e h_e^\phi \\ &- \sum_{r=1}^{R-1} \sum_{j=1}^{J} \sum_{q=1}^{J} h_{rj}^\phi F_{jq} h_{r+1,q}^\phi, \end{aligned} \tag{16}$$

where h_s^ϕ and h_e^ϕ are two constant scalar variables ($h_s^\phi \equiv 1$, $h_e^\phi \equiv 1$), which represent the virtual beginning state unit and ending state unit of a dialogue. F^s is a vector with size J, and its elements measure the dependency between h_s^ϕ and the latent softmax units of the first utterance. F^e also contains J elements, and in contrast to F^s, F^e represents the dependency measure between h_e^ϕ and the latent softmax units of the last utterance. F is a symmetric matrix for formulating dependency between each two adjacent hidden units pair (h_r^ϕ, h_{r+1}^ϕ), $r = 1, ..., R-1$.

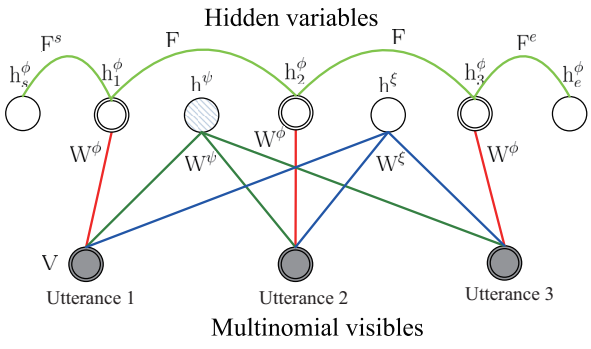

Figure 3: Hidden softmax sequence model. A connection between each pair of adjacent hidden softmax units is added to formulate the dependency between the two corresponding latent states.

3.4 Parameter Learning

Exact maximum likelihood learning in the proposed model is intractable. "Contrastive Divergence" (Hinton, 2002) can be used for HSM's learning, however, it can not be utilized for HSSM, because the hidden-to-hidden interaction term, $\{F, F^s, F^e\}$, result in the intractability when obtaining exact samples from the conditional distribution $P(h_{rj}^\phi = 1|\mathbf{V})$, $r = [1, R]$, $j \in [1, J]$. We use the mean-field variational inference (Hinton and Zemel, 1994; Neal and Hinton, 1998; Jordan et al., 1999) and a stochastic approximation procedure (SAP) (Tieleman, 2008) to estimate HSSM's parameters. The variational learning is utilized to get the data-dependent expectations, and SAP is utilized to estimate the model's expectation. The log-likelihood of the HSSM has the following variational lower bound:

$$\log P(\mathbf{V}; \theta) \geq \sum_{\mathbf{h}} Q(\mathbf{h}) \log P(\mathbf{V}, \mathbf{h}; \theta) + H(Q). \tag{17}$$

$Q(\mathbf{h})$ can be any distribution of $\mathbf{h}$ in theory. $\theta = \{W^\phi, W^\psi, W^\xi, F, F^s, F^e\}$ (the bias terms are omitted for clarity) are the model parameters. $\mathbf{h} = \{\mathbf{h}^\phi, \mathbf{h}^\psi, \mathbf{h}^\xi\}$ represent all the hidden variables. $H(\cdot)$ is the entropy functional. In variational learning, we try to find parameters that minimize the Kullback-Leibler divergences between $Q(\mathbf{h})$ and the true posterior $P(\mathbf{h}|\mathbf{V}; \theta)$. A naive mean-field approach can be chosen to obtain a fully factorized distribution for $Q(\mathbf{h})$:

$$Q(\mathbf{h}) = \left[\prod_{r=1}^{R} q(h^\phi)\right] q(h^\psi)\, q(h^\xi), \tag{18}$$

where $q(h_{rj}^\phi = 1) = \mu_{rj}^\phi$, $q(h^\psi = 1) = \mu^\psi$, $q(h^\xi = 1) = \mu^\xi$. $\boldsymbol{\mu} = \{\mu^\phi, \mu^\psi, \mu^\xi\}$ are the parameters of $Q(\mathbf{h})$. Then the lower bound on the log-probability $\log P(\mathbf{V}; \theta)$ has the form:

$$\begin{aligned} \log P(\mathbf{V}; \theta) \geq &- \bar{E}_\phi(\mathbf{V}, \mu^\phi) - \bar{\mathbf{E}}_\psi(\mathbf{V}, \mu^\psi) - \bar{\mathbf{E}}_\xi(\mathbf{V}, \mu^\xi) \\ &- C(\mathbf{V}) - \bar{E}_\Phi(\mu^\phi, \mu^\phi) - \log \mathcal{Z}, \end{aligned} \tag{19}$$

where $\bar{E}_\phi(\mathbf{V}, \mu^\phi)$, $\bar{E}_\psi(\mathbf{V}, \mu^\psi)$, $\bar{E}_\xi(\mathbf{V}, \mu^\xi)$, and $\bar{E}_\Phi(\mu^\phi, \mu^\phi)$ have the same forms, by replacing $\boldsymbol{\mu}$ with $\mathbf{h}$, as Eqs. (7), (8), (9), and (16), respectively.

We can maximize this lower bound with respect to parameters $\boldsymbol{\mu}$ for fixed θ, and obtain the mean-field fixed-point equations:

$$\mu_{rj}^\phi = \frac{exp(\sum_{k=1}^{K} W_{jk}^\phi \hat{v}_{rk} + D_r a_j^\phi + D_{prev}^j + D_{next}^j - 1)}{\sum_{j'=1}^{J} exp(\sum_{k=1}^{K} W_{j'k}^\phi \hat{v}_{rk} + D_r a_{j'}^\phi + D_{prev}^{j'} + D_{next}^{j'} - 1)}, \tag{20}$$

$$\mu^{\psi} = \sigma(\sum_{k=1}^{K} W_k^{\psi} \hat{v}_k + Da^{\psi}) \quad (21)$$

$$\mu^{\xi} = \sigma(\sum_{k=1}^{K} W_k^{\xi} \hat{v}_k + Da^{\xi}), \quad (22)$$

where D_{prev}^j and D_{next}^j are two terms relevant to the derivative of the RHS of Eq. (19) with respect to μ_{rj}^{ϕ}, defined by

$$D_{prev}^j = \begin{cases} F_j^s, & r = 1 \\ \sum_{q=1}^{J} \mu_{r-1,q}^{\phi} F_{qj}, & r > 1 \end{cases}$$

$$D_{next}^j = \begin{cases} \sum_{q=1}^{J} F_{jq} \mu_{r+1,q}^{\phi}, & r < R. \\ F_j^e, & r = R \end{cases}$$

The updating of $\boldsymbol{\mu}$ can be carried out iteratively until convergence. Then, $(\mathbf{V}, \boldsymbol{\mu})$ can be considered as a special "state" of HSSM, thus the SAP can be applied to update the model's parameters, θ, for fixed $(\mathbf{V}, \boldsymbol{\mu})$.

4 Experiments and Discussions

It's not easy to evaluate the performance of a dialogue structure analysis model. In this study, we examined our model via qualitative visualization and quantitative analysis as done in (Ritter et al., 2010; Zhai and Williams, 2014). We implemented five conventional models to conduct an extensive comparing study on the two corpora: Twitter-Post and AirTicketBooking. Conventional models include: LMHMM (Chotimongkol, 2008), LMHMMS (Ritter et al., 2010), TMHMM, TMHMMS, and TMHMMSS (Zhai and Williams, 2014). In our experiments, for each corpus we randomly select 80% dialogues for training, and use the rest 20% for testing. We select three different number (10, 20 and 30) of latent states to evaluate all the models. In TMHMM, TMHMMS and TMHMMSS, the number of "topics" in the latent states and a dialogue is a hyper-parameter. We conducted a series of experiments with varying numbers of topics, and the results illustrated that 20 is the best choice on the two corpora. So, for all the following experimental results of TMHMM, TMHMMS and TMHMMSS, the corresponding topic configurations are set to 20.

The number of estimation iterations for all the models on training sets is set to 10,000; and on held-out test sets, the numver of iterations for inference is set to 1000. In order to speed-up the learning of HSSM, datasets are divided into mini-batches, each has 15 dialogues. In addition, the learning rate and momentum are set to 0.1 and 0.9, respectively.

4.1 Qualitative Evaluation

Dialogues in Twitter-Post always begin with three latent states: broadcasting what they (Twitter users) are doing now ("Status"), broadcasting an interesting link or quote to their followers ("Reference Broadcast"), or asking a question to their followers ("Question to Followers").[2] We find that structures discoverd by HSSM and LMHMMS with 10 latent states are most reasonable to interpret. For example, after the initiating state ("Status", "Reference Broadcast", or "Question to Followers"), it was often followed a "Reaction" to "Reference Broadcast" (or "Status"), or a "Comment" to "Status", or a "Question" to "Status" ("Reference Broadcast", or "Question to Followers"') etc. Compared with LMHMMS, besides obtaining similar latent states, HSSM exhibits powerful ability in learning sequential dependency relationship between latent states. Take the following simple Twitter dialogue session as an example:

: *rt i like katy perry lt lt we see tht lol*
: *lol gd morning*
: *lol gd morning how u*
: *i'm gr8 n urself*
: *i'm good gettin ready to head out*
: *oh ok well ur day n up its cold out here*
...

LMHMMS labelled the second utterance ("*lol gd morning* ") and the third utterance ("*lol good morning how u* ") into the same latent state, while HSSM treats them as two different latent states (Though they both have almost the same words). The result is reasonable: the first "*gd morning*" is a greeting, while the second "*gd morning*" is a response.

For AirTicketBooking dataset, the state-transition diagram generated with our model under the setting of 10 latent states is presented in Figure 4. And several utterance examples corresponding to the latent staes are also showed in Table 2. In general, conversations begin with sever agent's short greeting, such as "Hi, very glad to be of service.", and then transit to checking the passenger's identity information or

[2]For simplicity and readability in consistent, we follow the same latent state names used in (Ritter et al., 2010)

inquiring the passenger's air ticket demand; or it's directly interrupted by the passenger with booking demand which is always associated with place information. After that, conversations are carried out with other booking related issues, such as checking ticket price or flight time.

The flowchart produced by HSSM can be reasonably interpreted with knowledge of air ticket booking domain, and it most consistent with the agent's real workflow of the Ticket Booking Corporation[3] compared with other models. We notice that conventional models can not clearly distinguish some relevant latent states from each other. For example, these baseline models always confound the latent state "Price Info" with the latent state "Reservation", due to certain words assigned large weights in the two states, such as "打折 (discount)", and "信用卡 (credit card)" etc. Furthermore, Only HSSM and LMHMMS have dialogue specific topics, and experimental results illustrate that HSSM can learn much better than LMHMMS which always mis-recognize corpus general words as belonging to dialogue specific topic (An example is presented in Table 3).

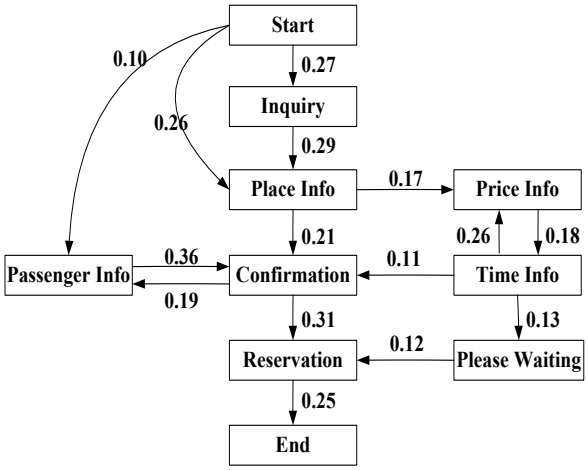

Figure 4: Transitions between latent states on AirTicketBooking generated by our HSSM model under the setting of $J = 10$ latent states. Transition probability cut-off is 0.10.

4.2 Quantitative Evaluation

For quantitative evaluation, we examine HSSM and traditional models with log likelihood and an ordering task on the held-out test set of Twitter-Post and AirTicketBooking.

Reservation	请预定一张，我想用信用卡支付。	Please make a reservation, I want to use a credit card to pay.
End	欢迎下次来电，再见。	Welcome to call next time. Bye.

Table 2: Utterance examples of latent states discovered by our model.

Model	Top Words
HSSM	十点, 李东, 福州, 厦门, 上航, ... ten o'clock, Dong Li (name), Fuzhou (city), Xiamen (city), Shanghai Airlines, ...
LMHMMS	有, 十点, 额, 李东, 预留, ... have, ten o'clock, er, Dong Li (name), reserve, ...

Table 3: One example of dialogue specific topic learned on the same dialogue session with HSSM and LMHMMS, respectively.

Log Likelihood The likelihood metric measures the probability of generating the test set using a specified model. The likelihood of LMHMM and TMHMM can be directed computed with the forward algorithm. However, since likelihoods of LMHMMS, TMHMMS and TMHMMSS are intractable to compute due to the local dependencies with respect to certain latent variables, Chib-style estimating algorithms (Wallach et al., 2009) are employed in our experiments. For HSSM, the partition function is a key problem for calculating the likelihood, and it can be effectively estimated by Annealed Importance Sampling (AIS) (Neal, 2001; Salakhutdinov and Murray, 2008).

Figure 5 presents the likelihood of different models on the two held-out datasets. We can observe that HSSM achieves better performance on likelihood than all the other models under different number of latent states. On Twitter-Post dataset our model slightly surpasses LMHMMS, and it performs much better than all traditional models on AirTicketBooking dataset.

Ordering Test Following previous work (Barzilay and Lee, 2004; Ritter et al., 2010; Zhai and Williams, 2014), we utilize Kendall's τ (Kendall, 1938) as evaluation metric, which measures the similarity between any two sequential data and ranges from -1 (indicating a reverse ordering) to $+1$ (indicating an identical

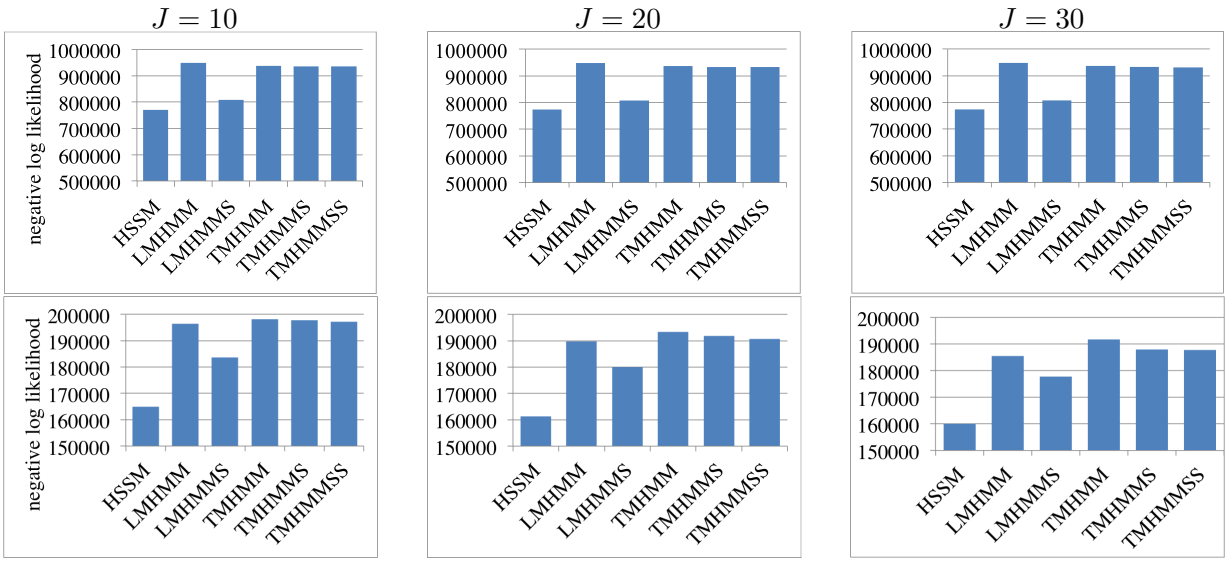

Figure 5: Negative log likelihood (smaller is better) on held-out datasets of Twitter-Post (upper) and AirTicketBooking (lower) under different number of latent states J.

ordering). This is the basic idea: for each dialogue session with n utterances in the test set, we firstly generate all $n!$ permutations of the utterances; then evaluate the probability of each permutation, and measure the similarity, i.e. Kendall's τ, between the max-probability permutation and the original order; finally, we average τ values for all dialogue sessions as the model's ordering test score. As pointed out by Zhai et al. (2014), it's however infeasible to enumerate all possible permutations of dialogue sessions when the number of utterances in large. In experiments, we employ the incrementally adding permutation strategy, as used by Zhai et al. (2014), to build up the permutation set. The results of ordering test are presented in Figure 6. We can see that HSSM exhibits better performance than all the other models. For the conventional models, it is interesting that LMHMMS, TMHMMS and TMHMMSS achieve worse performances than LMHMM and TMHMM. This is likely because the latter two models allow words to be emitted only from latent states (Zhai and Williams, 2014), while the former three models allow words to be generated from additional sources. This also implies HSSM's effectiveness of modeling distinct information uderlying dialogues.

4.3 Discussion

The expermental results illustrate the effectiveness of the proposed undirected dialogue structure analysis model based on Boltzmann machine. The conducted experiments also demonstrate that undirected models have three main merits for text modeling, which are also demonstrated by Hinton and Salakhutdinov (2009), Srivastava et al. (2013) through other tasks. Boltzmann machine based undirected models are able to generalize much better than traditional directed generative model; and model learning is more stable. Besides, an undirected model is more suitable for describing complex dependencies between different kinds of variables.

We also notice that all the models can, to some degree, capture the sequential structure in the dialogues, however, each model has a special characteristic which makes itself fit a certain kind of dataset better. HSSM and LMHMMS are more appropriate for modeling the open domain dataset, such as Twitter-Post used in this paper, and the task-oriented domain dataset with one relatively concentrated topic in the corpus and special information for each dialogue, such as AirTicketBooking. As we known, dialogue specific topics in HSSM or LMHMMS are used and trained only within corresponding dialogues. They are crucial for absorbing certain words that have important meaning but do not belongs to latent states. In addition, for differet dataset, dialogue specific topics may have different effect to the modeling. Take the Twitter-Post for an example, dialogue specific topics formulate actual themes of dialogues, such as a pop song, a sport news. As for the AirTicketBooking dataset, dialogue specific

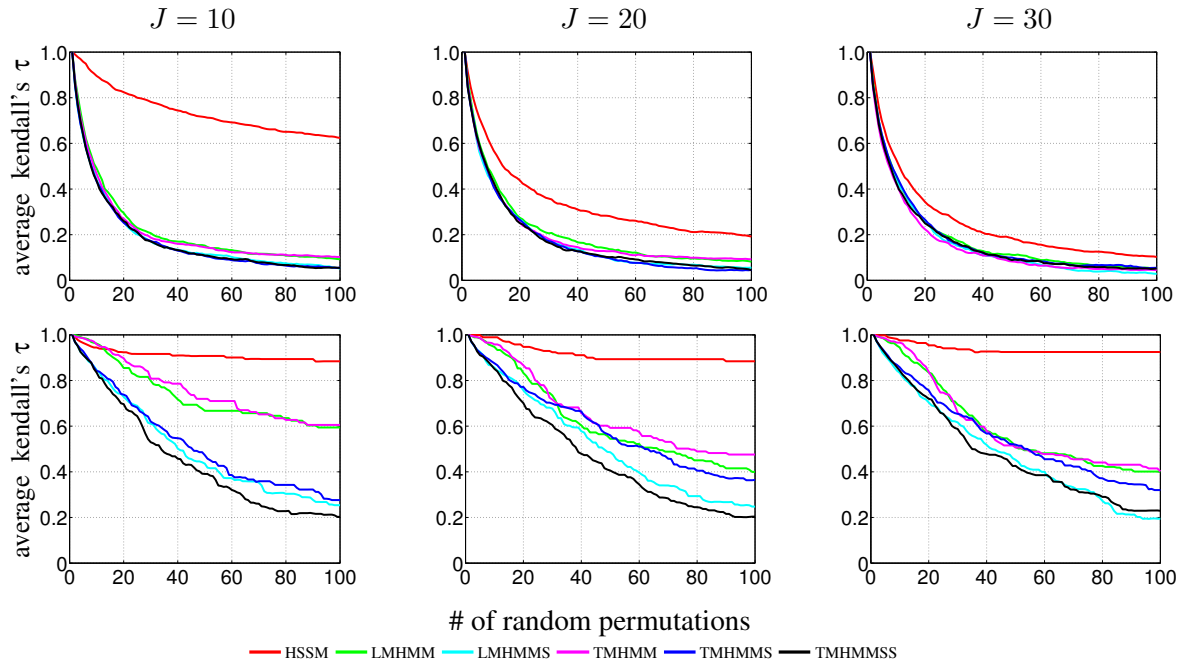

Figure 6: Average Kendall's τ measure (larger is better) on held-out datasets of Twitter-Post (upper) and AirTicketBooking (lower) under different number of latent states J.

topics always represent some special information, such as the personal information, including name, phone number, birthday, etc. In summary, each dialogue specific topic reflects special information which is different from other dialogues.

The three models, TMHMM, TMHMMS and TMHMMSS, which do not include dialogue specific topics, should be utilized on the task-oriented domain dataset, in which each dialogue has little special or personnal information. For example, the three models perform well on the the BusTime and TechSupport datasets (Zhai and Williams, 2014), in which name entities are all replaced by different semantic types (e.g. phone numbers are replaced by "<phone>", E-mail addresses are replaced by "<email>", etc).

5 Conclusions

We develope an undirected generative model, HSSM, for dialogue structure analysis, and examine the effectiveness of our model on two different datasets, Twitter posts occurred in open-domain and task-oriented dialogues from airline ticket booking domain. Qualitative evaluations and quantitative experimental results demonstrate that the proposed model achieves better performance than state-of-the-art approaches. Compared with traditional models, the proposed HSSM has more powerful ability of discovering structures of latent states and modeling different word sources, including latent states, dialogue specific topics and global general topic.

According to recent study (Srivastava et al., 2013), a deep network model exhibits much benefits for latent variable learning. A dialogue may actually have a hierarchy structure of latent states, therefore the proposed model can be extended to a deep model to capture more complex structures. Another possible way to extend the model is to consider modeling long distance dependency between latent states. This may further improve the model's performance.

Acknowledgments

We are grateful to anonymous reviewers for their helpful comments and suggestions. We would like to thank Alan Ritter for kindly providing the raw Twitter dataset.

Summarizing Source Code using a Neural Attention Model

Srinivasan Iyer **Ioannis Konstas** **Alvin Cheung** **Luke Zettlemoyer**
Computer Science & Engineering

Abstract

High quality source code is often paired with high level summaries of the computation it performs, for example in code documentation or in descriptions posted in online forums. Such summaries are extremely useful for applications such as code search but are expensive to manually author, hence only done for a small fraction of all code that is produced. In this paper, we present the first completely data-driven approach for generating high level summaries of source code. Our model, CODE-NN , uses Long Short Term Memory (LSTM) networks with attention to produce sentences that describe C# code snippets and SQL queries. CODE-NN is trained on a new corpus that is automatically collected from StackOverflow, which we release. Experiments demonstrate strong performance on two tasks: (1) code summarization, where we establish the first end-to-end learning results and outperform strong baselines, and (2) code retrieval, where our learned model improves the state of the art on a recently introduced C# benchmark by a large margin.

1 Introduction

Billions of lines of source code reside in online repositories (Dyer et al., 2013), and high quality code is often coupled with natural language (NL) in the form of instructions, comments, and documentation. Short summaries of the overall computation the code performs provide a particularly useful form of documentation for a range of applications, such as code search or tutorials. However, such summaries are expensive to manually author.

1. Source Code (C#):

```
public int TextWidth(string text) {
  TextBlock t = new TextBlock();
  t.Text = text;
  return
    (int)Math.Ceiling(t.ActualWidth);
}
```

Descriptions:
a. Get rendered width of string rounded up to the nearest integer
b. Compute the actual textwidth inside a textblock

2. Source Code (C#):

```
  var input = "Hello";
  var regEx = new Regex("World");
  return !regEx.IsMatch(input);
```

Descriptions:
a. Return if the input doesn't contain a particular word in it
b. Lookup a substring in a string using regex

3. Source Code (SQL):

```
SELECT Max(marks) FROM stud_records
  WHERE marks <
  (SELECT Max(marks) FROM stud_records);
```

Descriptions:
a. Get the second largest value of a column
b. Retrieve the next max record in a table

Figure 1: Code snippets in C# and SQL and their summaries in NL, from StackOverflow. Our goal is to automatically generate summaries from code snippets.

As a result, this laborious process is only done for a small fraction of all code that is produced.

In this paper, we present the first completely data-driven approach for generating short high-level summaries of source code snippets in natural language. We focus on C#, a general-purpose imperative language, and SQL, a declarative language for querying databases. Figure 1 shows example code snippets with descriptions that summarize the overall function of the code, with the goal to generate high level descriptions, such as

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2073–2083,
Berlin, Germany, August 7-12, 2016.

lookup a substring in a string. Generating such a summary is often challenging because the text can include complex, non-local aspects of the code (e.g., consider the phrase 'second largest' in Example 3 in Figure 1). In addition to being directly useful for interpreting uncommented code, high-quality generation models can also be used for code retrieval, and in turn, for natural language programming by applying nearest neighbor techniques to a large corpus of automatically summarized code.

Natural language generation has traditionally been addressed as a pipeline of modules that decide 'what to say' (content selection) and 'how to say it' (realization) separately (Reiter and Dale, 2000; Wong and Mooney, 2007; Chen et al., 2010; Lu and Ng, 2011). Such approaches require supervision at each stage and do not scale well to large domains. We instead propose an end-to-end neural network called CODE-NN that jointly performs content selection using an attention mechanism, and surface realization using Long Short Term Memory (LSTM) networks. The system generates a summary one word at a time, guided by an attention mechanism over embeddings of the source code, and by context from previously generated words provided by a LSTM network (Hochreiter and Schmidhuber, 1997). The simplicity of the model allows it to be learned from the training data without the burden of feature engineering (Angeli et al., 2010) or the use of an expensive approximate decoding algorithm (Konstas and Lapata, 2013).

Our model is trained on a new dataset of code snippets with short descriptions, created using data gathered from Stackoverflow,[1] a popular programming help website. Since access is open and unrestricted, the content is inherently noisy (ungrammatical, non-parsable, lacking content), but as we will see, it still provides strong signal for learning. To reliably evaluate our model, we also collect a clean, human-annotated test set.[2]

We evaluate CODE-NN on two tasks: code summarization and code retrieval (Section 2). For summarization, we evaluate using automatic metrics such as METEOR and BLEU-4, together with a human study for naturalness and informativeness of the output. The results show that CODE-NN outperforms a number of strong baselines and, to the best of our knowledge, CODE-NN is the first approach that learns to generate summaries of source code from easily gathered online data. We further use CODE-NN for code retrieval for programming related questions on a recent C# benchmark, and results show that CODE-NN improves the state of the art (Allamanis et al. (2015b)) for mean reciprocal rank (MRR) by a wide margin.

[2] Data and code are available at `https://github.com/sriniiyer/codenn`.

2 Tasks

CODE-NN generates a NL summary of source code snippets (GEN task). We have also used CODE-NN on the inverse task to retrieve source code given a question in NL (RET task).

Formally, let U_C be the set of all code snippets and U_N be the set of all summaries in NL. For a training corpus with J code snippet and summary pairs $(c_j, n_j), 1 \leq j \leq J, c_j \in U_C, n_j \in U_N$, we define the following two tasks:

GEN For a given code snippet $c \in U_C$, the goal is to produce a NL sentence $n^* \in U_N$ that maximizes some scoring function $s \in (U_C \times U_N \rightarrow \mathbb{R})$:

$$n^* = \underset{n}{\operatorname{argmax}}\ s(c, n) \tag{1}$$

RET We also use the scoring function s to retrieve the highest scoring code snippet c_j^* from our training corpus, given a NL question $n \in U_N$:

$$c_j^* = \underset{c_j}{\operatorname{argmax}}\ s(c_j, n), 1 \leq j \leq J \tag{2}$$

In this work, s is computed using an LSTM neural attention model, to be described in Section 5.

3 Related Work

Although we focus on generating high-level summaries of source code snippets, there has been work on producing code descriptions at other levels of abstraction. Movshovitz-Attias and Cohen (2013) study the task of predicting class-level comments by learning n-gram and topic models from open source Java projects and testing it using a character-saving metric on existing comments. Allamanis et al. (2015a) create models for suggesting method and class names by embedding them in a high dimensional continuous space. Sridhara et al. (2010) present a pipeline that generates summaries of Java methods by selecting relevant content and generating phrases using templates to describe them. There is also work on improving program comprehension (Haiduc et al.,

2010), identifying cross-cutting source code concerns (Rastkar et al., 2011), and summarizing software bug reports (Rastkar et al., 2010). To the best of our knowledge, we are the first to use learning techniques to construct completely new sentences from arbitrary code snippets.

Source code summarization is also related to generation from formal meaning representations. Wong and Mooney (2007) present a system that learns to generate sentences from lambda calculus expressions by inverting a semantic parser. Mei et al. (2016), Konstas and Lapata (2013), and Angeli et al. (2010) create learning algorithms for text generation from database records, again assuming data that pairs sentences with formal meaning representations. In contrast, we present algorithms for learning from easily gathered web data.

In the database community, Simitsis and Ioannidis (2009) recognize the need for SQL database systems to talk back to users. Koutrika et al. (2010) built an interactive system (LOGOS) that translates SQL queries to text using NL templates and database schemas. Similarly there has been work on translating SPARQL queries to natural language using rules to create dependency trees for each section of the query, followed by a transformation step to make the output more natural (Ngonga Ngomo et al., 2013). These approaches are not learning based, and require significant manual template-engineering efforts.

We use recurrent neural networks (RNN) based on LSTMs and neural attention to jointly model source code and NL. Recently, RNN-based approaches have gained popularity for text generation and have been used in machine translation (Sutskever et al., 2011), image and video description (Karpathy and Li, 2015; Venugopalan et al., 2015; Devlin et al., 2015), sentence summarization (Rush et al., 2015), and Chinese poetry generation (Zhang and Lapata, 2014). Perhaps most closely related, Wen et al. (2015) generate text for spoken dialogue systems with a two-stage approach, comprising an LSTM decoder semantically conditioned on the logical representation of speech acts, and a reranker to generate the final output. In contrast, we design an end-to-end attention-based model for source code.

For code retrieval, Allamanis et al. (2015b) proposed a system that uses Stackoverflow data and web search logs to create models for retrieving C# code snippets given NL questions and vice versa. They construct distributional representations of code structure and language and combine them using additive and multiplicative models to score (code, language) pairs, an approach that could work well for retrieval but cannot be used for generation. We learn a neural generation model without using search logs and show that it can also be used to score code for retrieval, with much higher accuracy.

Synthesizing code from language is an alternative to code retrieval and has been studied in both the Systems and NLP research communities. Giordani and Moschitti (2012), Li and Jagadish (2014), and Gulwani and Marron (2014) synthesize source code from NL queries for database and spreadsheet applications. Similarly, Lei et al. (2013) interpret NL instructions to machine-executable code, and Kushman and Barzilay (2013) convert language to regular expressions. Unlike most synthesis methods, CODE-NN is domain agnostic, as we demonstrate its applications on both C# and SQL.

4 Dataset

We collected data from StackOverflow (SO), a popular website for posting programming-related questions. Anonymized versions of all the posts can be freely downloaded.[3] Each post can have multiple tags. Using the *C#* tag for C# and the *sql*, *database* and *oracle* tags for SQL, we were able to collect 934,464 and 977,623 posts respectively.[4] Each post comprises a short title, a detailed question, and one or more responses, of which one can be marked as accepted. We found that the text in the question and responses is domain-specific and verbose, mixed with details that are irrelevant for our tasks. Also, code snippets in responses that were not accepted were frequently incorrect or tangential to the question asked. Thus, we extracted only the title from the post and use the code snippet from those accepted answers that contain exactly one code snippet (using <code> tags). We add the resulting (title, query) pairs to our corpus, resulting in a total of 145,841 pairs for C# and 41,340 pairs for SQL.

Cleaning We train a semi-supervised classifier to filter titles like *'Difficult C# if then logic'* or *'How can I make this query easier to write?'* that bear no relation to the corresponding code snippet.

[3] http://archive.org/details/stackexchange

[4] The data was downloaded in Dec 2014.

To do so, we annotate 100 titles as being *clean* or *not clean* for each language and use them to bootstrap the algorithm. We then use the remaining titles in our training set as an unsupervised signal, and obtain a classification accuracy of over 73% on a manually labeled test set for both languages. For the final dataset, we retain 66,015 C# (title, query) pairs and 32,337 SQL pairs that are classified as clean, and use 80% of these datasets for training, 10% for validation and 10% for testing.

Parsing Given the informal nature of StackOverflow, the code snippets are approximate answers that are usually incomplete. For example, we observe that only 12% of the SQL queries parse without any syntactic errors (using zql[5]). We therefore aim to perform a best-effort parse of the code snippet, using modified versions of an ANTLR parser for C# (Parr, 2013) and *python-sqlparse* (Albrecht, 2015) for SQL. We strip out all comments and to avoid being context specific, we replace literals with tokens denoting their types. In addition, for SQL, we replace table and column names with numbered placeholder tokens while preserving any dependencies in the query. For example, the SQL query in Figure 1 is represented as `SELECT MAX(col0) FROM tab0 WHERE col0 < (SELECT MAX(col0) FROM tab0)`.

Data Statistics The structural complexity and size of the code snippets in our dataset makes our tasks challenging. More than 40% of our C# corpus comprises snippets with three or more statements and functions, and 20% contains loops and conditionals. Also, over a third of our SQL queries contain one or more subqueries and multiple tables, columns and functions (like `MIN`, `MAX`, `SUM`). On average, our C# snippets are 38 tokens long and the queries in our corpus are 46 tokens long, while titles are 9-12 words long. Table 2 shows the complete data statistics.

Human Annotation For the GEN task, we use n-gram based metrics (see Section 6.1.2) of the summary generated by our model with respect to the actual title in our corpus. Titles can be short, and a given code snippet can be described in many different ways with little overlapping content between them. For example, the descriptions for the second code snippet in Figure 1 share very few words with each other. To address these limitations, we extend our test set by asking human annotators to provide two additional titles for 200 snippets chosen at random from the test set, making a total of three reference titles for each code snippet. To collect this data, annotators were shown only the code snippets and were asked to write a short summary after looking at a few example summaries. They were also asked to "think of a question that they could ask on a programming help website, to get the code snippet as a response." This encouraged them to briefly describe the key feature that the code is trying to demonstrate. We use half of this test set for model tuning (DEV, see Section 5) and the rest for evaluation (EVAL).

5 The CODE-NN Model

Description We present an end-to-end generation system that performs content selection and surface realization jointly. Our approach uses an attention-based neural network to model the conditional distribution of a NL summary n given a code snippet c. Specifically, we use an LSTM model that is guided by attention on the source code snippet to generate a summary one word at a time, as shown in Figure 2.[6]

Formally, we represent a NL summary $n = n_1, \ldots, n_l$ as a sequence of 1-hot vectors

[6] We experimented with other sequence (Sutskever et al., 2014) and tree based architectures (Tai et al., 2015) as well. None of these models significantly improved performance, however, this is an important area for future work.

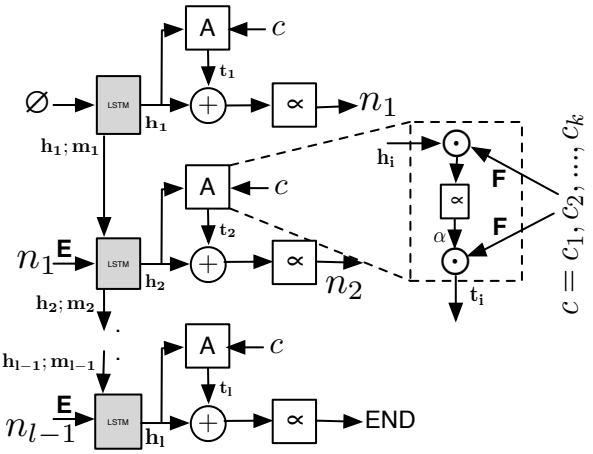

Figure 2: Generation of a title $n = n_1, \ldots,$ END given code snippet $c_1, ..., c_k$. The attention cell computes a distributional representation t_i of the code snippet based on the current LSTM hidden state h_i. A combination of t_i and h_i is used to generate the next word, n_i, which feeds back into the next LSTM cell. This is repeated until a fixed number of words or END is generated. $\propto$ blocks denote softmax operations.

$\mathbf{n_1}, \ldots, \mathbf{n_l} \in \{0,1\}^{|N|}$, where N is the vocabulary of the summaries. Our model computes the probability of n (scoring function s in Eq. 1) as a product of the conditional next-word probabilities

$$s(c, n) = \prod_{i=1}^{l} p(n_i | n_1, \ldots, n_{i-1})$$

with,

$$p(n_i | n_1, \ldots, n_{i-1}) \propto \mathbf{W} \tanh(\mathbf{W_1 h_i} + \mathbf{W_2 t_i})$$

where, $\mathbf{W} \in \mathbb{R}^{|N| \times H}$ and $\mathbf{W_1}, \mathbf{W_2} \in \mathbb{R}^{H \times H}$, H being the embedding dimensionality of the summaries. $\mathbf{t_i}$ is the contribution from the attention model on the source code (see below). $\mathbf{h_i}$ represents the hidden state of the LSTM cell at the current time step and is computed based on the previously generated word, the previous LSTM cell state $\mathbf{m_{i-1}}$ and the previous LSTM hidden state $\mathbf{h_{i-1}}$ as

$$\mathbf{m_i}; \mathbf{h_i} = f(\mathbf{n_{i-1}E}, \mathbf{m_{i-1}}, \mathbf{h_{i-1}}; \theta)$$

where $\mathbf{E} \in \mathbb{R}^{|N| \times H}$ is a word embedding matrix for the summaries. We compute f using the LSTM cell architecture used by Zaremba et al. (2014).

Attention The generation of each word is guided by a global attention model (Luong et al., 2015), which computes a weighted sum of the embeddings of the code snippet tokens based on the current LSTM state (see right part in Figure 2). Formally, we represent c as a set of 1-hot vectors $\mathbf{c_1}, \ldots, \mathbf{c_k} \in \{0,1\}^{|C|}$ for each source code token; C is the vocabulary of all tokens in our code snippets. Our attention model computes,

$$\mathbf{t_i} = \sum_{j=1}^{k} \alpha_{i,j} \cdot \mathbf{c_j F}$$

where $\mathbf{F} \in \mathbb{R}^{|C| \times H}$ is a token embedding matrix and each $\alpha_{i,j}$ is proportional to the dot product between the current internal LSTM hidden state $\mathbf{h_i}$ and the corresponding token embedding $\mathbf{c_j}$:

$$\alpha_{i,j} = \frac{\exp(\mathbf{h_i}^{\mathrm{T}} \mathbf{c_j F})}{\sum_{j=1}^{k} \exp(\mathbf{h_i}^{\mathrm{T}} \mathbf{c_j F})}$$

Training We perform supervised end-to-end training using backpropagation (Werbos, 1990) to learn the parameters of the embedding matrices $\mathbf{F}$ and $\mathbf{E}$, transformation matrices $\mathbf{W}$, $\mathbf{W_1}$ and $\mathbf{W_2}$, and parameters θ of the LSTM cell that computes f. We use multiple epochs of minibatch stochastic gradient descent and update all parameters to minimize the negative log likelihood (NLL) of our training set. To prevent over-fitting we make use of dropout layers (Srivastava et al., 2014) at the summary embeddings and the output softmax layer. Using pre-trained embeddings (Mikolov et al., (2013)) for the summary embedding matrix or adding additional LSTM layers did not improve performance for the GEN task. Since the NLL training objective does not directly optimize for our evaluation metric (METEOR), we compute METEOR (see Section 6.1.2) on a small development set (DEV) after every epoch and save the intermediate model that gives the maximum score, as the final model.

Decoding Given a trained model and an input code snippet c, finding the most optimal title entails generating the title n^* that maximizes $s(c, n)$ (see Eq. 1). We approximate n^* by performing beam search on the space of all possible summaries using the model output.

Implementation Details We add special START and END tokens to our training sequences and replace all tokens and output words occurring

with a frequency of less than 3 with an UNK token, making $|C| = 31,667$ and $|N| = 7,470$ for C# and $|C| = 747$ and $|N| = 2,506$ for SQL. Our hyper-parameters are set based on performance on the validation set. We use a minibatch size of 100 and set the dimensionality of the LSTM hidden states, token embeddings, and summary embeddings (H) to 400. We initialize all model parameters uniformly between -0.35 and 0.35. We start with a learning rate of 0.5 and start decaying it by a factor of 0.8 after 60 epochs if accuracy on the validation set goes down, and terminate training when the learning rate goes below 0.001. We cap the parameter gradients to 5 and use a dropout rate of 0.5.

We use the Torch framework[7] to train our models on GPUs. Training runs for about 80 epochs and takes approximately 7 hours. We compute METEOR score at every epoch on the development set (DEV) to choose the best final model, with the best results obtained between 60 and 70 epochs. For decoding, we set the beam size to 10, and the maximum summary length to 20 words.

6 Experimental Setup

6.1 GEN Task

6.1.1 Baselines

For the GEN task, we compare CODE-NN with a number of competitive systems, none of which had been previously applied to generate text from source code, and hence we adapt them slightly for this task, as explained below.

IR is an information retrieval baseline that outputs the title associated with the code c_j in the training set that is closest to the input code c in terms of token Levenshtein distance. In this case s from Eq.1 becomes,

$$s(c, n_j) = -1 \times \text{lev}(c_j, c), 1 \leq j \leq J$$

MOSES (Koehn et al., 2007) is a popular phrase-based machine translation system. We perform generation by treating the tokenized code snippet as the source language, and the title as the target. We train a 3-gram language model using KenLM (Heafield, 2011) to use with MOSES, and perform MIRA-based tuning (Cherry and Foster, 2012) of hyper-parameters using DEV.

SUM-NN is the neural attention-based abstractive summarization model of Rush et al. (2015). It uses an encoder-decoder architecture with an attention mechanism based on a fixed context window of previously generated words. The decoder is a feed-forward neural language model that generates the next word based on previous words in a context window of size k. In contrast, we decode using an LSTM network that can model long range dependencies and our attention weights are tied to the LSTM hidden states. We set the embedding and hidden state dimensions and context window size by tuning on our validation set. We found this model to generate overly short titles like *'sql server 2008'* when a length restriction was not imposed on the output text. Therefore, we fix the output length to be the average title length in the training set while decoding.

[7] http://torch.ch

6.1.2 Evaluation Metrics

We evaluate the GEN task using automatic metrics, and also perform a human study.

Automatic Evaluation We report METEOR (Banerjee and Lavie, 2005) and sentence level BLEU-4 (Papineni et al., 2002) scores. METEOR is recall-oriented and measures how well our model captures content from the references in our output. BLEU-4 measures the average n-gram precision on a set of reference sentences, with a penalty for overly short sentences. Since the generated summaries are short and there are multiple alternate summaries for a given code snippet, higher order n-grams may not overlap. We remedy this problem by using +1 smoothing (Lin and Och, 2004). We compute these metrics on the tuning set DEV and the held-out evaluation set EVAL.

Human Evaluation Since automatic metrics do not always agree with the actual quality of the results (Stent et al., 2005), we perform human evaluation studies to measure the output of our system and baselines across two modalities, namely naturalness and informativeness. For the former, we asked 5 native English speakers to rate each title against grammaticality and fluency, on a scale between 1 and 5. For *informativeness* (i.e., the amount of content carried over from the input code to the NL summary, ignoring fluency of the text), we asked 5 human evaluators familiar with C# and SQL to evaluate the system output by rating the factual overlap of the summary with the reference titles, on a scale between 1 and 5.

6.2 RET task

6.2.1 Model and Baselines

CODE-NN As described in Section 2, for a given NL question n in the RET task, we rank all code snippets c_j in our corpus by computing the scoring function $s(c_j, n)$, and return the query c_j^* that maximizes it (Eq. 2).

RET-IR is an information retrieval baseline that ranks the candidate code snippets using cosine similarity between the given NL question n and all summaries n_j in the retrieval set, based on their vector representations using TF-IDF weights over unigrams. The scoring function s in Eq. 2 becomes:

$$s(c_j, n) = \frac{\text{tf-idf}(n_j) \cdot \text{tf-idf}(n)}{\|\text{tf-idf}(n_j)\|\|\text{tf-idf}(n)\|}, 1 \leq j \leq J$$

6.2.2 Evaluation Metrics

We assess ranking quality by computing the Mean Reciprocal Rank (MRR) of c_j^*. For every snippet c_j in EVAL (and DEV), we use two of the three references (title and human annotation), namely $n_{j,1}, n_{j,2}$. We then build a retrieval set comprising $(c_j, n_{j,1})$ together with 49 random distractor pairs $(c', n'), c' \neq c_j$ from the test set. Using $n_{j,2}$ as the natural language question, we rank all 50 items in this retrieval set and use the rank of query c_j^* to compute MRR. We average MRR over all returned queries c_j^* in the test set, and repeat this experiment for several different random sets of distractors.

6.3 Tasks from Allamanis et al. (2015b)

Allamanis et al. (2015b) take a retrieval approach to answer C# related natural language questions (L to C), similar to our RET task. In addition, they also use retrieval to summarize C# source code (C to L) and evaluate both tasks using the MRR metric. Although they also use data from Stackoverflow, their dataset preparation and cleaning methods differs significantly from ours. For example, they filter out posts where the question has fewer than 2 votes, the answer has fewer than 3 votes, or the post has fewer than 1000 views. Additionally, they also filter code snippets that cannot be parsed by Roslyn (.NET compiler) or are longer than 300 characters. Thus, to directly compare with their model, we re-train our generation model on their dataset and use our model score for retrieval of both code and summaries.

	Model	METEOR	BLEU-4
C#	IR	7.9 (6.1)	13.7 (12.6)
	MOSES	9.1 (9.7)	11.6 (11.5)
	SUM-NN	10.6 (10.3)	19.3 (18.2)
	CODE-NN	**12.3 (13.4)**	**20.5 (20.4)**
SQL	IR	6.3 (8.0)	13.5 (13.0)
	MOSES	8.3 (9.7)	15.4 (15.9)
	SUM-NN	6.4 (8.7)	13.3 (14.2)
	CODE-NN	**10.9 (14.0)**	**18.4 (17.0)**

Table 3: Performance on EVAL for the GEN task. Performance on DEV is indicated in parentheses.

	Model	Naturalness	Informativeness
C#	IR	3.42	2.25
	MOSES	1.41	2.42
	SUM-NN	**4.61***	1.99
	CODE-NN	**4.48**	**2.83**
SQL	IR	3.21	2.58
	MOSES	2.80	2.54
	SUM-NN	4.44	2.75
	CODE-NN	**4.54**	**3.12**

Table 4: Naturalness and Informativeness measures of model outputs. Stat. sig. between CODE-NN and others is computed with a 2-tailed Student's t-test; $p < 0.05$ except for *.

7 Results

7.1 GEN Task

Table 3 shows automatic evaluation metrics for our model and baselines. CODE-NN outperforms all the other methods in terms of METEOR and BLEU-4 score. We attribute this to its ability to perform better content selection, focusing on the more salient parts of the code by using its attention mechanism jointly with its LSTM memory cells. The neural models have better performance on C# than SQL. This is in part because, unlike SQL, C# code contains informative intermediate variable names that are directly related to the objective of the code. On the other hand, SQL is more challenging in that it only has a handful of keywords and functions, and summarization models need to rely on other structural aspects of the code.

Informativeness and naturalness scores for each model from our human evaluation study are presented in Table 4. In general, CODE-NN performs well across both dimensions. Its superior performance in terms of informativeness further supports our claim that it manages to select content more effectively. Although SUM-NN performs similar to CODE-NN on naturalness, its output lacks content and has very little variation (see Section 7.4), which also explains its surprisingly low

	Model	MRR
C#	RET-IR	0.42 ± 0.02 (0.44 ± 0.01)
	CODE-NN	$\mathbf{0.58 \pm 0.01}$ $(\mathbf{0.66 \pm 0.02})$
SQL	RET-IR	0.28 ± 0.01 (0.4 ± 0.01)
	CODE-NN	$\mathbf{0.44 \pm 0.01}$ $(\mathbf{0.54 \pm 0.02})$

Table 5: MRR for the RET task. Dev set results in parentheses.

	Model	MRR
L to C	Allamanis	0.182 ± 0.009
	CODE-NN	$\mathbf{0.590 \pm 0.044}$
C to L	Allamanis	0.434 ± 0.003
	CODE-NN	$\mathbf{0.461 \pm 0.046}$

Table 6: MRR values for the Language to Code (L to C) and the Code to Language (C to L) tasks using the C# dataset of Allamanis et al. (2015b)

score on informativeness.

7.2 RET Task

Table 5 shows the MRR on the RET task for CODE-NN and RET-IR, averaged over 20 runs for C# and SQL. CODE-NN outperforms the baseline by about 16% for C# and SQL. RET-IR can only output code snippets that are annotated with NL as potential matches. On the other hand, CODE-NN can rank even unannotated code snippets and nominate them as potential candidates. Hence, it can leverage vast amounts of such code available in online repositories like Github. To speed up retrieval when using CODE-NN , it could be one of the later stages in a multi-stage retrieval system and candidates may also be ranked in parallel.

7.3 Comparison with Allamanis et al.

We train CODE-NN on their dataset and evaluate using the same MRR testing framework (see Table 6). Our model performs significantly better for the Language to Code task (L to C) and slightly better for the Code to Language task (C to L). The attention mechanism together with the LSTM network is able to generate better scores for (language, code) pairs.

7.4 Qualitative Analysis

Figure 3 shows the relative magnitudes of the attention weights ($\alpha_{i,j}$) for example C# and SQL code snippets while generating their corresponding summaries. Darker regions represent stronger weights. CODE-NN automatically learns to do high-quality content selection by aligning key summary words with informative tokens in the code snippet.

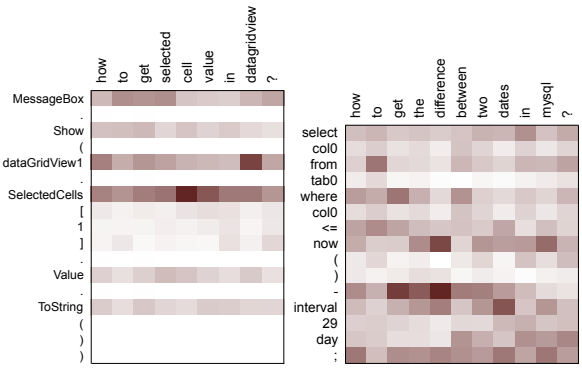

Figure 3: Heatmap of attention weights $\alpha_{i,j}$ for example C# (left) and SQL (right) code snippets. The model learns to align key summary words (like cell) with the corresponding tokens in the input (SelectedCells).

Table 8 shows examples of the output generated by our model and baselines for code snippets in DEV. Most of the models produce meaningful output for simple code snippets (first example) but degrade on longer, compositional inputs. For example, the last SQL query listed in Table 8 includes a subquery, where a complete description should include both summing and concatenation. CODE-NN describes the summation (but not concatenation), while others return non-relevant descriptions.

Finally, we performed manual error analysis on 50 randomly selected examples from DEV (Table 7) for each language. Redundancy is a major source of error, i.e., generation of extraneous content-bearing phrases, along with missing content, e.g., in the last example of Table 8 there is no reference to the concatenation operations present in the beginning of the query. Sometimes the output from our model can be out of context, in the sense that it does not match the input code. This often happens for low frequency tokens (7% of cases), for which CODE-NN realizes them with generic phrases. This also happens when there are very long range dependencies or compositional structures in the input, such as nested queries (13% of the cases).

8 Conclusion

In this paper, we presented CODE-NN , an end-to-end neural attention model using LSTMs to

Error	% Cases
Correct	37%
Redundancy	17%
Missing Info	26%
Out of context	20%

Table 7: Error analysis on 50 examples in DEV

generate summaries of C# and SQL code by learning from noisy online programming websites. Our model outperforms competitive baselines and achieves state of the art performance on automatic metrics, namely METEOR and BLEU, as well as on a human evaluation study. We also used CODE-NN to answer programming questions by retrieving the most appropriate code snippets from a corpus, and beat previous baselines for this task in terms of MRR. We have published our C# and SQL datasets, the accompanying human annotated test sets, and our code for the tasks described in this paper.

In future work, we plan to develop better models for capturing the structure of the input, as well as extend the use of our system to other applications such as automatic documentation of source code.

Acknowledgements

We thank Mike Lewis, Chloé Kiddon, Kenton Lee, Eunsol Choi and the anonymous reviewers for comments on an earlier version. We also thank Bill Howe, Dan Halperin and Mark Yatskar for helpful discussions and Miltiadis Allamanis for providing the dataset for the comparison study. Abstract

To create accessible content for deaf users, we investigate automatically synthesizing animations of American Sign Language (ASL), including grammatically important facial expressions and head movements. Based on recordings of humans performing various types of syntactic face and head movements (which include idiosyncratic variation), we evaluate the efficacy of Continuous Profile Models (CPMs) at identifying an essential "latent trace" of the performance, for use in producing ASL animations. A metric-based evaluation and a study with deaf users indicated that this approach was more effective than a prior method for producing animations.

1 Introduction and Motivation

While there is much written content online, many people who are deaf have difficulty reading text or may prefer sign language. For example, in the U.S., standardized testing indicates that a majority of deaf high school graduates (age 18+) have a fourth-grade reading level or below (Traxler, 2000) (U.S. fourth-grade students are typically age 9). While it is possible to create video-recordings of a human performing American Sign Language (ASL) for use on websites, updating such material is expensive (i.e., re-recording). Thus, researchers investigate technology to automate the synthesis of animations of a signing virtual human, to make it more cost-effective for organizations to provide sign language content online that is easily updated and maintained. Animations can be automatically synthesized from a symbolic specification of the message authored by a human or perhaps by machine translation, e.g. (Ebling and Glauert, 2013; Filhol et al., 2013; Stein et al., 2012).

1.1 ASL Syntactic Facial Expressions

Facial expressions are essential in ASL, conveying emotion, semantic variations, and syntactic structure. Prior research has verified that ASL animations with missing or poor facial expressions are significantly less understandable for deaf users (Kacorri et al., 2014; Kacorri et al., 2013b; Kacorri et al., 2013a). While artists can produce individual animations with beautiful expressions, such work is time-consuming. For efficiently maintainable online content, we need automatic synthesis of ASL from a sparse script representing the lexical items and basic elements of the sentence.

Specifically, we are studying how to model and generate ASL animations that include syntactic facial expressions, conveying grammatical information during entire phrases and therefore constrained by the timing of the manual signs in a phrase (Baker-Shenk, 1983). Generally speaking, in ASL, upper face movements (examined in this paper) convey syntactic information across entire phrases, with the mouth movements conveying lexical or adverbial information.

The meaning of a sequence of signs performed with the hands depends on the co-occuring facial expression. (While we use the term "facial expressions," these phenomena also include movements of the head.) For instance, the ASL sentence "BOB LIKE CHOCOLATE" (English: "Bob likes chocolate.") becomes a yes/no question (English: "Does Bob like chocolate?"), with the addition of a YesNo facial expression during the sentence. The addition of a Negative facial expression during the verb phrase "LIKE CHOCOLATE" changes the meaning of the sentence to "Bob doesn't like chocolate." (The lexical item NOT may optionally be used.) For interrogative questions, a WhQuestion facial expression must occur during the sentence, e.g., "BOB LIKE

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2084–2093,
Berlin, Germany, August 7-12, 2016.

WHAT." The five types of ASL facial expressions investigated in this paper include:

- YesNo: The signer raises his eyebrows while tilting the head forward to indicate that the sentence is a polar question.
- WhQuestion: The signer furrows his eyebrows and tilts his head forward during a sentence to indicate an interrogative question, typically with a "WH" word such as what, who, where, when, how, which, etc.
- Rhetorical: The signer raises his eyebrows and tilts his head backward and to the side to indicate a rhetorical question.
- Topic: The signer raises his eyebrows and tilts his head backward during a clause-initial phrase that should be interpreted as a topic.
- Negative: The signer shakes his head left and right during the verb phrase to indicate negated meaning, often with the sign NOT.

1.2 Prior Work

A survey of recent work of several researchers on producing animations of sign language with facial expressions appears in (Kacorri, 2015). There is recent interest in data-driven approaches using facial motion-capture of human performances to generate sign language animations: For example, (Schmidt et al., 2013) used clustering techniques to select facial expressions that co-occur with individual lexical items, and (Gibet et al., 2011) studied how to map facial motion-capture data to animation controls.

In the most closely related prior work, we had investigated how to generate a face animation based on a set of video recordings of a human signer performing facial expressions (Kacorri et al., 2016), with head and face movement data automatically extracted from the video, and with individual recordings labeled as each of the five syntactic types, as listed in section 1.1. We wanted to identify a single exemplar recording in our dataset, for each of the syntactic types, that could be used as the basis for generating the movements of virtual human character. (In a collection of recordings of face and head movement, there will naturally be non-essential individual variation in the movements; thus, it may be desirable to select a recording that is maximally stereotypical of a set of recordings.) To do so, we made use of a variant of Dynamic Time Warping (DTW) as a distance metric to select the recording with minimal pairwise normalized DTW distance from all of the examples of each syntactic type. We had used this "centroid" recording as the basis for producing a novel animation of the face and head movements for a sign language sentence.

2 Method

In this paper, we present a new methodology for generating face and head movements for sign language animations, given a set of human recordings of various syntactic types of facial expressions. Whereas we had previously selected a single exemplar recording of a human performance to serve as a basis for producing an animation (Kacorri et al., 2016), in this work, we investigate how to construct a model that generalizes across the entire set of recordings, to produce an "average" of the face and head movements, which can serve as a basis for generating an animation. To enable comparison of our new methodology to our prior technique, we make use of an identical training dataset as in (Kacorri et al., 2016) and an identical animation rendering pipeline, described in (Huenerfauth and Kacorri, 2015a). Briefly, the animation pipeline accepts a script of the hand location, hand orientation, and hand-shape information to pose and move the arms of the character over time, and it also accepts a file containing a stream of face movement information in MPEG4 Facial Animation Parameters format (ISO/IEC, 1999) to produce a virtual human animation.

2.1 Dataset and Feature Extraction

ASL is a low-resource language, and it does not have a writing system in common use. Therefore, ASL corpora are generally small in size and in limited supply; they are usually produced through manual annotation of video recordings. Thus, researchers generally work with relatively small datasets. In this work, we make use of two datasets that consist of video recordings of humans performing ASL with annotation labeling the times in the video when each of the five types of syntactic facial expressions listed in section 1.1 occur.

The training dataset used in this study was described in (Kacorri et al., 2016), and consists of 199 examples of facial expressions performed by a female signer recorded at Boston University. While the Training dataset can naturally be partitioned into five subsets, based on each of the five syntactic facial expression types, because adjacent

Type	Subgroup "_A" (Num. of Videos)	Subgroup "_B" (Num. of Videos)
YesNo	Immediately preceded by a facial expression with raised eyebrows, e.g. Topic. (9)	Not immediately preceded by an eyebrow-raising expression. (10)
WhQuestion	Performed during a single word, namely the wh-word (e.g., what, where, when). (4)	Performed during a phrase consisting of multiple words. (8)
Rhetorical	Performed during a single word, namely the wh-word (e.g., what, where, when). (2)	Performed during a phrase consisting of multiple words. (8)
Topic	Performed during a single word. (29)	Performed during a phrase consisting of multiple words. (15)
Negative	Immediately preceded by a facial expression with raised eyebrows, e.g. Topic. (16)	Not immediately preceded by eyebrow-raising expression. (25)

Table 1: Ten subgroups of the training dataset.

facial expressions or phrase durations may affect the performance of ASL facial expressions, in this work, we sub-divide the dataset further, into ten sub-groups, as summarized in Table 1.

The "gold-standard" dataset used in this study was shared with the research community by (Huenerfauth and Kacorri, 2014); we use 10 examples of ASL facial expressions (one for each sub-group listed in Table 1) performed by a male signer who was recorded at the Linguistic and Assistive Technologies laboratory.

To extract face and head movement information from the video, a face-tracker (Visage, 2016) was used to produce a set of MPEG4 facial animation parameters for each frame of video: These values represent face-landmark or head movements of the human appearing in the video, including 14 features used in this study: head_x, head_y, head_z, head_pitch, head_yaw, head_roll, raise_l_i_brow, raise_r_i_brow, raise_l_m_brow, raise_r_m_brow, raise_l_o_brow, raise_r_o_brow, squeeze_l_brow, squeeze_r_brow. The first six values represent head location and orientation. The next six values represent vertical movement of the outer ("o_"), middle ("m_"), or inner ("i_") portion of the right ("r_") or left ("l_") eyebrows. The final values represent horizontal movement of the eyebrows.

2.2 Continuous Profile Models (CPM)

Continuous Profile Model (CPM) aligns a set of related time series data while accounting for changes in amplitude. This model has been previously evaluated on speech signals and on other biological time-series data (Listgarten et al., 2004). With the assumption that a noisy, stochastic process generates the observed time series data, the approach automatically infers the underlying noiseless representation of the data, the so-called "latent trace." Figure 6 (on the last page of this paper) shows an example of multiple time series in unaligned and aligned space, with CPM identifying the the latent trace.

Given a set K of observed time series $\vec{x}^k = (x_1^k, x_2^k, ..., x_N^k)$, CPM assumes there is a latent trace $\vec{z} = (z_1, z_2, ..., z_M)$. While not a requirement of the model, the length of the time series data is assumed to be the same (N) and the length of the latent trace used in practice is $M = (2+\varepsilon)N$, where an ideal M would be large relative to N to allow precise mapping between observed data and an underlying point on the latent trace. Higher temporal resolution of the latent trace also accommodates flexible alignments by allowing an observational series to advance along the latent trace in small or large jumps (Listgarten, 2007).

Continuous Profile Models (CPMs) build on Hidden Markov Models (HMMs) (Poritz, 1988) and share similarities with Profile HMMs which augment HMMs by two constrained-transition states: 'Insert' and 'Delete' (emitting no observations). Similar to the Profile HMM, the CPM has strict left-to-right transition rules, constrained to only move forward along a sequence. Figure 1 includes a visualization we created, which illustrates the graphical model of a CPM.

2.3 Obtaining the CPM Latent Trace

We applied the CPM model to time align and coherently integrate time series data from multiple ASL facial expression performances of a particular type, e.g., Topic_A as listed in section 2.1, with the goal of using the inferred 'latent traces' to drive ASL animations with facial expressions of that type. This section describes our work to train the CPM and to obtain the latent traces; implementation details appear in Appendix A.

The input time-series data for each CPM model is the face and head movement data extracted from ASL videos of one of the facial expression types,

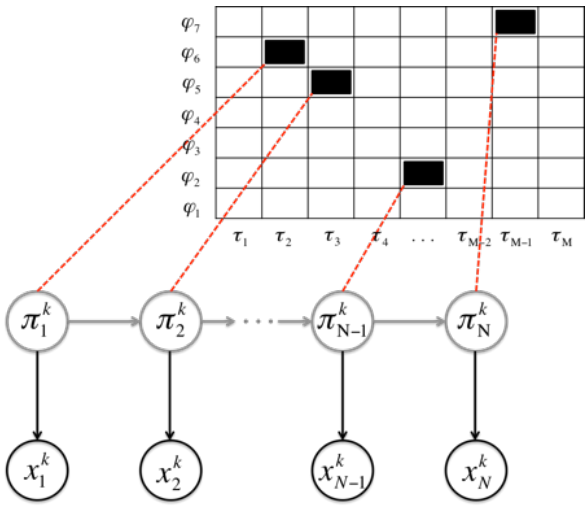

Figure 1: Depiction of a CPM for series x^k, with hidden state variables π_i^k underlying each observation x_i^k. The table illustrates the state-space: time-state/scale-state pairs mapped to the hidden variables, where time states belong to the integer set $(1...M)$ and scale states belong to an ordered set, here with 7 evenly spaced scales in logarithmic space as in (Listgarten et al., 2004).

as shown in Table 2. For each dataset, all the training examples are stretched (resampled using cubic interpolation) to meet the length of the longest example in the set. The length of time series, N, corresponds to the duration in video frames of the longest example in the data set. The recordings in the training set have 14 dimensions, corresponding to the 14 facial features listed in Section 2.1. As discussed above, the latent trace has a time axis of length M, which is approximately double the temporal resolution of the original training examples.

CPM Models	**Training Data** $\#Examples \times N \times \#Features$	**Latent Trace** $M \times \#Features$ where $M = (2+\varepsilon)N$
YesNo_A	9 x 51 x 14	105 x 14
YesNo_B	10 x 78 x 14	160 x 14
WhQuestion_A	4 x 24 x 14	50 x 14
WhQuestion_B	8 x 41 x 14	84 x 14
Rhetorical_A	2 x 16 x 14	33 x 14
Rhetorical_B	8 x 55 x 14	113 x 14
Topic_A	29 x 29 x 14	60 x 14
Topic_B	15 x 45 x 14	93 x 14
Negative_A	16 x 67 x 14	138 x 14
Negative_B	25 x 76 x 14	156 x 14

Table 2: Training data and the obtained latent traces for each of the CPM models on ASL facial expression subcategories.

To demonstrate our experiments, Figure 6 illustrates one of the subcategories, Rhetorical_B. (This figure appears at the end of the paper, due to its large size.) We illustrate the training set, before and after the alignment and amplitude normalization with the CPM, and the obtained latent trace for this subcategory. Figure 6a and Figure 6b illustrate each of the 8 training examples with a subplot extending from $[0, N]$ in the x-axis, which is the observed time axis in video frames. Each of the 14 plots represents one of the head or face features. Figure 6c illustrates the learned latent trace with a subplot extending from $[0, M]$ in the x-axis, which is the latent time axis. While the training set for this subcategory is very small and has high variability, upon visual inspection of Figure 6, we can observe that the learned latent trace shares similarities with most of the time series in the training set without being identical to any of them.

We expect that during the Rhetorical facial expression (Section 2.1), the signer's eyebrows will rise and the head will be tilted back and to the side. In the latent trace, the inner, middle, and outer portions of the left eyebrow rise (Figure 6c, plots 7, 9, 11), and so do the inner, middle, and outer portions of the right eyebrow (Figure 6c, plots 8, 10, 12). Note how the height of the lines in those plots rise, which indicates increased eyebrow height. For the Rhetorical facial expression, we would also expect symmetry in the horizontal displacement of the eyebrows, and we see such mirroring in the latent-trace: In (Figure 6c, plots 13-14), note the tendency for the line in plot 13 (left eyebrow) to increase in height as the line in plot 14 (right eyebrow) decreases in height, and vice versa.

3 Evaluation

This section presents two forms of evaluation of the CPM latent trace model for ASL facial expression synthesis. In Section 3.1, the CPM model will be compared to a "gold-standard" performance of each sub-category of ASL facial expression using a distance-metric-based evaluation, and in Section 3.2, the results of a user-study will be presented, in which ASL signers evaluated animations of ASL based upon the CPM model.

To provide a basis of comparison, in this section, we evaluate the CPM approach in comparison to an alternative approach that we call 'Centroid', which we described in prior work in (Ka-

corri et al., 2016), where we used a multivariate DTW to select one of the time series in the training set as a representative performance of the facial expression. The centroid examples are actual recordings of human ASL signers that are used to drive an animation. Appendix A lists the codenames of the videos from the training dataset selected as centroids and the codenames of the videos used in the gold-standard dataset (Huenerfauth and Kacorri, 2014).

3.1 Metric Evaluation

The gold-standard recordings of a male ASL signer were described in Section 2.1. In addition to the video recordings (which were processed to extract face and head movement data), we have annotation of the timing of the facial expressions and the sequence of signs performed on the hands. To compare the quality of our CPM model and that of the Centroid approach, we used each method to produce a candidate sequence of face and head movements for the sentence performed by the human in the gold-standard recording. Thus, the extracted facial expressions from the human recording can serve as a gold standard for how the face and head should move. In this section, we compare: (a) the distance of the CPM latent trace from the gold standard to (b) the distance of the centroid form the gold standard. It is notable that these gold-standard recordings were previously "unseen" during the creation of the CPM or Centroid models, that is, they were not used in the training data set during the creation of either model.

Since there was variability in the length of the latent trace, centroid, and gold-standard videos, for a fairer comparison, we first resampled these time series, using cubic interpolation, to match the duration (in milliseconds) of the gold-standard ASL sentence, and then we used multivariate DTW to estimate their distance, following the methodology of (Kacorri et al., 2016) and (Kacorri and Huenerfauth, 2015). In prior work (Kacorri and Huenerfauth, 2015), we had shown that a scoring algorithm based on DTW had moderate (yet significant) correlation with scores that participants assigned to ASL animation with facial expressions.

Figure 2 shows an example of a DTW distance scoring between the gold standard and each of the latent trace and the centroid, for one face feature

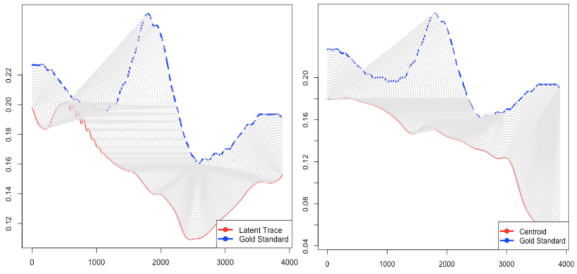

Figure 2: DTW distances on the squeeze_l_brow feature (left eyebrow horizontal movement), during a Negative_A facial expression: (left) between the CPM latent trace and gold standard and (right) between the centroid and gold standard. The timeline is given in milliseconds.

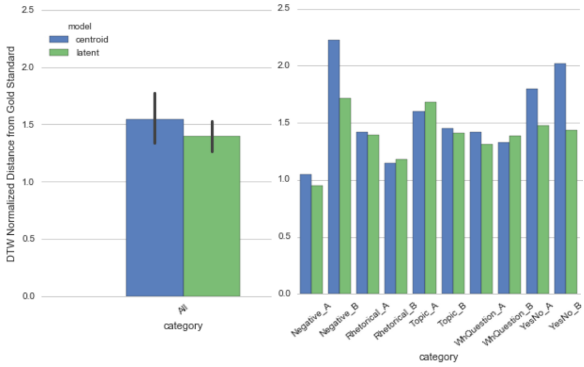

Figure 3: Overall normalized DTW distances for latent trace and centroid (left) and per each subcategory of ASL facial expression (right).

(horizontal movement of the left eyebrow) during a Negative_A facial expression. Given that the centroid and the training data for the latent trace are driven by recordings of a (female) signer and the gold standard is a different (male) signer, there are differences between these facial expressions due to idiosyncratic aspects of individual signers. Thus the metric evaluation in this section is challenging because it is an inter-signer evaluation.

Figure 3 illustrates the overall calculated DTW distances, including a graph with the results broken down per subcategory of ASL facial expression. The results indicate that the CPM latent trace is closer to the gold standard than the centroid is. Note that the distance values are not zero since the latent trace and the centroid are being compared to a recording from a different signer on novel, previously unseen, ASL sentences. The results in these graphs suggest that the latent trace model out-performed the centroid approach.

Figure 4: Screenshots of YesNo_A stimuli of three types: a) neutral, b) centroid, and c) latent trace.

3.2 User Evaluation

To further assess our ASL synthesis approach, we conducted a user study where ASL signers watched short animations of ASL sentences with identical hand movements but differing in their face, head, and torso movements. There were three conditions in this between-subjects study: a) animations with a static neutral face throughout the animation (as a lower baseline), b) animations with facial expressions driven by the centroid human recording, and c) animations with facial expressions driven by the CPM latent trace based on multiple recordings of a human performing that type of facial expression. Figure 4 illustrates screenshots of each stimulus type for a YesNo_A facial expression. The specific sentences used for this study were drawn from a standard test set of stimuli released to the research community by (Huenerfauth and Kacorri, 2014) for evaluating animations of sign language with facial expressions.

All three types of stimuli (neutral, centroid and latent trace), shared identical animation-control scripts specifying the hand and arm movements; these scripts were hand-crafted by ASL signers in a pose-by-pose manner. For the neutral animations, we did not specify any torso, head, nor face movements; rather, we left them in their neutral pose throughout the sentences. As for the centroid and latent trace animations, we applied the head and face movements (as specified by the centroid model or by the latent trace model) only to the portion of the animation where the facial expression of interest occurs, leaving the head and face for the rest of the animation to a neutral pose. For instance, during a stimulus that contains a Wh-question, the face and head are animated only during the Wh-question, but they are left in a neutral pose for the rest of the stimulus (which may include other sentences). The period of time when the facial expression occurred was time-aligned with the subset of words (the sequence of signs performed on the hands) for the appropriate syntactic domain; the phrase-beginning and phrase-ending was aligned with the performance of the facial expression. Thus, the difference in appearance between our animation stimuli was subtle: The only portion of the animations that differed between the three conditions (neutral, centroid, and latent-trace) was the face and the head movements during the span of time when the syntactic facial expression should occur (e.g., during the Wh-question).

We resampled the centroid and CPM time series, using cubic interpolation, to match the duration (in milliseconds) of the animation they would be applied to. To convert the centroid and latent trace time series into the input for the animation-generation system, we used the MPEG4-features-to-animation pipeline described in (Kacorri et al., 2016). That platform is based upon the open-source EMBR animation system for producing human animation (Heloir and Kipp, 2009); specifically, the facial expressions were represented as an EMBR PoseSequence with a pose defined every 133 milliseconds.

In prior work (Huenerfauth and Kacorri, 2015b), we investigated key methodological considerations in conducting a study to evaluate sign language animations with deaf users, including the use of appropriate baselines for comparison, appropriate presentation of questions and instructions, demographic and technology experience factors influencing acceptance of signing avatars, and other factors that we have considered in the design of this current study. Our recent work (Kacorri et al., 2015) has established a set of demographic and technology experience questions which can be used to screen for the most critical participants in a user study of ASL signers to evaluate animation. Specifically, we screened for participants that identified themselves as "deaf/Deaf" or "hard-of-hearing," who had grown up using ASL at home or had attended an ASL-based school as a young child, such as a residential or daytime school.

Deaf researchers (all fluent ASL signers) recruited and collected data from participants, during meetings conducted in ASL. Initial advertise-

ments were sent to local email distribution lists and Facebook groups. A total of 17 participants met the above criteria, where 14 participants self-identified as deaf/Deaf and 3 as hard-of-hearing. Of our participants in the study, 10 had attended a residential school for deaf students, and 7, a daytime school for deaf students. 14 participants had learned ASL prior to age 5, and the remaining 3 had been using ASL for over 7 years. There were 8 men and 9 women of ages 19-29 (average age 22.8). In prior work, we (Kacorri et al., 2015) have advocated that participants in studies evaluating sign language animation complete a two standardized surveys about their technology experience (MediaSharing and AnimationAttitude) and that researchers report these values for participants, to enable comparison across studies. In our study, participant scores for MediaSharing varied between 3 and 6, with a mean score of 4.3, and scores for AnimationAttitude varied from 2 to 6, with a mean score of 3.8.

At the beginning of the study, participants viewed a sample animation, to familiarize them with the experiment and the questions they would be asked about each animation. (This sample used a different stimulus than the other ten animations shown in the study.) Next, they responded to a set of questions that measured their subjective impression of each animation, using a 1-to-10 scalar response. Each question was conveyed using ASL through an onscreen video, and the following English question text was shown on the questionnaire: (a) Good ASL grammar? (10=Perfect, 1=Bad); (b) Easy to understand? (10=Clear, 1=Confusing); (c) Natural? (10=Moves like person, 1=Like robot). These questions have been used in many prior experimental studies to evaluate animations of ASL, e.g. (Kacorri and Huenerfauth, 2015), and were shared with research community as a standard evaluation tool in (Huenerfauth and Kacorri, 2014). To calculate a single score for each animation, the scalar response scores for the three questions were averaged.

Figure 5 shows distributions of subjective scores as boxplots with a 1.5 interquartile range (IQR). For comparison, means are denoted with a star and their values are labeled above each boxplot. When comparing the subjective scores that participants assigned to the animations in Figure 5, we found a significant difference (Kruskal-Wallis test used since the data was not normally

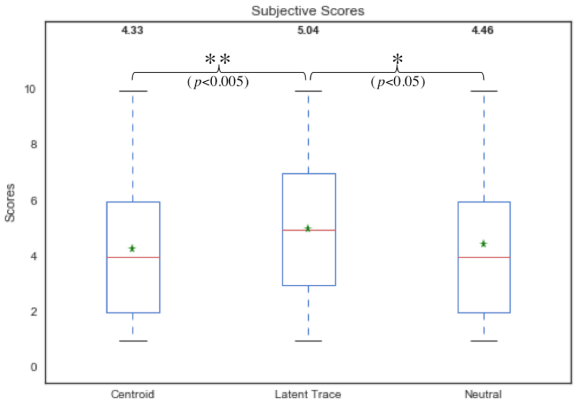

Figure 5: Subjective scores for centroid, latent trace, and neutral animations.

distributed) between the latent trace and centroid ($p < 0.005$) and between the latent trace and neutral ($p < 0.05$).

In summary, our CPM modeling approach for generating an animation out-performed an animation produced from an actual recording of a single human performance (the "centroid" approach). In prior methodological studies, we demonstrated that it is valid to use either videos of humans or animations (driven by a human performance) as the baseline for comparison in a study of ASL animation (Kacorri et al., 2013a). As suggested by Figure 4, the differences in face and head movements between the Centroid and CPM conditions were subtle, yet fluent ASL signers rated the CPM animations higher in this study.

4 Conclusion and Future Work

To facilitate the creation of ASL content that can easily be updated or maintained, we have investigated technologies for automating the synthesis of ASL animations from a sparse representation of the message. Specifically, this paper has focused on the synthesis of syntactic ASL facial expressions, which are essential to sentence meaning, using a data-driven methodology in which recordings of human ASL signers are used as a basis for generating face and head movements for animation. To avoid idiosyncratic aspects of a single performance, we have modeled a facial expression based on the underlying trace of the movement trained on multiple recordings of different sentences where this type of facial expression occurs. We obtain the latent trace with Continuous Profile Model (CPM), a probabilistic generative model that relies on Hidden Markov Models. We

assessed our modeling approach through comparison to an alternative centroid approach, where a single performance was selected as a representative. Through both a metric evaluation and an experimental user study, we found that the facial expressions driven by our CPM models produce high-quality facial expressions that are more similar to human performance of novel sentences.

While this work used the latent trace as the basis for animation, in future work, we also plan to explore methods for sampling from the model to produce variations in face and head movement. In addition, to aid CPM convergence to a good local optimum, in future work we will investigate dimensionality reduction approaches that are reversible such as Principal Component Analysis (Pearson, 1901) and other pre-processing approaches similar to (Listgarten, 2007), where the training data set is coarsely pre-aligned and pre-scaled based on the center of mass of the time series. In addition we plan to further investigate how to fine-tune some of the hyper parameters of the CPM such as spline scaling, single global scaling factor, convergence tolerance, and initialization of the latent trace with a centroid. In subsequent work, we would like to explore alternatives for enhancing CPMs by incorporating contextual features in the training data set such as timing of hand movements, and preceding, succeeding, and co-occurring facial expressions.

A Appendix: Supplemental Material

In Section 2.3, we made use of a freely available CPM implementation available from http://www.cs.toronto.edu/~jenn/CPM/ in MATLAB, Version 8.5.0.197613 (R2015a).

One parameter for regularizing the latent trace (Listgarten, 2007) is a smoothing parameter (λ), with values being dataset-dependent. To select a good λ, we experimented with held-out data and found that $\lambda = 4$ and $NumberOfIterations = 3$ resulted in a latent trace curve that captures the shape of the ASL features well. Other CPM parameters were:

- $USE\_SPLINE = 0$: if set to 1, uses spline scaling rather than HMM scale states
- $oneScaleOnly = 0$: no HMM scale states (only a single global scaling factor is applied to each time series.)
- $extraPercent(\varepsilon)$ = 0.05: slack on the length of the latent trace M, where $M = (2 + \varepsilon)N$.
- $learnStateTransitions = 0$: whether to learn the HMM state-transition probabilities
- $learnGlobalScaleFactor = 1$: learn single global scale factor for each time series

Section 3.1 described how the centroids were selected from among videos in the Boston University dataset (Neidle et al., 2014), and the gold standard videos were selected from among videos in a different dataset (Huenerfauth and Kacorri, 2014). Table 3 lists the code names of the selected videos, using the nomenclature of each dataset.

Subcategory	Centroid Codename	Gold-Standard Codename
YesNo_A	2011-12-01_0037-cam2-05	Y4
YesNo_B	2011-12-01_0037-cam2-09	Y3
WhQuestion_A	2011-12-01_0038-cam2-05	W1
WhQuestion_B	2011-12-01_0038-cam2-07	W2

Evaluating Sentiment Analysis in the Context of Securities Trading

Abstract

There are numerous studies suggesting that published news stories have an important effect on the direction of the stock market, its volatility, the volume of trades, and the value of individual stocks mentioned in the news. There is even some published research suggesting that automated sentiment analysis of news documents, quarterly reports, blogs and/or twitter data can be productively used as part of a trading strategy. This paper presents just such a family of trading strategies, and then uses this application to re-examine some of the tacit assumptions behind how sentiment analyzers are generally evaluated, in spite of the contexts of their application. This discrepancy comes at a cost.

1 Introduction

The proliferation of opinion-rich text on the World Wide Web, which includes anything from product reviews to political blog posts, led to the growth of sentiment analysis as a research field more than a decade ago. The market need to quantify opinions expressed in social media and the blogosphere has provided a great opportunity for sentiment analysis technology to make an impact in many sectors, including the financial industry, in which interest in automatically detecting news sentiment in order to inform trading strategies extends back at least 10 years. In this case, sentiment takes on a slightly different meaning; positive sentiment is not the emotional and subjective use of laudatory language. Rather, a news article that contains positive sentiment is optimistic about the future financial prospects of a company.

Zhang and Skiena (2010) experimented with news sentiment to inform simple market neutral trading algorithms, and produced an impressive maximum yearly return of around 30% — even more when using sentiment from blogs and twitter data. They did so, however, without an appropriate baseline, making it very difficult to appreciate the significance of this number. Using a very standard, and in fact somewhat dated sentiment analyzer, we are regularly able to garner annualized returns over twice that percentage, and in a manner that highlights two of the better design decisions that Zhang and Skiena (2010) made, viz., (1) their decision to trade based upon numerical SVM scores rather than upon discrete positive or negative sentiment classes, and (2) their decision to go long (resp., short) in the n best- (worst-) ranking securities rather than to treat all positive (negative) securities equally.

On the other hand, we trade based upon the raw SVM score itself, rather than its relative rank within a basket of other securities as Zhang and Skiena (2010) did, and we experimentally tune a threshold for that score that determines whether to go long, neutral or short. We sampled our stocks for both training and evaluation in two runs, one without *survivor bias*, the tendency for long positions in stocks that are publicly traded as of the date of the experiment to pay better using historical trading data than long positions in random stocks sampled on the trading days themselves. Most of the evaluations of sentiment-based trading either unwittingly adopt this bias, or do not need to address it because their returns are computed over very brief historical periods. We also provide appropriate trading baselines as well as Sharpe ratios (Sharpe, 1966) to attempt to quantify the relative risk inherent to our experimental strategies. As tacitly assumed by most of the work on this subject, our trading strategy is not portfolio-limited, and our returns are calculated on a percentage basis with theoretical, commission-free trades.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2094–2103,
Berlin, Germany, August 7-12, 2016.

It is important to understand at the outset, however, that the purpose of this research was not to beat Zhang and Skiena's (2010) returns (although we have), nor merely to conduct the first properly controlled, sufficiently explicit, scientific test of the descriptive hypothesis that sentiment analysis is of benefit to securities trading (although, to our knowledge, we did). The main purpose of this study was in fact to reappraise the evaluation standards used by the sentiment analysis community. It is not at all uncommon within this community to evaluate a sentiment analyzer with a variety of classification accuracy or hypothesis testing scores such as F-measures, SARs, kappas or Krippendorf alphas derived from human-subject annotations — even when more extensional measures are available, such as actual market returns from historical data in the case of securities trading. With Hollywood films, another popular domain for automatic sentiment analysis, one might refer to box-office returns or the number of award nominations that a film receives rather than to its star-rankings on review websites where pile-on and confirmation biases are widely known to be rampant. Are the opinions of human judges, paid or unpaid, a sufficient proxy for the business cases that actually drive the demand for sentiment analyzers?

We regret to report that they do not seem to be. As a case study to demonstrate this point (Section 4.3), we exhibit one particular modification to our experimental financial sentiment analyzer that, when evaluated against an evaluation test set sampled from the same pool of human-subject annotations as the analyzer's training data, returns poorer performance, but when evaluated against actual market returns, yields better performance. This should worry any researcher who relies on classification accuracies, because the improvements that they report, whether due to better feature selection or different pattern recognition algorithms, may in fact not be improvements at all. Differences in the amount or degree of improvement might arguably be rescalable, but Section 4.3 shows that such intrinsic measures are not even accurate up to a determination of the delta's *sign*.

On the other hand, the results reported here should not be construed as an indictment of sentiment analysis as a technology or its potential application. In fact, one of our baselines alternatively attempts to train the same classifier directly on market returns, and the experimental approach handily beats that, too. It is important to train on human-annotated sentiments, but then it is equally important to tune, and eventually evaluate, on an empirically grounded task-specific measure, such as market returns. This paper thus presents, to our knowledge, the first real proof that sentiment is worth analyzing in this or any other domain.

A likely machine-learning explanation for this experimental result is that whenever two unbiased estimators are pitted against each other, they often result in an improved combined performance because each acts as a regularizer against the other. If true, this merely attests to the relative independence of task-based and human-annotated knowledge sources. A more HCI-oriented view, however, would argue that direct human-subject annotations are highly problematic unless the annotations have been elicited in manner that is *ecologically valid*. When human subjects are paid to annotate quarterly reports or business news, they are paid regardless of the quality of their annotations, the quality of their training, or even their degree of comprehension of what they are supposed to be doing. When human subjects post film reviews on web-sites, they are participating in a cultural activity in which the quality of the film under consideration is only one factor. These sources of annotation have not been properly controlled in previous experiments on sentiment analysis.

Regardless of the explanation, this is a lesson that applies to many more areas of NLP than just sentiment analysis, and to far more recent instances of sentiment analysis than the one that we based our experiments on here. Indeed, we chose sentiment analysis because this is an area that *can* set a higher standard; it has the right size for an NLP component to be embedded in real applications and to be evaluated properly. This is noteworthy because it is challenging to explain why recent publications in sentiment analysis research would so dramatically increase the value that they assign to sentence-level sentiment scoring algorithms based on syntactically compositional derivations of "good-for/ bad-for" annotation (Anand and Reschke, 2010; Deng et al., 2013), when statistical parsing itself has spent the last twenty-five years staggering through a linguistically induced delirium as it attempts to document any of its putative advances without recourse to clear empirical evidence that PTB-style syntactic derivations are a reliable approximation of seman-

tic content or structure.

We submit, in light of our experience with the present study, that the most crucial obstacle facing the state of the art in sentiment analysis is not a granularity problem, nor a pattern recognition problem, but an evaluation problem. Those evaluations must be task-specific to be reliable, and sentiment analysis, in spite of our careless use of the term in the NLP community, is not a task. Stock trading is a task — one of many in which a sentiment analyzer is a potentially useful component. This paper provides an example of how to test that utility.

2 Related Work in Financial Sentiment Analysis

Studies confirming the relationship between media and market performance date back to at least Niederhoffer (1971), who looked at NY Times headlines and determined that large market changes were more likely following world events than on random days. Conversely, Tetlock (2007) looked at media pessimism and concluded that high media pessimism predicts downward prices. Tetlock (2007) also developed a trading strategy, achieving modest annualized returns of 7.3%. Engle and Ng (1993) looked at the effects of news on volatility, showing that bad news introduces more volatility than good news. Chan (2003) claimed that prices are slow to reflect bad news and stocks with news exhibit momentum. Antweiler and Frank (2004) showed that there is a significant, but negative correlation between the number of messages on financial discussion boards about a stock and its returns, but that this trend is economically insignificant. Aside from Tetlock (2007), none of this work evaluated the effectiveness of an actual sentiment-based trading strategy.

There is, of course, a great deal of work on automated sentiment analysis itself; see Pang and Lee (2008) for a survey. More recent developments germane to our work include the use of information retrieval weighting schemes (Paltoglou and Thelwall, 2010), with which accuracies of up to 96.6% have models based upon Latent Dirichlet Allocation (LDA) (Lin and He, 2009).

There has also been some work that analyzes the sentiment of financial documents without actually using those results in trading strategies (Koppel and Shtrimberg, 2004; Ahmad et al., 2006; Fu et al., 2008; O'Hare et al., 2009; Devitt and Ahmad, 2007; Drury and Almeida, 2011). As to the relationship between sentiment and stock price, Das and Chen (2007) performed sentiment analysis on discussion board posts. Using this, they built a "sentiment index" that computed the time-varying sentiment of the 24 stocks in the Morgan Stanley High-Tech Index (MSH), and tracked how well their index followed the aggregate price of the MSH itself. Their sentiment analyzer was based upon a voting algorithm, although they also discussed a vector distance algorithm that performed better. Their baseline, the Rainbow algorithm, also came within 1 percentage point of their reported accuracy. This is one of the very few studies that has evaluated sentiment analysis itself (as opposed to a sentiment-based trading strategy) against market returns (versus gold-standard sentiment annotations). Das and Chen (2007) focused exclusively on discussion board messages and their evaluation was limited to the stocks on the MSH, whereas we focus on Reuters newswire and evaluate over a wide range of NYSE-listed stocks and market capitalization levels.

Butler and Keselj (2009) try to determine sentiment from corporate annual reports using both character n-gram profiles and readability scores. They also developed a sentiment-based trading strategy with high returns, but do not report how the strategy works or how they computed the returns, making the results difficult to compare to ours. Basing a trading strategy upon annual reports also calls into question the frequency with which the trading strategy could be exercised.

The work most similar to ours is Zhang and Skiena's (2010). They look at both financial blog posts and financial news, forming a market-neutral trading strategy whereby each day, companies are ranked by their reported sentiment. The strategy then goes long and short on equal numbers of positive- and negative-sentiment stocks, respectively. They conduct their trading evaluation over the period from 2005 to 2009, and report a yearly return of roughly 30% when using news data, and yearly returns of up to 80% when they use Twitter and blog data. Crucially, they trade based upon the ranked relative order of documents by sentiment rather than upon the documents' raw sentiment scores.

Zhang and Skiena (2010) compare their strategy to two baselines. The "Worst-sentiment" Strategy trades the opposite of their strategy: short

on positive-sentiment stocks and long on negative sentiment stocks. The "Random-selection" Strategy randomly picks stocks to go long and short on. As trading strategies, these baselines set a very low standard. Our evaluation uses standard trading benchmarks such as momentum trading and holding the S&P, as well as oracle trading strategies over the same holding periods.

3 Method and Materials

3.1 News Data

Our dataset combines two collections of *Reuters* news documents. The first was obtained for a roughly evenly weighted collection of 22 small-, mid- and large-cap companies, randomly sampled from the list of all companies traded on the NYSE as of 10^{th} March, 1997. The second was obtained for a collection of 20 companies randomly sampled from those companies that were publicly traded in March, 1997 and still listed on 10^{th} March, 2013. For both collections of companies, we collected every chronologically third Reuters news document about them from the period March, 1997 to March, 2013. The news articles prior to 10^{th} March, 2005 were used as training data, and the news articles on or after 10^{th} March, 2005 were reserved as testing data.[1] We split the dataset at a fixed date rather than randomly in order not to incorporate future news into the classifier through lexical choice.

In total, there were 1256 financial news documents. Each was labelled by two human annotators as being negative, positive, or neutral in sentiment. The annotators were instructed to gauge the author's belief about the company, rather than to make a personal assessment of the company's prospects. Only the 991 documents that were labelled twice as negative or positive were used for training and evaluation.

3.2 Sentiment Analysis Algorithm

For each selected document, we first filter out all punctuation characters and the most common 429 stop words. Because this is a document-level sentiment scoring task, not sentence-level, our sentiment analyzer is a support-vector machine with a linear kernel function implemented using SVM^{light} (Joachims, 1999), using all of its default parameters.[2] We have experimented with raw term frequencies, binary term-presence features, and term frequencies weighted by the BM25 scheme, which had the most resilience in the study of information-retrieval weighting schemes for sentiment analysis by Paltoglou and Thelwall (2010). We performed 10 fold cross-validation on the training data, constructing our folds so that each contains an approximately equal number of negative and positive examples. This ensures that we do not accidentally bias a fold.

Representation	Accuracy
bm25_freq	81.143%
term_presence	80.164%
bm25_freq_sw	79.827%
freq_with_sw	75.564%
freq	79.276%

Table 1: Average 10-fold cross validation accuracy of the sentiment classifier using different term-frequency weighting schemes. The same folds were used in all feature sets.

Pang et al. (2002) use word presence features with no stop list, instead excluding all words with frequencies of 3 or less. Pang et al. (2002) normalize their word presence feature vectors, rather than term weighting with an IR-based scheme like BM25, which also involves a normalization step. Pang et al. (2002) also use an SVM with a linear kernel on their features, but they train and compute sentiment values on film reviews rather than financial texts, and their human judges also classified the training films on a scale from 1 to 5, whereas ours used a scale that can be viewed as being from -1 to 1, with specific qualitative interpretations assigned to each number. Antweiler and Frank (2004) use SVMs with a polynomial kernel (of unstated degree) to train on word frequencies relative to a three-valued classification, but they only count frequencies for the 1000 words with the highest mutual information scores relative to the classification labels. Butler and Keselj (2009) also use an SVM trained upon a very different set of features, and with a polynomial kernel of degree

[1] An anonymous reviewer expressed concern about chronological bias in the training data relative to the test data because of this decision. While this may indeed influence our results, ecological validity requires us to situate all training data before some date, and all testing data after that date, because traders only have access to historical data before making a future trade.

[2] There has been one important piece of work (Tang et al., 2015) on neural computing architectures for document-level sentiment scoring (most neural computing architectures for sentiment scoring are sentence-level), but the performance of this type of architecture is not mature enough to replace SVMs just yet.

3.

As a sanity check, we measured our sentiment analyzer's accuracy on film reviews by training and evaluating on Pang and Lee's (2004) film review dataset, which contains 1000 positively and 1000 negatively labelled reviews. Pang and Lee conveniently labelled the folds that they used when they ran their experiments. Using these same folds, we obtain an average accuracy of 86.85%, which is comparable to Pang and Lee's 86.4% score for subjectivity extraction. The purpose of this comparison is simply to demonstrate that our implementation is a faithful rendering of Pang and Lee's (2004) algorithm.

Table 1 shows the performance of SVM with BM25 weighting on our Reuters evaluation set versus several baselines. All baselines are identical except for the term weighting schemes used, and whether stop words were removed. As can be observed, SVM-BM25 has the highest sentiment classification accuracy: 80.164% on average over the 10 folds. This compares favourably with previous reports of 70.3% average accuracy over 10 folds on financial news documents (Koppel and Shtrimberg, 2004). We will nevertheless adhere to normalized term presence for now, in order to stay close to Pang and Lee's (2004) implementation.

3.3 Trading Algorithm

Overall, our trading strategy is simple: go long when the classifier reports positive sentiment in a news article about a company, and short when the classifier reports negative sentiment.

We will embed the aforementioned sentiment analyzer into three different trading algorithms. In Section 4.1, we use the discrete polarity returned by the classifier to decide whether go long/abstain/short a stock. In Section 4.2.1 we instead use the distance of the current document from the classifier's decision boundary reported by the SVM. These distances do have meaningful interpretations apart from their internal use in assigning class labels. Platt (Platt, 1999) showed that they can be converted into posterior probabilities, for example, by fitting a sigmoid function onto them, but we will simply use the raw distances. In Section 4.2.2, we impose a safety zone onto the interpretation of these raw distance scores.

4 Experiments

In the experiments of this section, we will evaluate an entire trading strategy, which includes the sentiment analyzer and the particulars of the trading algorithm itself. The purpose of these experiments is to refine the trading strategy itself and so the sentiment analyzer will be held constant. In Section 4.3, we will hold the trading strategy constant, and instead vary the document representation features in the underlying sentiment analyzer.

In all three experiments, we compare the per-position returns of the following four standard strategies, where the number of days for which a position is held remains constant:

1. The momentum strategy computes the price of the stock h days ago, where h is the holding period. Then, it goes long for h days if the previous price is lower than the current price. It goes short otherwise.
2. The S&P strategy simply goes long on the *S&P 500* for the holding period. This strategy completely ignores the stock in question and the news about it.
3. The oracle S&P strategy computes the value of the *S&P 500* index h days into the future. If the future value is greater than the current day's value, then it goes long on the *S&P 500* index. Otherwise, it goes short.
4. The oracle strategy computes the value of the stock h days into the future. If the future value is greater than the current day's value, then it goes long on the stock. Otherwise, it goes short.

The oracle and oracle S&P strategies are included as toplines to determine how close the experimental strategies come to ones with perfect knowledge of the future. "Market-trained" is the same as "experimental" at test time, but trains the sentiment analyzer on the market return of the stock in question for h days following a training article's publication, rather than the article's annotation.

4.1 Experiment One: Utilizing Sentiment Labels

Given a news document for a publicly traded company, the trading agent first computes the sentiment class of the document. If the sentiment is positive, the agent goes long on the stock on the date the news is released; if negative, it goes short.

Strategy	Period	Return	S. Ratio
Experimental	30 days	-0.037%	-0.002
	5 days	0.763%	0.094
	3 days	0.742%	0.100
	1 day	0.716%	0.108
Momentum	30 days	1.176%	0.066
	5 days	0.366%	0.045
	3 days	0.713%	0.096
	1 day	0.017%	-0.002
S&P	30 days	0.318%	0.059

Table 2: Returns and Sharpe ratios for the Experimental, baseline and topline trading strategies over 30, 5, 3, and 1 day(s) holding periods.

All trades are made based on the adjusted closing price on this date. We evaluate the performance of this strategy using four different holding periods: 30, 5, 3, and 1 day(s).

The returns and Sharpe ratios are presented in Table 2 for the four different holding periods and the five different trading strategies. The Sharpe ratio is a return-to-risk ratio, with a high value indicating good return for relatively low risk. The Sharpe ratio is calculated as: $S = \frac{E[R_a - R_b]}{\sqrt{\text{var}(R_a - R_b)}}$, where R_a is the return of a single asset and R_b is the risk-free return of a 10-year U.S. Treasury note.

The returns from this experimental trading system are fairly low, although they do beat the baselines. A one-way ANOVA test among the experimental, momentum and S&P strategies using the percent returns from the individual trades yields p values of 0.06493, 0.08162, 0.1792, and 0.4164, respectively, thus failing to reject the null hypothesis that the returns are not significantly higher.[3]

[3]An anonymous reviewer observed that Tetlock (2007) showed a statistically significant improvement from the use of sentiment, apparently contradicting this result. Tetlock's (2007) sentiment-based trading strategy used a safety zone (see Section 4.2.2), and was never compared to a realistic baseline or control strategy. Instead, Tetlock's (2007) significance test was conducted to demonstrate that his returns (positive in 12 of 15 calendar years of historical market data) were unlikely to have been generated by chance from a normal distribution centred at zero.

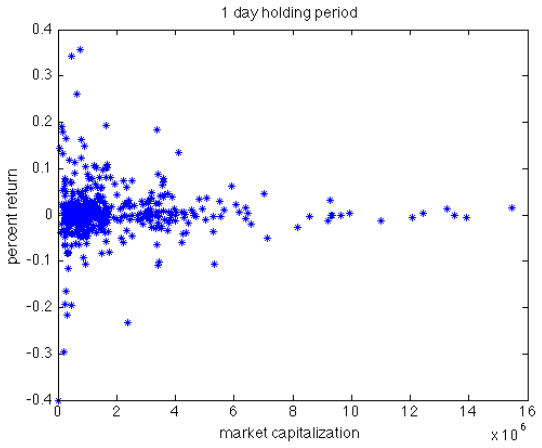

Figure 1: Percent returns for 1 day holding period versus market capitalization of the traded stocks.

Furthermore, the means and medians of all three trading strategies are approximately the same and centred around 0. The standard deviations of the experimental strategy and the momentum strategy are nearly identical, differing only in the thousandths digit. The standard deviations for the S&P strategy differ from the other two strategies due to the fact that the strategy buys and sells the entire S&P 500 index and not the individual stocks described in the news articles. There is, in fact, no convincing evidence that discrete sentiment class leads to an improved trading strategy from this or any other study with which we are familiar, based on their published details. One may note, however, that the returns from the experimental strategy have slightly higher Sharpe ratios than either of the baselines.

One may also note that using a sentiment analyzer mostly beats training directly on market data. This vindicates using sentiment annotation as an information source.

Figure 1 shows the market capitalizations of each individual trade's companies plotted against their percent return with a 1 day holding period. The correlation between the two variables is not significant. Returns for the other holding periods are similarly dispersed.

The importance of having good baselines is demonstrated by the fact that when we annualize our returns for the 3-day holding period, we get 70.086%. This number appears very high, but the annualized return from the momentum strategy is

70.066%[4], which is not significantly lower.

Figure 2 shows the percent change in share value plotted against the raw SVM score for the different holding periods. We can see a weak correlation between the two. For the 30 days, 5 days, 3 days, and 1 day holding periods, the correlations are 0.017, 0.16, 0.16, and 0.16, respectively. The line of best fit is shown. This prompts our next experiment.

4.2 Utilizing SVM scores

4.2.1 Experiment Two: Variable Single Threshold

Before, we labelled documents as positive (negative) when the score was above (below) 0, because 0 was the decision boundary. But 0 might not be the best threshold, θ, for high returns. To determine θ, we divided the evaluation dataset, i.e. the dataset with news articles dated on or after March 10, 2005, into two folds having an equal number of documents with positive and negative sentiment. We used the first fold to determine θ and traded using the data from the second fold and θ. For every news article, if the SVM score for that article is above (below) θ, then we go long (short) on the appropriate stock on the day the article was released. A separate theta was determined for each holding period. We varied θ from -1 to 1 in increments of 0.1.

Using this method, we were able to obtain significantly higher returns. In order of 30, 5, 3, and 1 day holding periods, the returns were 0.057%, 1.107%, 1.238%, and 0.745% ($p < 0.001$ in every case). This is a large improvement over the previous returns, as they are average per-position figures.[5]

4.2.2 Experiment Three: Safety Zones

For every news item classified, SVM outputs a score. For a binary SVM with a linear kernel function f, given some feature vector $\mathbf{x}$, $f(\mathbf{x})$ can be viewed as the signed distance of $\mathbf{x}$ from the decision boundary (Boser et al., 1992). It is then possibly justified to interpret raw SVM scores as degrees to which an article is positive or negative.

As in the previous section, we separate the evaluation set into the same two folds, only now we use two thresholds, $\theta \geq \zeta$. We will go long when the SVM score is above θ, abstain when the SVM score is between θ and ζ, and go short when the SVM score is below ζ. This is a strict generalization of the above experiment, in which $\zeta = \theta$.

For convenience, we will assume in this section that $\zeta = -\theta$, leaving us again with one parameter to estimate. We again vary θ from 0 to 1 in increments of 0.1. Figure 3 shows the returns as a function of θ for each holding period on the development dataset. If we increased the upper bound on θ to be greater than 1, then there would be too few trading examples (less than 10) to reliably calculate the Sharpe ratio. Using this method with $\theta = 1$, we were able to obtain even higher returns: 3.843%, 1.851%, 1.691, and 2.251% for the 30, 5, 3, and 1 day holding periods, versus 0.057%, 1.107%, 1.238%, and 0.745% in the second task-based experiment.

Representation	Accuracy	30 days	5 days	3 days	1 day
term_presence	80.164%	3.843%	1.851%	1.691%	2.251%
bm25_freq	81.143%	1.110%	1.770%	1.781%	0.814%
bm25_freq_dnc	62.094%	3.458%	2.834%	2.813%	2.586%
bm25_freq_sw	79.827%	0.390%	1.685%	1.581%	1.250%
freq	79.276%	1.596%	1.221%	1.344%	1.330%
freq_with_sw	75.564%	1.752%	0.638%	1.056%	2.205%

Table 3: Sentiment classification accuracy (average 10-fold cross-validation) and trade returns of different feature sets and term frequency weighting schemes in Exp. 3. The same folds were used for the different representations. The non-annualized returns are presented in columns 3-6.

4.3 Experiment Four: Feature Selection

In our final experiment, let us now hold the trading strategy fixed (at the third one, with safety zones) and turn to the underlying sentiment analyzer. With a good trading strategy in place, it is clearly possible to vary some aspect of the sentiment analyzer in order to determine its best setting in this context. We will measure both market return and classifier accuracy to determine whether they agree. Is the latter a suitable proxy for the former? Indeed, we may hope that classifier accuracy will be more portable to other possible tasks, but then it must at least correlate well with task-based performance.

In addition to evaluating those feature sets attempted in Section 3.2, we now hypothesize that the passive voice may be useful to emphasize in our representations, as the existential passive can be used to evade responsibility. So we add to the

[4]The momentum strategy has a different number of possible trades in any actual calendar year because it is a function of the holding period.

[5]Training directly on market data, by comparison, yields -0.258%, -0.282%, -0.036% and -0.388%, respectively.

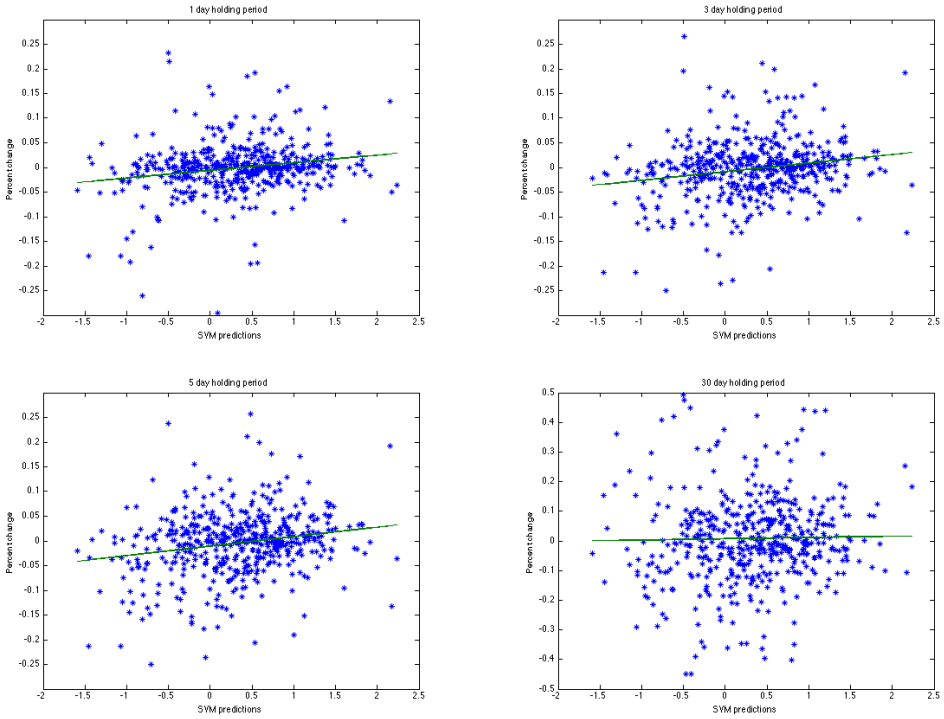

Figure 2: Percent change of trade returns plotted against SVM values for the 1, 3, 5, and 30 day holding periods in Exp. 1. Graphs are cropped to zoom in.

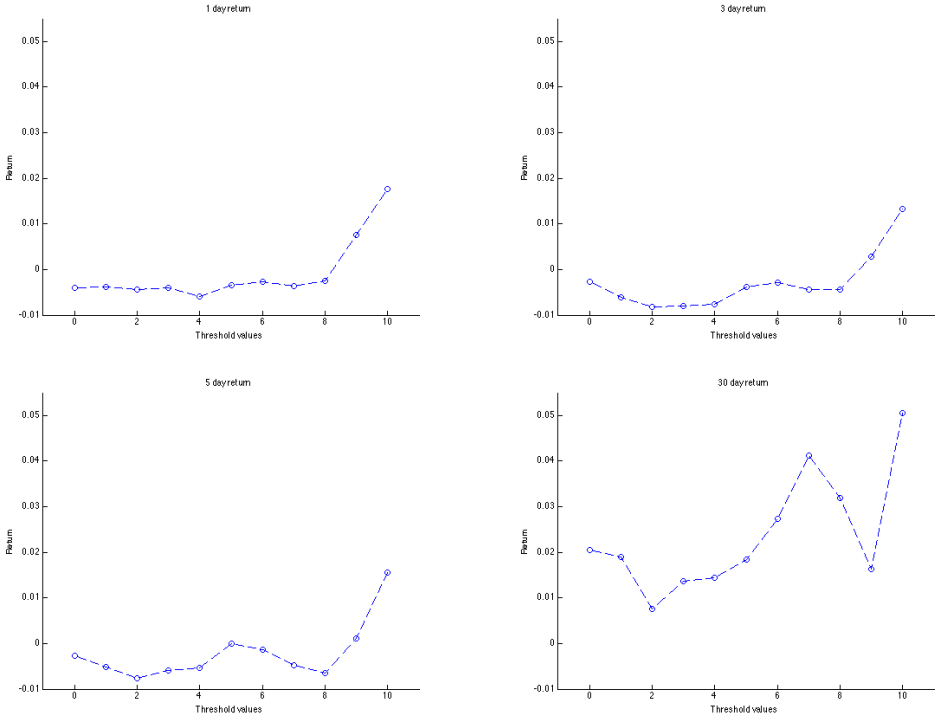

Figure 3: Returns for different thresholds on the development data for 30, 5, 3, and 1 day holding periods in Exp. 2 with safety zone.

BM25 weighted vector the counts of word tokens ending in "n" or "d" as well as the total count of every conjugated form of the copular verb: "be", "is", "am", "are", "were", "was", and "been". These three features are superficial indicators of the passive voice. Clearly, we could have used a part-of-speech tagger to detect the passive voice more reliably, but we are more interested here in how well our task-based evaluation will correspond to a more customary classifier-accuracy evaluation, rather than finding the world's best indicators of the passive voice.

Table 3 presents returns obtained from these 6 feature sets. The feature set with BM25-weighted term frequencies plus the number of copulars and tokens ending in "n", "d" (bm25_freq_dnc) yields higher returns than any other representation attempted on the 5, 3, and 1 day holding periods, and the second-highest on the 30 days holding period. But it has the worst classification accuracy by far: a full 18 percentage points below term presence. This is a very compelling illustration of how misleading an intrinsic evaluation can be.

5 Conclusion

In this paper, we examined sentiment analysis applied to stock trading strategies. We built a binary sentiment classifier that achieves high accuracy when tested on movie data and financial news data from *Reuters*. In four task-based experiments, we evaluated the usefulness of sentiment analysis to simple trading strategies. Although high annual returns are achieved simply by utilizing sentiment labels while trading, they can be increased by incorporating the output of the SVM's decision function. But classification accuracy alone is not an accurate predictor of task-based performance. This calls into question the suitability of intrinsic sentiment classification accuracy, particularly (as here) when the relative cost of a task-based evaluation may be comparably low. We have also determined that training on human-annotated sentiment does in fact perform better than training on market returns themselves. So sentiment analysis is an important component, but it must be tuned against task data.

Our price data only included adjusted opening and closing prices and most of our news data contain only the date of the article, with no specific time. This limits our ability to test much shorter-term trading strategies.

Deriving sentiment labels for supervised training is an important topic for future study, as is inferring the sentiment of published news from stock price fluctuations instead of the reverse. We should also study how "sentiment" is defined in the financial world. This study has used a rather general definition of news sentiment, and a more precise definition may improve trading performance.

Abstract

The run time complexity of state-of-the-art inference algorithms in graph-based dependency parsing is super-linear in the number of input words (n). Recently, pruning algorithms for these models have shown to cut a large portion of the graph edges, with minimal damage to the resulting parse trees. Solving the inference problem in run time complexity determined solely by the number of edges (m) is hence of obvious importance.

We propose such an inference algorithm for first-order models, which encodes the problem as a minimum spanning tree (MST) problem in an *undirected graph*. This allows us to utilize state-of-the-art undirected MST algorithms whose run time is $O(m)$ at expectation and with a very high probability. A directed parse tree is then inferred from the undirected MST and is subsequently improved with respect to the directed parsing model through local greedy updates, both steps running in $O(n)$ time. In experiments with 18 languages, a variant of the first-order MSTParser (McDonald et al., 2005b) that employs our algorithm performs very similarly to the original parser that runs an $O(n^2)$ directed MST inference.

1 Introduction

Dependency parsers are major components of a large number of NLP applications. As application models are applied to constantly growing amounts of data, efficiency becomes a major consideration.

In graph-based dependency parsing models (Eisner, 2000; McDonald et al., 2005a; McDonald et al., 2005b; Carreras, 2007; Koo and Collins, 2010b), given an n word sentence and a model order k, the run time of exact inference is $O(n^3)$ for $k = 1$ and $O(n^{k+1})$ for $k > 1$ in the projective case (Eisner, 1996; McDonald and Pereira, 2006). In the non-projective case it is $O(n^2)$ for $k = 1$ and NP-hard for $k \geq 2$ (McDonald and Satta, 2007). [1] Consequently, a number of approximated parsers have been introduced, utilizing a variety of techniques: the Eisner algorithm (McDonald and Pereira, 2006), belief propagation (Smith and Eisner, 2008), dual decomposition (Koo and Collins, 2010b; Martins et al., 2013) and multi-commodity flows (Martins et al., 2009; Martins et al., 2011). The run time of all these approximations is super-linear in n.

Recent pruning algorithms for graph-based dependency parsing (Rush and Petrov, 2012; Riedel et al., 2012; Zhang and McDonald, 2012) have shown to cut a very large portion of the graph edges, with minimal damage to the resulting parse trees. For example, Rush and Petrov (2012) demonstrated that a single $O(n)$ pass of vine-pruning (Eisner and Smith, 2005) can preserve $> 98\%$ of the correct edges, while ruling out $> 86\%$ of all possible edges. Such results give strong motivation to solving the inference problem in a run time complexity that is determined solely by the number of edges (m). [2]

[1]We refer to parsing approaches that produce only projective dependency trees as projective parsing and to approaches that produce all types of dependency trees as non-projective parsing.

[2]Some pruning algorithms require initial construction of the full graph, which requires exactly $n(n-1)$ edge weight computations. Utilizing other techniques, such as length-dictionary pruning, graph construction and pruning can be

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2104–2113,
Berlin, Germany, August 7-12, 2016.

In this paper we propose to formulate the inference problem in first-order (arc-factored) dependency parsing as a minimum spanning tree (MST) problem in *an undirected graph*. Our formulation allows us to employ state-of-the-art algorithms for the MST problem in undirected graphs, whose run time depends solely on the number of edges in the graph. Importantly, a parser that employs our undirected inference algorithm can generate all possible trees, projective and non-projective.

Particularly, the undirected MST problem (§ 2) has a randomized algorithm which is $O(m)$ at expectation and with a very high probability ((Karger et al., 1995)), as well as an $O(m \cdot \alpha(m,n))$ worst-case deterministic algorithm (Pettie and Ramachandran, 2002), where $\alpha(m,n)$ is a certain natural inverse of Ackermann's function (Hazewinkel, 2001). As the inverse of Ackermann's function grows extremely slowly [3] the deterministic algorithm is in practice linear in m (§ 3). In the rest of the paper we hence refer to the run time of these two algorithms as *practically linear* in the number of edges m.

Our algorithm has four steps (§ 4). First, it encodes the first-order dependency parsing inference problem as an undirected MST problem, in up to $O(m)$ time. Then, it computes the MST of the resulting undirected graph. Next, it infers a *unique* directed parse tree from the undirected MST. Finally, the resulting directed tree is greedily improved with respect to the directed parsing model. Importantly, the last two steps take $O(n)$ time, which makes the total run time of our algorithm $O(m)$ at expectation and with very high probability. [4]

We integrated our inference algorithm into the first-order parser of (McDonald et al., 2005b) and compared the resulting parser to the original parser which employs the Chu-Liu-Edmonds algorithm (CLE, (Chu and Liu, 1965; Edmonds, 1967)) for inference. CLE is the most efficient exact inference algorithm for graph-based first-order non-projective parsers, running at $O(n^2)$ time.[5]

We experimented (§ 5) with 17 languages from the CoNLL 2006 and 2007 shared tasks on multilingual dependency parsing (Buchholz and Marsi, 2006; Nilsson et al., 2007) and in three English setups. Our results reveal that the two algorithms perform very similarly. While the averaged unlabeled attachment accuracy score (UAS) of the original parser is 0.97% higher than ours, in 11 of 20 test setups the number of sentences that are better parsed by our parser is larger than the number of sentences that are better parsed by the original parser.

Importantly, in this work we present an edge-linear first-order dependency parser which achieves similar accuracy to the existing one, making it an excellent candidate to be used for efficient MST computation in k-best trees methods, or to be utilized as an inference/initialization subroutine as a part of more complex approximation frameworks such as belief propagation. In addition, our model produces a different solution compared to the existing one (see Table 2), paving the way for using methods such as dual decomposition to combine these two models into a superior one.

Undirected inference has been recently explored in the context of transition based parsing (Gómez-Rodríguez and Fernández-González, 2012; Gómez-Rodríguez et al., 2015), with the motivation of preventing the propagation of erroneous early edge directionality decisions to subsequent parsing decisions. Yet, to the best of our knowledge this is the first paper to address undirected inference for graph based dependency parsing. Our motivation and algorithmic challenges are substantially different from those of the earlier transition based work.

2 Undirected MST with the Boruvka Algorithm

In this section we define the MST problem in undirected graphs. We then discuss the Burovka algorithm (Boruvka, 1926; Nesetril et al., 2001) which forms the basis for the randomized algorithm of (Karger et al., 1995) we employ in this paper. In the next section we will describe the Karger et al. (1995) algorithm in more details.

Problem Definition. For a connected undirected graph $G(V,E)$, where V is the set of n vertices

jointly performed in $O(n)$ steps. We therefore do not include initial graph construction and pruning in our complexity computations.

[3] $\alpha(m,n)$ is less than 5 for any practical input sizes (m,n).

[4] The output dependency tree contains exactly $n-1$ edges, therefore $m \geq n-1$, which makes $O(m)+O(n)=O(m)$.

[5] CLE has faster implementations: $O(m+nlogn)$ (Gabow et al., 1986) as well as $O(mlogn)$ for sparse graphs (Tarjan, 1977), both are super-linear in n for connected graphs. We refer here to the classical implementation employed by modern parsers (e.g. (McDonald et al., 2005b; Martins et al., 2013)).

and E the set of m weighted edges, the MST problem is defined as finding the sub-graph of G which is the tree (a connected acyclic graph) with the lowest sum of edge weights. The opposite problem – finding the maximum spanning tree – can be solved by the same algorithms used for the minimum variant by simply negating the graph's edge weights.

Graph Contraction. In order to understand the Boruvka algorithm, let us first define the *Graph Contraction* operation. For a given undirected graph $G(V, E)$ and a subset $\tilde{E} \subseteq E$, this operation creates a new graph, $G_C(V_C, E_C)$. In this new graph, V_C consists of a vertex for each connected component in $\tilde{G}(V, \tilde{E})$ (these vertices are referred to as *super-vertices*). E_C, in turn, consists of one edge, $(\hat{u}, \hat{v})$, for each edge $(u, v) \in E \setminus \tilde{E}$, where $\hat{u}, \hat{v} \in V_C$ correspond to $\tilde{G}$'s connected components to which u and v respectively belong. Note that this definition may result in multiple edges between two vertices in V_C (denoted *repetitive edges*) as well as in edges from a vertex in V_C to itself (denoted *self edges*).

Algorithm 1 The basic step of the Boruvka algorithm for the undirected MST problem.

Contract_graph

Input: a graph $G(V, E)$, a subset $\tilde{E} \subseteq E$
$C \leftarrow$ connected components of $\tilde{G}(V, \tilde{E})$
return $G_C(C, E \setminus \tilde{E})$

Boruvka-step

Input: a graph $G(V, E)$
1: **for all** $(u, v) \in E$ **do**
2: **if** $w(u, v) < w(u.minEdge)$ **then**
3: $u.minEdge \leftarrow (u, v)$
4: **end if**
5: **if** $w(u, v) < w(v.minEdge)$ **then**
6: $v.minEdge \leftarrow (u, v)$
7: **end if**
8: **end for**
9: **for all** $v \in V$ **do**
10: $E_m \leftarrow E_m \cup \{v.minEdge\}$
11: **end for**
12: $G_B(V_B, E_B) \leftarrow$ Contract_graph$(G(V, E), E_m)$
13: Remove from E_B self edges and non-minimal repetitive edges
14: **return** $G_B(V_B, E_B), E_m$

The Boruvka-Step. Next, we define the basic step of the Borukva algorithm (see example in Figure 1 and pseudocode in Algorithm 1). In each such step, the algorithm creates a subset $E_m \subset E$ by selecting the minimally weighted edge for each vertex in the input graph $G(V, E)$ (Figure 1 (a,b) and Algorithm 1 (lines 1-11)). Then, it performs the contraction operation on the graph G and E_m to receive a new graph $G_B(V_B, E_B)$ (Figure 1 (c) and Algorithm 1 (12)). Finally, it removes from E_B all self-edges and repetitive edges that are not the minimal edges between the vertices V_B's which they connect (Figure 1 (d) and Algorithm 1 (13)). The set E_m created in each such step is guaranteed to consist only of edges that belong to G's MST and is therefore also returned by the Boruvka step.

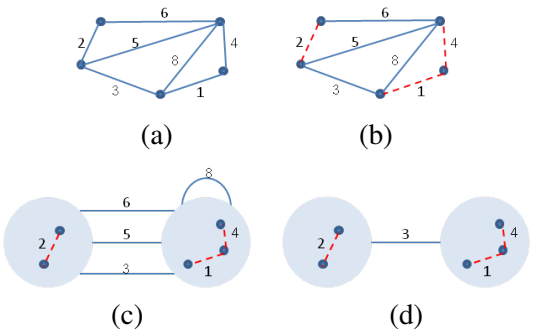

Figure 1: An illustration of a *Boruvka step*: (a) The original graph; (b) Choosing the minimal edge for each vertex (marked in red); (c) The contracted graph; (d) The contracted graph after removing one self edge and two non-minimal repetitive edges.

The Boruvka algorithm runs successive Boruvka-steps until it is left with a single super-vertex. The MST of the original graph G is given by the unification of the E_m sets returned in each step. The resulting computational complexity is $O(m \log n)$ (Nesetril et al., 2001). We now turn to describe how the undirected MST problem can be solved in a time practically linear in the number of graph edges.

3 Undirected MST in Edge Linear Time

There are two algorithms that solve the undirected MST problem in time practically linear in the number of edges in the input graph. These algorithms are based on substantially different approaches: one is deterministic and the other is randomized [6].

[6]Both these algorithms deal with a slightly more general case where the graph is not necessarily connected, in which case the *minimum spanning forest (MSF)* is computed. In our case, where the graph is connected, the MSF reduces to an MST.

The complexity of the first, deterministic, algorithm (Chazelle, 2000; Pettie and Ramachandran, 2002) is $O(m \cdot \alpha(m,n))$, where $\alpha(m,n)$ is a natural inverse of Ackermann's function, whose value for any practical values of n and m is lower than 5. As this algorithm employs very complex data-structures, we do not implement it in this paper.

The second, randomized, algorithm (Karger et al., 1995) has an expected run time of $O(m+n)$ (which for connected graphs is $O(m)$), and this run time is achieved with a high probability of $1 - exp(-\Omega(m))$. [7] In this paper we employ only this algorithm for first-order graph-based parsing inference, and hence describe it in details in this section.

Definitions and Properties. We first quote two properties of undirected graphs (Tarjan, 1983): (1) The **cycle property**: The heaviest edge in a cycle in a graph does not appear in the MSF; and (2) The **cut property**: For any proper nonempty subset V' of the graph vertices, the lightest edge with exactly one endpoint in V' is included in the MSF.

We continue with a number of definitions and observations. Given an undirected graph $G(V,E)$ with weighted edges, and a forest F in that graph, $F(u,v)$ is the path in that forest between u and v (if such a path exists), and $s_F(u,v)$ is the maximum weight of an edge in $F(u,v)$ (if the path does not exist then $s_F(u,v) = \infty$). An edge $(u,v) \in E$ is called *F-heavy* if $s(u,v) > s_F(u,v)$, otherwise it is called *F-light*. An alternative equivalent definition is that an edge is *F-heavy* if adding it to F creates a cycle in which it is the heaviest edge. An important observation (derived from the cycle property) is that for any forest F, no *F-heavy* edge can possibly be a part of an MSF for G. It has been shown that given a forest F, all the *F-heavy* edges in G can be found in $O(m)$ time (Dixon et al., 1992; King, 1995).

Algorithm. The randomized algorithm can be outlined as follows (see pseudocode in algorithm 2): first, two successive Boruvka-steps are applied to the graph (line 4, *Boruvka-step2* stands for two successive Boruvka-steps), reducing the number of vertices by (at least) a factor of 4 to receive a contracted graph G_C and an edge set E_m (§ 2). Then, a subgraph G_s is randomly constructed, such that each edge in G_C, along with the vertices which it connects, is included in G_s with probability $\frac{1}{2}$ (lines 5-10). Next, the algorithm is recursively applied to G_s to obtain its minimum spanning forest F (line 11). Then, all *F-heavy* edges are removed from G_C (line 12), and the algorithm is recursively applied to the resulting graph to obtain a spanning forest F_C (line 13). The union of that forest with the edges E_m forms the requested spanning forest (line 14).

Algorithm 2 Pseudocode for the Randomized MSF algorithm of(Karger et al., 1995).

Randomized_MSF

Input: a graph $G(V,E)$

1: **if** E is empty **then**
2: **return** $\emptyset$
3: **end if**
4: $G_C(V_C,E_C), E_m \leftarrow$ Boruvka-step2(G)
5: **for all** $(u,v) \in E_C$ **do**
6: **if** coin-flip == head **then**
7: $E_s \leftarrow E_s \cup \{(u,v)\}$
8: $V_s \leftarrow V_s \cup \{u,v\}$
9: **end if**
10: **end for**
11: $F \leftarrow$ Randomized_MSF($G_s(V_s,E_s)$)
12: remove all *F-heavy* edges from $G_C(V_C,E_C)$
13: $F_C \leftarrow$ Randomized_MSF($G_C(V_C,E_C)$)
14: **return** $F_C \cup E_m$

Correctness. The correctness of the algorithm is proved by induction. By the cut property, every edge returned by the Boruvka step (line 4), is part of the MSF. Therefore, the rest of the edges in the original graph's MSF form an MSF for the contracted graph. The removed *F-heavy* edges are, by the cycle property, not part of the MSF (line 12). By the induction assumption, the MSF of the remaining graph is then given by the second recursive call (line 13).

4 Undirected MST Inference for Dependency Parsing

There are several challenges in the construction of an *undirected MST parser*: an MST parser that employs an undirected MST algorithm for inference.[8] These challenges stem from the mismatch between the undirected nature of the inference algorithm and the directed nature of the resulting

[7] This complexity analysis is beyond the scope of this paper.

[8] Henceforth, we refer to an MST parser that employs a directed MST algorithm for inference as *directed MST parser*.

parse tree.

The first problem is that of *undirected encoding*. Unlike directed MST parsers that explicitly encode the directed nature of dependency parsing into a directed input graph to which an MST algorithm is applied (McDonald et al., 2005b), an undirected MST parser needs to encode directionality information into an undirected graph. In this section we consider two solutions to this problem.

The second problem is that of *scheme conversion*. The output of an undirected MST algorithm is an undirected tree while the dependency parsing problem requires finding a directed parse tree. In this section we show that for rooted undirected spanning trees there is only one way to define the edge directions under the constraint that the root vertex has no incoming edges and that each non-root vertex has exactly one incoming edge in the resulting directed spanning tree. As dependency parse trees obey the first constraint and the second constraint is a definitive property of directed trees, the output of an undirected MST parser can be transformed into a directed tree using a simple $O(n)$ time procedure.

Unfortunately, as we will see in § 5, even with our best undirected encoding method, an undirected MST parser does not produce directed trees of the same quality as its directed counterpart. At the last part of this section we therefore present a simple, $O(n)$ time, *local enhancement procedure*, that improves the score of the directed tree generated from the output of the undirected MST parser with respect to the edge scores of a standard directed MST parser. That is, our procedure improves the output of the undirected MST parser with respect to a directed model without having to compute the MST of the latter, which would take $O(n^2)$ time.

We conclude this section with a final remark stating that the output class of our inference algorithm is non-projective. That is, it can generate all possible parse trees, projective and non-projective.

Undirected Encoding Our challenge here is to design an encoding scheme that encodes directionality information into the graph of the undirected MST problem. One approach would be to compute directed edge weights according to a feature representation scheme for directed edges (e.g. one of the schemes employed by existing directed MST parsers) and then transform these directed weights into undirected ones.

Specifically, given two vertices u and v with directed edges (u, v) and (v, u), weighted with $s_d(u, v)$ and $s_d(v, u)$ respectively, the goal is to compute the weight $s_u(u\hat{,}v)$ of the undirected edge $(u\hat{,}v)$ connecting them in the undirected graph. We do this using a pre-determined function $f : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$, such that $f(s_d(u, v), s_d(v, u)) = s_u(u\hat{,}v)$. f can take several forms including mean, product and so on. In our experiments the mean proved to be the best choice.

Training with the above approach is implemented as follows. w, the parameter vector of the parser, consists of the weights of *directed features*. At each training iteration, w is used for the computation of $s_d(u, v) = w \cdot \phi(u, v)$ and $s_d(v, u) = w \cdot \phi(v, u)$ (where $\phi(u, v)$ and $\phi(v, u)$ are the feature representations of these directed edges). Then, f is applied to compute the undirected edge score $s_u(u\hat{,}v)$. Next, the undirected MST algorithm is run on the resulting weighted undirected graph, and its output MST is transformed into a directed tree (see below). Finally, this directed tree is used for the update of w with respect to the gold standard (directed) tree.

At test time, the vector w which resulted from the training process is used for s_d computations. Undirected graph construction, undirected MST computation and the undirected to directed tree conversion process are conducted exactly as in training. [9]

Unfortunately, preliminary experiments in our development setup revealed that this approach yields parse trees of much lower quality compared to the trees generated by the directed MST parser that employed the original directed feature set. In § 5 we discuss these results in details.

An alternative approach is to employ an undirected feature set. To implement this approach, we employed the feature set of the MST parser ((McDonald et al., 2005a), Table 1) with one difference: some of the features are directional, distinguishing between the properties of the source (parent) and the target (child) vertices. We stripped those features from that information, which resulted in an undirected version of the feature set.

Under this feature representation, training with undirected inference is simple. w, the parameter vector of the parser, now consists of the weights

[9] In evaluation setup experiments we also considered a variant of this model where the training process utilized directed MST inference. As this variant performed poorly, we exclude it from our discussion in the rest of the paper.

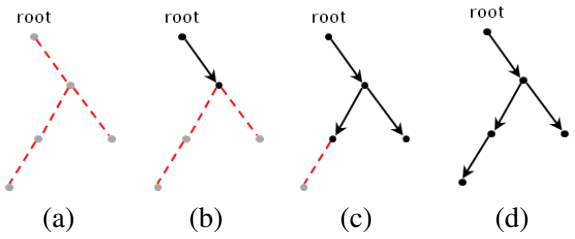

Figure 2: An illustration of directing an undirected tree, given a constrained root vertex: (a) The initial undirected tree; (b) Directing the root's outgoing edge; (c) Directing the root's child's outgoing edges; (d) Directing the last remaining edge, resulting in a directed tree.

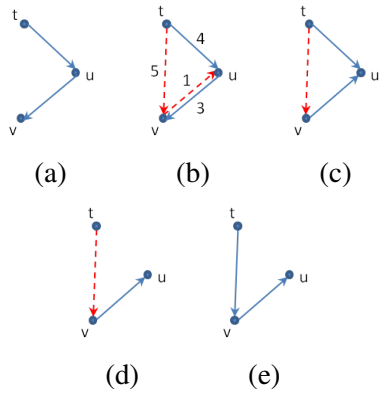

Figure 3: An illustration of the local enhancement procedure for an edge (u, v) in the du-tree. Solid lines indicate edges in the du-tree, while dashed lines indicate edges not in the du-tree. (a) Example subtree; (b) Evaluate $gain = s_d(t,u) + s_d(u,v) - (s_d(t,v) + s_d(v,u)) = 4+3-(5+1) = 1$; (c) In case a modification is made, first replace (u, v) with (v, u); and then (d) Remove the edge (t, u); and, finally, (e) Add the edge (t, v).

of *undirected features*. Once the undirected MST is computed by an undirected MST algorithm, w can be updated with respect to an undirected variant of the gold parse trees. At test time, the algorithm constructs an undirected graph using the vector w resulted from the training process. This graph's undirected MST is computed and then transformed into a directed tree.

Interestingly, although this approach does not explicitly encode edge directionality information into the undirected model, it performed very well in our experiments (§ 5), especially when combined with the local enhancement procedure described below.

Scheme Conversion Once the undirected MST is found, we need to direct its edges in order for the end result to be a directed dependency parse tree. Following a standard practice in graph-based dependency parsing (e.g. (McDonald et al., 2005b)), before inference is performed we add a dummy root vertex to the initial input graph with edges connecting it to all of the other vertices in the graph. Consequently, the final undirected tree will have a designated root vertex. In the resulting directed tree, this vertex is constrained to have only outgoing edges. As observed by Gómez-Rodríguez and Fernández-González (2012), this effectively forces the direction for the rest of the edges in the tree.

Given a root vertex that follows the above constraint, and together with the definitive property of directed trees stating that each non-root vertex in the graph has exactly one incoming edge, we can direct the edges of the undirected tree using a simple BFS-like algorithm (Figure 2). Starting with the root vertex, we mark its undirected edges as outgoing, mark the vertex itself as *done* and its descendants as *open*. We then recursively repeat the same procedure for each open vertex until there are no such vertices left in the tree, at which point we have a directed tree. Note that given the constraints on the root vertex, there is no other way to direct the undirected tree edges. This procedure runs in $O(n)$ time, as it requires a constant number of operations for each of the $n-1$ edges of the undirected spanning tree.

In the rest of the paper we refer to the *directed* tree generated by the undirected and directed MST parsers as *du-tree* and *dd-tree* respectively.

Local Enhancement Procedure As noted above, experiments in our development setup (§ 5) revealed that the directed parser performs somewhat better than the undirected one. This motivated us to develop a local enhancement procedure that improves the tree produced by the undirected model with respect to the directed model without compromising our $O(m)$ run time. Our enhancement procedure is motivated by development experiments, revealing the much smaller gap between the quality of the du-tree and dd-tree of the same sentence under undirected evaluation compared to directed evaluation (§ 5 demonstrates this for test results).

For a du-tree that contains the vertex u and the edges (t, u) and (u, v), we therefore consider the replacement of (u, v) with (v, u). Note that after this change our graph would no longer be a directed tree, since it would cause u to have two parents, v and t, and v to have no parent. This, however, can be rectified by replacing the edge (t, u) with the edge (t, v).

It is easy to infer whether this change results in a better (lower weight) spanning tree under the directed model by computing the equation: $gain = s_d(t,u) + s_d(u,v) - (s_d(t,v) + s_d(v,u))$, where $s_d(x,y)$ is the score of the edge (x,y) according to the directed model. This is illustrated in Figure 3.

Given the du-tree, we traverse its edges and compute the above gain for each. We then choose the edge with the maximal positive gain, as this forms the maximal possible decrease in the directed model score using modifications of the type we consider, and perform the corresponding modification. In our experiments we performed this procedure five times per inference problem.[10] This procedure performs a constant number of operations for each of the $n-1$ edges of the du-tree, resulting in $O(n)$ run time.

Output Class. Our undirected MST parser is non-projective. This stems from the fact that the undirected MST algorithms we discuss in § 3 do not enforce any structural constraint, and particularly the non-crossing constraint, on the resulting undirected MST. As the scheme conversion (edge directing) and the local enhancement procedures described in this section do not enforce any such constraint as well, the resulting tree can take any possible structure.

5 Experiments and Results

Experimental setup We evaluate four models: (a) The original directed parser (D-MST, (McDonald et al., 2005b)); (b) Our undirected MST parser with undirected features and with the local enhancement procedure (U-MST-uf-lep);[11] (c) Our undirected MST parser with undirected features but without the local enhancement procedure (U-MST-uf); and (d) Our undirected MST parser with directed features (U-MST-df). All models are implemented within the MSTParser code[12].

The MSTParser does not prune its input graphs. To demonstrate the value of undirected parsing for sparse input graphs, we implemented the length-dictionary pruning strategy which eliminates all edges longer than the maximum length observed for each *directed* head-modifier POS pair in the training data. An undirected edge $\hat{(u,v)}$ is pruned iff both directed edges (u,v) and (v,u) are to be pruned according to the pruning method. To estimate the accuracy/graph-size tradeoff provided by undirected parsing (models (b)-(d)), we apply the pruning strategy only to these models leaving the the D-MST model (model (a)) untouched. This way D-MST runs on a complete directed graph with n^2 edges.

Our models were developed in a monolingual setup: training on sections 2-21 of WSJ PTB (Marcus et al., 1993) and testing on section 22. The development phase was devoted to the various decisions detailed throughout this paper and to the tuning of the single hyperparameter: the number of times the local enhancement procedure is executed.

We tested the models in 3 English and 17 multilingual setups. The English setups are: (a) *PTB*: training on sections 2-21 of the WSJ PTB and testing on its section 23; (b) *GENIA*: training with a random sample of 90% of the 4661 GENIA corpus (Ohta et al., 2002) sentences and testing on the other 10%; and (c) *QBank*: a setup identical to (b) for the 3987 QuestionBank (Judge et al., 2006) sentences. Multilingual parsing was performed with the multilingual datasets of the CoNLL 2006 (Buchholz and Marsi, 2006) and 2007 (Nilsson et al., 2007) shared tasks on multilingual dependency parsing, following their standard train/test split. Following previous work, punctuation was excluded from the evaluation.

Length-dictionary pruning reduces the number of undirected edges by 27.02% on average across our 20 setups (std = 11.02%, median = 23.85%), leaving an average of 73.98% of the edges in the undirected graph. In 17 of 20 setups the reduction is above 20%. Note that the number of edges in a complete directed graph is twice the number in its undirected counterpart. Therefore, on average, the number of input edges in the pruned undirected models amounts to $\frac{73.98\%}{2} = 36.49\%$ of the number of edges in the complete directed graphs. In fact, every edge-related operation (such as feature extraction) in the undirected model is actually performed on half of the number of edges compared to the directed model, saving run-time not only in the MST-inference stage but in every stage involving these operations. In addition, some pruning methods, such as length-dictionary pruning (used

[10] This hyperparameter was estimated once on our English development setup, and used for all 20 multilingual test setups.

[11] The directed edge weights for the local enhancement procedure (s_d in § 4) were computed using the trained D-MST parser.

Improvement over the directed UAS score of D-MST is given in parenthesis.

in this work) perform feature extraction only for existing (un-pruned) edges, meaning that any reduction in the number of edges also reduces feature extraction operations.

For each model we report the standard directed unlabeled attachment accuracy score (D-UAS). In addition, since this paper explores the value of undirected inference for a problem that is directed in nature, we also report the undirected unlabeled attachment accuracy score (U-UAS), hoping that these results will shed light on the differences between the trees generated by the different models.

Results Table 1 presents our main results. While the directed MST parser (D-MST) is the best performing model across almost all test sets and evaluation measures, it outperforms our best model, U-MST-uf-lep, by a very small margin.

Particularly, for D-UAS, D-MST outperforms U-MST-uf-lep by up to 1% in 14 out of 20 setups (in 6 setups the difference is up to 0.5%). In 5 other setups the difference between the models is between 1% and 2%, and only in one setup it is above 2% (2.6%). Similarly, for U-UAS, in 2 setups the models achieve the same performance, in 15 setups the difference is less than 1% and in the other setups the differences is 1.1% - 1.5%. The average differences are 0.97% and 0.67% for D-UAS and U-UAS respectively.

The table further demonstrates the value of the local enhancement procedure. Indeed, U-MST-uf-lep outperforms U-MST in all 20 setups in D-UAS evaluation and in 15 out of 20 setups in U-UAS evaluation (in one setup there is a tie). However, the improvement this procedure provides is much more noticeable for D-UAS, with an averaged improvement of 2.35% across setups, compared to an averaged U-UAS improvement of only 0.26% across setups. While half of the changes performed by the local enhancement procedure are in edge directions, its marginal U-UAS improvement indicates that almost all of its power comes from edge direction changes. This calls for an improved enhancement procedure.

Finally, moving to directed features (the U-MST-df model), both D-UAS and U-UAS substantially degrade, with more noticeable degradation in the former. We hypothesize that this stems from the idiosyncrasy between the directed parameter update and the undirected inference in this model.

Table 2 reveals the complementary nature of our U-MST-uf-lep model and the classical D-MST: each of the models outperforms the other on an average of 22.2% of the sentences across test setups. An oracle model that selects the parse tree of the best model for each sentence would improve D-UAS by an average of 1.2% over D-MST across the test setups.

The results demonstrate the power of first-order graph-based dependency parsing with undirected inference. Although using a substantially different inference algorithm, our U-MST-uf-lep model performs very similarly to the standard MST parser which employs directed MST inference.

6 Discussion

We present a first-order graph-based dependency parsing model which runs in edge linear time at expectation and with very high probability. In extensive multilingual experiments our model performs very similarly to a standard directed first-order parser. Moreover, our results demonstrate the complementary nature of the models, with our model outperforming its directed counterpart on an average of 22.2% of the test sentences.

Beyond its practical implications, our work provides a novel intellectual contribution in demonstrating the power of undirected graph based methods in solving an NLP problem that is directed in nature. We believe this contribution has the potential to affect future research on additional NLP problems.

The potential embodied in this work extends to a number of promising research directions:

- Our algorithm may be used for efficient MST computation in k-best trees methods which are instrumental in margin-based training algorithms. For example, McDonald et al. (2005b) observed that k calls to the CLU algorithm might prove to be too inefficient; our more efficient algorithm may provide the remedy.

- It may also be utilized as an inference/initialization subroutine as a part of more complex approximation frameworks such as belief propagation (e.g. Smith and Eisner (2008), Gormley et al. (2015)).

- Finally, the complementary nature of the directed and undirected parsers motivates the development of methods for their combination, such as dual decomposition (e.g. Rush et al. (2010), Koo et al. (2010a)). Particularly, we have shown that our undirected inference algorithm converges to a different solution than the standard directed solution while still maintaining high quality (Table 2). Such techniques can exploit this diversity to produce a higher quality unified solution.

We intend to investigate all of these directions in future work. In addition, we are currently exploring potential extensions of the techniques presented in this paper to higher order, projective and non-projective, dependency parsing.

Abstract

Conventional topic models are ineffective for topic extraction from microblog messages since the lack of structure and context among the posts renders poor message-level word co-occurrence patterns. In this work, we organize microblog posts as conversation trees based on reposting and replying relations, which enrich context information to alleviate data sparseness. Our model generates words according to topic dependencies derived from the conversation structures. In specific, we differentiate messages as leader messages, which initiate key aspects of previously focused topics or shift the focus to different topics, and follower messages that do not introduce any new information but simply echo topics from the messages that they repost or reply. Our model captures the different extents that leader and follower messages may contain the key topical words, thus further enhances the quality of the induced topics. The results of thorough experiments demonstrate the effectiveness of our proposed model.

1 Introduction

The increasing popularity of microblog platforms results in a huge volume of user-generated short posts. Automatically modeling topics out of such massive microblog posts can uncover the hidden semantic structures of the underlying collection and can be useful to downstream applications such as microblog summarization (Harabagiu and Hickl, 2011), user profiling (Weng et al., 2010), event tracking (Lin et al., 2010) and so on.

Popular topic models, like Probabilistic Latent Semantic Analysis (pLSA) (Hofmann, 1999) and Latent Dirichlet Allocation (LDA) (Blei et al., 2003b), model the semantic relationships between words based on their co-occurrences in documents. They have demonstrated their success in conventional documents such as news reports and scientific articles, but perform poorly when directly applied to short and colloquial microblog content due to severe sparsity in microblog messages (Wang and McCallum, 2006; Hong and Davison, 2010).

A common way to deal with short text sparsity is to aggregate short messages into long pseudo-documents. Most of the studies heuristically aggregate messages based on authorship (Zhao et al., 2011; Hong and Davison, 2010), shared words (Weng et al., 2010), or hashtags (Ramage et al., 2010; Mehrotra et al., 2013). Some works directly take into account the word relations to alleviate document-level word sparseness (Yan et al., 2013; Sridhar, 2015). More recently, a self-aggregation-based topic model called SATM (Quan et al., 2015) was proposed to aggregate texts jointly with topic inference.

However, we argue that the existing aggregation strategies are suboptimal for modeling topics in short texts. Microblogs allow users to share and comment on messages with friends through reposting or replying, similar to our everyday conversations. Intuitively, the conversation structures can not only enrich context, but also provide useful clues for identifying relevant topics. This is nonetheless ignored in previous approaches. Moreover, the occurrence of non-topic words such as emotional, sentimental, functional and even meaningless words are very common in microblog posts, which may distract the models from recognizing topic-related key words and thus fail to produce coherent and meaningful topics.

We propose a novel topic model by utilizing the structures of conversations in microblogs. We link microblog posts using reposting and replying rela-

Berlin, Germany, August 7-12, 2016.

tions to build conversation trees. Particularly, the root of a conversation tree refers to the original post and its edges represent the reposting/replying relations.

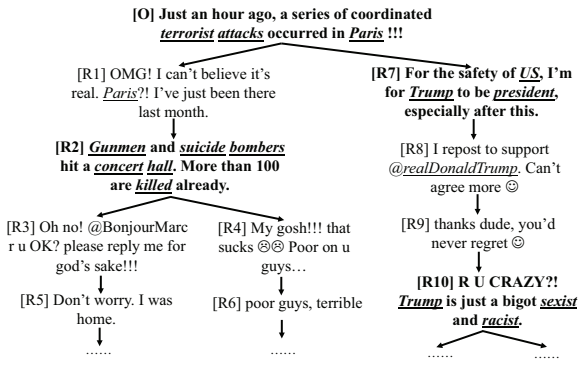

Figure 1: An example of conversation tree. [O]: the original post; [Ri]: the i-th repost/reply; Arrow lines: reposting/replying relations; Dark black posts: leaders to be detected; Underlined italic words: key words representing topics

Figure 1 illustrates an example of a conversation tree, in which messages can initiate a new topic such as [O] and [R7] or raise a new aspect (subtopic) of the previously discussed topics such as [R2] and [R10]. These messages are named as **leaders**, which contain salient content in topic description, e.g., the italic and underlined words in Figure 1. The remaining messages, named as **followers**, do not raise new issues but simply respond to their reposted or replied messages following what has been raised by the leaders and often contain non-topic words, e.g., *OMG*, *OK*, *agree*, etc.

Conversation tree structures from microblogs have been previously shown helpful to microblog summarization (Li et al., 2015), but have never been explored for topic modeling. We follows Li et al. (2015) to detect leaders and followers across paths of conversation trees using Conditional Random Fields (CRF) trained on annotated data. The detected leader/follower information is then incorporated as prior knowledge into our proposed topic model.

Our experimental results show that our model, which captures parent-child topic correlations in conversation trees and generates topics by considering messages being leaders or followers separately, is able to induce high-quality topics and outperforms a number of competitive baselines. In summary, our contributions are three-fold:

- We propose a novel topic model, which explicitly exploits the topic dependencies contained in conversation structures to enhance topic assignments.
- Our model differentiates the generative process of topical and non-topic words, according to the message where a word is drawn from being a leader or a follower. This helps the model distinguish the topic-specific information from background noise.
- Our model outperforms state-of-the-art topic models when evaluated on a large real-world microblog dataset containing over 60K conversation trees, which is publicly available[1].

2 Related Works

Topic models aim to discover the latent semantic information, i.e., topics, from texts and have been extensively studied. One of the most popular and well-known topic models is LDA (Blei et al., 2003b). It utilizes Dirichlet priors to generate document-topic and topic-word distributions, and has been shown effective in extracting topics from conventional documents.

Nevertheless, prior research has demonstrated that standard topic models, essentially focusing on document-level word co-occurrences, are not suitable for short and informal microblog messages due to severe data sparsity exhibited in short texts (Wang and McCallum, 2006; Hong and Davison, 2010). Therefore, how to enrich and exploit context information becomes a main concern. Weng et al. (2010), Hong et al. (2010) and Zhao et al. (2011) first heuristically aggregated messages posted by the same user or sharing the same words before applying classic topic models to extract topics. However, such a simple strategy poses some problems. For example, it is common that a user has various interests and posts messages covering a wide range of topics. Ramage et al. (2010) and Mehrotra et al. (2013) used hashtags as labels to train supervised topic models. But these models depend on large-scale hashtag-labeled data for model training, and their performance is inevitably compromised when facing unseen topics irrelevant to any hashtag in training data due to the rapid change and wide variety of topics in social media.

SATM (Quan et al., 2015) combined short texts aggregation and topic induction into a unified model. But in their work, no prior knowledge

[1] http://www1.se.cuhk.edu.hk/~lijing/data/microblog-topic-extraction-data.zip

was given to ensure the quality of text aggregation, which therefore can affect the performance of topic inference. In this work, we organize microblog messages as conversation trees based on reposting/reply relations, which is a more advantageous message aggregation strategy.

Another line of research tackled the word sparseness by modeling word relations instead of word occurrences in documents. For example, Gaussian Mixture Topic Model (GMTM) (Sridhar, 2015) utilized word embeddings to model the distributional similarities of words and then inferred clusters of words represented by word distributions using Gaussian Mixture Model (GMM) that capture the notion of latent topics. However, GMTM heavily relies on meaningful word embeddings that require a large volume of high-quality external resources for training.

Biterm Topic Model (BTM) (Yan et al., 2013) directly explores unordered word-pair co-occurrence patterns in each individual message. Our model learns topics from aggregated messages based on conversation trees, which naturally provide richer context since word co-occurrence patterns can be captured from multiple relevant messages.

3 LeadLDA Topic Model

In this section, we describe how to extract topics from a microblog collection utilizing conversation tree structures, where the trees are organized based on reposting and replying relations among the messages[2].

To identify key topic-related content from colloquial texts, we differentiate the messages as *leaders* and *followers*. Following Li et al. (2015), we extract all root-to-leaf paths on conversation trees and utilize the state-of-the-art sequence learning model CRF (Lafferty et al., 2001) to detect the leaders[3]. As a result, the posterior probability of each node being a leader or follower is obtained by averaging the different marginal probabilities of the same node over all the tree paths that contain the node. Then, the obtained probability distribution is considered as the observed prior variable input into our model.

[2]Reposting/replying relations are straightforward to obtain by using microblog APIs from Twitter and Sina Weibo.

[3]The CRF model for leader detection was trained on a public corpus with all the messages annotated on the tree paths. Details are described in Section 4.

3.1 Topics and Conversation Trees

Previous works (Zhao et al., 2011; Yan et al., 2013; Quan et al., 2015) have proven that assuming each short post contains a single topic is useful to alleviate the data sparsity problem. Thus, given a corpus of microblog posts organized as conversation trees and the estimated leader probabilities of tree nodes, we assume that each message only contains a single topic and a tree covers a mixture of multiple topics. Since leader messages subsume the content of their followers, the topic of a leader can be generated from the topic distribution of the entire tree. Consequently, the topic mixture of a conversation tree is determined by the topic assignments to the leader messages on it. The topics of followers, however, exhibit strong and explicit dependencies on the topics of their ancestors. So, their topics need to be generated in consideration of local constraints. Here, we mainly address how to model the topic dependencies of followers.

Enlighten by the general Structural Topic Model (strTM) (Wang et al., 2011), which incorporates document structures into topic model by explicitly modeling topic dependencies between adjacent sentences, we exploit the topical transitions between parents and children in the trees for guiding topic assignments.

Intuitively, the emergence of a leader results in potential topic shift. It tends to weaken the topic similarities between the emerging leaders and their predecessors. For example, [R7] in Figure 1 transfers the topic to a new focus, thus weakens the tie with its parent. We can simplify our case by assuming that followers are topically responsive just up to (hence not further than) their nearest ancestor leaders. Thus, we can dismantle each conversation tree into forest by removing the links between leaders and their parents hence producing a set of subgraphs like [R2]–[R6] and [R7]–[R9] in Figure 1. Then, we model the internal topic dependencies within each subgraph by inferring the parent-child topic transition probabilities satisfying the first-order Markov properties in a similar way as estimating the transition distribution of adjacent sentences in strTM (Wang et al., 2011). At topic assignment stage, the topic of a follower will be assigned by referring to its parent's topic and the transition distribution that captures topic similarities of followers to their parents (see Section 3.2).

In addition, every word in the corpus is either

a topical or non-topic (i.e., background) word, which highly depends on whether it occurs in a leader or a follower message.

Figure 2 illustrates the graphical model of our generative process, which is named as LeadLDA.

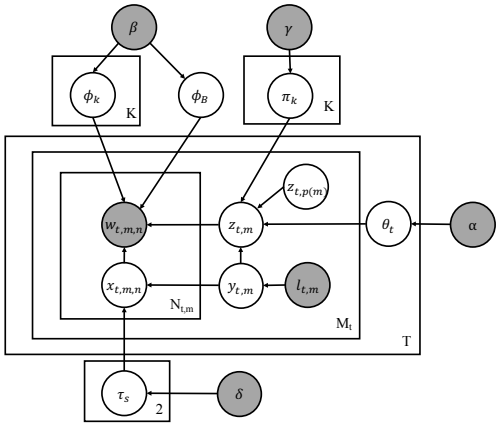

Figure 2: Graphical Model of LeadLDA

3.2 Topic Modeling

Formally, we assume that the microblog posts are organized as T conversation trees. Each tree t contains M_t message nodes and each message m contains $N_{t,m}$ words in the vocabulary. The vocabulary size is V and there are K topics embedded in the corpus represented by word distribution $\phi_k \sim Dir(\beta)$ $(k = 1, 2, ..., K)$. Also, a background word distribution $\phi_B \sim Dir(\beta)$ is included to capture the general information, which is not topic specific. ϕ_k and ϕ_B are multinomial distributions over the vocabulary. A tree t is modeled as a mixture of topics $\theta_t \sim Dir(\alpha)$ and any message m on t is assumed to contain a single topic $z_{t,m} \in \{1, 2, ..., K\}$.

(1) Topic assignments: The topic assignments of LeadLDA is inspired by Griffiths et al. (2004) that combines syntactic and semantic dependencies between words. LeadLDA integrates the outcomes of leader detection with a binomial switcher $y_{t,m} \in \{0, 1\}$ indicating whether m is a leader $(y_{t,m} = 1)$ or a follower $(y_{t,m} = 0)$, given each message m on the tree t. $y_{t,m}$ is parameterized by its leader probability $l_{t,m}$, which is the posterior probability output from the leader detection model and serves as an observed prior variable.

According to the notion of leaders, they initiate key aspects of previously discussed topics or signal a new topic shifting the focus of its descendant followers. So, the topics of leaders on tree t are directly sampled from the topic mixture θ_t.

To model the internal topic correlations within the subgraph of conversation tree consisting of a leader and all its followers, we capture parent-child topic transitions $\pi_k \sim Dir(\gamma)$, which is a distribution over K topics, and use $\pi_{k,j}$ to denote the probability of a follower assigned topic j when the topic of its parent is k. Specifically, if message m is sampled as a follower and the topic assignment to its parent message is $z_{t,p(m)}$, where $p(m)$ indexes the parent of m, then $z_{t,m}$ (i.e., the topic of m) is generated from topic transition distribution $\pi_{z_{t,p(m)}}$. In particular, since the root of a conversation tree has no parent and can only be a leader, we make the leader probability $l_{t,root} = 1$ to force its topic only to be generated from the topic distribution of tree t.

(2) Topical and non-topic words: We separately model the distributions of leader and follower messages emitting topical or non-topic words with τ_0 and τ_1, respectively, both of which are drawn from a symmetric Beta prior parametererized by δ. Specifically, for each word n in message m on tree t, we add a binomial background switcher $x_{t,m,n}$ controlled by whether m is a leader or a follower, i.e., $x_{t,m,n} \sim Bi(\tau_{y_{t,m}})$, which indicates n is a topical word if $x_{t,m,n} = 0$ or a background word if $x_{t,m,n} = 1$, and $x_{t,m,n}$ controls n to be generated from the topic-word distribution $\phi_{z_{t,m}}$, where $z_{t,m}$ is the topic of m, or from background word distribution ϕ_B modeling non-topic information.

(3) Generation process: To sum up, conditioned on the hyper-parameters $\Theta = (\alpha, \beta, \gamma, \delta)$, the generation process of a conversation tree t can be described as follows:

- Draw $\theta_t \sim Dir(\alpha)$
- For message $m = 1$ to M_t on tree t
  - Draw $y_{t,m} \sim Bi(l_{t,m})$
  - If $y_{t,m} == 1$
    - Draw $z_{t,m} \sim Mult(\theta_t)$
  - If $y_{t,m} == 0$
    - Draw $z_{t,m} \sim Mult(\pi_{z_{t,p(m)}})$
  - For word $n = 1$ to $N_{t,m}$ in m
    - Draw $x_{t,m,n} \sim Bi(\tau_{y_{t,m}})$
    - If $x_{t,m,n} == 0$
      - Draw $w_{t,m,n} \sim Mult(\phi_{z_{t,m}})$
    - If $x_{t,m,n} == 1$
      - Draw $w_{t,m,n} \sim Mult(\phi_B)$

$C^{LB}_{s,(r)}$	# of words with background switchers assigned as r and occurring in messages with leader switchers s.
$C^{LB}_{s,(\cdot)}$	# of words occurring in messages whose leader switchers are s, i.e., $\sum_{r\in\{0,1\}} C^{LB}_{s,(r)}$.
$N^{B}_{(r)}$	# of words occurring in message (t,m) and with background switchers assigned as r.
$N^{B}_{(\cdot)}$	# of words in message (t,m), i.e., $N^{B}_{(\cdot)} = \sum_{r\in\{0,1\}} N^{B}_{(r)}$.
$C^{TW}_{k,(v)}$	# of words indexing v in vocabulary, sampled as topic (non-background) words, and occurring in messages assigned topic k.
$C^{TW}_{k,(\cdot)}$	# of words assigned as topic (non-background) word and occurring in messages assigned topics k, i.e., $C^{TW}_{k,(\cdot)} = \sum_{v=1}^{V} C^{TW}_{k,(v)}$.
$N^{W}_{(v)}$	# of words indexing v in vocabulary that occur in message (t,m) and are assigned as topic (non-background) word.
$N^{W}_{(\cdot)}$	# of words assigned as topic (non-background) words and occurring in message (t,m), i.e., $N^{W}_{(\cdot)} = \sum_{v=1}^{V} N^{W}_{(v)}$.
$C^{TR}_{i,(j)}$	# of messages sampled as followers and assigned topic j, whose parents are assigned topic i.
$C^{TR}_{i,(\cdot)}$	# of messages sampled as followers whose parents are assigned topic i, i.e., $C^{TR}_{i,(\cdot)} = \sum_{j=1}^{K} C^{TR}_{i,(j)}$.
$I(\cdot)$	An indicator function, whose value is 1 when its argument inside () is true, and 0 otherwise.
$N^{CT}_{(j)}$	# of messages that are children of message (t,m), sampled as followers and assigned topic j.
$N^{CT}_{(\cdot)}$	# of message (t,m)'s children sampled as followers, i.e., $N^{CT}_{(\cdot)} = \sum_{j=1}^{K} N^{CT}_{(j)}$
$C^{TT}_{t,(k)}$	# of messages on conversation tree t sampled as leaders and assigned topic k.
$C^{TT}_{t,(\cdot)}$	# of messages on conversation tree t sampled as leaders, i.e., $C^{TT}_{t,(\cdot)} = \sum_{k=1}^{K} C^{TT}_{t,(k)}$
$C^{BW}_{(v)}$	# of words indexing v in vocabulary and assigned as background (non-topic) words
$C^{BW}_{(\cdot)}$	# of words assigned as background (non-topic) words, i.e., $C^{BW}_{(\cdot)} = \sum_{v=1}^{V} C^{BW}_{(v)}$

Table 1: The notations of symbols in the sampling formulas (1) and (2). (t,m): message m on conversation tree t.

3.3 Inference for Parameters

We use collapsed Gibbs Sampling (Griffiths, 2002) to carry out posterior inference for parameter learning. The hidden multinomial variables, i.e., message-level variables (y and z) and word-level variables (x) are sampled in turn, conditioned on a complete assignment of all other hidden variables. Due to the space limitation, we leave out the details of derivation but give the core formulas in the sampling steps.

We first define the notations of all variables needed by the formulation of Gibbs sampling, which are described in Table 1. In particular, the various C variables refer to counts excluding the message m on conversation tree t.

For each message m on a tree t, we sample the leader switcher $y_{t,m}$ and topic assignment $z_{t,m}$ according to the following conditional probability distribution:

$$\begin{aligned} &p(y_{t,m}=s, z_{t,m}=k|\mathbf{y}_{\neg(t,m)}, \mathbf{z}_{\neg(t,m)}, \mathbf{w}, \mathbf{x}, \mathbf{l}, \Theta) \\ \propto &\frac{\Gamma(C^{LB}_{s,(\cdot)}+2\delta)}{\Gamma(C^{LB}_{s,(\cdot)}+N^{B}_{(\cdot)}+2\delta)} \prod_{r\in\{0,1\}} \frac{\Gamma(C^{LB}_{s,(r)}+N^{B}_{(r)}+\delta)}{\Gamma(C^{LB}_{s,(r)}+\delta)} \\ \cdot &\frac{\Gamma(C^{TW}_{k,(\cdot)}+V\beta)}{\Gamma(C^{TW}_{k,(\cdot)}+N^{W}_{(\cdot)}+V\beta)} \prod_{v=1}^{V} \frac{\Gamma(C^{TW}_{k,(v)}+N^{W}_{(v)}+\beta)}{\Gamma(C^{TW}_{k,(v)}+\beta)} \\ \cdot &g(s,k,t,m) \end{aligned} \tag{1}$$

where $g(s,k,t,m)$ takes different forms depending on the value of s:

$$\begin{aligned} g(0,k,t,m) = &\frac{\Gamma(C^{TR}_{z_{t,p(m)},(\cdot)}+K\gamma)}{\Gamma(C^{TR}_{z_{t,p(m)},(\cdot)}+I(z_{t,p(m)}\neq k)+K\gamma)} \\ \cdot &\frac{\Gamma(C^{TR}_{k,(\cdot)}+K\gamma)}{\Gamma(C^{TR}_{k,(\cdot)}+I(z_{t,p(m)}=k)+N^{CT}_{(\cdot)}+K\gamma)} \\ \cdot &\prod_{j=1}^{K} \frac{\Gamma(C^{TR}_{k,(j)}+N^{CT}_{(j)}+I(z_{t,p(m)}=j=k)+\gamma)}{\Gamma(C^{TR}_{k,(j)}+\gamma)} \\ \cdot &\frac{\Gamma(C^{TR}_{z_{t,p(m)},(k)}+I(z_{t,p(m)}\neq k)+\gamma)}{\Gamma(C^{TR}_{z_{t,p(m)},(k)}+\gamma)} \cdot (1-l_{t,m}) \end{aligned}$$

and

$$g(1,k,t,m) = \frac{C^{TT}_{t,(k)}+\alpha}{C^{TT}_{t,(\cdot)}+K\alpha} \cdot l_{t,m}$$

For each word n in m on t, the sampling formula of its background switcher is given as the following:

$$\begin{aligned} &p(x_{t,m,n}=r|\mathbf{x}_{\neg(t,m,n)}, \mathbf{y}, \mathbf{z}, \mathbf{w}, \mathbf{l}, \Theta) \\ \propto &\frac{C^{LB}_{y_{t,m},(r)}+\delta}{C^{LB}_{y_{t,m},(\cdot)}+2\delta} \cdot h(r,t,m,n) \end{aligned} \tag{2}$$

where

$$h(r,t,m,n) = \begin{cases} \frac{C^{TW}_{z_{t,m},(w_{t,m,n})}+\beta}{C^{TW}_{z_{t,m},(\cdot)}+V\beta} & \text{if } r=0 \\ \frac{C^{BW}_{(w_{t,m,n})}+\beta}{C^{BW}_{(\cdot)}+V\beta} & \text{if } r=1 \end{cases}$$

4 Data Collection and Experiment Setup

To evaluate our LeadLDA model, we conducted experiments on real-world microblog dataset collected from Sina Weibo that has the same 140-character limitation and shares the similar market penetration as Twitter (Rapoza, 2011). For the hyper-parameters of LeadLDA, we fixed $\alpha = 50/K$, $\beta = 0.1$, following the common practice in previous works (Griffiths and Steyvers, 2004; Quan et al., 2015). Since there is no analogue of γ and δ in prior works, where γ controls topic dependencies of follower messages to their ancestors and δ controls the different tendencies of

Month	# of trees	# of messages	Vocab size
May	10,812	38,926	6,011
June	29,547	98,001	9,539
July	26,103	102,670	10,121

Table 2: Statistics of our three evaluation datasets

leaders and followers covering topical and non-topic words. We tuned γ and δ by grid search on a large development set containing around 120K posts and obtained $\gamma = 50/K$, $\delta = 0.5$.

Because the content of posts are often incomplete and informal, it is difficult to manually annotate topics in a large scale. Therefore, we follow Yan et al. (2013) to utilize hashtags led by '#', which are manual topic labels provided by users, as ground-truth categories of microblog messages. We collected the real-time trending hashtags on Sina Weibo and utilized the hashtag-search API[4] to crawl the posts matching the given hashtag queries. In the end, we built a corpus containing 596,318 posts during May 1 – July 31, 2014.

To examine the performance of models on various topic distributions, we split the corpus into 3 datasets, each containing messages of one month. Similar to Yan et al. (2013), for each dataset, we manually selected 50 frequent hashtags as topics, e.g. #mh17, #worldcup, etc. The experiments were conducted on the subsets of posts with the selected hashtags. Table 2 shows the statistics of the three subsets used in our experiments.

We preprocessed the datasets before topic extraction in the following steps: 1) Use FudanNLP toolkit (Qiu et al., 2013) for word segmentation, stop words removal and POS tagging for Chinese Weibo messages; 2) Generate a vocabulary for each dataset and remove words occurring less than 5 times; 3) Remove all hashtags in texts before input them to models, since the models are expected to extract topics without knowing the hashtags, which are ground-truth topics; 4) For LeadLDA, we use the CRF-based leader detection model (Li et al., 2015) to classify messages as leaders and followers. The leader detection model was implemented by using CRF++[5], which was trained on the public dataset composed of 1,300 conversation paths and achieved state-of-the-art 73.7% F1-score of classification accuracy (Li et al., 2015).

5 Experimental Results

We evaluated topic models with two sets of K, i.e., the number of topics. One is $K = 50$, to match the count of hashtags following Yan et al. (2013), and the other is $K = 100$, much larger than the "real" number of topics. We compared LeadLDA with the following 5 state-of-the-art basedlines.

TreeLDA: Analogous to Zhao et al. (2011), where they aggregated messages posted by the same author, TreeLDA aggregates messages from one conversation tree as a pseudo-document. Additionally, it includes a background word distribution to capture non-topic words controlled by a general Beta prior without differentiating leaders and followers. TreeLDA can be considered as a degeneration of LeadLDA, where topics assigned to all messages are generated from the topic distributions of the conversation trees they are on.

StructLDA: It is another variant of LeadLDA, where topics assigned to all messages are generated based on topic transitions from their parents. The strTM (Wang et al., 2011) utilized a similar model to capture the topic dependencies of adjacent sentences in a document. Following strTM, we add a dummy topic T_{start} emitting no word to the "pseudo parents" of root messages. Also, we add the same background word distribution to capture non-topic words as TreeLDA does.

BTM: Biterm Topic Model (BTM)[6] (Yan et al., 2013) directly models topics of all word pairs (biterms) in each post, which outperformed LDA, Mixture of Unigrams model, and the model proposed by Zhao et al. (2011) that aggregated posts by authorship to enrich context.

SATM: A general unified model proposed by Quan et al. (2015) that aggregates documents and infers topics simultaneously. We implemented SATM and examined its effectiveness specifically on microblog data.

GMTM: To tackle word sparseness, Sridhar et al. (2015) utilized Gaussian Mixture Model (GMM) to cluster word embeddings generated by a log-linear word2vec model[7].

The hyper-parameters of BTM, SATM and GMTM were set according to the best hyper-parameters reported in their original papers. For TreeLDA and StructLDA, the parameter settings were kept the same as LeadLDA since they are its

[6] https://github.com/xiaohuiyan/BTM

[7] https://code.google.com/archive/p/word2vec/

variants. And the background switchers were parameterized by symmetric Beta prior on 0.5, following Chemudugunta et al. (2006). We ran Gibbs samplings (in LeadLDA, TreeLDA, StructLDA, BTM and SATM) and EM algorithm (in GMTM) with 1,000 iterations to ensure convergence.

Topic model evaluation is inherently difficult. In previous works, perplexity is a popular metric to evaluate the predictive abilities of topic models given held-out dataset with unseen words (Blei et al., 2003b). However, Chang et al. (2009) have demonstrated that models with high perplexity do not necessarily generate semantically coherent topics in human perception. Therefore, we conducted objective and subjective analysis on the coherence of produced topics.

5.1 Objective Analysis

The quality of topics is commonly measured by coherence scores (Mimno et al., 2011), assuming that words representing a coherent topic are likely to co-occur within the same document. However, due to the severe sparsity of short text posts, we modify the calculation of commonly-used topic coherence measure based on word co-occurrences in messages tagged with the same hashtag, named as hashtag-document, assuming that those messages discuss related topics[8].

Specifically, we calculate the coherence score of a topic given the top N words ranked by likelihood as below:

$$\mathcal{C} = \frac{1}{K} \cdot \sum_{k=1}^{K} \sum_{i=2}^{N} \sum_{j=1}^{i-1} log \frac{D(w_i^k, w_j^k) + 1}{D(w_j^k)}, \qquad (3)$$

where w_i^k represents the i-th word in topic k ranked by $p(w|k)$, $D(w_i^k, w_j^k)$ refers to the count of hashtag-documents where word w_i^k and w_j^k co-occur, and $D(w_i^k)$ denotes the number of hashtag-documents that contain word w_i^k.

Table 3 shows the absolute values of $\mathcal{C}$ scores for topics produced on three evaluation datasets (May, June and July), and the top 10, 15, 20 words of topics were selected for evaluation. Lower scores indicate better coherence in the induced topic.

We have the following observations:

• GMTM gave the worst coherence scores, which may be ascribed to its heavy reliance on relevant large-scale high-quality external data, without which the trained word embedding model failed to capture meaningful semantic features for words, and hence could not yield coherent topics.

• TreeLDA and StructLDA produced competitive results compared to the state-of-the-art baseline models, which indicates the effectiveness of using conversation structures to enrich context and thus generate topics of reasonably good quality.

• The coherence of topics generated by LeadLDA outperformed all the baselines on the three datasets, most of time by large margins and was only outperformed by BTM on the May dataset when $K = 50$ and $N = 10$. The generally higher performance of LeadLDA is due to three reasons: 1) It effectively identifies topics using the conversation tree structures, which provide richer context information; 2) It jointly models the topics of leaders and the topic dependencies of other messages on a tree. TreeLDA and StructLDA, each only considering one of the factors, performed worse than LeadLDA; 3) LeadLDA separately models the probabilities of leaders and followers containing topical or non-topic words while the baselines only model the general background information regardless of the different types of messages. This implies that leaders and followers do have different capacities in covering key topical words or background noise, which is useful to identify key words for topic representation.

5.2 Subjective Analysis

To evaluate the coherence of induced topics from human perspective, we invited two annotators to subjectively rate the quality of every topic (by displaying the top 20 words) generated by different models on a 1-5 Likert scale. A higher rating indicates better quality of topics. The Fless's Kappa of annotators' ratings measured for various models on different datasets given $K = 50$ and 100 range from 0.62 to 0.70, indicating substantial agreements (Landis and Koch, 1977).

Table 4 shows the overall subjective ratings. We noticed that humans preferred topics produced given $K = 100$ to $K = 50$, but coherence scores gave generally better grades to models for $K = 50$, which matched the number of topics in ground truth. This is because models more or less mixed more common words when K is larger. Coherence score calculation (Equation (3)) penalizes common words that occur in many documents, whereas humans could somehow "guess" the meaning of topics based on the rest of words thus gave relatively good ratings. Nevertheless, annotators gave remarkably higher ratings to LeadLDA than baselines on all datasets regardless of K being 50 or 100, which confirmed that LeadLDA effectively yielded good-quality topics.

For a detailed analysis, Figure 3 lists the top 20 words about "MH17 crash" induced by different models[9] when $K = 50$. We have the following observations:

Model	May		June		July	
	K50	K100	K50	K100	K50	K100
TREE	3.12	3.41	3.42	3.44	3.03	3.48
STR	3.05	3.45	3.38	3.48	3.08	3.53
BTM	3.04	3.26	3.40	3.37	3.15	3.57
SATM	3.08	3.43	3.30	3.55	3.09	3.54
GMTM	2.02	2.37	1.99	2.27	1.97	1.90
LEAD	**3.40**	**3.57**	**3.52**	**3.63**	**3.55**	**3.72**

Table 4: Subjective ratings of topics. The meanings of K50, K100, TREE, STR and LEAD are the same as in Table 3.

- BTM, based on word-pair co-occurrences, mistakenly grouped "Fok's family" (a tycoon family in Hong Kong), which co-occurred frequently with "Hong Kong" in other topics, into the topic of "MH17 crash". "Hong Kong" is relevant here as a Hong Kong passenger died in the MH17 crash.
- The topical words generated by SATM were mixed with words relevant to the bus explosion in Guangzhou, since it aggregated messages according to topic affinities based on the topics learned in the previous step. Thus the posts about bus explosion and MH17 crash, both pertaining to disasters, were aggregated together mistakenly, which generated spurious topic results.
- Both TreeLDA and StructLDA generated topics containing non-topic words like "microblog" and "dear". This means that without distinguishing leaders and followers, it is difficult to filter out non-topic words. The topic quality of StructLDA nevertheless seems better than

[9] As shown in Table 3 and 4, the topic coherence scores of GMTM were the worst. Hence, the topic generated by GMTM is not shown due to space limitation.

TreeLDA, which implies the usefulness of exploiting topic dependencies of posts in conversation structures.

• LeadLDA not only produced more semantically coherent words describing the topic, but also revealed some important details, e.g., MH17 was shot down by a missile.

6 Conclusion and Future Works

This paper has proposed a novel topic model by considering the conversation tree structures of microblog posts. By rigorously comparing our proposed model with a number of competitive baselines on real-world microblog datasets, we have demonstrated the effectiveness of using conversation structures to help model topics embedded in short and colloquial microblog messages.

This work has proven that detecting leaders and followers, which are coarse-grained discourse derived from conversation structures, is useful to model microblogging topics. In the next step, we plan to exploit fine-grained discourse structures, e.g., dialogue acts (Ritter et al., 2010), and propose a unified model that jointly inferring discourse roles and topics of posts in context of conversation tree structures. Another extension is to extract topic hierarchies by integrating the conversation structures into hierarchical topic models like HLDA (Blei et al., 2003a) to extract fine-grained topics from microblog posts.

Abstract

Distant supervised relation extraction has been widely used to find novel relational facts from text. However, distant supervision inevitably accompanies with the wrong labelling problem, and these noisy data will substantially hurt the performance of relation extraction. To alleviate this issue, we propose a sentence-level attention-based model for relation extraction. In this model, we employ convolutional neural networks to embed the semantics of sentences. Afterwards, we build sentence-level attention over multiple instances, which is expected to dynamically reduce the weights of those noisy instances. Experimental results on real-world datasets show that, our model can make full use of all informative sentences and effectively reduce the influence of wrong labelled instances. Our model achieves significant and consistent improvements on relation extraction as compared with baselines. The source code of this paper can be obtained from `https://github.com/thunlp/NRE`.

1 Introduction

In recent years, various large-scale knowledge bases (KBs) such as Freebase (Bollacker et al., 2008), DBpedia (Auer et al., 2007) and YAGO (Suchanek et al., 2007) have been built and widely used in many natural language processing (NLP) tasks, including web search and question answering. These KBs mostly compose of relational facts with triple format, e.g., (*Microsoft*, `founder`, *Bill Gates*). Although existing KBs contain a massive amount of facts, they are still far from complete compared to the infinite real-world facts. To enrich KBs, many efforts have been invested in automatically finding unknown relational facts. Therefore, relation extraction (RE), the process of generating relational data from plain text, is a crucial task in NLP.

Most existing supervised RE systems require a large amount of labelled relation-specific training data, which is very time consuming and labor intensive. (Mintz et al., 2009) proposes distant supervision to automatically generate training data via aligning KBs and texts. They assume that if two entities have a relation in KBs, then all sentences that contain these two entities will express this relation. For example, (*Microsoft*, `founder`, *Bill Gates*) is a relational fact in KB. Distant supervision will regard all sentences that contain these two entities as active instances for relation `founder`. Although distant supervision is an effective strategy to automatically label training data, it always suffers from wrong labelling problem. For example, the sentence "*Bill Gates 's turn to philanthropy was linked to the antitrust problems Microsoft had in the U.S. and the European union.*" does not express the relation `founder` but will still be regarded as an active instance. Hence, (Riedel et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012) adopt multi-instance learning to alleviate the wrong labelling problem. The main weakness of these conventional methods is that most features are explicitly derived from NLP tools such as POS tagging and the errors generated by NLP tools will propagate in these methods.

Some recent works (Socher et al., 2012; Zeng et al., 2014; dos Santos et al., 2015) attempt to use deep neural networks in relation classification without handcrafted features. These methods build classifier based on sentence-level annotated data, which cannot be applied in large-scale

Berlin, Germany, August 7-12, 2016.

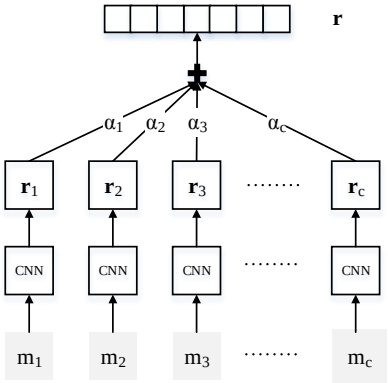

Figure 1: The architecture of sentence-level attention-based CNN, where m_i indicates the original sentence for an entity pair, α_i is the weight given by sentence-level attention.

KBs due to the lack of human-annotated training data. Therefore, (Zeng et al., 2015) incorporates multi-instance learning with neural network model, which can build relation extractor based on distant supervision data. Although the method achieves significant improvement in relation extraction, it is still far from satisfactory. The method assumes that at least one sentence that mentions these two entities will express their relation, and only selects the most likely sentence for each entity pair in training and prediction. It's apparent that the method will lose a large amount of rich information containing in neglected sentences.

In this paper, we propose a sentence-level attention-based convolutional neural network (CNN) for distant supervised relation extraction. As illustrated in Fig. 1, we employ a CNN to embed the semantics of sentences. Afterwards, to utilize all informative sentences, we represent the relation as semantic composition of sentence embeddings. To address the wrong labelling problem, we build sentence-level attention over multiple instances, which is expected to dynamically reduce the weights of those noisy instances. Finally, we extract relation with the relation vector weighted by sentence-level attention. We evaluate our model on a real-world dataset in the task of relation extraction. The experimental results show that our model achieves significant and consistent improvements in relation extraction as compared with the state-of-the-art methods.

The contributions of this paper can be summarized as follows:

- As compared to existing neural relation extraction model, our model can make full use of all informative sentences of each entity pair.
- To address the wrong labelling problem in distant supervision, we propose selective attention to de-emphasize those noisy instances.
- In the experiments, we show that selective attention is beneficial to two kinds of CNN models in the task of relation extraction.

2 Related Work

Relation extraction is one of the most important tasks in NLP. Many efforts have been invested in relation extraction, especially in supervised relation extraction. Most of these methods need a great deal of annotated data, which is time consuming and labor intensive. To address this issue, (Mintz et al., 2009) aligns plain text with Freebase by distant supervision. However, distant supervision inevitably accompanies with the wrong labelling problem. To alleviate the wrong labelling problem, (Riedel et al., 2010) models distant supervision for relation extraction as a multi-instance single-label problem, and (Hoffmann et al., 2011; Surdeanu et al., 2012) adopt multi-instance multi-label learning in relation extraction. Multi-instance learning was originally proposed to address the issue of ambiguously-labelled training data when predicting the activity of drugs (Dietterich et al., 1997). Multi-instance learning considers the reliability of the labels for each instance. (Bunescu and Mooney, 2007) connects weak supervision with multi-instance learning and extends it to relation extraction. But all the feature-based methods depend strongly on the quality of the features generated by NLP tools, which will suffer from error propagation problem.

Recently, deep learning (Bengio, 2009) has been widely used for various areas, including computer vision, speech recognition and so on. It has also been successfully applied to different NLP tasks such as part-of-speech tagging (Collobert et al., 2011), sentiment analysis (dos Santos and Gatti, 2014), parsing (Socher et al., 2013), and machine translation (Sutskever et al., 2014). Due to the recent success in deep learning, many researchers have investigated the possibility of using neural networks to automatically learn features

for relation extraction. (Socher et al., 2012) uses a recursive neural network in relation extraction. They parse the sentences first and then represent each node in the parsing tree as a vector. Moreover, (Zeng et al., 2014; dos Santos et al., 2015) adopt an end-to-end convolutional neural network for relation extraction. Besides, (Xie et al., 2016) attempts to incorporate the text information of entities for relation extraction.

Although these methods achieve great success, they still extract relations on sentence-level and suffer from a lack of sufficient training data. In addition, the multi-instance learning strategy of conventional methods cannot be easily applied in neural network models. Therefore, (Zeng et al., 2015) combines at-least-one multi-instance learning with neural network model to extract relations on distant supervision data. However, they assume that only one sentence is active for each entity pair. Hence, it will lose a large amount of rich information containing in those neglected sentences. Different from their methods, we propose sentence-level attention over multiple instances, which can utilize all informative sentences.

The attention-based models have attracted a lot of interests of researchers recently. The selectivity of attention-based models allows them to learn alignments between different modalities. It has been applied to various areas such as image classification (Mnih et al., 2014), speech recognition (Chorowski et al., 2014), image caption generation (Xu et al., 2015) and machine translation (Bahdanau et al., 2014). To the best of our knowledge, this is the first effort to adopt attention-based model in distant supervised relation extraction.

3 Methodology

Given a set of sentences $\{x_1, x_2, \cdots, x_n\}$ and two corresponding entities, our model measures the probability of each relation r. In this section, we will introduce our model in two main parts:

- **Sentence Encoder.** Given a sentence x and two target entities, a convolutional neutral network (CNN) is used to construct a distributed representation $\mathbf{x}$ of the sentence.
- **Selective Attention over Instances**. When the distributed vector representations of all sentences are learnt, we use sentence-level attention to select the sentences which really express the corresponding relation.

3.1 Sentence Encoder

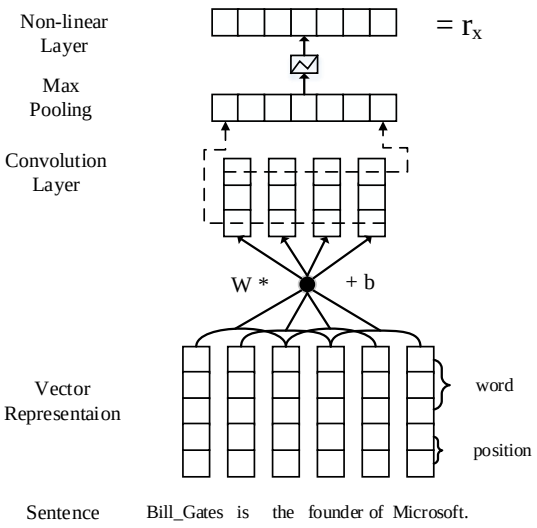

Figure 2: The architecture of CNN/PCNN used for sentence encoder.

As shown in Fig. 2, we transform the sentence x into its distributed representation $\mathbf{x}$ by a CNN. First, words in the sentence are transformed into dense real-valued feature vectors. Next, convolutional layer, max-pooling layer and non-linear transformation layer are used to construct a distributed representation of the sentence, i.e., $\mathbf{x}$.

3.1.1 Input Representation

The inputs of the CNN are raw words of the sentence x. We first transform words into low-dimensional vectors. Here, each input word is transformed into a vector via word embedding matrix. In addition, to specify the position of each entity pair, we also use position embeddings for all words in the sentence.

Word Embeddings. Word embeddings aim to transform words into distributed representations which capture syntactic and semantic meanings of the words. Given a sentence x consisting of m words $x = \{w_1, w_2, \cdots, w_m\}$, every word w_i is represented by a real-valued vector. Word representations are encoded by column vectors in an embedding matrix $\mathbf{V} \in \mathbb{R}^{d^a \times |V|}$where V is a fixed-sized vocabulary.

Position Embeddings. In the task of relation extraction, the words close to the target entities are usually informative to determine the relation between entities. Similar to (Zeng et al., 2014), we use position embeddings specified by entity pairs. It can help the CNN to keep track of how close

each word is to head or tail entities. It is defined as the combination of the relative distances from the current word to head or tail entities. For example, in the sentence "Bill_Gates is the founder of Microsoft.", the relative distance from the word "founder" to head entity *Bill_Gates* is 3 and tail entity *Microsoft* is 2.

In the example shown in Fig. 2, it is assumed that the dimension d^a of the word embedding is 3 and the dimension d^b of the position embedding is 1. Finally, we concatenate the word embeddings and position embeddings of all words and denote it as a vector sequence $\mathbf{w} = \{\mathbf{w}_1, \mathbf{w}_2, \cdots, \mathbf{w}_m\}$, where $\mathbf{w}_i \in \mathbb{R}^d (d = d^a + d^b \times 2)$.

3.1.2 Convolution, Max-pooling and Non-linear Layers

In relation extraction, the main challenges are that the length of the sentences is variable and the important information can appear in any area of the sentences. Hence, we should utilize all local features and perform relation prediction globally. Here, we use a convolutional layer to merge all these features. The convolutional layer first extracts local features with a sliding window of length l over the sentence. In the example shown in Fig. 2, we assume that the length of the sliding window l is 3. Then, it combines all local features via a max-pooling operation to obtain a fixed-sized vector for the input sentence.

Here, convolution is defined as an operation between a vector sequence $\mathbf{w}$ and a convolution matrix $\mathbf{W} \in \mathbb{R}^{d^c \times (l \times d)}$, where d^c is the sentence embedding size. Let us define the vector $\mathbf{q}_i \in \mathbb{R}^{l \times d}$ as the concatenation of a sequence of w word embeddings within the i-th window:

$$\mathbf{q}_i = \mathbf{w}_{i-l+1:i} \quad (1 \leq i \leq m + l - 1). \tag{1}$$

Since the window may be outside of the sentence boundaries when it slides near the boundary, we set special padding tokens for the sentence. It means that we regard all out-of-range input vectors $\mathbf{w}_i (i < 1 \text{ or } i > m)$ as zero vector.

Hence, the i-th filter of convolutional layer is computed as:

$$\mathbf{p}_i = [\mathbf{W}\mathbf{q} + \mathbf{b}]_i \tag{2}$$

where $\mathbf{b}$ is bias vector. And the i-th element of the vector $\mathbf{x} \in \mathbb{R}^{d^c}$ as follows:

$$[\mathbf{x}]_i = \max(\mathbf{p}_i), \tag{3}$$

Further, PCNN (Zeng et al., 2015), which is a variation of CNN, adopts piecewise max pooling in relation extraction. Each convolutional filter $\mathbf{p}_i$ is divided into three segments $(\mathbf{p}_{i1}, \mathbf{p}_{i2}, \mathbf{p}_{i3})$ by head and tail entities. And the max pooling procedure is performed in three segments separately, which is defined as:

$$[\mathbf{x}]_{ij} = \max(\mathbf{p}_{ij}), \tag{4}$$

And $[\mathbf{x}]_i$ is set as the concatenation of $[\mathbf{x}]_{ij}$.

Finally, we apply a non-linear function at the output, such as the hyperbolic tangent.

3.2 Selective Attention over Instances

Suppose there is a set S contains n sentences for entity pair $(head, tail)$, i.e., $S = \{x_1, x_2, \cdots, x_n\}$.

To exploit the information of all sentences, our model represents the set S with a real-valued vector $\mathbf{s}$ when predicting relation r. It is straightforward that the representation of the set S depends on all sentences' representations $\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n$. Each sentence representation $\mathbf{x}_i$ contains information about whether entity pair $(head, tail)$ contains relation r for input sentence x_i.

The set vector $\mathbf{s}$ is, then, computed as a weighted sum of these sentence vector $\mathbf{x}_i$:

$$\mathbf{s} = \sum_i \alpha_i \mathbf{x}_i, \tag{5}$$

where α_i is the weight of each sentence vector $\mathbf{x}_i$. In this paper, we define α_i in two ways:

Average: We assume that all sentences in the set X have the same contribution to the representation of the set. It means the embedding of the set S is the average of all the sentence vectors:

$$\mathbf{s} = \sum_i \frac{1}{n} \mathbf{x}_i, \tag{6}$$

It's a naive baseline of our selective attention.

Selective Attention: However, the wrong labelling problem inevitably occurs. Thus, if we regard each sentence equally, the wrong labelling sentences will bring in massive of noise during training and testing. Hence, we use a selective attention to de-emphasize the noisy sentence. Hence, α_i is further defined as:

$$\alpha_i = \frac{\exp(e_i)}{\sum_k \exp(e_k)}, \tag{7}$$

where e_i is referred as a query-based function which scores how well the input sentence x_i and the predict relation r matches. We select the bilinear form which achieves best performance in different alternatives:

$$e_i = \mathbf{x}_i \mathbf{A} \mathbf{r}, \tag{8}$$

where $\mathbf{A}$ is a weighted diagonal matrix, and $\mathbf{r}$ is the query vector associated with relation r which indicates the representation of relation r.

Finally, we define the conditional probability $p(r|S, \theta)$ through a softmax layer as follows:

$$p(r|S, \theta) = \frac{\exp(o_r)}{\sum_{k=1}^{n_r} \exp(o_k)}, \tag{9}$$

where n_r is the total number of relations and $\mathbf{o}$ is the final output of the neural network which corresponds to the scores associated to all relation types, which is defined as follows:

$$\mathbf{o} = \mathbf{M}\mathbf{s} + \mathbf{d}, \tag{10}$$

where $\mathbf{d} \in \mathbb{R}^{n_r}$ is a bias vector and $\mathbf{M}$ is the representation matrix of relations.

(Zeng et al., 2015) follows the assumption that at least one mention of the entity pair will reflect their relation, and only uses the sentence with the highest probability in each set for training. Hence, the method which they adopted for multi-instance learning can be regarded as a special case as our selective attention when the weight of the sentence with the highest probability is set to 1 and others to 0.

3.3 Optimization and Implementation Details

Here we introduce the learning and optimization details of our model. We define the objective function using cross-entropy at the set level as follows:

$$J(\theta) = \sum_{i=1}^{s} \log p(r_i|S_i, \theta), \tag{11}$$

where s indicates the number of sentence sets and θ indicates all parameters of our model. To solve the optimization problem, we adopt stochastic gradient descent (SGD) to minimize the objective function. For learning, we iterate by randomly selecting a mini-batch from the training set until converge.

In the implementation, we employ dropout (Srivastava et al., 2014) on the output layer to prevent overfitting. The dropout layer is defined as an element-wise multiplication with a a vector $\mathbf{h}$ of Bernoulli random variables with probability p. Then equation (10) is rewritten as:

$$\mathbf{o} = \mathbf{M}(\mathbf{s} \circ \mathbf{h}) + \mathbf{d}. \tag{12}$$

In the test phase, the learnt set representations are scaled by p, i.e., $\hat{\mathbf{s}}_i = p\mathbf{s}_i$. And the scaled set vector $\hat{\mathbf{r}}_i$ is finally used to predict relations.

4 Experiments

Our experiments are intended to demonstrate that our neural models with sentence-level selective attention can alleviate the wrong labelling problem and take full advantage of informative sentences for distant supervised relation extraction. To this end, we first introduce the dataset and evaluation metrics used in the experiments. Next, we use cross-validation to determine the parameters of our model. And then we evaluate the effects of our selective attention and show its performance on the data with different set size. Finally, we compare the performance of our method to several state-of-the-art feature-based methods.

4.1 Dataset and Evaluation Metrics

We evaluate our model on a widely used dataset[1] which is developed by (Riedel et al., 2010) and has also been used by (Hoffmann et al., 2011; Surdeanu et al., 2012). This dataset was generated by aligning Freebase relations with the New York Times corpus (NYT). Entity mentions are found using the Stanford named entity tagger (Finkel et al., 2005), and are further matched to the names of Freebase entities. The Freebase relations are divided into two parts, one for training and one for testing. It aligns the the sentences from the corpus of the years 2005-2006 and regards them as training instances. And the testing instances are the aligned sentences from 2007. There are 53 possible relationships including a special relation NA which indicates there is no relation between head and tail entities. The training data contains 522,611 sentences, 281,270 entity pairs and 18,252 relational facts. The testing set contains 172,448 sentences, 96,678 entity pairs and 1,950 relational facts.

Similar to previous work (Mintz et al., 2009), we evaluate our model in the held-out evaluation. It evaluates our model by comparing the relation

[1] http://iesl.cs.umass.edu/riedel/ecml/

facts discovered from the test articles with those in Freebase. It assumes that the testing systems have similar performances in relation facts inside and outside Freebase. Hence, the held-out evaluation provides an approximate measure of precision without time consumed human evaluation. We report both the aggregate curves precision/recall curves and Precision@N (P@N) in our experiments.

4.2 Experimental Settings

4.2.1 Word Embeddings

In this paper, we use the word2vec tool [2] to train the word embeddings on NYT corpus. We keep the words which appear more than 100 times in the corpus as vocabulary. Besides, we concatenate the words of an entity when it has multiple words.

4.2.2 Parameter Settings

Following previous work, we tune our models using three-fold validation on the training set. We use a grid search to determine the optimal parameters and select learning rate λ for SGD among $\{0.1, 0.01, 0.001, 0.0001\}$, the sliding window size $l \in \{1, 2, 3, \cdots, 8\}$, the sentence embedding size $n \in \{50, 60, \cdots, 300\}$, and the batch size B among $\{40, 160, 640, 1280\}$. For other parameters, since they have little effect on the results, we follow the settings used in (Zeng et al., 2014). For training, we set the iteration number over all the training data as 25. In Table 1 we show all parameters used in the experiments.

Table 1: Parameter settings

Window size l	3
Sentence embedding size d^c	230
Word dimension d^a	50
Position dimension d^b	5
Batch size B	160
Learning rate λ	0.01
Dropout probability p	0.5

4.3 Effect of Sentence-level Selective Attention

To demonstrate the effects of the sentence-level selective attention, we empirically compare different methods through held-out evaluation. We select the CNN model proposed in (Zeng et al., 2014) and the PCNN model proposed in (Zeng et al., 2015) as our sentence encoders and implement them by ourselves which achieve comparable results as the authors reported. And we compare the performance of the two different kinds of CNN with sentence-level attention (ATT) , its naive version (AVE) which represents each sentence set as the average vector of sentences inside the set and the at-least-one multi-instance learning (ONE) used in (Zeng et al., 2015).

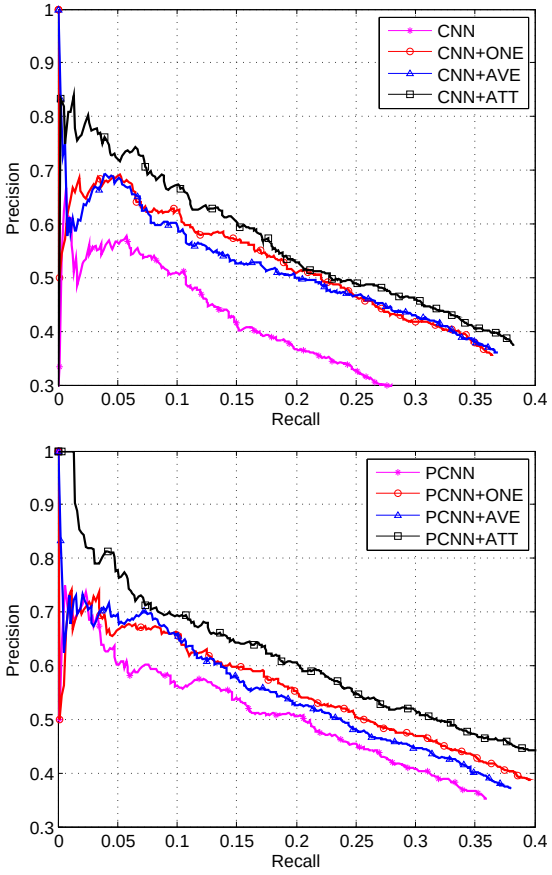

Figure 3: Top: Aggregate precion/recall curves of CNN, CNN+ONE, CNN+AVE, CNN+ATT. Bottom: Aggregate precion/recall curves of PCNN, PCNN+ONE, PCNN+AVE, PCNN+ATT

From Fig. 3, we have the following observation: (1) For both CNN and PCNN, the ONE method brings better performance as compared to CNN/PCNN. The reason is that the original distant supervision training data contains a lot of noise and the noisy data will damage the performance of relation extraction. (2) For both CNN and PCNN, the AVE method is useful for relation extraction as compared to CNN/PCNN. It indicates that considering more sentences is beneficial to relation extraction since the noise can be reduced by mutual complementation of information. (3) For both

[2] https://code.google.com/p/word2vec/

CNN and PCNN, the AVE method has a similar performance compared to the ONE method. It indicates that, although the AVE method brings in information of more sentences, since it regards each sentence equally, it also brings in the noise from the wrong labelling sentences which may hurt the performance of relation extraction. (4) For both CNN and PCNN, the ATT method achieves the highest precision over the entire range of recall compared to other methods including the AVE method. It indicates that the proposed selective attention is beneficial. It can effectively filter out meaningless sentences and alleviate the wrong labelling problem in distant supervised relation extraction.

4.4 Effect of Sentence Number

In the original testing data set, there are 74,857 entity pairs that correspond to only one sentence, nearly 3/4 over all entity pairs. Since the superiority of our selective attention lies in the entity pairs containing multiple sentences, we compare the performance of CNN/PCNN+ONE, CNN/PCNN+AVE and CNN/PCNN+ATT on the entity pairs which have more than one sentence. And then we examine these three methods in three test settings:

- **One**: For each testing entity pair, we randomly select one sentence and use this sentence to predict relation.
- **Two**: For each testing entity pair, we randomly select two sentences and proceed relation extraction.
- **All**: We use all sentences of each entity pair for relation extraction.

Note that, we use all the sentences in training. We will report the P@100, P@200, P@300 and the mean of them for each model in held-out evaluation.

Table 2 shows the P@N for compared models in three test settings. From the table, we can see that: (1) For both CNN and PCNN, the ATT method achieves the best performance in all test settings. It demonstrates the effectiveness of sentence-level selective attention for multi-instance learning. (2) For both CNN and PCNN, the AVE method is comparable to the ATT method in the One test setting. However, when the number of testing sentences per entity pair grows, the performance of the AVE methods has almost no improvement. It even drops gradually in P@100, P@200 as the sentence number increases. The reason is that, since we regard each sentence equally, the noise contained in the sentences that do not express any relation will have negative influence in the performance of relation extraction. (3) CNN+AVE and CNN+ATT have 5% to 8% improvements compared to CNN+ONE in the ONE test setting. Since each entity pair has only one sentence in this test setting, the only difference of these methods is from training. Hence, it shows that utilizing all sentences will bring in more information although it may also bring in some extra noises. (4) For both CNN and PCNN, the ATT method outperforms other two baselines over 5% and 9% in the Two and All test settings. It indicates that by taking more useful information into account, the relational facts which CNN+ATT ranks higher are more reliable and beneficial to relation extraction.

4.5 Comparison with Feature-based Approaches

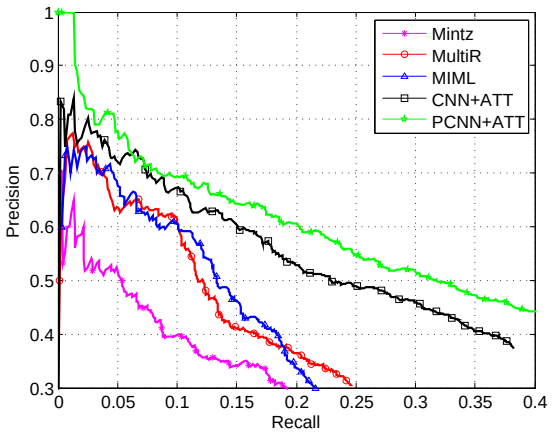

Figure 4: Performance comparison of proposed model and traditional methods

To evaluate the proposed method, we select the following three feature-based methods for comparison through held-out evaluation:

Mintz (Mintz et al., 2009) is a traditional distant supervised model.

MultiR (Hoffmann et al., 2011) proposes a probabilistic, graphical model of multi-instance learning which handles overlapping relations.

MIML (Surdeanu et al., 2012) jointly models both multiple instances and multiple relations.

We implement them with the source codes released by the authors.

Table 2: P@N for relation extraction in the entity pairs with different number of sentences

Test Settings	One				Two				All			
P@N(%)	100	200	300	Mean	100	200	300	Mean	100	200	300	Mean
CNN+ONE	68.3	60.7	53.8	60.9	70.3	62.7	55.8	62.9	67.3	64.7	58.1	63.4
+AVE	75.2	67.2	58.8	67.1	68.3	63.2	60.5	64.0	64.4	60.2	60.1	60.4
+ATT	**76.2**	65.2	**60.8**	67.4	76.2	65.7	62.1	68.0	**76.2**	68.6	59.8	68.2
PCNN+ONE	73.3	64.8	56.8	65.0	70.3	67.2	63.1	66.9	72.3	69.7	64.1	68.7
+AVE	71.3	63.7	57.8	64.3	73.3	65.2	62.1	66.9	73.3	66.7	62.8	67.6
+ATT	73.3	**69.2**	**60.8**	**67.8**	**77.2**	**71.6**	**66.1**	**71.6**	**76.2**	**73.1**	**67.4**	**72.2**

Fig. 4 shows the precision/recall curves for each method. We can observe that: (1) CNN/PCNN+ATT significantly outperforms all feature-based methods over the entire range of recall. When the recall is greater than 0.1, the performance of feature-based method drop out quickly. In contrast, our model has a reasonable precision until the recall approximately reaches 0.3. It demonstrates that the human-designed feature cannot concisely express the semantic meaning of the sentences, and the inevitable error brought by NLP tools will hurt the performance of relation extraction. In contrast, CNN/PCNN+ATT which learns the representation of each sentences automatically can express each sentence well. (2) PCNN+ATT performs much better as compared to CNN+ATT over the entire range of recall. It means that the selective attention considers the global information of all sentences except the information inside each sentence. Hence, the performance of our model can be further improved if we have a better sentence encoder.

4.6 Case Study

Table 3 shows two examples of selective attention from the testing data. For each relation, we show the corresponding sentences with highest and lowest attention weight respectively. And we highlight the entity pairs with bold formatting.

From the table we find that: The former example is related to the relation `employer_of`. The sentence with low attention weight does not express the relation between two entities, while the high one shows that *Mel Karmazin* is the chief executive of *Sirius Satellite Radio*. The later example is related to the relation `place_of_birth`. The sentence with low attention weight expresses where *Ernst Haefliger* is died in, while the high one expresses where he is born in.

Table 3: Some examples of selective attention in NYT corpus

Relation	employer_of
Low	When Howard Stern was preparing to take his talk show to **Sirius Satellite Radio**, following his former boss, **Mel Karmazin**, Mr. Hollander argued that ...
High	**Mel Karmazin**, the chief executive of **Sirius Satellite Radio**, made a lot of phone calls ...
Relation	place_of_birth
Low	**Ernst Haefliger**, a Swiss tenor who ... roles , died on Saturday in **Davos**, Switzerland, where he maintained a second home.
High	**Ernst Haefliger** was born in **Davos** on July 6, 1919, and studied at the Wettinger Seminary ...

5 Conclusion and Future Works

In this paper, we develop CNN with sentence-level selective attention. Our model can make full use of all informative sentences and alleviate the wrong labelling problem for distant supervised relation extraction. In experiments, we evaluate our model on relation extraction task. The experimental results show that our model significantly and consistently outperforms state-of-the-art feature-based methods and neural network methods.

In the future, we will explore the following directions:

- Our model incorporates multi-instance learning with neural network via instance-level selective attention. It can be used in not only distant supervised relation extraction but also other multi-instance learning tasks. We will explore our model in other area such as text

categorization.

- CNN is one of the effective neural networks for neural relation extraction. Researchers also propose many other neural network models for relation extraction. In the future, we will incorporate our instance-level selective attention technique with those models for relation extraction.

Abstract

Frames defined in FrameNet (FN) share highly similar structures with events in ACE event extraction program. An event in ACE is composed of an event trigger and a set of arguments. Analogously, a frame in FN is composed of a lexical unit and a set of frame elements, which play similar roles as triggers and arguments of ACE events respectively. Besides having similar structures, many frames in FN actually express certain types of events. The above observations motivate us to explore whether there exists a good mapping from frames to event-types and if it is possible to improve event detection by using FN. In this paper, we propose a global inference approach to detect events in FN. Further, based on the detected results, we analyze possible mappings from frames to event-types. Finally, we improve the performance of event detection and achieve a new state-of-the-art result by using the events automatically detected from FN.

1 Introduction

In the ACE (Automatic Context Extraction) event extraction program, an event is represented as a structure consisting of an event trigger and a set of arguments. This paper tackles with the event detection (ED) task, which is a crucial component in the overall task of event extraction. The goal of ED is to identify event triggers and their corresponding event types from the given documents.

FrameNet (FN) (Baker et al., 1998; Fillmore et al., 2003) is a linguistic resource storing considerable information about lexical and predicate-argument semantics. In FN, a frame is defined as a composition of a Lexical Unit (LU) and a set of Frame Elements (FE). Most frames contain a set of exemplars with annotated LUs and FEs (see Figure 2 and Section 2.2 for details).

From the above definitions of events and frames, it is not hard to find that the frames defined in FN share highly similar structures as the events defined in ACE. Firstly, the LU of a Frame plays a similar role as the trigger of an event. ACE defines the trigger of an event as the word or phrase which most clearly expresses an event occurrence. For example, the following sentence "*He **died** in the hospital.*" expresses a `Die` event, whose trigger is the word *died*. Analogously, the LU of a frame is also the word or phrase which is capable of indicating the occurrence of the expressed semantic frame. For example, the sentence "*Aeroplanes **bombed** London.*" expresses an `Attack`[1] frame, whose LU is the word *bombed*. Secondly, the FEs of a frame also play similar roles as arguments of an event. Both of them indicate the participants involved in the corresponding frame or event. For example, in the first sentence, *He* and *hospital* are the arguments, and in the second sentence, *Aeroplanes* and *London* are the FEs.

Besides having similar structure as events, many frames in FN actually express certain types of events defined in ACE. Table 1 shows some examples of frames which also express events.

Frame	Event	Sample in FN
Attack	Attack	*Aeroplanes **bombed** London.*
Invading	Attack	*Hitler **invaded** Austria .*
Fining	Fine	*The court **fined** her $40.*
Execution	Execute	*He was **executed** yesterday.*

Table 1: Examples of frames expressing events.

The aforementioned observations motivate us to

[1]The notation of frames distinguishes from that of events by the italic decoration.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2134–2143,
Berlin, Germany, August 7-12, 2016.

explore: (1) whether there exists a good mapping from frames to event-types, and (2) whether it is possible to improve ED by using FN.

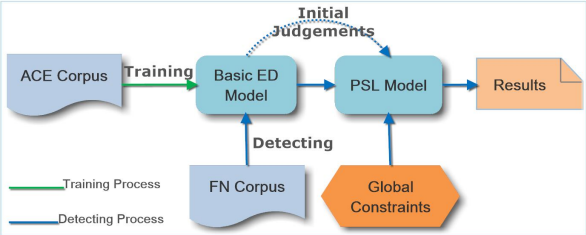

Figure 1: Our framework for detecting events in FN (including training and detecting processes).

For the first issue, we investigate whether a frame could be mapped to an event-type based on events expressed by exemplars annotated for that frame. Therefore the key is to detect events from the given exemplar sentences in FN. To achieve this goal, we propose a global inference approach (see figure 1). We firstly learn a basic ED model based on the ACE labeled corpus and employ it to yield initial judgements for each sentence in FN. Then, we apply a set of soft constraints for global inference based on the following hypotheses: 1). Sentences belonging to the same LU tend to express events of the same type; 2). Sentences belonging to related frames tend to express events of the same type; 3). Sentences belonging to the same frame tend to express events of the same type. All of the above constraints and initial judgments are formalized as first-order logic formulas and modeled by Probabilistic Soft Logic (PSL) (Kimmig et al., 2012; Bach et al., 2013). Finally, we obtain the final results via PSL-based global inference. We conduct both manual and automatic evaluations for the detected results.

For the second issue, ED generally suffers from data sparseness due to lack of labeled samples. Some types, such as `Nominate` and `Extradite`, contain even less than 10 labeled samples. Apparently, from such a small scale of training data is difficult to yield a satisfying performance. We notice that ACE corpus only contains about 6,000 labeled instances, while FN contains more than 150,000 exemplars. Thus, a straightforward solution to alleviate the data sparseness problem is to expand the ACE training data by using events detected from FN. The experimental results show that events from FN significantly improve the performance of the event detection task.

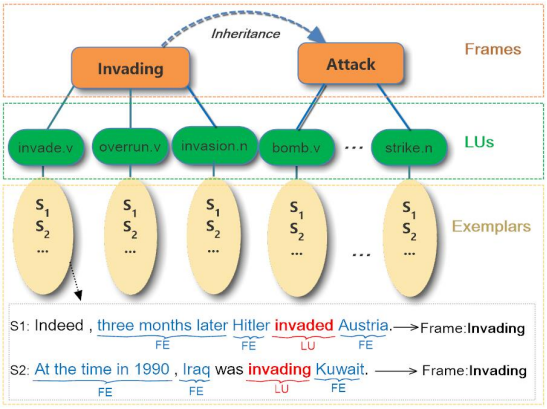

Figure 2: The hierarchy of FN corpus, where each S_k under a LU is a exemplar annotated for that LU. *Inheritance* is a semantic relation between the frames `Invading` and `Attack`.

To sum up, our main contributions are: (1) To our knowledge, this is the first work performing event detection over ACE and FN to explore the relationships between frames and events. (2) We propose a global inference approach to detect events in FN, which is demonstrated very effective by our experiments. Moreover, based on the detected results, we analyze possible mappings from frames to event-types (all the detecting and mapping results are released for further use by the NLP community[2]). (3) We improve the performance of event detection significantly and achieve a new state-of-the-art result by using events automatically detected from FN as extra training data.

2 Background

2.1 ACE Event Extraction

In ACE evaluations, an event is defined as a specific occurrence involving several participants. ACE event evaluation includes 8 types of events, with 33 subtypes. Following previous work, we treat them simply as 33 separate event types and ignore the hierarchical structure among them. In this paper, we use the ACE 2005 corpus[3] in our experiments. It contains 599 documents, which include about 6,000 labeled events.

2.2 FrameNet

The FrameNet is a taxonomy of manually identified semantic frames for English[4]. Figure 2 shows

[2]Available at https://github.com/subacl/acl16

[3]https://catalog.ldc.upenn.edu/LDC2006T06

[4]We use the latest released version, FrameNet 1.5 in this work (http://framenet.icsi.berkeley.edu).

the hierarchy of FN corpus. Listed in the FN with each frame are a set of lemmas with part of speech (i.e "invade.v") that can evoke the frame, which are called lexical units (LUs). Accompanying most LUs in the FN is a set of exemplars annotated for them. Moreover, there are a set of labeled relations between frames, such as *Inheritance*.

FN contains more than 1,000 various frames and 10,000 LUs with 150,000 annotated exemplars. Eight relations are defined between frames in FN, but in this paper we only use the following three of them because the others do not satisfy our hypotheses (see section 4.2):

Inheritance: A inherited from *B* indicates that *A* must correspond to an equally or more specific fact about *B*. It is a directional relation.

See_also: A and *B* connected by this relation indicates that they are similar frames.

Perspective_on: A and *B* connected by this relation means that they are different points-of-view about the same fact (i.e. `Receiving` vs. `Transfer`).

2.3 Related Work

Event extraction is an increasingly hot and challenging research topic in NLP. Many approaches have been proposed for this task. Nearly all the existing methods on ACE event task use supervised paradigm. We further divide them into feature-based methods and representation-based methods.

In feature-based methods, a diverse set of strategies has been exploited to convert classification clues into feature vectors. Ahn (2006) uses the lexical features(e.g., full word), syntactic features (e.g., dependency features) and external-knowledge features(WordNet (Miller, 1995)) to extract the event. Inspired by the hypothesis of One Sense Per Discourse (Yarowsky, 1995), Ji and Grishman (2008) combined global evidence from related documents with local decisions for the event extraction. To capture more clues from the texts, Gupta and Ji (2009), Liao and Grishman (2010) and Hong et al. (2011) proposed the cross-event and cross-entity inference for the ACE event task. Li et al. (2013) proposed a joint model to capture the combinational features of triggers and arguments. Liu et al. (2016) proposed a global inference approach to employ both latent local and global information for event detection.

In representation-based methods, candidate event mentions are represented by embedding, which typically are fed into neural networks. Two similarly related work has been proposed on event detection (Chen et al., 2015; Nguyen and Grishman, 2015). Nguyen and Grishman (2015) employed Convolutional Neural Networks (CNNs) to automatically extract sentence-level features for event detection. Chen et al. (2015) proposed dynamic multi-pooling operation on CNNs to capture better sentence-level features.

FrameNet is a typical resource for frame-semantic parsing, which consists of the resolution of predicate sense into a frame, and the analysis of the frame's participants (Thompson et al., 2003; Giuglea and Moschitti, 2006; Hermann et al., 2014; Das et al., 2014). Other tasks which have been studied based on FN include question answering (Narayanan and Harabagiu, 2004; Shen and Lapata, 2007), textual entailment (Burchardt et al., 2009) and paraphrase recognition (Padó and Lapata, 2005). This is the first work to explore the application of FN to event detection.

3 Basic Event Detection Model

Alike to existing work, we model event detection (ED) as a word classification task. In the ED task, each word in the given sentence is treated as a candidate trigger and the goal is to classify each of these candidates into one of 34 classes (33 event types plus a NA class). However, in this work, as we assumed that the LU of a frame is analogical to the trigger of an event, we only treat the LU annotated in the given sentence as a trigger candidate. Each sentence in FN only contains one candidate trigger, thus "the candidate" denotes both the candidate trigger of a sentence and the sentence itself for FN in the remainder of this paper. Another notable difference is that we train the detection model on one corpus (ACE) but apply it on another (FN). That means our task is also a **cross-domain** problem. To tackle with it, our basic ED approach follows representation-based paradigm, which has been demonstrated effective in the cross-domain situation (Nguyen and Grishman, 2015).

3.1 Model

We employ a simple three-layer (a input layer, a hidden layer and a soft-max output layer) Artificial Neural Networks (ANNs) (Hagan et al., 1996) to model the ED task. In our model, adjacent layers are fully connected.

Word embeddings learned from large amount of unlabeled data have been shown to be able to capture the meaningful semantic regularities of words

(Bengio et al., 2003; Erhan et al., 2010). This paper uses unsupervised learned word embeddings as the source of base features. We use the Skip-gram model (Mikolov et al., 2013) to learn word embeddings on the NYT corpus[5].

Given a sentence, we concatenate the embedding vector of the candidate trigger and the average embedding vector of the words in the sentence as the input to our model. We train the model using a simple optimization technique called stochastic gradient descent (SGD) over shuffled mini-batches with the Adadelta update rule (Zeiler, 2012). Regularization is implemented by a dropout (Kim, 2014; Hinton et al., 2012). The experiments show that this simple model is surprisingly effective for event detection.

4 Event Detection in FrameNet

To detect events in FN, we first learned the basic ED model based on ACE labeled corpus and then employ it to generate initial judgements (possible event types with confidence values) for each sentence in FN. Then, we apply a set of constraints for global inference based on the PSL model.

4.1 Probabilistic Soft Logic

PSL is a framework for collective, probabilistic reasoning in relational domains (Kimmig et al., 2012; Bach et al., 2013). Similar to Markov Logic Networks (MLNs) (Richardson and Domingos, 2006), it uses weighted first-order logic formulas to compactly encode complex undirected probabilistic graphical models. However, PSL brings two remarkable advantages compared with MLNs. First, PSL relaxes the boolean truth values of MLNs to continuous, soft truth values. This allows for easy integration of continuous values, such as similarity scores. Second, PSL restricts the syntax of first order formulas to that of rules with conjunctive bodies. Together with the soft truth values constraint, the inference in PSL is a convex optimization problem in continuous space and thus can be solved using efficient inference approaches. For further details, see the references (Kimmig et al., 2012; Bach et al., 2013).

4.2 Global Constraints

Our global inference approach is based on the following three hypotheses.

[5]https://catalog.ldc.upenn.edu/LDC2008T19

H1: Same Frame Same Event
This hypothesis indicates that sentences under the same frame tend to express events of the same type. For example, all exemplars annotated for the frame `Rape` express events of type `Attack`, and all sentences under the frame `Clothing` express NA (none) events. With this hypothesis, sentences annotated for the same frame help each other to infer their event types during global inference.

H2: Related Frame Same Event
This hypothesis is an extension of *H1*, which relaxes "the same frame" constraint to "related frames". In this paper, frames are considered to be related if and only if they are connected by one of the following three relations: *Inheritance*, *See_also* and *Perspective_on* (see section 2.2). For example, the frame `Invading` is inherited from `Attack`, and they actually express the same type of event, `Attack`. With this hypothesis, sentences under related frames help each other to infer their event types during global inference.

The previous two hypotheses are basically true for most frames but not perfect. For example, for the frame `Dead_or_alive`, only a few of the sentences under it express `Die` events while the remainder do not. To amend the this flaw, we introduce the third hypothesis.

H3: Same LU Same Event
This hypothesis indicates that sentences under the same LU tend to express events of the same type (as a remind, LUs are under frames). It is looser than the previous two hypotheses thus holds true in more situations. For example, *H3* holds true for the frame `Dead_or_alive` which violates *H1* and *H2*. In FN, LUs annotated for that frame are *alive.a, dead.a, deceased.a, lifeless.a, living.n, undead.a* and *undead.n*. All exemplars under *dead.a, deceased.a* and *lifeless.a* express `Die` events. Therefore, this hypothesis amends the flaws of the former two hypotheses.

On the other hand, the first two hypotheses also help *H3* in some cases. For example, most of the sentences belonging to the LU *suit.n* under the frame `Clothing` are misidentified as `Sue` events due to the ambiguity of the word "suit". However, in this situation, *H1* can help to rectify it because the majority of LUs under `Clothing` are not ambiguous words. Thus, under the first hypothesis, the misidentified results are expected to be corrected by the the results of other exemplars belonging to `Clothing`.

4.3 Inference

To model the above hypotheses as logic formulas in PSL, we introduce a set of predicates (see Table 2), which are grouped into two categories: observed predicates and target predicates. Observed predicates are used to encode evidences, which are always assumed to be known during the inference, while target predicates are unknown and thus need to be predicted.

$CandEvt(c,t)$ is introduced to represent $conf(c,t)$, which is the confidence value generated by the basic ED model for classifying the candidate c as an event of the type t. $SameFr(c_1,c_2)$ indicates whether the candidates c_1 and c_2 belong to the same frame. It is initialized by the indicator function $I_{sf}(c_1,c_2)$, which is defined as follows:

$$I_{sf}(c_1,c_2) = \begin{cases} 1 & c_1, c_2 \text{ from the same frame} \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

$SameLU(c_1,c_2)$ is similar, but applies for candidates under the same LU. The last three observed predicates in Table 2 are used to encode the aforementioned semantic relations between frames. For example, $Inherit(c_1,c_2)$ indicates whether the frame of c_1 is inherited from that of c_2, and it is initialized by the indicator function $I_{ih}(c_1,c_2)$, which is set to 1 if and only if the frame of c_1 is inherited from that of c_2, otherwise 0. $Evt(c,t)$ is the only target predicate, which indicates that the candidate c triggers an event of type t.

Type	Predicate	Assignment
Observed	$CandEvt(c,t)$	$conf(c,t)$
	$SameFr(c_1,c_2)$	$I_{sf}(c_1,c_2)$
	$SameLU(c_1,c_2)$	$I_{sl}(c_1,c_2)$
	$Inherit(c_1,c_2)$	$I_{ih}(c_1,c_2)$
	$SeeAlso(c_1,c_2)$	$I_{sa}(c_1,c_2)$
	$Perspect(c_1,c_2)$	$I_{pe}(c_1,c_2)$
Target	$Evt(c,t)$	—

Table 2: Predicates and their initial assignments.

Putting all the predicates together, we design a set of formulas to apply the aforementioned hypotheses in PSL (see Table 3). Formula f_1 connects the target predicate with the initial judgements from the basic ED model. Formulas f_2 and f_3 respectively encode *H1* and *H3*. Finally, the remaining formulas are designed for various relations between frames in *H2*. We tune the formulas's weights via grid search (see Section 5.4). The inference results provide us with the most likely

	Formulas
f_1	$CandEvt(c,t) \rightarrow Evt(c,t)$
f_2	$SameFr(c_1,c_2) \wedge Evt(c_1,t) \rightarrow Evt(c_2,t)$
f_3	$SameLU(c_1,c_2) \wedge Evt(c_1,t) \rightarrow Evt(c_2,t)$
f_4	$Inherit(c_1,c_2) \wedge Evt(c_1,t) \rightarrow Evt(c_2,t)$
f_5	$SeeAlso(c_1,c_2) \wedge Evt(c_1,t) \rightarrow Evt(c_2,t)$
f_6	$Perspect(c_1,c_2) \wedge Evt(c_1,t) \rightarrow Evt(c_2,t)$

Table 3: Formulas in the PSL model

interpretation, that is, the soft-truth values of the predicate Evt. The final detected event type t of candidate c is decided by the the equation:

$$t = \underset{t'}{\operatorname{argmax}}\, Evt(c,t') \quad (2)$$

5 Evaluations

In this section, we present the experiments and the results achieved. We first manually evaluate our novel PSL-based ED model on the FN corpus. Then, we also conduct automatic evaluations for the events detected from FN based on ACE corpus. Finally, we analyze possible mappings from frames/LUs to event types.

5.1 Data

We learned the basic ED model on ACE2005 dataset. In order to evaluate the learned model, we followed the evaluation of (Li et al., 2013): randomly selected 30 articles from different genres as the development set, and we subsequently conducted a test on a separate set of 40 ACE 2005 newswire documents. We used the remaining 529 articles as the training data set.

We apply our proposed PSL-based approach to detect events in FrameNet. Via collecting all exemplars annotated in FN, we totally obtain 154,484 sentences for detection.

5.2 Setup and Performance of Basic Model

We have presented the basic ED model in Section 3. Hyperparameters were tuned by grid search on the development data set. In our experiments, we set the size of the hidden layer to 300, the size of word embedding to 200, the batch size to 100 and the dropout rate to 0.5.

Table 4 shows the experimental results, from which we can see that the three-layer *ANN* model is surprisingly effective for event detection, which even yields competitive results compared with *Nguyen's CNN* and *Chen's DMCNN*. We believe the reason is that, compared with *CNN* and *DMCNN*,

Methods	Pre	Rec	F1
Nguyen's CNN (2015)	71.8	**66.4**	69.0
Chen's DMCNN (2015)	75.6	63.6	69.1
Liu's Approach (2016)	75.3	64.4	**69.4**
ANN (ours)	**79.5**	60.7	68.8
ANN-Random (ours)	**81.0**	49.5	61.5

Table 4: Performance of the basic ED model. *ANN* uses pre-trained word embeddings while *ANN-Random* uses randomly initialized embeddings.

ANN focuses on capturing lexical features which have been proved much more important than sentence features for the ED task by (Chen et al., 2015). Moreover, our basic model achieves much higher precision than state-of-the-art approaches (79.5% vs. 75.6%).

We also investigate the performance of the basic ED model without pre-trained word embeddings[6] (denoted by *ANN-Random*). The result shows that randomly initialized word embeddings decrease the F_1 score by 7.3 (61.5 vs. 68.8). The main reasons are: 1). ACE corpus only contains 599 articles, which are far insufficient to train good embeddings. 2). Words only existing in the test dataset always retain random embeddings.

5.3 Baselines

For comparison, we designed four baseline systems that utilize different hypotheses to detect events in FN.

(1) *ANN* is the first baseline, which directly uses a basic ED model learned on ACE training corpus to detect events in FN. This system does not apply any hypotheses between frames and events.

(2) *SameFrame (SF)* is the second baseline system, which applies *H1* over the results from *ANN*. For each frame, we introduce a score function $\phi(f,t)$ to estimate the probability that the frame f could be mapped to the event type t as follows:

$$\phi(f,t) = \frac{1}{||S_f||} \sum_{c \in S_f} I(c,t) \quad (3)$$

where S_f is the set of sentences under the frame f; $I(c,t)$ is an indicator function which is true if and only if *ANN* predicts the candidate c as an event of type t. Then for each frame f satisfying $\phi(f,t) > \alpha$, we mapped it to event type t, where α is a hyperparameter. Finally, all sentences under mapped frames are labeled as events. Note that, unlike the PSL-based approach which applies constraints as soft rules, this system utilizes *H1* as a hard constraint.

(3) *RelatedFrame (RF)* is the third baseline system, which applies *H2* over the results from *ANN*. For each frame f, we merge it and its related frames into a super frame, $f^{'}$. Similar with *SF*, a score function $\zeta(f^{'},t)$, which shares the same expression to equation 3, is introduced. For the merged frame satisfying $\zeta(f^{'},t) > \beta$, we mapped it to the event type t. Finally, all sentences under $f^{'}$ are labeled as events.

(4) *SameLU (SL)* is the last baseline, which applies the hypothesis *H3* over the results from *ANN*. Also, a score function $\psi(l,t)$ is introduced:

$$\psi(l,t) = \frac{1}{||S_l||} \sum_{c \in S_l} I(c,t) \quad (4)$$

where S_l is the set of sentences under the LU l. For each LU satisfying $\psi(l,t) > \gamma$, we mapped it to the event type t. Finally, all sentences under l are labeled as events.

5.4 Manual Evaluations

In this section, we manually evaluate the precision of the baseline systems and our proposed PSL-based approach. For fair comparison, we set α, β and γ to 0.32, 0.29 and 0.42 respectively to ensure they yield approximately the same amount of events as the first baseline system *ANN*. We tune the weights of formulas in PSL via grid search by using ACE development dataset. In details, we firstly detect events in FN under different configurations of formulas' weights and add them to ACE training dataset, respectively. Consequently, we obtain several different expanded training datasets. Then, we separately train a set of basic ED models based on each of these training datasets and evaluate them over the development corpus. Finally, the best weights are selected according to their performances on the development dataset. The weights of $f_1 \sim f_5$ used in this work are 100, 10, 100, 5, 5 and 1, respectively.

Manual Annotations

Firstly, we randomly select 200 samples from the results of each system. Each selected sample is a sentence with a highlighted trigger and a predicted event type. Figure 3 illustrates three samples. The first line of each sample is a sentence labeled with the trigger. The next line is the predicted event

[6]We thank the anonymous reviewer for this suggestion.

type of that sentence. Annotators are asked to assign one of two labels to each sample (annotating in the third line):

Y: the word highlighted in the given sentence indeed triggers an event of the predicted type.

N: the word highlighted in the given sentence does not trigger any event of the predicted type.

We can see that, it is very easy to annotate a sample for annotators, thus the annotated results are expected to be of high quality.

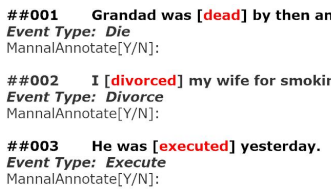

Figure 3: Examples of manual annotations.

To make the annotation more credible, each sample is independently annotated by three annotators[7] (including one of the authors and two of our colleagues who are familiar with ACE event task) and the final decision is made by voting.

Results

Table 5 shows the results of manual evaluations. Through the comparison of *ANN* and *SF*, we can see that the application of *H1* caused a loss of 5.5 point. It happens mainly because the performance of *SF* is very sensitive to the wrongly mapped frames. That is, if a frame is mismapped, then all sentences under it would be mislabeled as events. Thus, even a single mismapped frame could significantly hurt the performance. This result also proves that *H1* is inappropriate to be used as a hard constraint. As *H2* is only an extension of *H1*, *RF* performs similarly with *SF*. Moreover, *SL* obtains a gain of 2.0% improvement compared with *ANN*, which demonstrates that the "same LU" hypothesis is very useful. Finally, with all the hypotheses, the *PSL-based* approach achieves the best performance, which demonstrates that our hypotheses are useful and it is an effective way to jointly utilize them as soft constraints through PSL for event detection in FN.

5.5 Automatic Evaluations

To prepare for automatic evaluations, we respectively add the events detected from FN by each of the aforementioned five systems to ACE training corpus. Consequently, we obtain five expanded training datasets: *ACE-ANN-FN, ACE-SF-FN, ACE-RF-FN, ACE-SL-FN* and *ACE-PSL-FN*. Then, we separately train five basic ED models on each of these corpus and evaluate them on the ACE testing data set. This experiment is an indirect evaluation of the events detected from FN, which is based on the intuition that events with higher accuracy are expected to bring more improvements to the basic model.

[7]The inter-agreement rate is 86.1%

Methods		Precision (%)
Baselines	ANN	77.5
	SF	72.0
	RF	71.0
	SL	79.5
PSL-based Approach		**81.0**

Table 5: Results of manual evaluations.

Training Corpus	Pre	Rec	F_1
ACE-ANN-FN	77.2	63.5	69.7
ACE-SF-FN	73.2	64.1	68.4
ACE-RF-FN	72.6	63.9	68.0
ACE-SL-FN	77.5	64.3	70.3
ACE-PSL-FN	**77.6**	**65.2**	**70.7**

Table 6: Automatic evaluations of events from FN.

Table 6 presents the results where we measure precision, recall and F_1. Compared with *ACE-ANN-FN*, events from *SF* and *RF* hurt the performance. As analyzed in previous section, *SF* and *RF* yield quite a few false events, which dramatically hurt the accuracy. Moreover, *ACE-SL-FN* obtains a score of 70.3% in F_1 measure, which outperforms *ACE-ANN-FN*. This result illustrates the effectiveness of our "same LU" hypothesis. Finally and most importantly, consistent with the results of manual evaluations, *ACE-PSL-FN* performs the best, which further proves the effectiveness of our proposed approach for event detection in FN.

5.6 Improving Event Detection Using FN

Event detection generally suffers from data sparseness due to lack of labeled samples. In this section, we investigate the effects of alleviating the aforementioned problem by using the events detected from FN as extra training data. Our investigation is conducted by the comparison of two basic ED models, *ANN* and *ANN-FN*: the former is trained on ACE training corpus and the latter is trained on the new training corpus *ACE-PSL-FN* (introduced in the previous section), which contains 3,816 extra events detected from FN.

Methods	Pre	Rec	F_1
Nguyen's CNN(2015)	71.8	**66.4**	69.0
Chen's DMCNN(2015)	75.6	63.6	69.1
Liu's Approach(2016)	75.3	64.4	69.4
ANN (Ours)	**79.5**	60.7	68.8
ANN-FN (Ours)	77.6	65.2	**70.7**

Table 7: Effects of expanding training data using events automatically detected from FN.

Table 7 presents the experimental results. Compared with *ANN*, *ANN-FN* achieves a significant improvement of 1.9% in F_1 measure. It happens mainly because that the high accurate extra training data makes the model obtain a higher recall (from 60.7% to 65.2%) with less decrease of precision (from 79.5% to 77.6%). The result demonstrates the effectiveness of alleviating the data sparseness problem of ED by using events detected from FN. Moreover, compared with state-of-the-art methods, *ANN-FN* outperforms all of them with remarkable improvements (more than 1.3%).

5.7 Analysis of Frame-Event Mapping

In this section, we illustrate the details of mappings from frames to event types. The mapping pairs are obtained by computing the function ϕ (see Section 5.3) for each (frame, event-type) pair (f, t) based on the events detected by the PSL-based approach. Table 8 presents the top 10 mappings. We manually evaluate their quality by investigating: (1) whether the definition of each frame is compatible with its mapped event type; (2) whether exemplars annotated for each frame actually express events of its mapped event type.

For the first issue, we manually compare the definitions of each mapped pair. Except `Relational_nat_features`[8], definitions of all the mapped pairs are compatible. For the second issue, we randomly sample 20 exemplars (if possible) from each frame and manually annotate them. Except the above frame and `Invading`, exemplars of the remaining frames all express the right events. The only exemplar of `Invading` failing to express its mapped event is as follows: "*The **invasion** of China by western culture has had a number of far-reaching effects on Confucianism.*" ACE requires an `Attack` event to be a physical act, while the invasion of culture is unphysical. Thus, the above sentence does not express an `Attack` event. To sum up, the quality of our mappings is good, which demonstrates that the hypothesis *H1* is basically true.

[8]The full name is Relational_natural_relations in FN.

Frame	Event	N_e/$\|\|S_f\|\|$	ϕ
Hit_target	Attack	2/2	1.0
Relational nat_features	Meet	1/1	1.0
Invading	Attack	120/121	0.99
Fining	Fine	26/27	0.96
Being_born	Be-Born	32/36	0.88
Rape	Attack	104/125	0.83
Sentencing	Sentence	57/70	0.81
Attack	Attack	99/129	0.77
Quitting	End-Position	102/137	0.74
Notification of_charges	Charge-Indict	73/103	0.71

Table 8: Top 10 mappings from frames to event types. N_e is the number of exemplars detected as events; $||S_f||$ and ϕ hold the same meanings as mentioned in Section 5.3.

5.8 Analysis of LU-Event Mapping

This section illustrates the details of mappings from LUs to event types. The mapping pairs are obtained by computing the function ψ (see Section 5.3). Table 9 presents the top 10 mappings. In FN, each LU belongs to a frame. In table 9, we omit the frame of each LU because of space limitation[9].

LU	Event	N_e/$\|\|S_l\|\|$	ψ
gunfight.n	Attack	14/14	1.0
injure.v	Injure	14/14	1.0
divorce.n	Divorce	11/11	1.0
decapitation.n	Die	5/5	1.0
trial.n	Trial-Hearing	25/25	1.0
assault.v	Attack	21/21	1.0
fight.v	Attack	12/12	1.0
arrest.n	Arrest-Jail	38/38	1.0
divorce.v	Divorce	35/35	1.0
shoot.v	Attack	2/2	1.0

Table 9: Top 10 mappings from LUs to event types. N_e is the number of exemplars detected as events; $||S_l||$ and ψ hold the same meanings as mentioned in Section 5.3.

To investigate the mapping quality, we manu-

[9]Their frames separately are Hostile_encounter, Cause_harm, Forming_relationships, Killing, Trial, Attack, Quarreling, Arrest, Forming_relationships and Hit_target.

ally annotate the exemplars under these LUs. The result shows that all exemplars are rightly mapped. These mappings are quite good. We believe the reason is that an LU is hardly ambiguous due to its high specificity, which is not only specified by a lemma but also by a frame and a part of speech tag. Table 9 only presents the top 10 mappings. In fact, we obtain 54 mappings in total with $\psi = 1.0$. We released all the detected events and mapping results for further use by the NLP community.

6 Conclusions and Future Work

Motivated by the high similarity between frames and events, we conduct this work to study their relations. The key of this research is to detect events in FN. To solve this problem, we proposed a PSL-based global inference approach based on three hypotheses between frames and events. For evaluation, we first conduct manual evaluations on events detected from FN. The results reveal that our hypotheses are very useful and it is an effective way to jointly utilize them as soft rules through PSL. In addition, we also perform automatic evaluations. The results further demonstrate the effectiveness of our proposed approach for detecting events in FN. Furthermore, based on the detected results, we analyze the mappings from frames/LUs to event types. Finally, we alleviate the data sparseness problem of ED by using events detected from FN as extra training data. Consequently, we obtain a remarkable improvement and achieve a new state-of-the-art result for the ED task.

Event detection is only a component of the overall task of event extraction, which also includes event role detection. In the future, we will extend this work to the complete event extraction task. Furthermore, event schemas in ACE are quite coarse. For example, all kinds of violent acts, such as street fights and wars, are treated as a single event type `Attack`. We plan to refine the event schemas by the finer-grained frames defined in FN (i.e. `Attack` may be divided into *`Terrorism`*, *`Invading`*, etc.).

Abstract

Solving simple arithmetic word problems is one of the challenges in Natural Language Understanding. This paper presents a novel method to learn to use formulas to solve simple arithmetic word problems. Our system, analyzes each of the sentences to identify the variables and their attributes; and automatically maps this information into a higher level representation. It then uses that representation to recognize the presence of a formula along with its associated variables. An equation is then generated from the formal description of the formula. In the training phase, it learns to score the <formula, variables> pair from the systematically generated higher level representation. It is able to solve 86.07% of the problems in a corpus of standard primary school test questions and beats the state-of-the-art by a margin of 8.07%.

1 Introduction

Developing algorithms to solve math word problems (Table 1) has been an interest of NLP researchers for a long time (Feigenbaum and Feldman, 1963). It is an interesting topic of study from the point of view of natural language understanding and reasoning for several reasons. First, it incorporates rigorous standards of accurate comprehension. Second, we know of a good representation to solve the word problems, namely algebraic equations. Finally, the evaluation is straightforward and the problems can be collected easily.

In the recent years several challenges have been proposed for natural language understanding. This includes the Winograd Schema challenge for commonsense reasoning (Levesque, 2011), Story Comprehension Challenge (Richardson et al., 2013), Facebook bAbl task (Weston et al., 2015), Semantic Textual Similarity (Agirre et al., 2012) and Textual Entailment (Bowman et al., 2015; Dagan et al., 2010). The study of word math problems is also an important problem as quantitative reasoning is inextricably related to human life. Clark & Etzioni (Clark, 2015; Clark and Etzioni, 2016) discuss various properties of math word (and science) problems emphasizing elementary school science and math tests as a driver for AI.

Researchers at Allen AI Institute have published two standard datasets as part of the Project Euclid[1] for future endeavors in this regard. One of them contains simple addition-subtraction arithmetic problems (Hosseini et al., 2014) and the other contains general arithmetic problems (Koncel-Kedziorski et al., 2015). In this research, we focus on the former one, namely the *AddSub* dataset.

Dan grew 42 turnips and 38 cantelopes . Jessica grew 47 turnips . How many turnips did they grow in total ?	
Formula	**Associated variables**
part-whole	*whole:* x, *parts:* $\{42, 47\}$
Equation	$x = 42 + 47$

Table 1: Solving a word problem using *part-whole*

Broadly speaking, common to the existing approaches (Kushman et al., 2014; Hosseini et al., 2014; Zhou et al., 2015; Shi et al., 2015; Roy and Roth, 2015) is the task of grounding, that takes as input a word problem in the natural language and represents it in a formal language, such as, a system of equations, expression trees or states (Hosseini et al., 2014), from which the answer can be easily computed. In this work, we divide this task of grounding into two parts as follows:

[1] http://allenai.org/euclid.html

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2144–2153,
Berlin, Germany, August 7-12, 2016.

In the first step, the system learns to connect the assertions in a word problem to abstract mathematical concepts or *formulas*. In the second step, it maps that formula into an algebraic equation. Examples of such formulas in the arithmetic domain includes *part whole* which says, 'the whole is equal to the sum of its parts', or the *Unitary Method* that is used to solve problems like '*A man walks seven miles in two hours. What is his average speed?*'.

Consider the problem in Table 1. If the system can determine it is a 'part whole' problem where the unknown quantity X plays the role of *whole* and its *parts* are 42 and 47, it can easily express the relation as $X = 42 + 47$. The translation of a formula to an equation requires only the knowledge of the formula and can be formally encoded. Thus, we are interested in the question, 'how can an agent learn to apply the formulas for the word problems?' Solving a word problem in general, requires several such applications in series or parallel, generating multiple equations. However, in this research, we restrict the problems to be of a single equation which requires only one application.

Our system currently considers three mathematical concepts: 1) the concept of *part whole*, 2) the concept of *change* and 3) the concept of *comparison*. These concepts are sufficient to solve the arithmetic word problems in *AddSub*. Table 2 illustrates each of these three concepts with examples. The *part whole* problems deal with the part whole relationships and ask for either the part or the whole. The *change* problems make use of the relationship between the new value of a quantity and its original value after the occurrence of a series of increase or decrease. The question then asks for either the initial value of the quantity or the final value of the quantity or the change. In case of *comparison problems*, the equation can be visualized as a comparison between two quantities and the question typically looks for either the larger quantity or the smaller quantity or the difference. While the equations are simple, the problems describe a wide variety of scenarios and the system needs to make sense of multiple sentences without a priori restrictions on the syntax or the vocabulary to solve the problem.

Training has been done in a supervised fashion. For each example problem, we specify the formula that should be applied to generate the appropriate equation and the relevant variables. The system then learns to apply the formulas for new problems. It achieves an accuracy of 86.07% on the *AddSub* corpus containing 395 word arithmetic problems with a margin of 8.07% with the current state-of-the-art (Roy and Roth, 2015).

Our contributions are three-fold: (a) We model the application of a formula and present a novel method to learn to apply a formula; (b) We annotate the publicly available *AddSub* corpus with the

Change
RESULT UNKNOWN
Mary had 18 baseball cards , and 8 were torn . Fred gave Mary 26 new baseball cards . Mary bought 40 baseball cards . How many baseball cards does Mary have now ?
CHANGE UNKNOWN
There were 28 bales of hay in the barn . Tim stacked bales in the barn today . There are now 54 bales of hay in the barn . How many bales did he store in the barn ?
START UNKNOWN
Sam 's dog had puppies and 8 had spots . He gave 2 to his friends . He now has 6 puppies . How many puppies did he have to start with?
Part Whole
TOTAL SET UNKNOWN
Tom went to 4 hockey games this year , but missed 7 . He went to 9 games last year . How many hockey games did Tom go to in all ?
PART UNKNOWN
Sara 's high school played 12 basketball games this year . The team won most of their games . They were defeated during 4 games . How many games did they win ?
Comparision
DIFFERENCE UNKNOWN
Last year , egg producers in Douglas County produced 1416 eggs . This year , those same farms produced 4636 eggs . How many more eggs did the farms produce this year ?
LARGE QUANTITY UNKNOWN

correct formula and its associated variables; and (c) We make the code publicly available. [2]

The rest of the paper is organized as follows. In section 2, we formally define the problem and describe our learning algorithm. In section 3, we define our feature function. In section 4, we discuss related works. Section 5 provides a detailed description of the experimental evaluation. Finally, we conclude the paper in section 6.

2 Problem Formulation

A single equation word arithmetic problem P is a sequence of k words $\langle w_1, ..., w_k \rangle$ and contains a set of *variables* $\mathbb{V}_P = \{v_0, v_1, ..., v_{n-1}, x\}$ where $v_0, v_1, ..., v_{n-1}$ are *numbers* in P and x is the *unknown* whose value is the answer we seek (Koncel-Kedziorski et al., 2015). Let $\mathcal{P}_{addsub}$ be the set of all such problems, where each problem $P \in \mathcal{P}_{addsub}$ can be solved by a evaluating a valid mathematical equation E formed by combining the elements of $\mathbb{V}_P$ and the binary operators from $\mathcal{O} = \{+, -\}$.

We assume that each target equation E of $P \in \mathcal{P}_{addsub}$ is generated by applying one of the possible mathematical formulas from $\mathcal{C} = \{C_{partwhole}, C_{change}, C_{comparision}\}$. Let $\mathcal{P}^1_{addsub} \subseteq \mathcal{P}_{addsub}$ be the set of all problems where the target equation E can be generated by a single application of one of the possible formulas from $\mathcal{C}$. The goal is then to find the correct application of a formula for the problem $P \in \mathcal{P}^1_{addsub}$.

2.1 Modelling Formulas And their Applications

We model each formula as a template that has predefined slots and can be mapped to an equation when the slots are filled with variables. Application of a formula $C \in \mathcal{C}$ to the problem P, is then defined as the instantiation of the template by a subset of $\mathbb{V}_P$ that contains the *unknown*.

Part Whole The concept of *part whole* has two slots, one for the *whole* that accepts a single variable and the other for its *parts* that accepts a set of variables of size at least two. If the value of the whole is w and the value of the parts are $p_1, p_2, ..., p_m$, then that application is mapped to the equation, $w = p_1 + p_2 + ... + p_m$, denoting that *whole is equal to the sum of its parts*.

[2]The code and data is publicly available at *https://github.com/ari9dam/MathStudent*.

Change The *change* concept has four slots, namely *start, end, gains, losses* which respectively denote the original value of a variable, the final value of that variable, and the set of increments and decrements that happen to the original value of the variable. The *start* slot can be empty; in that case it is assumed to be 0. For example, consider the problem, '*Joan found 70 seashells on the beach . she gave Sam some of her seashells. She has 27 seashell . How many seashells did she give to Sam?*'. In this case, our assumption is that before finding the 70 seashells *Joan* had an empty hand. Given an instantiation of *change* concept the equation is generated as follows:

$$val_{start} + \sum_{g \in gains} val_g = \sum_{l \in losses} val_l + val_{end}$$

Comparision The *comparision* concept has three slots namely the *large* quantity, the *small* quantity and their *difference*. An instantiation of the *comparision* concept is mapped to the following equation: $large = small + difference$.

2.2 The Space of Possible Applications

Consider the problem in Table 1. Even though the correct application is an instance of *part whole* formula with *whole* = x and the *parts* being $\{42, 47\}$, there are many other possible applications, such as, *partWhole(whole=47, parts=x,42)*, *change(start=47, losses={x}, gains={}, end = 42)*, *comparison(large=47, small=x, difference=42)*. Note that, *comparison(large=47, small=38, difference=42)* is not a valid application since none of the associated variables is an *unknown*. Let A_P be the set of all possible applications to the problem P. The following *lemma* characterizes the size of A_P as a function of the number of variables in P.

Lemma 2.2.1. *Let $P \in \mathcal{P}^1_{addsub}$ be an arithmetic word problem with n variables ($|\mathbb{V}_P| = n$), then the following are true:*

1. *The number of possible applications of part whole formula to the problem P, $N_{partwhole}$ is $(n+1)2^{n-2} + 1$.*
2. *The number of possible applications of change formula to the problem P, N_{change} is $3^{n-3}(2n^2 + 6n + 1) - 2n + 1$.*
3. *The number of possible applications of comparison formula to the problem P, $N_{comparison}$ is $3(n-1)(n-2)$.*

4. *The number of all possible applications to the problem P is $N_{partwhole} + N_{change} + N_{comparison}$.*

Proof of lemma 2.2.1 is provided in the Appendix. The total number of applications for problems having 3, 6, 7, 8 number of variables are 47, 3,105, 11,755, 43,699 respectively. Addition-Subtraction arithmetic problems hardly contain more than 6 variables. So, the number of possible applications is not intractable in practice.

The total number of applications increases rapidly mainly due to the *change* concept. Since, the template involves two sets, there is a 3^{n-3} factor present in the formula of N_{change}. However, any application of *change* concept with *gains* and *losses* slots containing a collection of variables can be broken down into multiple instances of *change* concept where the *gains* and *losses* slots accepts only a single variable by introducing more intermediate *unknown* variables. Since, for any formula that does not have a slot that accepts a set, the number of applications is polynomial in the number of variables, there is a possibility to reduce the application space. We plan to explore this possibility in our future work. For the *part whole* concept, even though there is a exponential term involved, it is practically tractable (for $n = 10$, $N_{partwhole} = 2,817$). In practice, we believe that there will hardly be any *part whole* application involving more than 10 variables. For formulas that are used for other categories of word math problems (algebraic or arithmetic), such as the *unitary method*, formulas for *ratio*, *percentage*, *time-distance* and *rate of interest*, none of them have any slot that accepts sets of variables. Thus, further increase in the space of possible applications will be polynomial.

2.3 Probabilistic Model

For each problem P there are different possible applications $y \in A_P$, however not all of them are meaningful. To capture the semantics of the word problem to discriminate between competing applications we use the log-linear model, which has a feature function ϕ and parameter vector $\theta \in \mathbb{R}^d$. The feature function $\phi : H \rightarrow \mathbb{R}^d$ takes as input a problem P and a possible application y and maps it to a d-dimensional real vector (*feature vector*) that aims to capture the important information required to discriminate between competing applications. Here, the set H is defined as $\{(P, y) : P \in \mathcal{P}^1_{addsub} \wedge y \in A_P\}$, to accommodate the dependency of the possible applications on the problem instance. Given the definition of the feature function ϕ and the parameter vector θ, the probability of an application y given a problem P is defined as,

$$p(y|P;\theta) = \frac{e^{\theta.\phi(P,y)}}{\sum_{y' \in A_P} e^{\theta.\phi(P,y')}}$$

Here, . denotes dot product. Section 3 defines the feature function. Assuming that the parameter θ is known, the function f that computes the correct application is defined as,

$$f(P) = \arg\max_{y \in A_P} p(y|P;\theta)$$

2.4 Parameter Estimation

To learn the function f, we need to estimate the parameter vector θ. For that, we assume access to n training examples, $\{P_i, y_i^* : i = 1 \ldots n\}$, each containing a word problem P_i and the correct application y_i^* for the problem P_i. We estimate θ by minimizing the negative of the conditional log-likelihood of the data:

$$\begin{aligned} O(\theta) &= -\sum_{i=1}^{n} log\ p(y_i^*|P_i;\theta) \\ &= -\sum_{i=1}^{n} [\theta.\phi(P_i, y_i^*) - log \sum_{y \in A_{P_i}} e^{\theta.\phi(P_i,y)}] \end{aligned}$$

We use stochastic gradient descent to optimize the parameters. The gradient of the objective function is given by:

$$\begin{aligned} \frac{\nabla O}{\nabla \theta} = -\sum_{i=1}^{n} [\phi(P_i, y_i^*) - \\ \sum_{y \in A_{P_i}} p(y|P_i;\theta) \times \phi(P_i, y)] \end{aligned} \quad (1)$$

Note that, even though the space of possible applications vary with the problem P_i, the gradient for the example containing the problem P_i can be easily computed.

3 Feature Function ϕ

A formula captures the relationship between variables in a compact way which is sufficient to generate an appropriate equation. In a word problem, those relations are hidden in the assertions

of the story. The goal of the feature function is thus to gather enough information from the story so that underlying mathematical relation between the variables can be discovered. The feature function thus needs to be aware of the mathematical relations so that it knows what information it needs to find. It should also be "familiar" with the word problem language so that it can extract the information from the text. In this research, the feature function has access to machine readable dictionaries such as WordNet (Miller, 1995), ConceptNet (Liu and Singh, 2004) which captures inter word relationships such as hypernymy, synonymy, antonymy etc, and syntactic and dependency parsers that help to extract the subject, verb, object, preposition and temporal information from the sentences in the text. Given these resources, the feature function first computes a list of attributes for each variable. Then, for each application y it uses that information, to compute if some aspects of the expected relationship described in y is satisfied by the variables in y.

Let the first b dimensions of the feature vector contain part whole related features, the next c dimensions are for change related features and the remaining d features are for comparison concept. Then the feature vector for a problem P and an application of a formula y is computed in the following way:

Data: A word problem P, an application y
Result: d-dimensional feature vector, fv
Initialize $fv := 0$
if *y is instance of part whole* **then**
  compute $fv[1 : b]$
end
if *y is instance of change* **then**
  compute $fv[b + 1 : b + c]$
end
if *y is instance of comparision* **then**
  compute $fv[b + c + 1 : b + c + d]$
end

Algorithm 1: Skeleton of the feature function ϕ

The rest of the section is organized as follows. We first describe the attributes of the variables that are computed from the text. Then, we define a list of boolean variables which computes semantic relations between the attributes of each pair of variables. Finally, we present the complete definition of the feature function using the description of the attributes and the boolean variables.

3.1 Attributes of Variables

For each occurrence of a number in the text a variable is created with the attribute *value* referring to that numeric value. An unknown variable is created corresponding to the question. A special attribute *type* denotes the kind of object the variable refers to. Table 3 shows several examples of the *type* attribute. It plays an important role in identifying irrelevant numbers while answering the question.

Text	Type
John had **70** seashells	seashells
70 seashells and **8** were broken	seashells
61 male and 78 female salmon	male, salmon
35 pears and 27 apples	pear

Table 3: Example of *type* for highlighted variables.

The other attributes of a variable captures its linguistic context to surrogate the meaning of the variable. This includes the *verb* attribute i.e. the verb attached to the variable, and attributes corresponding to Stanford dependency relations (De Marneffe and Manning, 2008), such as *nsubj*, *tmod*, *prep in*, that spans from either the words in associated *verb* or words in the *type*. These attributes were computed using Stanford Core NLP (Manning et al., 2014). For the sentence, "John found 70 seashells on the beach." the attributes of the variable are the following: { **value** : {70}, **verb :** {*found*} , **nsubj :** {*John*}, **prep on :** {*beach* }}.

3.2 Cross Attribute Relations

Once the variables are created and their attributes are extracted, our system computes a set of boolean variables, each denoting whether the attribute a_1 of the variable v_1 has the same value as the attribute a_2 of the variable v_2. The value of each attribute is a set of words, consequently set equality is used to calculate attribute equality. Two words are considered equal if their lemma matches.

Four more boolean variables are computed for each pair of variables based on the attribute *type* and they are defined as follows:

subType: Variable v_1 is a $subType$ of variable v_2 if $v_2.type \subset v_1.type$ or their type consists of a single word and there exists the *IsA* relation between them in ConceptNet (Speer and Havasi, 2013; Liu and Singh, 2004).

disjointType is true if $v_1.type \bigcap v_2.type = \phi$

intersectingType is true if v_1 is neither a $subType$ of v_2 nor is $disjointType$ nor $equal$.

We further compute some more variables by utilizing several relations that exist between words:

antonym: For every pair of variables v_1 and v_2, we compute an antonym variable that is true if there exists a pair of word in $(v_1.verb \bigcup v1.adj) \times (v_2.verb \bigcup v2.adj)$ that are antonym to each other in WordNet irrespective of their part of speech tag.

relatedVerbs: The verbs of two variables are related if there exists a *RelatedTo* relations in ConceptNet between them.

subjConsume: The *nsubj* of v_1 consumes the *nsubj* of v_2 if the formers refers to a group and the latter is a part of that group. For example, in the problem, '*Joan grew 29 carrots and 14 watermelons . Jessica grew 11 carrots . How many carrots did they grow in all ?*', the *nsubj* of the *unknown* variable consumes others. This is computed using Stanford co-reference resolution. For the situation where there is a variable with *nsubj* as 'they' and it does not refer to any entity, the *subjConsume* variable is assumed to be implicitly true for any variable having a *nsubj* of type *person*.

3.3 Features: Part Whole

The *part whole* features look for some combinations of the boolean variables and the presence of some cue words (e.g. 'all') in the attribute list. These features capture the underlying reasonings that can affect the decision of applying a *part whole* concept. We describe the conditions which when satisfied activate the features. If active, the value of a feature is the number of variables associated with the application y and 0 otherwise. This is also true for *change* and *comparision* features also. *Part whole* features are computed only when the y is an instance of the formula *part whole*. The same applies for *change* and *comparision* features.

Generic Word Cue This feature is activated if $y.whole$ has a word in its attributes that belongs to the "total words set" containing the followings words "all", "total", "overall", "altogether", "together" and "combine"; and none of the variables in *parts* are marked with these words.

ISA Type Cue is active if all the part variables are *subType* of the whole.

Type-Verb Cue is active if the type and verb attributes of v_{whole} matches that of all the variables in the part slot of y.

Type-Individual Group Cue is active if the variable v_{whole} *subjConsume* each part variable v_p in y and their type matches.

Type-Verb-Tmod Cue is active if the variable in the slot *whole* is the *unknown* and for each part variable v_p their *verb*, *type* and *tmod* (time modifier of the verb) attributes match.

Type-SubType-Verb Cue is active if the variable in the slot *whole* is either the *unknown* or marked with a word in "total words set" and for all parts v_p, their verb matches and one of the type or *subType* boolean variable is true.

Type-SubType-Related Verb Cue is similar to *Type-SubType-Verb Cue* however relaxes the *verb* match conditions to *related verb* match. This is helpful in problems like '*Mary went to the mall. She spent $ 13.04 on a shirt and $ 12.27 on a jacket . She went to 2 shops . In total , how much money did Mary spend on clothing ? '*.

Type-Loose Verb Cue ConceptNet does not contain all relations between verbs. For example, according to ConceptNet 'buy' and 'spend' are related however there is no relation in ConceptNet between 'purchase' and 'spend'. To handle these situations, we use this feature which is similar to the previous one. The difference is that it assumes that the verbs of part-whole variable pairs are related if all verbs associated with the parts are same, even though there is no relation in ConceptNet.

Type-Verb-Prep Cue is active if type and verb matches. The whole does not have a "preposition" but parts have and they are different.

Other Cues There are also features that add *nsubj* match criteria to the above ones. The *prior* feature for *part whole* is that the whole if not unknown, is smaller than the sum of the parts. There is one more feature that is active if the two part variables are antonym to each other; one of type or subType should be true.

3.4 Features: Change

The *change* features are computed from a set of 10 simple indicator variables, which are computed in the following way:

Start Cue is active if the verb associated with the variable in *start* slot has one of the following possessive verbs : {'call for', 'be', 'contain', 'remain', 'want', 'has', 'have', 'hold', ...}; the type and *nsubj* of start variable match with the end variable and the tense of the end does not precede the start. The list of 'possessive verbs' is automatically constructed by adding all the verbs associated with the *start* and the *end* slot variables in annotated corpus.

Start Explicit Cue is active if one of following words, "started with", "initially", "begining", "originally" appear in the context of the start variable and the type of start and end variables match.

Start prior is active if the verb associated with the variable in *start* slot is a member of the set 'possessive verbs' and the variable appears in first sentence.

Start Default Cue is active if the start variable has a "possessive verb" with past tense.

End Cue is active if the verb associated with the variable in slot end has a possessive verb with the tense of the verb not preceding the tense of the start, in case the start is not missing. The type and nsubj should match with either the start or the gains in case the start is missing.

End Prior is true if v_{end} has a possessive verb and an unknown quantity and at least one of v_{end} or v_{start} does not have a *nsubj* attribute.

Gain Cue is active if for all variables in the *gains* slot, the type matches with either v_{end} or v_{start} and one of the following is true: 1) the nsubj of the variable matches with v_{end} or v_{start} and the verb implies gain (such as 'find') and 2) the nsubj of the variable does not match with v_{end} or v_{start} and the verb implies losing (e.g. spend). The set of gain and loss verbs are collected from the annotated corpus by following the above procedure.

Gain Prior is true if the problem contains only three variables, with $v_{start} < v_{end}$ and the only variable in the *gain* slot, associated with non-possessive verb is the unknown.

Loss Cue & Loss prior are designed in a fashion similar to the Gain cue and Gain Prior.

Let us say bad_{gains} denotes that none of the gain prior or gain cue is active even though the gain slot is not empty. bad_{losses} is defined similarly and let $bad = bad_{gains} \vee bad_{losses}$. Then the change features are computed from these boolean indicators using logical operators *and, or, not*. Table4 shows some of the change features.

$!bad \wedge gain_{cue} \wedge start_{default} \wedge end_{cue}$
$!bad \wedge !gain_{cue} \wedge loss_{cue} \wedge start_{default} \wedge end_{cue}$
$!bad \wedge (gain_{cue} \vee loss_{cue}) \wedge start_{cue} \wedge !start_{default} \wedge end_{cue}$
$!bad \wedge (gain_{cue} \vee loss_{cue}) \wedge start_{explicit} \wedge !start_{default} \wedge end_{cue}$
$!bad \wedge (gain_{cue} \vee loss_{cue}) \wedge start_{prior} \wedge (end_{cue} \| \| end_{prior})$
$!bad \wedge (gain_{cue} \vee loss_{cue}) \wedge (start_{prior} \vee start_{cue}) \wedge !start_{default} \wedge end_{prior}$

Table 4: Activation criteria of some *change* related features.

3.5 Features: Comparison

The features for the "compare" concept are relatively straight forward.

Difference Unknown Que If the application y states that the unknown quantity is the difference between the larger and smaller quantity, it is natural to see if the variable in the *difference* slot is marked with a comparative adjective or comparative adverb. The prior is that the value of the larger quantity must be bigger than the small one. Another two features add the type and subject matching criteria along with the previous ones.

Large & Small Unknown Que These features can be active only when the variable in the *large* or *small* slot is unknown. To detect if the referent is bigger or smaller, it is important to know the meaning of the comparative words such as 'less' and 'longer'. Since, the corpus contains only *33* comparison problems we collect these comparative words from web which are then divided into two categories. With these categories, the features are designed in a fashion similar to *change* features that looks for type, subject matches.

3.6 Handling Arbitrary Number of Variables

This approach can handle arbitrary number of variables. To see that consider the problem, 'Sally found 9 seashells , Tom found 7 seashells , and Jessica found 5 seashells on the beach . How many seashells did they find together ?'. Let us say that feature vector contains only the '*Type-Individual Group Cue*' feature and the weight

of that feature is 1. Consider the two following applications: y_1 = *partWhole(x,{9,7})* and y_2 = *partWhole(x,{9,7, 5})*. For both y_1 and y_2 the '*Type-Individual Group Cue*' feature is active since the subject of the unknown x refers to a group that contains the subject of all part variables in y_1 and y_2 and their types match. However, as mentioned in section 3.3, when active, the value of a feature is the number of variables associated with the application. Thus $\frac{p(y_2;P,\theta)}{p(y_1;P,\theta)} = \frac{e^4}{e^3} = e$. Thus, y_2 is more probable than y_1.

4 Related Works

Researchers in early years have studied math word problems in a constrained domain by either limiting the input sentences to a fixed set of patterns (Bobrow, 1964b; Bobrow, 1964a; Hinsley et al., 1977) or by directly operating on a propositional representation instead of a natural language text (Kintsch and Greeno, 1985; Fletcher, 1985). Mukherjee and Garain (2008) survey these works.

Among the recent algorithms, the most general ones are the work in (Kushman et al., 2014; Zhou et al., 2015) . Both algorithms try to map a word math problem to a 'system template' that contains a set of 'equation templates' such as $ax + by = c$. These 'system templates' are collected from the training data. They implicitly assume that these templates will reoccur in the new examples which is a major drawback of these algorithms. Also, Koncel-Kedziorski et al. (2015) show that the work of Kushman et al. (2014) heavily relies on the overlap between train and test data and when this overlap is reduced the system performs poorly.

Work of (Koncel-Kedziorski et al., 2015; Roy and Roth, 2015) on the other hand try to map the math word problem to an expression tree. Even though, these algorithms can handle all the four arithmetic operators they cannot solve problems that require more than one equation. Moreover, experiments show that our system is much more robust to diversity in the problem types between training and test data for the problems it handles.

The system ARIS in (Hosseini et al., 2014) solves the addition-subtraction problems by categorizing the verbs into seven categories such as 'positive transfer', 'loss' etc. It represents the information in a problem as a state and then updates the state according to the category of a verb as the story progresses. Both ARIS and our system share the property that they give some explanation behind the equation they create. However, the verb categorization approach of ARIS can only solve a subset of addition-subtraction problems (see error analysis in (Hosseini et al., 2014)); whereas the usage of formulas to model the word problem world, gives our system the ability to accommodate other math word problems as well.

5 Experimental Evaluation

5.1 Dataset

The *AddSub* dataset consist of a total of 395 addition-subtraction arithmetic problems for third, fourth, and fifth graders. The dataset is divided into three diverse set MA1, MA2, IXL containing 134, 140 and 121 problems respectively. As mentioned in (Hosseini et al., 2014), the problems in MA2 have more irrelevant information compared to the other two datasets, and IXL includes more information gaps.

5.2 Result

Hosseini et al. (2014) evaluate their system using 3-fold cross validation. We follow that same procedure. Table 5 shows the accuracy of our system on each dataset (when trained on the other two datasets). Table 6 shows the distribution of the *part whole, change, comparison* problems and the accuracy on recognizing the correct formula.

	MA1	IXL	MA2	Avg
ARIS	83.6	75.0	74.4	77.7
KAZB	89.6	51.1	51.2	64.0
ALGES	-	-	-	77.0
Roy & Roth	-	-	-	78.0
Majority	45.5	71.4	23.7	48.9
Our System	96.27	82.14	79.33	86.07

Table 5: Comparision with ARIS, KAZB (Kushman et al., 2014), ALGES (Koncel-Kedziorski et al., 2015) and the state of the art Roy & Roth on the accuracy of solving arithmetic problems.

As we can see in Table 6 only IXL contains problems of type 'comparison'. So, to study the accuracy in detecting the *compare* formula we uniformly distribute the 33 examples over the 3 datasets. Doing that results in only two errors in the recognition of a *compare* formula and also increases the overall accuracy of solving arithmetic problems to 90.38%.

5.3 Error Analysis

An equation that can be generated from a *change* or *comparision* formula can also be generated by a *part whole* formula. Four such errors happened for the *change* problems and out of the 33 *compare* problems, 18 were solved by *part whole*. Also, there are 3 problems that require two applications. One example of such problem is, "*There are 48 erasers in the drawer and 30 erasers on the desk. Alyssa placed 39 erasers and 45 rulers on the desk. How many erasers are now there in total ?*". To solve this we need to first combine the two numbers 48 and 30 to find the total number of erasers she initially had. This requires the knowledge of 'part-whole'. Now, that sum of 48 and 30, 39 and x can be connected together using the 'change' formula. With respect to 'solving' arithmetic problems, we find the following categories as the major source of errors:

Problem Representation: Solving problems in this category requires involved representation. Consider the problem, '*Sally paid $* 12.32 *total for peaches , after a '*3 *dollar' coupon , and $* 11.54 *for cherries . In total , how much money did Sally spend?*'. Since the associated verb for the variable 3 dollar is 'pay', our system incorrectly thinks that *Sally* did spend it.

Information Gap: Often, information that is critical to solve a problem is not present in the text. E.g. *Last year , 90171 people were born in a country , and 16320 people immigrated to it . How many new people began living in the country last year ?*. To correctly solve this problem, it is important to know that both the event 'born' and 'immigration' imply the 'began living' event, however that information is missing in the text. Another example is the problem, "*Keith spent $6.51 on a rabbit toy , $5.79 on pet food , and a cage cost him $12.51 . He found a dollar bill on the ground. What was the total cost of Keith 's purchases?* ". It is important to know here that if a cage cost Keith $12.51 then Keith has spent $12.51 for cage.

Modals: Consider the question '*Jason went to 11 football games this month . He went to 17 games last month , and plans to go to 16 games next month . How many games will he attend in all?*' To solve this question one needs to understand the meanings of the verb "plan" and "will". If we replace "will" in the question by "did" the answer will be different. Currently our algorithm cannot solve this problem and we need to either use a better representation or a more powerful learning algorithm to be able to answer correctly. Another interesting example of this kind is the following: "For his car , Mike spent $118.54 on speakers and $106.33 on new tires . Mike wanted 3 CD 's for $4.58 but decided not to . In total , how much did Mike spend on car parts?"

Type		MA1	IXL	MA2
part whole	Total	59	89	51
	correct	59	81	40
change	Total	74	18	68
	correct	70	15	56
compare	Total	0	33	0
	correct	0	0	0

Table 6: Accuracy on recognizing the correct application. None of the MA1 and MA2 dataset contains "compare" problems so the cross validation accuracy on "IXL" for "compare" problems is 0.

Incomplete IsA Knowledge: For the problem "Tom bought a skateboard for $ 9.46 , and spent $ 9.56 on marbles . Tom also spent $ 14.50 on shorts . In total , how much did Tom spend on toys ? ", it is important to know that 'skateboard' and 'marbles' are toys but 'shorts' are not. However, such knowledge is not always present in ConceptNet which results in error.

Parser Issue: Error in dependency parsing is another source of error. Since the attribute values are computed from the dependency parse tree, a wrong assignment (mostly for verbs) often makes the entity irrelevant to the computation.

6 Conclusion

Solving math word problems often requires explicit modeling of the word. In this research, we use well-known math formulas to model the word problem and develop an algorithm that learns to map the assertions in the story to the correct formula. Our future plan is to apply this model to general arithmetic problems which require multiple applications of formulas.

Abstract

In this paper we explore the correlation between the sound of words and their meaning, by testing if the polarity ('good guy' or 'bad guy') of a character's role in a work of fiction can be predicted by the name of the character in the absence of any other context. Our approach is based on phonological and other features proposed in prior theoretical studies of fictional names. These features are used to construct a predictive model over a manually annotated corpus of characters from motion pictures. By experimenting with different mixtures of features, we identify phonological features as being the most discriminative by comparison to social and other types of features, and we delve into a discussion of specific phonological and phonotactic indicators of a character's role's polarity.

1 Introduction

Could it be possible for fictional characters' names such as 'Dr. No' and 'Hannibal Lecter' to be attributed to positive characters whereas names such as 'Jane Eyre' and 'Mary Poppins' to negative ones? Could someone guess who is the hero and who is the competitor based only on the name of the character and what would be the factors that contribute to such intuition? Literary theory suggests that it should be possible, because fictional character names function as expressions of experience, ethos, teleology, values, culture, ideology, and attitudes of the character.

However, work in literary theory, psychology, linguistics and philosophy has studied fictional names by analysing individual works or small clusters of closely related works, such as those of a particular author. By contrast, we apply tools from computational linguistics at a larger scale aiming to identify more general patterns that are not tied to any specific creator's idiosyncrasies and preferences; in the hope that extracting such patterns can provide valuable insights about how the sound of names and, more generally, words correlates with their meaning.

At the core of our approach is the idea that the names of fictional characters follow (possibly subconsciously) a perception of what a positive or a negative name ought to sound like that is shared between the creator and the audience. Naturally the personal preferences or experiences of the creator might add noise, but fictional characters' names will at least not suffer (or suffer less) from the systematic cultural bias bound to exist in real persons' names.

In the remainder of this paper, we first present the relevant background, including both theoretical work and computational work relevant to peoples' names (Section 2). Based on this theoretical work, we then proceed to formulate a set of features that can be computationally extracted from names, and which we hypothesise to be discriminative enough to allow for the construction of a model that accurately predicts whether a character plays a positive or negative role in a work of fiction (Section 3). In order to test this hypothesis, we constructed a corpus of characters from popular English-language motion pictures. After describing corpus construction and presenting results (Section 4), we proceed to discuss these results (Section 5) and conclude (Section 6).

2 Background

2.1 Onomastics

The procedure of naming an individual, a location or an object is of particular importance and serves

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2154–2163,
Berlin, Germany, August 7-12, 2016.

purposes beyond the obvious purpose of referring to distinct entities. Characteristics such as place of origin, gender, and socioeconomic status can often be guessed from the name or nickname that has been attributed to an individual. *Onomastics*, the study of the origin, history, and use of proper names has attracted scholarly attention as early as antiquity and Plato's 'Cratylos' (Hajdú, 1980).

In fiction and art, in particular, names are chosen or invented without having to follow the naming conventions that are common in many cultures. This allows creators to apply other criteria in selecting a name for their characters, one of which being the intuitions and preconceptions about the character that the name alone implies to the audience. Black and Wilcox (2011) note that writers take informed and careful decisions when attributing names to their characters. Specifically, while care is taken to have names that are easily identifiable and phonologically attractive, or that are important for personal reasons, these are not the only considerations: names are chosen so that they match the personality, the past, and the cultural background of a character.

According to Algeo (2010) behind each name lies a story while Ashley (2003) suggests that a literary name must be treated as a small poem with all the wealth of information that implies. Markey (1982) and Nicolaisen (2008) raised concerns on whether onomastics can be applied to names in art given the different functional roles of names as well as their intrinsic characteristics, namely sensitivity and creativity. 'Redende namen' (significant names) is a widespread theory that seeks the relationship between name and form (Rudnyckyj, 1959). According to this theory, there is a close relationship between the form of a name and its role. This consideration is still prevalent to date as shown by Chen (2008) in her analysis of names in comic books, where names transparently convey the intentions of the creator for the role of each character. Another concern is whether the study of literary names should be examined individually for each creative work or if generalizations can be made (Butler, 2013). However, the scope of most studies is limited to individual projects or creators, creating an opportunity for computational methods that can identify generalizations and patterns across larger bodies of literary work than what is manually feasible.

2.2 Related Work

Although serving radically different purposes and applications than our investigation, various methods for the computational analysis of proper nouns have been developed in natural language processing. Without a doubt, some of the oldest and most mature technologies that exploit the properties of proper nouns are those addressing *named entity recognition and categorization (NERC)*. In this direction, there is a recently ongoing effort for the extension of NERC tools so that they cover the needs of literary texts (Borin et al., 2007; Volk et al., 2009; Kokkinakis and Malm, 2011).

Moving beyond recognition, effort has been made to explore characteristics and relationships of literary characters (Nastase et al., 2007). Typically, however, these efforts take advantage of the context, and very little work tries to extract characteristics of literary characters from their names alone. One example is the application of language identification methods in order to extract the cultural background of proper names (Konstantopoulos, 2007; Bhargava and Kondrak, 2010; Florou and Konstantopoulos, 2011). This work showed that people's names in isolation are more amenable to language identification than common nouns. Konstantopoulos (2007), in particular, reports inconclusive results at pinpointing the discriminative features that are present in people's names but not in other words.

Another relatively recent and related research direction that does not focus on proper nouns investigates elements of euphony mostly by examining phonetic devices. The focus is to identify how the sound of words can foster its effectiveness in terms of persuasion (Guerini et al., 2015) or memorability (Danescu-Niculescu-Mizil et al., 2012).

3 Approach

These earlier attempts relied on the examination of predictive models of n-grams in order to identify the n-grams that are the best discriminants. The aim was that by inspecting these most discriminative n-grams, meaningful patterns would emerge and serve as the vehicle for formulating hypotheses about the correlation between what names sound like and the cultural background of the persons bearing them.

This approaches largely ignored the background in onomastics and literary research. By contrast, we exploit this prior body of theoretical work

to define more sophisticated features that directly correspond to theoretical hypotheses. Our empirical experiments are now aimed at identifying the features (and thus hypotheses) that are the most discriminative, rather than at hoping that a coherent hypothesis can be formulated by observing patterns in n-gram features.

In the remainder of this section, we will present these hypotheses and the machine-extracted features that reflect them. The features are also collected in Table 1.

3.1 Emotions

Hypothesis 1 *The (positive or negative) polarity of the sentiment that a character's name evokes is associated with the polarity of the character's role.*

The understanding of how the language transmits emotions has attracted significant research attention in the field of Computational Linguistics. Most of the relevant literature is directed towards calculating sentiment for units at the document or sentence level. These works are usually boosted by semantic dictionaries that provide information about the emotional hue of concepts such as the Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2001), the Harvard General Inquirer (Stone et al., 1966), the WordNet Affect (Strapparava and Valitutti, 2004) and SentiWordNet (Esuli and Sebastiani, 2006). In our task, the absence of context and the inherent arbitrariness in naming (even in fictional names) increases the difficulty in conveying emotional quality to names. More specifically, the intriguing part was to associate fictional names with concepts from a semantic sentiment resource in order to approximate a sentiment value. To achieve this we used SentiWordNet: a linguistic resource that has derived from the annotation of WordNet synsets according to the estimated degree of positive, negative or neutral hue. The overall valence for a given name is calculated as the sum of the valence of its elements (first name, surname). The valence of each name element is the average valence of all SentiWordNet concepts that are associated with it. To associate a name element and a SentiWordNet concept we used the Soundex phonetic distance and the Levenshtein lexicographic distance (Levenshtein, 1966). A heuristic threshold is used to decide whether a name and a SentiWordNet concept are associated.

More formally, the valence $\mathrm{val}(n)$ of a name n comprising name elements e_i is calculated as follows:

$$\mathrm{val}(e_i) = \frac{\sum_{u \in \mathrm{ass}_S(e_i)} \mathrm{swn}(u) + \sum_{v \in \mathrm{ass}_L(e_i)} \mathrm{swn}(v)}{|\mathrm{ass}_S(e_i)| + |\mathrm{ass}_L(e_i)|}$$

$$\mathrm{val}(n) = \sum_i \mathrm{val}(e_i)$$

where $\mathrm{ass}_S(\cdot)$ is the set of SentiWordNet concepts that are Soundex-associated with the given name element, $\mathrm{ass}_L(\cdot)$ the set of SentiWordNet concepts that are Levenshtein-associated with the given name element, and $\mathrm{swn}(\cdot)$ the valence assigned to the given concept by SentiWordNet.

3.2 Stylistic and poetic features

Hypothesis 2 *Assuming Ashley's (2003) and Butler's (2013) position that 'a name can be a whole "poem" in as little as a single word' we assume that stylistic features usually found in poems can be extracted from the names of fictional charac-*

ters, and that such features correlate with the polarity of their roles.

The first quantitative analysis efforts of the poetic style can be found in the 1940s and in the study of the poet and literary critic Josephine Miles (1946; 1967) where she studied the features of poems over time. Despite the great contribution of this work and others that followed, the creation of a framework for quantitative poetic style analysis remained limited to a small number of poems and much of the work was done manually. The work of Kaplan and Blei (2007) is an attempt to automate and analyze large volumes of poems exploring phonological, spelling and syntax features. For our work, we identified the following poetic devices that can be applied to isolated names:

- **Alliteration:** a stylistic literary device identified by the repeated sound of the first consonant in a series of multiple words, or the repetition of the same sounds of the same kinds of sounds at the beginning of words or in stressed syllables of a phrase.
  Examples: Peter **P**arker, **P**eter **P**an
- **Consonance:** a poetic device characterized by the repetition of the same consonant two or more times in short succession.
  Examples: **L**ill**l**ian He**ll**man, F**r**eddy K**r**uege**r**, Hannibal **L**ecter, **K**risten Parke**r**
- **Assonance:** a poetic device characterized by the repetition of the same vowel two or more times in short succession.
  Examples: Bobb**ie** R**i**tch**ie**

3.3 Phonological features

Hypothesis 3 *The presence of specific phonological features can reveal evidence of the role of a character in an artistic artifact.*

Linguistic theory widely adopts the concept of arbitrary relationship between the *signifier* and the *signified* (de Saussure, 1916 1983; Jakobson, 1965). However, an increasing volume of works in various fields investigates the existence of non-arbitrary relations between phonological representation and semantics, a phenomenon known as *phonological iconicity*. Standing from the side of Computational Linguistics and with the intuition that in fictional names the correlation between a word's form and the emotion it expresses will be stronger, we examined a wide range of phonology-related features, shown in Table 1. It should be noted that these features are extracted from the phonetic representation of names derived by applying the spelling-to-phoneme module of the *espeak* speech synthesizer.[1]

3.4 Sociolinguistic features

Hypothesis 4 *We hypothesize that social aspects of names — such as frequency of use or use of foreign names in a given environment — can relate to role of a fictional character. For instance, a 'girl next door' role is more likely to be assigned a very popular female name than a name that sounds hostile or foreign.*

The frequency of names in U.S.A was calculated based on the Social Security Death Index (SSDI), a publicly available database that records deaths of U.S.A citizens since 1936.[2] The same dataset was also used to build a model for recognizing foreign-looking names. More specifically, we trained n-gram language models of order 2–5 against the dataset for both orthographic and phonetic representation using the berkeleylm library (Pauls and Klein, 2011). We then heuristically defined a threshold that correlates well with foreign-looking suffixes. Analogously with the name frequency we extract the gender of each name using a baby names dataset that includes gender information.[3] For unisex names the prevalent gender was picked. Finally, honorific titles (e.g. Professor, Phd, Mr, Mrs etc.) were also extracted from names. Honorific titles are intriguing due to their ambiguous meaning since they can express respect and irony in different contexts.

3.5 Domain features

Hypothesis 5 *We pursued indications to check if domain-related features such as the appearance time of a character in a movie, the movie title or the movie genre is associated (correlates) with the problem under study.*

In this category lies the $feature_{sameastitle}$ since anyone with a quick glance in a list of films would notice that a fictional name often consists of, or is the part of, the movie title, as in, There's Something about Mary, Hannibal, Thelma & Louise, Rocky, etc. On IMDB character names are presented in the form of a list in

[1] Please cf. `http://espeak.sourceforge.net`

[2] Please cf. `https://archive.org/details/DeathMasterFile`

[3] Specifically, we used `https://www.ssa.gov/oact/babynames/state/index.html`

descending order based on screen credits. In the $feature_{creditindex}$ we want to check if the naming process is more assiduous for the roles of protagonists based on this list. In the same direction, we examine the $feature_{genre}$ for a possible correlation between the role of a character and the genre of a film.

4 Experiments and Results

4.1 Data Collection and Annotation

In order to validate our approach, we first need a corpus of names of fictional characters, annotated with the polarity of their role. As such a resource does not exist to the best of our knowledge, we have created it for the purposes of the work described here.

Our decision to use motion pictures rather than other fictional work is motivated by the relative ease of finding annotators familiar with the plot of these works, so that we could get reliable annotations of the polarity of the leading roles. We compiled a list of 409 movies based on the following criteria:

- That they are widely known films, covering all genres of film production. We automatically crosschecked if the candidate movies are included in DBPedia[4] and YAGO[5], as these are indicators that the films are known to the general public.
- That they have received some award or are positively evaluated by users (i.e., have an IMDB rating of 5.0 or higher). The underlying assumption is that this criterion selects major productions where care has been given to even the most minute detail, including the names of the major characters and what these names connote to the audience.
- That they are recent productions, so that annotators can easily recall the plot and the characters.

We then asked volunteers to select any movie from the list that they where very familiar with, and to assign one of *positive*, *negative* or *neutral* to the top-most characters in the credits list, working only as far down the credits list as they felt confident to. The three categories were defined as follows in the annotation guidelines:

Figure 1: Character annotation tool

- Positive: when the role of the character in the plot left a positive impression on you when you saw the movie.
- Negative: when the role of a character left a negative impression on you when you saw the movie.
- Neutral: when the role of the character is important for the plot, but you are in doubt or cannot recall whether it was a positive or a negative role.

Neutral tags are ignored in our experiments. They were foreseen only to allow annotators to skip characters and still have a sense of accomplishment, so that they only make choices that they are confident with.

We used the Hypothes.is[6] open source annotation application. The annotation was carried out by having volunteers install the Hypothes.is Web browser extension and then visit the IMDB[7] page of any of the movies on our list (direct links were provided to them in the guidelines). IMDB was chosen due to its popularity, so that annotators would already be familiar with the online environment. The annotators tagged the character names directly on the IMDB page and the annotations where collected for us by Hypothes.is (Figure 1).

Eight annotators participated in the procedure and provided 1102 positive and 434 negative tags for characters of 202 movies, out of the 409 movies in the original list. Table 2 gives the annotation distribution per movie genre.

The reliability of the annotated collection by means of inter-rater agreement was also measured. For this purpose, various standard agreement measures (Meyer et al., 2014) were calculated, all showing very high agreement among the annotators (Table 3). This demonstrates that the annota-

tion task is well-formulated, but does not guarantee that our classification task is consistent, since the latter will use different information than that used by the annotators. That is to say, the annotators had access to their understanding of the movies' plot to carry out the task, whereas our classification task will be performed over the characters' names alone.

The collection is publicly available, including the guidelines and instructions to the annotators, the source code for the annotation tool, and the source code for the tool that compiles Weka ARFF files from the JSON output of the annotation tool.[8]

4.2 Experimental Design

The experimental design consisted of an iterated approach performing experiments with different sets of features. This process was driven by a preliminary chi-squared analysis in order to exploit feature significance. The algorithms that are used for the experiments are Naive Bayes and J48

[8] https://bitbucket.org/dataengineering/fictionalnames

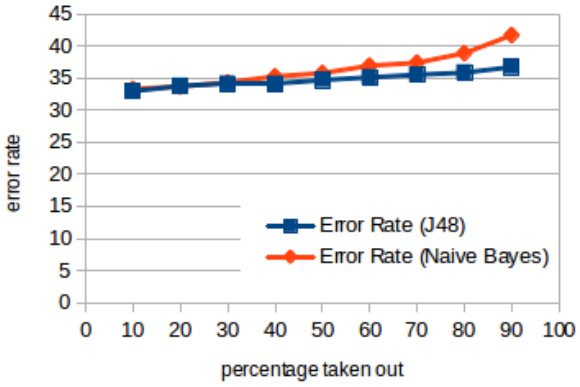

Figure 2: Learning curve for the number of instances

	All		Without domain	
	NB	J48	NB	J48

Prec.	0.731	0.822	0.515	0.801
F-score	0.618	0.823	0.6	0.802

Table 4: Comparison of Naive Bayes and J48

(Salzberg, 1994) decision trees. Each experiment is done using a 10-fold cross validation on the available data, using a confidence factor of 0.25 for post-pruning. For all the experiments we used the Weka toolkit (Hall et al., 2009). Due to the imbalance of our dataset in favor of positive classes (see Table 2), we sub-sampled the dataset maintaining the initial genre distribution. We also applied *principal component analysis (PCA)* in order to guarantee the independence of the classification features, as required by the Naive Bayes algorithm. To explore the behavior of the algorithms to the change of trained data we generated the learning curves shown in Figure 2. In both cases the learning curves are well-behaved since the error rate grows monotonically as the training set shrinks. However, the precision, recall, and F-scores achieved by J48 are significantly better that those of Naive Bayes (Table 4).

This preliminary experiment led us to use J48 for the main experiment, where we try different features in order to understand which are the most discriminative ones. These results are collected in Table 5 and discussed immediately below.

5 Discussion of Results

A first observation that can be easily made is that the domain features are good discriminants. As these features exploit information such as credit-

	Rec.	Prec.	F-score
Without domain features	0.803	0.801	0.802
Only domain features	0.725	0.699	0.667
Only phonological features	0.790	0.786	0.787
Without poetic features	0.836	0.832	0.833
Without consonance feature	0.823	0.820	0.821
Without emotions features	0.814	0.810	0.811
Without phonological features	0.798	0.792	0.793
Without social features	0.807	0.803	0.804
All features	0.824	0.822	0.823

Table 5: Performance of J48 for different feature settings

Most frequent in positive characters	
Phoneme n-gram	Examples
/lɪ/	Ned Alleyn (Shakespeare in Love)
/an/	Anouk Rocher (Chocolat)
/aɪ/	Eliza Doolittle (My Fair Lady)
/nɪ/	Linguini (Ratatouille)
/ɪst/	Kevin McCallister (Home Alone)
/ɹəʊ/	Frodo (The Lord of the Rings)
/and/	Dylan Sanders (Charlie's Angels)
/stə/	C.C. Baxter (The Apartment)
Most frequent in negative characters	
Phoneme n-gram	Examples
/ən/	Tom Buchanan (The Great Gatsby)
/əʊ/	Iago (Aladdin)
/tə/	Norrington (Pirates of the Caribbean)
/ɪɪ/	Tom Ripley (The Talented Mr. Ripley)
/mən/	Norman Bates (Psycho)
/mɪs/	Mystique (X-Men)
/ktə/	Hannibal Lecter (Hannibal)

Table 6: Frequent phoneme {2,3}-grams

ing order that is outside the scope of our hypotheses, there were expected to be good discriminants and are included for comparison only.

By comparing the performance of all features (F = 82%), domain-only features (F = 68%), and all-except-domain features (F = 80%), we can immediately understand that our name-intrinsic features are better discriminants than domain features; in fact, name-intrinsic features not just better than domain features, they are by themselves almost as good as domain and name-intrinsic features combined. This is a significant finding, as it validates our core hypothesis that there is a correlation between what fictional character names look and sound like and the role they play in the plot of the fictional work they appear in.

We will now proceed to look in more detail into the different categories of features used, in order to gain further insights about specific discriminants.

5.1 Phonological Features

The phonological features are important separation criteria as evidenced by the drop in performance when they are excluded from the experimental setup (Table 5). Specifically, using all features except phonological features is equivalent to using phonological features alone (about F = 79% in both cases) and slightly worse that using all name-intrinsic features (about F = 80%). By comparison, removing any other category *increases* performance, leading us to believe that all other features are actually adding noise (rather than discriminatory power) to the feature space.

In order to delve more into this category of features, we proceeded with an n-gram analysis (of order 1 through 4) to look for correlations between phonemes. The results clearly demonstrated the positive effect of the number of vowels (normalized by the length of the utterance) to the positive category. As far as the consonants are concerned, voiced (e.g. /ʌ/, /g/, /d/, /w/) seem to relate more to the negative class. Table 7 summarizes a more fine-grained analysis for the consonants based on their categorization.

The environment plays an important role, with specific combinations showing tendencies that are not observed with isolated phonemes. For example, diphoneme /an/ relates to positive class while /ən/ to negative. Table 6 lists some frequent phoneme 2- and 3-gram examples. The position of each phoneme also seems to play an crucial role

Phonemes	Class
/p/, /b/ (bilabial plosive)	P
/l/ (alveolar lateral)	P
/f/, /v/ (labiodental africative)	N
/k/, /g/ (velar plosive)	N
/t/, /d/ (alveolar plosive)	N
/dʒ/, /tʃ/ (affricate)	N
/m/, /n/ (nasal)	N
/ɹ/ (alveolar retroflex)	N

Table 7: Consonants behavior

in the classification task. Specifically, we note that starting with a vowel or a consonant are among the most discriminating features. These observations are consistent to a great extent with work in psychology and literary theory that studied phonological iconicity for common words (Nastase et al., 2007; Auracher et al., 2011; Schmidtke et al., 2014).

Some contradictory conclusions in these works are attributed by researchers to the methodologies applied, while at the same time concerns are raised whether such methodologies can inductively lead to cross-language and general conclusions (Auracher et al., 2011). Table 8 summarizes some of the outcomes of these works.

5.2 Emotion and Affect

The analysis showed that the features that calculate the emotional load of fictional names based on SentiWordNet contribute to the classification task. However, we believe that there is still room for improvement for the performance of this feature mainly towards the optimization of the selection threshold in order to reduce the degree of false positive matches as well as the addition of more lexical resources for example WordNet Affect or LIWC.

5.3 Social Features

The annual publication *It's a Man's (Celluloid) World* examines the representation of female characters every year. According to its 2015 results (Lauzen, 2015), gender stereotypes were abundant with female characters being younger than their male counterparts and more likely to have prosocial goals including supporting and helping others. This bias makes the gender feature discriminative, but in a way that is not linguistically interesting: female characters are simply related to the positive class.

Reference	Description
Taylor and Taylor (1965)	evidence that pleasantness relations are language specific
Fonagy (1961)	sonorants (e.g., /l/,/m/) more common in tender poems, plosives (e.g., /k/,/t/) in aggressive ones
Miall (2001)	Passages about Hell from Miltons "Paradise Lost" were found to contain significantly more front vowels and hard consonants than passages about Eden while the latter contained more medium back vowels
Whissell (1999)	plosives correlate with unpleasant words
Auracher et al. (2011)	nasals (e.g., /m/) relate to sadness, plosives (e.g., /p/) to happiness, parallels across remote languages
Zajonc et al. (1989)	umlaut /y/ causes negative affective states

Table 8: Phonological iconicity studies

A somewhat surprising result was that the foreign suffix feature is not discriminative. The hypothesis that the concept of the 'other' is stereotyped negatively does not seem to be true in our dataset. A closer investigation might identify genres where this hypothesis holds (e.g., war movies), but this would be implicit pragmatic information about the context of the film rather than a linguistically interesting finding.

5.4 Poetic and Stylistic Features

The experimental findings show that literary devices can actually be identified in fictional characters names, but the same findings also indicate that they do not contribute significantly to the classification task. More specifically, consonance is the only stylistic/poetic feature that affects classification.

6 Conclusions and Future Work

In this paper we test the hypothesis that the sound and the form of fictional characters' names correlates with meaning, in our particular case with

the respective characters' role in the work of fiction. We restricted our study to fictional characters since they are not tied to cultural conventions of naming, such as names that run in a family, so that we are able to look for patterns that are perceived as positive or negative by the audience and used as such (consciously or not) by the creator.

Our experiments have verified that features intrinsic to the names and without any reference to the plot or, in general, any other context are discriminative. Furthermore, we have discovered that the most discriminative features are of phonological nature, rather than features that hint at pragmatic information such as the gender or origin of the character. A further contribution of our work is that we ran an annotation campaign and created an annotated corpus of fictional movie characters and their corresponding polarity. This corpus is offered publicly, and can serve experimentation in the digital humanities beyond the scope of the experiments presented here.

Our future research will test the correlation between the polarity and the name of a fictional character beyond the movie domain. It would, for example, be interesting to seek differences between spoken names (as in films) and names that are only meant to be read (as in literature). In addition, using written literature will allow us to compare texts from different periods, pushing earlier than the relatively young age of motion pictures. Character polarity annotations in written literature could be created by, for example, applying sentiment analysis to the full text of the work.

Abstract

We examine adjective-noun (AN) composition in the task of recognizing textual entailment (RTE). We analyze behavior of ANs in large corpora and show that, despite conventional wisdom, adjectives do not always restrict the denotation of the nouns they modify. We use natural logic to characterize the variety of entailment relations that can result from AN composition. Predicting these relations depends on context and on commonsense knowledge, making AN composition especially challenging for current RTE systems. We demonstrate the inability of current state-of-the-art systems to handle AN composition in a simplified RTE task which involves the insertion of only a single word.

1 Overview

The ability to perform inference over utterances is a necessary component of natural language understanding (NLU). Determining whether one sentence reasonably implies another is a complex task, often requiring a combination of logical deduction and simple common-sense. NLU tasks are made more complicated by the fact that language is compositional: understanding the meaning of a sentence requires understanding not only the meanings of the individual words, but also understanding how those meanings combine.

Adjectival modification is one of the most basic types of composition in natural language. Most existing work in NLU makes a simplifying assumption that adjectives tend to be *restrictive*– i.e. adding an adjective modifier limits the set of things to which the noun phrase can refer. For example, the set of *little dogs* is a subset of the set of *dogs*, and we cannot in general say that *dog* entails *little dog*. This assumption has been exploited by high-performing RTE systems (MacCartney and Manning, 2008; Stern and Dagan, 2012), as well as used as the basis for learning new entailment rules (Baroni et al., 2012; Young et al., 2014).

However, this simplified view of adjectival modification often breaks down in practice. Consider the question of whether *laugh* entails *bitter laugh* in the following sentences:

1. Again his *laugh* echoed in the gorge.
2. Her *laugh* was rather derisive.

In (1), we have no reason to believe the man's laugh is bitter. In (2), however, it seems clear from context that we are dealing with an unpleasant person for whom *laugh* entails *bitter laugh*. Automatic NLU should be capable of similar reasoning, taking both context and common sense into account when making inferences.

This work aims to deepen our understanding of AN composition in relation to automated NLU. The contributions of this paper are as follows:

- We conduct an empirical analysis of ANs and their entailment properties.
- We define a task for directly evaluating a system's ability to predict compositional entailment of ANs in context.
- We benchmark several state-of-the-art RTE systems on this task.

2 Recognizing Textual Entailment

The task of recognizing textual entailment (RTE) (Dagan et al., 2006) is commonly used to evaluate the state-of-the-art of automatic NLU. The RTE task is: given two utterances, a *premise* (p) and a *hypothesis* (h), would a human reading p typically infer that h is most likely true? Systems are expected to produce either a binary (YES/NO) or trinary (ENTAILMENT/CONTRADICTION/UNKNOWN) output.

The type of knowledge tested in the RTE task has shifted in recent years. While older datasets mostly captured logical reasoning (Cooper et al., 1996) and lexical knowledge (Giampiccolo et al., 2007) (see Examples (1) and (2) in Table 1), the recent datasets have become increasingly reliant on common-sense knowledge of scenes and events (Marelli et al., 2014). In Example (4) in Table 1, for which the gold label is ENTAILMENT, it is perfectly reasonable to assume the dogs are playing. However, this is not necessarily true that *running* entails *playing*– maybe the dogs are being

Table 1: Examples of sentence pairs coming from various RTE datasets, and the types of inference highlighted by each. While linguistic phenomena like implicature (3) have yet to be explicitly included in RTE tasks, commonsense inferences like those in (4) (from the SICK dataset) have become a common part of NLU tasks like RTE, question answering, and image labeling.

chased by a bear and are running for their lives! Example (4) is just one of many RTE problems which rely on intuition rather than strict logical inference.

Transformation-based RTE. There have been an enormous range of approaches to automatic RTE– from those based on theorem proving (Bjerva et al., 2014) to those based on vector space models of semantics (Bowman et al., 2015a). Transformation-based RTE systems attempt to solve the RTE problem by identifying a sequence of *atomic edits* (MacCartney, 2009) which can be applied, one by one, in order to transform p into h. Each edit can be associated with some entailment relation. Then, the entailment relation that holds between p and h overall is a function of the entailment relations associated with each atomic edit. This approach is appealing in that it breaks potentially complex p/h pairs into a series of bite-sized pieces. Transformation-based RTE is widely used, not only in rule-based approaches (MacCartney and Manning, 2008; Young et al., 2014), but also in statistical RTE systems (Stern and Dagan, 2012; Padó et al., 2014).

MacCartney (2009) defines an *atomic edit* applied to a linguistic expression as the deletion DEL, insertion INS, or substitution SUB of a subexpression. If x is a linguistic expression and e is an atomic edit, than $e(x)$ is the result of applying the edit e to the expression x. For example:

$$\begin{array}{lcl} x & = & a_1\ \textit{girl}_2\ \textit{in}_3\ a_4\ \textit{red}_5\ \textit{dress}_6 \\ e & = & \text{DEL}(\textit{red}, 5) \\ e(x) & = & a_1\ \textit{girl}_2\ \textit{in}_3\ a_4\ \textit{dress}_5 \end{array}$$

We say that the entailment relation that holds between x and $e(x)$ is *generated* by the edit e. In the above example, we would say that e generates a *forward entailment* ($\sqsubset$) since *a girl in a red dress* entails *a girl in a dress*.

3 Natural Logic Entailment Relations

Natural logic (MacCartney, 2009) is a formalism that describes entailment relationships between natural language strings, rather than operating over mathematical formulae. Natural logic enables both light-weight representation and robust inference, and is an increasingly popular choice for NLU tasks (Angeli and Manning, 2014; Bowman et al., 2015b; Pavlick et al., 2015). There are seven "basic entailment relations" described by natural logic, five of which we explore here.[1]

These five relations, as they might hold between an AN and the head N, are summarized in Figure 1. The *forward entailment* relation is the restrictive case, in which the AN (*brown dog*) is a subset of (and thus entails) the N (*dog*) but the N does not entail the AN (*dog* does not entail *brown dog*). The symmetric *reverse entailment* can also occur, in which the N is a subset of the set denoted by the AN. An example of this is the AN *possible solution*: i.e. all actual *solutions* are *possible solutions*, but there are an abundance of *possible solutions* that are not and will never be actual *solutions*. In the *equivalence* relation, AN and N denote the same set (e.g. the *entire universe* is the same as the *universe*), whereas in the *alternation* relation, AN and N denote disjoint sets (e.g. a *former senator* is not a *senator*). In the *independence* relation, the AN has no determinable entailment relationship to the N (e.g. an *alleged criminal* may or may not be a *criminal*).

4 Simplified RTE Task

The focus of this work is to determine the entailment relation that exists between an AN and its head N in a given context. To do this, we define a simplified entailment task identical to the normal RTE task, with the constraint that p and h differ only by one atomic edit e as defined in Section 2. We look only at insertion INS(A) and deletion DEL(A), where A must be a single adjective.

We use a 3-way entailment classification where the possible labels are ENTAILMENT, CONTRADICTION, and UNKNOWN. This allows us to recover the basic entailment relation from Section 3: by determining the labels associated with the INS operation and the DEL

[1] We omit two relationships: *negation* and *cover*. These relations require that the sets denoted by the strings being compared are "exhaustive." In this work, this requirement would be met when everything in the universe is either an instance of the noun or it is an instance of the adjective-noun (or possibly both). This is a hard constraint to meet, and we believe that the interesting relations that result from AN composition are adequately captured by the remaining 5 relations.

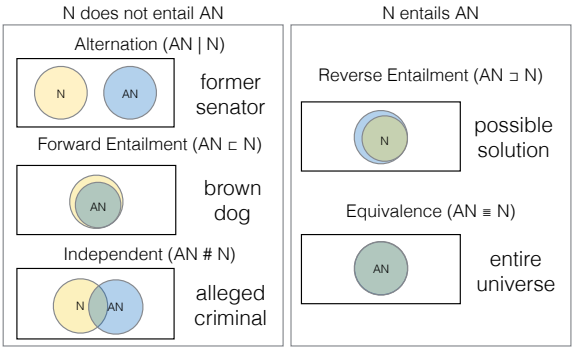

Figure 1: Different entailment relations that can exist between an adjective-noun and the head noun. The best-known case is that of *forward entailment*, in which the AN denotes a subset of the N (e.g. *brown dog*). However, many other relationships may exist, as modeled by natural logic.

operation, we can uniquely identify each of the five relations (Table 2).

	INS	DEL
Equivalence	ENTAILMENT	ENTAILMENT
Forward Entail.	ENTAILMENT	UNKNOWN
Reverse Entail.	UNKNOWN	ENTAILMENT
Independence	UNKNOWN	UNKNOWN
Alternation	CONTRADICTION	CONTRADICTION

Table 2: Entailment generated by INS(A) or DEL(A) for possible relations holding between AN and N. Both INS and DEL are required to distinguish all five entailment relations.

4.1 Limitations

Modeling denotations of ANs and N. We note that this task design does not directly ask about the relationship between the sets denoted by the AN and by the N (as shown in Figure 1). Rather than asking "Is this instance of AN an instance of N?" we ask "Is this statement that is true of AN also true of N?" While these are not the same question, they are often conflated in NLP, for example, in information extraction, when we use statements about ANs as justification for extracting facts about the head N (Angeli et al., 2015). We focus on the latter question and accept that this prevents us from drawing conclusions about the actual set theoretic relation between the denotation of AN and the denotation of N. However, we are able to draw conclusions about the practical entailment relation between statements about the AN and statements about the N.

Monotonicity. In this simplified RTE task, we assume that the entailment relation that holds overall between p and h is attributable wholly to the atomic edit (i.e. the inserted or deleted adjective). This is an over-simplification. In practice, several factors can cause the entailment relation that holds between the sentences overall to differ from the relation that holds between the AN and the N. For example, quantifiers and other downward-monotone operators can block or reverse entailments (*brown dog* $\rightarrow$ *dog*, but *no brown dog* $\not\rightarrow$ *no dog*). While we make some effort to avoid selecting such sentences for our analysis (Section 5.3), fully identifying and handling such cases is beyond the scope of this paper. We acknowledge that monotone operators and other complicating factors (e.g. multiword expressions) might be present in our data, but we believe, based on manual inspection, that they not frequent enough to substantially effect our analyses.

5 Experimental Design

To build an intuition about the behavior of ANs in practice, we collect human judgments of the entailments generated by inserting and deleting adjectives from sentences drawn from large corpora. In this section, we motivate our design decisions, before carrying out our full analysis in Section 6.

5.1 Human judgments of entailment

People often draw conclusions based on "assumptions that seem plausible, rather than assumptions that are known to be true" (Kadmon, 2001). We therefore collect annotations on a 5-point scale, ranging from 1 (definite contradiction) to 5 (definite entailment), with 2 and 4 capturing likely (but not certain) contradiction/entailment respectively. We recruit annotators on Amazon Mechanical Turk. We tell each annotator to assume that the premise "is true, or describes a real scenario" and then, using their best judgement, to indicate how likely it is, on a scale of 1 to 5, that the hypothesis "is also true, or describes the same scenario." They are given short descriptions and several examples of sentence pairs that constitute each score along the 1 to 5 scale. They are also given the option to say that "the sentence does not make sense," to account for poorly constructed p/h pairs, or errors in our parsing. We use the mean score of the three annotators as the true score for each sentence pair.

Inter-annotator agreement. To ensure that our judgements are reproducible, we re-annotate a random 10% of our pairs, using the same annotation setup but a different set of annotators. We compute the intra-class correlation (ICC) between the scores received on the first round of annotation, and those received in the second pass. ICC is related to Pearson correlation, and is used to measure consistency among annotations when the group of annotators measuring each observation is not fixed, as opposed to metrics like Fleiss's κ which assume a fixed set of annotators. On our data, the ICC is 0.77 (95% CI 0.73 - 0.81) indicating very high agreement. These twice-annotated pairs will become our test set in Section 7.

5.2 Data

Selecting contexts. We first investigate whether, in naturally occurring data, there is a difference between contexts in which the author uses the AN and contexts in which the author uses only the (unmodified) N. In other words, in order to study the effect of an A (e.g. *financial*) on the denotation of an N (e.g. *system*), is it better to look at contexts like (a) below, in which the author originally used the AN *financial system*, or to use contexts like (b), in which the author used only the N *system*?

(a) The TED spread is an indication of investor confidence in the U.S. *financial system*.

(b) Wellers hopes the *system* will be fully operational by 2015.

We will refer to contexts like (a) as *natural* contexts, and those like (b) as *artificial*. We take sample of 500 ANs from the Annotated Gigaword corpus (Napoles et al., 2012), and choose three natural and three artificial contexts for each. We generate p/h pairs by deleting/inserting the A for the natural/artificial contexts, respectively, and collect human judgements on the effect of the INS(A) operation for both cases.

Figure 2 displays the results of this pilot study. In sentences which contain the AN naturally, there is a clear bias toward judgements of "entailment." That is, in contexts when an AN appears, it is often the case that this A is superfluous: the information carried by the A is sufficiently entailed by the context that removing it does not remove information. Sentences (a) and (b) above provide intuition: in the case of sentence (a), trigger phrases like *investor confidence* make it clear that the *system* we are discussing is the *financial system*, whether or not the adjective *financial* actually appears. No such triggers exist in sentence (b).

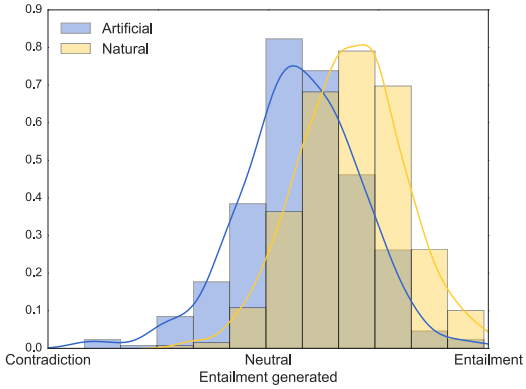

Figure 2: p/h pairs derived from natural contexts result in a notable bias toward judgements of "entailment" for the INS(A) operation, compared to p/h pairs derived from artificial contexts.

Selecting ANs. We next investigate whether the frequency with which an AN is used effects its tendency to entail/be entailed by the head N. Again, we run a small pilot study. We choose 500 ANs stratified across different levels of frequency of occurrence in order to determine if sampling the most frequent ANs introduces bias into our annotation. We see no significant relationship between the frequency with which an AN appears and the entailment judgements we received.

5.3 Final design decisions

As a result of the above pilot experiments, we proceed with our study as follows. First, we use only artificial contexts, as we believe this will result in a greater variety of entailment relations and will avoid systematically biasing our judgements toward entailments. Second, we use the most frequent AN pairs, as these will better represent the types of ANs that NLU systems are likely to encounter in practice.

We look at four different corpora capturing four different genres: Annotated Gigaword (Napoles et al., 2012) (**News**), image captions (Young et al., 2014) (**Image Captions**), the Internet Argument Corpus (Walker et al., 2012) (**Forums**), and the prose fiction subset of GutenTag dataset (Brooke et al., 2015) (**Literature**). From each corpus, we select the 100 nouns which occur with the largest number of unique adjectives. Then, for each noun, we take the 10 adjectives with which the noun occurs most often. For each AN, we choose 3 contexts[2] in which the N appears unmodified, and generate p/h pairs by inserting the A into each.

We collect 3 judgements for each p/h pair. Since this task is subjective, and we want to focus our analysis on clean instances on which human agreement is high, we remove pairs for which one or more of the annotators chose the "does not make sense" option and pairs for which we do not have at least 2 out of 3 agreement (i.e. at least two workers must have chosen the same score on the 5-point scale). In the end, we have a total of 5,560 annotated p/h pairs[3] coming roughly evenly from our 4 genres.

6 Empirical Analysis

Figure 3 shows how the entailment relations are distributed in each genre. In Image Captions, the vast majority of ANs are in a *forward entailment* (restrictive) relation with their head N. In the other genres, however, a substantial fraction (36% for Forums) are in equivalence relations: i.e. the AN denotes the same set as is denoted by the N alone.

When does N entail AN? If it is possible to insert adjectives into a sentence without adding new information, when does this happen? When is adjectival

[2] As a heuristic, we skip sentences containing obvious downward-monotone operators, e.g. *not*, *every* (Section 4).

[3] Our data is available at `http://www.seas.upenn.edu/~nlp/resources/AN-composition.tgz`

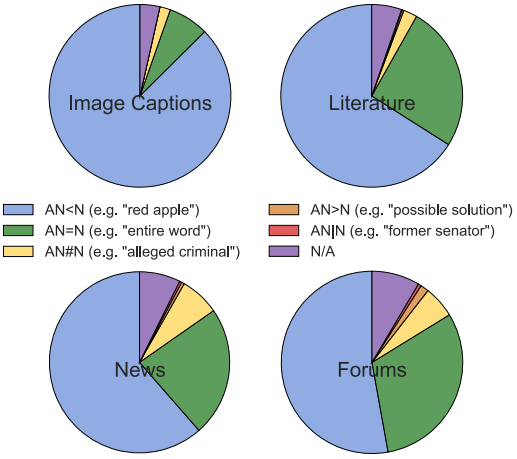

Figure 3: Basic entailment relations assigned to ANs according to the 5,560 p/h pairs our data.

modification not restrictive? Based on our qualitative analysis, two clear patterns stand out:

1) **When the adjective is prototypical of the noun it modifies.** In general, we see that adding adjectives which are seen as attributes of the "prototypical" instance of the noun tend to generate entailments. E.g. people are generally comfortable concluding that *beach→sandy beach*. The same adjective may be prototypical and thus entailed in the context of one noun, but generate a contradiction in the context of another. E.g. if someone has a *baby*, it is probably fine to say they have a *little baby*, but if someone has *control*, it would be a lie to say they have *little control* (Figure 4).[4]

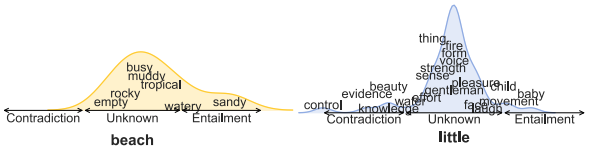

Figure 4: Inserting adjectives that are seen as "prototypical" of the noun tends to generate entailments. E.g., *beach* generally entails *sandy beach*.

2) **When the adjective invokes a sense of salience or importance.** Nouns are assumed to be salient and relevant. E.g. *answers* are assumed (perhaps naively) to be *correct*, and *problems* are assumed (perhaps melodramatically) to be *current* and *huge*. Inserting adjectives like *false* or *empty* tend to generate contradictions (Figure 5).

What do the different natural logic relations look like in practice? Table 3 shows examples of ANs and

[4]These curves show the distribution over entailment scores associated with the INS(A) operation. Yellow curves show, for a single N, the distribution over all the As that modify it. Blue curves show, for a single A, the distribution over all the Ns it modifies.

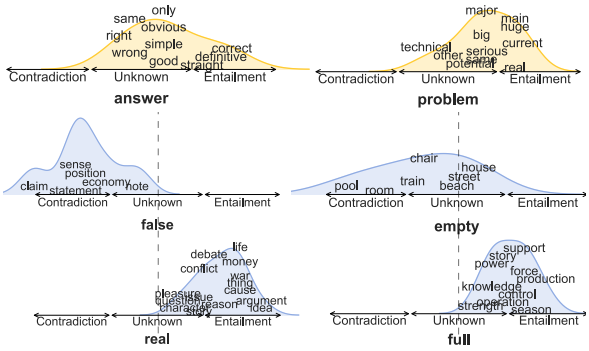

Figure 5: Unless otherwise specified, nouns are considered to be salient and relevant. *Answers* are assumed to be *correct*, and *problems* to be *current*.

contexts exhibiting each of the basic entailment relations. Some entailment inferences depend entirely on contextual information (Example 2a) while others arise from common-sense inference (Example 2b). Many of the most interesting examples fall into the *independence* relation. Recall from Section 3 that independence, in theory, covers ANs such as *alleged criminal*, in which the AN may or may not entail the N. In practice, the cases we observe falling into the independence relation tend to be those which are especially effected by world knowledge. In Example 3, *local economy* is considered to be independent of *economy* when used in the context of *President Obama*: i.e. the assumption that the president would be discussing the national economy is so strong that even when the president says *the local economy is improving*, people do not take this to mean that he has said *the economy is improving*.

Undefined entailment relations. Our annotation methodology– i.e. inferring entailment relations based on the entailments generated by INS and DEL edits– does not enforce that all of the ANs fit into one of the five entailment relations defined by natural logic. Specifically, we observe many instances (∼5% of p/h pairs) in which INS is determined to generate a contradiction, while DEL is said to generate an entailment. In terms of set theory, this is equivalent to the (non-sensical) setting in which "every AN is an instance of N, but no N is an instance of AN." On inspection, these again represent cases in which common-sense assumptions dominate the inference. In Example 6, when given the premise *Bush travels to Michigan to discuss the economy*, annotators are confident enough that *economy* does not entail *Japanese economy* (why on earth would Bush travel to Michigan to discuss the Japanese economy?) that they label the insertion of *Japanese* as generating a contradiction. However, when presented with the p/h in the opposite direction, annotators agree that the *Japanese economy* does indeed entail the *economy*. These examples highlight the flexibility with which humans perform natural language inference, and the need for automated systems to

(1)	AN $\sqsubset$ N	He underwent a [successful] operation on his leg at a Lisbon hospital in December.
(2a)	AN $\equiv$ N	The [deadly] attack killed at least 12 civilians.
(2b)	AN $\equiv$ N	The [entire] bill is now subject to approval by the parliament.
(3)	AN # N	President Obama cited the data as evidence that the [local] economy is improving.
(4)	AN $\sqsupset$ N	The [militant] movement was crushed by the People's Liberation Army.

(6)	AN ? N	Bush travels Monday to Michigan to make remarks on the [Japanese] economy.

Table 3: Examples of ANs in context exhibiting each of the different entailment relations. Note that these are "artificial" contexts (Section 5.2), meaning the adjective was not originally a part of the sentence.

be equally flexible.

Take aways. Our analysis in this section results in three key conclusions about AN composition. 1) Despite common assumptions, adjectives do not always restrict the denotation of a noun. Rather, adjectival modification can result in a range of entailment relations, including equivalence and contradiction. 2) There are patterns to when the insertion of an adjective is or is not entailment-preserving, but recognizing these patterns requires common-sense and a notion of "prototypical" instances of nouns. 3) The entailment relation that holds between an AN and the head N is highly context dependent. These observations describe sizable obstacles for automatic NLU systems. Common-sense reasoning is still a major challenge for computers, both in terms of how to learn world knowledge and in how to represent it. In addition, context-sensitivity means that entailment properties of ANs cannot be simply stored in a lexicon and looked-up at run time. Such properties make AN composition an important problem on which to focus NLU research.

7 Benchmarking Current SOTA

We have highlighted why AN composition is an interesting and likely challenging phenomenon for automated NLU systems. We now turn our investigation to the performance of state-of-the-art RTE systems, in order to quantify how well AN composition is currently handled.

The Add-One Entailment Task. We define the "Add-One Entailment" task to be identical to the normal RTE task, except with the constraint that the premise p and the hypothesis h differ only by the atomic insertion of an adjective: $h = e(p)$ where e=INS(A) and A is a single adjective. To provide a consistent interface with a range of RTE systems, we use a binary label set: NON-ENTAILMENT (which encompasses both CONTRADICTION and UNKNOWN) and ENTAILMENT. We want to test on only straightforward examples, so as not to punish systems for failing to classify examples which humans themselves find difficult to judge. In our test set, therefore, we label pairs with mean human scores ≤ 3 as NON-ENTAILMENT, pairs with scores ≥ 4 as ENTAILMENT, and throw away the pairs which fall into the ambiguous range in between.[5] Our resulting train, dev, and test sets contain 4,481, 510, and 387 pairs, respectively. These splits cover disjoint sets of ANs– i.e. none of the ANs appearing in test were seen in train. Individual adjectives and/or nouns can appear in both train and test. The dataset consists of roughly 85% NON-ENTAILMENT and 15% ENTAILMENT. Inter-annotator agreement achieves 93% accuracy.

7.1 RTE Systems

We test a variety of state-of-the-art RTE systems, covering several popular approaches to RTE. These systems are described in more detail below.

Classifier-based. The Excitement Open RTE platform (Magnini et al., 2014) includes a suite of RTE systems, including baseline systems as well as feature-rich supervised systems which provide state-of-the-art performance on the RTE3 datasets (Giampiccolo et al., 2007). We test two systems from Excitement: the simple Maximum Entropy (**MaxEnt**) model which uses a suite of dense, similarity-based features (e.g. word overlap, cosine similarity), and the more sophisticated Maximum Entropy model (**MaxEnt+LR**) which uses the same similarity-based features but additionally incorporates features from external lexical resources such as WordNet (Miller, 1995) and VerbOcean (Chklovski and Pantel, 2004). We also train a standard unigram model (**BOW**).

Transformation-based. The Excitement platform also includes a transformation-based RTE system called **BIUTEE** (Stern and Dagan, 2012). The BIUTEE system derives a sequence of edits that can be used to transform the premise into the hypothesis. These edits are represented using feature vectors, and the system searches over edit sequences for the lowest cost "proof" of either entailment or non-entailment. The feature weights are set by logistic regression during training.

Deep learning. Bowman et al. (2015a) recently reported very promising results using deep learning ar-

[5] For our training and dev sets, we include all pairs, considering scores < 3.5 as NON-ENTAILMENT and scores ≥ 3.5 as ENTAILMENT. We tried removing "ambiguous" pairs from the training and dev sets as well, but it did not improve the systems' performances on the test set.

chitectures and large training data for the RTE task. We test the performance of those same implementations on our Add-One task. Specifically, we test the following models: a basic Sum-of-words model (**Sum**), which represents both p and h as the sum of their word embeddings, an **RNN** model, and an **LSTM** model. We also train a bag-of-vectors model (**BOV**), which is simply a logistic regression whose features are the concatenated averaged word embeddings of p and h.

For the LSTM, in addition to the normal training setting– i.e. training only on the 5K Add-One training pairs– we test a transfer-learning setting (**Transfer**). In transfer learning, the model trains first on a large general dataset before fine-tuning its parameters on the smaller set of target-domain training data. For our Transfer model, we train first on the 500K pair SNLI dataset (Bowman et al., 2015a) until convergence, and then fine-tune on the 5K Add-One pairs. This setup enabled Bowman et al. (2015a) to train a high-performance LSTM for the SICK dataset, which is of similar size to our Add-One dataset (∼5K training pairs).

7.2 Results

Out of the box performances. To calibrate expectations, we first report the performance of each of the systems on the datasets for which they were originally designed. For the Excitement systems, this is the RTE3 dataset (Table 6a). For the deep learning systems, this is the SNLI dataset (Table 6b). For the deep learning systems, in addition to reporting performance when trained on the SNLI corpus (500K p/h pairs), we report the performance in a reduced training setting in which systems only have access to 5K p/h pairs. This is equivalent to the amount of data we have available for the Add-One task, and is intended to give a sense of the performance improvements we should expect from these systems given the size of the training data.

7.3 Performance on Add-One RTE.

Finally, we train each of the systems on the 5,000 Add-One p/h pairs in our dataset and test on our held-out set of 387 pairs. Figure 7 reports the results in terms of accuracy and precision/recall for the ENTAILMENT class. The baseline strategy of predicting the majority class for each adjective, based on the training data, reaches close to human performance (92% accuracy). Given the simplicity of the task (p and h differ by a single word), this baseline strategy should be achievable. However, none of the systems tested come close to this level of performance, suggesting that they fail to learn even the most-likely entailment generated by adjectives (e.g. that INS(*brown*) probably generates NON-ENTAILMENT and INS(*possible*) probably generates ENTAILMENT). The best performing system is the RNN, which achieves 87% accuracy, only two points above the baseline of always guessing NON-ENTAILMENT.

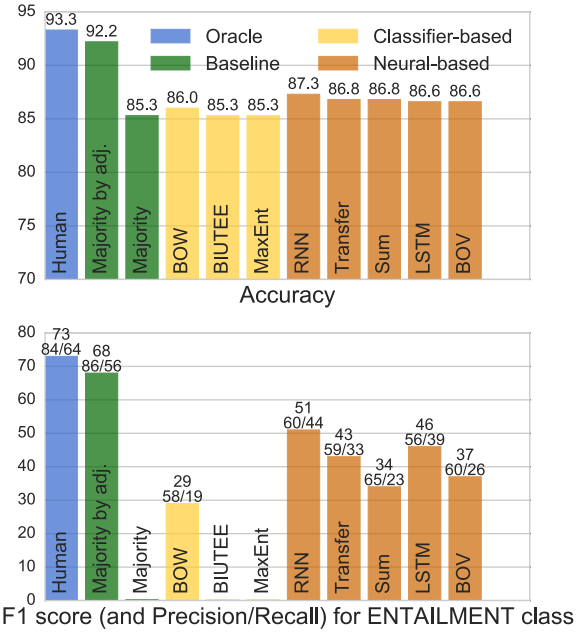

Figure 7: Performances of all systems on AddOne RTE task. The strategy of predicting the majority class for each adjective– based on the training data– reaches near human performance. None of the systems tested come close to human levels, indicating that the systems fail even to memorize the most-likely class for each adjective in training.

8 Related Work

Past work, both in linguistics and in NLP, has explored different classes of adjectives (e.g. privative, intensional) as they relate to entailment (Kamp and Partee, 1995; Partee, 2007; Boleda et al., 2013; Nayak et al., 2014). In general, prior studies have focused on modeling properties of the adjectives alone, ignoring the context-dependent nature of AN/N entailments– i.e. in prior work *little* is always restrictive, whether it is modifying *baby* or *control*. Pustejovsky (2013) offer a preliminary analysis of the contextual complexities surrounding adjective inference, which reinforces many of the observations we have made here. Hartung and Frank (2011) analyze adjectives in terms of the properties they modify but don't address them from an entailment perspective. Tien Nguyen et al. (2014) look at the

adjectives in the restricted domain of computer vision.

Other past work has employed first-order logic and other formal representations of adjectives in order to provide compositional entailment predictions (Amoia and Gardent, 2006; Amoia and Gardent, 2007; McCrae et al., 2014). Although theoretically appealing, such rigid logics are unlikely to provide the flexibility needed to handle the type of common-sense inferences we have discussed here. Distributional representations provide much greater flexibility in terms of representation (Baroni and Zamparelli, 2010; Guevara, 2010; Boleda et al., 2013). However, work on distributional AN composition has so far remained out-of-context, and has mostly been evaluated in terms of overall "similarity" rather than directly addressing the entailment properties associated with composition.

9 Conclusion

We have investigated the problem of adjective-noun composition, specifically in relation to the task of RTE. AN composition is capable of producing a range of natural logic entailment relationship, at odds with commonly-used heuristics which treat all adjectives a restrictive. We have shown that predicting these entailment relations is dependent on context and on world knowledge, making it a difficult problem for current NLU technologies. When tested, state-of-the-art RTE systems fail to learn to differentiate entailment-preserving insertions of adjectives from non-entailing ones. This is an important distinction for carrying out human-like reasoning, and our results reveal important weaknesses in the representations and algorithms employed by current NLU systems. The Add-One Entailment task we have introduced will allow ongoing RTE research to better diagnose systems' abilities to capture these subtleties of ANs, which that have practical effects on natural language inference.

Modeling Stance in Student Essays

Abstract

Essay stance classification, the task of determining how much an essay's author agrees with a given proposition, is an important yet under-investigated subtask in understanding an argumentative essay's overall content. We introduce a new corpus of argumentative student essays annotated with stance information and propose a computational model for automatically predicting essay stance. In an evaluation on 826 essays, our approach significantly outperforms four baselines, one of which relies on features previously developed specifically for stance classification in student essays, yielding relative error reductions of at least 11.3% and 5.3%, in micro and macro F-score, respectively.

1 Introduction

State-of-the-art automated essay scoring engines such as E-*rater* (Attali and Burstein, 2006) do not grade essay content, focusing instead on providing diagnostic trait feedback on categories such as grammar, usage, mechanics, style and organization. Hence, persuasiveness and other content-dependent dimensions of argumentative essay quality are largely ignored in existing automated essay scoring research. While full-fledged content-based essay scoring is still beyond the reach of state-of-the-art essay scoring engines, recent work has enabled us to move one step closer to this ambitious goal by analyzing essay content, attempting to determine the argumentative structure of student essays (Stab and Gurevych, 2014) and the persuasiveness of the arguments made in these essays (Persing and Ng, 2015).

Stance classification is an important first step in determining how persuasive an argumentative student essay is because persuasiveness depends on how well the author argues *w.r.t. the stance she takes* using the supporting evidence she provides. For instance, if her stance is *Agree Somewhat*, a persuasive argument would involve explaining what reservations she has about the given proposition. As another example, an argumentative essay in which the author takes a *neutral* stance or the author presents evidence that does not support the stance she claims to take should receive a low persuasiveness score.

Given the important role played by stance classification in determining an essay's persuasiveness, our goal in this paper is to examine stance classification in argumentative student essays. While there is a large body of work on stance classification[1], stance classification in argumentative essays is largely under-investigated and is different from previous work in several respects. First, in automated essay grading, the majority of the essays to be assessed are written by students who are learners of English. Hence our stance classification task could be complicated by the authors' lack of fluency in English. Second, essays are longer and more formally written than the text typically used in previous stance classification research (e.g., debate posts). In particular, a student essay writer typically expresses her stance on the essay's topic in a thesis sentence/clause, while a debate post's author may never even explicitly express her stance. Although the explicit expression of stance in essays seems to make our task easier,

[1]Previous approaches to stance classification have focused on three discussion/debate settings, namely congressional floor debates (Thomas et al., 2006; Bansal et al., 2008; Balahur et al., 2009; Yessenalina et al., 2010; Burfoot et al., 2011), company-internal discussions (Agrawal et al., 2003; Murakami and Raymond, 2010), and online social, political, and ideological debates (Wang and Rosé, 2010; Biran and Rambow, 2011; Walker et al., 2012; Abu-Jbara et al., 2013; Hasan and Ng, 2013; Boltužić and Šnajder, 2014; Sobhani et al., 2015; Sridhar et al., 2015).

Prompt	Prompt Parts
Most university degrees are theoretical and do not prepare students for the real world. They are therefore of very little value.	1) Most university degrees are theoretical. 2) Most university degrees do not prepare students for the real world. 3) Most university degrees are of very little value.
The prison system is outdated. No civilized society should punish its criminals: it should rehabilitate them.	1) The prison system is outdated. 2) No civilized society should punish its criminals. 3) Civilized societies should rehabilitate criminals.

Table 1: Some examples of essay prompts and their associated parts.

identifying stancetaking text in the midst of non-stancetaking sentences in a potentially long essay, as we will see, is by no means a trivial task.

To our knowledge, the essay stance classification task has only been attempted by Faulkner (2014). However, the version of the task we address is different from his. First, Faulkner only performed two-class stance classification: while his corpus contains essays labeled with *For* (Agree), *Against* (Disagree), and *Neither*, he simplified the task by leaving out the arguably most difficult-to-identify stance, *Neither*. In contrast, we perform *fine-grained* stance classification, where we allow essay stance to take one of six values: *Agree Strongly*, *Agree Somewhat*, *Neutral*, *Disagree Somewhat*, *Disagree Strongly*, and *Never Addressed*, given the practical need to perform fine-grained stance classification in student essays, as discussed above. Second, given that many essay prompts are composed of multiple simpler propositions (e.g., the prompt "Most university degrees are theoretical and do not prepare students for the real world" has two parts, "Most university degrees are theoretical" and "Most university degrees do not prepare students for the real world."), we manually split such prompts into *prompt part*s and determine the stance of the author w.r.t. each part, whereas Faulkner assigned an overall stance to a given prompt regardless of whether it is composed of multiple propositions. The distinction is important because an analysis of our annotations described in Section 2 shows that essay authors take different stances w.r.t. different prompt parts in 49% of essays, and in 39% of essays, authors even take stances with different polarities w.r.t. different prompt parts.

In sum, our contributions in this paper are two-fold. First, we propose a computational model for essay stance classification that outperforms four baselines, including our re-implementation of Faulkner's approach. Second, in order to stimulate further research on this task, we make our annotations publicly available. Since progress on this task is hindered in part by the lack of a publicly annotated corpus, we believe that our data set will be a valuable resource for the NLP community.

2 Corpus

We use as our corpus the 4.5 million word International Corpus of Learner English (ICLE) (Granger et al., 2009), which consists of more than 6000 essays on a variety of different topics written by university undergraduates from 16 countries and 16 native languages who are learners of English as a Foreign Language. 91% of the ICLE texts are written in response to prompts that trigger argumentative essays, and thus are expected to take a stance on some issue. We select 11 such prompts, and from the subset of argumentative essays written in response to them, we select 826 essays to annotate for training and testing our stance classification system.[2] Table 1 shows two of the 11 topics selected for annotation.

We pair each of the 826 essays with each of the prompt parts to which it responds, resulting in 1,593 *instance*s.[3] We then familiarize two human annotators, both of whom are native speakers of English, with the stance definitions in Table 2 and ask them to assign each instance the stance label they believe the essay's author would have chosen if asked how strongly she agrees with the prompt part. We additionally furnish the annotators with descriptions of situations that might cause an author to select the more ambiguous classes. For example, an author might choose Agree Somewhat if she appears to mostly agree with the prompt part, but qualifies her opinion in a way that is not captured by the prompt part's bluntness (e.g. an author who claims the prison system in a lot of countries is outdated would Agree Somewhat with the first part of Table 1's second prompt). Or she may choose Disagree Somewhat if she appears to dis-

[2] See our website at `http://www.hlt.utdallas.edu/~persingq/ICLE/` for the complete list of essay stance annotations.

[3] We do not segment the essays' texts according to which prompt part is being responded to. Each (entire) essay is viewed as a response to all of its associated prompt parts.

Stance	Definition
Agree Strongly (885)	The author seems to agree with and care about the claim.
Agree Somewhat (148)	The author generally agrees with the claim, but might be hesitant to choose "Agree Strongly".
Neutral (28)	The author agrees with the claim as much as s/he disagrees with it.
Disagree Somewhat (91)	The author generally disagrees with the claim, but might be hesitant to choose "Disagree Strongly".
Disagree Strongly (416)	The author seems to disagree with and care about the claim.
Never Addressed (25)	A stance cannot be inferred because the proposition was never addressed.

Table 2: Stance label counts and definitions.

agree with the prompt part, but mentions the disagreement only in passing because she does not care much about the topic.

To ensure consistency in annotation, we randomly select 100 essays (187 instances) for annotation by both annotators. Their labels agree in 84.5% of the instances, yielding a Cohen's (1960) Kappa of 0.76. Each case of disagreement is resolved through discussion between the annotators.

3 Baseline Stance Classification Systems

In this section, we describe four baseline systems.

3.1 Agree Strongly Baseline

Given the imbalanced stance distribution shown in Table 2, we create a simple but by no means weak baseline, which predicts that every instance has most frequent class label (Agree Strongly), regardless of the prompt part or the essay's contents.

3.2 N-Gram Baseline

Previous work on stance classification, which assumes that stance-annotated training data is available for every topic for which stance classification is performed, has shown that the N-Gram baseline is a strong baseline. Not only is this assumption unrealistic in practice, but it has led to undesirable consequences. For instance, the proposition "feminists have done more harm to the cause of women than good" elicits much more disagreement than normal. So, if instances from this proposition appeared in both the training and test sets, the unigram feature "feminist" would be strongly correlated with the disagreement classes even though intuitively it tells us nothing about stance. This partly explains why the N-Gram baseline was strong in previous work (Somasundaran and Wiebe, 2010). In light of this problem, we perform leave-one-out cross validation where we partition the instances by *prompt*, leaving the instances created for one prompt out in each test set.

To understand how strong n-grams are when evaluated in our leave-one-prompt-out cross-validation setting, we employ them as features in our second baseline. Specifically, we train a multiclass classifier on our data set using a feature set composed solely of unigram, bigram, and trigram features, each of which indicates the number of times the corresponding n-gram is present in the associated essay.

3.3 Duplicated Faulkner Baseline

While it is true that no system exists for solving our exact problem, the system proposed by Faulkner (2014) comes fairly close. Hence, as our third baseline, we train a multiclass classifier on our data set for fine-grained essay stance classification using the two types of features proposed by Faulkner, as described below.

Part-of-speech (POS) generalized dependency subtrees. Faulkner first constructs a lexicon of stance words in the style of Somasundaran and Wiebe (2010). The lexicon consists of (1) the set of stemmed first unigrams appearing in all stance-annotated text spans in the Multi-Perspective Question Answering (MPQA) corpus (Wiebe et al., 2005), and (2) the set of boosters (clearly, decidedly), hedges (claim, estimate), and engagement markers (demonstrate, evaluate) from the appendix of Hyland (2005). He then manually removes from this list any words that appear not to be stancetaking, resulting in a 453 word lexicon.

Stance words target propositions, which Faulkner notes, usually contain some opinion-bearing language that can serve as a proxy for the targeted proposition. In order to find the locations in an essay where a stance is being taken, he first finds each stance word in the essay. Then he finds the shortest path from the stance word to an opinion word in the sentence's dependency tree, using the MPQA subjectivity lexicon of opinion words (Wiebe et al., 2005). If this nearest opinion word appears in the stance word's immediate or embedded clause, he creates a binary feature by concatenating all the words in the dependency path, POS generalizing all words other than the stance and opinion word, and finally prepending

"not" if the stance word is adjacent to a negator in the dependency tree. Thus given the sentence "I **can** only say that this statement is completely *true*." he would add the feature *can-V-true*, which suggests agreement with the prompt.

Prompt topic words. Recall that for the previous feature type, a feature was generated whenever an opinion word occurred in a stance word's immediate or embedded clause. Each content word in this clause is used as a binary feature if its similarity with one of the prompt's content words meets an empirically determined threshold.

3.4 N-Gram+Duplicated Faulkner Baseline

To build a stronger baseline, we employ as our fourth baseline a classifier trained on both n-gram features and duplicated Faulkner's features.

4 Our Approach

Our approach to stance classification is a learning-based approach where we train a multiclass classifier using four types of features: n-gram features (Section 3.2), duplicated Faulkner's features (Section 3.3), and two novel types of features, stancetaking path-based features (Section 4.1) and knowledge-based features (Section 4.2).

4.1 Stancetaking Path-Based Features

Recall that, in order to identify his POS generalized dependency subtrees, Faulkner relies on two lexica, a lexicon of stancetaking words and a lexicon of opinion-bearing words. He then extracts a feature any time words from the two lexica are syntactically close enough. A major problem with this approach is that the lexica are so broad that nearly 80% of sentences in our corpus contain text that can be identified as stancetaking using this method. Intuitively, an essay may state its stance w.r.t. a prompt part in a thesis or conclusion sentence, but most of essay's text will be at most tangentially related to any particular prompt part. For this reason, we propose to identifying stancetaking text to target *only text that appears directly related to the prompt part*. Below we first show how we identify and stance-labeling relevant stancetaking dependency paths, and then describe the features we derive from these paths.

4.1.1 Identifying relevant stancetaking paths

As noted above, we first identify stancetaking text that appears directly related to the prompt part.

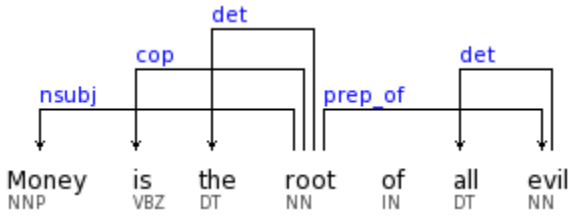

Figure 1: Automatic dependency parse of a prompt part.

To begin, we note that the prompt parts themselves must express a stance on a topic if they can be agreed or disagreed with. By examining the dependency parses[4] of the prompt parts, we can recognize elements of how stancetaking text is structured. From the prompt part shown in Figure 1, for example, we notice that the important words that express a stance in the sentence are "money", "root", and "evil". By analyzing the dependency structure in this and other prompt parts, we discovered that stancetaking text often consists of (1) a **subject** word, which is the child in an nsubj or nsubjpass relation, (2) a **governor** word which is the subject's parent, and (3) an **object**, which is a content word from which there is a (not always direct) dependency path from the governor. We therefore abstract a stance in an essay as a dependency path from a subject to an object that passes through the governor. Thus, the stancetaking dependency path we identify from the prompt part shown in Figure 1 could be represented as money-root-evil.

The obvious problem with identifying stancetaking text in this way is that nearly all sentences contain this kind of stancetaking structure, and just as with Faulkner's dependency paths, there is little reason to believe that any particular path is relevant to an instance's prompt part. Does this mean that nearly all sentences are stancetaking? We would argue that they can be, as even sentences that appear on their face to be mere statements of fact with no apparent value judgment can be viewed as taking a stance on the factuality of the statement, and people often disagree about the factuality of statements. For this reason, after we have identified a stancetaking path, we must determine whether the stance being expressed is relevant to the prompt part before extracting features from it.

[4]Dependency parsing, POS tagging, and lemmatization are performed automatically using the Stanford CoreNLP system (Manning et al., 2014)

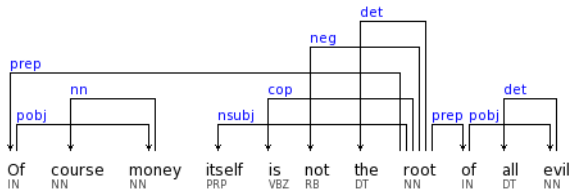

Figure 2: Automatic dependency parse of an essay sentence.

For this reason, we ignore all stancetaking paths that do not meet the following three relevance conditions. First, the lemma of the path's governor must match the lemma of a governor in the prompt part. Second, the lemma of the path's object must match the lemma of some content word[5] in the prompt part. Finally, the containing sentence must not contain a question mark or a quotation, as such sentences are usually rhetorical in nature. We do not require that the subject word match the prompt part's subject word because this substantially reduces coverage for various reasons. For one, of the three words (subject, governor, object), the subject is the word most likely to be replaced with some other word like a pronoun, and possibly because the essays were written by non-native English speakers, automatic coreference resolution cannot reliably identify these cases. We also do not fully trust that the subject identified by the dependency parser will reliably match the subject we are looking for. Given these constraints, we can automatically identify the "itself-root-of-evil" dependency path in Figure 2 as a relevant stancetaking path.

4.1.2 Stance-labeling the paths

Next, we determine whether a stancetaking path identified in the previous step appears to agree or disagree with the prompt part.

To begin, we count the number of negations occurring in the prompt part. Any word like "no", "not", or "none" counts as a negation unless it begins a non-negation phrase like "no doubt" or "not only".[6] Thus, the count of negations in the prompt part in Figure 1 is 0.

After that, we count the number of times the identified stancetaking path is negated. Because these paths occur in student essays and are therefore often not as simply-stated as the prompt parts, this is a little bit more complicated than just counting the containing sentence's negations since the sentence may contain a lot of additional material. To do this, we construct a list of all the dependency nodes in the stancetaking path as well as all of their dependency tree children. We then remove from this list any node that, in the sentence, occurs after the last node in the stancetaking path. The total negation count we are looking for is the number of nodes in this list that correspond to negation words (unless the negation word begins a negation phrase). Thus, because the word "not" is the child of "root" in the path "itself-root-of-evil" we identified in Figure 2, we consider this path to have been negated one time.

Finally, we sum the prompt part negations and the stancetaking path negations. If this sum is even, we believe that the relevant stancetaking path agrees with the prompt part in the instance. If it is odd, however (as in the case of the prompt part and stancetaking text in the dependency tree figures), we believe that it disagrees with the prompt part. To illustrate why we are concerned with whether this sum is even, consider the following examples. If both the prompt part and the stancetaking text are negated, both disagree with the opposite of the prompt part's stance. Thus, they agree with each other, and their negation sum is even (2). If the stancetaking path was negated twice, however, the sum would be odd (3) due to the stance path's double negations canceling each other out, and the stancetaking path would disagree with the prompt part.

4.1.3 Deriving path-based features

We extract four features from the relevant stancetaking dependency paths identified and stance-labeled so far, as described below.

The first feature encodes the count of relevant stancetaking paths that appear to agree with the prompt part. The second feature encodes the count of relevant stancetaking paths that appear to disagree with the prompt part. While we expect these first two features to be correlated with the agreement and disagreement classes, respectively, they may not be sufficient to distinguish between agreeing and disagreeing instances. It is possible, for example, that both features may be greater than zero in a single instance if we have identified one stancetaking path that appears to agree

[5]For our purpose, a content word (1) is a noun, pronoun, verb, adjective, or adverb, (2) is not a stopword, and (3) is at the root, is a child in a dobj or pobj relation, or is the child in a conj relation whose parent is the child in a dobj or pobj relation in the dependency tree.

[6]See our website at `http://www.hlt.utdallas.edu/~persingq/ICLE/` for our list of manually constructed negation words and non-negation phrases.

with the prompt part and another stancetaking path that appears to disagree with the prompt part. It is not clear whether this situation is indicative of only the Neutral class, or perhaps it indicates partial (Somewhat) (Dis)Agreement, or maybe our method of detecting disagreement is not reliable enough, and it therefore makes sense, when we get these conflicting signals, to ignore them entirely and just assign the instance to the most frequent (Agree Strongly) class. For that matter, if neither feature is greater than zero, does this mean that the instance Never Addressed the prompt part, or does it instead mean that our method for identifying stancetaking paths doesn't have high enough recall to work on all instances? We let our learner sort these problems out by adding two more binary features to our instances, one which indicates that both of the first two features are zero, and one that indicates whether both are greater than zero.

4.2 Knowledge-Based Features

Our second feature type is composed of five linguistically informed binary features that correspond to five of the six classes in our fine-grained stance classification task. Intuitively, if an instance has one of these features turned on, it should be assigned to the feature's corresponding class.

1. Neutral. Stancetaking text indicating neutrality tends to be phrased somewhat differently than stancetaking text indicating any other class. In particular, neutral text often makes claims that are about the prompt part's subject, but which are tangential to the proposition expressed in the prompt part. For this reason, we search the essay for words that match the prompt part's subject lemmatically.

After identifying a sentence that is about the prompt part's subject in this way, we check whether the sentence begins with any neutral indicating phrase.[7] If we find a sentence that both begins with a neutral phrase and is about the prompt part's subject, we turn the Neutral feature on. Thus, sentences like the following can be captured: "*In all probability* university students wonder whether or not they spend their time uselessly in studying through four or five years in order to take their *degree*."

2. (Dis)Agree Somewhat. In order to set the values of the features associated with the Somewhat classes, we first identify relevant stancetaking paths as described above. We then trim the list of paths by removing any path whose governor or subject does not have a hedge word as an adverb modifier child in the dependency tree.[8] Thus, we are able to determine that the essay containing the sentence "There is *nearly* no place left for dream and imagination" is likely to belong to one of the Somewhat classes w.r.t. the prompt part "There is no longer a place for dreaming and imagination."

The question now is how to determine which (if any) of the Somewhat classes it should belong to. We analyze all the paths from the list for negation in much the same way we described above, but with one major difference. We hypothesize that when taking a Somewhat stance, students are more likely to explicitly state that the stance being taken is their opinion rather than stating the stance bluntly without attribution. For example, one Disagree Somewhat essay includes the sentence, "*I* **never** *believed* these people were honest if saying that money is just the root of all evil." In order to determine that this sentence contains an indication of the Disagree Somewhat class, we need to account for the negation that occurs at the beginning, far away from the stancetaking path (money-root-of-evil). To do this, we semantically parse the sentence using SEMAFOR (Das et al., 2010). Each of the *semantic frames* detected by SEMAFOR describes an event that occurs in a sentence, and the event's *frame elements* may be the people or other entities that participate in the event. One of the semantic frames detected in this example sentence describes a Believer (I) and the content of his or her belief (all the text after "believed"). Because the sentence includes a semantic frame that (1) contains a first person (I, we) Cognizer, Speaker, Perceiver, or Believer element, (2) contains an element that covers all the text in the dependency path (a Content frame element, in this case), and (3) the word that triggers the frame ("believed") has a negator child in the dependency tree, we add one to this relevant stancetaking path's negation count. This makes this hedged stancetaking path's negation count odd, so we believe that this sentence likely disagrees with its instance's prompt part somewhat. If we find a hedged stancetaking

[7] We construct a list of neutral phrases for introducing another person's ideas from a writing skills website (`http://www.myenglishteacher.eu/question/other-ways-to-say-according-to/`).

[8] See our website at `http://www.hlt.utdallas.edu/~persingq/ICLE/` for our manually constructed list of hedge words.

path with an odd negation count, we turn on the Disagree Somewhat feature. Similarly, if we find a hedged stancetaking path with an even negation count, we turn on the Agree Somewhat feature.

3. (Dis)Agree Strongly. When we believe there is strong evidence that an instance should belong to one of the Strongly classes, we turn on the corresponding (Dis)Agree Strongly feature. In particular, if we find a relevant stancetaking path that appears to agree with the prompt part (as described in Section 4.1.2), but do not find any such path that appears to disagree with it, we turn on the Agree Strongly feature. Similarly, if we find a relevant stancetaking path that appears to disagree with the prompt part, but do not find a relevant stancetaking path that appears to agree with it, we turn on the Disagree Strongly feature.

5 Evaluation

5.1 Experimental Setup

Data partition. All our results are obtained via leave-one-prompt-out cross-validation experiments. So, in each fold experiment, we partition the instances from our 11 prompts into a training set (10 prompts) and a test set (1 prompt).

Evaluation metrics. We employ two metrics to evaluate our systems: (1) micro F-score, which treats each instance as having equal weight; and (2) macro F-score, which treats each class as having equal weight.[9] To gain insights into how different systems perform on different classes, we additionally report per-class F-scores.

Training. We train the baselines and our approach using two learning algorithms, MALLET's (McCallum, 2002) implementation of maximum entropy (MaxEnt) classification and our own implementation of the one nearest neighbor (1NN) algorithm using the cosine similarity metric. Note that these two learners have their own strengths and weaknesses: in comparison to 1NN, MaxEnt is better at exploiting high-dimensional features but less robust to skewed class distributions. For the baseline systems, we select the learner by performing cross validation on the training folds to maximize the average of micro and macro F-scores in each fold experiment.

When training our approach, we perform exhaustive feature selection to determine which subset of the four sets of features (i.e., n-gram, duplicated Faulkner, path-based, and knowledge-based features) should be used. Specifically, we select the feature groups and learner jointly by performing cross validation on the training folds, choosing the combination yielding the highest average of micro and macro F-scores in each fold experiment. To prevent any feature type from dominating the others, to each feature we apply a weight of one divided by the number of features having its type.

Testing. In case of a tie when applying 1NN, the tie is broken by selecting the class appearing higher in Table 2.

5.2 Results and Discussion

Results on fine-grained essay stance classification are shown in Table 3. The first four rows show our baselines' performances. Among the four baselines, Always Agree Strongly performs best w.r.t. micro F-score, obtaining a score of 55.6%, whereas Duplicated Faulkner performs best w.r.t. macro F-score, obtaining a score of 15.6%. Despite its poor performance, Duplicated Faulkner is a state-of-the-art approach on this task. Its poor performance can be attributed to three major factors. First, it was intended to identify only Agree and Disagree instances (note that Faulkner simply removed neutral instances from his experimental setup), which should not prevent them from performing well w.r.t. micro F-score. Second, it is far too permissive, generating features from a large majority of sentences while relevant sentences are far rarer. Third, while it does succeed at predicting Disagree Strongly far more frequently than either of the other baselines that excludes the Faulkner feature set, the problem's class skewness means that a learner is much more likely to be punished for predicting minority classes, which are more difficult to predict with high precision.

The fact that it makes an attempt to solve the problem rather than relying on class skewness for good performance makes Duplicated Faulkner a more interesting baseline than either N-Gram or Always Agree Strongly, even though both technically outperform it w.r.t. micro F-score. Similarly, the statistically significant improvements in micro and macro F-score our approach achieves over the best baselines are more impressive when taking the skewness problem into consideration.

The results of our approach, which has access

[9] Since stance classification is a multiclass, single-label task, micro F-score, precision, recall, and accuracy are all equivalent.

	System	Micro-F	Macro-F	A+	A−	Neu	D−	D+	Nev
1	Always Agree Strongly	55.6	11.9	71.4	.0	.0	.0	.0	.0
2	N-Gram	55.4	12.0	71.3	.0	.0	.0	.5	.0
3	Duplicated Faulkner	50.8	15.6	66.8	4.0	.0	.0	22.9	.0
4	N-Gram + Duplicated Faulkner	53.4	15.4	69.1	2.5	.0	.0	20.6	.0
5	Our approach	**60.6**	**20.1**	73.6	.0	.0	2.1	44.8	.0

Table 3: Cross-validation results for fine-grained essay stance classification, including per-class F-scores for Agree Strongly (A+), Agree Somewhat (A−), Neutral (Neu), Disagree Somewhat (D−), Disagree Strongly (D+), and Never Addressed (Nev).

to all four feature groups, are shown in row 5 of the table. It obtains micro and macro F-scores of 60.6% and 20.1%, which correspond to statistically significant relative error reductions over the best baselines of 11.3% and 5.3%, respectively.[10]

Recall that we turned on one of our knowledge-based features only when we believed there was strong evidence that an instance belonged to its associated class. To get an idea of how useful these features are, we calculate the precision, recall, and F-score that would be obtained for each class if we treated our knowledge-based features as heuristic classifiers. The respective precisions, recalls, and F-scores we obtained are: 0.66/0.28/0.40 (A+), 0.50/0.02/0.04 (A−), 0.00/0.00/0.00 (Neu), 0.50/0.01/0.02 (D−), and 0.63/0.31/0.42 (D+). Since the rule predictions are encoded as features for the learner, they may not necessarily be used by the learner even if the underlying rules are precise. For instance, despite the rule's high precision on the Agree Somewhat class, the learner did not make use of its predictions due to its low coverage.

5.3 Additional Experiments

Since all the systems we examined fared poorly on identifying Somewhat classes, one may wonder how these systems would perform if we considered a simplified version of the task where we merged each Somewhat class with the corresponding Strongly class. In particular, since Faulkner's approach was originally not designed to distinguish between Strongly and Somewhat classes, it may seem fairer to compare our approach against Duplicated Faulkner on the four-class essay stance classification task, where stance can take one of four values: Agree (created by merging Agree Strongly and Agree Somewhat), Disagree (created by merging Disagree Strongly and Disagree Somewhat), Neutral, and Never Addressed.

In the results for the different systems on this four-class stance classification task, shown in Table 4, we see that the same patterns we noticed in the six-class version of the task persist. The approaches' relative order w.r.t. micro and macro F-score remains the same, though they are adjusted upwards due to the problem's increased simplicity. Our approach's performance on Agree increases (compared to Agree Strongly) because Agree is a bigger class, making predictions of the class safer. Our approach's performance decreases on Disagree (compared to Disagree Strongly) since it is not good at predicting Disagree Somewhat instances which are part of the class.

5.4 Error Analysis

To gain additional insights into our approach, we analyze its six major sources of error below.

Stances not presented in a straightforward manner. As an example, consider "To my opinion this technological progress triggers off the imagination in a certain way." To identify this sentence as strongly disagreeing with the proposition "there is no longer a place for dreaming and imagination", we need to understand (1) the world knowledge that technological progress is occurring, (2) that "triggers off the imagination in a certain way" means that the technological progress coincides with imagination occurring, (3) that if imagination is occurring, there must be "a place for dreaming and imagination", and (4) that the prompt part is negated. In general, in order to construct reliable features to increase our coverage of essays that express their stance like this, we would need additional world knowledge and a deeper understanding of the text.

Rhetorical statements occasionally misidentified as stancetaking. For example, our method

[10] All significance tests are approximate randomization tests with $p < 0.01$. Boldfaced results are significant w.r.t. micro F-score for the Always Agree Strongly baseline, and macro F-score w.r.t. the Duplicated Faulkner baseline.

	System	Micro-F	Macro-F	A	Neu	D	Nev
1	Always Agree Strongly	64.8	19.7	78.7	.0	.0	.0
2	N-Gram	64.3	19.7	78.2	.0	.8	.0
3	Duplicated Faulkner	62.3	25.1	75.1	.0	25.2	.0
4	N-Gram + Duplicated Faulkner	62.6	23.7	75.8	.0	19.0	.0
5	Our approach	**67.6**	**29.1**	78.5	.0	38.0	.0

Table 4: Cross-validation results for four-class essay stance classification for Agree (A), Neutral (Neu), Disagree (D), and Never Addressed (Nev).

for identifying stancetaking paths misidentifies "I am going to discuss the topic that television is the opium of the masses in modern society" as stancetaking. To handle this, we need to incorporate more sophisticated methods for detecting rhetorical statements than those we are using (e.g., ignoring sentences ending in question marks).

Negation expressed without negation words. Our techniques for capturing negation are unable to detect when negation is expressed without the use of simple negation words. For example, "In this sense money is the root of life" should strongly disagree with "money is the root of all evil". The author replaced "life" with "evil", and detecting that this constitutes something like negation would require semantic knowledge about words that are somehow opposite of each other.

Insufficient feature/heuristic coverage of the Disagree Strongly class. Our stancetaking path-based features that we identified as intuitively having a connection to the Disagree Strongly class together cover only 51% of Disagree Strongly instances, meaning that it is in principle impossible for our system to identify the remaining 49%. However, our decision to incorporate only features that are expected to have fairly high precision for some class was intentional, as the lesson we learned from the Faulkner-based system is that it is difficult to learn a good classifier for stance classification using a large number of weakly or non-predictive features. To solve this problem, we would therefore need to exploit other aspects of strongly disagreeing essays that act as reliable predictors of the class.

Rarity of minority class instances. It is perhaps not surprising that our learning-based approach performs poorly on the minority classes. Even though the knowledge-based features were designed in part to improve the prediction of minority classes, our results suggest that the resulting features were not effectively exploited by the learners. To address this problem, one could employ a hybrid rule-based and learning-based approach where we use our machine-learned classifier to classify an instance only if it cannot be classified by any of these rules.

Lack of obvious similarity between instances of the same class. For example, if the most straightforward stancetaking sentence in an Agree Somewhat instance reads something like this, "In conclusion, I will not go to such extremes as to declare nihilistically that university does not prepare me for the real world in the least", (given the prompt part "Most university degrees do not prepare us for real life"), and we somehow managed to identify the instance's class as Agree Somewhat, what would the instance have in common with other Agree Somewhat instances? Given the numerous ways of expressing a stance, we believe a deeper understanding of essay text is required in order automatically detect how instances like this are similar to instances of the same class, and such similarities are required for learning in general.

6 Conclusion

We examined the new task of fine-grained essay stance classification, in which we determine stance for each prompt part and allow stance to take one of six values. We addressed this task by proposing two novel types of features, stancetaking path-based features and knowledge-based features. In an evaluation on 826 argumentative essays, our learning-based approach, which combines our novel features with n-gram features and Faulkner's features, significantly outperformed four baselines, including our re-implementation of Faulkner's system. Compared to the best baselines, our approach yielded relative error reductions of 11.3% and 5.3%, in micro and macro F-score, respectively. Nevertheless, accurately predicting the Somewhat, Neutral, and Never Addressed stances remains a challenging task. To stimulate further research on this task, we make all of our stance annotations publicly available.

A New Psychometric-inspired Evaluation Metric for Chinese Word Segmentation

Abstract

Word segmentation is a fundamental task for Chinese language processing. However, with the successive improvements, the standard metric is becoming hard to distinguish state-of-the-art word segmentation systems. In this paper, we propose a new psychometric-inspired evaluation metric for Chinese word segmentation, which addresses to balance the very skewed word distribution at different levels of difficulty[1]. The performance on a real evaluation shows that the proposed metric gives more reasonable and distinguishable scores and correlates well with human judgement. In addition, the proposed metric can be easily extended to evaluate other sequence labelling based NLP tasks.

1 Introduction

Word segmentation is a fundamental task for Chinese language processing. In recent years, Chinese word segmentation (CWS) has undergone great development, which is, to some degree, driven by evaluation conferences of CWS, such as SIGHAN Bakeoffs (Emerson, 2005; Levow, 2006; Jin and Chen, 2008; Zhao and Liu, 2010). The current state-of-the-art methods regard word segmentation as a sequence labeling problem (Xue, 2003; Peng et al., 2004). The goal of sequence labeling is to assign labels to all elements in a sequence, which can be handled with supervised learning algorithms, such as maximum entropy (ME) (Berger et al., 1996), conditional random fields (CRF) (Lafferty et al., 2001) and Perceptron (Collins, 2002).

Benefiting from the public datasets and feature engineering, Chinese word segmentation achieves quite high precision after years of intensive research. To evaluate a word segmenter, the standard metric consists of **precision** p, **recall** r, and an evenly-weighted **F-score** f_1.

However, with the successive improvement of performance, state-of-the-art segmenters are hard to be distinguished under the standard metric. Therefore, researchers also report results with some other measures, such as out-of-vocabulary (OOV) recall, to show their strengths besides p, r and f_1.

Furthermore, although state-of-the-art methods have achieved high performances on p, r and f_1, there exists inconsistence between the evaluation ranking and the intuitive feelings towards the segmentation results of these methods. The inconsistence is caused by two reasons:

(1) The high performance is due to the fact that the distribution of difficulties of words is unbalanced. The proportion of trivial cases is very high, such as '的 ('s)', '我们 (we)', which results in that the non-trivial cases are relatively despised. Therefore, a good measure should have a capability to balance the skewed distribution by weighting the test cases.

(2) Human judgement depends on difficulties of segmentations. A segmenter can earn extra credits when correctly segmenting a difficult word than an easy word. Conversely, a segmenter can take extra penalties when wrongly segmenting an easy word than a difficult word.

Taking a sentence and two predicted segmentations as an example:
S : 白藜芦醇 是 一 种 酚类 物质
(Trans: Resveratrol is a kind of phenols material.)
P1: 白 藜芦 醇 是 一种 酚类 物质
P2: 白藜 芦醇 是 一 种 酚类物 质

We can see that the two segmentations have the

[1]We release the word difficulty of the popular word segmentation datasets at http://nlp.fudan.edu.cn/data/ .

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2185–2194,
Berlin, Germany, August 7-12, 2016.

same scores in p, r and f_1. But intuitively, P1 should be better than P2, since P2 is worse even on the trivial cases, such as '酚类 (phenols)' and '物质 (material)'.

Therefore, we think that an appropriate evaluation metric should not only provide an all-around quantitative analysis of system performances, but also explicitly reveal the strengths and potential weaknesses of a model.

Inspired by psychometrics, we propose a new evaluation metric for Chinese word segmentation in this paper. Given a labeled dataset, not all words have the same contribution to judge the performance of a segmenter. Based on psychometric research (Lord et al., 1968), we assign a difficulty value to each word. The difficulty of a word is automatically rated by a committee of segmenters, which are diversified by training on different datasets and features. We design a balanced precision, recall to pay different attentions to words according to their difficulties.

We also give detailed analysis on a real evaluation of Chinese word segmentation with our proposed metric. The analysis result shows that the new metric gives a more balanced evaluation result towards the human intuition of the segmentation quality. We will release the weighted datasets focused this paper to the academic community.

Although our proposed metric is applied to Chinese word segmentation for a case study, it can be easily extended to other sequence labelling based NLP tasks.

2 Standard Evaluation Metric

The standard evaluation usually uses three measures: precision, recall and balanced F-score.

Precision p is defined as the number of correctly segmented words divided by the total number of words in the automatically segmented corpus.

Recall r is defined as the number of correctly segmented words divided by the total number of words in the gold standard, which is the manually annotated corpus.

F-score f_1 the harmonic mean of precision and recall.

Given a sentence, the gold-standard segmentation of a sentence is $w_1, \cdots, W_N$, N is the number of words. The predicted segmentation is $w'_1, \cdots, w'_{N'}$, N' is the number of words. Among that, the number of words correctly identified by the predicted segmentation is c, and the number of incorrectly predicted words is e.

p, r and f_1 are defined as follows:

$$p = \frac{c}{N'}, \tag{1}$$

$$r = \frac{c}{N}, \tag{2}$$

$$f_1 = \frac{2 \times p \times r}{p + r}. \tag{3}$$

As a complement to these metrics, researchers also use the recall of out-of-vocabulary (OOV) words to measure the segmenter's performance in detecting unknown words.

3 A New Psychometric-inspired Evaluation Metric

We involve the basic idea from psychometrics and improve the evaluation metric by assigning weights to test cases.

3.1 Background Theory

This work is inspired by the test theory in psychometrics (Lord et al., 1968). Psychologists, as well as educators, have studied the way of analyzing items in a psychological test, such as IQ test. The general idea is that test cases should be given different weights, which reflects the effectiveness of a certain item to a certain measuring object.

Similarly, we consider an evaluation task as a kind of special psychological test. The psychological traits, or the ability of the model, is not an explicit characteristics. We propose that the test cases for NLP task should also be assigned a real value to account for the credits that the tagger earned from answering the test case.

In analogy to the way of computing difficulty in psychometrics, the difficulty of a target word w_i is defined as the error rate of a committee in the case of word segmentation.

Given a committee of K base segmenters, we can get K segmentations for sentence $w_1, \cdots, W_N$. We use a mark $m_i^k \in \{0, 1\}$ to indicate whether word w_i is correctly segmented by the k-th segmenter.

The number of words c^k correctly identified by the k-th segmenter is

$$c^k = \sum_{i=1}^{N} m_i^k. \tag{4}$$

Thus, we can calculate the degree of difficulty of each word w_i.

$$d_i = \frac{1}{K}\sum_{k=1}^{K}(1 - m_i^k). \quad (5)$$

This methodology of measuring test item difficulty is also widely applied in assessing standardized exams such as TOEFL (Service, 2000).

3.2 Psychometric-Inspired Evaluation Metric

Since the distribution of the difficulties of words is very skew, we design a new metric to balance the weights of different words according to their difficulties. In addition, we also should keep strictly a fair rule for rewards and punishments.

Intuitively, if the difficulty of a word is high, a correct segmentation should be given an extra rewards; otherwise, if the difficulty of a word is low, it is reasonable to give an extra punishment to a wrong segmentation.

Our new metric of precision, recall and balanced F-score is designed as follows.

Balanced Recall Given a new predicted segmentation, the mark $m_i \in \{0, 1\}$ indicates whether word w_i is correctly segmented. d_i is the degree of difficulty of word w_i.

According to the difficulties of each word, we can calculated the reward recall r_{reward} which biased for the difficult cases.

$$r_{reward} = \frac{\sum_{i=1}^{N} d_i \times m_i}{\sum_{i=1}^{N} d_i}, \quad (6)$$

where $r'_{reward} \in [0, 1]$ is biased recall, which places more attention on the difficult cases and less attention on the easy cases.

Conversely, we can calculated another punishment recall $r_{punishment}$ which biased for the easy cases.

$$r_{punishment} = \frac{\sum_{i=1}^{N} (1 - d_i) \times m_i}{\sum_{i=1}^{N} (1 - d_i)}, \quad (7)$$

where $r_{punishment} \in [0, 1]$ is biased recall, which places more attention on the easy cases and less attention on the difficult cases.

$r_{punishment}$ can be interpreted as a punishment as bellows.

$$r_{punishment} = \frac{\sum_{i=1}^{N} (1 - d_i) \times m_i}{\sum_{i=1}^{N} (1 - d_i)}, \quad (8)$$

$$= 1 - \frac{\sum_{i=1}^{N} (1 - d_i) \times (1 - m_i)}{\sum_{i=1}^{N} (1 - d_i)}. \quad (9)$$

From Eq (9), we can see that an extra punishment is given to wrong segmentation for low difficult word. In detailed, for a word w_i that is easy to segment, its weights $(1 - d_i)$ is relative higher. When its segmentation is wrong, $m_i = 0$. Therefore, $(1 - d_i) \times (1 - m_i) = (1 - d_i)$ will be larger, which results to a smaller final score.

To balance the reward and punishment, a balanced recall r_b is used, which is the harmonic mean of r_{reward} and $r_{punishment}$.

$$r_b = \frac{2 \times r_{punishment} \times r_{reward}}{r_{punishment} + r_{reward}} \quad (10)$$

Balanced Precision Given a new predicted segmentation, the mark $m'_i \in \{0, 1\}$ to indicate whether segment s'_i is correctly segmented. d'_i is the degree of difficulty of segment s'_i, which is an average difficulty of the corresponding gold words.

Similar to balanced recall, we use the same way to calculate balance precision p_b. Here N' is the number of words in the predicted segmentation. d'_i is the weight for the predicted segmentation unit w'_i. It equals to the word difficulty of the corresponding word w that cover the right boundary of w'_i in the gold segmentation.

$$p_{reward} = \frac{\sum_{i=1}^{N} (1 - d_i) \times m_i}{\sum_{i=1}^{N'} (1 - d'_i)}, \quad (11)$$

$$p_{punishment} = \frac{\sum_{i=1}^{N} (1 - d_i) \times m_i}{\sum_{i=1}^{N'} (1 - d'_i)}, \quad (12)$$

$$p_b = \frac{2 \times p_{reward} \times p_{punishment}}{p_{reward} + p_{punishment}}. \quad (13)$$

$$(14)$$

Balanced F-score The final balanced F-score is

$$f_b = \frac{2 \times p_{balanced} \times r_{balanced}}{p_{balanced} + r_{balanced}}. \quad (15)$$

4 Committee of Segmenters

It is infeasible to manually judge the difficulty of each word in a dataset. Therefore, an empirical method is needed to rate each word. Since the difficulty is also not derivable from the observation of the surface forms of the text, we use a committee of automatic segmenters instead. To keep fairness

F1	$C_iT_0, (i = -1, 0, 1)$
	$C_{i:i+1}T_0, (i = -1, 0)$
	$T_{-1,0}$
F2	$C_iT_0, (i = -2, -1, 0, 1, 2)$
	$C_{i:i+1}T_0, (i = -2, -1, 0, 1)$
	$T_{-1,0}$
F3	$C_iT_0, (i = -2, -1, 0, 1, 2)$
	$C_{i:i+1}T_0, (i = -2, -1, 0, 1)$
	$C_{i:i+2}T_0, (i = -2, -1, 0)$
	$T_{-1,0}$

Table 1: Feature templates. C represents a Chinese character, and T represents the character-based tag in set {B, M, E, S}. The subscript indicates its position relative to the current character, whose subscript is 0. $C_{i:j}$ represents the subsequence of characters form relative position i to j.

and justice of the committee, we need a large number of diversified committee members.

Thus, the grading result of committee is fair and accurate, avoiding the laborious human annotation and the deviation caused by the subjective factor of the artificial judgement.

4.1 Building the Committee

Base Segmenters The committee is composed of a series of base segmenters, which are based on discriminative character-based sequence labeling method. Each character is labeled as one of {B, M, E, S} to indicate the segmentation. 'B' indicates the beginning character of a word. 'M' indicates the middle character of a word. 'E' indicates the end character of a word. 'S' indicates that the word consists of only a single character.

Diversity of Committee To objectively assess the difficulty of a word, we need to maintain a large enough committee with diversity.

To encourage diversity among committee members, we train them with different datasets and features. Specifically, each base segmenter adopts one of three types of feature templates (shown in Table 1), and are trained on randomly sampling training sets. To keep a large diversity, we set sampling ratio to be 10%, 20% and 30%. In short, each base segmenter is constructed with a random combination of the candidate feature template and the sampling ratio for training dataset.

Size of Committee To obtain a valid and reliable assessment for a word, we need to choose the

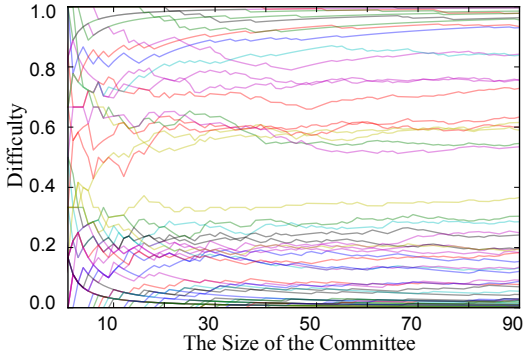

Figure 1: Judgement of difficulty against the committee size. Each line represents a sampled word.

appropriate size of committee. For a given test case, the judgement of its difficulty should be relatively stable. We analyze how the judgement of its difficulty changes as the size of committee increases.

Figure 2 show PKU data from SIGHAN 2005 (Emerson, 2005) the difficulty is stable when the sample size is large enough.

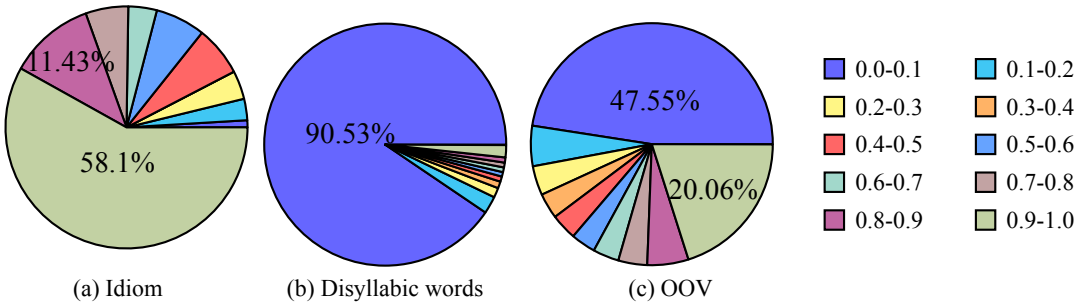
4.2 Interpreting Difficulty with Linguistic Features

Since we get the difficulty for each word empirically, we naturally want to know whether the difficulty is explainable, as what TOEFL researchers have done (Freedle and Kostin, 1993; Kostin, 2004). We would like to know whether the variation of word difficulty can be partially expalined by a series of traceable linguistic features.

Based on the knowledge about the characteristics of Chinese grammar and the practical experiences of corpus annotation, we consider the following surface linguistic features. In order to explicitly display the relationship between the linguistic predictors and the distribution of the word difficulty at a micro level, we divide the difficulty scale into ten discrete intervals and calculate the distributions of these linguistic features on different ranges of difficulty.

Here, we interpret the difficulties of the words from the perspective of three important linguistic features:

Idiom In Chinese, the 4-character idioms have special linguistic structures. These structure usually form a different pattern that is hard for the machine algorithm to understand. Therefore,



(a) Idiom (b) Disyllabic words (c) OOV

Figure 2: Difficulty distribution of (a) idioms, (b) dysyllabic words and (c) Out-of-vocabulary words from PKU dataset. Similar pattern has also been found in other datasets.

it is reasonable to hypothesize that the an idiom phrase is more likely to be a difficult word for word segmentation task. We can see from Figure 2a that 58.1% of idioms have a difficulty at (0.9,1]. The proportion does increase with the degree of difficulty, which corresponds with the human intuition.

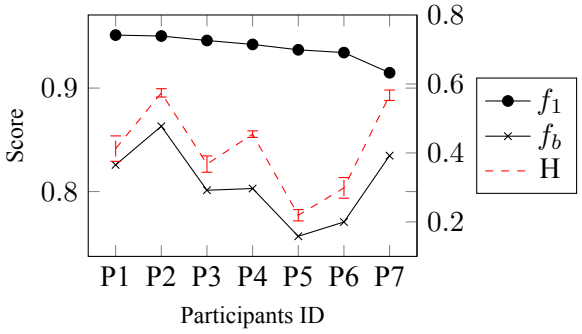
Dissyllabic Word Disyllabic word is a word formed by two consecutive Chinese characters. We can see from Figure 2b that the frequency of disyllabic words has a negative correlations with the degree of difficulty. This is an interesting result. It means that a two-syllable word pattern is easy for a machine algorithm to recognize. This is consistent with the lexical statistics (Yip, 2000), which shows that dissyllabic words account for 64% of the common words in Chinese.

Out-of-vocabulary Word Processing out-of-vocabulary (OOV) word is regarded as one of the key factors to the improvement of model performance. Since these words never occur in the training dataset, it is for sure that the word segmentation system will find it hard to correctly recognize these words from the contexts. We can see from Figure 2c that OOV generally has high difficulty. However, a lot of OOV is relatively easy for segmenters.

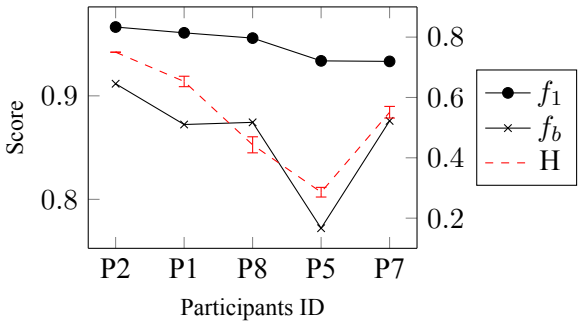
All the linguistic predictors above prove that the degree of difficulty, namely the weight for each word, is not only rooted in the foundation of test theory, but also correlated with linguistic intuition.

5 Evaluation with New Metric

Here we demonstrate the effectiveness of the proposed method in a real evaluation by re-analyzing the submission results from NLPCC



(a) Closed Track



(b) Open Track

Figure 3: Comparisons of standard metric and our new metric for the closed track and the open track of NLPCC 2015 Weibo Text Word Segmentation Shared Task. The black lines for f_1 and f_b are plotted against the left y-axis. The red lines for human judgement scores are plotted against the right y-axis.

2015 Shared Task[2] of Chinese word segmentation. The dataset of this shared task is collected from micro-blog text. For convenience, we use WB to represent this dataset in the following discussions.

We select the submissions of all 7 participants from the closed track and the submissions of all

[2]Conference on Natural Language Processing and Chinese Computing. http://tcci.ccf.org.cn/conference/2015/

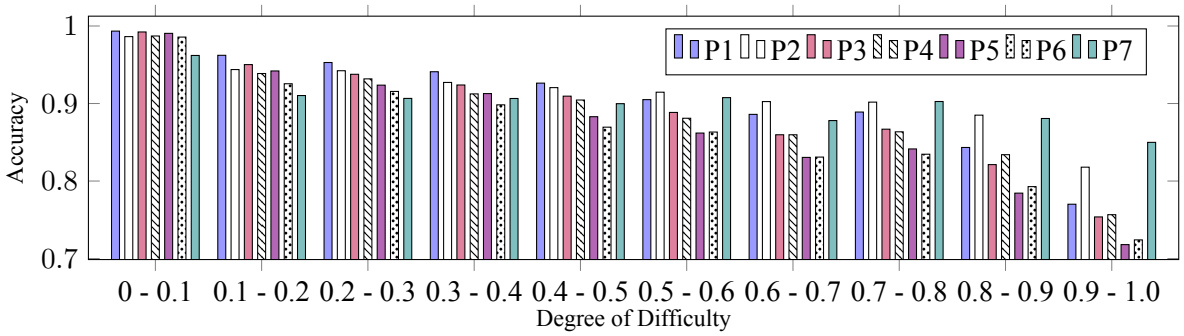


Figure 4: Accuracies of different participants in Closed Track by different difficulties on WB dataset.

5 participants from the open track. In the closed track, participants could only use information found in the provided training data. In the open track, participants could use the information which should be public and be easily obtained.

We compare the standard precision, recall and F-score with our new metric. The result is displayed in Figure 3. Considering the related privacy issues, we will refer to the participants as P1, P2, etc. The order of these participants in the sub-figures is sorted according to the original ranking given by the standard metric in each track. The same ID number refers to the same participants.

It is interesting to see that the proposed metric gives out significantly different rankings for the participants, compared to the original rankings. Based on the standard metric, Participant 1 (P1) ranks the top in closed track while P7 is ranked as the worst in both tracks. However, P2 ranks first under the evaluation of the new metric in the Closed track. P7 also get higher ranking than its original one.

5.1 Correlation with Human Judgement

To tell whether the standard metric or the proposed metric is more reasonable, we asked three experts to evaluate the quality of the submissions from the participants. We randomly selected 50 test sentences from the WB dataset. For each test sentence, we present all the submitted candidate segmentation results to the human judges in random order. Then, the judges are asked to choose the best candidate(s) with the highest segmentation quality as well as the second-best candidate(s) among all the submissions. Human judges had no access to the source of the sentences.

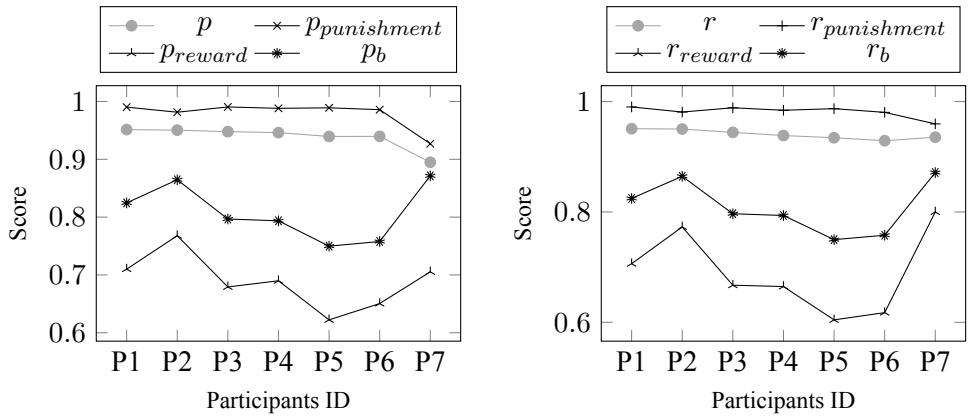
Once we collect the human judgement of the segmentation quality, we can compute the score for each participants. If a candidate segmentation result from a certain participant is ranked first for n times, then this participants earned n point. If second for m times, then this participants earned $\frac{m}{2}$ points. Then we can get the probability of a participants being ranked the best or sub-best by computing $\frac{n+\frac{m}{2}}{50}$. Finally, we get the human-intuition-based gold ranking of the participants through the means of scores from all the human judges.

It is worth noticing that the ranking result of our proposed metric correlates with the human judgements better than that of the standard metric, as is shown in Figure 3. The Pearson correlation between our proposed metric and human judgements are 0.9056 ($p = 0.004$) for closed session and 0.8799 ($p = 0.04$) for open session while the Pearson correlation between standard metric and human judgements are only 0.096 ($p = 0.836$) for closed session and 0.670 ($p = 0.216$). This evidence strongly supports that the proposed method is a good approximate of human judgements.

5.2 Detailed Analysis

Since we have empirically got the degree of difficulty for each word in the test dataset, we can compute the distribution of the difficulty for words that have been correctly segmented. We divided the whole range of difficulty into 10 intervals. Then, we count the ratio of the correct segmented units for each difficulty interval. In this way, we can quantitatively measure to what extent the segmentation system performs on difficult test cases and easy test cases.

As is shown in Figure 4, P7 works better on difficult cases than other systems, but the worst on easy cases. This explains why P7 gets good rank based on the new evaluation metric. Besides,



(a) Standard and Weighted Precision

(b) Standard and Weighted Recall

Figure 5: Comparisons of standard and weighted precision and recall on NLPCC Closed Track.

if we compare P1 and P2, we will notice that P2 performs just slightly worse than P1 on easy cases, but much better than P1 on difficult cases. Therefore, conventional evaluation metric rank P1 as the top system because the P1 gets a lot of credits from a large portion of easy cases. Unlike conventional metric, our new metric achieves balance between hard cases and easy cases and ranks P2 as the top system.

The experiment result indicates that the new metric can reveal the implicit difference and improvement of the model, while standard metric cannot provide us with such a fine-grained result.

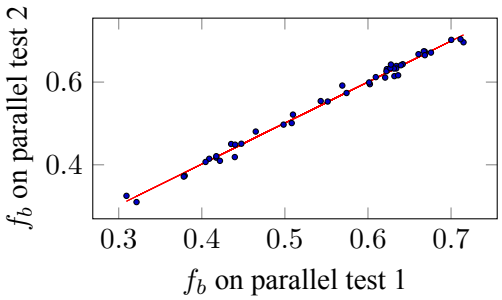


Figure 6: Correlation between the evaluation results f_b of two parallel testsets with the proposed metrics on a collection of models. The Pearson correlation is 0.9961, $p = 0.000$.

5.3 Validity and Reliability

Jones (1994) concluded some important criteria for the evaluation metrics of NLP system. It is very important to check the validity and reliability of a new metric.

Previous section has displayed the validity of the proposed evaluation metric by comparing the evaluation results with human judgements. The evaluation results with our new metric correlated with human intuition well.

Regarding reliability, we perform the parallel-test experiment. We randomly split the test dataset into two halves. These two halves have similar difficulty distribution and, therefore, can be considered as a parallel test. Then different models, including those used in the first experiment, are evaluated on the first half and the second half. The results in Figure 6 shows that the performances of different models with our proposed evaluation metric are significantly correlated in two parallel tests.

5.4 Visualization of the Weight

As is known, there might be some annotation inconsistency in the dataset. We find that most of the cases with high weight are really valuable difficult test cases, such as the visualized sentences from WB dataset in Figure 7. In the first sentence, the word ‘BMW 族’ (NOUN.People who take bus, metro and then walk to the destination) is an OOV word and contains English characters. The weight of this word, as expected, is very high. In the second sentence, the word ‘素不相识’ (VERB.not familiar with each other) is a 4-character Chinese idiom. the conjunction word ‘就算’ (CONJ.even if) has structural ambiguity. It can also be decomposed into a two-word phrase ‘就’ (ADV.just) and ‘算’ (VERB.count). From the visualization of the weight, we can see that these difficult words are all given high weights.

Data	Corpus Size	p	r	$f1$	p_b	r_b	f_b
PKU	20%	90.04	89.90	89.97	45.22	43.37	44.28
	50%	92.87	91.58	92.22	54.24	49.12	51.55

	50%	89.34	89.03	89.19	50.31	49.26	49.78
	80%	91.42	91.10	91.26	60.48	59.25	59.86
	100%	92.00	91.77	91.89	63.72	62.70	63.20
SXU	20%	89.70	89.31	89.50	43.53	42.35	42.93
	50%	93.04	92.42	92.73	56.21	54.27	55.23
	80%	94.45	93.94	94.19	64.55	62.50	63.51
	100%	94.89	94.61	94.75	68.10	66.63	67.36

Table 2: Model evaluation with standard metric and our new metric. Models vary in the amount of training data and feature types.

6 Comparisons on SIGHAN datasets

In this section, we give comparisons on SIGHAN datasets. We use four simplified Chinese datasets: PKU and MSR (SIGHAN 2005) as well as NCC and SXU (SIGHAN 2008).

For each dataset, we train four segmenters with varying abilities, based on 20%, 50%, 80% and 100% of training data respectively. The used feature template is F2 in Table 1.

Table 2 shows the different evaluation results with standard metric and our balanced metric. We can see that the proposed evaluation metric generally gives lower and more distinguishable score, compared with the standard metric.

7 Related work

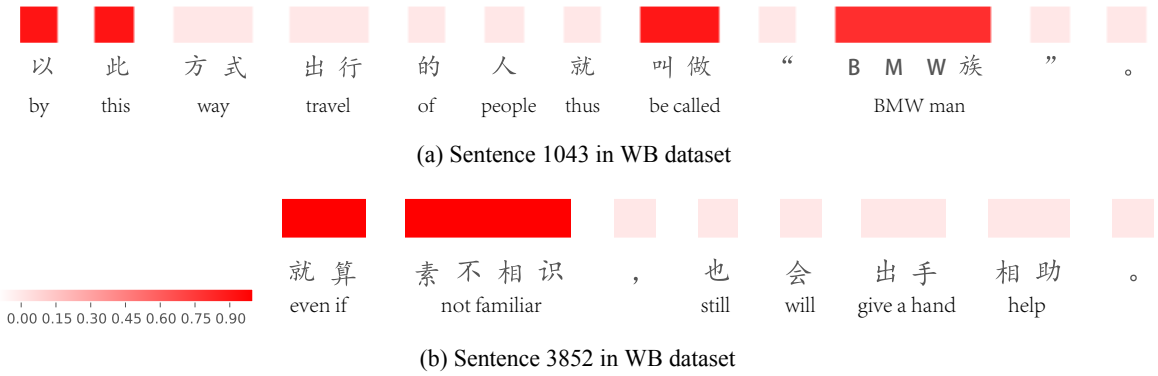
Evaluation metrics has been a focused topic for a long time. Researchers have been trying to evaluate various NLP tasks towards human intuition (Papineni et al., 2002; Graham, 2015a; Graham, 2015b). Previous work (Fournier and Inkpen, 2012; Fournier, 2013; Pevzner and Hearst, 2002) mainly deal with the near-miss error case on the context of text segmentation. Much attention has been given to different penalization for the error. These work criticize that traditional metrics such as precision, recall and F-score, consider all the error similar. In this sense, some studies aimed at assigning different penalization to the word. We think that these explorations can be regarded as the foreshadowing of our evaluation metric that balances reward and punishment.

Our paper differs from previous research in that we take the difficulty of the test case into consideration, while previous works only focus on the variation of error types and penalisation. We involve the basic idea from psychometrics and improve the evaluation with a balance between difficult cases and easy cases, reward and punishment.

We would like to emphasize that our weighted evaluation metric is not a replacement of the traditional precision, recall, and F-score. Instead, our new weighted metrics can reveal more details that traditional evaluation may not be able to present.

8 Conclusion

In this paper, we put forward a new psychometric-inspired method for Chinese word segmentation evaluation by weighting all the words in test dataset based on the methodology applied to psychological tests and standardized exams. We empirically analyze the validity and reliability of the new metric on a real evaluation dataset. Experiment results reveal that our weighted evaluation metrics gives more reasonable and distinguishable scores and



(a) Sentence 1043 in WB dataset

(b) Sentence 3852 in WB dataset

Figure 7: Visualising the word weight of WB dataset.

correlates well with human judgement. We will release the weighted datasets to the academic community.

Additionally, the proposed evaluation metric can be easily extended to word segmentation task for other languages (e.g. Japanese) and other sequence labelling-based NLP tasks, with just tiny changes. Our metric also points out a promising direction for the researchers to take into the account of the biased distribution of test case difficulty and focus on tackling the hard bones of natural language processing.

Temporal Anchoring of Events for the TimeBank Corpus

Abstract

Today's extraction of temporal information for events heavily depends on annotated temporal links. These so called TLINKs capture the relation between pairs of event mentions and time expressions. One problem is that the number of possible TLINKs grows quadratic with the number of event mentions, therefore most annotation studies concentrate on links for mentions in the same or in adjacent sentences. However, as our annotation study shows, this restriction results for 58% of the event mentions in a less precise information when the event took place.

This paper proposes a new annotation scheme to anchor events in time. Not only is the annotation effort much lower as it scales linear with the number of events, it also gives a more precise anchoring when the events have happened as the complete document can be taken into account. Using this scheme, we annotated a subset of the TimeBank Corpus and compare our results to other annotation schemes. Additionally, we present some baseline experiments to automatically anchor events in time. Our annotation scheme, the automated system and the annotated corpus are publicly available.[1]

1 Introduction

In automatic text analysis, it is often important to precisely know when an event occurred. A user might be interested in retrieving news articles that discuss certain events which happened in a given time period, for example articles discussing car bombings in the 1990s. The user might not only be interested in articles from that time period, but also in more recent articles that cover events from that period. Knowing when an event happened is also essential for time aware summarization, automated timeline generation as well as automatic knowledge base creation. In many cases, time plays a crucial role for facts stored in a knowledge base, for example for the facts when a person was born or died. Also, some facts are only true for a certain time period, like being the president of a country. Event extraction can be used to automatically infer many facts for knowledge bases, however, to be useful, it is crucial that the date when the event happened can precisely be extracted.

The TimeBank Corpus (Pustejovsky et al., 2003) is a widely used corpus using the TimeML specifications (Saurí et al., 2004) for the annotations of event mentions and temporal expressions. In order to anchor events in time, the TimeBank Corpus uses the concept of temporal links (TLINKs) that were introduced by Setzer (2001). A TLINK states the temporal relation between two events or an event and a time expression. For example, an event could happen *before*, *simultaneous*, or *after* a certain expression of time. The TimeBank Corpus served as dataset for the shared tasks TempEval-1, 2 and 3 (Verhagen et al., 2007; Verhagen et al., 2010; UzZaman et al., 2013).

In this paper we describe a new approach to anchor every event in time. Instead of using temporal links between events and temporal expressions, we consider the event time as an argument of the event mention. The annotators are asked to write down the date when an event happened in a normalized format for every event mention. The annotation effort is for this reason identical

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2195–2204,
Berlin, Germany, August 7-12, 2016.

to the number of event mentions, i.e. for a document with 200 event mentions, the annotators must perform 200 annotations. When annotating the event mentions, the annotators are asked to take the complete document into account. Section 3 presents our annotation scheme, and section 4 gives details about the conducted annotation study.

The number of possible TLINKs scales quadratic with the number of events and temporal expressions. Some documents of the TimeBank Corpus contain more than 200 events and temporal expressions, resulting in more than 20.000 possible TLINKs. Hand-labeling all links is extremely time-consuming and even when using transitive closures and computational support, it is not feasible to annotate all possible TLINKs for a larger set of documents. Therefore, all annotation studies limited the number of TLINKs to annotate. For example, in the original TimeBank Corpus, only links that are salient were annotated. Which TLINKs are salient is fairly vague and results in a comparably low reported inter-annotator agreement. Furthermore, around 62% of all events do not have any attached TLINK, i.e. for most of the events in the original TimeBank Corpus, no temporal statement can be made.

In contrast to the sparse annotation of TLINKs used in the TimeBank Corpus, the TimeBank-Dense Corpus (Cassidy et al., 2014) used a dense annotation and all temporal links for events and time expressions in the same sentence and in directly succeeding sentences were annotated. For a subset of 36 documents with 1729 events and 289 time expressions, they annotated 12,715 temporal links, which is around 6.3 links per event and time expression. Besides the large effort needed for a dense annotation, a major downside is the limitation that events and time expressions must be in the same or in adjacent sentences. Our annotation study showed that in 58.72% of the cases the most informative temporal expression is more than one sentence apart from the event mention. For around 25% of the events, the most informative temporal expression is even five or more sentences away. Limiting the TLINKs to pairs that are at most one sentence apart poses the risk that important TLINKs are not annotated and consequently cannot be learned by automated systems.

A further drawback of TLINKs is that it can be difficult or even impossible to encode temporal information that originates from different parts in the text. Given the sentence:

> *December 30th, 2015 - During New Year's Eve, it is traditionally very busy in the center of Brussels and people gather for the fireworks display. But the upcoming [display]$_{Event}$ was canceled today due to terror alerts.*

For a human it is simple to infer the date for the event *display*. But it is not possible to encode this knowledge using TLINKs, as the date is not explicitly mentioned in the text.

To make our annotations comparable to the dense TLINK annotation scheme of the TimeBank-Dense Corpus (Cassidy et al., 2014), we annotated the same documents and compare the results in section 5. For 385 out of 872 events (44.14%), our annotation scheme results in a more precise value on which date an event happened.

Section 6 presents a baseline system to extract event times. For a subset of events, it achieves an F_1-score of 49.01% while human agreement for these events is 80.50%.

2 Previous Annotation Work

The majority of corpora on events uses sparse temporal links (TLINKs) to enable anchoring of events in time. The original TimeBank (Pustejovsky et al., 2003) only annotated salient temporal relations. The subsequent TempEval competitions (Verhagen et al., 2007; Verhagen et al., 2010; UzZaman et al., 2013) are based on the original TimeBank annotations, but tried to improve the coverage and added some further temporal links for mentions in the same sentence. The MEANtime corpus (van Erp et al., 2015) applied a sparse annotation and only temporal links between events and temporal expressions in the same and in succeeding sentences were annotated. The MEANtime corpus distinguishes between main event mentions and subordinated event mentions, and the focus for TLINKs was on main events.

More dense annotations were applied by Bramsen et al. (2006), Kolomiyets et al. (2012), Do et al. (2012) and by Cassidy et al. (2014). While Bramsen et al., Kolomiyets et al., and Do et al. only annotated some temporal links, Cassidy et al. annotated all Event-Event, Event-Time, and Time-Time pairs in the same sentence as well as in directly succeeding sentences leading to the densest annotation for the TimeBank Corpus.

A drawback of the previous annotation works is the limitation that only links between expressions in the same or in succeeding sentences are annotated. In case the important temporal expression, that defines when the event occurred, is more than one sentence away, the TLINK will not be annotated. Consequently, retrieving the information when the event occurred is not possible. Increasing this window size would result in a significantly increased annotation effort as the number of links grows quadratic with the number of expressions.

Our annotation is the first for the TimeBank Corpus that does not try to annotate the quadratic growing number of temporal links. Instead, we consider the event time as an argument of the individual event mention and it is annotated directly by the annotators. This reduces the annotation effort by 85% in comparison to the TimeBank-Dense Corpus. This allows an annotator to annotate significant more documents in the same time. Also, all temporal information, independent where it is mentioned in the document, can be taken into account resulting in a much more precise anchoring of events in time, as section 5 shows.

3 Event Time Annotation Scheme

The annotation guidelines for the TimeBank Corpus (Saurí et al., 2004) define an *event* as a cover term for situations that *happen* or *occur*. Events can be *punctual* or last for *a period of time*. They also consider as events those predicates describing *states* or *circumstances* in which something holds true. For the TimeBank Corpus, the smallest extent of text (usually a single word) that expresses the occurrence of an event is annotated.

The aspectual type of the annotated events in the TimeBank Corpus can be distinguished into *achievement events*, *accomplishment events*, and *states* (Pustejovsky, 1991). An achievement is an event that results into an instantaneous change of some sort. Examples of *achievement events* are *to find*, *to be born*, or *to die*. *Accomplishment events* also result into a change of some sort, however, the change spans over a longer time period. Examples are *to build something* or *to walk somewhere*. States on the other hand do not describe a change of some sort, but that something holds true for some time, for example, *being sick* or *to love someone*. The aspectual type of an event does not only depend on the event itself, but also on the context in which the event is expressed.

Our annotation scheme was created with the goal of being able to create a knowledge base from the extracted events in combination with their event times. Punctual events are a single dot on the time axis while events that last for a period of time have a begin and an end point. It can be difficult to distinguish between punctual events and events with a short duration. Furthermore, the documents typically do not report precise starting and ending times for events, hence we decided to distinguish between events that happened at a *Single Day* and *Multi-Day Events* that span over multiple days. We used days as the smallest granularity for the annotation as none of the annotated articles contained any information on the hour, the minute or the second when the event happened. In case a corpus contains this information, the annotation scheme could be extended to include this information as well.

For *Single Day Events*, the event time is written in the format *YYYY-MM-DD*. For *Multi-Day Events*, the annotator annotates the *begin point* and the *end point* of the event. In case no statement can be made on when an event happened, the event will be annotated with the label *not applicable*. This applies only to 0.67% of the annotated events in the TimeBank Corpus which is mainly due to annotation errors in the TimeBank Corpus.

> *He was **sent** into space on May 26, 1980. He **spent** six days aboard the Salyut 6 spacecraft.*

The first event in this text, ***sent***, will be annotated with the event time *1980-05-26*. The second event, ***spent***, is a Multi-Day Event and is annotated with the event time *beginPoint=1980-05-26* and *endPoint=1980-06-01*.

In case the exact event time is not stated in the document, the annotators are asked to narrow down the possible event time as precisely as possible. For this purpose, they can annotate the event time with *after YYYY-MM-DD* and *before YYYY-MM-DD*.

> *In 1996 he was **appointed** military attache at the Hungarian embassy in Washington. [...] McBride was **part** of a seven-member crew aboard the Orbiter Challenger in October 1984*

The event ***appointed*** is annotated *after 1996-01-01 before 1996-12-31* as the event must have happened sometime in 1996. The Multi-Day Event

part is annotated with *beginPoint=after 1984-10-01 before 1984-10-31* and *endPoint=after 1984-10-01 before 1984-10-31*.

To speed up the annotation process, annotators were allowed to write *YYYY-MM-xx* to express that something happened sometime within the specified month and *YYYY-xx-xx* to express that the event happened sometime during the specified year. Annotators were also allowed to annotate events that happened at the Document Creation Time with the label *DCT*.

The proposed annotation scheme requires that event mentions are already annotated. For our annotation study we used the event mentions that were already defined in the TimeBank Corpus. In contrast to the annotation of TLINKs, temporal expressions must not be annotated in the corpus.

4 Annotation Study

The annotation study was performed on the same subset of documents as used by the TimeBank-Dense Corpus (Cassidy et al., 2014) with the event mentions that are present in the TempEval-3 dataset (UzZaman et al., 2013). Cassidy et al. selected 36 random documents from the TimeBank Corpus (Pustejovsky et al., 2003). These 36 documents include a total of 1498 annotated events. This allows to compare our annotations to those of the TimeBank-Dense Corpus (see section 5).

Each document has been independently annotated by two annotators according to the annotation scheme introduced above. We used the freely available WebAnno (Yimam et al., 2013). To speed up the annotation process, the existent temporal expressions that are defined in the TimeBank Corpus were highlighted. These temporal expressions are in principle not required to perform our annotations, but the highlighting of them helps to determine the event time. Figure 1 depicts a sample annotation made by WebAnno. The two annotators were trained on 15 documents distinct from the 36 documents annotated for the study. During the training stage, the annotators discussed the decisions they have made with each other.

After both annotators completed the annotation task, the two annotations were curated by one person to derive one final annotation. The curator examined the events where the annotators disagreed and decided on the final annotation. The final annotation might be a merge of the two provided annotations.

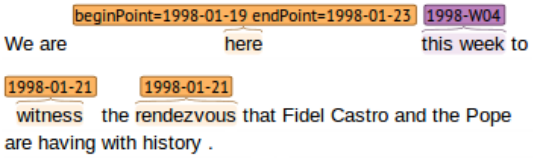

Figure 1: Sample Annotation made with WebAnno. The violet annotations are existing annotations of temporal expressions from the TimeBank Corpus. The span for the beige annotations, the event mentions, come also from the TimeBank Corpus. Our annotators added the value for the event time for those beige annotations.

4.1 Inter-Annotator-Agreement

We use Krippendorff's α (Krippendorff, 2004) with the nominal metric to compute the Inter-Annotator-Agreement (IAA). The nominal metric considers all distinct labels equally distant from one another, i.e. partial agreement is not measured. The annotators must therefore completely agree.

Using this metric, the Krippendorff's α for the 36 annotated documents is $\alpha = 0.617$. Cassidy et al. (2014) reported a Kappa agreement between $0.56 - 0.64$ for their annotation of TLINKs. Comparing these numbers is difficult, as the annotation tasks were different. According to Landis and Koch (1977), these numbers lie on the border of a moderate and a substantial level of agreement.

4.2 Disagreement Analysis

In 648 out of 1498 annotated events, the annotators disagreed on the event time. In 42.3% of the disagreements, the annotators disagreed on whether the event mention is a Single Day Event or a Multi-Day Event. Such disagreement occurs when it is unclear from the text whether the event lasted for one or for several days. For example, an article reported on a meeting and due to a lack of precise temporal information in the document, one annotator assumed that the meeting lasted for one day, the other that it lasted for several days. A different source for the disagreement has been the annotation of states. They can either be annotated with the date where the text gives evidence that they hold true, or they can be annotated as a Multi-Day Event that begins before that date and ends after that date.

Different annotations for Multi-Day Events account for 231 out of the 648 disagreements (35.6%). In this category, the annotators disagreed

on the begin point in 110 cases (47.6%), on the end point in 57 cases (24.7%) and on the begin as well as on the end point in 64 cases (27.7%). The Krippendorff's α for all begin point annotations is 0.629 and for all end point annotations it is 0.737.

A disagreement on Single Day Events was observed for 143 event mentions and accounts for 22.1% of the disagreements. The observed agreement for Single Day Events is 80.5% or $\alpha = 0.799$. Most disagreements for Single Day Events were whether the event occurred on the same date as the document was written or if it occurred before the document was written.

4.3 Measuring Partial Agreement

One issue of the strict nominal metric is that it does not take partial agreement into account. In several cases, the two annotators agreed in principle on the event time, but might have labeled it slightly differently. One annotator might have taken more clues from the text into account to narrow down when an event has happened. One annotator for example, has annotated an event with the label *after 1998-08-01 before 1998-08-31*. The second annotator has taken an additional textual clue into account, which was that the event must have happened in the first half of August 1998 and annotated it as *after 1998-08-01 before 1998-08-15*. Even though both annotators agree in principle, when using the nominal metric it would be considered as a distinct annotation.

To measure this effect, we created a relaxed metric to measure mutual exclusivity:

$$d_{ME}(a,b) = \begin{cases} 1 \text{ if } a \text{ and } b \text{ are mutual exclusive} \\ 0 \text{ else} \end{cases}$$

The metric measures whether two annotations can be satisfied at the same time. Given the event happened on August 5th, 1998, then the two annotations *after 1998-08-01 before 1998-08-31* and *after 1998-08-01 before 1998-08-15* would both be satisfied. In contrast, the two annotations *after 1998-02-01* and *before 1997-12-31* can never be satisfied at the same time and are therefore mutual exclusive.

Out of the 648 disagreements, 71 annotations were mutually exclusive. Computing the Krippendorff's α with the above metric yields a value of $\alpha_{ME} = 0.912$.

4.4 Annotation Statistics

Table 1 gives an overview of the assigned labels. Around 58.21% of the events are either instantaneous events or their duration is at most one day. 41.12% of the events are Multi-Day Events that take place over multiple days. While for Single Day Events there is a precise date for 55.73% of the events, the fraction is much lower for Multi-Day Events. In this category, only in 19.81% of the cases the begin point is precisely mentioned in the article and only in 15.75% of the cases, the end point is precisely mentioned.

The most prominent label for Single Day Events is the Document Creation Time (DCT). 48.28% of Single Day Events happened on the day the article was created, 33.49% of these events happened at least one day before the DCT and 17.43% of the mentions refer to future events. This distribution shows, that the news articles and TV broadcast transcripts from the TimeBank Corpus mainly report on events that happened on the same day.

For Multi-Day Events, the distribution looks different. In 76.46% of the cases, the event started in the past, and in 65.10% of the cases, it is still ongoing.

4.5 Most Informative Temporal Expression

Not all temporal expressions in a text are of the same relevance for an event. In fact, in many cases only a single temporal expression is of importance, which is the expression stating when the event occurred. Our annotations allow us to determine *most informative* temporal expression for an event. We define the most informative temporal expression as the expression that has been used by the annotator to determine the event time. We checked for all annotations whether the event date can be found as a temporal expression in the document and computed the distance to the closest one with a matching value. The distance is measured as the number of sentences. 421 out of 1498 events happened on the Document Creation Time and were excluded from this computation. The Document Creation Time is provided as additional metadata in the TimeBank Corpus, and it is often not explicitly mentioned in the document text.

Figure 2 shows the distance between the most informative temporal expression and the event mention. In 23.68% of the cases, the time expression is in the same sentence, and in 17.59% of the cases, the time expression is either in the

	# Events	%
Single Day Events	**872**	**58.21%**
with precise date	486	55.73%
after + before	145	16.63%
after	124	14.22%
before	117	13.42%
past events	292	33.49%
events at DCT	421	48.28%
future events	152	17.43%
Multi-Day Events	**616**	**41.12%**
precise begin point	122	19.81%
precise end point	97	15.75%
begins in the past	471	76.46%
begins on the DCT	38	6.17%
begins in the future	105	17.05%
ends in the past	179	29.06%
ends on the DCT	26	4.22%
ends in the future	401	65.10%
Not applicable	**10**	**0.67%**

Table 1: Statistic on the annotated event times. Single Day Events happen on a single day, Multi-Day Events take place over multiple days. The event time can either be precise or the annotators used *before* and *after* to narrow down the event time, e.g. the event has happened in a certain month and year. DCT = Document Creation Time.

next or in the previous sentence. It follows that in 58.72%, of the cases the most informative time expression cannot be found in the same or in the preceding or succeeding sentence. This is important to note, as previous shared tasks like TempEval-1,-2, and -3 (Verhagen et al., 2007; Verhagen et al., 2010; UzZaman et al., 2013) and previous annotation studies like the TimeBank-Dense Corpus (Cassidy et al., 2014) only considered the relation between event mentions and temporal expressions in the same and in adjacent sentences. However, for the majority of events, the most informative temporal expression is not in the same or in the preceding / succeeding sentence.

For 7.31% of the annotated events, no matching temporal expression was found in the document. Those were mainly events where the event time was inferred by the annotators from multiple temporal expressions in the document. An example is that the year of the event was mentioned in the beginning of the document and the month of the event was mentioned in a later part of the document.

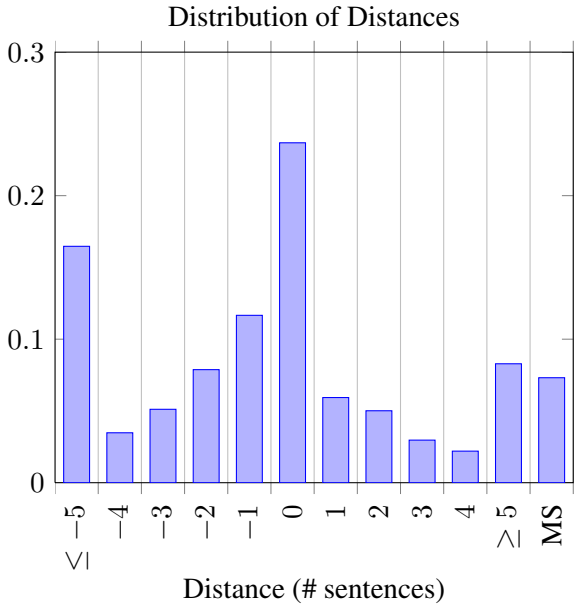

Figure 2: Distribution of distances in sentences between the event mention and the most informative temporal expression. For 58.72% of the event mentions, the most informative time expression is not in the same or in the previous/next sentence. For 7.3% of the mentions, the time expression originates from multiple sources (MS).

5 Comparison of Annotation Schemes

Depending on the application scenario and the text domain, the use of TLINKs or the proposed annotation scheme may be advantageous. TLINKs have the capability to capture the temporal order of events, even when temporal expressions are completely absent in a document, which is often the case for novels. The proposed annotation scheme has the advantage that temporal information, independent where and in which form it is mentioned in the document, can be taken into account. However, the proposed scheme requires that the events can be anchored on a time axis, which is easy for news articles and encyclopedic text but hard for novels and narratives.

In this section, we evaluate the application scenario of temporal knowledge base population and time-aware information retrieval. For temporal knowledge base population, it is important to derive the date for facts and events as precisely as possible (Surdeanu, 2013). Those facts can either be instantaneous, e.g. a person died, or they can last for a longer time like a military conflict.

Similar requirements are given for time-aware information retrieval, where it can be important to know at which point in time something occurred (Kanhabua and Nørvåg, 2012).

We use the TimeBank-Dense Corpus (Cassidy et al., 2014) with its TLINKs annotations and compare those to our event time annotations. The TimeBank-Dense Corpus annotated all TLINKs between Event-Event, Event-Time, and Time-Time pairs in the same sentence and between succeeding sentences as well as all Event-DCT and Time-DCT pairs. Six different link types were defined: `BEFORE`, `AFTER`, `INCLUDES`, `IS_INCLUDED`, `SIMULTANOUS`, and `VAGUE`, where `VAGUE` encodes that the annotators where not able to make a statement on the temporal relation of the pair.

We studied how well the event time is captured by the dense TLINK annotation. We used transitive closure rules as described by Chambers et al. (2014) to deduct also TLINKs for pairs that were not annotated. For example, when $event_1$ happened before $event_2$ and $event_2$ happened before $date_1$, we can infer that $event_1$ happened before $date_1$. Using this transitivity allows to infer relations for pairs that are more than one sentence apart. For all annotated events, we evaluated all TLINKs, including the TLINKs inferred from the transitivity rules, and derived the event time as precisely as possible. We then computed how precise the inferred event times are in comparison to our annotations. Preciseness is measured in the number of days. An event that is annotated with *1998-02-13* has the preciseness of 1 day. If the inferred event time from the TLINKs is *after 1998-02-01 and before 1998-02-15*, then the preciseness is 15 days. A more precise anchoring is preferred.

The TimeBank-Dense Corpus does not have a link type to mark that an event has started or ended at a certain time point. This makes the TLINK annotation impractical for the durative events that span over multiple days. According to our annotation study, 41.12% of the events in the TimeBank Corpus last for longer time periods. For these 41.12%, it cannot be inferred from when to when the events lasted.

In 487 out of the 872 Single Day Events (55.85%), the TLINKs give a result with the same precision as our annotations. For 198 events (22.71%), our annotation is more precise, i.e. the time window where the event might have happened is smaller. For 187 events (21.44%), no event time could be inferred from the TLINKs. This is due to the fact that there was no link to any temporal expression even when transitivity was taken into account.

For the 487 events where the TLINKs resulted in an event time as precise as our annotation, the vast majority of them were events that happened at the Document Creation Time. As depicted in Table 1, 421 events happened at DCT. For those events the precise date can directly be derived from the annotated link between each event mention and the DCT. For all other events that did not happen at the Document Creation Time, the TLINKs result for the most cases in a less precise anchoring in time and for around a fifth of these cases in no temporal anchoring at all while we do anchor them.

We can conclude, that even a dense TLINK annotation gives suboptimal information on when events have happened, and due to the restriction that TLINKs are only annotated in the same and in adjacent sentences, a lot of relevant temporal information gets lost.

6 Automated Event Time Extraction

In this section, we present a baseline system for automatic event time extraction. The system uses temporal relations in which the event is involved and anchors the event to the most precise time. For this purpose, we have defined a two-step process to determine the events' time. Given a set of documents in which the events and time expressions are already annotated, the system first obtains a set of possible times for each of the events. Second, the most precise time is selected or generated for each event.

For the first step, we use the multi-pass architecture introduced by Chambers et al. (2014) that was trained and evaluated on the TimeBank-Dense Corpus (Cassidy et al., 2014). Chambers et al. describe multiple rules and machine learning based classifiers to extract relations between events and temporal expressions. This architecture extracts temporal relations of the type `BEFORE`, `AFTER`, `INCLUDES`, `IS_INCLUDED`, and `SIMULTANOUS`. The classifiers are combined into a precision-ranked cascade of sieves. The architecture presented by Chambers et al. does not produce temporal information that an event has started or ended at a certain time point and can

therefore only be used for Single Day Events.

We use these sieves to add the value of the temporal expression and the corresponding relation to a set of possible times for each event. In fact, for each event we generate a set of <relation, time> tuples in which the event is involved.

> *Police **confirmed Friday** that the body found along a highway*

For example, the one sieve adds [IS_INCLUDED, $Friday_{1998-02-13}$] and a second sieve adds [BEFORE, $DCT_{1998-02-14}$] to the set of possible event times for the *confirmed* event.

Applying the sequence of the sieves will obtain all various temporal links for each event. In the next step, if the event has a relation of type SIMULTANEOUS, IS_INCLUDED or INCLUDES, the system sets the event time to the value of the time expression. If the event has a relation of type BEFORE and/or AFTER, the system narrows down the event time as precisely as possible. If the sieve determines the relation type as VAGUE, the set of possible event times remains unchanged.

Algorithm 1 demonstrates how the event time is selected or generated from a set of possible times.

Algorithm 1 Automatic Event Time Extraction

```
function EventTime(times)
    if times is empty then
        return 'Not Available'                ▷ the event has no non-vague relation
    end if
    min_before_time = DATE.MAX_VALUE
    max_after_time = DATE.MIN_VALUE
    for [relation, time] in times do
        if relation is SIMULTANEOUS or IS_INCLUDED or INCLUDES then
            return time
        else if relation is BEFORE and time < min_before_time then
            min_before_time = time
        else if relation is AFTER and time > max_after_time then
            max_after_time = time
        end if
    end for
    event_time = AFTER + max_after_time + BEFORE + min_before_time
    return event_time
end function
```

Applying the proposed method on the TimeBank-Dense Corpus, we obtained some value for the event time for 593 of 872 (68%) Single Day Events. For 359 events (41%), the system generates the event time with the same precision as our annotations. Table 2 gives statistics of the automatically obtained event times.

To evaluate the output of the proposed system, we evaluated how precise the automatically obtained event times are in comparison with our annotations. Table 3 shows for 41% of events, the proposed system generates the same event time as our annotations. For 21% events our annotation is more precise, i.e. the time window where the event might have happened is smaller. For 47 events (5.38%), the system infers an event time that is in conflict with the human annotation, for example a disagreement if an event happened before or after DCT. Considering event times that have the same preciseness as our annotations as true positives, the precision of the proposed system is 60.54% and the recall is 41.17% for Single Day Events. As presented in section 4, human annotators agree in 80.50% of the cases on the label for Single Day Events. The less precise and non-inferred event times are mainly due to the fact that temporal expressions, that are more than one sentence apart, are not taken into account by the sieve architecture.

Single Day Events	# Events	%
with precise date	260	29.82%
after + before	16	1.84%
after	99	11.35%
before	218	25%
not available	279	31.99%

Table 2: Statistics on the automatically obtained event times for events happened on a single day. The obtained event time can either be precise or the system used *before* and *after* to narrow down the event time. For 279 events, the system cannot infer any event time.

Obtained event time	# Events	%
same as human annotation	359	41.17%
less precise	187	21.44%
conflicting annotations	47	5.38%
cannot infer event time	279	31.99%
Precision		**60.54%**
Recall		**41.17%**
F_1-Score		**49.01%**
Human F_1-Score		**80.50%**

Table 3: Evaluation results of proposed system in comparison with our annotations.

In this work we focused on the automated anchoring of Single Day Events and presented a baseline system that relies on the work of Chambers et al. (2014). The F_1-score with 49.01% is in comparison to the human score of 80.50% comparatively low. However, only in 5.38% of the cases, the automatically inferred event time is plain wrong. In the most cases, no event time could be inferred (31.99%) or it was less precise

than the human annotation (21.44%).

Extending the described approach to Multi-Day-Events is not straight forward. The TimeBank-Dense Corpus and consequently the system by Chambers et al. does not include a TLINK type to note that an event has started or ended at a certain date, hence, extracting the begin point and end point for Multi-Day-Events is not possible. A fundamental adaption of the system by Chambers et al. would be required.

In contrast to Single Day Events, extracting the event time for Multi-Day Events requires more advanced logic. The start date of the event must be before the end date of the event. The relation to events that are included in the Multi-Day Events must be checked to avoid inconsistencies. The development of an automated system for Multi-Day Events is subject of our ongoing work.

7 Conclusion

We presented a new annotation scheme for anchoring events in time and annotated a subset of the TimeBank Corpus (Pustejovsky et al., 2003) using this annotation scheme. The annotation guidelines as well as the annotated corpus are publicly available.[2] In the performed annotation study, the Krippendorff's α inter-annotator agreement was considerably high at $\alpha = 0.617$. The largest disagreement resulted from events in which it was not explicitly mentioned when the event happened. Using a more relaxed measure for Krippendorff's α which only assigns a distance to mutual exclusive annotations, the agreement changed to $\alpha_{ME} = 0.912$. We can conclude that after little training, annotators are able to perform the annotation with a high agreement.

The effort for annotating TLINKs on the other hand scales quadratic with the number of events and temporal expressions. This imposes the often used restriction that only temporal links between events and temporal expressions in the same or in succeeding sentences are annotated. Even with this restriction, the annotation effort is quite significant, as on average 6.3 links per mention must be annotated. As Figure 2 depicts, in more than 58.72% of the cases the most informative temporal expression is more than one sentence apart from the event mention. As a consequence, inferring from TLINKs when an event happened is less precise as temporal information that is more than one sentence away can often not be taken into account.

For the 872 Single Day Events, the correct event time could be inferred from the TLINKs only in 487 cases. For 187 Single Day Events, no event time at all could be inferred, as no temporal expression was within the one sentence window of that event.

A drawback of the proposed scheme is the lack of temporal ordering of events beyond the smallest unit of granularity, which was in our case one day. The scheme is suitable to note that several events occurred at the same date, but their order on that date cannot be encoded. In case the temporal ordering is important for the application scenario, the annotation scheme could be extended and TLINKs could be annotated for events that fall on the same date. Another option is to increase the granularity, but this requires that the information in the documents also allow this more precise anchoring.

Abstract

We focus on two leading state-of-the-art approaches to grammatical error correction – machine learning classification and machine translation. Based on the comparative study of the two learning frameworks and through error analysis of the output of the state-of-the-art systems, we identify key strengths and weaknesses of each of these approaches and demonstrate their complementarity. In particular, the machine translation method learns from parallel data without requiring further linguistic input and is better at correcting complex mistakes. The classification approach possesses other desirable characteristics, such as the ability to easily generalize beyond what was seen in training, the ability to train without human-annotated data, and the flexibility to adjust knowledge sources for individual error types.

Based on this analysis, we develop an algorithmic approach that combines the strengths of both methods. We present several systems based on resources used in previous work with a relative improvement of over 20% (and 7.4 F score points) over the previous state-of-the-art.

1 Introduction

For the majority of English speakers today, English is not the first language. These writers make a variety of grammar and usage mistakes that are not addressed by standard proofing tools. Recently, there has been a spike in research on grammatical error correction (GEC), correcting writing mistakes made by learners of English as a Second Language, including four shared tasks: HOO (Dale and Kilgarriff, 2011; Dale et al., 2012) and CoNLL (Ng et al., 2013; Ng et al., 2014). These shared tasks facilitated progress on the problem within the framework of two leading methods – machine learning classification and statistical machine translation (MT).

System	Method	Performance		
		P	R	F0.5
CoNLL-2014 top 3	MT	41.62	21.40	35.01
CoNLL-2014 top 2	Classif.	41.78	24.88	36.79
CoNLL-2014 top 1	MT, rules	39.71	30.10	37.33
Susanto et al. (2014)	MT, classif.	53.55	19.14	39.39
Miz. & Mats. (2016)	MT	45.80	26.60	40.00
This work	MT, classif.	60.17	25.64	**47.40**

Table 1: **(Lack of) progress in GEC over the last few years**.

The top CoNLL system combined a rule-based module with MT (Felice et al., 2014). The second system that scored almost as highly used machine learning classification (Rozovskaya et al., 2014), and the third system used MT (Junczys-Dowmunt and Grundkiewicz, 2014). Furthermore, Susanto et al. (2014) showed that a combination of the two methods is beneficial, but the advantages of each method have not been fully exploited.

Despite success of various methods and the growing interest in the task, the key differences between the leading approaches have not been identified or made explicit, which could explain the lack of progress on the task. Table 1 shows existing state-of-the-art since CoNLL-2014. The top results are close, suggesting that several groups have competitive systems. Two improvements (of $<$3 points) were published since then (Susanto et al., 2014; Mizumoto and Matsumoto, 2016).

The purpose of this work is to gain a better understanding of the values offered by each method and to facilitate progress on the task, building on the advantages of each approach. Through better understanding of the methods, we exploit the strengths of each technique and, building on existing architecture, develop superior systems within

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2205–2215,
Berlin, Germany, August 7-12, 2016.

each framework. Further combination of these systems yields even more significant improvements over existing state-of-the-art. We make the following contributions:

• We examine two state-of-the-art approaches to GEC and identify strengths and weaknesses of the respective learning frameworks.

• We perform an error analysis of the output of two state-of-the-art systems, and demonstrate how the methods differ with respect to the types of language misuse handled by each.

• We exploit the strengths of each framework: with classifiers, we explore the ability to learn from native data, i.e. without supervision, and the flexibility to adjust knowledge sources to specific error types; with MT, we leverage the ability to learn without further linguistic input and to better identify complex mistakes that cannot be easily defined in a classifier framework.

• As a result, we build several systems that combine the strengths of both frameworks and demonstrate substantial progress on the task. Specifically, the best system outperforms the previous best result by 7.4 F score points.

Section 2 describes related work. Section 3 presents error analysis. In Section 4, we develop classifier and MT systems that make use of the strengths of each framework. Section 5 shows how to combine the two approaches. Section 6 concludes.

2 Related Work

We first introduce the CoNLL-2014 shared task and briefly describe the state-of-the-art GEC systems in the competition and beyond. Next, an overview of the two leading methods is presented.

2.1 CoNLL-2014 shared task and approaches

CoNLL-2014 training data (henceforth CoNLL-train) is a corpus of learner essays (1.2M words) written by students at the National University of Singapore (Dahlmeier et al., 2013), corrected and error-tagged. The CoNLL-2013 test set was included in CoNLL-2014 and is used as development. Both the development and the test sets are also from the student population studying at the same University but annotated separately. We report results on the CoNLL-2014 test.

The annotation includes specifying the relevant correction as well as the information about each error type. The tagset consists of 28 categories. Table 2 illustrates the 11 most frequent errors in the development data; errors are marked with an asterisk, and ∅ denotes a missing word. The majority of these errors are related to grammar but also include *mechanical*, *collocation*, and other errors.

An F-based scorer, named M2, was used to score the systems (Dahlmeier and Ng, 2012). The metric in CoNLL-2014 was F0.5, i.e. weighing precision twice as much as recall. Two types of annotations were used: original and revised. We follow the recommendations of the organizers and use the original data (Ng et al., 2014).

The approaches varied widely: classifiers, MT, rules, hybrid systems. Table 3 summarizes the top five systems. The top team used a hybrid system that combined rules and MT. The second system developed classifiers for common grammatical errors. The third system used MT.

As for external resources, the top 1 and top 3 teams used additional learner data to train their MT systems, the Cambridge University Press Learners' Corpus and the Lang-8 corpus (Mizumoto et al., 2011), respectively. Many teams also used native English datasets. The most common ones are the Web1T corpus (Brants and Franz, 2006), the CommonCrawl dataset, which is similar to Web1T, and the English Wikipedia. Several teams used off-the-shelf spellcheckers.

In addition, Susanto et al. (2014) made an attempt at combining MT and classifiers. They used CoNLL-train and Lang-8 as non-native data and English Wikipedia as native data. We believe that the reason this study did not yield significant improvements (Table 1) is that individual strengths of each framework have not been fully exploited. Further, each system was applied separately and decisions were combined using a general MT combination technique (Heafield et al., 2009). Finally, Mizumoto and Matsumoto (2016) attempt to improve an MT system also trained on Lang-8 with discriminative re-ranking using part-of-speech (POS) and dependency features but only obtain a small improvement. These results suggest that standard combination and re-ranking techniques are not sufficient.

2.2 Overview of the State-of-the-Art

The statistical machine translation approach is based on the noisy-channel model. The best translation for a foreign sentence f is:

$$e^* = \arg\max_e p(e)p(f|e)$$

Error type	Rel. freq. (%)	Examples
Article (*ArtOrDet*)	19.93	*∅/*The* government should help encourage *the/∅ breakthroughs as well as *a/∅ complete medication system .
Wrong collocation (*Wci*)	12.51	Some people started to **think/wonder* if electronic products can replace human beings for better performances .
Noun number (*Nn*)	11.44	There are many reports around the internet and on newspaper stating that some users ' **iPhone/iPhones* exploded .
Preposition (*Prep*)	8.98	I do not agree **on/with* this argument...
Word form (*Wform*)	6.56	...the application of surveillance technology serves as a warning to the **murders/murderers* and they might not commit more murder .
Orthography/punctuation (*Mec*)	5.75	Even British Prime Minister , Gordon Brown *∅/, has urged that all cars in **britain/Britain* to be green by 2020 .
Verb tense (*Vt*)	4.56	Through the thousands of years , most Chinese scholars **are/{have been}* greatly affected by Confucianism .
Linking words/phrases (*Trans*)	4.10	**However/Although* , video surveillance may be a great help .
Local redundancy (*Rloc-*)	3.70	Some solutions *{*as examples*}/∅ would be to design plants/fertilizers that give higher yield ...
Subject-verb agreement (*SVA*)	3.58	However , tracking people **are/is* different from tracking goods .
Verb form (*Vform*)	3.52	Travelers survive in desert thanks to GPS **guide/guiding* them .

Table 2: **Example errors.** In the parentheses, the error codes used in the shared task are shown. Errors exemplifying the relevant phenomena are marked; the sentences may contain other mistakes.

Rank	System name	F0.5	Approach	External training data		External error modules
				Native data	Learner data	
1	CAMB	37.33	Rules and MT	Microsoft Web LM	Cambridge Corpus, Eng. Vocab Profile	Cambridge "Write and Improve"
2	CUUI	36.79	Classif.; patterns	Web1T		
3	AMU	35.01	MT	Wikipedia, CommonCrawl	Lang-8	
4	POST	30.88	LM and rules	Web1T		PyEnchant Spell
5	NTHU	29.92	Rules, MT, classif.	Web1T, Gigaword, BNC, Google Books		Spellcheckers: Aspell, GingerIt

Table 3: **The top 5 systems in CoNLL-2014.** The last column lists external proofing tools used. LM stands for *language models*.

The model consists of two components: a *language model* assigning a probability $p(e)$ for any target sentence *e*, and a translation model that assigns a conditional probability $p(f|e)$. The language model is learned using a monolingual corpus in the target language. The parameters of the *translation model* are estimated from a parallel corpus, i.e. the set of foreign sentences and their corresponding translations into the target language. In error correction, the task is cast as translating from erroneous learner writing into corrected well-formed English. The MT approach relies on the availability of a parallel corpus for learning the translation model. In case of error correction, a set of learner sentences and their corrections functions as a parallel corpus.

State-of-the-art MT systems are phrase-based, i.e. parallel data is used to derive a phrase-based lexicon (Koehn et al., 2003). The resulting lexicon consists of a list of pairs (seq_f, seq_e) where seq_f is a sequence of one or more foreign words, seq_e is a predicted translation. Each pair comes with an associated score. At decoding time, all phrases from sentence f are collected with their corresponding translations observed in training. These are scored together with the language modeling scores and may include other features. The phrase-based approach by Koehn et al. (2003) uses a log-linear model (Och and Ney, 2002), and the best correction maximizes the following:

$$\begin{aligned} e^* &= \arg\max_e P(e|f) \\ &= \arg\max_e \exp(\sum_{m=1}^{M} \lambda_m h_m(e,f)) \end{aligned} \quad (1)$$

where h_m is a feature function, such as language model score and translation scores, and λ_m corresponds to a feature weight.

The classifier approach is based on the context-sensitive spelling correction methodology (Golding and Roth, 1996; Golding and Roth, 1999; Banko and Brill, 2001; Carlson et al., 2001; Carlson and Fette, 2007) and goes back to earlier approaches to article and preposition error correction (Izumi et al., 2003; Han et al., 2006; Gamon et al., 2008; Felice and Pulman, 2008; Tetreault et al., 2010; Gamon, 2010; Dahlmeier and Ng, 2011; Dahlmeier and Ng, 2012). The classifier approach to error correction has been prominent for a long time before MT, since building a classifier does not require having annotated learner data.

Property	MT	Classifier
(1a) **Error coverage**: ability to address a wide variety of error phenomena	**+**All errors occurring in the training data are automatically covered	**-**Only errors covered by the classifiers; new errors need to be added explicitly
(1b) **Error complexity**: ability to handle complex and interacting mistakes that go beyond word boundaries	**+**Automatically through parallel data, via phrase-based lexicons	**-**Need to develop via specific approaches
(2) **Generalizability**: going beyond the error confusions observed in training	**-**Only confusions observed in training can be corrected	**+**Easily generalizable via confusion sets and features
(3) **Supervision/Annotation**: role of learner data in training the system	**-**Required	**+**Not required
(4) **System flexibility**: adapting knowledge sources per error phenomena	**-**Not easy to integrate error-specific knowledge resources	**+**Flexible; phenomenon-specific knowledge sources

Table 4: **Summary of the key properties of the MT and the classifier-based approaches.** We use $+$ and $-$ to indicate a positive or a negative value with respect to each factor.

Classifiers are trained individually for a specific error type. Because an error type needs to be defined, typically only well-defined mistakes can be addressed in a straightforward way. Given an error type, a *confusion set* is specified and includes a list of confusable words. For some errors, confusion sets are constructed using a closed list (e.g. prepositions). For other error types, NLP tools are required. To identify locations where an article was likely omitted incorrectly, for example, a phrase chunker is used. Each occurrence of a confusable word in text is represented as a vector of features derived from a *context window* around the target. The problem is cast as a multi-class classification task.

In the classifier paradigm, there are various algorithms – generative (Gamon, 2010; Park and Levy, 2011), discriminative (Han et al., 2006; Gamon et al., 2008; Felice and Pulman, 2008; Tetreault et al., 2010), and joint approaches (Dahlmeier and Ng, 2012; Rozovskaya and Roth, 2013). Earlier works trained on native data (due to lack of annotation). Later approaches incorporated learner data in training in various ways (Han et al., 2010; Gamon, 2010; Rozovskaya and Roth, 2010a; Dahlmeier and Ng, 2011).

3 Error Analysis of MT and Classifiers

This section presents error analysis of the MT and classifier approaches. We begin by identifying several key properties that distinguish between MT systems and classifier systems and that we use to characterize the learning frameworks and the outputs of the systems:

(1a) Error coverage denotes the ability of a system to identify and correct a variety of error types.

(1b) Error complexity indicates the capacity of a system to address complex mistakes such as those where multiple errors interact.

(2) Generalizibility refers to the ability of a system to identify mistakes in new unseen contexts and propose corrections beyond those observed in training data.

(3) The role of supervision or having annotated learner data for training.

(4) System flexibility is a property of the system that allows it to adapt resources specially to correct various phenomena. The two paradigms are summarized in Table 4. We use $+$ and $-$ to indicate whether a learning framework has desirable (+) or undesirable characteristic with regard to each factor.

The first three properties characterize system output, while (3) and (4) arise from the system frameworks. Below we analyze the output of several state-of-the-art CoNLL-2014 systems in more detail.[1] Section 4 explores (3) and (4) that relate to the learning frameworks.

3.1 Error Coverage and Complexity

Error coverage To understand how systems differ with respect to error coverage, we consider recall of each system per error type. Error-type *recall* can be easily computed using error tags and is reported in the CoNLL overview paper.

The recall numbers show substantial variations among the systems. If we consider error categories that have non-negligible recall numbers (higher than 10%), classifier-based approaches have a much lower proportion of error types for which 10% recall was achieved. Among the 28 error types, the top classifier systems – Columbia University-University of Illinois (CUUI, top-2) and National Tsing Hua University (NTHU, top-5) – have a recall higher than 10% for 8 and 9 error types, respectively. In contrast, the two MT-based systems – Cambridge University (CAMB,

Table 5: **Complex and interacting mistakes that MT successfully addresses.** Output of the MT-based AMU system.

top-1) and the Adam Mickiewicz University system (AMU, top-3) – have 15 and 17 error types, respectively, for which the recall is at least 10%.

These recall discrepancies indicate that the MT approach has a better overall coverage, which is intuitive given that all types of confusions are automatically added through phrase-based translation tables in MT, while classifiers must explicitly model each error type. Note, however, that these numbers do not necessarily indicate good type-based performance, since high recall may correspond to low precision.

Error complexity In the MT approach, error confusions are learned automatically via the phrase translation tables extracted from the parallel training data. Thus, an MT system can easily handle interacting and complex errors where replacements involve a sequence of words. Table 5 illustrates complex and interacting mistakes that the MT approach is able to handle. Example (1) contains a phrase-level correction that includes both a preposition replacement and an adjective change. (2) is an instance of an interacting mistake where there is a dependency between the article and the noun number, and a mistake can be corrected by changing one of the properties but not both. (3), (4) and (5) require multiple simultaneous corrections on various words in a phrase. (6) is an example of an incorrect adjectival form, an error that is typically not modeled with standard classifiers.

3.2 Generalizability

Because MT systems extract error/correction pairs from phrase-translation tables, they can only identify erroneous surface forms observed in training and propose corrections that occurred with the corresponding surface forms. Crucially, in a standard MT scenario, any resulting translation consists of "matches" mined from the translation tables, so a standard MT model lacks lexical abstractions that might help generalize, thus out-of-vocabulary words is a well-known problem in MT (Daume and Jagarlamudi, 2011). While more advanced MT models can abstract by adding higher-level features such as POS, previous attempt yielded only marginal improvements (Mizumoto and Matsumoto, 2016), since one typically needs different types of abstractions depending on the error type, as we show below.

Error type	AMU (MT)			CUUI (Classif.)		
	P	R	F0.5	P	R	F0.5
Orthog./punc. (*Mec*)	61.6	16.3	**39.6**	53.3	8.7	26.4
Article (*ArtOrDet*)	38.0	10.9	25.4	31.8	47.9	**34.0**
Preposition (*Prep*)	54.9	10.4	**29.5**	31.7	8.8	20.9
Noun number (*Nn*)	49.6	43.2	**48.2**	42.5	46.2	43.2
Verb tense (*Vt*)	30.2	9.3	20.8	61.1	5.4	19.9
Subj.-verb agr. (*SVA*)	48.3	14.9	33.3	57.7	57.7	**57.7**
Verb form (*Vform*)	40.5	16.8	31.8	69.2	15.1	**40.3**
Word form (*Wform*)	59.0	36.6	**52.6**	60.0	13.5	35.6

Table 6: **Performance of MT and classifier systems from CoNLL-2014 on common errors.**

With classifiers, it is easy to generalize using higher-level information that goes beyond surface form and to adjust the abstraction to the error type. Many grammatical errors may benefit from generalizations based on POS or parse information; we can thus expect that classifiers will do better on errors that require linguistic abstractions.

To validate this hypothesis, we evaluate type-based performance of two systems: a top-3 MT-based AMU system and a top-2 classifier-based CUUI; we do not include the top-1 system, since it is a hybrid system that also uses rules.

Unlike recall, estimating type-based *precision* requires knowing the type of the correction supplied by the system, which is not specified in the output. We thus manually analyze the output of the AMU and CUUI systems for seven common error categories and assign to each correction an appropriate type to estimate precision and F0.5 (Table 6). The CUUI system addresses all of these errors, with the exception of mechanical (Mec), of which it handles a small subset. The AMU system does better on mechanical, preposition, word form, and noun number. CUUI does better on articles, verb agreement, and verb form.

We now consider examples of errors that are corrected by the classifier-based CUUI system in these three categories but are missed by the MT-based AMU system (Table 7). Examples (1) and

(1)	**Long-distance dependencies: verb agreement** As a result , in the case that when one of the members **happen/happens* to feel uncomfortable or abnormal , he or she should be aware that . . .
(2)	A study of New York University in 2010 shown that patients with family members around generally **recovers/recover* 2-4 days faster than those taken care by professional nurses .
	Confusions not found in training: verb agreement and verb form
(3)	Hence , the social media sites **serves/serve* as a platform for the connection .
(4)	After **came/coming* back from the hospital , the man told his parents that the problem was that he carried . . .
(5)	social media is the only resource they can approach to know everything **happened/happening* in their country . . .
	Superfluous words: articles
(6)	For **an/∅* example , if exercising is helpful, we can always look for more chances for the family to go exercise .
(7)	. . . as soon a person is made aware of his or her genetic profile , he or she has **a/∅* knowledge about others .
	Omissions: articles
(8)	In this case , if one of the family members or close relatives is found to carry **∅/a* genetic risk . . .

Table 7: **Generalizing beyond surface form:** Examples of mistakes that classifiers successfully address. Output of the classifier-based CUUI system.

(2) illustrate verb errors with long-distance subjects ("one" and "patients"). This is handled in the classification approach via syntactic features. An MT system misses these errors because it is limited to edits within short spans. Examples (3), (4), and (5) illustrate verb mistakes for which the correct replacements were not observed in training but that are nonetheless corrected by generalizing beyond surface form. Finally, (6) and (7) illustrate omission and insertion errors, a majority of article mistakes. The MT system is especially bad at correcting such mistakes. Notably, the classifier-based CUUI system correctly identified *twice* as many omitted articles and more than *20 times* more superfluous articles than the MT-based AMU system. This happens because an MT system is restricted to suggesting deletions and insertions in those contexts that were observed in training, whereas a classifier uses shallow parse information, which allows it to insert or delete an article in front of every eligible noun phrase. These examples demonstrate that the ability of a system to generalize beyond the surface forms is indeed beneficial for *long-distance dependencies*, for abstracting away from surface forms when *formulating confusion sets*, and for mistakes involving *omitting or inserting a word*.

4 Developing New State-of-the-Art MT and Classifier Systems

In this section, we explore the advantages of each learning approach, as identified in the previous section, within each learning framework. To this end, drawing on the strengths of each framework, we develop new state-of-the-art MT and classifier systems.[2] In the next section, we will use these MT and classifier components and show how to exploit the strengths of each framework in combination. Table 8 summarizes the data used. Results are reported with respect to all errors in the test data. This is different from performance for individual errors in Table 6.

System	Learner		Native	
	CoNLL-train 1.2M	Lang-8 48M	Eng. Wiki. 2B	Web1T 1T
MT	✓	✓	✓	-
Classif.	✓	-	-	✓

Table 8: **Data used in the experiments.** Corpora sizes are in the number of words.

4.1 Machine Translation Systems

A key advantage of the MT framework is that, unlike with classifiers, error confusions are learned from parallel data automatically, without further (linguistic) input. We build two MT systems that differ only in the use of parallel data: the CoNLL-2014 training data and Lang-8. Our MT systems are trained using Moses (Koehn et al., 2007) and follow the standard approach (Junczys-Dowmunt and Grundkiewicz, 2014; Susanto et al., 2014). Both systems use two 5-gram language models – English Wikipedia and the corrected side of CoNLL-train – trained with KenLM (Heafield et al., 2013). Table 9 reports the performance of the systems. As shown, performance increases by more than 11 points when a larger parallel corpus is used. The best MT system outperforms the top CoNLL system by 2 points.

4.2 Classifiers

We now present several classifier systems, exploring the two important properties of the classification framework – the ability to train without super-

[2]Implementation details can be found at `cogcomp.cs.illinois.edu/page/publication_view/793`

vision and system flexibility (see Table 4).

4.2.1 Supervision

Supervision in the form of annotated learner data plays an important role in developing an error correction system but is expensive. Native data, in contrast, is cheap and available in large quantities. Therefore, the fact that, unlike with MT, it is possible to build a classifier system without any annotated data, is a clear advantage of classifiers.

Training without supervision is possible in the classification framework, as follows. For a given mistake type, e.g. preposition, a classifier is trained on native data that is assumed to be correct; the classifier uses context words around each preposition as features. The resulting model is then applied to learner prepositions and will predict the most likely preposition in a given context. If the preposition predicted by the classifier is different from what the author used in text, this preposition is flagged as a mistake. We refer the reader to Rozovskaya and Roth (2010b) and Rozovskaya and Roth (2011) for a description of training classifiers with and without supervision for error correction tasks. Below, we address two questions related to the use of supervision:

• **Training with supervision**: When training using learner data, how does a classifier-based system compare against an MT system?

• **Training without supervision**: How well can we do by building a classifier system with native data only, compared to MT and classifier-based systems that use supervision?

Our classifier system is based on the implementation framework of the second CoNLL-2014 system (Rozovskaya et al., 2014) and consists of classifiers for 7 most common grammatical errors in CoNLL-train: article; preposition; noun number; verb agreement; verb form; verb tense; word form. All modules take as input the corpus documents pre-processed with a POS tagger[3] (Even-Zohar and Roth, 2001), a shallow parser[4] (Punyakanok and Roth, 2001), a syntactic parser (Klein and Manning, 2003) and a dependency converter (Marneffe et al., 2006).

CoNLL-2014 top 3	41.62	21.40	35.01

Table 10: **Classifier systems trained with and without supervision.** *Learner* data refers to CoNLL-train. *Native* data refers to Web1T. The MT system uses CoNLL-train for parallel data.

Classifiers are trained either on learner data (CoNLL-train) or native data (Web1T). Classifiers built on CoNLL-train are trained discriminatively with the Averaged Perceptron algorithm (Rizzolo and Roth, 2010) and use rich POS and syntactic features tailored to specific error types that are standard for these tasks (Lee and Seneff, 2008; Han et al., 2006; Tetreault et al., 2010; Rozovskaya et al., 2011); Naïve Bayes classifiers are trained on Web1T with word n-gram features. A detailed description of the classifiers and the features used can be found in Rozovskaya and Roth (2014). We also add several novel ideas that are described below.

Table 10 shows the performance of two classifier systems, trained with supervision (on CoNLL-train) and without supervision on native data (Web1T), and compares these to an MT approach trained on CoNLL-train. The first classifier system performs comparably to the MT system (27.76 vs. 28.25), however, the native-trained classifier system outperforms both, and does not use any annotated data. The native-trained classifier system would place fourth in CoNLL-2014.

4.2.2 Flexibility

We now explore another advantage of the classifier-based approach, that of allowing for a flexible architecture where we can tailor knowledge sources for individual phenomena. In Section 4.2.1, we already took advantage of the fact that in the classifier framework it is easy to incorporate features suited to individual error types. We now show that by *adding supervision in a way tailored toward specific errors* we can further improve the classifier-based approach.

Adding Supervision in a Tailored Way There is a trade-off between training on native and learner

	Training data	Performance P	R	F0.5
(1)	Learner	32.15	17.96	27.76
(2)	Native	38.41	23.05	33.89
(3)	Tailored	57.07	14.74	**36.26**

Table 11: **Classifiers: supervision in a tailored way**. Trained on (1) learner data (CoNLL-train); (2) native data (Web1T); (3) data sources tailored per error type.

data. The advantage of training on native data is clearly the size, which is important for estimating context parameters. Learner data provides additional information, such as learner error patterns and the manner of non-native writing.

Instead of choosing to train on one data type, the classifier framework allows one to combine the two data sources in various ways: voting (Rozovskaya et al., 2014), alternating structure optimization (Dahlmeier and Ng, 2011), training a meta-classifier (Gamon, 2010), and extracting error patterns (Rozovskaya and Roth, 2011). We compare two approaches of adding supervision:
(1) **Learner error patterns:** Error patterns are extracted from learner data and "injected" into models trained on native data (Rozovskaya and Roth, 2011). Learner data is used to estimate mistake parameters; contextual cues are based on native data.
(2) **Learner error patterns+native predictions:** Classifiers are trained on native data. Classifier predictions are used as features in models trained on learner data. Learner data thus contributes both the specific manner of learner writing and the mistake parameters. The native data contributes contextual information.

We found that (2) is superior to (1) for article, agreement, and preposition errors; (1) works better on verb form and word form errors; and noun number errors perform best when a classifier is trained on native data. (Learner error patterns were found not to be beneficial for correcting noun number errors (Rozovskaya and Roth, 2014)). Tailored supervision yields an improvement of almost 3 points over the system trained on native data and almost 9 points over the system trained on learner data (Table 11).

Adding Mechanical Errors Finally, we add components for *mechanical* errors: punctuation, spelling, and capitalization. These are distinguished from the grammatical mistakes, as they are not specific to GEC and can be handled with existing resources or simple methods.

For capitalization and missing commas, we compile a list of patterns using CoNLL training data. We also use an off-the-shelf speller (Flor, 2012; Flor and Futagi, 2012). Results are shown in Table 12. Performance improves by almost 5 and 7 points for the native-trained system and for the best configuration of classifiers with supervision. Both systems also outperform the top CoNLL system, by 1 and 6 points, respectively. The result of 43.11 by the best classifier configuration substantially outperforms the existing state-of-the-art: a combination of two MT systems and two classifier systems, and MT with re-ranking (Susanto et al., 2014; Mizumoto and Matsumoto, 2016).

System/training data	Performance P	R	F0.5

Table 13: **Pipelines: select classifiers and MT.**

5 Combining MT and Classifier Systems

Since MT and classifiers differ with respect to the types of errors they can better handle, we combine these systems in a pipeline architecture where the MT is applied to the output of classifiers. Classifiers are applied first, since MT is better at handling complex phenomena. First, we add the speller and those classifier components that perform substantially better than MT (articles and verb agreement), due to the ability of classifiers to generalize beyond lexical information. The added classifiers are part of the best system in Table 12.

Results are shown in Table 13. Adding classifiers improves the performance, thereby demon-

System	Performance

Table 15: **Best systems in this work.** Comparison to existing state-of-the-art.

strating that the classifiers address a complementary set of mistakes. Adding all three modules improves the results from 28.25 to 40.10 and from 39.48 to 46.51 for the MT systems trained on CoNLL-train and Lang-8, respectively. Notably, the CoNLL-train MT system especially benefits, which shows that when the parallel data is small, it is particularly worthwhile to add classifiers.

It should be stressed that even with a smaller parallel corpus, when the three modules are added, the resulting system is very competitive with previous state-of-the-art that uses a lot more supervision: Susanto et al. (2014) and Mizumoto and Matsumoto (2016) use Lang-8. These results show that *when one has an MT system, it is possible to improve by investing effort into building select classifiers for phenomena that are most challenging for MT*.

Finally, Table 14 demonstrates that combining MT with the best classifier system improves the result further when the MT system is trained on Lang-8, but not when the MT system is trained on CoNLL-train. We also note that the CoNLL-train MT system also has a much lower precision than the other systems. We conclude that when only a limited amount of data is available, the classifier approach on its own performs better.

As a summary, Table 15 lists the best systems developed in this work – a classifier system, a pipeline of select classifiers and MT, and a pipeline consisting of the best classifier and the MT systems – and compares to existing state-of-the-art. Our classifier system is a 3-point improvement over the existing state-of-the-art, while the best pipeline is a 7.4-point improvement (20% relative improvement).

6 Discussion and Conclusions

A recent surge in GEC research has produced two leading state-of-the-art approaches – machine learning classification and machine translation. Based on the analysis of the methods and an error analysis on the outputs of state-of-the-art systems that adopt these approaches, we explained the differences and the key advantages of each. With respect to error phenomena, we showed that while MT is better at handling complex mistakes, classifiers are better at correcting mistakes that require abstracting beyond lexical context. We further showed that the key strengths of the classification framework are its flexibility and the ability to train without supervision.

We built several systems that draw on the strengths of each approach individually and in a pipeline. The best classifier system and the pipelines outperform reported best results on the task, often by a large margin.

The purpose of this work is to gain a better understanding of the advantages offered by each learning method in order to make further progress on the GEC task. We showed that the values provided by each method can be exploited within each approach and in combination, depending on the resources available, such as annotated learner data (MT), and additional linguistic resources (classifiers). As a result, we built robust systems and showed substantial improvement over existing state-of-the-art.

For future work, we intend to study the problem in the context of other languages. However, it is important to realize that the problem is far from being solved even in English, and the current work makes very significant progress on it.

Acknowledgments

The authors thank Michael Flor for his help with running the spelling system on the data and John Wieting for sharing the English Wikipedia corpus. Recurrent neural network models for disease name recognition using domain invariant features

Sunil Kumar Sahu and **Ashish Anand**

Abstract

Hand-crafted features based on linguistic and domain-knowledge play crucial role in determining the performance of disease name recognition systems. Such methods are further limited by the scope of these features or in other words, their ability to cover the contexts or word dependencies within a sentence. In this work, we focus on reducing such dependencies and propose a domain-invariant framework for the disease name recognition task. In particular, we propose various end-to-end recurrent neural network (RNN) models for the tasks of disease name recognition and their classification into four pre-defined categories. We also utilize convolution neural network (CNN) in cascade of RNN to get character-based embedded features and employ it with word-embedded features in our model. We compare our models with the state-of-the-art results for the two tasks on NCBI disease dataset. Our results for the disease mention recognition task indicate that state-of-the-art performance can be obtained without relying on feature engineering. Further the proposed models obtained improved performance on the classification task of disease names.

1 Introduction

Automatic recognition of disease names in biomedical and clinical texts is of utmost importance for development of more sophisticated NLP systems such as information extraction, question answering, text summarization and so on (Rosario and Hearst, 2004). Complicate and inconsistent terminologies, ambiguities caused by use of abbreviations and acronyms, new disease names, multiple names (possibly of varying number of words) for the same disease, complicated syntactic structure referring to multiple related names or entities are some of the major reasons for making automatic identification of the task difficult and challenging (Leaman et al., 2009). State-of-the-art disease name recognition systems (Mahbub Chowdhury and Lavelli, 2010; Doğan and Lu, 2012; Dogan et al., 2014) depends on user defined features which in turn try to capture context keeping in mind above mentioned challenges. Feature engineering not only requires linguistic as well as domain insight but also is time consuming and is corpus dependent.

Recently window based neural network approach of (Collobert and Weston, 2008; Collobert et al., 2011) got lot of attention in different sequence tagging tasks in NLP. It gave state-of-art results in many sequence labeling problems without using many hand designed or manually engineered features. One major drawback of this approach is its inability to capture features from outside window. Consider a sentence *"Given that the skin of these adult mice also exhibits signs of de novo hair-follicle morphogenesis, we wondered whether human pilomatricomas might originate from hair matrix cells and whether they might possess beta-catenin-stabilizing mutations"* (taken *verbatim* from PMID: 10192393), words such as *signs* and *originate* appearing both sides of the word *"pilomatricomas"*, play important role in deciding it is a disease. Any model relying on features defined based on words occurring within a fixed window of neighboring words will fail to capture information of influential words occurring outside this window.

Our motivation can be summarized in the following question: *can we identify disease name and categorize them without relying on feature en-*

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2216–2225,
Berlin, Germany, August 7-12, 2016.

gineering, domain-knowledge or task specific resources? In other words, we can say this work is motivated towards mitigating the two issues: first, feature engineering relying on linguistic and domain-specific knowledge; and second, bring flexibility in capturing influential words affecting model decisions irrespective of their occurrence anywhere within the sentence. For the first, we used character-based embedding (likely to capture orthographic and morphological features) as well as word embedding (likely to capture lexico-semantic features) as features of the neural network models.

For the second issue, we explore various recurrent neural network (RNN) architectures for their ability to capture long distance contexts. We experiment with bidirectional RNN (Bi-RNN), bidirectional long short term memory network (Bi-LSTM) and bidirectional gated recurrent unit (Bi-GRU). In each of these models we used sentence level log likelihood approach at the top layer of the neural architecture. The main contributions of the work can be summarized as follows

- Domain invariant features with various RNN architectures for the disease name recognition and classification tasks,
- Comparative study on the use of character based embedded features, word embedding features and combined features in the RNN models.
- Failure analysis to check where exactly our models are failed in the considered tasks.

Although there are some related works (discussed in sec 6), this is the first study, to the best of our knowledge, which comprehensively uses various RNN architectures without resorting to feature engineering for disease name recognition and classification tasks.

Our results show near state-of-the-art performance can be achieved on the disease name recognition task. More significantly, the proposed models obtain significantly improved performance on the disease name classification task.

2 Methods

We first give overview of the complete model used for the two tasks. Next we explained embedded features used in different neural network models. We provide short description of different RNN models in the section 2.3. Training and inference strategies are explained in the section 2.4.

2.1 Model Architectures

Similar to any named entity recognition task, we formulate the disease mention recognition task as a token level sequence tagging problem. Each word has to be labeled with one of the defined tags. We choose *BIO model* of tagging, where *B* stands for beginning, *I* for intermediate and *O* for outsider or other. This way we have two possible tags for all entities of interest, i.e., for all disease mentions, and one tag for other entities.

Generic neural architecture is shown in the figure 1. In the very first step, each word is mapped to its embedded features.

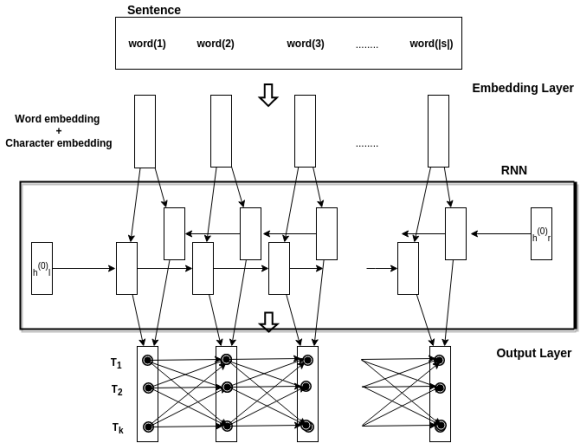

Figure 1: Generic bidirectional recurrent neural network with sentence level log likelihood at the top-layer for sequence tagging task

We call this layer as *embedding layer*. This layer acts as input to hidden layers of RNN model. We study the three different RNN models, and have described them briefly in the section 2.3. Output of the hidden layers is then fed to the output layer to compute the scores for all tags of interest (Collobert et al., 2011; Huang et al., 2015). In output layer we are using sentence level log likelihood, to make inference. Table 1 briefly describes all notations used in the paper.

2.2 Features

Distributed Word Representation (WE)

Distributed word representation or word embedding or simply word vector (Bengio et al., 2003; Collobert and Weston, 2008) is the technique of learning vector representation of a word in a given

Symbols	Explanation
V	Vocabulary of words $(v_1, v_2 ... v_{\|V\|})$
C	Vocabulary of characters $(c_1, c_2 .. c_{\|C\|})$
T	Tag set $(t_1, t_2 ... t_{\|T\|})$
d^{we}	Dimension of word embedding
d^{chr}	Dimension of character embedding
d^{ce}	Dimension of character level word embedding
$M^{we} \in \mathbb{R}^{d^{we} X \|V\|}$	word embedding matrix, where every column M_i^{we} is a vector representation of corresponding word v_i in *V*
$M^{cw} \in \mathbb{R}^{d^{chr} X \|C\|}$	character embedding matrix, where every column M_i^{cw} is a vector representation of corresponding character c_i in *C*.
$w^{(i)} \in \mathbb{R}^{d^{we}}$	word embedding of v_i
$y^{(i)} \in \mathbb{R}^{d^{ce}}$	character level word embedding of v_i
$x^{(i)} \in \mathbb{R}^{d^{we}+d^{ce}}$	feature vector of word $w^{(i)}$. We get this after concatenating $w^{(i)}$ and $y^{(i)}$
$z^{(i)} \in \mathbb{R}^{\|T\|}$	score for i^{th} word in sentence at output layer of neural network. Here j^{th} element will indicate the score for t_j^{th} tag.
W_*^*, U_*^*, V_*^*	Parameters of different neural networks

Table 1: Notation

corpus. Word vectors are present in columns of matrix M^{we}. We can get this vector by taking product of matrix M^{we} and *one hot vector* of v_i.

$$w^{(i)} = M^{we} h^{(i)} \quad (1)$$

Here $h^{(i)}$ is the one hot vector representation of i^{th} word in *V*. We use pre-trained 50 dimensional word vectors learned using skipgram method on a biomedical corpus (Mikolov et al., 2013b; Mikolov et al., 2013a; TH et al., 2015).

Character Level Word Embedding (CE)

Word embedding preserve syntactic and semantic information well but fails to seize morphological and shape information. However, for the disease entity recognition task, such information can play an important role. For instance, letter *-o-* in the word *gastroenteritis* is used to combine various body parts *gastro* for *stomach*, *enter* for *intestines*, and *itis* indicates *inflammation*. Hence taken together it implies *inflammation of stomach and intestines*, where *-itis* play significant role in determining it is actually a disease name.

Character level word embedding was first introduced by (dos Santos and Zadrozny, 2014) with the motivation to capture word shape and morphological features in word embedding. Character level word embedding also automatically mitigate the problem of out of vocabulary words as we can embed any word by its characters through character level embedding. In this case, a vector is initialized for every character in the corpus. Then we learn vector representation for any word by applying CNN on each vector of character sequence of that word as shown in figure 2. These character vectors will get update while training RNN in supervised manner only. Since number of characters in the dataset is not high we assume that every character vectors will get sufficient updation while training RNN itself.

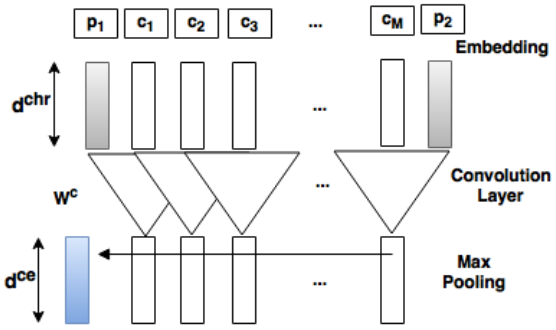

Figure 2: CNN with Max Pooling for Character Level Embedding (p_1 and p_2 are padding). Here, filter length is 3.

Let $\{p_1, c_1, c_2 ... c_M, p_2\}$ is sequence of characters for a word with padding at beginning and ending of word and let $\{a_l, a_1, a_2 ... a_M, a_r\}$ is its sequence of character vector, which we obtain by multiplying M^{cw} with one hot vector of corresponding character. To obtain character level word embedding we need to feed this in convolution neural network (CNN) with max pooling layer (dos Santos and Zadrozny, 2014). Let $W^c \in$

$\mathbb{R}^{d^{ce}X(d^{chr}Xk)}$ is a filter and b^c bias of CNN, then

$$[y^{(i)}]_j = \max_{1<m<M}[W^c q^{(m)} + b^c]_j \quad (2)$$

Here k is window size, $q^{(m)}$ is obtained by concatenating the vector of $(k-1)/2$ character left to $(k-1)/2$ character right of c_m. Same filter will be used for all window of characters and max pooling operation is performed on results of all. We learn 100 dimensional character embedding for all characters in a given dataset (avoiding case sensitivity) and 25 dimensional character level word embedding from character sequence of words.

2.3 Recurrent Neural Network Models

Recurrent Neural Network (RNN) is a class of artificial neural networks which utilizes sequential information and maintains history through its intermediate layers (Graves et al., 2009; Graves, 2013). We experiment with three different variants of RNN, which are briefly described in subsequent subsections.

Bi-directional Recurrent Neural Network

In Bi-RNN, context of the word is captured through past and future words. This is achieved by having two hidden components in the intermediate layer, as schematically shown in the fig 1. One component process the information in forward direction (left to right) and other in reverse direction. Subsequently outputs of these components then concatenated and fed to the output layer to get score for all tags of the considered word. Let $x^{(t)}$ is a feature vector of t^{th} word in sentence (concatenation of corresponding embedding features w^{t_i} and y^{t_i}) and $h_l^{(t-1)}$ is the computation of last hidden state at $(t-1)^{th}$ word, then computation of hidden and output layer values would be:

$$h_l^{(t)} = tanh(U^l x^{(t)} + W^l h_l^{(t-1)})$$

$$z^{(t)} = V(h_l^{(t)} : h_r^{(t)}) \quad (3)$$

Here $U^l \in \mathbb{R}^{n_H \times n_I}$ and $W^l \in \mathbb{R}^{n_H \times n_H}$, where n_I is input vector of length $d^{we} + d^{ce}$, n_H is hidden layer size and $V \in \mathbb{R}^{n_O \times (n_H + n_H)}$ is the output layer parameter. $h_l^{(t)}$ and $h_r^{(t)}$ correspond to left and right hidden layer components respectively and $h_r^{(t)}$ is calculated similarly to $h_l^{(t)}$ by reversing the words in the sentence. At the beginning $h_l^{(0)}$ and $h_r^{(0)}$ are initialized randomly.

Bi-directional Long Short Term Memory Network

Traditional RNN models suffer from both vanishing and exploding gradient (Pascanu et al., 2012; Bengio et al., 2013). Such models are likely to fail where we need longer contexts to do the job. These issues were the main motivation behind the LSTM model (Hochreiter and Schmidhuber, 1997). LSTM layer is just another way to compute a hidden state which introduces a new structure called a memory cell (c_t) and three gates called as input (i_t), output (o_t) and forget (f_t) gates.

These gates are composed of sigmoid activation function and responsible for regulating information in memory cell. The input gate by allowing incoming signal to alter the state of the memory cell, regulates proportion of history information memory cell will keep. On the other hand, the output gate regulates what proportion of stored information in the memory cell will influence other neurons. Finally, the forget gate can modulate the memory cells and allowing the cell to remember or forget its previous state. Computation of memory cell ($c^{(t)}$) is done through previous memory cell and candidate hidden state ($g^{(t)}$) which we compute through current input and the previous hidden state. The final output of hidden state would be calculated based on memory cell and forget gate.

In our experiment we used model discussed in (Graves, 2013; Huang et al., 2015). Let $x^{(t)}$ is feature vector for t^{th} word in a sentence and $h_l^{(t-1)}$ is previous hidden state then computation of hidden ($h_l^{(t)}$) and output layer ($z^{(t)}$) of LSTM would be.

$$\begin{aligned}
i_l^{(t)} &= \sigma(U_l^{(i)} x^{(t)} + W_l^{(i)} h_l^{(t-1)} + b_l^i) \\
f_l^{(t)} &= \sigma(U_l^{(f)} x^{(t)} + W_l^{(f)} h_l^{(t-1)} + b_l^f) \\
o_l^{(t)} &= \sigma(U_l^{(o)} x^{(t)} + W_l^{(o)} h_l^{(t-1)} + b_l^o) \\
g_l^{(t)} &= tanh(U_l^{(g)} x^{(t)} + W_l^{(g)} h_l^{(t-1)} + b_l^g) \\
c_l^{(t)} &= c_l^{(t-1)} * f_l + g_l * i_l \\
h_l^{(t)} &= tanh(c_l^{(t)}) * o_l
\end{aligned}$$

Where σ is sigmoid activation function, $*$ is a element wise product, $U_l^{(i)}, U_l^{(f)}, U_l^{(o)}, U_l^{(g)} \in \mathbb{R}^{n_H \times n_I}$ and $W_l^{(i)}, W_l^{(o)}, W_l^{(f)}, W_l^{(g)} \in \mathbb{R}^{n_H \times n_H}$, where n_I is input size ($d^{we} + d^{ce}$) and n_H is hidden layer size. We compute $h_r^{(t)}$ in similar manner as $h_l^{(t)}$ by reversing the all words of sentence. Let $V \in \mathbb{R}^{n_O \times (n_H + n_H)}$ (n_O size of output layer) is

the parameter of output layer of LSTM then computation of output layer will be:

$$z^{(t)} = V(h_l^{(t)} : h_r^{(t)}) \quad (4)$$

Bi-directional Gated Recurrent Unit Network

A gated recurrent unit (GRU) was proposed by (Cho et al., 2014) to make each recurrent unit to adaptively capture dependencies of different time scales. Similar to the LSTM unit, the GRU has gating units reset *r* and update z gates that modulate the flow of information inside the unit, however, without having a separate memory cells. The resulting model is simpler than standard LSTM models.

We follow (Chung et al., 2014) model of GRU to transform the extracted word embedding and character embedding features to score for all tags. Let $x^{(t)}$ embedding feature for *t*th word in sentence and $h_l^{(t-1)}$ is computation of hidden state for $(t-1)$th word then computation of GRU would be:

$$z_l^{(t)} = \sigma(U_l^{(z)} x^{(t)} + W_l^{(z)} h_l^{(t-1)} + b_l^{(z)})$$
$$r_l^{(t)} = \sigma(U_l^{(r)} x^{(t)} + W_l^{(r)} h_l^{(t-1)} + b_l^{(r)})$$
$$\tilde{h}_l^{(t)} = \tanh(U_l^{(h)} x^{(t)} + W_l^{(h)} h_l^{(t-1)} * r_l + b_l^{(h)})$$
$$h_l^{(t)} = z_l^{(t)} * \tilde{h}_l + (1 - z_l^{(t)}) * h_l^{(t-1)}$$

$$z^{(t)} = V(h_l^{(t)} : h_r^{(t)}) \quad (5)$$

Where $*$ is pair wise multiplication, $U_l^{(z)}, U_l^{(r)}$, $U_l^{(h)}, U_l^{(h)} \in \mathbb{R}^{n_H \times n_I}$ and $W_l^{(z)}, W_l^{(r)} W_l^{(h)} \in \mathbb{R}^{n_H \times n_H}$ are parameters of GRU. $V \in \mathbb{R}^{n_O \times (n_H + n_H)}$ is output layer parameter. Computation of $h_r^{(t)}$ is done in similar manner as $h_l^{(t)}$ by reversing the words of sentence.

2.4 Training and Inference

Equations 3, 4 and 5 are the scores of all possible tags for t^{th} word sentence. We follow *sentence-level log-likelihood (SLL)* (Collobert et al., 2011) approach equivalent to linear-chain CRF to infer the scores of a particular tag sequence for the given word sequence. Let $[w]_1^{|s|}$ is sentence and $[t]_1^{|s|}$ is the tag sequence for which we want to find the joint score, then score for the whole sentence with the particular tag sequence would be:

$$s([w]_1^{|s|}, [t]_1^{|s|}) = \sum_{1 \le i \le |s|} (W_{t_{i-1}, t_i}^{trans} + z_{t_i}^{(i)}), \quad (6)$$

where W^{trans} is transition score matrix and $W_{i,j}^{trans}$ is indicating the transition score moving from tag t_i to t_j; t_j is tag for the j^{th} word; $z_{t_i}^{(i)}$ is the output score from the neural network model for the tag t_i of i^{th} word. To train our model we used cross entropy loss function and adagrad (Duchi et al., 2010) approach to optimize the loss function. Entire neural network parameters, word embedding, character embedding and W^{trans} (transition score matrix used in the SLL) was updated during training. Entire code has been implemented using theano (Bastien et al., 2012) library in python language.

3 Experiments

3.1 Dataset

We used NCBI dataset (Doğan and Lu, 2012), the most comprehensive publicly available dataset annotated with disease mentions, in this work. NCBI dataset has been manually annotated by a group of medical practitioners for identifying diseases and their types in biomedical articles. All disease mentions were categorized into four different categories, namely, *specific disease*, *disease class*, *composite disease* and *modifier*. A word is annotated as *specific disease*, if it indicates a particular disease. *Disease class* category indicates a word describing a family of many specific diseases, such as autoimmune disorder. A string signifying two or more different disease mentions is annotated with *composite mention*. *Modifier* category indicates disease mention has been used as modifiers for other concepts. This dataset is a extension of the AZDC dataset (Leaman et al., 2009) which was annotated with disease mentions only and not with their categories. Statistics of the dataset is mentioned in the Table 2.

Corpus	***Train set***	***Dev set***	***Test set***
sentences	5661	939	961
disease	5148	791	961
spe. dis.	2959	409	556
disease class	781	127	121
modifier	1292	218	264
comp. men.	116	37	20

Table 2: Dataset statistics. spe. dis. : specific disease and comp. men.: composite mention

In our evaluation we used this dataset in two settings, **A**: *disease mention recognition*, where all

Task	Model	Validation Set			Test Set		
		Precision	Recall	F1 Score	Precision	Recall	F1 Score
A	NN+CE	76.98	75.80	76.39	78.51	72.75	75.52
	Bi-RNN+CE	71.96	74.90	73.40	74.14	72.12	73.11
	Bi-GRU+CE	76.28	74.14	75.19	76.03	69.81	72.79
	Bi-LSTM+CE	81.52	72.86	**76.94**	76.98	75.80	**76.39**
B	NN+CE	67.27	53.45	59.57	67.90	49.95	57.56
	Bi-RNN+CE	61.34	56.32	58.72	60.32	57.28	58.76
	Bi-GRU+CE	61.94	59.11	**60.49**	62.56	56.50	59.38
	Bi-LSTM+CE	61.82	57.03	59.33	64.74	55.53	**59.78**

Table 3: Performance of various models using 25 dimensional CE features, A:Disease name recognition, B: Disease classification task

disease types are flattened into a single category and, the **B**: *disease class recognition*, where we need to decide exact categories of disease mentions. It is noteworthy to mention that the Task B is more challenging as it requires model to capture semantic contexts to put disease mentions into appropriate categories.

4 Results and Discussion

Evaluation of different models using CE

We first evaluate the performance of different RNNs using only character embedding features. We compare the results of RNN models with window based neural network (Collobert et al., 2011) using sentence level log likelihood approach (NN + CE). For the window based neural network, we considered window size 5 (two words from both left and right, and one central word) and same settings of character embedding were used as features. The same set of parameters are used in all experiments unless we mention specifically otherwise. We used exact matching scheme to evaluate performance of all models.

Table 3 shows the results obtained by different RNN models with only character level word embedding features. For the task A (Disease name recognition) Bi-LSTM and NN models gave competitive performance on the test set, while Bi-RNN and Bi-GRU did not perform so well. On the other hand for the task B, there is $2.08\% - 3.8\%$ improved performance (F1-score) shown by RNN models over the NN model again on the test set. Bi-LSTM model obtained F1-score of 59.78% while NN model gave 57.56%. As discussed earlier, task B is difficult than task A as disease category is more likely to be influenced by the words falling outside the context window considered in window based methods. This could be reason for RNN models to perform well over the NN model. This hypothesis will be stronger if we observe similar pattern in our other experiments.

Evaluation of different models with WE and WE+CE

Next we investigated the results obtained by the various models using only 50 dim word embedding features. The first part of table 4 shows the results obtained by different RNNs and the window based neural network (NN). In this case RNN models are giving better results than the NN model for both the tasks. In particular performance of Bi-LSTM models are best than others in both the tasks. We observe that for the task A, RNN models obtained 1.2% to 3% improvement in F1-score than the baseline NN performance. Similarly 2.55% to 4% improvement in F1-score are observed for the task B, with Bi-LSTM model obtaining more than 4% improvement.

In second part of this table we compare the results obtained by various models using the features set obtained by combining the two feature sets. If we look at performance of individual model using three different set of features, model using only word embedding features seems to give consistently best performance. Among all models, Bi-LSTM using word embedding features obtained best F1-scores of 79.13% and 63.16% for the tasks A and B respectively.

Importance of tuning pre-trained word vectors

We further empirically evaluate the importance of updating of word vectors while training. For this, we performed another set of experiments, where pre-trained word vectors are not updated while

Task	Model	Validation Set			Test Set		
		Precision	Recall	F1 Score	Precision	Recall	F1 Score
A	NN+WE	81.86	76.82	79.26	80.32	73.58	76.81
	Bi-RNN+WE	84.14	77.46	80.67	82.49	73.58	77.78

	Bi-LSTM+WE+CE	64.92	58.61	61.60	61.14	60.54	60.84

Table 4: Performance of various models using 50 dimensional WE features. A:Disease name recognition, B: Disease classification task

training. Results obtained on the validation dataset of the Task A are shown in the Table 5. One can observe that performance of all models have deteriorated. Next, instead of using pre-trained word vectors, we initialized each word with zero vector but kept updating them while training. Although performance (Table 6) deteriorated (compare to Table 4) but not as much as in table 5. This observation highlights the importance of tuning word vectors for a specific task during training.

Model	*P*	*R*	*F*
NN+WE	74.02	67.86	70.81
Bi-RNN+WE	72.17	64.40	68.06
Bi-GRU+WE	77.06	70.55	73.66
Bi-LSTM+WE	77.32	73.75	75.49

Table 5: Performance of different models with *50 dim embedded vectors* in **Task A** *validation set* **when word vectors are not getting updated while training**

Comparison with State-of-art

At the end we are comparing our results with state-of-the art results reported in (Doğan and Lu, 2012) on this dataset using BANNER (Leaman and Gonzalez, 2008) in table 7. BANNER is a CRF based bio entity recognition model, which uses general linguistic, orthographic, syntactic dependency features. Although the result reported in (Doğan and Lu, 2012) (F1-score = 81.8) is better than that of our RNN models but it should be noted that competitive result (F1-score = 79.13%) is obtained by the proposed Bi-LSTM model which does not depend on any feature engineering or domain-specific resources and is using only word embedding features trained in unsupervised manner on a huge corpus.

Model	*P*	*R*	*F*
NN+RV	81.64	74.01	77.64
Bi-RNN+RV	82.32	72.73	77.2
Bi-GRU+RV	82.48	74.14	78.08
Bi-LSTM+RV	83.41	72.73	77.70

Table 6: Results of different models with *50 dim random vectors* in **Task A** *validation set*

For the task B, we did not find any paper except (Li, 2012). Li (2012) used linear soft margin support vector (SVM) machine with a number of hand designed features including dictionary based features. The best performing proposed model shows more than 37% improvement in F1-score (benchmark: 46% vs Bi-LSTM+WE: 63.16%).

5 Failure Analysis

To see where exactly our models failed to recognize diseases, we analyzed the results carefully.

Task	Model	Validation Set			Test Set		
		P	R	F	P	R	F
A	Bi-LSTM+WE	85.13	77.72	81.26	84.87	74.11	79.13
	BANNER (Doğan and Lu, 2012)	-	-	**81.9**	-	-	**81.8**
B	Bi-LSTM+WE	67.48	58.01	**62.39**	68.97	58.25	**63.16**
	SM-SVM(Li, 2012)	-	-	-	66.1	35.2	46.0

Table 7: Comparisons of our best model results and state-of-art results. SM-SVM :Soft Margin Support Vector Machine

We found that significant proportion of errors are coming due to use of acronyms of diseases and use of disease form which is rarely appearing in our corpus. Examples of few such cases are *"CD", "HNPCC","SCA1"*. We observe that this error is occurring because we do not have exact word embedding for these words. Most of the acronyms in the disease corpus were mapped to rare-word embedding[1]. Another major proportion of errors in our results were due to difficulty in recognizing nested forms of disease names. For example, in all of the following cases: *"hereditary forms of 'ovarian cancer'" , "inherited 'breast cancer'", "male and female 'breast cancer'"*, part of phrase such as *ovarian cancer* in *hereditary forms of ovarian cancer*, *breast cancer* in *inherited breast cancer* and *male and female breast cancer* are disease names and our models are detecting this very well. However, according to annotation scheme if any disease is part of nested disease name, annotators considered whole phrase as a single disease. So even our model is able to detect part of the disease accurately but due to the exact matching scheme, this will be false positive for us.

6 Related Research

In biomedical domain, named entity recognition has attracted much attention for identification of entities such as genes and proteins (Settles, 2005; Leaman and Gonzalez, 2008; Leaman et al., 2009) but not as much for disease name recognition. Notable works, such as of Chowdhury and Lavelli (2010), are mainly conditional random field (CRF) based models using lots of manually designed template features. These include linguistic, orthographic, contextual and dictionary based features. However, they have evaluated their model on the AZDC dataset which is small compared to the NCBI dataset, which we have considered in this study. Nikfarjam et al. (2015) have proposed a CRF based sequence tagging model, where cluster id of embedded word as an extra feature with manually engineered features is used for adverse drug reaction recognition in tweets.

Recently deep neural network models with minimal dependency on feature engineering have been used in few studies in NLP including NER tasks (Collobert et al., 2011; Collobert and Weston, 2008). dos Santos et al. (2015) used deep neural network based model such as window based network to recognize named entity in Portuguese and Spanish texts. In this work, they exploit the power of CNN to get morphological and shape features of words in character level word embedding, and used it as feature with concatenation of word embedding. Their results indicate that CNN are able to preserve morphological and shape features through character level word embedding. Our models are quite similar to this model but we used different variety of RNN in place of window based neural network.

Labeau et al. (2015) used Bi-RNN with character level word embedding only as a feature for PoS tagging in German text. Their results also show that with only character level word embedding we can get state-of-art results in PoS tagging in German text. Our model used word embedding as well as character level word embedding together as features and also we have tried more sophisticated RNN models such as LSTM and GRU in bi-directional structure. More recent work of Huang et al. (2015) used LSTM and CRF in variety of combination such as only LSTM, LSTM with CRF and Bi-LSTM with CRF for PoS tagging, chunking and NER tasks in general texts. Their results shows that Bi-LSTM with CRF gave best results in all these tasks. These two works have used either Bi-RNN with character embedding features or Bi-LSTM with word embedding

[1]we obtained pre-trained word-embedding features from (TH et al., 2015) and in their pre-processing strategy, all words of frequency less than 50 were mapped to rare-word.

features in general or news wire texts, whereas in this work we compare the performance of three different types of RNNs: Bi-RNN, Bi-GRU and Bi-LSTM with both word embedding and character embedding features in biomedical text for disease name recognition.

7 Conclusions

In this work, we used three different variants of bidirectional RNN models with word embedding features for the first time for disease name and class recognition tasks. Bidirectional RNN models are used to capture both forward and backward long term dependencies among words within a sentence. We have shown that these models are able to obtain quite competitive results compared to the benchmark result on the disease name recognition task. Further our results have shown a significantly improved results on the relatively harder task of disease classification which has not been studied much. All our results were obtained without putting any effort on feature engineering or requiring domain-specific knowledge. Our results also indicate that RNN based models perform better than window based neural network model for the two tasks. This could be due to the implicit ability of RNN models to capture variable range dependencies of words compared to explicit dependency on context window size of window based neural network models.

Abstract

We present the first domain adaptation model for authorship attribution to leverage unlabeled data. The model includes extensions to structural correspondence learning needed to make it appropriate for the task. For example, we propose a median-based classification instead of the standard binary classification used in previous work. Our results show that punctuation-based character n-grams form excellent pivot features. We also show how singular value decomposition plays a critical role in achieving domain adaptation, and that replacing (instead of concatenating) non-pivot features with correspondence features yields better performance.

1 Introduction

Authorship Attribution (AA) can be used for historical purposes, such as disentangling the different authors contributing to a literary work. It can also help in understanding language evolution and change at the individual level, revealing a writer's changes in linguistic patterns over time (Hirst and Feng, 2012). Authorship attribution can also help to settle disputes over the original creators of a given piece of text. Or it can help build a prosecution case against an online abuser, an important application especially considering the rising trends in cyber-bullying and other electronic forms of teen violence[1]. The absorbing social media networks, together with the ever increasing use of electronic communications will require robust approaches to authorship attribution that can help to determine with certainty the author of a text, determine the provenance of a written sample, and in sum, help us determine the trustworthiness of electronic data.

[1] http://cyberbullying.org/

One of the scenarios that has received limited attention is cross-domain authorship attribution, when we need to identify the author of a text but all the text with known authors is from a different topic, genre, or modality. Here we propose to solve the problem of cross-domain authorship attribution by adapting the Structural Correspondence Learning (SCL) algorithm proposed by Blitzer et al. (2006). We make the following contributions:

- We introduce the first domain adaptation model for authorship attribution that combines labeled data in a source domain with unlabeled data from a target domain to improve performance on the target domain.
- We examine two sets of features that have previously been successful in cross-domain authorship attribution, explain how these can be used to select the "pivot" features required by SCL, and show that typed n-gram features (which differentiate between the *the* in ***the**ir* and the *the* in *brea**the***) produce simpler models that are just as accurate.
- We propose a new approach for defining SCL's pivot feature classification task so that it is able to handle count-based features, and show that this median-based approach outperforms the standard SCL approach.
- We examine the importance of the dimensionality reduction step in SCL, and show that the singular value decomposition increases robustness even beyond the robustness achieved by SCL's learned feature transformations.
- We propose an alternative approach to combining features within SCL, and show that excluding the non-pivot features from the final classifier generally improves performance.

Our experimental results show that using standard SCL for this domain adaptation authorship attribution task improves prediction accuracy by

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2226–2235,
Berlin, Germany, August 7-12, 2016.

only 1% over a model without any domain adaptation. In contrast, our proposed improvements to SCL reach an accuracy boost of more than 15% over the no domain adaptation model and of 14% over the standard SCL formulation. The extensions to SCL that we propose in this work are likely to yield performance improvements in other tasks where SCL has been successfully applied, such as part-of-speech tagging and sentiment analysis. We plan to investigate this further in the future.

2 Related Work

Cross-Domain Authorship Attribution Almost all previous authorship attribution studies have tackled traditional (single-domain) authorship problems where the distribution of the test data is the same as that of the training data (Madigan et al., 2005; Stamatatos, 2006; Luyckx and Daelemans, 2008; Escalante et al., 2011). However, there are a handful of authorship attribution studies that explore cross-domain authorship attribution scenarios (Mikros and Argiri, 2007; Goldstein-Stewart et al., 2009; Schein et al., 2010; Stamatatos, 2013; Sapkota et al., 2014). Here, following prior work, cross-domain is a cover term for cross-topic, cross-genre, cross-modality, etc., though most work focuses on the cross-topic scenario.

Mikros and Argiri (2007) illustrated that many stylometric variables are actually discriminating topic rather than author. Therefore, the authors suggest their use in authorship attribution should be done with care. However, the study did not attempt to construct authorship attribution models where the source and target domains differ.

Goldstein-Stewart et al. (2009) performed a study on cross-topic authorship attribution by concatenating the texts of an author from different genres on the same topics. Such concatenation allows some cross-topic analysis, but as each test document contains a mix of genres it is not representative of real world authorship attribution problems.

Stamatatos (2013) and Sapkota et al. (2014) explored a wide variety of features, including lexical, stopword, stylistic, and character n-gram, and demonstrated that character n-grams are the most effective features in cross-topic authorship attribution. Stamatatos (2013) concluded that avoiding rare features is effective in both intra-topic and cross-topic authorship attribution by training a SVM classifier on one fixed topic and testing on each of the remaining topics. Sapkota et al. (2014), rather than fixing a single training topic in advance, considered all possible training/testing topic combinations to investigate cross-topic authorship attribution. This showed that training on documents from multiple topics (thematic areas) improves performance in cross-topic authorship attribution (Sapkota et al., 2014), even when controlling the amount of training data.

However, none of these studies exploited domain adaptation methods that combine labeled data in a source domain with unlabeled data from a target domain to improve performance on the target domain. Instead, they focused on identifying relevant features and simply evaluating them when trained on source-domain data and tested on target-domain data. To our knowledge, we are the first to leverage unlabeled data from the target domain to improve authorship attribution.

Domain Adaptation Domain adaptation is the problem of modifying a model trained on data from a source domain to a different, possibly related, target domain. Given the effort and the cost involved in labeling data for a new target domain, there is a lot of interest in the design of domain adaptation techniques. In NLP related tasks, researchers have explored domain adaptation for part-of-speech tagging, parsing, semantic role labeling, word-sense disambiguation, and sentiment analysis (Li, 2012).

Daumé (2007) proposed a feature space transformation method for domain adaptation based on a simple idea of feature augmentation. The basic idea is to create three versions of each feature from the original problem: the general (domain-independent) version, the source specific version, and the target specific version. While generally successful, there are some limitations of this method. First, it requires labeled instances in the target domain. Second, since this method simply duplicates each feature in the source domain as domain-independent and domain-specific versions, it is unable to extract the potential correlations when the features in the two domains are different, but have some hidden correspondences.

In contrast, structural correspondence learning (SCL) is a feature space transformation method that requires no labeled instances from the target domain, and can capture the hidden correlations among different domain-independent features. SCL's basic idea is to use unlabeled data from both the source and target domains to obtain a common feature representation that is meaningful across

domains (Blitzer et al., 2006). Although the distributions of source and target domain differ, the assumption is that there will still be some general features that share similar characteristics in both domains. SCL has been applied to tasks such as sentiment analysis, dependency parsing, and part-of-speech tagging, but has not yet been explored for the problem of authorship attribution.

The common feature representation in SCL is created by learning a projection to "pivot" features from all other features. These pivot features are a critical component of the successful use of SCL, and their selection is something that has to be done carefully and specifically to the task at the hand. Tan and Cheng (2009) studied sentiment analysis, using frequently occurring sentiment words as pivot features. Similarly, Zhang et al. (2010) proposed a simple and efficient method for selecting pivot features in domain adaptive sentiment analysis: choose the frequently occurring words or word-bigrams among domains computed after applying some selection criterion. In dependency parsing, Shimizu and Nakagawa (2007) chose the presence of a preposition, a determiner, or a helping verb between two tokens as the pivot features. For part-of-speech tagging, Blitzer et al. (2006) used words that occur more than 50 times in both domains as the pivot features, resulting in mostly function words. In cross-lingual adaptation using SCL, semantically related pairs of words from source and target domains were used as pivot features (Prettenhofer and Stein, 2011). For authorship attribution, we propose two ways of selecting pivot and non-pivot features based on character n-grams.

Another important aspect of the SCL algorithm is associating a binary classification problem with each pivot feature. The original SCL algorithm assumes that pivot features are binary-valued, so creating a binary classification problem for each pivot feature is trivial: is the value 0 or 1? Most previous work on part-of-speech tagging, sentiment analysis, and dependency parsing also had only binary-valued pivot features. However, for authorship attribution, all features are count-based, so translation from a pivot feature value to a binary classification problem is not trivial. We propose a median-based solution to this problem.

3 Methodology

Structural Correspondence Learning (Blitzer et al., 2006) uses only unlabeled data to find a common feature representation for a source and a target domain. The idea is to first manually identify "pivot" features that are likely to have similar behavior across both domains. SCL then learns a transformation from the remaining non-pivot features into the pivot feature space. The result is a new set of features that are derived from all the non-pivot features, but should be domain independent like the pivot features. A classifier is then trained on the combination of the original and the new features.

Table 1 gives the details of the SCL algorithm. First, for each pivot feature, we train a linear classifier to predict the value of that pivot feature using only the non-pivot features. The weight vectors learned for these linear classifiers, $\hat{w}_i$, are then concatenated into a matrix, W, which represents a projection from non-pivot features to pivot features. Singular value decomposition is used to reduce the dimensionality of the projection matrix, yielding a reduced-dimensionality projection matrix θ. Finally, a classifier is trained on the combination of the original features and the features generated by applying the reduced-dimensionality projection matrix θ to the non-pivot features $\mathbf{x}_{[p:m]}$.

3.1 Standard SCL parameter definitions

Standard SCL does not define how pivot features are selected; this must be done manually for each new task. However, SCL does provide standard definitions for the loss function (L), the conversion to binary values (B_i), the dimensionality of the new correspondence space (d), and the feature combination function (C).

L is defined as Huber's robust loss:

$$L(a, b) = \begin{cases} \max(0, 1 - ab)^2 & \text{if } ab \geq -1 \\ -4ab & \text{otherwise} \end{cases}$$

The conversion from pivot feature values to binary classification is defined as:

$$B_i(y) = \begin{cases} 1 & \text{if } y > 0 \\ 0 & \text{otherwise} \end{cases}$$

A few different dimensionalities for the reduced feature space have been explored (Prettenhofer and Stein, 2011), but most implementations have followed the standard SCL description (Blitzer et al., 2006) with d defined as:

$$d = 25$$

The feature combination function, C, is defined as simple concatenation, i.e., use all of the old pivot

Input:

- $S = \{\mathbf{x} : \mathbf{x} \in \mathbb{R}^m\}$, the labeled instances from source domain
- $U = \{\mathbf{x} : \mathbf{x} \in \mathbb{R}^m\}$, the unlabeled instances from both domains
- p and n such that $\mathbf{x}_{[0:p]}$ are the p pivot features and $\mathbf{x}_{[p:m]}$ are $n = m - p$ non-pivot features
- $f : S \rightarrow A$, the source domain labels, where A is the set of authors
- $L : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}$, a loss function
- $B_i : \mathbb{R} \rightarrow \{0, 1\}$ for $0 \leq i < p$, a conversion from a real-valued pivot feature i to binary classification
- d, the size of the reduced-dimensionality correspondence space to learn
- $C : \mathbb{R}^m \times \mathbb{R}^d \rightarrow \mathbb{R}^k$, a function for combining the original and new features

Output:

- $\theta \in \mathbb{R}^{n \times d}$, a projection from non-pivot features to the correspondence space
- $h : \mathbb{R}^{m+d} \rightarrow A$, the trained predictor

Algorithm:

1. For each pivot feature $i : 0 \leq i < p$, learn prediction weights $\hat{w}_i = \min_{\mathbf{w} \in \mathbb{R}^n} \sum_{\mathbf{x} \in U} L(\mathbf{w}^\top \mathbf{x}_{[p:m]}, B(x_i))$
2. Construct a matrix $W \in \mathbb{R}^{n \times p}$ using each $\hat{w}_i$ as a column
3. Apply singular value decomposition $W = U \Sigma V^\top$ where $U \in \mathbb{R}^{n \times n}$, $\Sigma \in \mathbb{R}^{n \times p}$, $V^\top \in \mathbb{R}^{p \times p}$
4. Select the reduced-dimensionality projection, $\theta = {U_{[0:d,:]}}^\top$
5. Train a classifier h from $\left\{ \left([C(\mathbf{x}, \mathbf{x}_{[p:m]}\theta), f(\mathbf{x}) \right) : \mathbf{x} \in S \right\}$

Table 1: The structural correspondence learning (SCL) algorithm

features, all the old non-pivot features, and all the new correspondence features:

$$C(\mathbf{x}, \mathbf{z}) = [\mathbf{x}; \mathbf{z}]$$

We call this the *pivot+nonpivot+new* setting of C.

The following sections discuss alternative parameter choices for pivot features, B_i, d, and C.

3.2 Pivot Features for Authorship Attribution

The SCL algorithm depends heavily on the pivot features being domain-independent features, and as discussed in Section 2, which features make sense as pivot features varies widely by task. No previous studies have explored structural correspondence learning for authorship attribution, so one of the outstanding questions we tackle here is how to identify pivot features. Research has shown that the most discriminative features in attribution and the most robust features across domains are character n-grams (Stamatatos, 2013; Sapkota et al., 2014). We thus consider two types of character n-grams used in authorship attribution that might make good pivot features.

3.2.1 Untyped Character N-grams

Classical character n-grams are simply the sequences of characters in the text. For example, given the text:

> The structural correspondence

character 3-gram features would look like:

```
"The", "he ", "e s", " st",
"str",  "tru", "ruc", "uct", ...
```

We propose to use as pivot features the p most frequent character n-grams. For non-pivot features, we use the remaining features from prior work (Sapkota et al., 2014). These include both the remaining (lower frequency) character n-grams, as well as stop-words and bag-of-words lexical features. We call this the *untyped* formulation of pivot features.

3.2.2 Typed Character N-grams

Sapkota et al. (2015) showed that classical character n-grams lose some information in merging together instances of n-grams like *the* which could be a prefix (***the**sis*), a suffix (*brea**the***), or a standalone word (***the***). Therefore, untyped character n-grams were separated into ten distinct categories. Four of the ten categories are related to affixes: prefix, suffix, space-prefix, and space-suffix. Three are word-related: whole-word, mid-word, and multi-word. The final three are related to the use of punctuation: beg-punct, mid-punct, and end-punct. For example, the character n-grams from the last section would instead be replaced with:

```
"whole-word:The", "space-suffix:he ",
"multi-word:e s", "space-prefix: st",
"prefix:str",  "mid-word:tru",
"mid-word:ruc", "mid-word:uct", ...
```

Sapkota et al. (2015) demonstrated that n-grams starting with a punctuation character (the *beg-punct* category) and with a punctuation character in the middle (the *mid-punct* category) were the most effective character n-grams for cross-domain authorship attribution. We therefore propose to use as pivot features the $p/2$ most frequent character n-grams from each of the *beg-punct* and *mid-punct* categories, yielding in total p pivot features. For non-pivot features, we use all of the remaining features of Sapkota et al. (2015). These include both the remaining (lower frequency) *beg-punct* and *mid-punct* character n-grams, as well as all of the character n-grams from the remaining eight categories. We call this the *typed* formulation of pivot features.[2]

3.3 Pivot feature binarization parameters

Authorship attribution typically relies on count-based features. However, the classic SCL algorithm assumes that all pivot features are binary, so that it can train binary classifiers to predict pivot feature values from non-pivot features. We propose a binarization function to produce a binary classification problem from a count-based pivot feature by testing whether the feature value is above or below the feature's median value in the training data:

$$B_i(y) = \begin{cases} 1 & \text{if } y > median(\{\mathbf{x}_i : \mathbf{x} \in S \cup U\}) \\ 0 & \text{otherwise} \end{cases}$$

The intuition is that for count-based features, "did this pivot feature appear at least once in the text" is not a very informative distinction, especially since the average document has hundreds of words, and pivot features are common. A more informative distinction is "was this pivot feature used more or less often than usual?" and that corresponds to the below-median vs. above-median classification.

3.4 Dimensionality reduction parameters

The reduced dimensionality (d) of the low-rank representation varies depending on the task at hand, though lower dimensionality may be preferred as it will result in faster run times. We empirically compare different choices for d: 25, 50, and 100.

We also consider the question, how critical is dimensionality reduction? For example, if there are only $p = 100$ pivot features, is there any need to run singular-value decomposition? The goal here is to determine if SCL is increasing the robustness across domains primarily through transforming non-pivot features into pivot-like features, or if the reduced dimensionality from the singular-value decomposition contributes something beyond that.

[2]Because the **untyped** and **typed** feature sets are designed to directly replicate Sapkota et al. (2014) and Sapkota et al. (2015), respectively, both include character n-grams, but only **untyped** includes stop-words and lexical features.

Average sentences/document	53
Average words/document	1034

Table 2: Statistics of the Guardian dataset.

3.5 Feature combination parameters

It's not really clear why the standard formulation of SCL uses the non-pivot features when training the final classifier. All of the non-pivot features are projected into the pivot feature space in the form of the new correspondence features, and the pivot feature space is, by design, the most domain independent part of the feature space. Thus, it seems reasonable to completely replace the non-pivot features with the new pivot-like features. We therefore consider a *pivot+new* setting of C:

$$\textit{pivot+new: } C(\mathbf{x}, \mathbf{z}) = [\mathbf{x}_{[0:p]}; \mathbf{z}]$$

We also consider other settings of C, primarily for understanding how the different pieces of the SCL feature space contribute to the overall model.

$$\begin{aligned} \textit{pivot: } C(\mathbf{x}, \mathbf{z}) &= \mathbf{x}_{[0:p]} \\ \textit{nonpivot: } C(\mathbf{x}, \mathbf{z}) &= \mathbf{x}_{[p:m]} \\ \textit{new: } C(\mathbf{x}, \mathbf{z}) &= \mathbf{z} \\ \textit{pivot+nonpivot: } C(\mathbf{x}, \mathbf{z}) &= \mathbf{x} \end{aligned}$$

Note that the *pivot+nonpivot* setting corresponds to a model that does not apply SCL at all.

4 Dataset

To explore cross-domain settings of authorship attribution, we need datasets containing documents from a number of authors from different domains (different topics, different genres). We use a corpus that consists of texts published in The Guardian daily newspaper that is actively used by the authorship attribution community in cross-domain studies (Stamatatos, 2013; Sapkota et al., 2014;

Sapkota et al., 2015). The Guardian corpus contains opinion articles written by 13 authors in four different topics: World, U.K., Society, and Politics. Following prior work, to make the collection balanced across authors, we choose at most ten documents per author for each of the four topics. Table 2 presents some statistics about the datasets.

5 Experimental Settings

We trained support vector machine (SVM) classifiers using the Weka implementation (Witten and Frank, 2005) with default parameters. For the *untyped* features, we used character 3-grams appearing at least 5 times in the training data, a list of 643 predefined stop-words, and the 3,500 most frequent non-stopword words as the lexical features. For the *typed* features, we used the top 3,500 most frequent 3-grams occurring at least five times in the training data for each of the 10 character n-gram categories. In both cases, we selected $p = 100$ pivot features as described in Section 3.2.

We measured performance in terms of accuracy across all possible topic pairings. That is, we paired each of the 4 topics in the Guardian corpus with each of the 3 remaining topics: train on Politics, test on Society; train on Politics, test on UK; train on Politics, test on World; etc. For each such model, we allowed SCL to learn feature correspondences from the labeled data of the 1 training topic and the unlabeled data of the 1 test topic. This resulted in 12 pairings of training/testing topics. We report both accuracy on the individual pairings and an overall average of the 12 accuracies.

We compare performance against two state-of-the-art baselines: Sapkota et al. (2014) and Sapkota et al. (2015), as described in Section 3.2, and whose features are denoted as **untyped** and **typed**, respectively. We replicate these models by using the *pivot+nonpivot* setting of C, i.e., not including any of the new SCL-based features.

6 Results

The following sections explore the results of our innovations in different areas: pivot features, feature binarizations, dimensionality reduction, and feature combination. For each section, we hold the other parameters constant and vary only the one parameter of interest. Thus, where not otherwise specified, we set parameters to the best values we observed in our experiments: we set the feature set to *typed*, the binarization $B_i(y)$ to the median, the reduced dimensionality d to 50, and the feature combination $C(\mathbf{x}, \mathbf{z})$ to *pivot+new* (i.e., we use the old pivot features alongside the new correspondence features). All reports of statistical significance are based on paired, two-tailed t-tests over the 12 different topic pairings.

Dataset	**untyped**	**typed**
Politics-Society	61.29	**67.74**
Politics-UK	**66.67**	63.33
Politics-World	58.97	**64.10**
Society-Politics	**62.96**	**62.96**
Society-UK	**72.50**	**72.50**
Society-World	**56.62**	48.08

UK-Society	66.13	**67.74**
UK-World	57.27	**58.97**
World-Politics	**62.50**	59.82
World-Society	61.29	**62.90**
World-UK	46.67	**54.44**
Average	61.80	**61.94**

Table 3: Accuracy of **untyped** and **typed** feature sets. The difference between the averages is not statistically significant (p=0.927).

6.1 Untyped vs. Typed features

Table 3 compares the **untyped** feature set to the **typed** feature set. Both feature sets perform reasonably well, and substantially better than a model without SCL, where the performance of **untyped** is 56.43 and **typed** is 53.62 (see the *pivot+nonpivot* columns of Table 6 and Table 7, discussed in Section 6.4). Recall that the **typed** formulation includes only character n-gram features, while the **untyped** formulation includes stopwords and lexical features as well. Thus, given their very similar performance in Table 3, **typed** being slightly better, we select the simpler **typed** feature formulation for the remaining experiments.

6.2 Greater-than-zero vs. Median Binarization

Table 4 compares choices for $B_i(y)$, the function for converting a pivot feature value into a binary classification problem. In every single train/test scenario, and for both **untyped** and **typed** feature sets, our proposed median-based binarization function yielded performance greater than or equal to that of the traditional SCL greater-than-zero binarization function. This confirms our hypothesis that count-based features were inadequately modeled

Table 5: Accuracy of different choices for dimensionality reduction with **typed** features. The pattern is similar for **untyped**. $d = 50$ is significantly better than no SVD (p=0.0009), but not significantly different from $d = 25$ (p=0.291) or $d = 100$ (p=0.211).

in standard SCL and that the median-based binarization function improves the modeling of such features.

6.3 Dimensionality Reduction Choices

Table 5 compares different choices for the dimensionality reduction parameter d, as well as the possibility of not performing any dimensionality reduction at all ("No-SVD"). While each value of d yields the best performance on some of the train/test scenarios, $d = 50$ achieves the highest average accuracy (61.94). Removing the SVD entirely generally performs worse, and though on a small number of train/test scenarios it outperforms $d = 25$ and $d = 100$, it is always worse than $d = 50$.

This shows that SCL's feature correspondences alone are not sufficient to achieve domain adaptation. Without the SVD, performance is barely above a model without SCL: 54.16 vs. 53.62 (see Section 6.4). Much of the benefit appears to be coming from the SVD's basis-shift, since $d = 100$ outperforms no-SVD by more than 5 points[3], while $d = 50$ only outperforms $d = 100$ by 2 points. These results are consistent with SCL's origins in alternating structural optimization (Ando and Zhang, 2005), where SVD is derived as a necessary step for identifying a shared low-dimensional subspace.

6.4 Replacing vs. Concatenating Features

Table 6 and Table 7 compare the performance of different choices for the feature combination function $C(\mathbf{x}, \mathbf{z})$ on **untyped** and **typed** features, respectively. Our proposed *pivot+new* combination function, which replaces the non-pivot features with the new correspondence features, performs better on average than the two state-of-the-art baselines with no domain adaptation (*pivot+nonpivot*) and than the two state-of-the-art baselines augmented with classic SCL (*pivot+nonpivot+new*): 61.80 vs. 56.43 and 56.93 for untyped, and 61.94 vs. 53.62 and 54.23 for typed). These 5-8 point performance gains confirm the utility of our proposed *pivot+new* combination function, which replaces the old non-pivot features with the new correspondence features. These gains are consistent with (Blitzer et al., 2006), who included both pivot and non-pivot features, but found that they had to give pivot features a weight "five times that of the [non-pivot] features" to see improved performance.

While our approach is better on average, in some individual scenarios, it performs worse than classic SCL or no domain adaptation. For example, on Politics-Society, Politics-UK, and World-UK, using **typed** features, *pivot+new* performs worse than no domain adaptation (*pivot+nonpivot*). Our results suggest a rule for predicting when this degradation will happen: *pivot+new* will outperform

[3]Recall that $p = 100$, so $d = 100$ means the full matrix.

Dataset	*pivot*	*nonpivot*	*new*	*pivot+nonpivot*	*pivot+nonpivot+new*	*pivot+new*
Politics-Society	54.84	75.81	62.9	75.81	**77.42**	61.29

Average	50.02	52.40	57.47	53.62	54.23	**61.94**

Table 7: Accuracy of different **typed** feature combinations. The best performance for each dataset is in bold. The performance of *pivot+new* is significantly better than *pivot+nonpivot* (p=0.041) but not significantly different from *pivot+nonpivot+new* (p=0.059).

both *pivot+nonpivot* and *pivot+nonpivot+new* iff the *new* features alone outperform the *nonpivot* features alone. This rule holds in all 12 of 12 train/test scenarios for **untyped** features and 11 of 12 scenarios for **typed** features (failing on only World-Society). Intuitively, if the *new* correspondence features that result from SCL aren't better than the features they were meant to replace, then it is unlikely that they will result in performance gains. This might happen if the pivot features are not strong enough predictors, either because they have been selected poorly or because there are too few of them.

7 Discussion

To the best of our knowledge, we are the first to introduce a domain adaption model for authorship attribution that combines labeled data in a source domain with unlabeled data from a target domain to improve performance on the target domain. We proposed several extensions to the popular structural correspondence learning (SCL) algorithm for domain adaptation to make it more amenable to tasks like authorship attribution. The SCL algorithm requires the manual identification of domain independent *pivot* features for each task, so we proposed two feature formulations using charac-

ter n-grams as the pivot features, and showed that both yielded state-of-the-art performance. We also showed that for the binary classification task that is used by SCL to learn the feature correspondences, replacing the traditional greater-than-zero classification task with a median-based classification task allowed the model to better handle our count-based features. We explored the dimensionality reduction step of SCL and showed that singular value decomposition (SVD) over the feature correspondence matrix is critical to achieving high performance. Finally, we introduced a new approach to combining the original features with the learned correspondence features, and showed that replacing (rather than concatenating) the non-pivot features with the correspondence features generally yields better performance.

In the future, we would like to extend this work in several ways. First, though our median-based approach was successful in converting pivot feature values to binary classification problems, learning a regression model might be an even better approach for count-based features. Second, since the SVD basis-shift seems to be the source of much of the gains, we would like to explore replacing the SVD with other algorithms, such as independent component analysis. Finally, we would like to explore further our finding that the performance of the overall model seems to be predicted by the difference in performance between the non-pivot features and the new correspondence features, especially to see if this can be predicted at training time rather than as a post-hoc analysis.

A Corpus-Based Analysis of Canonical Word Order of Japanese Double Object Constructions

Ryohei Sasano **Manabu Okumura**
Tokyo Institute of Technology
{sasano,oku}@pi.titech.ac.jp

Abstract

The canonical word order of Japanese double object constructions has attracted considerable attention among linguists and has been a topic of many studies. However, most of these studies require either manual analyses or measurements of human characteristics such as brain activities or reading times for each example. Thus, while these analyses are reliable for the examples they focus on, they cannot be generalized to other examples. On the other hand, the trend of actual usage can be collected automatically from a large corpus. Thus, in this paper, we assume that there is a relationship between the canonical word order and the proportion of each word order in a large corpus and present a corpus-based analysis of canonical word order of Japanese double object constructions.

1 Introduction

Japanese has a much freer word order than English. For example, a Japanese double object construction has six possible word orders as follows:

(1) a: *Ken-ga Aya-ni camera-wo miseta.*
Ken-NOM Aya-DAT camera-ACC showed

b: *Ken-ga camera-wo Aya-ni miseta.*
Ken-NOM camera-ACC Aya-DAT showed

c: *Aya-ni Ken-ga camera-wo miseta.*
Aya-DAT Ken-NOM camera-ACC showed

d: *Aya-ni camera-wo Ken-ga miseta.*
Aya-DAT camera-ACC Ken-NOM showed

e: *Camera-wo Ken-ga Aya-ni miseta.*
camera-ACC Ken-NOM Aya-DAT showed

f: *Camera-wo Aya-ni Ken-ga miseta.*
camera-ACC Aya-DAT Ken-NOM showed

In these examples, the position of the verb *miseta* (showed) is fixed but the positions of its nominative (NOM), dative (DAT), and accusative (ACC) arguments are scrambled. Note that, although the word orders are different, they have essentially the same meaning "Ken showed a camera to Aya."

In the field of linguistics, each language is assumed to have a basic word order that is fundamental to its sentence structure and in most cases there is a generally accepted theory on the word order for each structure. That is, even if there are several possible word orders for essentially same sentences consisting of the same elements, only one of them is regarded as the canonical word order and the others are considered to be generated by scrambling it. However, in the case of Japanese double object constructions, there are several claims on the canonical argument order.

There have been a number of studies on the canonical word order of Japanese double object constructions ranging from theoretical studies (Hoji, 1985; Miyagawa and Tsujioka, 2004) to empirical ones based on psychological experiments (Koizumi and Tamaoka, 2004; Nakamoto et al., 2006; Shigenaga, 2014) and brain science (Koso et al., 2004; Inubushi et al., 2009). However, most of them required either manual analyses or measurements of human characteristics such as brain activities or reading times for each example. Thus, while these analyses are reliable for the example they focus on, they cannot be easily generalized to other examples[1]. That is, another manual analysis or measurement is required to consider the canonical word order of another example.

On the other hand, the trend of actual usage can be collected from a large corpus. While it is difficult to say whether a word order is canonical or

[1]Note that in this work, we assume that there could be different canonical word orders for different double-object sentences as will be explained in Section 2.2.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2236–2244,
Berlin, Germany, August 7-12, 2016.

not from one specific example, we can consider that a word order would be canonical if it is overwhelmingly dominant in a large corpus. For example, since the DAT−ACC order[2] is overwhelmingly dominant in the case that the verb is *kanjiru* (feel), its dative argument is *kotoba* (word), and its accusative argument is *aijô* (affection) as shown in Example (2), we can consider that the DAT−ACC order would be canonical in this case. Note that, the numbers in parentheses represent the proportion of each word order in Examples (2) and (3); ϕ_X denotes the omitted noun or pronoun X in this paper.

(2) **DAT−ACC:** *Kotoba-ni aijô-wo kanjiru.*
(97.5%) word−DAT affection−ACC feel

ACC−DAT: *Aijô-wo kotoba-ni kanjiru.*
(2.5%) affection−ACC word−DAT feel

(ϕ_I feel the affection in ϕ_{your} words.)

On the contrary, since the ACC−DAT order is overwhelmingly dominant in the case that the verb is *sasou* (ask), its dative argument is *dêto* (date), and its accusative argument is *josei* (woman) as shown in Example (3), the ACC−DAT order is considered to be canonical in this case.

(3) **DAT−ACC:** *Dêto-ni josei-wo sasou.*
(0.4%) date−DAT woman−ACC ask

ACC−DAT: *Josei-wo dêto-ni sasou.*
(99.6%) woman−ACC date−DAT ask

(ϕ_I ask a woman out on a date.)

Therefore, in this paper, we assume that there is a relationship between the canonical word order and the proportion of each word order in a large corpus and attempt to evaluate several claims on the canonical word order of Japanese double object constructions on the basis of a large corpus. Since we extract examples of double object constructions only from reliable parts of parses of a very large corpus, consisting of more than 10 billion unique sentences, we can reliably leverage a large amount of examples. To the best of our knowledge, this is the first attempt to analyze the canonical word order of Japanese double object constructions on the basis of such a large corpus.

[2]Since Japanese word order is basically subject-object-verb (SOV) and thus the canonical position of nominative argument is considered to be the first position, we simply call the nominative, dative, accusative order as the DAT−ACC order, and the nominative, accusative, dative order as the ACC−DAT order in this paper.

2 Japanese double object constructions

2.1 Relevant Japanese grammar

We briefly describe the relevant Japanese grammar. Japanese word order is basically subject-object-verb (SOV) order, but the word order is often scrambled and does not mark syntactic relations. Instead, postpositional case particles function as case markers. For example, nominative, dative, and accusative cases are represented by case particles *ga*, *ni*, and *wo*, respectively.

In a double object construction, the subject, indirect object, and direct object are typically marked with the case particles *ga* (nominative), *ni* (dative), and *wo* (accusative), respectively, as shown in Example (4)-a.

(4) a: *Watashi-ga kare-ni camera-wo miseta.*
I−NOM him−DAT camera−ACC showed

b: *Watashi-wa kare-ni camera-wo miseta.*
I−TOP him−DAT camera−ACC showed

c: ϕ_I *kare-ni camera-wo miseta.*
ϕ_I-NOM him−DAT camera−ACC showed

(I showed him a camera.)

However, when an argument represents the topic of the sentence (TOP), the topic marker *wa* is used as a postpositional particle, and case particles *ga* and *wo* do not appear explicitly. For example, since *watashi* (I) in Example (4)-b represents the topic of the sentence, the nominative case particle *ga* is replaced by the topic marker *wa*.

Similarly, an argument modified by its predicate does not accompany a postpositional case particle that represents the syntactic relation between the predicate and argument. For example, since *camera* in Example (5) is modified by the predicate *miseta* (showed), the accusative case particle *wo* does not appear explicitly.

(5) *Watashi-ga kare-ni miseta camera.*
I−NOM him−DAT showed camera

(A camera that I showed him.)

In addition, arguments are often omitted in Japanese when we can easily guess what the omitted argument is or we do not suppose a specific object. For example, the nominative argument is omitted in Example (4)-c, since we can easily guess the subject is the first person.

These characteristics make it difficult to automatically extract examples of word orders in double object construction from a corpus.

2.2 Canonical argument order

There are three major claims as to the canonical argument order of Japanese double object constructions (Koizumi and Tamaoka, 2004).

One is the traditional analysis by Hoji (1985), which argues that only the nominative, dative, accusative (DAT−ACC) order like in Example (1)-a is canonical for all cases. The second claim, made by Matsuoka (2003), argues that Japanese double object constructions have two canonical word orders, the DAT−ACC order and the ACC−DAT order, depending on the verb types. The third claim, by Miyagawa (1997), asserts that both the DAT−ACC order and ACC−DAT order are canonical for all cases.

Note that, the definition of the term *canonical word order* varies from study to study. Some studies presume that there is only one canonical word order for one construction (Hoji, 1985), while others presume that a canonical word order can be different for each verb or each tuple of a verb and its arguments (Matsuoka, 2003). In addition, some studies presume that there can be multiple canonical word orders for one sentence (Miyagawa, 1997). In this paper, we basically adopt the position that there is only one canonical word order for one tuple of a verb and its arguments but the canonical word orders can be different for different tuples of a verb and its arguments.

2.3 Other features related to word order

There are a number of known features that affect word order. For example, it is often said that long arguments tend to be placed far from the verb, whereas short arguments tend to be placed near the verb. The From-Old-to-New Principle (Kuno, 2006) is also well known; it argues that the unmarked word order of constituents is old, predictable information first; and new, unpredictable information last. Note that these types of features are not specific to argument orders in Japanese double object constituents. For example, Bresnan et al. (2007) reported the similar features were also observed in the English dative alternation and useful for predicting the dative alternation.

However, since we are interested in the canonical word order, we do not want to take these features into account. In this work, we assume that these features can be ignored by using a very large corpus and analyzing the word order on the basis of statistical information acquired from the corpus.

3 Claims on the canonical word order of Japanese double object constructions

In this paper, we will address the following five claims on the canonical word order of Japanese double object constructions.

Claim A: The DAT−ACC order is canonical.

Claim B: There are two canonical word orders, the DAT−ACC and the ACC−DAT order, depending on the verb types.

Claim C: An argument whose grammatical case is infrequently omitted with a given verb tends to be placed near the verb.

Claim D: The canonical word order varies depending on the semantic role and animacy of the dative argument.

Claim E: An argument that frequently co-occurs with the verb tends to be placed near the verb.

Claim A (Hoji, 1985) presumes that there is only one canonical word order for Japanese double object constructions regardless of the verb type. On the other hand, Claims B and C argue that the canonical word order varies depending on verb, but they still do not take into account the lexical information of the arguments. Thus, these claims can be verified by investigating the distribution of word orders for each verb.

With regard to Claim B, Matsuoka (2003) classified causative-inchoative alternating verbs into two types: show-type and pass-type, and claimed the DAT−ACC order is the canonical order for show-type verbs, whereas the ACC−DAT order is the canonical order for pass-type verbs. The definitions of each verb type are as follows. In the case of show-type verbs, the dative argument of a causative sentence is the subject of its corresponding inchoative sentence as shown in Example (6). On the other hand, in the case of pass-type verbs, the accusative argument is the subject of its corresponding inchoative sentence as shown in Example (7).

(6) **Causative:** *Kare-ni camera-wo miseta.*
him−DAT camera−ACC showed
(ϕ_I showed him a camera.)

Inchoative: *Kare-ga mita.*
he−NOM saw
(He saw $\phi_{something}$.)

(7) **Causative:** *Camera-wo kare-ni watashita.*
camera−ACC him−DAT passed
(ϕ_I passed him a camera.)

Inchoative: *Camera-ga watatta.*
camera−NOM passed
(A camera passed to $\phi_{someone}$.)

Claim C is based on our observation. It is based on the assumption that if an argument of a verb is important for interpreting the meaning of the verb, it tends to be placed near the verb and does not tend to be omitted.

Claims D and E take into account the lexical information of arguments and assume that the canonical word order of Japanese double object constructions is affected by the characteristics of the dative and/or accusative arguments. With regard to Claim D, Matsuoka (2003) asserted that the canonical order varies depending on the semantic role of the dative argument. Specifically, the DAT−ACC order is more preferred when the semantic role of dative argument is animate *Possessor* than when the semantic role is inanimate *Goal*.

Claim E is based on our observation again, which argues that if the dative or accusative argument frequently co-occurs with the verb, it has a strong relationship with the verb, and thus is placed nearby. A typical example that satisfies this claim is idiomatic expressions as will be discussed in Section 5.4.

4 Example collection

A corpus-based analysis of canonical word order can leverage a much larger number of examples than approaches based on theoretical analysis, psychological experiments, or brain science can. However, automatically collected examples sometimes include inappropriate ones. For example, if we extract all sequences of a verb and its preceding argument candidates, the sequence "*Kagi-wo kare-ni iwareta*" (ϕ_I am told the key by him) is mistakenly extracted from Example (8), although *kagi-wo* is not actually an argument of *iwareta* but an argument of *oita*.

(8) *Kagi-wo kare-ni iwareta basho-ni oita.*
key−ACC him−DAT told place−DAT put
(ϕ_I put the key on the place where he told ϕ_{me}.)

As predicted, we can alleviate this problem by using a dependency parser. However, the accuracy of the state-of-the-art Japanese dependency parser is not very high, specifically about 92% for news paper articles (Yoshinaga and Kitsuregawa, 2014), and thus, inappropriate examples would be extracted even if we used one.

Therefore, in this work, we decided to extract examples only from reliable parts of dependency parses. Specifically, we used a corpus consisting of more than 10 billion unique sentences extracted from the Web, selected parse trees that have no syntactic ambiguity, and then extracted examples only from the selected parse trees. This strategy basically follows Kawahara and Kurohashi (2002)'s strategy for automatic case frame construction. The detailed procedure of example collection is as follows:

1. Extract Japanese Web pages using linguistic information, split the Web pages into sentences using periods and HTML tags, and merge sentences that are the exactly same into one sentence to avoid collecting the same example several times, which might be extracted from a mirror site.

2. Employ the Japanese morphological analyzer JUMAN[3] and the syntactic analyzer KNP[4], and extract examples of verbs and their arguments from parse trees that have no syntactic ambiguity[5].

3. Collect the examples if the verb satisfies all the following conditions:

   (a) The verb has an entry in the JUMAN dictionary and appears in the active voice.

   (b) The verb has more than 500 different examples of dative and accusative argument pairs.

   (c) The proportion of examples that include both the dative and accusative arguments out of all examples that include the target verb is larger than 5%.

We employ the syntactic analyzer KNP with options "-dpnd-fast -tab -check." KNP with these

[3]http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?JUMAN

[4]http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP

[5]Murawaki and Kurohashi (2012) reported that 20.7% of the dependency relations were extracted from a newspaper corpus and the accuracy was 98.3% when they adopted Kawahara and Kurohashi (2002)'s strategy.

options outputs all head candidates for each *bunsetsu*[6] on the basis of heuristic rules. We then extract the example of a verb and its argument if the argument candidate have only one head candidate.

For example, since Japanese is a head-final language and only the verb *bunsetsu* can be the head of the most noun *bunsetsu* in Japanese, *basho-ni* in Example (8) has only one head candidate *oita* (put), whereas *kagi-wo* and *kare-ni* have two head candidates *iwareta* (told) and *oita* (put). Thus, we extract only the example "*basho-ni oita*" from Example (8). In addition, when an argument consists of a compound noun, we only extract the head noun and its postpositional particle as the argument to avoid data sparsity.

Condition 3-(c) is set in order to extract only ditransitive verbs, which take both dative and accusative arguments. Although the threshold of 5% seems small at first glance, most verbs that satisfy it are actually ditransitive. This is because arguments are often omitted in Japanese, and thus, only some of the examples explicitly include both dative and accusative arguments even in the case of ditransitive verb.

Out of a corpus consisting of more than 10 billion unique sentences, 648 verbs satisfied these conditions. Hereafter, we will focus on these 648 verbs. The average number of occurrences of each verb was about 350 thousand and the average number of extracted examples that include both dative and accusative arguments was about 59 thousand.

5 Corpus-based analysis of canonical word order

Here, we present a corpus-based analysis of the canonical word order of Japanese double object constructions. We will address Claims A and C in Section 5.1, Claim B in Section 5.2, Claim D in Section 5.3, and Claim E in Section 5.4.

5.1 Word order for each verb

Let us examine the relation between the proportion of the DAT only example $R_{\text{DAT-only}}$ and the proportion of the ACC−DAT order $R_{\text{ACC-DAT}}$ for each of the 648 verbs to inspect Claims A and C.

[6]In Japanese, *bunsetsu* is a basic unit of dependency, consisting of one or more content words and the following zero or more function words. In this paper, we segment each example sentence into a sequence of *bunsetsu*.

$R_{\text{DAT-only}}$ is calculated as follows:

$$R_{\text{DAT-only}} = \frac{N_{\text{DAT-only}}}{N_{\text{DAT-only}} + N_{\text{ACC-only}}},$$

where $N_{\text{DAT/ACC-only}}$ is the number of example types that only include the corresponding argument out of the dative and accusative arguments. For example, we count the number of example types like Example (9) that include an accusative argument but do not include a dative argument to get the value of $N_{\text{ACC-only}}$. Accordingly, the large $R_{\text{DAT-only}}$ value indicates that the dative argument is less frequently omitted than the accusative argument.

(9) *Gakuchô-ga gakui-wo juyo-shita.*
president−NOM degree−ACC conferred
(The president conferred a degree on $\phi_{someone}$.)

However, if we use all extracted examples that include only one of the dative and accusative arguments for calculating $R_{\text{DAT-only}}$, the value is likely to suffer from a bias that the larger $R_{\text{ACC-DAT}}$ is, the larger $R_{\text{DAT-only}}$ becomes. This is because the arguments that tend to be placed near the verb have relatively few syntactic ambiguity. Since we extract the examples from the reliable parts of parses that have no syntactic ambiguity, these arguments tend to be included in the extracted examples more frequently than the other arguments.

To avoid this bias, we use only these examples in which the nominative case is also extracted for calculating $R_{\text{DAT-only}}$. This is based on the assumption that since Japanese word order is basically subject-object-verb order, if the nominative argument is collected but one of the dative and accusative arguments is not collected, the argument is actually omitted. Through a preliminary investigation on Kyoto University Text Corpus[7], we confirmed the effect of this constraint to avoid the bias.

On the other hand, $R_{\text{ACC-DAT}}$ is calculated as follows:

$$R_{\text{ACC-DAT}} = \frac{N_{\text{ACC-DAT}}}{N_{\text{DAT-ACC}} + N_{\text{ACC-DAT}}},$$

where $N_{\text{DAT-ACC/ACC-DAT}}$ is the number of example types that include both the dative and accusative arguments in the corresponding order.

Figure 1 shows the results. The left figure shows the relation between the proportion of the DAT

[7]Kyoto University Text Corpus 4.0: http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?Kyoto University Text Corpus

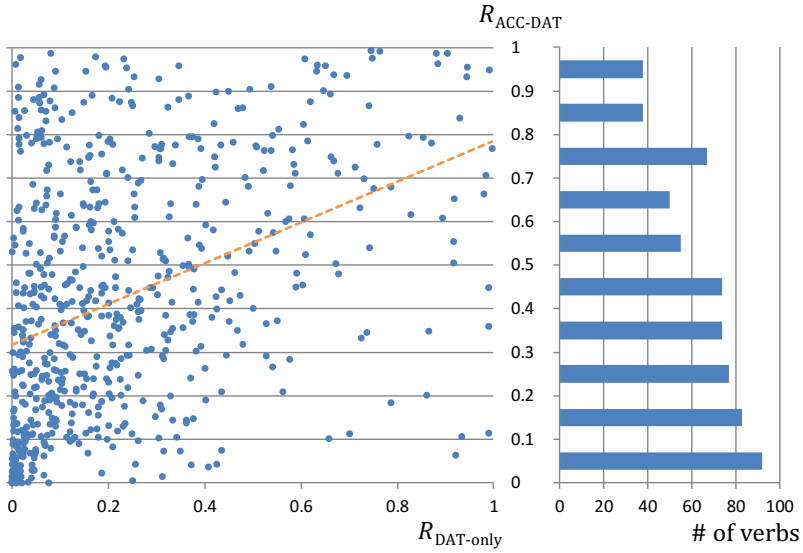

Figure 1: The left figure shows the relation between the proportion of the DAT only example $R_{\text{DAT-only}}$ (x-axis) and the proportion of the ACC−DAT order $R_{\text{ACC-DAT}}$ (y-axis). The right figure shows the number of verbs in the corresponding range of $R_{\text{ACC-DAT}}$.

only example $R_{\text{DAT-only}}$ and the proportion of the ACC−DAT order $R_{\text{ACC-DAT}}$ for each of the 648 verbs. The x-axis denotes $R_{\text{DAT-only}}$, the y-axis denotes $R_{\text{ACC-DAT}}$, and each point in the figure represents one of the 648 verbs. The dashed line is a linear regression line. The right figure shows the number of verbs in the corresponding range of $R_{\text{ACC-DAT}}$.

Pearson's correlation coefficient between $R_{\text{DAT-only}}$ and $R_{\text{ACC-DAT}}$ is 0.391, which weakly supports Claim C: an argument whose grammatical case is infrequently omitted with a given verb tends to be placed near the verb. The proportion of the ACC−DAT order for all 648 verbs is 0.328. Thus, if we presume that there is only one canonical word order for Japanese double object constructions, this result suggests that the DAT−ACC order is the canonical one, as claimed by Hoji (Claim A). However, the right figure shows that the proportions of the ACC−DAT order differ from verb to verb. Moreover, the values of $R_{\text{ACC-DAT}}$ for 435 out of 648 verbs are between 0.2 and 0.8. From these observations, we can say the preferred word order cannot be determined even if the verb is given in most cases.

5.2 Word order and verb type

To inspect Matsuoka (2003)'s claim that the DAT−ACC order is canonical for show-type verbs, whereas the ACC−DAT order is canonical for pass-type verbs, we investigated the proportions of the ACC−DAT order for several pass-type and show-type verbs. In this investigation, we used 11 pass-type verbs and 22 show-type verbs that were used by Koizumi and Tamaoka (2004) in their psychological experiments[8].

Table 1 shows the results. Although we can see that the macro average of $R_{\text{ACC-DAT}}$ of pass-type verbs is larger than that of show-type verbs, the difference is not significant[9]. Moreover, even in the case of pass-type verbs, the DAT−ACC order is dominant, which suggests Matsuoka (2003)'s claim is not true. Note that this conclusion is consistent with the experimental results reported by both Miyamoto and Takahashi (2002) and Koizumi and Tamaoka (2004).

5.3 Relation between word order and semantic role of the dative argument

Next, let us examine the relation between the category of the dative argument and the word order to verify the effect of the semantic role of the dative argument. We selected eight categories in the JUMAN dictionary[10] that appear more than 1 million times as dative arguments. Table 2 shows the results. We can see that there are differences in the

[8] We excluded a show-type verb *hakaseru* (dress), since it is divided into two morphemes by JUMAN. Instead, we added two show-type verbs *shiraseru* (notify) and *kotodukeru* (leave a message).

[9] The two-tailed p-value of permutation test is about 0.177.

[10] In JUMAN dictionary, 22 categories are defined and tagged to common nouns.

Show-type		Pass-type			
verb	$R_{\texttt{ACC-DAT}}$	verb	$R_{\texttt{ACC-DAT}}$	verb	$R_{\texttt{ACC-DAT}}$
shiraseru (notify)	0.522	*modosu* (put back)	0.771	*otosu* (drop)	0.351

Total	26500582	0.353	

Table 2: Proportions of the ACC−DAT order for each category of dative argument.

proportions of the ACC−DAT order. In particular, when the dative argument's category is PLACE-FUNCTION such as *shita* (bottom) and *yoko* (side) or ANIMAL-PART such as *te* (hand) and *mi* (body), the ACC−DAT order is more preferred than otherwise.

As mentioned in Section 3, Matsuoka (2003) claimed the DAT−ACC order is more preferred when the semantic role of the dative argument is animate *Possessor* than when the semantic role is inanimate *Goal*. Thus, we thought the DAT−ACC order would be preferred when the dative argument's category is PERSON, but we could not find such a trend. We think, however, this is due to that dative arguments of the PERSON category do not always have the semantic role of an animate *Possessor*. Thus, we conducted a further investigation in an attempt to verify Matsuoka (2003)'s claim.

First, we collected examples that satisfied the following two conditions: the accusative argument belongs to ARTIFACT-OTHER category, and the dative argument belongs to either PLACE-INSTITUTION or PERSON category. We call the former Type-A[11], and the latter Type-B hereafter, and consider that the semantic role of the dative argument is inanimate *Goal* in most cases of Type-A, whereas it is animate *Possessor* in most cases of Type-B. Example (10) shows typical examples of Type-A and Type-B. Here, the categories of *hon* (book), *gakkô* (school), and *sensei* (teacher) are ARTIFACT-OTHER, PLACE-INSTITUTION, and PERSON, respectively, and the semantic roles of dative arguments are considered to be *Goal* in (10)-a and *Possessor* in (10)-b.

(10) a: *Hon-wo* *gakkô-ni* *kaeshita.*
book−ACC school−DAT returned
($\phi_{someone}$ returned the book to school.)

b: *Sensei-ni* *hon-wo* *kaeshita.*
teacher−DAT book−ACC returned
($\phi_{someone}$ returned the book to the teacher.)

Next, we extracted verbs that had at least 100 examples of both types, calculated the proportion of the ACC−DAT order $R_{\texttt{ACC-DAT}}$ for each verb and type, and counted the number of verbs for which the values of $R_{\texttt{ACC-DAT}}$ were significantly different between Type-A and Type-B[12]. Out of 126 verbs that have at least 100 examples for both types, 64 verbs show the trend that Type-A prefers the ACC−DAT order more than Type-B does, and only 30 verbs have the opposite trend. This fact supports Matsuoka (2003)'s claim.

[11] That is, the categories of the accusative and dative arguments of a Type-A example are ARTIFACT-OTHER and PLACE-INSTITUTION, respectively.

[12] We conducted a two-proportion z-test with a significance level of 0.05.

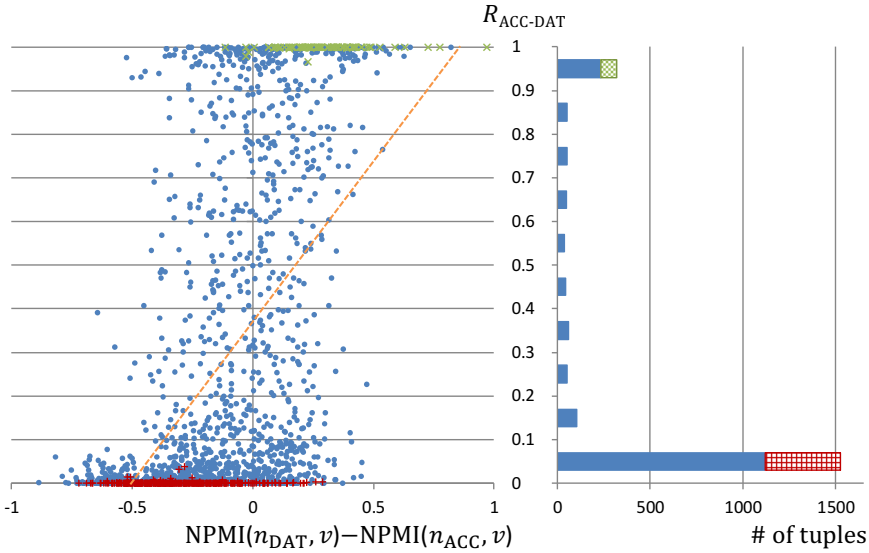

Figure 2: The left figure shows the relation between the difference of NPMI(n_{DAT}, v) from NPMI(n_{ACC}, v) (x-axis) and the proportion of the ACC−DAT order $R_{\text{ACC-DAT}}$ (y-axis). The tuples whose verb and accusative/dative argument are used as an idiom are represented by +/×. The right figure shows the number of tuples of a verb and its dative and accusative arguments in the corresponding range of $R_{\text{ACC-DAT}}$.

5.4 Relation between word order and degree of co-occurrence of verb and arguments

Now let us turn to the relation between the proportion of the ACC−DAT order $R_{\text{ACC-DAT}}$ and the degree of co-occurrence of a verb and its argument to verify Claim E. Here, we leverage the normalized pointwise mutual information (NPMI) for measuring the degree of co-occurrence between a verb and its argument. NPMI is a normalized version of PMI. The value ranges between [-1,+1] and takes -1 for never occurring together, 0 for independence, +1 for complete co-occurrence. The NPMI of a verb v and its argument n_c ($c \in \{\text{DAT}, \text{ACC}\}$) is calculated as

$$\text{NPMI}(n_c, v) = \frac{\text{PMI}(n_c, v)}{-\log(p(n_c, v))},$$

$$\text{where PMI}(n_c, v) = \log \frac{p(n_c, v)}{p(n_c)p(v)}.$$

We investigate the relation between the proportion of the ACC−DAT order $R_{\text{ACC-DAT}}$ and the difference of NPMI(n_{DAT}, v) from NPMI(n_{ACC}, v), i.e., NPMI(n_{DAT}, v) − NPMI(n_{ACC}, v). If Claim E is true, when the dative argument co-occurs with the verb frequently, the dative argument tends to be placed near the verb and thus the proportion of the ACC−DAT order would take a large value.

We investigated 2302 tuples of a verb and its dative and accusative arguments that appear more than 500 times in the corpus. The average number of occurrences of each tuple was 1532. Figure 2 shows the results. The left figure shows the relation between the difference of NPMI(n_{DAT}, v) from NPMI(n_{ACC}, v) and the proportion of the ACC−DAT order $R_{\text{ACC-DAT}}$. Each point in the figure represents one of the 2302 tuples. The dashed line is a linear regression line. The right figure shows the number of tuples in the corresponding range of $R_{\text{ACC-DAT}}$.

Pearson's correlation coefficient between the difference of NPMI and $R_{\text{ACC-DAT}}$ is 0.567, which supports Claim E: an argument that frequently co-occurs with the verb tends to be placed near the verb. Moreover, the values of $R_{\text{ACC-DAT}}$ are larger than 0.9 or smaller than 0.1 for 1631 out of 2302 tuples. This result indicates that if a tuple of a verb and its dative and accusative arguments is given, the preferred word order is determined. This is contrastive to the conclusion that the preferred word order cannot be determined even if the verb is given as discussed in Section 5.1.

One of the typical examples that satisfy Claim E is an idiomatic expression. Indeed, a verb and its argument that are used as an idiom co-occur frequently and are usually placed adjacent to each other. In addition, it is well known that if the argument order is scrambled, the idiomatic meaning disappears (Miyagawa and Tsujioka, 2004). Thus, we investigated to what extent idiomatic expres-

sions affected the findings discussed above. For all 2302 tuples, we manually judged whether the verb and the adjacent argument are used as an idiom in most cases. As a result, the verbs and their accusative arguments are judged as idiomatic for 404; the verbs and their dative arguments are judged as idiomatic for 84 out of 2302 tuples. We show these tuples by $+$ and $\times$ in Figure 2, respectively. As predicted, the values of $R_{\texttt{ACC-DAT}}$ are smaller than 0.1 for all of the former examples, and larger than 0.9 for all of the latter examples. However, even if we ignore these idiomatic examples, Pearson's correlation coefficient between the difference of NPMI and $R_{\texttt{ACC-DAT}}$ is 0.513, which is usually considered as moderate correlation.

6 Conclusion

This paper presented a corpus-based analysis of canonical word order of Japanese double object constructions. Our analysis suggests 1) the canonical word order of such constructions varies from verb to verb, 2) there is only a weak relation between the canonical word order and the verb type: show-type and pass-type, 3) an argument whose grammatical case is infrequently omitted with a given verb tends to be placed near the verb, 4) the canonical word order varies depending on the semantic role of the dative argument, and 5) an argument that frequently co-occurs with the verb tends to be placed near the verb.

Abstract

In this paper, with the help of knowledge base, we build and formulate a semantic space to connect the source and target languages, and apply it to the sequence-to-sequence framework to propose a Knowledge-Based Semantic Embedding (KBSE) method. In our KBSE method, the source sentence is firstly mapped into a knowledge based semantic space, and the target sentence is generated using a recurrent neural network with the internal meaning preserved. Experiments are conducted on two translation tasks, the electric business data and movie data, and the results show that our proposed method can achieve outstanding performance, compared with both the traditional SMT methods and the existing encoder-decoder models.

1 Introduction

Deep neural network based machine translation, such as sequence-to-sequence (S2S) model (Cho et al., 2014; Sutskever et al., 2014), try to learn translation relation in a continuous vector space. As shown in Figure 1, the S2S framework contains two parts: an encoder and a decoder. To compress a variable-length source sentence into a fixed-size vector, with a recurrent neural network (RNN), an encoder reads words one by one and generates a sequence of hidden vectors. By reading all the source words, the final hidden vector should contain the information of source sentence, and it is called the context vector. Based on the context vector, another RNN-based neural network is used to generate the target sentence.

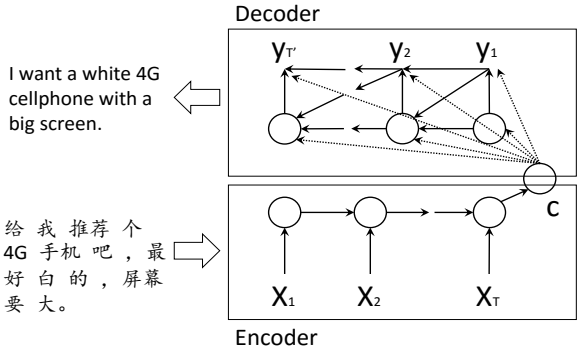

Figure 1: An illustration of the RNN-based neural network model for Chinese-to-English machine translation

The context vector plays a key role in the connection of source and target language spaces, and it should contain all the internal meaning extracted from source sentence, based on which, the decoder can generate the target sentence keeping the meaning unchanged. To extract the internal meaning and generate the target sentence, S2S framework usually needs large number of parameters, and a big bilingual corpus is acquired to train them.

In many cases, the internal meaning is not easy to learn, especially when the language is informal. For the same intention, there are various expressions with very different surface string, which aggravates the difficulty of internal meaning extraction. As shown in Table 1, there are three different expressions for a same intention, a customer wants a white 4G cellphone with a big screen. The first and second expressions (Source1 and Source2) are wordy and contain lots of verbiage. To extract the internal meaning, the encoder should ignore these verbiage and focus on key information. This is hard for the encoder-decoder mechanism, since it is not defined or formulated that what kind of information is key information. The meaning s-

Table 1: An example of various expressions for a same intention.

pace of the context vector is only a vector space of continuous numbers, and users cannot add external knowledge to constrain the internal meaning space. Therefore, the encoder-decoder system (Enc-Dec) does not generate the translation of "白色的"/"white", and fails to preserve the correct meaning of Source1, shown in Table 1.

No matter how different between the surface strings, the key information is the same (*want, white, 4G, big screen, cellphone*). This phenomenon motivates a translation process as: we firstly extract key information (such as entities and their relations) from the source sentence; then based on that, we generate target sentence, in which entities are translated with unchanged predication relations. To achieve this, background knowledge (such as, phone/computer, black/white, 3G/4G) should be considered.

In this paper, we propose a Knowledge-Based Semantic Embedding (KBSE) method for machine translation, as shown in Figure 2. Our KBSE contains two parts: a **Source Grounding** part to extract semantic information in source sentence, and a **Target Generation** part to generate target sentence. In KBSE, source monolingual data and a knowledge base is leveraged to learn an explicit semantic vector, in which the grounding space is defined by the given knowledge base, then the same knowledge base and a target monolingual data are used to learn a natural language generator, which produce the target sentence based on the learned explicit semantic vector. Different from S2S models using large bilingual corpus, our KBSE only needs monolingual data and corresponding knowledge base. Also the context/semantic vector in our KBSE is no longer implicit continuous number vector, but explicit semantic vector. The semantic space is defined by knowledge base, thus key information can be extracted and grounded from source sentence. In such a way, users can easily add external knowledge to guide the model to generate correct translation results.

We conduct experiments to evaluate our KBSE on two Chinese-to-English translation tasks, one in electric business domain, and the other in movie domain. Our method is compared with phrasal SMT method and the encoder-decoder method, and achieves significant improvement in both BLEU and human evaluation. KBSE is also combined with encoder-decoder method to get further improvement.

In the following, we first introduce our framework of KBSE in section 2, in which the details of **Source Grounding** and **Target Generation** are illustrated. Experiments is conducted in Section 3. Discussion and related work are detailed in Section 4, followed by conclusion and future work.

2 KBSE: Knowledge-Based Semantic Embedding

Our proposed KBSE contains two parts: **Source Grounding** part (in Section 2.1) embeds the source sentence into a knowledge semantic space, in which the grounded semantic information can be represented by semantic tuples; and **Target Generation** part (in Section 2.2) generates the target sentence based on these semantic tuples.

2.1 Source Grounding

Source	啊，那个有大屏幕的4G手机吗？要白色的。
Tuples	*Category.cellphone* *Appearance.color.white* *Appearance.size.big_screen* *Network.4G_network*

Table 2: Source sentence and the grounding result. Grounding result is organized as several tuples.

As shown in Table 2, given the source sentence, Source Grounding part tries to extract the semantic information, and map it to the tuples of knowledge base. It is worth noticing that the tuples are language-irrelevant, while the name of the entities inside can be in different languages. To get the semantic tuples, we first use RNN to encode the source sentence into a real space to get the sentence embedding, based on which, corresponding semantic tuples are generated with a neural-network-based hierarchical classifier. Since the knowledge base is organized in a tree structure, the tuples can be seen as several paths in the tree. For tuples in Table 2, Figure 3 shows the corresponding paths (in solid lines).

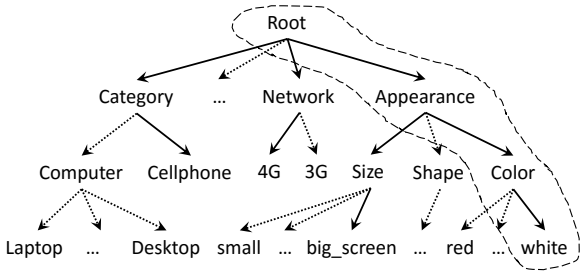

Figure 3: Illustration of the tuple tree for Table 2. Each tuple extracted from source sentence can be represented as a single path (solid line) in tuple tree. There are 4 solid line paths representing 4 tuples of Table 2. The path circled in dashed lines stands for the tuple *Appearance.color.white*.

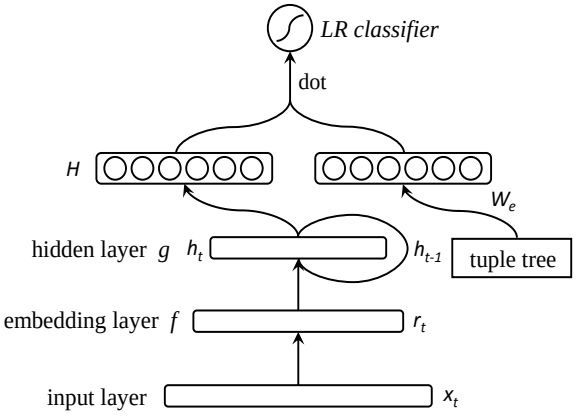

Figure 4: Illustration of Source Grounding. The input sentence **x** is transformed through an embedding layer f and a hidden layer g. Once we get the sentence embedding H, we calculate the inner product of H and the weight W_e for the specific edge e, and use a logistic regression as the classifier to decide whether this edge should be chosen.

2.1.1 Sentence Embedding

Sentence embedding is used to compress the variable-length source sentence into a fixed-size context vector. Given the input sentence $\mathbf{x} = (x_1 \ ... \ x_T)$, we feed each word one by one into an RNN, and the final hidden vector is used as the sentence embedding. In detail, as shown in Figure 4, at time-stamp t, an input word x_t is fed into the neural network. With the embedding layer f, the word is mapped into a real vector $r_t = f(x_t)$. Then the word embedding r_t is fed into an RNN g to get the hidden vector $h_t = g(r_t, h_{t-1})$. We input the words one by one at time $1, 2, ..., T$, and get the hidden vectors $h_1, h_2, ..., h_T$. The last hidden state h_T should contain all the information of the input sentence, and it is used as the sentence embedding H. To model the long dependency and memorize the information of words far from the end, Gated Recurrent Unit(GRU) (Cho et al., 2014) is leveraged as the recurrent function g.

2.1.2 Tuple Generation

In our system, we need a tuple tree for tuple generation. For those knowledge base who is naturally organized as tree structure, such as Freebase, we use its own stucture. Otherwise, we manually build the tuple tree as the representation of the introduced knowledge base. Given a knowl-

edge base for a specific domain, we divide the intention of this domain into several classes, while each class has subclasses. All the classes above can be organized as a tree structure, which is the tuple tree we used in our system, as shown in Figure 3. It is worth noticing that the knowledge base captures different intentions separately in different tree structures.

Following the hierarchical log-bilinear model (HLBL) (Mnih and Hinton, 2009; Mikolov et al., 2013), based on the sentence embedding H, we build our neural-network-based hierarchical classifier as follows: Each edge e of tuple tree has a weight vector w_e, which is randomly initialized, and learned with training data. We go through the tuple tree top-down to find the available paths. For each current node, we have a classifier to decide which children can be chosen. Since several children can be chosen at the same time independently, we use logistic regression as the classifier for each single edge, rather than a softmax classifier to choose one best child node.

For the source sentence and corresponding tuples in table 2, in the first layer, we should choose three children nodes: *Category*, *Appearance* and *Network*, and in the second layer with the parent node *Appearance*, two children nodes *color* and *size* should be selected recursively. As shown in Figure 4, the probability to choose an edge e with its connected child is computed as follows:

$$p(1|e,H) = \frac{1}{1+e^{-w_e \cdot H}} \tag{1}$$

where the operator $\cdot$ is the dot product function. The probability of the tuples conditioned on the source sentence $p(S|x_1 \ ... \ x_T)$ is the product of all the edges probabilities, calculated as follows:

$$\begin{aligned} p(S|x_1 \ ... \ x_T) &= p(S|H) \\ &= \prod_{e \in C} p(1|e,H) \prod_{e' \notin C} p(0|e',H) \end{aligned}$$

where $p(1|e,H)$ is the probability for an edge e belonging to the tuple set S, and $p(0|e',H)$ is the probability for an edge e' not in the tuple set S.

2.2 Target Generation

With the semantic tuples grounded from source sentence, in this section, we illustrate how to generate target sentence. The generation of the target sentence is another RNN, which predicts the next word y_{t+1} conditioned on the semantic vector C and all the previously predicted words $y_1, \ ..., \ y_t$. Given current word y_t, previous hidden vector h_{t-1}, and the semantic vector C, the probability of next target word y_{t+1} is calculated as:

$$h_t = g(h_{t-1}, y_t, C) \tag{2}$$

$$p(y_{t+1}|y_1 ... y_t, C) = \frac{e^{s(y_{t+1},h_t)}}{\sum_{y'} e^{s(y',h_t)}} \tag{3}$$

where equation (2) is used to generate the next hidden vector h_t, and equation (3) is the *softmax* function to compute the probability of the next word y_{t+1}. For the recurrent function g in equation (2), in order to generate target sentence preserving the semantic meaning stored in C , we modified GRU (Cho et al., 2014) following (Wen et al., 2015; Feng et al., 2016):

$$\begin{aligned} r_t &= \sigma(W^r y_t + U^r h_{t-1} + V^r c_t) \\ h_t^{'} &= \tanh(W y_t + U(r_t \odot h_{t-1}) + V c_t) \\ z_t &= \sigma(W^z y_t + U^z h_{t-1} + V^z c_t) \\ d_t &= \sigma(W^d y_t + U^d h_{t-1} + V^d c_t) \\ c_t &= d_t \odot c_{t-1} \\ h_t &= (1 \ - \ z_t) \odot h_t^{'} \ + \ z_t \odot h_{t-1} + \tanh(V^h c_t) \end{aligned}$$

in which, c_t is the semantic embedding at time t, which is initialized with C, and changed with a extraction gate d_t. The introduced extraction gate d_t retrieve and remove information from the semantic vector C to generate the corresponding target word.

To force our model to generate the target sentence keeping information contained in C unchanged, two additional terms are introduced into the cost function:

$$\sum_t \log(p(y_t|C)) + \|c_T\|_2 + \frac{1}{T}\sum_{j=1}^{T} \|d_t - d_{t-1}\|_2$$

where the first term is log-likelihood cost, the same as in the encoder-decoder. And the other two terms are introduced penalty terms. $\|c_T\|_2$ is for forcing the decoding neural network to extract as much information as possible from the semantic vector C, thus the generated target sentence keeps the same meaning with the source sentence. The third term is to restrict the extract gate from extracting too much information in semantic vector C at each time-stamp.

For the semantic tuples in Table 2, our modified RNN generates the target sentence word by word, until meets the end symbol character: "*I want a white 4G cellphone with a big screen.*".

2.3 Combination

The two components of KBSE (**Source Grounding** and **Target Generation**) are separately trained, and can be used in three ways:

- **Source Grounding** can be used to do semantic grounding for a given sentence and get the key information as a form of tuples;
- **Target Generation** can generate a natural language sentence based on the existing semantic tuples;
- Combining them, KBSE can be used to translation a source sentence into another language with a semantic space defined by a given knowledge base.

3 Experiments

To evaluate our proposed KBSE model, in this section, we conduct experiments on two Chinese-to-English translation tasks. One is from electric business domain, and the other is from movie domain.

3.1 Baseline and Comparison Systems

We select two baseline systems. The first one is an in-house implementation of hierarchical phrase-based SMT (Koehn et al., 2003; Chiang, 2007) with traditional features, which achieves a similar performance to the state-of-the-art phrase-based decoder in Moses [1] (Koehn et al., 2007). The 4-gram language model is trained with target sentences from training set plus the Gigaword corpus [2]. Our phrase-based system is trained with MERT (Och, 2003). The other system is the encoder-decoder system (van Merriënboer et al., 2015) [3], based on which our KBSE is implemented.

We also combine KBSE with encoder-decoder system, by adding the knowledge-based semantic embedding to be another context vector. Hence, for the decoder there are two context vectors, one from the encoder and the other is generated by the **Semantic Grounding** part. We call this model Enc-Dec+KBSE.

For our proposed KBSE, the number of hidden units in both parts are 300. Embedding size of both source and target are 200. Adadelta (Zeiler, 2012) is leveraged as the optimizer for neural network training. The batch size is set to 128, and learning rate is initialized as 0.5. The model weights are randomly initialized from uniform distribution between [-0.005, 0.005].

Source Sentence	Semantic Tuples
我要 iPhone 移 版 的	*Category.cellphone* *Carrier.China_Mobile* *Brand.iPhone*
黑客帝国 是 一部 由 沃卓斯基 兄弟 执导 的 科幻 电影 ， 影片 语言 为 英语 。	*Name.The_Matrix* *Genre.science_fiction* *Director.Wachowski_bro* *Language.English*
Semantic Tuples	**Target Sentence**
Category.cellphone *Appearance.color.white* *Appearance.size.big_screen* *Network.4G_network*	I want a white 4G phone with a big screen .
Name.Pirates_of_Caribbean *Released.2003* *Country.America* *Starring.Johnny_Depp*	The Pirates of the Caribbean is a 2003 American film, starring Johnny Depp .

Table 3: Illustration of dataset structure in this paper. We show one example for both corpus in both part, respectively.

3.2 Dataset Details

To train our KBSE system, we only need two kinds of pairs: the pair of source sentence and semantic tuples to train our **Source Grounding**, the pair of semantic tuples and target sentence to train our **Target Generation**. Examples of our training data in the electric business and movie domains are shown in Table 3. To control the training process of KBSE, we randomly split 1000 instances from both corpus for validation set and another 1000 instances for test set. Our corpus of electric business domain consists of bilingual sentence pairs labeled with KB tuples manually [4], which is a collection of source-KB-target triplets. For the Movie domain, all the data are mined from web, thus we only have small part of source-KB-target triplets. In order to show the advantage of our proposed KBSE, we also mined source-KB pairs and KB-target pairs separately. It should be noted that, similar as the encoder-decoder method, bilingual data is needed for Enc-Dec+KBSE, thus with the added knowledge tuples, Enc-Dec+KBSE are trained with source-KB-target triplets.

[3] The implementation is from https://github.com/mila-udem/blocks-examples

[4] Due to the coverage problem, knowledge bases of common domain (such as Freebase) are not used in this paper.

	Electric Business			Movie		
Model	**BLEU**	**HumanEval**	**Tuple F-score**	**BLEU**	**HumanEval**	**Tuple F-score**
SMT	54.30	78.6	-	42.08	51.4	-
Enc-Dec	60.31	90.8	-	44.27	65.8	-
KBSE	62.19	97.1	92.6	47.83	72.4	80.5
Enc-Dec + KBSE	64.52	97.9	-	46.35	74.6	-
KBSE upperbound	63.28	98.2	100	49.68	77.1	100

Table 4: The BLEU scores, human evaluation accuracy, tuple F-score for the proposed KBSE model and other benchmark models.

Our electric business corpus contains **50,169** source-KB-target triplets. For this data, we divide the intention of electric business into 11 classes, which are *Category, Function, Network, People, Price, Appearance, Carrier, Others, Performance, OS* and *Brand*. Each class above also has subclasses, for example *Category* class has subclass *computer* and *cellphone*, and *computer* class can be divided into *laptop, tablet_PC, desktop* and *AIO*.

Our movie corpus contains **44,826** source-KB-target triplets, together with **76,134** source-KB pairs and **85,923** KB-target pairs. The data is crawling from English Wikipedia [5] and the parallel web page in Chinese Wikipedia [6]. Simple rule method is used to extract sentences and KB pairs by matching the information in the infobox and the sentences in the page content. Since not all the entities from Chinese wikipedia has english name, we have an extra entity translator to translate them. For a fair comparison, this entity translator are also used in other systems. Due to the whole process is semi-automatic, there may be a few irregular results within. We divided the intention of movie data into 14 classes, which are *BasedOn, Budget, Country, Director, Distributor, Genre, Language, Name, Producer, Released, Starring, Studio, Theme* and *Writer*.

3.3 Evaluation

We use BLEU (Papineni et al., 2002) as the automatical evaluation matrix, significant testing is carried out using bootstrap re-sampling method (Koehn, 2004) with a 95% confidence level. As an addition, we also do human evaluation for all the comparison systems. Since the first part **Source Grounding** of our KBSE is separately trained, the F-score of KB tuples is also evaluated. Table 4 lists evaluation results for the electric business and movie data sets.

3.3.1 BLEU Evaluation

From Table 4, we can find that our proposed method can achieve much higher BLEU than SMT system, and we can also achieve 1.9 and 3.6 BLEU points improvement compared with the raw encoder-decoder system on both eletric business and movies data.

For the Enc-Dec+KBSE method, with the same training data on electric business domain, introducing knowledge semantic information can achieve about 4 BLEU points compared with the encoder-decoder and more than 2 BLEU points compared with our KBSE. Compared with encoder-decoder, Enc-Dec+KBSE method leverages the constrained semantic space, so that key semantic information can be extracted. Compared with KBSE, which relies on the knowledge base, Enc-Dec+KBSE method can reserve the information which is not formulated in the knowledge base, and also may fix errors generated in the source grounding part.

Since Enc-Dec+KBSE can only be trained with source-KB-target triplets, for the movie dataset, the performance is not as good as our KBSE, but still achieves a gain of more than 2 BLEU point compared with the raw Enc-Dec system. On movie data, our KBSE can achieve significant improvement compared with the models (SMT, Enc-Dec, Enc-Dec+KBSE) only using bilingual data. This shows the advantage of our proposed method, which is our model can leverage monolingual data to learn **Source Grounding** and **Target Generation** separately.

We also separately evaluate the **Source Grounding** and **Target Generation** parts. We evaluate the F-score of generated KB tuples

[5] https://en.wikipedia.org
[6] https://zh.wikipedia.org

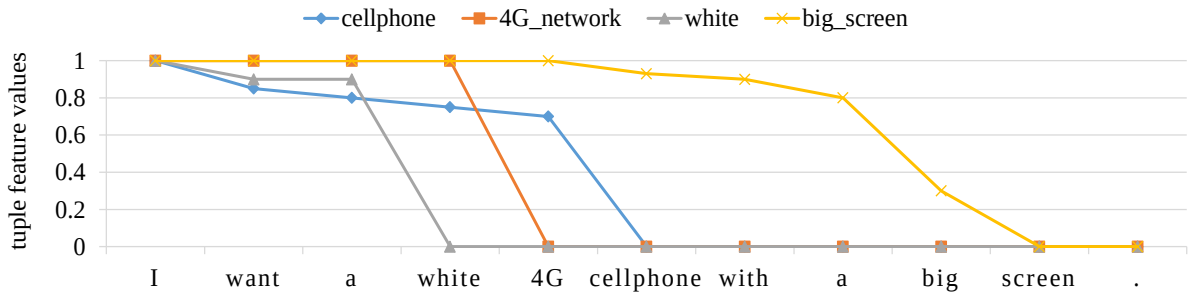

Figure 5: An example showing how the KB tuples control the tuple features flowing into the network via its learned semantic gates.

compared with the golden KB tuples. The result shows that our semantic grounding performance is quite high (92.6%), which means the first part can extract the semantic information in high coverage and accuracy. We evaluate the translation result by feeding the Target Generation network with human labeled KB tuples. The translation result (shown as KBSE upperbound in Table 4) with golden KB tuples can achieve about 1.1 and 1.8 BLEU scores improvement compared with KBSE with generated KB tuples in both dataset.

3.3.2 Human Evaluation

For the human evaluation, we do not need the whole sentence to be totally right. We focus on the key information, and if a translation is right by main information and grammar correction, we label it as correct translation, no matter how different of the translation compared with the reference on surface strings. Examples of correct and incorrect translations are shown in Table 5. As shown in Table 4, the human evaluation result shares the same trend as in BLEU evaluation. Our proposed method achieves the best results compared with SMT and raw encoder-decoder. In our method, important information are extracted and normalized by encoding the source sentence into the semantic space, and the correct translation of important information is key for human evaluation, thus our method can generate better translation.

3.4 Qualitative Analysis

In this section, we compare the translation result with baseline systems. Generally, since KB is introduced, our model is good at memorizing the key information of the source sentence. Also thanks to the strong learning ability of GRU, our model rarely make grammar mistakes. In many translations generated by traditional SMT, key information is lost. Encoder-Decoder system does much better, but some key information is also lost or even repetitively generated. Even for a long source sentence with a plenty of intentions, our model can generate the correct translation.

Target	I want a black Dell desktop.
Correct	I want a **Dell black** desktop. Could you please recommend me a black Dell desktop?
Incorrect	I want a **white** Dell desktop. I want a black Dell **laptop**. I want a black Dell desktop **desktop**.

Table 5: Some examples of which kind of sentence can be seen as a correct sentence and which will be seen as incorrect in the part of human evaluation.

To show the process of Target Generation, Figure 5 illustrates how the KB-tuples control the target sentence generation. Taking the semantic tuple *Appearance.color.white* as an example, the GRU keeps the feature value almost unchanged until the target word "white" is generated. Almost all the feature values drop from 1 to 0, when the corresponding words generated, except the tuple *Appearance.size.big_screen*. To express the meaning of this tuple, the decoding neural network should generate two words, "big" and "screen". When the sentence finished, all the feature values should be 0, with the constraint loss we introduced in Section 2.2.

Table 6 lists several translation example generated by our system, SMT system and the Encoder-Decoder system. The traditional SMT model sometimes generate same words or phrases several times, or some information is not translated. But our model rarely repeats or lose information. Besides, SMT often generate sentences unreadable, since some functional words are lost. But for KB-

Source	啊， 那个 有 大 屏幕 的 4G 手机 吗 ？ 要 白色 的 。
Reference	I want a 4G network cellphone with China Telecom supported.
KBSE	I need a white 4G cellphone with China Telecom supported.
Enc-Dec	I want a 3G cellphone with China Telecom.
SMT	Ah, that has a big screen, 4G network cellphone? give white.
Source	黑客帝国 是 一部 2003 年 由 沃卓斯基 兄弟 执导 的 电影， 里维斯 主演， 影片 语言 为 英语 。
Reference	The Matrix is a 2003 English film directed by Wachowski Brothers, starring Keanu Reeves.
KBSE	The Matrix is a 2003 English movie starring Keanu Reeves, directed by Wachowski Brothers.
Enc-Dec	The Matrix is a 2013 English movie directed by Wachowski, starring Johnny Depp.
SMT	The Matrix is directed by the Wachowski brothers film, and starring film language English.

Table 6: Examples of some translation results for our proposed KBSE system and the baseline systems.

SE, the target sentence is much easier to read. The Encoder-Decoder model learns the representation of the source sentence to a hidden vector, which is implicit and hard to tell whether the key information is kept. However KBSE learns the representation of the source sentence to a explicit tuple embedding, which contains domain specific information. So sometimes when encoder-decoder cannot memorize intention precisely, KBSE can do better.

3.5 Error Analysis

Our proposed KBSE relies on the knowledge base. To get the semantic vector of source sentence, our semantic space should be able to represent any necessary information in the sentence. For example, since our designed knowledge base do not have tuples for number of objects, some results of our KBSE generate the entities in wrong plurality form. Since our KBSE consists of two separate parts, the **Source Grounding** part and the **Target Generation** part, the errors generated in the first part cannot be corrected in the following process. As we mentioned in Section 3.3.1, combining KBSE with encoder-decoder can alleviate these two problems, by preserving information not captured and correct the errors generated in source grounding part.

4 Related Work

Unlike previous works using neural network to learn features for traditional log-linear model (Liu et al., 2013; Liu et al., 2014), Sutskever et al. (2014) introduced a general end-to-end approach based on an encoder-decoder framework. In order to compress the variable-sized source sentence into a fixed-length semantic vector, an encoder RNN reads the words in source sentence and generate a hidden state, based on which another decoder RNN is used to generate target sentence. Different from our work using a semantic space defined by knowledge base, the hidden state connecting the source and target RNNs is a vector of implicit and inexplicable real numbers.

Learning the semantic information from a sentence, which is also called semantic grounding, is widely used for question answering tasks (Liang et al., 2011; Berant et al., 2013; Bao et al., 2014; Berant and Liang, 2014). In (Yih et al., 2015), with a deep convolutional neural network (CNN), the question sentence is mapped into a query graph, based on which the answer is searched in knowledge base. In our paper, we use RNN to encode the sentence to do fair comparison with the encoder-decoder framework. We can try using CNN to replace RNN as the encoder in the future.

To generate a sentence from a semantic vector, Wen et al. (2015) proposed a LSTM-based natural language generator controlled by a semantic vector. The semantic vector memorizes what information should be generated for LSTM, and it varies along with the sentence generated. Our **Target Generation** part is similar with (Wen et al., 2015), while the semantic vector is not predefined, but generated by the **Source Grounding** part.

5 Conclusion and Future Work

In this paper, we propose a Knowledge Based Semantic Embedding method for machine translation, in which **Source Grounding** maps the source sentence into a semantic space, based on which **Target Generation** is used to generate the translation. Unlike the encoder-decoder neural network, in which the semantic space is implicit, the semantic space of KBSE is defined by a given knowledge base. Semantic vector generated by KBSE can extract and ground the key information, with the help of knowledge base, which is preserved in the translation sentence. Experiments are conducted on a electronic business and movie data sets,

and the results show that our proposed method can achieve significant improvement, compared with conventional phrase SMT system and the state-of-the-art encoder-decoder system.

In the future, we will conduct experiments on large corpus in different domains. We also want to introduce the attention method to leverage all the hidden states of the source sentence generated by recurrent neural network of **Source Grounding**.

One for All: Towards Language Independent Named Entity Linking

Avirup Sil and **Radu Florian**
IBM T. J. Watson Research Center
1101 Kitchawan Road
Yorktown Heights, NY 10598
avi@us.ibm.com, raduf@us.ibm.com

Abstract

Entity linking (EL) is the task of disambiguating mentions in text by associating them with entries in a predefined database of mentions (persons, organizations, etc). Most previous EL research has focused mainly on one language, English, with less attention being paid to other languages, such as Spanish or Chinese. In this paper, we introduce LIEL, a Language Independent Entity Linking system, which provides an EL framework which, once trained on one language, works remarkably well on a number of different languages without change. LIEL makes a joint global prediction over the entire document, employing a discriminative reranking framework with many domain and language-independent feature functions. Experiments on numerous benchmark datasets, show that the proposed system, once trained on one language, English, outperforms several state-of-the-art systems in English (by 4 points) and the trained model also works very well on Spanish (14 points better than a competitor system), demonstrating the viability of the approach.

1 Introduction

We live in a golden age of information, where we have access to vast amount of data in various forms: text, video and audio. Being able to analyze this data automatically, usually involves filling a relational database, which, in turn, requires the processing system to be able to identify actors across documents by assigning unique identifiers to them. Entity Linking (EL) is the task of mapping specific textual mentions of entities in a text document to an entry in a large catalog of entities, often called a knowledge base or KB, and is one of the major tasks in the Knowledge-Base Population track at the Text Analysis Conference (TAC) (Ji et al., 2014). The task also involves grouping together (clustering) NIL entities which do not have any target referents in the KB.

Previous work, pioneered by (Bunescu and Pasca, 2006; Cucerzan, 2007; Sil et al., 2012; Ratinov et al., 2011; Guo et al., 2013), have used Wikipedia as this target catalog of entities because of its wide coverage and its frequent updates made by the community. As with many NLP approaches, most of the previous EL research have focused on English, mainly because it has many NLP resources available, it is the most prevalent language on the web, and the fact that the English Wikipedia is the largest among all the Wikipedia datasets. However, there are plenty of web documents in other languages, such as Spanish (Fahrni et al., 2013; Ji et al., 2014), and Chinese (Cao et al., 2014; Shi et al., 2014), with a large number of speakers, and there is a need to be able to develop EL systems for these languages (and others!) quickly and inexpensively.

In this paper, we investigate the hypothesis that we can train an EL model that is entirely unlexicalized, by only allowing features that compute similarity between the text in the input document and the text/information in the KB. For this purpose, we propose a novel approach to entity linking, which we call Language Independent Entity Linking (henceforth LIEL). We test this hypothesis by applying the English-trained system on Spanish and Chinese datasets, with great success.

This paper has three novel contributions: 1) extending a powerful inference algorithm for global entity linking, built using similarity measures, corpus statistics, along with knowledge base statis-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2255–2264,
Berlin, Germany, August 7-12, 2016.

tics, 2) integrates many language-agnostic and domain independent features in an exponential framework, and 3) provide empirical evidence on a large variety of popular benchmark datasets that the resulting model outperforms or matches the best published results, and, most importantly, the trained model transfers well across languages, outperforming the state-of-the-art (SOTA) in Spanish and matching it in Chinese.

We organize the paper as follows: the next section motivates the problem and discusses the language-independent model along with the features. Section 3 describes our experiments and comparison with the state-of-the-art. Section 4 illustrates the related previous work and Section 5 concludes.

2 Problem Formulation

2.1 Motivation for Language Independence

Our strategy builds an un-lexicalized EL system by training it on labeled data, which consists of pairs of mentions in text and entries in a database extracted from a Wikipedia collection in English. Unlike traditional EL, however, the purpose here is to be able to perform entity linking with respect to any Wikipedia collection. Thus the strategy must take care to build a model that can transfer its learned model to a new Wikipedia collection, without change.

At a first glance, the problem seems very challenging - learning how to discriminate `Lincoln,_Nebraska` and `Abraham_Lincoln` [1], the former US President, seemingly bears little resemblance to disambiguating between different Spanish person entities named "Ali Quimico". The crux of the problem lies in the fact that Wikipedia-driven features are language-specific: for instance, counting how many times the category `2010 Deaths` appears in the context of an entity is highly useful in the English EL task, but not directly useful for Spanish EL. Also, learning vocabulary-specific information like the list of "deaths", "presidents", etc. is very useful for disambiguating person entities like "Lincoln" in English, but the same model, most likely, will not work for mentions like "李娜" in a Chinese document which might either refer to the famous athlete 李娜 (网球运动员) or the singer 李娜 (歌手).

[1] Teletype font denotes Wikipedia titles and categories.

Practically we assume the existence of a knowledge base that defines the space of entities we want to disambiguate against, where each entry contains a document with the entity; Wikipedia is a standard example for this[2]. If there are other properties associated with the entries, such as categories, in-links, out-links, redirects, etc., the system can make use of them, but they are theoretically not required. The task is defined as: given a mention m in a document d, find the entry e in the knowledge base that m maps to.

We expand on the architecture described in (Sil and Yates, 2013) (henceforth NEREL), because of the flexibility provided by the feature-based exponential framework which results in an English SOTA EL system. However, we design all our features in such a way that they measure the similarity between the context where the mention m appears in d and the entries in the knowledge base. For example, instead of counting how often the category `2010 Deaths` [3] appears in the context around an entity mention, we create a feature function such as **CATEGORY FREQUENCY**(m, e), which counts how often any category of entity referent e appears in the context of mention m. For entities like `Lincoln,_Nebraska` in the English EL, **CATEGORY FREQUENCY** will add together counts for appearances of categories like `Cities in Lancaster County, Nebraska` and `Lincoln metropolitan area`, among other categories. At the same time, in the Spanish EL domain, **CATEGORY FREQUENCY** will add together counts for `Políticos de Irak` and `Militares de Irak` for the KB id corresponding to "Ali Quimico". This feature is well-defined in both domains, and larger values of the feature indicate a better match between m and e. As mentioned earlier, it is our hypothesis, that the parameters trained for such features on one language (English, in our case) can be successfully used, without retraining, on other languages, namely Spanish and Chinese.

While training, the system will take as input a knowledge base in source language S, KB_S (extracted from Wikipedia) and a set of training examples (m_i, e_i, g_i), where instances m_i are mentions in a document of language S, e_i are entity links, $e_i \in KB_S$, and g_i are Boolean val-

[2] We will assume, without loss of generality, that the knowledge base is derived from Wikipedia.

[3] Or a specific Freebase type.

ues indicating the gold-standard match / mismatch between m_i and e_i. During decoding, given language T[4], the system must classify examples (m_j, e_j) drawn from a *target* language T and knowledge-base KB_T.

2.2 LIEL: Training and Inference

Our language-independent system consists of two components: 1. extracting mentions of named-entities from documents and 2. linking the detected mentions to a knowledge base, which in our case is Wikipedia (focus of this paper). We run the IBM Statistical Information and Relation Extraction (SIRE) [5] system which is a toolkit that performs mention detection, relation extraction, coreference resolution, *etc.* We use the system to extract mentions and perform coreference resolution: in particular, we use the CRF model of IBM SIRE for mention detection and a maximum entropy clustering algorithm for coreference resolution. The system identifies a set of 53 entity types. To improve the mention detection and resolution, case restoration is performed on the input data. Case restoration is helpful to improve the mention detection system's performance, especially for discussion forum data. Obviously, this processing step is language-dependent, as the information extraction system is - but we want to emphasize that the entity linking system is language independent.

In the EL step, we perform a full document entity disambiguation inference, described as follows. Given a document d, and a selected mention $m \in d$, our goal is to identify its label $\hat{e}$ that maximizes

$$\begin{aligned} \hat{e} &= P(e|m,d) \qquad (1) \\ &= \arg\max_{e:m} \sum_{k, m \in m_1^k, e_1^k} P\left(m_1^k|m,d\right) P\left(e_1^k|m_1^k,d\right) \end{aligned}$$

where m_1^k are mentions found in document d, and e_1^k are some label assignment. In effect, we are looking for the best mention labeling of the entire document m_1^k (that contains m) and a label to these mentions that would maximize the information extracted from the entire document. Since direct inference on Equation 1 is hard, if not intractable, we are going to select the most likely mention assignment instead (as found by an information extraction system): we will only consider the detected mentions $(m_1, \ldots, m_k)$, and other optional information that can be extracted from the document, such as links l, categories r, etc. The goal becomes identifying the set of labels $(e_1, \ldots, e_k)$ that maximize

$$P\left(e_1^k|m_1^k,d\right) \qquad (2)$$

Since searching over all possible sets of (mention, entity)-pairs for a document is still intractable for reasonable large values of k, typical approaches to EL make simplifying assumption on how to compute the probability in Equation 2. Several full-document EL approaches have investigated generating up to N global tuples of entity ids $(e_1, \ldots, e_k)$, and then build a model to rank these tuples of entity ids (Bunescu and Pasca, 2006; Cucerzan, 2007). However, Ratinov *et al.* (Ratinov et al., 2011) argue that this type of global model provides a relatively small improvement over the purely-local approach (where $P\left(e_1^k|m_1^k,d\right) = \prod_i P\left(e_i|m_i,d\right)$). In this paper, we follow an approach which combines both of these strategies.

Following the recent success of (Sil and Yates, 2013), we partition the full set of extracted mentions, $(m_i)_{i=1,n}^{-}$ of the input document d into smaller subsets of mentions which appear near one another: we consider two mentions that are closer then 4 words to be in the same connected component, then we take the transitive closure of this relation to partition the mention set. We refer to these sets as the *connected components* of d, or $CC(d)$. We perform classification over the set of entity-mention tuples $T(C) = \left\{\left(e_{i_1}, \ldots, e_{i_{n_C}}|m_{i_1}, \ldots, m_{i_{n_C}}\right)|e_{i_j} \in KB, \forall j\right\}$ [6] that are formed using candidate entities within the same connected component $C \in CC(d)$. Consider this small snippet of text:

"... Home Depot CEO Nardelli quits ..."

In this example text, the phrase "Home Depot CEO Nardelli" would constitute a connected component. Two of the entity-mention tuples for this connected component would be: (`Home_Depot`, `Robert_Nardelli` |"Home Depot", "Nardelli") and (`Home_Depot`, `Steve_Nardelli` | "Home Depot","Nardelli").

[4] Language prediction can be done relatively accurately, given a document; however, in this paper, we focus on the EL task, so we assume we know the identity of the target language T.

[5] The IBM SIRE system can be currently accessed at : http://www.ibm.com/smarterplanet/us/en/ibmwatson/developercloud/relationship-extraction.html

[6] For simplicity, we denote by $(e|m)$ the tuple (e, m), written like that to capture the fact that m is fixed, while e is predicted.

2.2.1 Collective Classification Model

To estimate $P(t|d, C)$, the probability of an entity-mention tuple t for a given connected component $C \in CC(d)$, LIEL uses a maximum-entropy model:

$$P(t|d, C) = \frac{\exp(\mathbf{w} \cdot \mathbf{f}(t, d, C))}{\sum_{t' \in T(C)} \exp(\mathbf{w} \cdot \mathbf{f}(t', d, C))} \quad (3)$$

where $\mathbf{f}(t, d, C)$ is a feature vector associated with t, d, and C, and w is a weight vector. For training, we use L2-regularized conditional log likelihood (CLL) as the objective

$$CLL(G, \mathbf{w}) = \sum_{(t,d,C) \in G} \log P(t|d, C, \mathbf{w}) - \sigma \|\mathbf{w}\|_2^2 \quad (4)$$

where G is the gold-standard training data, consisting of pairs (t, d, C), where t is the correct tuple of entities and mentions for connected component C in document d, and σ is a regularization parameter. Given that the function 4 is convex, we use LBFGS (Liu and Nocedal, 1989) to find the globally optimal parameter settings over the training data.

2.3 Extracting potential target entities

From the dump of our Wikipedia data, we extract all the mentions that can refer to Wikipedia titles, and construct a set of disambiguation candidates for each mention (which are basically the hyperlinks in Wikipedia). This is, hence, an anchor-title index that maps each distinct hyperlink anchor-text to its corresponding Wikipedia titles and also stores their relative popularity score. For example, the anchor text (or mention) "Titanic" is used in Wikipedia to refer both to the ship or to the movie. To retrieve the disambiguation candidates e_i for a given mention m_i, we query the anchor-title index that we constructed and use lexical sub-word matching. e_i is taken to be the set of titles (or entities, in the case of EL) most frequently linked to with anchor text m_i in Wikipedia. We use only the top 40 most frequent Wikipedia candidates for the anchor text for computational efficiency purposes for most of our experiments. We call this step "Fast Search" since it produces a bunch of candidate links by just looking up an index.

2.3.1 Decoding

At decoding time, given a document d, we identify its connected components $CC(d)$ and run inference on each component C containing the desired input mention m. To further reduce the run time, for each mention $m_j \in C$, we obtain the set of potential labels e_j using the algorithm described in Section 2.3, and then exhaustively find the pair that maximizes equation 3. For each candidate link, we also add a NIL candidate to fast match to let the system link mentions to ids not in a KB.

2.4 Language-Independent Feature Functions

LIEL makes use of new as well as well-established features in the EL literature. However, we make sure to use only non-lexical features. The local and global feature functions computed from this extracted information are described below.

Generically, we have two types of basic features: one that takes as input a KB entry e, the mention m and its document and a second type that scores two KB entries, e_1 and e_2. When computing the probability in Equation 3, where we consider a set of KB entries t[7], we either sum or apply a boolean AND operator (in case of boolean features) among all entities $e \in t$, while the entity-entity functions are summed/and'ed for consecutive entities in t. We describe the features in these terms, for simplicity.

2.4.1 Mention-Entity Pair Features

Text-based Features: We assume the existence of a document with most entries in the KB, and the system uses similarity between the input document and these KB documents. The basic intuition behind these features, inspired by Ratinov *et al.*(2011), is that a mention $m \in d$ is more likely to refer to entity e if its KB page, $W(e)$, has high textual similarity to input document d. Let $Text(W(e))$ be the vector space model associated with $W(e)$, $Top(W(e))$ be the vector of the top most frequently occurring words (excluding stop-words) from $W(e)$, and $Context(W(e))$ be the vector space of the 100 word window around the first occurrence of m in $W(e)$. Similarly, we create vector space models $Text(m)$ and $Context(m)$. We then use cosine similarity over these vector space models as features:
i. cosine($Text(W(e)), Text(m)$),
ii. cosine($Text(W(e)), Context(m)$),
iii. cosine($Context(W(e)), Text(m)$),
iv. cosine($Context(W(e)), Context(m)$),
v. cosine($Top(W(e)), Text(m)$),

[7]Recall that the probability is computed for all the entity assignments for mentions in a clique.

vi. cosine $(Top\,(W\,(e))\,, Context\,(m))$.

KB Link Properties: LIEL can make use of existing relations in the KB, such as inlinks, outlinks, redirects, and categories. Practically, for each such relation l, a KB entry e has an associated set of strings $I(l, e)$[8]; given a mention-side set M (either $Text(m)$ or $Context(m)$), LIEL computes **FREQUENCY** feature functions for the names of the Categories, Inlinks, Outlinks and Redirects, we compute

$$f(e, m, d) = |I(l, e) \cap M|$$

Title Features: LIEL also contains a number of features that make use of the Wikipedia title of the entity links in t (remember t = entity mention tuples and not a Wikipedia title) :

- **NIL FREQUENCY**: Computes the frequency of entities that link to NIL
- **EXACT MATCH FREQUENCY**: returns 1 if the surface form of m is a redirect for e;
- **MATCH ALL**: returns true if m matches *exactly* the title of e;
- **MATCH ACRONYM**: returns true if m is an acronym for a redirect of e;
- **LINK PRIOR**: the prior link probability $P(e|m)$, computed from anchor-title pairs in KB (described in Section 2.3).

2.4.2 Entity-Entity Pair Features

Coherence Features: To better model consecutive entity assignments, LIEL computes a coherence feature function called **OUTLINK OVERLAP**. For every consecutive pair of entities (e_1, e_2) that belongs to mentions in t, the feature computes $\text{Jaccard}(Out(e_1), Out(e_2))$, where $Out(e)$ denotes the Outlinks of e. Similarly, we also compute **INLINK OVERLAP**.

LIEL also uses categories in Wikipedia which exist in all languages. The first feature **ENTITY CATEGORY PMI**, inspired by Sil and Yates (2013), make use of Wikipedia's category information system to find patterns of entities that commonly appear next to one another. Let $\mathcal{C}(e)$ be the set of Wikipedia categories for entity e. We manually inspect and remove a handful of common Wikipedia categories based on threshold frequency on our training data, which are associated with almost every entity in text, like `Living People` etc., since they have lower discriminating power. These are analogous to all WP languages. From the training data, the system first computes point-wise mutual information (PMI) (Turney, 2002) scores for the Wikipedia categories of pairs of entities, (e_1, e_2):

$$PMI(\mathcal{C}(e_1), \mathcal{C}(e_2)) = \frac{\sum_{j=1}^{n_{t_\mathcal{C}}-1} \mathbf{1}[\mathcal{C}(e_1) = \mathcal{C}(e_{i_j}) \wedge \mathcal{C}(e_2) = \mathcal{C}(e_{i_{j+1}})]}{\sum_j \mathbf{1}[\mathcal{C}(e_1) = \mathcal{C}(e_{i_j})] \times \sum_j \mathbf{1}[\mathcal{C}(e_2) = \mathcal{C}(e_{i_j})]}$$

- **ENTITY CATEGORY PMI** adds these PMI scores up for every consecutive (e_1, e_2) pair in t.
- **CATEGORICAL RELATION FREQUENCY** We would like to boost consecutive entity assignments that have been seen in the training data. For instance, for the text "England captain Broad fined for..", we wish to encourage the tuple that links "England" to the entity id of the team name `England cricket team`, and "Broad" to the entity id of the person `Stuart Broad`. Wikipedia contains a relation displayed by the category called `English_cricketers` that indicates that `Stuart Broad` is a team member of `England cricket team`, and counts the number of such relations between every consecutive pair of entities in $(e, e') \in t$.
- **TITLE CO-OCCURRENCE FREQUENCY** feature computes for every pair of consecutive entities $(e, e') \in t$, the number of times that e' appears as a link in the Wikipedia page for e, and *vice versa* (similar to (Cucerzan, 2007). It adds these counts up to get a single number for t.

3 Experiments

We evaluate LIEL's capability by testing against several state-of-the-art EL systems on English, then apply the English-trained system to Spanish and Chinese EL tasks to test its language transcendability.

3.1 Datasets

English: The 3 benchmark datasets for the English EL task are: **i)** ACE (Ratinov et al., 2011), **ii)** MSNBC (Cucerzan, 2007) and **iii)** TAC 2014 (Ji et

[8]For instance, redirect strings for "Obama" are "Barack Obama", "Barack Obama Jr." and "Barack Hussein Obama".

Name	$\|M\|$	In KB	Not in KB
ACE	257	100%	0
MSNBC	747	90%	10%
TAC_En14	5234	54%	46%
TAC_Es13	2117	62%	38%
TAC_Es14	2057	72%	28%
TAC_Zh13	2155	57%	43%
WikiTrain	158715	100%	0%

Table 1: Data statistics: number of mention queries, % of mention queries that have their referents present in the Wikipedia/KB, and % of mention queries that have no referents in Wikipedia/KB as per our datasets. En=English, Es=Spanish and Zh=Chinese for the evaluation data for TAC for the years 2013 and 2014.

al., 2014)[9], which contain data from diverse genre like discussion forum, blogs and news. Table 1 provides key statistics on these datasets. In the TAC[10] evaluation setting, EL systems are given as input a document and a query mention with its offsets in the input document. As the output, systems need to predict the KB id of the input query mention if it exists in the KB or NIL if it does not. Further, they need to cluster the mentions which contain the same NIL ids across queries.

The training dataset, WikiTrain, consists of 10,000 random Wikipedia pages, where all of the phrases that link to other Wikipedia articles are treated as mentions, and the target Wikipedia page is the label. The dataset was made available by Ratinov *et al.* and (Sil and Yates, 2013), added Freebase to Wikipedia mappings resulting in 158,715 labeled mentions with an average of 12.62 candidates per mention. The total number of unique mentions in the data set is 77,230 with a total of 974,381 candidate entities and 643,810 unique candidate entities. The Wikipedia dump that we used as our knowledge-base for English, Spanish and Chinese is the April 2014 dump. The TAC dataset involves the TAC KB which is a dump of May 2008 of English Wikipedia. LIEL links entities to the Wikipedia 2014 dump and uses the redirect information to link back to the TAC KB.

Spanish: We evaluate LIEL on both the 2013 and 2014 benchmark datasets of the TAC Spanish evaluation.

Chinese: We test LIEL on the TAC 2013 Chinese dataset.

3.2 Evaluation Metric

We follow standard measures used in the literature for the entity linking task. To evaluate EL accuracy on ACE and MSNBC, we report on a Bag-of-Titles (BOT) F1 evaluation as introduced by (Milne and Witten, 2008; Ratinov et al., 2011). In BOT-F1, we compare the set of Wikipedia titles output for a document with the gold set of titles for that document (ignoring duplicates), and compute standard precision, recall, and F1 measures. On the TAC dataset, we use standard metrics B^3+ variant of precision, recall and F1. On these datasets, the $B^3 + F1$ metric includes the clustering score for the NIL entities, and hence systems that only perform binary NIL prediction would be heavily penalized[11].

3.3 Comparison with the State-of-the-art

To follow the guidelines for the TAC NIST evaluation, we anonymize participant system names as System 1 through 9. Interested readers may look at their system description and scores in (Ji et al., 2014; Fahrni et al., 2013; Miao et al., 2013; Mayfield, 2013; Merhav et al., 2013). Out of these systems, System 1 and System 7 obtained the top score in Spanish and Chinese EL evaluation at TAC 2013 and hence can be treated as the current state-of-the-art for the respective EL tasks. We also compare LIEL with some traditional "wikifiers" like MW08 (Milne and Witten, 2008) and UIUC (Cheng and Roth, 2013) and also NEREL (Sil and Yates, 2013) which is the system which LIEL resembles the most.

3.4 Parameter Settings

LIEL has two tuning parameters: σ, the regularization weight; and the number of candidate links per mention we select from the Wikipedia dump. We set the value of σ by trying five possible values in the range [0.1, 10] on held-out data (the TAC 2009 data). We found $\sigma = 0.5$ to work best for our experiments. We chose to select a maximum of 40 candidate entities from Wikipedia for each candidate mention (or fewer if the dump had fewer than 40 links with nonzero probability).

[9]This is the traditional Entity Linking (EL) task and not Entity Discovery and Linking (EDL), since we are comparing the linking capability in this paper.

[10]For more details on TAC see http://nlp.cs.rpi.edu/kbp/2014/index.html

[11]For more details on the scoring metric used for TAC EL see: http://nlp.cs.rpi.edu/kbp/2014/scoring.html

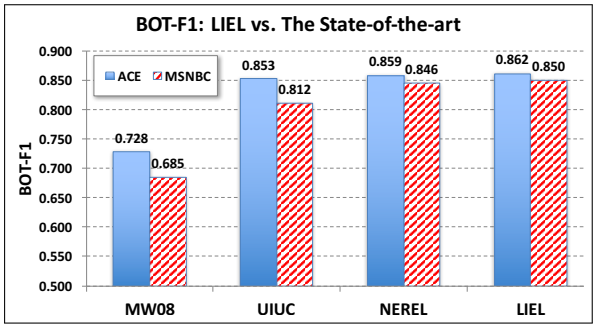

Figure 1: LIEL outperforms all its competitors on both ACE and MSNBC.

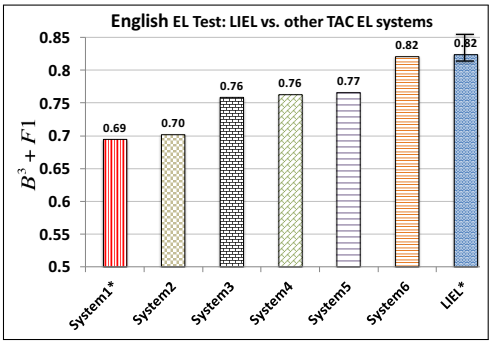

Figure 2: Comparison of several state-of-the-art English EL systems along with LIEL on the latest TAC 2014 dataset and LIEL obtains the best score. * indicates systems that perform multilingual EL.

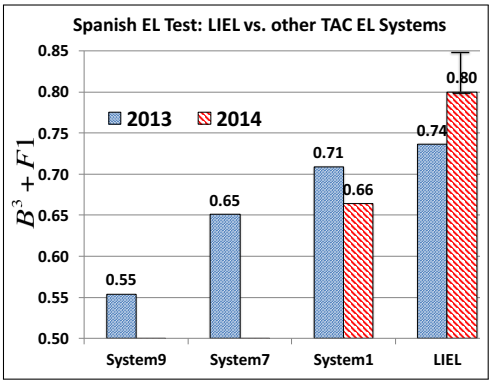

Figure 3: System performance on the TAC 2013 and 2014 Spanish datasets are shown. LIEL outperforms all the systems in terms of overall F1 score.

3.5 Results

English: Figure 1 compares LIEL with previously reported results by MW08, UIUC and NEREL on the ACE and MSNBC datasets in (Cheng and Roth, 2013; Sil and Yates, 2013). LIEL achieves an F1 score of 86.2 on ACE and 85.0 on MSNBC, clearly outperforming the others *e.g.* 3.8% absolute value higher than UIUC on MSNBC. We believe that LIEL's strong model comprising relational information (coherence features from large corpus statistics), textual and title lets it outperform UIUC and MW08 where the former uses relational information and the latter a naive version of LIEL's coherence features. Comparison with NEREL is slightly unfair (though we outperform them marginally) since they use both Freebase and Wikipedia as their KB whereas we are comparing with systems which only use Wikipedia as their KB.

To test the robustness of LIEL on a diverse genre of data, we also compare it with some of the other state-of-the-art systems on the latest benchmark TAC 2014 dataset. Figure 2 shows our results when compared with the top systems in the evaluation. Encouragingly, LIEL's performance is tied with the top performer, System 6, and outperforms all the other top participants from this challenging annual evaluation. Note that LIEL obtains 0.13 points more than System 1, the only other multi-lingual EL system and, in that sense, LIEL's major competitor. Several other factors are evident from the results: System 1 and 2 are statistically tied and so are System 3, 4 and 5. We also show the bootstrapped percentile confidence intervals (Singh and Xie, 2008) for LIEL which are [0.813, 0.841]: (we do not have access to the other competing systems).

3.5.1 Foreign Language Experiments

Note that LIEL was *trained only* on the English Wikitrain dataset (Section 3.1), and then applied, *unchanged*, to all the evaluation datasets across languages and domains described in Section 3.1. Hence, it is the same instance of the model for all languages. As we will observe, this one system consistently outperforms the state of the art, even though it is using exactly the same trained model across the datasets. We consider this to be the take-away message of this paper.

Spanish: LIEL obtains a $B^3 + F1$ score of 0.736 on the TAC 2013 dataset and clearly outperforms the SOTA, System 1, which obtains 0.709 as shown in Figure 3 and considerably higher than the other participating systems. We could only obtain the results for Systems 9 and 7 on 2013. On the 2014 evaluation dataset, LIEL obtains a higher gain of 0.136 points (precision of 0.814 and recall of 0.787) over its major competitor System 1, showing the power of its language-independent model.

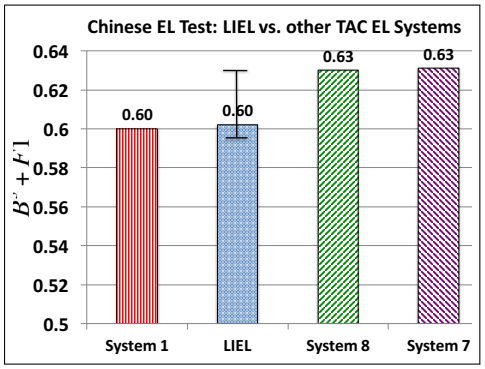

Figure 4: LIEL achieves competitive performance in Chinese EL further proving its robustness to multilingual data.

Chinese: Figure 4 shows the results of LIEL's performance on the Chinese benchmark dataset compared to the state-of-the-art. Systems 7 and 8 obtains almost similar scores. We observe that LIEL is tied with System 1 and achieves competitive performance compared to Systems 7 and 8 (note that LIEL has a confidence interval of [0.597, 0.632]) which requires labeled Chinese TAC data to be trained on and the same model does not work for other languages. Emphasizing again: LIEL is trained only *once*, on English, and tested on Chinese unchanged.

3.5.2 Error Analysis

While we see LIEL's strong multi-lingual empirical results, it is important to note some of the areas which confuses the system. Firstly, a major source of error which affects LIEL's performance is due to coreference resolution *e.g.* from the text "*Beltran Leyva, also known as "The Bearded One," is ...*", TAC's mention query asks the systems to provide the disambiguation for *The Bearded One*. LIEL predicts that the *The Bearded One* refers to the entity `Richard Branson`, which is the most common entity in Wikipedia that refers to that nickname (based on our dump), while, clearly, the correct entity should have been *Beltran Levya*. We believe that this type of an error can be handled by performing joint EL and coreference resolution, which is a promising future research area for LIEL.

Contextual information can also hurt system performance *e.g.* from the text, ".. *dijo Alex Sánchez , analista..*", LIEL predicts the Wikipedia title `Alex Sánchez (outfielder)` for the mention *Alex Sánchez* since the document talks about sports and player names. The query mention was actually referring to a journalist, not in the KB, and hence a NIL. Handling sparse entities, similar to this, are also an important future direction.

4 Related Work

Entity linking has been introduced and actively developed under the NIST-organized Text Analysis Conference, specifically the Knowledge Base Population track. The top performing English EL system in the TAC evaluation has been the MS_MLI system (Cucerzan and Sil, 2013), which has obtained the top score in TAC evaluation in the past 4 years (2011 through 2014): the system links all mentions in a document simultaneously, with the constraint that their resolved links should be globally consistent on the category level as much as possible. Since global disambiguation can be expensive, (Milne and Witten, 2008) uses the set of unambiguous mentions in the text surrounding a mention to define the mention's context, and uses the Normalized Google Distance (Cilibrasi and Vitanyi, 2007) to compute the similarity between this context and the candidate Wikipedia entry. The UIUC system, (Cheng and Roth, 2013), another state-of-the-art EL system, which is an extension of (Ratinov et al., 2011), adds relational inference for wikification. NEREL (Sil and Yates, 2013) is a powerful joint entity extraction and linking system. However, by construction their model is not language-independent due to the heavy reliance on type systems of structured knowledgebases like Freebase. It also makes use of lexical features from Wikipedia as their model performs joint entity extraction and disambiguation. Some of the other systems which use a graph based algorithm such as partitioning are LCC, NYU (Ji et al., 2014) and HITS (Fahrni et al., 2013) which obtained competitive score in the TAC evaluations. Among all these systems, only the HITS system has ventured beyond English and has obtained the top score in Spanish EL evaluation at TAC 2013. It is the only multilingual EL system in the literature which performs reliably well across a series of languages and benchmark datasets. Recently, (Wang et al., 2015) show a new domain and language-independent EL system but they make use of translation tables for non-English (Chinese) EL; thereby not making the system entirely language-independent. Empirically their performance comes close to System 1 which LIEL outperforms. The BASIS system (Merhav et al.,

2013), is the state-of-the-art for Chinese EL as it obtained the top score in TAC 2013. The FUJITSU system (Miao et al., 2013) obtained similar scores. It is worth noting that these systems, unlike LIEL, are heavily language dependent, *e.g.* performing lexicon specific information extraction, using inter-language links to map between the languages or training using labeled Chinese data.

In more specialized domains, Dai *et al.* (2011) employed a Markov logic network for building an EL system with good results in a bio-medical domain; it would be interesting to find out how their techniques might extended to other languages/corpora. Phan *et al.* (2008) utilize topic models derived from Wikipedia to help classify short text segment, while Guo *et al.* (2013) investigate methods for disambiguating entities in tweets. Neither of these methods do show how to transfer the EL system developed for short texts to different languages, if at all.

The large majority of entity linking research outside of TAC involves a closely related task - wikification (Bunescu and Pasca, 2006; Cucerzan, 2007; Ratinov et al., 2011; Guo et al., 2013), and has been mainly performed on English datasets, for obvious reasons (data, tools availability). These systems usually achieve high accuracy on the language they are trained on. Multilingual studies, e.g. (McNamee et al., 2011), use a large number of pipelines and complex statistical machine translation tools to first translate the original document contexts into English equivalents and transform the cross-lingual EL task into a monolingual EL one. The performance of the entity linking system is highly dependent on the existence and potential of the statistical machine translation system in the given pair of languages.

5 Conclusion

In this paper we discussed a new strategy for multilingual entity linking that, once trained on one language source with accompanying knowledge base, performs without adaptation in multiple target languages. Our proposed system, LIEL is trained on the English Wikipedia corpus, after building its own knowledge-base by exploiting the rich information present in Wikipedia. One of the main characteristics of the system is that it makes effective use of features that are built exclusively around computing similarity between the text/context of the mention and the document text of the candidate entity, allowing it to transcend language and perform inference on a completely new language or domain, without change or adaptation.

The system displays a robust and strong empirical evidence by not only outperforming all state-of-the-art English EL systems, but also achieving very good performance on multiple Spanish and Chinese entity linking benchmark datasets, and it does so without the need to switch, retrain, or even translate, a major differentiating factor from the existing multi-lingual EL systems out there.

On Approximately Searching for Similar Word Embeddings

Abstract

We discuss an approximate similarity search for word embeddings, which is an operation to approximately find embeddings close to a given vector. We compared several metric-based search algorithms with hash-, tree-, and graph-based indexing from different aspects. Our experimental results showed that a graph-based indexing exhibits robust performance and additionally provided useful information, e.g., vector normalization achieves an efficient search with cosine similarity.

1 Introduction

An embedding or distributed representation of a word is a real-valued vector that represents its "meaning" on the basis of *distributional semantics*, where the meaning of a word is determined by its context or surrounding words. For a given meaning space, searching for similar embeddings is one of the most basic operations in natural language processing and can be applied to various applications, e.g., extracting synonyms, inferring the meanings of polysemous words, aligning words in two sentences in different languages, solving analogical reasoning questions, and searching for documents related to a query.

In this paper, we address how to quickly and accurately find similar embeddings in a continuous space for such applications. This is important from a practical standpoint, e.g., when we want to develop a real-time query expansion system on a search engine on the basis of an embedding similarity. A key difference from the existing work is that embeddings are not high-dimensional sparse (traditional count) vectors, but (relatively) low-dimensional dense vectors. We therefore need to use approximate search methods instead of inverted-index-based methods (Zobel and Moffat, 2006). Three types of indexing are generally used in approximate similarity search: hash-, tree-, and graph-based indexing. Hash-based indexing is the most common in natural language processing due to its simplicity, while tree/graph-based indexing is preferred in image processing because of its performance. We compare several algorithms with these three indexing types and clarify which algorithm is most effective for similarity search for word embeddings from different aspects.

To the best of our knowledge, no other study has compared approximate similarity search methods focusing on neural word embeddings. Although one study has compared similarity search methods for (count-based) vectors on the basis of distributional semantics (Gorman and Curran, 2006), our study advances this topic and makes the following contributions: (a) we focus on neural word embeddings learned by a recently developed skip-gram model (Mikolov, 2013), (b) show that a graph-based search method clearly performs better than the best one reported in the Gorman and Curran study from different aspects, and (c) report the useful facts that normalizing vectors can achieve an effective search with cosine similarity, the search performance is more strongly related to a learning model of embeddings than its training data, the distribution shape of embeddings is a key factor relating to the search performance, and the final performance of a target application can be far different from the search performance. We believe that our timely results can lead to the practical use of embeddings, especially for real-time applications in the real world.

The rest of the paper is organized as follows. In Section 2, we briefly survey hash-, tree-, and graph-based indexing methods for achieving similarity search in a metric space. In Section 3, we

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2265–2275,
Berlin, Germany, August 7-12, 2016.

compare several similarity search algorithms from different aspects and discuss the results. Finally, Section 4 concludes the paper.

2 Similarity Search

We briefly survey similarity search algorithms for real-valued vectors, where we focus on approximate algorithms that can deal with large scale data. In fact, word embeddings are usually trained on a very large corpus. For example, well known pre-trained word embeddings (Mikolov, 2013) were trained on the Google News dataset and consist of about 1,000 billion words with 300-dimensional real-valued vectors. Search tasks on large-scale real-valued vectors have been more actively studied in the image processing field than in the natural language processing field, since such tasks naturally correspond to searching for similar images with their feature vectors.

Many similarity search algorithms have been developed and are classified roughly into three indexing types: hash-, tree-, and graph-based. In natural language processing, hash-based indexing seems to be preferred because of its simplicity and ease of treating both sparse and dense vectors, while in image processing, tree- and graph-based indexing are preferred because of their performance and flexibility in adjusting parameters. We explain these three indexing types in more detail below.

2.1 Hash-based Indexing

Hash-based indexing is a method to reduce the dimensionality of high-dimensional spaces by using some hash functions so that we can efficiently search in the reduced space. Locality-sensitive hashing (LSH) (Gionis et al., 1999) is a widely used hash-based indexing algorithm, which maps similar vectors to the same hash values with high probability by using multiple hash functions.

There are many hash-based indexing algorithms that extend LSH for different metric spaces. Datar et al. (2004) applied the LSH scheme to L^p spaces, or Lebesgue spaces, and experimentally showed that it outperformed the existing methods for the case of $p = 2$. Weiss et al. (2009) showed that the problem of finding the best hash function is closely related to the problem of graph partitioning and proposed an efficient approximate algorithm by reducing the problem to calculating thresholded eigenvectors of the graph Laplacian. In this paper, we focus on approximation of k-nearest neighbors and are not concerned about the hash-based indexing algorithms, since they are basically designed for finding (not k-nearest) neighbors within a fixed radius of a given point, i.e., a so-called *radius search*.

2.2 Tree-based Indexing

Tree-based indexing is used to recursively divide the entire search space into hierarchical subspaces, where the subspaces are not necessarily disjointed, so that the search space forms a tree structure. Given a search query, we can efficiently find the subspaces including the query by descending from the root note to the leaf nodes in the tree structure and then obtain its search results by scanning only neighbors belonging to the subspaces. Note that in contrast to the hash-based indexing, we can easily extend the size of search results or the number of nearest neighbors by ascending to the parent subspaces.

Arya et al. (1998) proposed the balanced box-decomposition tree (BBD-tree) as a variant of the kd-tree (Bentley, 1975) for approximately searching for similar vectors on the basis of Minkowski metrics, i.e., in L^p spaces when $p \geq 1$. Fast library for approximate nearest neighbors (FLANN) (Muja and Lowe, 2008) is an open-source library for approximate similarity search. FLANN automatically determines the optimal one from three indices: a randomized kd-tree where multiple kd-trees are searched in parallel (Silpa-Anan and Hartley, 2008), a k-means tree that is constructed by hierarchical k-means partitioning (Nister and Stewenius, 2006), and a mix of both kd-tree and k-means tree. Spatial approximation sample hierarchy (SASH) (Houle and Sakuma, 2005) achieves approximate search with multiple hierarchical structures created by random sampling. According to the results in the previous study (Gorman and Curran, 2006), SASH performed the best for vectors on the basis of distributional semantics, and its performance surpassed that of LSH.

2.3 Graph-based Indexing

Graph-based indexing is a method to approximately find nearest neighbors by using a neighborhood graph, where each node is connected to its nearest neighbors calculated on the basis of a certain metric. A simple search procedure for a given query is achieved as follows. An arbitrary node in the graph is selected as a candidate for the

true nearest neighbor. In the process of checking the nearest neighbor of the candidate, if the query is closer to the neighbor than the candidate, the candidate is replaced by the neighbor. Otherwise, the search procedure terminates by returning the current candidate as the nearest neighbor of the query. This procedure can be regarded as a best-first search, and the result is an approximation of that of an exact search.

Sebastian and Kimia (2002) first used a k-nearest neighbor graph (KNNG) as a search index, and Hajebi et al. (2011) improved the search performance by performing hill-climbing starting from a randomly sampled node of a KNNG. Their experimental results with image features, i.e., scale invariant feature transform (SIFT), showed that a similarity search based on a KNNG outperforms randomized kd-trees and LSH. Although the brute force construction cost of a KNNG drastically increases as the number of nodes increases because the construction procedure needs to calculate the nearest neighbors for each node, we can efficiently approximate a KNNG (so-called ANNG) by incrementally constructing an ANNG with approximate k-nearest neighbors calculated on a partially constructed ANNG. Neighborhood graph and tree for indexing (NGT) (Iwasaki, 2015) is a library released from Yahoo! JAPAN that achieves a similarity search on an ANNG; it has already been applied to several services.

3 Experiments

In this paper, we focused on the pure similarity search task of word embeddings rather than complex application tasks for avoiding extraneous factors, since many practical tasks can be formulated as k-nearest neighbor search. For example, assuming search engines, we can formalize query expansion, term deletion, and misspelling correction as finding frequent similar words, infrequent similar words, and similar words with different spellings, respectively.

We chose FLANN from the tree-based methods and NGT from the graph-based methods since they are expected to be suitable for practical use. FLANN and NGT are compared with SASH, which was the best method reported in a previous study (Gorman and Curran, 2006). In addition, we consider LSH only for confirmation, since it is widely used in natural language processing, although several studies have reported that LSH performed worse than SASH and FLANN. We used the E2LSH package (Andoni, 2004), which includes an implementation of a practical LSH algorithm.

3.1 Problem Definition

The purpose of an approximate similarity search is to quickly and accurately find vectors close to a given vector. We formulate this task as a problem to find k-nearest neighbors as follows. Let (X, d) be a metric space. We denote by $N_k(x, d)$ the set of k-nearest neighbors of a vector $x \in X$ with respect to a metric d. Formally, the following condition holds: $\forall y \in N_k(x, d), \forall z \in X \setminus N_k(x, d)$, $d(x, y) \leq d(x, z)$. Our goal with this problem is to approximate $N_k(x, d)$ for a given vector x.

We calculate the precision of an approximate search method A using the so-called *precision at k or P@k*, which is a widely used evaluation measure in information retrieval. The precision at k of A is defined as $|N_k(x, d) \cap \tilde{N}_k(x, A)|/k$, where $\tilde{N}_k(x, A)$ is the set of approximate k-nearest neighbors of a vector x calculated by A. Since we use the same size k for an exact set $N_k(x, d)$ and its approximate set $\tilde{N}_k(x, A)$, there is no trade-off between precision and recall.

3.2 Basic Settings

This section describes the basic settings in our experiments, where we changed a specific setting (e.g., number of dimensions) in order to evaluate the performance in each experiment. All the experiments were conducted on machines with two Xeon L5630 2.13-GHz processors and 24 GB of main memory running Linux operating systems.

We prepared 200-dimensional word embeddings learned from English Wikipedia in February 2015, which contains about 3 billion sentences spanning about 2 million words and 35 billion tokens, after preprocessing with the widely used script (Mahoney, 2011), which was also used for the word2vec demo (Mikolov, 2013). We used the skip-gram learning model with hierarchical softmax training in the word2vec tool, where the window size is 5, and the down-sampling parameter is 0.001.

We constructed and evaluated the index by dividing the learned embeddings into 2 million embeddings for training and 1,000 embeddings for testing by random sampling, after normalizing them so that the norm of each embedding was one. We built the search index of each search method

for the training set on the basis of the Euclidean distance. The Euclidean distance of normalized vectors is closely related to the cosine similarity, as described later. We prepared the top-10 (exact) nearest neighbors in the training set corresponding to each embedding in the testing set and plotted the average precision at 10 over the test set versus its computation time (log-scale), by changing the parameter for precision of each method as described below. Note that it is difficult to compare different algorithms in terms of either precision or computation time, since there is a trade-off between precision and computation time in approximate search.

We set the parameters of the three search methods SASH, FLANN, and NGT as follows. We determined stable parameters for indexing using grid search and changed an appropriate parameter that affected the accuracy when evaluating each method. For confirmation, we added LSH in the first experiment but did not use it in the other experiments since it clearly performs worse than the other methods.

SASH We set the maximum number (p) of parents per node to 6 for indexing and changed the scale factor for searching[1].

FLANN We set the target precision to 0.8, the build weight to 0, and the sample fraction to 0.01 for indexing, and we changed the number of features to be checked in the search[2]. The k-means index was always selected as the optimal index in our experiments.

NGT We set the edge number (E) to 10 for indexing and changed the search range (e) for searching.

LSH We set the success probability ($1 - \delta$) to 0.9 and changed the radius (R) for indexing. Note that there are no parameters for searching since LSH was developed to reduce dimensionality, and we need to construct multiple indices for adjusting its accuracy.

[1]The scale factor is implemented as "scaleFactor" in the source code (Houle, 2005), although there is no description in the original paper (Houle and Sakuma, 2005).

[2]Since FLANN is a library integrating several algorithms, the parameters can be described only by variables in the source code (Muja and Lowe, 2008). The target precision, build weight, and sample fraction for auto-tuned indexing are implemented as "target_precision", "build_weight", and "sample_fraction" in the structure "AutotunedIndexParams", respectively. The number of features is implemented as "checks" in the structure "SearchParams".

3.3 Results

In this section we report the results of the performance comparison of SASH, FLANN, and NGT from the following different aspects: the distance function for indexing, the number of dimensions of embeddings, the number of neighbors to be evaluated, the size of a training set for indexing, the learning model/data used for embeddings, and the target task to be solved.

3.3.1 Distance Function for Indexing

We evaluated the performance by changing the distance function for indexing. In natural language processing, cosine similarity $\cos(x, y) = \frac{x \cdot y}{\|x\| \, \|y\|}$ of two vectors x and y is widely used from a practical perspective, and cosine distance $d^{\cos}(x, y) = 1 - \cos(x, y)$ as its complement seems to be appropriate for the distance function for indexing. Unfortunately, however, the cosine distance is not strictly metric but *semimetric* since the triangle inequality is not satisfied. Thus, we cannot directly use the cosine distance because the triangle inequality is a key element for efficient indexing in a metric space. In this paper, we use two alternatives: normalized and angular distances.

The former is the Euclidean distance after normalizing vectors, i.e., $d^{\text{norm}}(x, y) = d^{\text{euc}}(\frac{x}{\|x\|}, \frac{y}{\|y\|})$, where $d^{\text{euc}}(x, y) = \|x - y\|$. The set of k-nearest neighbors by d^{norm} is theoretically the same as that by $d^{\cos}$, i.e., $N_k(x, d^{\text{norm}}) = N_k(x, d^{\cos})$, since $d^{\text{norm}}(x, y)^2 = \frac{\|x\|^2}{\|x\|^2} + \frac{\|y\|^2}{\|y\|^2} - 2\frac{x}{\|x\|} \cdot \frac{y}{\|y\|} = 2d^{\cos}(x, y)$. The latter is the angle between two vectors, i.e., $d^{\text{arc}}(x, y) = \arccos(\cos(x, y))$. The set of k-nearest neighbors by d^{arc} is also the same as that by $d^{\cos}$, i.e., $N_k(x, d^{\text{arc}}) = N_k(x, d^{\cos})$, since $\arccos$ is a monotone decreasing function. Note that d^{arc} is not strictly metric, but it satisfies the triangle inequality, i.e., *pseudometric*.

Figure 1 plots the performances of SASH, FLANN, and NGT using the normalized, angular, and ordinal Euclidean distances. Higher precision at the same computational time (upper left line) indicates a better result. The graphs show that NGT performed the best for the normalized distance (a), while SASH performed the best for the angular distance (b). This large difference is caused by the long computational time of d^{arc}. Because we only want the maximum performance in graphs (a) and (b) for each method, we used only the normalized distance in the later experiments since the perfor-

Distance	Method	Time (min)
Normalized	SASH	74.6
	FLANN	56.5
	NGT	**33.9**
	LSH	44.6
Angular	SASH	252.4
	FLANN	654.9
	NGT	**155.4**
Euclidean	SASH	58.1
	FLANN	**20.2**
	NGT	83.0

Table 1: Indexing time of SASH, FLANN, NGT, and LSH using the normalized, angular, Euclidean distance functions.

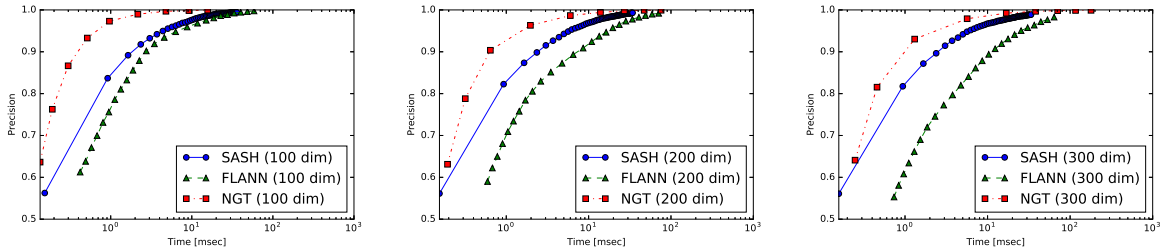
mance of SASH in graph (a) is almost the same as that in (b). For confirmation, we added the result of LSH in graph (a) only. The graph clearly indicates that the performance of LSH is very low even for neural word embeddings, which supports the results in the previous study (Gorman and Curran, 2006), and therefore we did not use LSH in the later experiments.

Graph (c) shows that the performance using the Euclidean distance has a similar tendency to that using the normalized distance, but its computation time is much worse than that using the normalized distance. The reason for this is that it is essentially difficult to search for distant vectors in a metric-based index, and normalization can reduce the number of distant embeddings by aligning them on a hypersphere. In fact, we can confirm that the number of distant embeddings was reduced after normalization according to Figure 2, which visualizes 1,000 embeddings before/after normalization on a two-dimensional space by multi-dimensional scaling (MDS) (Borg and Groenen, 2005), where the radius of each circle represents the search time of the corresponding embedding calculated by NGT. MDS is a dimensionality reduction method to place each point in a low-dimensional space such that the distances between any two points are preserved as much as possible. Note that the scale of graph (b) is about five times larger than that of graph (a). This also suggests that the normalized distance should be preferred even when it has almost the same precision as the Euclidean distance.

Table 1 lists the indexing times of SASH, FLANN, and NGT on the basis of the normalized, angular, and Euclidean distances, where LSH is also added only in the result of the normalized distance. The table indicates that NGT performed the best for the normalized and angular distances, while FLANN performed the best for the Euclidean distance. However, all methods seem to be suitable for practical use in terms of indexing because we can create an index of English Wikipedia embeddings in several hours (only once). The large indexing time with the angular distance also supports our suggestion that the normalized distance should be used.

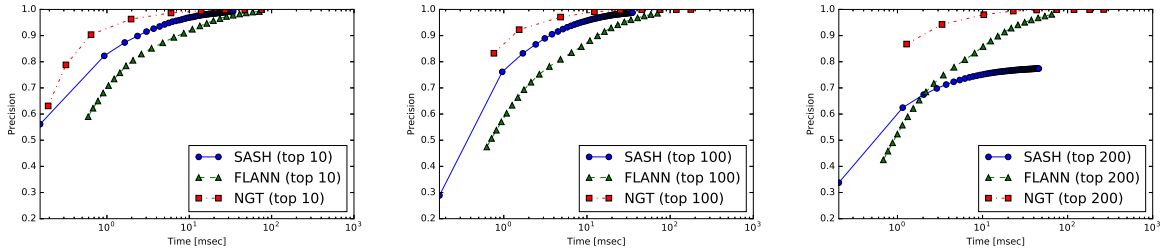
3.3.2 Number of Dimensions of Embeddings

We also evaluated the performances by changing the number of dimensions of embeddings. Since the optimal number of dimensions should depend on the tasks, we wanted to see how the search



(a) 100 dimensions (b) 200 dimensions (c) 300 dimensions

Figure 3: Precision versus computation time of SASH, FLANN, and NGT using 100-, 200-, and 300-dimensional embeddings.



(a) P@10 (b) P@100 (c) P@200

Figure 4: Precision versus computation time of SASH, FLANN, and NGT using precision at 10, 100, and 200.

methods performed when the number of dimensions varied, while the number of dimensions of image features is usually fixed. For example, SIFT features (Lowe, 1999) are represented as 128-dimensional vectors.

Figure 3 plots the performances of SASH, FLANN, and NGT using 100-, 200-, and 300-dimensional embeddings. The graphs indicate that NGT always performed the best. SASH is expected to perform well when the number of dimensions is large, since FLANN and NGT perform worse as the number of dimensions becomes larger. However, NGT would be a better choice since most existing pre-trained embeddings (Turian et al., 2010; Mikolov, 2013; Pennington et al., 2014a) have a few hundred dimensions.

3.3.3 Number of Neighbors to Be Evaluated

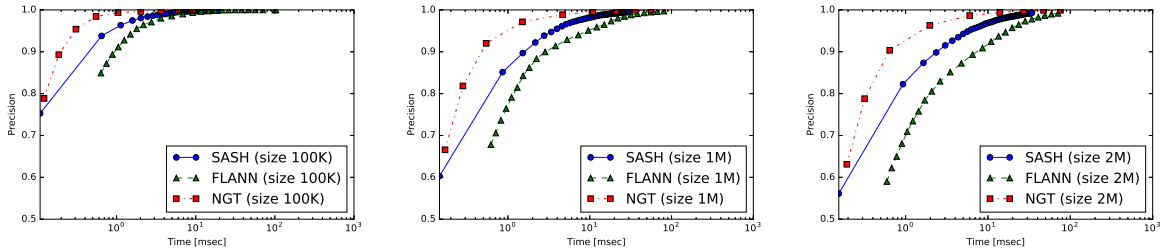
We also conducted performance evaluations by changing the number k of neighbors, i.e., the size of the set of k-nearest neighbors, to calculate the precision at k. We need to change the number k on demand from target applications. For example, we may use small numbers for extracting synonyms and large numbers for selecting candidates for news recommendations, where they will be reduced via another sophisticated selection process.

The performances of SASH, FLANN, and NGT using 10-, 100-, and 200-nearest neighbors are shown in Figure 4. The graphs indicate that NGT performed the best in this measure also. With 200-nearest neighbors, the performance of SASH dropped sharply, which means that SASH is not robust for the indexing parameter. One possible reason is that searching for relatively distant neighbors is difficult for a tree-based index, where the divided subspaces are not appropriate.

3.3.4 Size of Training Set for Indexing

We conducted further performance evaluations by changing the size of a training set, i.e., the number of embeddings used for indexing. We wanted to know how the search methods performed with different sized search indices since a large search index will bring about extra operational costs in a practical sense, and a small search index is preferred for a small application system.

Figure 5 plots the performances of SASH, FLANN, and NGT using 100K, 1M, and 2M training sets, which were randomly sampled so that each training set can be virtually regarded as embeddings with a vocabulary of its training set size. The graphs indicate that NGT always performed the best for all search index sizes. Moreover, we can see that all results for each method have a similar tendency. This fact implies that a distribution of embeddings is related to the search per-



(a) 100K (b) 1M (c) 2M

formance, and the next section will actually confirm the same property on another dataset used for learning embeddings.

3.3.5 Model and Data Used for Embeddings

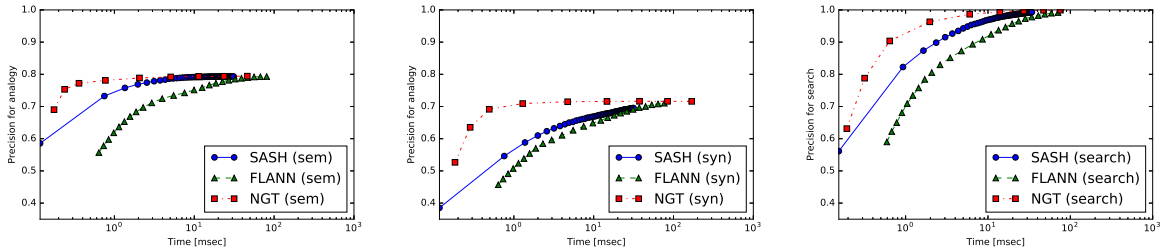
We also conducted performance evaluations by changing the learning models and training data for embeddings. We used the following three pre-trained embeddings to investigate the performance when changing the data distributions used for indexing.

GN 300-dimensional embeddings (Mikolov, 2013) learned by the skip-gram model with negative sampling (Mikolov et al., 2013a) using part of the Google News dataset, which contains about 3 million words and phrases and 100 billion tokens.

CW 200-dimensional embeddings (Turian et al., 2010) learned by deep neural networks (Collobert and Weston, 2008) using the RCV1 corpus, which contains about 269 thousand words and 63 million tokens.

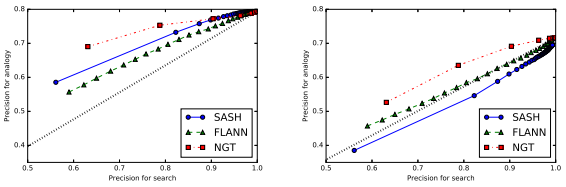
GV 300-dimensional embeddings (Pennington et al., 2014a) learned by the global vectors for word representation (GloVe) model (Pennington et al., 2014b) using Common Crawl corpora, which contain about 2 million words and 42 billion tokens.

The performances of SASH, FLANN, and NGT using GN, CW, and GV embeddings are plotted in Figure 6. The graphs indicate that NGT consistently performed the best over different learning models. A comparison of the results using GN embeddings and the previous results using Wikipedia embeddings reveals that they had almost the same tendency. This fast can be acceptable assuming an empirical rule that a corpus follows a power law or Zipf's law. On the other hand, graphs (a), (b), and (c) have quite different tendencies. Specifically, all search methods compete with each other for CW embeddings, while they could not perform well for GV embeddings. This implies that the performance of a search method can be affected by learning models rather than training sets used for embeddings.



(a) Semantic analogy (b) Syntactic analogy (c) Similarity search

Figure 8: Precision versus computation time of SASH, FLANN, and NGT using the semantic analogy, syntactic analogy, and similarity search tasks.



(a) Semantic analogy (b) Syntactic analogy

Figure 9: Precision of the semantic and syntactic analogy tasks versus that of the similarity search task.

	EW	GN	CW	GV
Variance	0.0033	0.0033	0.0050	0.0033
Kurtosis	0.034	-0.026	-0.075	0.57

Table 2: Variance and kurtosis of English Wikipedia (EW), GN, CW, and GV embeddings.

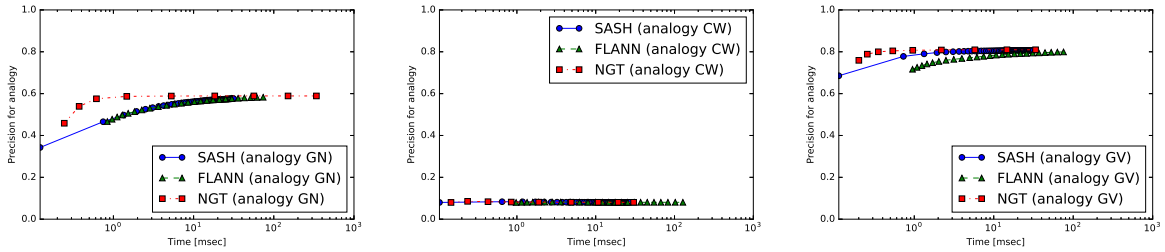
We further investigated why GV embeddings deteriorate the search performance. Table 2 lists the variance and kurtosis of Wikipedia, GN, CW, and GV embeddings for clarifying the variation or dispersion of these distributions. Kurtosis $K(X)$ is a measure of the "tailedness" of the probability distribution of a random variable X, defined by $K(X) = \mu_4/\mu_2^2 - 3$, where μ_n represents the n-th central moment, i.e., $\mathbb{E}[(X - \mathbb{E}[X])^n]$. The constant "3" in the above definition sets the kurtosis of a normal distribution to 0. The table clearly indicates that GV has a heavy tailed distribution in accordance with the kurtosis values, although all variances have almost the same value. In fact, GV has several high kurtosis peaks, while GN has only small values, according to Figure 7, which visualizes the kurtosis of each dimension. Note that the y-axis scale of graph (b) is about 20 times larger than that of graph (a). Because distant points in a metric space tend to deteriorate the performance in a search process, we need to pay attention to the distribution shape of embeddings as well as their quality, so as to efficiently search for similar embeddings.

3.3.6 Target Task to Be Solved

We finally evaluated the performance by changing the target task to be solved by using embeddings. We wanted to know how the search methods performed with different task settings since even if the precision of the search task is not good, it might be sufficient for another task to be solved on the basis of similarity search. In this section, we address well known analogy tasks (Mikolov et al., 2013a), where semantic and syntactic analogy questions are considered, e.g., "Which word corresponds to Japan when Paris corresponds to France?", the answer being "Tokyo". These questions can be solved by searching for the nearest neighbors of analogical vectors generated via arithmetic operations., i.e., vec("Paris") − vec("France") + vec("Japan"), where vec(w) represents an embedding of word w.

Figure 8 plots the performances of SASH, FLANN, and NGT using the semantic and syntactic analogy tasks as well as that using the similarity search task (in Figure 1), which is added for comparison. The graphs indicate that NGT clearly performed the best even in the analogy tasks. Comparing the curves of NGT, we can see that those in graphs (a) and (b) are quite different from that in (c), and the analogy precisions can maintain their quality, even when the search precision is about 0.9.

For further analysis, we aligned the precisions of the search task with those of the analogy tasks in Figure 9, where each point represents the results calculated with the same parameters. The dotted line without markers in each graph is a line from the origin (0, 0) to the point where the analogy precision is maximum when the search precision



(a) Analogy by GN (b) Analogy by CW (c) Analogy by GV

Figure 10: Precision versus computation time of SASH, FLANN, and NGT for the analogy task (including both semantic and syntactic questions) using GN, CW, and GV embeddings.

is 1.0, and thus it naively estimates a deterioration rate of the analogy precision on the basis of the search precision. The graphs indicate that the search precision can be far different from the estimated precision of another task. In fact, when the search precision by NGT is 0.8 in Figure 9 (a), the analogy precision 0.75 is unexpectedly high, since the naive estimation is 0.64 calculated by the maximum analogy precision 0.8 times the search precision 0.8. This suggests that it is a good idea to check the final performance of a target application, although the search performance is valuable from a standpoint of general versatility.

Finally, we conducted performance evaluations for the analogy task instead of the search task by changing the learning models and training data for embeddings as in Section 3.3.5, in order to support the robustness of NGT even for an operation more sophisticated than just finding similar words. Figure 10 plots the performances of SASH, FLANN, and NGT for the analogy task including both semantic and syntactic questions using GN, CW, and GV embeddings. The graphs indicate that NGT performed the best over different learning models even for the analogy task. Although the precisions of CW embeddings in graph (b) are very low, the result seems to be acceptable according to the previous work (Mikolov et al., 2013b), which reported that the precisions of a syntactic analogy task using CW embeddings in similar settings were at most 5 % (0.05). The results of GN and GV embeddings in graphs (a) and (c) show a similar tendency to those of Wikipedia embeddings in Figure 8. However, the overall performance for the analogy task using GV embeddings is unexpectedly high, contrary to the results for the search task in Figure 6 (c). One of the reasons is that arithmetic operations for solving analogy questions can reduce kurtosis peaks, although we omitted the kurtosis results due to space limitation. This fact also supports our finding that distant points in a metric space tend to deteriorate the performance in a search process.

4 Conclusion

We investigated approximate similarity search for word embeddings. We compared three methods: a graph-based method (NGT), a tree-based method (FLANN), the SASH method, which was reported to have the best performance in a previous study (Gorman and Curran, 2006). The results of experiments we conducted from various aspects indicated that NGT generally performed the best and that the distribution shape of embeddings is a key factor relating to the search performance. Our future research includes improving the search performance for embeddings with heavy-tailed distributions and creating embeddings that can keep both task quality and search performance high.

We will release the source code used for our comparative experiments from the NGT page (Iwasaki, 2015). Since we need to implement additional glue codes for running FLANN and SASH, our code would be useful for researchers who want to compare their results with ours.

Abstract

Learning distributed representations for relation instances is a central technique in downstream NLP applications. In order to address semantic modeling of relational patterns, this paper constructs a new dataset that provides multiple similarity ratings for every pair of relational patterns on the existing dataset (Zeichner et al., 2012). In addition, we conduct a comparative study of different encoders including additive composition, RNN, LSTM, and GRU for composing distributed representations of relational patterns. We also present Gated Additive Composition, which is an enhancement of additive composition with the gating mechanism. Experiments show that the new dataset does not only enable detailed analyses of the different encoders, but also provides a gauge to predict successes of distributed representations of relational patterns in the relation classification task.

1 Introduction

Knowledge about entities and their relations (relation instances) are crucial for a wide spectrum of NLP applications, e.g., information retrieval, question answering, and recognizing textual entailment. Learning distributed representations for relation instances is a central technique in downstream applications as a number of recent studies demonstrated the usefulness of distributed representations for words (Mikolov et al., 2013; Pennington et al., 2014) and sentences (Sutskever et al., 2014; Cho et al., 2014; Kiros et al., 2015).

In particular, semantic modeling of relations and their textual realizations (*relational patterns* hereafter) is extremely important because a relation (e.g., causality) can be mentioned by various expressions (e.g., "*X* cause *Y*", "*X* lead to *Y*", "*Y* is associated with *X*"). To make matters worse, relational patterns are highly productive: we can produce a emphasized causality pattern "*X* increase the severe risk of *Y*" from "*X* increase the risk of *Y*" by inserting *severe* to the pattern.

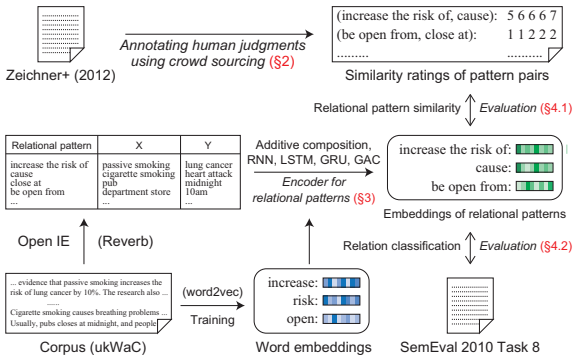

Figure 1: Overview of this study.

To model the meanings of relational patterns, the previous studies built a co-occurrence matrix between relational patterns (e.g., "*X* increase the risk of *Y*") and entity pairs (e.g., "*X*: smoking, *Y*: cancer") (Lin and Pantel, 2001; Nakashole et al., 2012). Based on the distributional hypothesis (Harris, 1954), we can compute a semantic vector of a relational pattern from the co-occurrence matrix, and measure the similarity of two relational patterns as the cosine similarity of the vectors. Nowadays, several studies adopt distributed representations computed by neural networks for semantic modeling of relational patterns (Yih et al., 2014; Takase et al., 2016).

Notwithstanding, the previous studies paid little attention to explicitly evaluate semantic modeling of relational patterns. In this paper, we construct a new dataset that contains a pair of relational patterns with five similarity ratings judged by human annotators. The new dataset shows a

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2276–2286,
Berlin, Germany, August 7-12, 2016.

high inter-annotator agreement, following the annotation guideline of Mitchell and Lapata (2010). The dataset is publicly available on the Web site[1].

In addition, we conduct a comparative study of different encoders for composing distributed representations of relational patterns. During the comparative study, we present Gated Additive Composition, which is an enhancement of additive composition with the gating mechanism. We utilize the Skip-gram objective for training the parameters of the encoders on a large unlabeled corpus. Experiments show that the new dataset does not only enable detailed analyses of the different encoders, but also provides a gauge to predict successes of distributed representations of relational patterns in another task (relation classification). Figure 1 illustrates the overview of this study.

2 Data Construction

2.1 Target relation instances

We build a new dataset upon the work of Zeichner et al. (2012), which consists of relational patterns with semantic inference labels annotated. The dataset includes 5,555 pairs[2] extracted by Reverb (Fader et al., 2011), 2,447 pairs with inference relation and 3,108 pairs (the rest) without one.

Initially, we considered using this high-quality dataset as it is for semantic modeling of relational patterns. However, we found that inference relations exhibit quite different properties from those of semantic similarity. Take a relational pattern pair "*X* be the part of *Y*" and "*X* be an essential part of *Y*" filled with "*X* = the small intestine, *Y* = the digestive system" as an instance. The pattern "*X* be the part of *Y*" does not entail "*X* be an essential part of *Y*" because the meaning of the former does not include 'essential'. Nevertheless, both statements are similar, representing the same relation (PART-OF). Another uncomfortable pair is "*X* fall down *Y*" and "*X* go up *Y*" filled with "*X* = the dude, *Y* = the stairs". The dataset indicates that the former entails the latter probably because falling down from the stairs requires going up there, but they present the opposite meaning. For this reason, we decided to re-annotate semantic similarity judgments on every pair of relational patterns on the dataset.

2.2 Annotation guideline

We use instance-based judgment in a similar manner to that of Zeichner et al. (2012) to secure a high inter-annotator agreement. In instance-based judgment, an annotator judges a pair of relational patterns whose variable slots are filled with the same entity pair. In other words, he or she does not make a judgment for a pair of relational patterns with variables, "*X* prevent *Y*" and "*X* reduce the risk of *Y*", but two instantiated statements "Cephalexin prevent the bacteria" and "Cephalexin reduce the risk of the bacteria" ("*X* = Cephalexin, *Y* = the bacteria"). We use the entity pairs provided in Zeichner et al. (2012).

We asked annotators to make a judgment for a pair of relation instances by choosing a rating from 1 (dissimilar) to 7 (very similar). We provided the following instructions for judgment, which is compatible with Mitchell and Lapata (2010): (1) rate 6 or 7 if the meanings of two statements are the same or mostly the same (e.g., "Palmer team with Jack Nicklaus" and "Palmer join with Jack Nicklaus"); (2) rate 1 or 2 if two statements are dissimilar or unrelated (e.g., "the kids grow up with him" and "the kids forget about him"); (3) rate 3, 4, or 5 if two statements have some relationships (e.g., "Many of you know about the site" and "Many of you get more information about the site", where the two statements differ but also reasonably resemble to some extent).

2.3 Annotation procedure

We use a crowdsourcing service CrowdFlower[3] to collect similarity judgments from the crowds. CrowdFlower has the mechanism to assess the reliability of annotators using Gold Standard Data (Gold, hereafter), which consists of pairs of relational patterns with similarity scores assigned. Gold examples are regularly inserted throughout the judgment job to enable measurement of the performance of each worker[4]. Two authors of this paper annotated 100 pairs extracted randomly from 5,555 pairs, and prepared 80 Gold examples showing high agreement. Ratings of the Gold examples were used merely for quality assessment of the workers. In other words, we discarded the

[1] http://github.com/takase/relPatSim

[2] More precisely, the dataset includes 1,012 *meaningless* pairs in addition to 5,555 pairs. A pair of relational patterns was annotated as *meaningless* if the annotators were unable to understand the meaning of the patterns easily. We ignore the *meaningless* pairs in this study.

[3] http://www.crowdflower.com/

[4] We allow ± 1 differences in rating when we measure the performance of the workers.

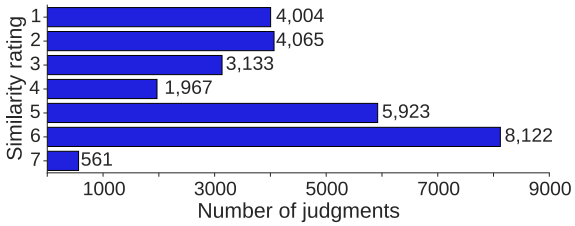

Figure 2: Number of judgments for each similarity rating. The total number of judgments is $27,775$ ($5,555$ pairs $\times$ 5 workers).

similarity ratings of the Gold examples, and used those judged by the workers.

To build a high quality dataset, we use judgments from workers whose confidence values (reliability scores) computed by CrowdFlower are greater than 75%. Additionally, we force every pair to have at least five judgments from the workers. Consequently, 60 workers participated in this job. In the final version of this dataset, each pair has five similarity ratings judged by the five most reliable workers who were involved in the pair.

Figure 2 presents the number of judgments for each similarity rating. Workers seldom rated 7 for a pair of relational patterns, probably because most pairs have at least one difference in content words. The mean of the standard deviations of similarity ratings of all pairs is 1.16. Moreover, we computed Spearman's ρ between similarity judgments from each worker and the mean of five judgments in the dataset. The mean of Spearman's ρ of workers involved in the dataset is 0.728. These statistics show a high inter-annotator agreement of the dataset.

3 Encoder for Relational Patterns

The new dataset built in the previous section raises two new questions — *What is the reasonable method (encoder) for computing the distributed representations of relational patterns? Is this dataset useful to predict successes of distributed representations of relational patterns in real applications?* In order to answer these questions, this section explores various methods for learning distributed representations of relational patterns.

3.1 Baseline methods without supervision

A naïve approach would be to regard a relational pattern as a single unit (word) and to train word/pattern embeddings as usual. In fact, Mikolov et al. (2013) implemented this approach as a preprocessing step, mining phrasal expressions with strong collocations from a training corpus. However, this approach might be affected by data sparseness, which lowers the quality of distributed representations.

Another simple but effective approach is *additive composition* (Mitchell and Lapata, 2010), where the distributed representation of a relational pattern is computed by the mean of embeddings of constituent words. Presuming that a relational pattern consists of a sequence of T words $w_1, ..., w_T$, then we let $x_t \in \mathbb{R}^d$ the embedding of the word w_t. This approach computes $\frac{1}{T}\sum_{t=1}^{T} x_t$ as the embedding of the relational pattern. Muraoka et al. (2014) reported that the additive composition is a strong baseline among various methods.

3.2 Recurrent Neural Network

Recently, a number of studies model semantic compositions of phrases and sentences by using (a variant of) Recurrent Neural Network (RNN) (Sutskever et al., 2014; Tang et al., 2015). For a given embedding x_t at position t, the vanilla RNN (Elman, 1990) computes the hidden state $h_t \in \mathbb{R}^d$ by the following recursive equation[5],

$$h_t = g(W_x x_t + W_h h_{t-1}). \quad (1)$$

Here, W_x and W_h are $d \times d$ matrices (parameters), $g(.)$ is the elementwise activation function ($\tanh$). We set $h_0 = 0$ at $t = 1$. In essence, RNN computes the hidden state h_t based on the one at the previous position (h_{t-1}) and the word embedding x_t. Applying Equation 1 from $t = 1$ to T, we use h_T as the distributed representation of the relational pattern.

3.3 RNN variants

We also employ Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) (Cho et al., 2014) as an encoder for relational patterns. LSTM has been applied successfully to various NLP tasks including word segmentation (Chen et al., 2015), dependency parsing (Dyer et al., 2015), machine translation (Sutskever et al., 2014), and sentiment analysis (Tai et al., 2015). GRU is also successful in machine translation (Cho et al., 2014) and various

[5]We do not use a bias term in this study. We set the number of dimensions of hidden states identical to that of word embeddings (d) so that we can adapt the objective function of the Skip-gram model for training (Section 3.5).

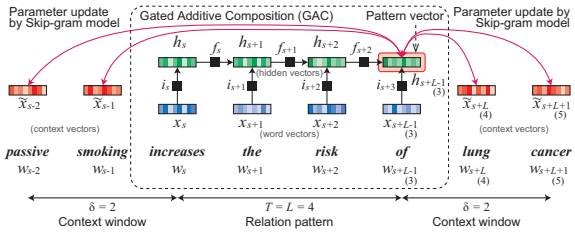

Figure 3: Overview of GAC trained with Skip-gram model. GAC computes the distributed representation of a relational pattern using the input gate and forget gate, and learns parameters by predicting surrounding words (Skip-gram model).

tasks including sentence similarity, paraphrase detection, and sentiment analysis (Kiros et al., 2015).

LSTM and GRU are similar in that the both architectures have gates (input, forget, and output for LSTM; reset and update for GRU) to remedy the gradient vanishing or explosion problem in training RNNs. Although some researchers reported that GRU is superior to LSTM (Chung et al., 2014), we have no consensus about the superiority. Besides, we are not sure whether LSTM or GRU is really necessary for relational patterns, which ususlly consist of a few words. Thus, we compare RNN, LSTM, and GRU empirically with the same training data and the same training procedure. Similarly to RNN, we use the hidden state h_T of LSTM[6] or GRU as the distributed representation of a relation pattern.

3.4 Gated Additive Composition (GAC)

In addition to the gradient problem, LSTM or GRU may be suitable for relational patterns, having the mechanism of adaptive control of gates for input words and hidden states. Consider the relational pattern "*X* have access to *Y*", whose meaning is mostly identical to that of "*X* access *Y*". Because 'have' in the pattern is a light verb, it may be harmful to incorporate the semantic vector of 'have' into the distributed representation of the pattern. The same may be true for the functional word 'to' in the pattern. However, the additive composition nor RNN does not have a mechanism to ignore the semantic vectors of these words. It is interesting to explore a method somewhere between additive composition and LSTM/GRU: additive composition with the gating mechanism.

For this reason, we present an another variant of RNN in this study. Inspired by the input and forget gates in LSTM, we compute the input gate $i_t \in \mathbb{R}^d$ and forget gate $f_t \in \mathbb{R}^d$ at position t. We use them to control the amount to propagate to the hidden state h_t from the current word x_t and the previous state h_{t-1}.

$$i_t = \sigma(W_{ix}x_t + W_{ih}h_{t-1}) \quad (2)$$

$$f_t = \sigma(W_{fx}x_t + W_{fh}h_{t-1}) \quad (3)$$

$$h_t = g(f_t \odot h_{t-1} + i_t \odot x_t) \quad (4)$$

Here, W_{ix}, W_{ih}, W_{fx}, W_{fh} are $d \times d$ matrices. Equation 4 is interpreted as a weighted additive composition between the vector of the current word x_t and the vector of the previous hidden state h_{t-1}. The elementwise weights are controlled by the input gate i_t and forget gate f_t; we expect that input gates are closed (close to zero) and forget gates are opened (close to one) when the current word is a control verb or function word. We name this architecture *gated additive composition* (GAC).

3.5 Parameter estimation: Skip-gram model

To train the parameters of the encoders (RNN, LSTM, GRU, and GAC) on an unlabeled text corpus, we adapt the Skip-gram model (Mikolov et al., 2013). Formally, we designate an occurrence of a relational pattern p as a subsequence of L words $w_s, ..., w_{s+L-1}$ in a corpus. We define δ words appearing before and after pattern p as the context words, and let $C_p = (s-\delta, ..., s-1, s+L, ..., s+L+\delta)$ denote the indices of the context words. We define the log-likelihood of the relational pattern l_p, following the objective function of Skip-gram with negative sampling (SGNS) (Levy and Goldberg, 2014).

$$l_p = \sum_{\tau \in C_p} \left(\log \sigma(h_p^\top \tilde{x}_\tau) + \sum_{k=1}^{K} \log \sigma(-h_p^\top \tilde{x}_{\tilde{\tau}}) \right) \quad (5)$$

In this formula: K denotes the number of negative samples; $h_p \in \mathbb{R}^d$ is the vector for the relational pattern p computed by each encoder such as RNN; $\tilde{x}_\tau \in \mathbb{R}^d$ is the context vector for the word w_τ[7]; $x_{\tilde{\tau}'} \in \mathbb{R}^d$ is the context vector for the word

[6] We omitted peephole connections and bias terms.

[7] The Skip-gram model has two kinds of vectors x_t and $\tilde{x}_t$ assigned for a word w_t. Equation 2 of the original paper (Mikolov et al., 2013) denotes x_t (word vector) as v (input vector) and $\tilde{x}_t$ (context vector) as v' (output vector). The word2vec implementation does not write context (output) vectors but only word (input) vectors to a model file. Therefore, we modified the source code to save context vectors, and use them in Equation 5. This modification ensures the consistency of the entire model.

that were sampled from the unigram distribution[8] at every iteration of $\sum_k$.

At every occurrence of a relational pattern in the corpus, we use Stochastic Gradient Descent (SGD) and backpropagation through time (BPTT) for training the parameters (matrices) in encoders. More specifically, we initialize the word vectors x_t and context vectors $\tilde{x}_t$ with pre-trained values, and compute gradients for Equation 5 to update the parameters in encoders. In this way, each encoder is trained to compose a vector of a relational pattern so that it can predict the surrounding context words. An advantage of this parameter estimation is that the distributed representations of words and relational patterns stay in the same vector space. Figure 3 visualizes the training process for GAC.

4 Experiments

In Section 4.1, we investigate the performance of the distributed representations computed by different encoders on the pattern similarity task. Section 4.2 examines the contribution of the distributed representations on SemEval 2010 Task 8, and discusses the usefulness of the new dataset to predict successes of the relation classification task.

4.1 Relational pattern similarity

For every pair in the dataset built in Section 2, we compose the vectors of the two relational patterns using an encoder described in Section 3, and compute the cosine similarity of the two vectors. Repeating this process for all pairs in the dataset, we measure Spearman's ρ between the similarity values computed by the encoder and similarity ratings assigned by humans.

4.1.1 Training procedure

We used ukWaC[9] as the training corpus for the encoders. This corpus includes the text of 2 billion words from Web pages crawled in the .uk domain. Part-of-speech tags and lemmas are annotated by TreeTagger[10]. We used lowercased lemmas throughout the experiments. We apply word2vec to this corpus to pre-train word vectors x_t and context vectors $\tilde{x}_t$. All encoders use word vectors x_t to compose vectors of relational patterns; and the Skip-gram model uses context vectors $\tilde{x}_t$ to compute the objective function and gradients. We fix the vectors x_t and $\tilde{x}_t$ with pre-trained values during training.

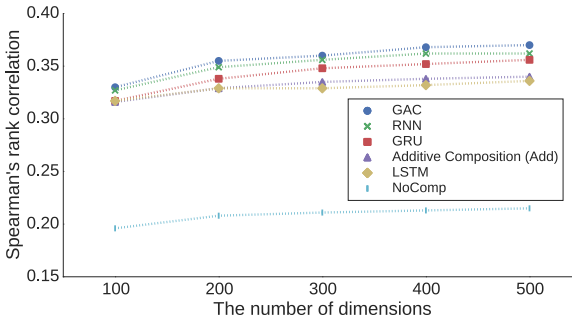

Figure 4: Performance of each method on the relational pattern similarity task with variation in the number of dimensions.

We used Reverb (Fader et al., 2011) to the ukWaC corpus to extract relational pattern candidates. To remove unuseful relational patterns, we applied filtering rules that are compatible with those used in the publicly available extraction result[11]. Additionally, we discarded relational patterns appearing in the evaluation dataset throughout the experiments to assess the performance under which an encoder composes vectors of unseen relational patterns. This preprocessing yielded $127,677$ relational patterns.

All encoders were implemented on Chainer[12], a flexible framework of neural networks. The hyperparameters of the Skip-gram model are identical to those in Mikolov et al. (2013): the width of context window $\delta = 5$, the number of negative samples $K = 5$, the subsampling of 10^{-5}. For each encoder that requires training, we tried 0.025, 0.0025, and 0.00025 as an initial learning rate, and selected the best value for the encoder. In contrast to the presentation of Section 3, we compose a pattern vector in backward order (from the last to the first) because preliminary experiments showed a slight improvement with this treatment.

4.1.2 Results and discussions

Figure 4 shows Spearman's rank correlations of different encoders when the number of dimensions of vectors is 100–500. The figure shows that GAC achieves the best performance on all dimensions.

Figure 4 includes the performance of the naïve approach, "NoComp", which regards a relational pattern as a single unit (word). In this approach,

[8] We use the probability distribution of words raised to the 3/4 power (Mikolov et al., 2013).

Table 1: Spearman's rank correlations on different pattern lengths (number of dimensions $d = 500$).

we allocated a vector h_p for each relational pattern p in Equation 5 instead of the vector composition, and trained the vectors of relational patterns using the Skip-gram model. The performance was poor for two reasons: we were unable to compute similarity values for 1,744 pairs because relational patterns in these pairs do not appear in ukWaC; and relational patterns could not obtain sufficient statistics because of data sparseness.

Table 1 reports Spearman's rank correlations computed for each pattern length. Here, the length of a relational-pattern pair is defined by the maximum of the lengths of two patterns in the pair. In length of 1, all methods achieve the same correlation score because they use the same word vector x_t. The table shows that additive composition (Add) performs well for shorter relational patterns (lengths of 2 and 3) but poorly for longer ones (lengths of 4 and 5+). GAC also exhibits the similar tendency to Add, but it outperforms Add for shorter patterns (lengths of 2 and 3) probably because of the adaptive control of input and forget gates. In contrast, RNN and its variants (RNN, GRU, and LSTM) enjoy the advantage on longer patterns (lengths of 4 and 5+).

To examine the roles of input and forget gates of GAC, we visualize the moments when input/forget gates are wide open or closed. More precisely, we extract the input word and scanned words when $|i_t|_2$ or $|f_t|_2$ is small (close to zero) or large (close to one) on the relational-pattern dataset. We restate that we compose a pattern vector in backward order (from the last to the first): GAC scans 'of', 'author', and 'be' in this order for composing the vector of the relational pattern 'be author of'.

Table 2 displays the top three examples identified using the procedure. The table shows two groups of tendencies. Input gates open and forget gates close when scanned words are only a preposition and the current word is a content word. In these situations, GAC tries to read the semantic vector of the content word and to ignore the semantic vector of the preposition. In contrast, input gates close and forget gates open when the current word is 'be' or 'a' and scanned words form a noun phrase (e.g., "charter member of"), a complement (e.g., "eligible to participate in"), or a passive voice (e.g., "require(d) to submit"). This behavior is also reasonable because GAC emphasizes informative words more than functional words.

	w_t	w_{t+1} w_{t+2} ...
large i_t (input open)	reimburse payable liable	for in to
small i_t (input close)	a a be	charter member of valuable member of an avid reader of
large f_t (forget open)	be be be	eligible to participate in require to submit request to submit
small f_t (forget close)	coauthor capital center	of of of

Table 2: Prominent moments for input/forget gates.

4.2 Relation classification

4.2.1 Experimental settings

To examine the usefulness of the dataset and distributed representations for a different application, we address the task of relation classification on the SemEval 2010 Task 8 dataset (Hendrickx et al., 2010). In other words, we explore whether high-quality distributed representations of relational patterns are effective to identify a relation type of an entity pair.

The dataset consists of $10,717$ relation instances ($8,000$ training and $2,717$ test instances) with their relation types annotated. The dataset

Method	Feature set	F1
SVM	BoW, POS	77.3
SVM + NoComp	embeddings, BoW, POS	79.9
SVM + LSTM	embeddings, BoW, POS	81.1
SVM + Add	embeddings, BoW, POS	81.1
SVM + GRU	embeddings, BoW, POS	81.4
SVM + RNN	embeddings, BoW, POS	81.7
SVM + GAC	embeddings, BoW, POS	82.0
	+ dependency, WordNet, NE	83.7
Ranking loss + GAC w/ fine-tuning	embeddings, BoW, POS	
	+ dependency, WordNet, NE	84.2
SVM (Rink and Harabagiu, 2010)	BoW, POS, dependency, Google n-gram, etc.	82.2
MV-RNN (Socher et al., 2012)	embeddings, parse trees	79.1
	+ WordNet, POS, NE	82.4
FCM (Gormley et al., 2015) w/o fine-tuning	embeddings, dependency	79.4
	+ WordNet	82.0
w/ fine-tuning	embeddings, dependency	82.2
	+ NE	83.4
RelEmb (Hashimoto et al., 2015)	embeddings	82.8
	+ dependency, WordNet, NE	83.5
CR-CNN (dos Santos et al., 2015) w/ Other	embeddings, word position embeddings	82.7
w/o Other	embeddings, word position embeddings	84.1
depLCNN (Xu et al., 2015)	embeddings, dependency	81.9
	+ WordNet	83.7
depLCNN + NS	embeddings, dependency	84.0
	+ WordNet	85.6

Table 3: F1 scores on the SemEval 2010 dataset.

defines 9 directed relations (e.g.,CAUSE-EFFECT) and 1 undirected relation OTHER. Given a pair of entity mentions, the task is to identify a relation type in 19 candidate labels (2×9 directed + 1 undirected relations). For example, given the pair of entity mentions e_1 = 'burst' and e_2 = 'pressure' in the sentence "The *burst* has been caused by water hammer *pressure*", a system is expected to predict CAUSE-EFFECT(e_2, e_1).

We used Support Vector Machines (SVM) with a Radial Basis Function (RBF) kernel implemented in libsvm[13]. Basic features are: part-of-speech tags (predicted by TreeTagger), surface forms, lemmas of words appearing between an entity pair, and lemmas of the words in the entity pair. Additionally, we incorporate distributed representations of a relational pattern, entities, and a word before and after the entity pair (number of dimensions $d = 500$). In this task, we regard words appearing between an entity pair as a relational pattern. We compare the vector representations of relational patterns computed by the five encoders presented in Section 4.1: additive composition, RNN, GRU, LSTM, and GAC. Hyperparameters related to SVM were tuned by 5-fold cross validation on the training data.

4.2.2 Results and discussions

Table 3 presents the macro-averaged F1 scores on the SemEval 2010 Task 8 dataset. The first group of the table provides basic features and enhancements with the distributed representations. We can observe a significant improvement even from the distributed representation of NoComp (77.3 to 79.9). Moreover, the distributed representation that exhibited the high performance on the pattern similarity task was also successful on this task; GAC, which yielded the highest performance on the pattern similarity task, also achieved the best performance (82.0) of all encoders on this task.

It is noteworthy that the improvements brought by the different encoders on this task roughly cor-

respond to the performance on the pattern similarity task. This fact implies two potential impacts. First, the distributed representations of relational patterns are useful and easily transferable to other tasks such as knowledge base population. Second, the pattern similarity dataset provides a gauge to predict successes of distributed representations in another task.

We could further improve the performance of SVM + GAC by incorporating external resources in the similar manner as the previous studies did. Concretely, SVM + GAC achieved 83.7 F1 score by adding features for WordNet, named entities (NE), and dependency paths explained in Hashimoto et al. (2015). Moreover, we could obtain 84.2 F1 score, using the ranking based loss function (dos Santos et al., 2015) and fine-tuning of the distributed representations initially trained by GAC. Currently, this is the second best score among the performance values reported in the previous studies on this task (the second group of Table 3). If we could use the negative sampling technique proposed by Xu et al. (2015), we might improve the performance further[14].

5 Related Work

Mitchell and Lapata (2010) was a pioneering work in semantic modeling of short phrases. They constructed the dataset that contains two-word phrase pairs with semantic similarity judged by human annotators. Korkontzelos et al. (2013) provided a semantic similarity dataset with pairs of two words and a single word. Wieting et al. (2015) annotated a part of PPDB (Ganitkevitch et al., 2013) to evaluate semantic modeling of paraphrases. Although the target unit of semantic modeling is different from that for these previous studies, we follow the annotation guideline and instruction of Mitchell and Lapata (2010) to build the new dataset.

The task addressed in this paper is also related to the Semantic Textual Similarity (STS) task (Agirre et al., 2012). STS is the task to measure the degree of semantic similarity between two sentences. Even though a relational pattern appears as a part of a sentence, it may be difficult to transfer findings from one to another: for example, the encoders of RNN and its variants explored in this study may exhibit different characteristics, influenced by the length and complexity of input text expressions.

In addition to data construction, this paper addresses semantic modeling of relational patterns. Nakashole et al. (2012) approached the similar task by constructing a taxonomy of relational patterns. They represented a vector of a relational pattern as the distribution of entity pairs co-occurring with the relational pattern. Grycner et al. (2015) extended Nakashole et al. (2012) to generalize dimensions of the vector space (entity pairs) by incorporating hyponymy relation between entities. They also used external resources to recognize the transitivity of pattern pairs and applied transitivities to find patterns in entailment relation. These studies did not consider semantic composition of relational patterns. Thus, they might suffer from the data sparseness problem, as shown by NoComp in Figure 4.

Numerous studies have been aimed at encoding distributed representations of phrases and sentences from word embeddings by using: Recursive Neural Network (Socher et al., 2011), Matrix Vector Recursive Neural Network (Socher et al., 2012), Recursive Neural Network with different weight matrices corresponding to syntactic categories (Socher et al., 2013) or word types (Takase et al., 2016), RNN (Sutskever et al., 2011), LSTM (Sutskever et al., 2014), GRU (Cho et al., 2014), PAS-CLBLM (Hashimoto et al., 2014), etc. As described in Section 3, we applied RNN, GRU, and LSTM to compute distributed representations of relational patterns because recent papers have demonstrated their superiority in semantic composition (Sutskever et al., 2014; Tang et al., 2015). In this paper, we presented a comparative study of different encoders for semantic modeling of relational patterns.

To investigate usefulness of the distributed representations and the new dataset, we adopted the relation classification task (SemEval 2010 Task 8) as a real application. On the SemEval 2010 Task 8, several studies considered semantic composition. Gormley et al. (2015) proposed Feature-rich Compositional Embedding Model (FCM) that can combine binary features (e.g., positional indicators) with word embeddings via outer products. dos Santos et al. (2015) addressed the task using Convolutional Neural Network (CNN). Xu et al. (2015) achieved a higher performance than dos

[14] In fact, we made substantial efforts to introduce the negative sampling technique. However, Xu et al. (2015) omits the detail of the technique probably because of the severe page limit of short papers. For this reason, we could not reproduce their method in this study.

Santos et al. (2015) by application of CNN on dependency paths.

In addition to the relation classification task, we briefly describe other applications. To populate a knowledge base, Riedel et al. (2013) jointly learned latent feature vectors of entities, relational patterns, and relation types in the knowledge base. Toutanova et al. (2015) adapted CNN to capture the compositional structure of a relational pattern during the joint learning. For open domain question answering, Yih et al. (2014) proposed the method to map an interrogative sentence on an entity and a relation type contained in a knowledge base by using CNN.

Although these reports described good performance on the respective tasks, we are unsure of the generality of distributed representations trained for a specific task such as the relation classification. In contrast, this paper demonstrated the contribution of distributed representations trained in a generic manner (with the Skip-gram objective) to the task of relation classification.

6 Conclusion

In this paper, we addressed the semantic modeling of relational patterns. We introduced the new dataset in which humans rated multiple similarity scores for every pair of relational patterns on the dataset of semantic inference (Zeichner et al., 2012). Additionally, we explored different encoders for composing distributed representations of relational patterns. The experimental results shows that Gated Additive Composition (GAC), which is a combination of additive composition and the gating mechanism, is effective to compose distributed representations of relational patterns. Furthermore, we demonstrated that the presented dataset is useful to predict successes of the distributed representations in the relation classification task.

We expect that several further studies will use the new dataset not only for distributed representations of relational patterns but also for other NLP tasks (e.g., paraphrasing). Analyzing the internal mechanism of LSTM, GRU, and GAC, we plan to explore an alternative architecture of neural networks that is optimal for relational patterns.

The More Antecedents, the Merrier: Resolving Multi-Antecedent Anaphors

Hardik Vala[1], **Andrew Piper**[2], **Derek Ruths**[1]

Abstract

Anaphor resolution is an important task in NLP with many applications. Despite much research effort, it remains an open problem. The difficulty of the problem varies substantially across different sub-problems. One sub-problem, in particular, has been largely untouched by prior work despite occurring frequently throughout corpora: the anaphor that has multiple antecedents, which here we call *multi-antecedent anaphors* or m-anaphors. Current coreference resolvers restrict anaphors to at most a single antecedent. As we show in this paper, relaxing this constraint poses serious problems in coreference chain-building, where each chain is intended to refer to a single entity. This work provides a formalization of the new task with preliminary insights into multi-antecedent noun-phrase anaphors, and offers a method for resolving such cases that outperforms a number of baseline methods by a significant margin. Our system uses local agglomerative clustering on candidate antecedents and an existing coreference system to score clusters to determine which cluster of mentions is antecedent for a given anaphor. When we augment an existing coreference system with our proposed method, we observe a substantial increase in performance (0.6 absolute CoNLL F1) on an annotated corpus.

1 Introduction

Anaphor resolution is a very difficult task in Natural Language Understanding, involving the complex interaction of discourse cues, syntactic rules, and semantic phenomena. It is closely related to the task of coreference resolution (Van Deemter and Kibble, 2000), for which a myriad of solutions have been proposed (Clark and Manning, 2015; Peng et al., 2015; Wiseman et al., 2015; Björkelund and Farkas, 2012; Lee et al., 2011; Stoyanov et al., 2010; Ng, 2008; Bergsma and Lin, 2006; Soon et al., 2001). However, given the complexity of the problem, a comprehensive approach remains elusive. The difficulty varies drastically across different cases (proper nouns, pronouns, gerunds, etc.), each of which involves different assumptions about and models of various linguistic phenomena (e.g., vocabulary, syntax, and semantics). As a result, state-of-the-art systems yield varying performance across sub-problems (Mitkov, 2014; Kummerfeld and Klein, 2013; Björkelund and Nugues, 2011; Recasens and Hovy, 2009; Stoyanov et al., 2009; Bengtson and Roth, 2008; Van Deemter and Kibble, 2000; Ng and Cardie, 2002b; Kameyama, 1997).

To avoid the complexity of the overarching resolution task, many current systems — whether learning-based (Clark and Manning, 2015; Peng et al., 2015; Wiseman et al., 2015; Durrett and Klein, 2013; Björkelund and Farkas, 2012) or rule-based (Lee et al., 2011) — focus on a restricted version of the problem, where candidate anaphors are linked to at most one antecedent, from which coreference chains are built by propagating the induced equivalence relation, with each chain corresponding to an entity (Van Deemter and Kibble, 2000).

While this single-antecedent inference task does resolve a very large number of anaphors in any given text, it leaves one quite common sub-problem virtually untouched: anaphors that link to multiple antecedents. These have sometimes been called split-antecedent anaphors; here we use the term *multi-antecedent anaphors* or m-anaphors in

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2287–2296,
Berlin, Germany, August 7-12, 2016.

order to emphasize the existence of more than one (possibly more than two) antecedents for a given anaphor. Consider the following examples:

(1) *[Elizabeth]$_1$ met [Mary]$_2$ at the park and [they]$_{1,2}$ began their stroll to the river.*

(2) *Mrs. Dashwood, having moved to another country, saw her [mother]$_1$ and [sister-in-law]$_2$ demoted to occasional visitors. As such, however, her old [kin]$_{1,2}$ were treated by her new family with quiet civility.*

Such cases present a challenge to state-of-the-art methods: certain features well-suited for the single-antecedent case do not apply (e.g. gender and pluarity) (Recasens and Hovy, 2009; Stoyanov et al., 2009; Bergsma and Lin, 2006), and strong long-distance effects cannot be ignored (Ingria and Stallard, 1989). Moreover, the presence of multiple antecedents for a single anaphor violates the separation between coreference chains.

In this paper, we address the multi-antecedent case of noun-phrase (NP) anaphor resolution in English, the most widely understood and studied form of coreference resolution (Ng, 2010; Ng, 2008). While we frame the general question of multi-antecedent inference, we restrict our analyses to one particular sub-problem: resolving the antecedents of the pronouns *they* and *them*. These pronouns best isolate the characteristics of m-anaphors (see Section 2 for more on the motivation of this choice). We propose a system for resolving *they* and *them* that models grouping compatibility of mentions through a maximum entropy pairwise model, independently from coreference of groupings, which is handled through an existing coreference resolution system leveraging corpus knowledge.

This paper makes four core contributions. First, it provides a generalization of the anaphor resolution problem to permit linking to multiple antecedents. Second, we characterize core properties of m-anaphors and their linguistic environments in a large, annotated corpus. Third, we provide a entity-centric system for specifically resolving multi-antecedent cases that outperforms a number of baselines. And, finally, we show how to pair our system with an existing coreference system and show a gain of 0.6 points (CoNLL F1) on the complete coreference resolution task (resolving all anaphors, single- and multi-antecedent).

The rest of the paper is organized as follows: We introduce the terminology and problem statement for split-antecedent resolution in Section 2. A summary of the data is given in Section 3 and the behaviour of split-antecedent anaphors is analyzed in Section 4. Our approach to antecedent prediction is presented in Section 5 and the results and analysis are reported in Section 6. Finally, we review related work in Section 7 and conclude and discuss future work in Section 8.

2 Problem

This section establishes the terminology used throughout the paper and reformulates the anaphor resolution problem to incorporate linking to multiple antecedents.

2.1 Terminology

We introduce the term m-anaphor for convenience as a special case of anaphor that has to multiple antecedents. For example, *they* and *kin* in Examples (1) and (2), respectively, from the Introduction are m-anaphors. By extension, 1-anaphors are anaphors that have only one antecedent.

Similarly, we define an m-antecedent as one of multiple antecedents of an m-anaphor and we refer to m-antecedents with the same m-anaphor as *siblings*. In Example (1) from the Introduction, *Elizabeth* and *Mary* are sibling m-antecedents of *they*, and in Example (2), *mother* and *sister-in-law* are sibling m-antecedents of *kin*.

Finally, we refer to anaphors with two, three, and four m-antecedents as *2-anaphors*, *3-anaphors*, and *4-anaphors*, respectively. We provide two more examples:

(3) *[Mr. Holmes]$_1$ stared off into the distance. [Watson]$_2$ simply walked off. [Both]$_{1,2}$ were troubled by the news.*

(4) *Virginia found herself alone with her [brother]$_1$, and then the thought of her [sister]$_2$ came to mind. [She]$_3$ remembered the camping trip [they]$_{1,2,3}$ embarked on a few summers ago.*

The anaphor in Example (3) is a 2-anaphor and the anaphor in Example (4) is a 3-anaphor.

2.2 Definition

We define the NP anaphor resolution problem similar to Wiseman et al. (2015), Durrett and Klein

Pronoun	# m-anaphors
they	278
them	165
we	140
you	43
everybody	12

Table 1: Counts of the most frequent m-anaphoric pronouns in P&P.

(2013), and Hirschman (1997): Let $\mathcal{M}$ denote the set of all identified mentions in a document and let $M(x) \subseteq \mathcal{M}$ denote all mentions preceding a mention $x \in \mathcal{M}$. The objective of the task is, for each $x \in \mathcal{M}$, to find $C \subseteq M(x)$ such that all mentions in C are antecedent to x. If $C = \emptyset$, then x is non-anaphoric and if $|C| \geq 1$, then x is 1-anaphoric, and if $|C| > 1$, then x is m-anaphoric. Hence, this formulation generalizes the problem to account for multi-antecedent anaphors.

To constrain the scope of the study, we perform all our analyses on gold mentions, leaving the effect of imperfect mention detection as a problem for future work (this has been studied for the single-antecedent case in Stoyanov et al. (2009)). Moreover, we only consider mentions of *they* and *them* that are known to be m-anaphoric for three reasons. First, non-pronomial m-anaphors, i.e. proper and common nouns, are much more susceptible to long-distance effects and may require external knowledge to resolve. Second, by focusing on this case, we circumvent a host of very involved aspects of the complete m-anaphor resolution problem, i.e. determining whether a mention is m-anaphoric, 1-anaphoric, or not anaphoric at all. For example, *you* may refer to one person or multiple, *who* can be used as an interrogative (non-anaphoric) or reflexive pronoun (anaphoric)), pronouns such as *anyone* and *everyone* introduce many scoping difficulties, and pleonastic pronouns must be removed from the inference task entirely. Third, *they* and *them* are the most prevalent of all pronouns in our dataset (refer to Table 1).

3 Data

Our dataset comprises of the *Pride and Prejudice* novel (P&P) (121440 words) and 36 short stories from the *Scribner Anthology of Contemporary Short Fiction* (Martone et al., 1999) (Scribner) (total of 216901 words), representing an eclectic collection of stories from the modern era. For P&P, all mentions of character have been fully resolved to their antecedents, including mentions referencing multiple characters. For Scribner, all mentions of *they* and *them* are resolved (m-anaphoric, 1-anaphoric, and singleton), including those of non-person entities.

	they		*them*		Total	
	#	%	#	%	#	%
P&P	278	32.10	165	19.05	443	51.15
Scribner	243	12.96	79	4.21	322	17.17
Total	521	19.01	244	8.90	765	27.91

Table 2: Number of m-anaphoric *they* and *them* mentions and % of all *they* and *them* mentions that are m-anaphors.

These stories were annotated by three annotators according to a slightly modified version of the ACE coreference resolution task formulation (Doddington et al., 2004) to allow multiple antecedents. Annotations were conducted through the *brat*[1] annotation tool (Stenetorp et al., 2012)) and the inter-annotator agreement on the shared texts (3 stories from Scribner + 7 chapters from P&P) was 86.5%.

Overall, in P&P, 1289 m-anaphors were discovered, of which 34 (2.6%) were proper nouns, 536 (41.6%) were common nouns, and 719 (55.8%) were pronouns. Table 2 shows the number of gold m-anaphoric *they* and *them* mentions and the percentage of all *they* and *them* mentions that are m-anaphoric.

Literary works were chosen over other textual modalities, e.g. news articles, because they showed a higher density of m-anaphors (a preliminary annotation exercise showed that literary works contained 37% more m-anaphors per word).

The dataset is partitioned according to a roughly, 60/20/20 split into training, validation, and testing sets, where the split is applied to the text of P&P (e.g. the first 60% of story text is used for training), and the collection of Scribner stories (e.g. 60% of the stories were used for training).

4 Behaviour of m-anaphors

m-anaphors present a novel class of anaphor for which very little knowledge exists. To better understand the linguistic behaviour of m-anaphors, we perform the following analyses. First, we examine first and second order statistics of our

[1] `http://brat.nlplab.org`

	First	Second
Avg. distance (# words)	17.08	33.50
Std. distance (# words)	23.80	40.66
Avg. distance (# sent.)	1.19	2.28
Std. distance (# sent.)	3.18	5.10
Avg. # intermediates	1.44	4.21
Std. # intermediates	2.33	4.44

Table 3: Average and standard deviations of the word distance, sentence distance, and number of intermediate mentions between the first and second most recent mentions to an m-anaphor.

Feature	Coefficient	p-value
Sentence position = first	0.16	0.13
Sentence position = last	-0.18	0.006
Dependency = subject	0.27	0.05
Dependency = object	0.08	0.24
Dependency = preposition	-0.22	0.07
Coordinated = true	0.29	0.08
Presence of negation	0.06	0.31
Presence of modality	0.04	0.21

Table 4: Features for m-anaphoricity versus 1-anaphoricity with coefficients estimated from a maximum entropy model, and associated p-values.

dataset to gain insight into the distribution of m-anaphors across a number of dimensions. Second, we fit a maximum entropy model over common coreference features for distinguishing m-anaphoric and anaphoric mentions to evaluate the importance of various features in determining m-anaphoricity versus anaphoricity of mentions.

4.1 m-anaphor Statistics

The distribution of m-anaphors according to the number of referenced $m-$antecedents is as follows: 79.3% are 2-anaphors, 13.2% are 3-anaphors, 3.7% are 4-anaphors, and the remaining 3.8% refer to larger numbers of antecedents. Despite the bias towards 2-anaphors, the simple approach to m-anaphor resolution of taking the previous two mentions as m-antecedent siblings will fail according to Table 3. The usual presence of intermediate mentions between m-anaphors and their m-antecedents makes the resolution task non-trivial. Moreover, the large distances between m-anaphors and their antecedents attenuates any signal for coreference, introducing greater noise to the problem.

4.2 m-anaphoricity Features

The statistics discussed above shed light on the complexity of this problem. Here, we examine whether certain surface-level features of anaphoric phenomena from prior work exhibit any differences for m-anaphoric mentions over anaphoric ones. We construct a maximum entropy model from the training data over the combination of syntactic and semantic features in Table 4, inspired by Wiseman et al. (2015), Durrett and Klein (2013), and Recasens et al. (2013b). The binary classification decision is between m-anaphoric and 1-anaphoric mentions, coded as '1' and '0', respectively. Therefore, the estimated coefficients that are positive favor m-anaphoricity and those that are negative favor 1-anaphoricity.

Except for the feature testing on the last sentence position, none of the results in Table 4 were able to reach statistical significance, suggesting at a surface level, m-anaphoricity and 1-anaphoricity behave very similarly and operate in similar linguistic environments. One possibility is that a deeper set of features is required for distinguishing m-anaphors from 1-anaphors. We identify this as an important topic for future work in this area.

5 m-anaphor Resolution

Our approach to m-anaphor resolution draws inspiration from mention pair models for coreference that make independent binary classification decisions (Ng, 2010). In our method, we employ a maximum entropy model that makes binary decisions on mention pairs as well, but the decision corresponds to "group compatibility" of mentions, i.e. to what degree can a given set of mentions be the sibling m-antecedents to the same m-anaphor. This model is embedded in an agglomerative clustering process, after which a coreference decision is made between clusters and the given m-anaphor. Thus, our model treats the grouping of candidate mentions into sibling sets independently from antecedent-anaphor linking.

5.1 Architecture

Given an m-anaphor g in document $\mathcal{D}$, the steps of our approach are as follows:

1. Mentions preceding g within a k-sentence window are extracted as candidate m-antecedents to g.

2. Perform an agglomerative clustering of the candidate mentions using similarity metric

SIM_1 and average-linkage criteria. Let $\mathcal{C}$ represent the clustering.

3. Each non-singleton cluster $C \in \mathcal{C}$ is scored according to the probability of coreference of the m-anaphor to the cluster. This is done by appealing to an external corpus comprising of sentences containing either *they* or *them*. The grouping of sentences in the document containing all of the mentions in C (and sentences in-between) are compared to each *they* or *them* sentence in the external corpus (depending on the identity of g) using similarity metric SIM_2. The sentence yielding the maximum similarity is selected. The probability of coreference is then calculated by replacing the sentence grouping with the extracted sentence and applying an existing coreference system $COREF$ between g and its counterpart (*they* or *them*) in the extracted sentence.

4. The cluster C_{max} producing the highest probability of coreference is predicted as the group of m-antecedents for g.

Again, inspired by mention-pair models for coreference resolution (Clark and Manning, 2015; Björkelund and Farkas, 2012; Ng and Cardie, 2002a), the SIM_1 similarity metric is defined as $\sigma(\mathbf{w}^\top \mathbf{x})$, where $\mathbf{w}$ is a weight vector and $\mathbf{x}$ is a feature vector defined for a pair of mentions. The parameter vector $\mathbf{w}$ is learned using the standard cross-entropy loss function in a maximum entropy model, where the target variable is a decision on whether the mentions pairs are siblings or not. The learning is conducted over the training set with L2-regularization.

For SIM_2, which is responsible for selecting replacement sentences, we experiment with two different similarity metrics: (1) longest common subsequence normalized by sentence length (LCS) and (2) a subset tree kernel (Collins and Duffy, 2002) with a bag-of-words extension as described in Moschitti (2006), which also describes a simple adaptation to forests (for multiple sentences). The named entity (NE) mentions in sentences are replaced by corresponding NE type placeholders (PERSON, LOCATION, etc. as described in Finkel et al. (2005)) before comparison.

In the experiments to follow, we adopt the classification mention-pair model, a component of the statistical coreference resolution system available in the Stanford CoreNLP suite[2] system, described in Clark and Manning (2015), as $COREF$ for scoring coreference. The external corpus was built from texts comparable to our dataset. 651,108 sentences containing one of *they* or *them* were mined from a larger corpus of 798 literary texts spanning the nineteenth and twentieth centuries (including novels such as *To The Lighthouse*, by Virginia Woolf). Lastly, the candidate m-antecedents are extracted from a 5-sentence pre-window of the given m-anaphor (k = 5) and the regularization parameter in learning is set to 0.20.

5.2 Clustering Features

Table 5 depicts the features we chose to use in the pairwise similarity metric (SIM_1) for agglomerative clustering of candidate m-antecedents. All are common to many coreference resolver systems (Durrett and Klein, 2013; Recasens et al., 2013b; Stoyanov et al., 2010). We distinguish between mention features (Columns 1 & 2), which are defined for each candidate m-antecedent in a pair, and pairwise features (Columns 3-5), which are defined over a pair of candidate m-antecedents.

Three features, in particular, deserve further discussion. Under morphosyntax (Column 3), *[Type Conjunctions]* is a placeholder for a number of conjunctive boolean features derived from the noun type (pronoun/proper/common) of each antecedent in a pairing: e.g., pronoun-pronoun, pronoun-proper, proper-pronoun. Similarly, *[Dependency Conjunctions]* is a placeholder for conjunctive boolean features derived from the grammatical dependency of each antecedent in a pairing: e.g., subject-subject, subject-object, object-subject. The *[# Dependency Pairings]* is an ordinal version of the *Dependency Conjunctions* feature set - a count of the number of occurrences rather than an indicator variable.

The 'Governor = except' feature triggers if one of the mentions in the mention pair is governed by *except* or *exclude*. It represents a form of negation of group membership (e.g. *Everyone except for Mary visited Castlebary*).

Features were extracted using the Stanford CoreNLP system (Manning et al., 2014) and animacy information was specifically obtained through the Stanford deterministic coreference resolution module (Lee et al., 2011).

Morphosyntax (Mention)	Grammatical (Mention)	Morphosyntax (Pairwise)	Grammatical (Pairwise)	Semantic (Pairwise)
Type = pronoun	Sentence position = first	Head match	Word distance (max. 30)	Governor = except
Type = proper noun	Sentence position = last	[Type Conjunctions]	Sentence distance	# Conjunctive pairings
Animacy = animate	Dependency = subject		Coordination = and	[# Dependency Pairings]
Animacy = unknown	Dependency = object		[Dependency Conjunctions]	
Person = first	Dependency = preposition			
Person = third				
Singular = true				
Quantified = true				
# Modifiers				

Table 5: Features used in the clustering similarity metric, separated by category. The features *[Type Conjunctions]*, *[Dependency Conjunctions]*, and *[# Dependency Pairings]* are all placeholders for feature sets. See the text for details.

6 Experiments

In order to assess the performance of our method, we conduct two experiments. In the first, we assess performance of our system on the specific *they-them* m-anaphor resolution sub-task. Our system, and its variants, are compared against a number of baseline methods based on performance on the test set.

In the second experiment, we consider how our system improves the performance of a coreference resolution system when *all* anaphors (both 1-anaphors and m-anaphors) are considered.

6.1 Evaluation

Accuracy is measured in terms of the number of mention pairs correctly grouped as m-antecedents for a given m-anaphor — similar to previous works in anaphor resolution (Peng et al., 2015). We use the standard classification metrics for precision, recall, and F1-score. If $n_1, n_2, \ldots, n_N$ represent the number of gold m-antecedents for m-anaphors $g_1, g_2, \ldots, g_N$ in a document, and $m_1, m_2, \ldots, m_N$ are predicted, of which $k_1, k_2, \ldots, k_N$ are correct, then precision is defined as $\sum_i k_i / \sum_i m_i$ and recall as $\sum_i k_i / \sum_i n_i$, where i ranges from 1 to N.

In order to align ourselves with the gold labels, we adjust the predicted mention corresponding to an entity to the closest one preceding the given m-anaphor. Because a given entity may appear multiple times in a candidate mention window, the most recent one, relative to the m-anaphor, is not always the one carrying the strongest signal and hence is not always predicted as an antecedent. For the purposes of evaluation, such cases are considered correct. Automatic handling would involve a separate, single-antecedent coreference resolver, but given the thesis of this work is the multi-antecedent case, this choice is justified.

6.2 System Comparison

We first describe the various baselines and variants of our method we assess and then analyze the performance results.

Systems

- The "most-recent-k" baselines (denoted RECENT-k), which predict the most recent k mentions, relative to the m-anaphor, as the m-antecedents for k = 2, 3, 4.

- The random selection baseline (denoted RANDOM), which randomly predicts mentions in a 5-sentence pre-window as the antecedents according to a binomial with probability 0.5 (imposing the constraint that at least two must be predicted).

- A simple rule-based method (denoted RULE) which proceeds as follows:

  – If the m-anaphor occupies a subject or prepositional position, then predict the most recent mentions in subject positions if they are coordinated, otherwise take them from previous, distinct sentences. If no such mentions can be found take the most recent mentions in subject and object positions governed by the same verb.

  – If the m-anaphor occupies in object position, take the previous mentions in object or prepositional positions if they are coordinated, otherwise take them from previous, distinct sentences. If no such mentions can be found, take the most recent mentions in subject and object positions governed by the same verb.

  – Otherwise, take the two most recent mentions (usually arrive here if there is an error in the dependency parsing).

	Precision	Recall	F1
RECENT-2	21.46	17.68	19.39
RECENT-3	23.73	30.10	26.54
RECENT-4	21.43	38.82	27.62
RANDOM	30.02	29.11	29.56
RULE	39.23	17.45	24.16
LEE	**46.78**	9.91	16.36
M-LCS	41.35	37.81	39.50
M-TREE	41.94	**44.88**	**43.36**

Table 6: Test set performance of each system on the m-anaphor resolution task.

m-anaphor class	Precison	Recall	F1
2-anaphor	48.14	52.90	50.41
3-anaphor	35.92	34.77	35.34
4-anaphor	36.74	12.87	19.06

Table 7: Performance results of the M-TREE system on the different classes of m-anaphors.

- The system described in Lee et al. (2011) (denoted LEE), which performs some light m-anaphor resolution (solely for conjunctive cases).
- The two variants of the developed method, one using the LCS similarity metric (denoted M-LCS) and the other using the subset tree kernel (M-TREE).

Results and Discussion

Accuracy results on the test set for each of the systems are given in Table 6. Both the proposed systems, M-LCS and M-TREE, outperform all other methods by a substantial margin. The Stanford system achieves the highest precision, which is not surprising because it targets conjunctive mentions, which often serve as m-antecedents. Based on the analysis of Section 4, the poor performance of RECENT-2, RECENT-3, and RECENT-4 is expected.

The results for the best-performing system, M-TREE, on the different classes of m-anaphors is given in Table 7. M-TREE outperforms all other systems but exhibits a bias towards 2-anaphors, recent mentions, and mentions coordinated by conjunction. This is not surprising given such cases are the easiest to resolve.

6.3 Full Coreference Resolution

For the complete coreference resolution task, the M-TREE system can be integrated with an existing coreference system. For this experiment, we pair the full coreference resolution system of Clark and Manning (2015) with M-TREE, and we raise the prediction threshold of our model to 0.89, at which point precision on the validation set is 78.9. Moreover, we restrict ourselves to the P&P portion of the test set, given the Scribner stories only have gold labels for instances of *they* and *them*.

	MUC	B^3	CEAF_e	Avg.
CLARK	42.3	39.5	32.4	38.1
CLARK+M-TREE	**43.4**	**40.0**	**31.9**	**38.7**

Table 8: CoNLL metric scores for coreference resolution on the test portion of P&P for the Clark and Manning (2015) system, with (CLARK+M-TREE) and without (CLARK) the pairing with M-TREE.

The Clark and Manning (2015) system is first run over the test set, producing coreference chains which are then filtered for character entities using the approach of Vala et al. (2015). Our adjusted M-TREE system is then applied over all *they* and *them* mentions. Each such mention predicted as m-anaphoric is added to the coreference chains of the entities corresponding to the m-antecedent mentions.

To evaluate the accuracy against the gold mention clusters, each m-anaphoric *they* and *them* is added to each cluster containing a gold m-antecedent. The CoNLL metric scores (Bagga and Baldwin, 1998) of the coreference predictions are shown in Table 8, with the integrated system outperforming the Clark and Manning (2015) system by 0.6 average score (pairing the Clark and Manning (2015) system instead with an oracle m-anaphor resolver yields an average score of 44.8, an increase of 6.7 points).

7 Related Work

The formal problem statement for the noun phrase anaphor resolution we propose is an extension of the standard ACE (Doddington et al., 2004), MUC (Hirschman, 1997), and Ontonotes (Hovy et al., 2006) formulations, as well as the problem settings outlined in Wiseman et al. (2015) and Durrett and Klein (2013), to allow anaphors to link to multiple antecedents. Most previous works impose the constraint that anaphors can be assigned at most one antecedent. Some works cast the coreference resolution problem in an Integer Linear Programming framework, with an explicit constraint for

assigning at most one antecedent to an anaphor (Peng et al., 2015; Denis et al., 2007).

The early work of Ingria and Stallard (1989) proposes the resolution of pronouns without the restriction they be linked to at most one antecedent. The method uses an indexing scheme for parse trees, similar to Hobb's algorithm (Hobbs, 1978), that eliminates candidates antecedents as more information is acquired. Those pronouns with multiple candidates remaining after tree-traversal are predicted as m-anaphors. The method considers each parse tree in isolation, and hence does not permit inter-sentential linking, a severe limitation in corpora such as the one offered in this work.

Other researchers have evaluated noun phrase coreference resolvers along a number of dimensions, including different classes of anaphors (Mitkov, 2014; Kummerfeld and Klein, 2013; Björkelund and Nugues, 2011; Recasens and Hovy, 2009; Stoyanov et al., 2009; Bengtson and Roth, 2008; Van Deemter and Kibble, 2000; Ng and Cardie, 2002b; Kameyama, 1997). This work explores a new class of anaphor, previously unstudied, and evaluates its impact on the coreference resolution problem.

Many state-of-the-art systems for coreference resolution, especially supervised, are constrained to the single-antecedent case (Clark and Manning, 2015; Peng et al., 2015; Wiseman et al., 2015; Björkelund and Farkas, 2012; Ng, 2010; Stoyanov et al., 2010; Ng, 2008; Soon et al., 2001). The most well-known, benchmark datasets for coreference resolution (e.g. Ontonotes and ACE-2005), do not offer gold annotations for multi-antecendet anaphors. Our work presents the first dataset for tackling this problem.

The Lee et al. (2011) is a deterministic system that attempts to resolve the "easy" multi-antecedent cases, namely those in which mentions are joined by some conjunction. Our system goes beyond and attempts to predict more difficult cases as well.

Many of the individual features we employ in our model appear in a variety of other coreference systems, especially those involving mention-pair models (Durrett and Klein, 2013; Recasens et al., 2013b; Stoyanov et al., 2010). Recasens et al. (2013a) attempts to perform coreference resolution under conditions where many standard features for coreference are not suited. Peng et al. (2015) resort to corpus counts of predicates as features, much in the same way we obtain counts of mention pairings according to simple predicates on dependency structures.

The system of Clark and Manning (2015) also makes uses of agglomerative clustering, although it's employed in merging coreference chains, rather than candidate antecedent groupings.

Last, resorting to an external corpus for sentence structures is common practice in the Natural Language Generation literature for producing phrases that are coherent and consistent(Krishnamoorthy et al., 2013; Bangalore and Rambow, 2000; Langkilde and Knight, 1998).

8 Conclusion

We introduced a new class of anaphors to the anaphor resolution problem, m-anaphors, and extended the problem formulation to incorporate them. We offered insights into the linguistic behaviour of m-anaphors, finding that surface-level syntactic and semantic features do not carry enough discriminative power in distinguishing them from 1-anaphors. Furthermore, we developed a system combining a mention-pair model, an existing coreference resolver, and corpus knowledge to resolve m-anaphors that scores higher than a number of baseline methods. Finally, we paired this system with a coreference resolver to solve the general coreference resolution task, showing that m-anaphor prediction can help boost performance.

An important component of the m-anaphor resolution problem that falls outside the scope of this study, but is important for practical application, is the detection of m-anaphoric mentions. Section 4 gives some insight into the problem but a much deeper investigation is necessary to devise a detection method.

Moreover, for simplicity, this study focused solely on m-anaphoric *they* and *them* mentions, but as explained earlier, m-anaphoric mentions can take many forms, each introducing their own particular complexities that warrant special attention.

Regarding the system developed for m-anaphor resolution, resorting to an external corpus to obtain well-formed sentences proved to be very computationally expensive. In future work, we look to incorporate methods that incur less cost, possibly tolerating some error in the formation of

sentences without significantly degrading performance. Also, negation of group membership is a complex linguistic phenomenon that was handled in a crude manner in our system. We look to devote future work to handling such cases.

To promote further research into m-anaphors, we make all our data and software freely available at `http://www.github.com/networkdynamics/manaphor-acl2016`.

Automatic Labeling of Topic Models Using Text Summaries

Xiaojun Wan and Tianming Wang
Institute of Computer Science and Technology, The MOE Key Laboratory of Computational Linguistics, Peking University, Beijing 100871, China
{wanxiaojun, wangtm}@pku.edu.cn

Abstract

Labeling topics learned by topic models is a challenging problem. Previous studies have used words, phrases and images to label topics. In this paper, we propose to use text summaries for topic labeling. Several sentences are extracted from the most related documents to form the summary for each topic. In order to obtain summaries with both high relevance, coverage and discrimination for all the topics, we propose an algorithm based on submodular optimization. Both automatic and manual analysis have been conducted on two real document collections, and we find 1) the summaries extracted by our proposed algorithm are superior over the summaries extracted by existing popular summarization methods; 2) the use of summaries as labels has obvious advantages over the use of words and phrases.

1 Introduction

Statistical topic modelling plays very important roles in many research areas, such as text mining, natural language processing and information retrieval. Popular topic modeling techniques include Latent Dirichlet Allocation (LDA) (Blei et al., 2003) and Probabilistic Latent Semantic Analysis (pLSA) (Hofmann, 1999). These techniques can automatically discover the abstract "topics" that occur in a collection of documents. They model the documents as a mixture of topics, and each topic is modeled as a probability distribution over words.

Although the discovered topics' word distributions are sometimes intuitively meaningful, a major challenge shared by all such topic models is to accurately interpret the meaning of each topic (Mei et al., 2007). The interpretation of each topic is very important when people want to browse, understand and leverage the topic. However, it is usually very hard for a user to understand the discovered topics based only on the multinomial distribution of words. For example, here are the top terms for a discovered topic: {*fire miles area north southern people coast homes south damage northern river state friday central water rain high california weather*}. It is not easy for a user to fully understand this topic if the user is not very familiar with the document collection. The situation may become worse when the user faces with a number of discovered topics and the sets of top terms of the topics are often overlapping with each other on many practical document collections.

In order to address the above challenge, a few previous studies have proposed to use phrases, concepts and even images for labeling the discovered topics (Mei et al., 2007; Lau et al., 2011; Hulpus et al., 2013; Aletras and Stevenson, 2013). For example, we may automatically extract the phrase "*southern california*" to represent the example topic mentioned earlier. These topic labels can help the user to understand the topics to some extent. However, the use of phrases or concepts as topic labels are not very satisfactory in practice, because the phrases or concepts are still very short, and the information expressed in these short labels is not adequate for user's understanding. The case will become worse when some ambiguous phrase is used or multiple discrete phrases with poor coherence are used for a topic. To address the drawbacks of the above short labels, we need to provide more contextual information and consider using long text descriptions to represent the topics. The long text descriptions can be used independently or used as beneficial complement to the short labels. For example, below is part of the summary label produced by our proposed method and it provides much more contextual information for understanding the topic.

The contributions of this paper are summarized as follows:

1) We are the first to invesitage using text summaries for topic labeling;

2) We propose a summarization algorithm based on submodular optimization to extract summaries with both high relevance, coverage and discrimination for all topics.

3) Automatic and manual analysis reveals the usefulness and advantages of the summaries produced by our algorithm.

2 Related Work

2.1 Topic Labeling

After topics are discovered by topic modeling techniques, these topics are conventionally represented by their top *N* words or terms (Blei et al., 2003; Griffiths and Steyvers, 2004). The words or terms in a topic are ranked based on the conditional probability $p(w_i|t_j)$ in that topic. It is sometimes not easy for users to understand each topic based on the terms. Sometimes topics are presented with manual labeling for exploring research publications (Wang and McCallum, 2006; Mei et al., 2006), and the labeling process is time consuming.

In order to make the topic representations more interpretable and make the topics easier to understand, there are a few studies proposing to automatically find phrases, concepts or even images for topic labeling. Mei et al. (2007) proposed to use phrases (chunks or ngrams) for topic labeling and cast the labeling problem as an optimization problem involving minimizing Kullback-Leibler (KL) divergence between word distributions and maximizing mutual information between a label and a topic model. Lau et al. (2011) also used phrases as topic labels and they proposed to use supervised learning techniques for ranking candidate labels. In their work, candidate labels include the top-5 topic terms and a few noun chunks extracted from related Wikipedia articles. Mao et al. (2012) proposed two effective algorithms that automatically assign concise labels to each topic in a hierarchy by exploiting sibling and parent-child relations among topics. Kou et al. (2015) proposed to map topics and candidate labels (phrases) to word vectors and letter trigram vectors in order to find which candidate label is more semantically related to that topic. Hulpus et al. (2013) took a new approach based on graph centrality measures to topic labelling by making use of structured data exposed by DBpedia. Different from the above works, Aletras and Stevenson (2013) proposed to use images for representing topics, where candidate images for each topic are retrieved from the web and the most suitable image is selected by using a graph-based algorithm. In a very recent study (Aletras et al., 2015), 3 different topic representations (lists of terms, textual phrase labels and images labels) are compared in a document retrieval task, and results show that textual phrase labels are easier for users to interpret than term lists and image labels.

The phrase-based labels in the above works are still very short and are sometimes not adequate for interpreting the topics. Unfortunately, none of previous works has investigated using textual summaries for representing topics yet.

2.2 Document Summarization

The task of document summarization aims to produce a summary with a length limit for a given document or document set. The task has been extensively investigated in the natural language processing and information retrieval fields, and most previous works focus on directly extracting sentences from a news document or collection to form the summary. The summary can be used for helping users quickly browse and understand a document or document collection.

Typical multi-document summarization methods include the centroid-based method (Radev et al., 2004), integer linear programming (ILP) (Gillick et al., 2008), sentence-based LDA (Chang and Chien, 2009), submodular function maximization (Lin and Bilmes, 2010; Lin and Bilmes, 2011), graph based methods (Erkan and Radev, 2004; Wan et al., 2007; Wan and Yang, 2008), and supervised learning based methods (Ouyang et al., 2007; Shen et al., 2007). Though different summarization methods have been proposed in recent years, the submodular function maximization method is still one of the state-of-the-art summarization methods. Moreover, the method is easy to follow and its framework is very flexible. One can design specific submodular functions for addressing special summarization tasks, without altering the overall greedy selection framework.

Though various summarization methods have been proposed, none of existing works has investigated or tried to adapt document summarization techniques for the task of automatic labeling of topic models.

3 Problem Formulation

Given a set of latent topics extracted from a text collection and each topic is represented by a multinomial distribution over words, our goal is to produce understandable text summaries as labels for interpreting all the topics. We now give two useful definitions for later use.

Topic: Each topic θ is a probability distribution of words $\{p_\theta(w)\}_{w\in V}$, where V is the vocabulary set, and we have $\sum_{w\in V} p_\theta(w) = 1$.

Topic Summary: In this study, a summary for each topic θ is a set of sentences extracted from the document collection and it can be used as a label to represent the latent meaning of θ. Typically, the length of the summary is limited to 250 words, as defined in recent DUC and TAC conferences.

Like the criteria for the topic labels in (Mei et al., 2007), the topic summary for each topic needs to meet the following two criteria:

High Relevance: The summary needs to be semantically relevant to the topic, i.e., the summary needs to be closely relevant to all representative documents of the topic. The higher the relevance is, the better the summary is. This criterion is intuitive because we do not expect to obtain a summary unrelated to the topic.

High Coverage: The summary needs to cover as much semantic information of the topic as possible. The summary usually consists of several sentences, and we do not expect all the sentences to focus on the same piece of semantic information. A summary with high coverage will certainly not contain redundant information. This criterion is very similar to the diversity requirement of multi-document summarization.

Since we usually produce a set of summaries for all the topics discovered in a document collection. In order to facilitate users to understand all the topics, the summaries need to meet the following additional criterion:

High Discrimination: The summaries for different topics need to have inter-topic discrimination. If the summaries for two or more topics are very similar with each other, users can hardly understand each topic appropriately. The higher the inter-topic discrimination is, the better the summaries are.

4 Our Method

Our proposed method is based on submodular optimization, and it can extract summaries with both high relevance, coverage and discrimination for all topics. We choose the framework of submodular optimization because the framework is very flexible and different objectives can be easily incorporated into the framework. The overall framework of our method consists of two phases: candidate sentence selection, and topic summary extraction. The two phrases are described in the next two subsections, respectively.

4.1 Candidate Sentence Selection

There are usually many thousands of sentences in a document collection for topic modelling, and all the sentences are more or less correlated with each topic. If we use all the sentences for summary extraction, the summarization efficiency will be very low. Moreover, many sentences are not suitable for summarization because of their low relevance with the topic. Therefore, we filter out the large number of unrelated sentences and treat the remaining sentences as candidates for summary extraction.

For each topic θ, we compute the Kullback-Leibler (KL) divergence between the word distributions of the topic and each sentence s in the whole document collection as follows:

$$KL(\theta, s) = \sum_{w\in TW\cup SW} p_\theta(w) * log \frac{p_\theta(w)}{tf(w,s)/len(s)}$$

where $p_\theta(w)$ is the probability of word w in topic θ. TW denotes the set of top 500 words in topic θ according to the probability distribution. SW denotes the set of words in sentence s after removing stop words. $tf(w,s)$ denotes the frequency of word w in sentence s, and $len(s)$ denotes the length of sentence s after removing stop words. For a word w which does not appear in SW, we set $tf(w,s)/len(s)$ to a very small value (0.00001 in this study).

Then we rank the sentences by an increasing order of the divergence scores and keep the top 500 sentences which are most related to the topic. These 500 sentences are treated as candidate sentences for the subsequent summarization step for each topic. Note that different topics have different candidate sentence sets.

4.2 Topic Summary Extraction

Our method for topic summary extraction is based on submodular optimization. For each topic θ associated with the candidate sentence set V, our

method aims to find an optimal summary $\tilde{E}$ from all possible summaries by maximizing a score function under budget constraint:

$$\tilde{E} = argmax_{E \subseteq V}\{f(E)\} \quad \text{s.t. } len(E) \leq L$$

where $len(E)$ denotes the length of summary *E*. Here *E* is also used to denote the set of sentences in the summary. *L* is a predefined length limit, i.e. 250 words in this study.

$f(E)$ is the score function to evaluate the overall quality of summary *E*. Usually, $f(E)$ is required to be a submodular function, so that we can use a simple greedy algorithm to find the near-optimal summary with theoretical guarantee. Formally, for any $A \subseteq B \subseteq V \backslash v$, we have

$$f(A + v) - f(A) \geq f(B + v) - f(B)$$

which means that the incremental "value" of *v* decreases as the context in which *v* is considered grows from *A* to *B*.

In this study, the score function $f(E)$ is decomposed into three parts and each part evaluates one aspect of the summary:

$$f(E) = REL(E) + COV(E) + DIS(E)$$

where $REL(E)$, $COV(E)$ and $DIS(E)$ evaluate the relevance, coverage and discrimination of summary *E* respectively. We will describe them in details respectively.

4.2.1 Relevance Function

Instead of intuitively measuring relevance between the summary and the topic via the KL divergence between the word distributions of them, we consider to measure the relevance of summary *E* for topic θ by the relevance of the sentences in the summary to all the candidate sentences for the topic as follows:

$$REL(E) = \sum_{s' \in V} \min\{\sum_{s \in E} sim(s', s), \alpha \sum_{s \in V} sim(s', s)\}$$

where *V* represents the candidate sentence set for topic θ, and *E* is used to represent the sentence set of the summary. $sim(s', s)$ is the standard cosine similarity between sentences s' and s. $\alpha \in [0,1]$ is a threshold co-efficient.

The above function is a monotone submodular function because $f(x) = min(x, a)$ where $a \geq 0$ is a concave non-decreasing function. $\sum_{s \in E} sim(s', s)$ measures how similar *E* is to sentence s' and then $\sum_{s \in V} sim(s', s)$ is the largest value that $\sum_{s \in E} sim(s', s)$ can achieve. Therefore, s' is saturated by *E* when $\sum_{s \in E} sim(s', s) \geq \alpha \sum_{s \in V} sim(s', s)$. When $s'$is already saturated by *E* in this way, any new sentence very similar to s' cannot further improve the overall relevance of *E*, and this sentence is less possible to be added to the summary.

4.2.2 Coverage Function

We want the summary to cover as many topic words as possible and contain as many different sentences as possible. The coverage function is thus defined as follows:

$$COV(E) = \beta * \sum_{w \in TW} \left\{ p_\theta(w) * \sqrt{\sum_{s \in E} tf(w, s)} \right\}$$

where $\beta \geq 0$ is a combination co-efficient.

The above function is a monotone submodular function and it encourages the summary *E* to contain many different words, rather than a small set of words. Because $f(x) = \sqrt{x}$ where $x \geq 0$ is a concave non-decreasing function, we have $f(x + y) \leq f(x) + f(y)$. The value of the function will be larger when we use *x* and *y* to represent two frequency values of two different words respectively than that when we use $(x + y)$ to represent the frequency value of a single word. Therefore, the use of this function encourages the coverage of more different words in the summary. In other words, the diversity of the summary is enhanced.

4.2.3 Discrimination Function

The function for measuring the discrimination between the summary *E* of topic θ and all other topics $\{\theta'\}$ is defined as follows:

$$DIS(E) = -\gamma \sum_{\theta'} \sum_{s \in E} \sum_{w \in TW} p_{\theta'}(w) * tf(w, s)$$

where $\gamma \geq 0$ is a combination co-efficient.

The above function is still a monotone submodular function. The negative sign indicates that the summary *E* of topic θ needs to be as irrelevant with any other topic as possible, and thus making different topic summaries have much differences.

4.2.4 Greedy Selection

Since $REL(E)$, $COV(E)$ and $DIS(E)$ are all submodular functions, $f(E)$ is also a submodular function. In order to find a good approximation to the optimal summary, we use a greedy algorithm similar to (Lin and Bilmes, 2010) to select sentence one by one and produce the final summary, as shown in Algorithm 1.

Algorithm 1 Greedy algorithm for summary extraction

1: $E \leftarrow \emptyset$
2: $U \leftarrow V$
3: **while** $U \neq \emptyset$ **do**
4: $\hat{s} \leftarrow argmax_{s \in U} \frac{f(E \cup \{s\}) - f(E)}{len(s)^{\varepsilon}}$
5: $E \leftarrow E \cup \{\hat{s}\}$ if $\sum_{s \in E} len(s) + len(\hat{s}) \leq L$ and $f(E \cup \{s\}) - f(E) \geq 0$
6: $U \leftarrow U \setminus \{\hat{s}\}$
7: **end while**
8: return E

In the algorithm, $len(s)$ denotes the length of sentence *s* and $\varepsilon > 0$ is the scaling factor. At each iteration, the sentence with the largest ratio of objective function gain to scaled cost is found in step 4, and if adding the sentence can increase the objective function value while not violating the length constraint, it is then selected into the summary and otherwise bypassed.

5 Evaluation and Results

5.1 Evaluation Setup

We used two document collections as evaluation datasets, as in (Mei et al. 2007): AP news and SIGMOD proceedings. The AP news dataset contains a set of 2250 AP news articles, which are provided by TREC. There is a total of 43803 sentences in the AP news dataset and the vocabulary size is 37547 (after removing stop words). The SIGMOD proceeding dataset contains a set of 2128 abstracts of SIGMOD proceedings between the year 1976 and 2015, downloaded from the ACM digital library. There is a total of 15211sentences in the SIGMOD proceeding dataset and the vocabulary size is 13688.

For topic modeling, we adopted the most popular LDA to discover topics in the two datasets, respectively. Particularly, we used the LDA module implemented in the MALLET toolkit[1]. Without loss of generality, we extracted 25 topics from the AP news dataset and 25 topics from the SIGMOD proceeding dataset.

The parameter values of our proposed summarization method is either directly borrowed from previous works or empirically set as follows: $\alpha = 0.05$, $\beta = 250$, $\gamma = 300$ and $\varepsilon = 0.15$.

We have two goals in the evaluation: comparison of different summarization methods for topic labeling, and comparison of different kinds of labels (summaries, words, and phrases).

In particular, we compare our proposed summarization method (denoted as **Our Method**) with the following typical summarization methods and all of them extract summaries from the same candidate sentence set for each topic:

MEAD: It uses a heuristic way to obtain each sentence's score by summing the scores based on different features (Radev et al., 2004): centroid-based weight, position and similarity with first sentence.

LexRank: It constructs a graph based on the sentences and their similarity relationships and then applies the PageRank algorithm for sentence ranking (Erkan and Radev, 2004).

TopicLexRank: It is an improved version of LexRank by considering the probability distribution of top 500 words in a topic as a prior vector, and then applies the topic-sensitive PageRank algorithm for sentence ranking, similar to (Wan 2008).

Submodular(REL): It is based on submodular function maximization but only the relevance function is considered.

Submodular(REL+COV): It is based on submodular function maximization and combines two functions: the relevance function and the coverage function.

We also compare the following three different kinds of labels:

Word label: It shows ten topic words as labels for each topic, which is the most intuitive interpretation of the topic.

Phrase label: It uses three phrases as labels for each topic, and the phrase labels are extracted by using the method proposed in (Mei et al., 2007), which is very closely related to our work and considered a strong baseline in this study.

Summary Label: It uses a topic summary with a length of 250 words to label each topic and the summary is produced by our proposed method.

5.2 Evaluation Results

5.2.1 Automatic Comparison of Summarization Methods

In this section, we compare different summarization methods with the following automatic measures:

[1] http://mallet.cs.umass.edu/

KL divergence between word distributions of summary and topic: For each summarization method, we compute the KL divergence between the word distributions of each topic and the summary for the topic, then average the KL divergence across all topics. Table 1 shows the results. We can see that our method and Submodular(REL+COV) have the lowest KL divergence with the topic, which means our method can produce summaries relevant to the topic representation.

Topic word coverage: For each summarization method, we compute the ratio of the words covered by the summary out of top 20 words for each topic, and then average the ratio across all topics. We use top 20 words instead of 500 words because we want to focus on the most important words. The results are shown in Table 2. We can see that our method has almost the best coverage ratio and the produced summary can cover most important words in a topic.

Submodular (REL+COV)	0.023206	0.362795	0.048872	0.524863
Our Method	0.010304	0.093017	0.024551	0.116905

Table 3. Comparison of the average and max similarity between different topic summaries

Similarity between topic summaries: For each summarization method, we compute the cosine similarity between the summaries of any two topics, and then obtain the average similarity and the maximum similarity. Seen from Table 3, the topic summaries produced by our method has the lowest average and maximum similarity with each other, and thus the summaries for different topics have much difference.

5.2.2 Manual Comparison of Summarization Methods

In this section, we compare our summarization method with three typical summarization methods (MEAD, TopicLexRank and Submodular(REL)) manually. We employed three human judges to read and rank the four summaries produced for each topic by the four methods in three aspects: relevance between the summary and the topic with the corresponding sentence set, the content coverage (or diversity) in the summary and the discrimination between different summaries. The human judges were encouraged to read a few closely related documents for better understanding each topic. Note that the judges did not know which summary was generated by our method and which summaries were generated by the baseline methods. The rank k for each summary ranges from 1 to 4 (1 means the best, and 4 means the worst; we allow equal ranks), and the score is thus (4-k). We average the scores across all summaries and all judges and the results on the two datasets are shown in Tables 4 and 5, respectively. In the table, the higher the score is, the better the corresponding summaries are. We can see that our proposed method outperforms all the three baselines over almost all metrics.

5.2.3 Manual Comparison of Different Kinds of Labels

In this section, we manually compare the three kinds of labels: words, phrases and summary, as

mentioned in Section 5.1. Similarly, the three human judges were asked to read and rank the three kinds of labels in the same three aspects: relevance between the label and the topic with the corresponding sentence set, the content coverage (or diversity) in the label and the discrimination between different labels. The rank *k* for each kind of labels ranges from 1 to 3 (1 means the best, and 3 means the worst; we allow equal ranks), and the score is thus (3-*k*). We average the scores across all labels and all judges and the results on the two datasets are shown in Tables 6 and 7, respectively. It is clear that the summary labels produced by our proposed method have obvious advantages over the conventional word labels and phrase labels. The summary labels have better evaluation results on relevance, coverage and discrimination.

	relevance	coverage	discrimination
Word label	0.67	0.67	1.11

5.2.4 Example Analysis

In this section, we demonstrate some running examples on the SIGMOD proceeding dataset. Two topics and the three kinds of labels are shown below. For brevity, we only show the first 100 words of the summaries to users unless they want to see more. We can see that the word labels are very confusing, and the phrase labels for the two topics are totally overlapping with each other and have no discrimination. Therefore, it is hard to understand the two topics by looking at the word or phrase labels. Fortunately, by carefully reading the topic summaries, we can understand what the two topics are really about. In this example, the first topic is about data analysis and data integration, while the second topic is about data privacy. Though the summary labels are much longer than the word labels or phrase labels, users can obtain more reliable information after reading the summary labels and the summaries can help users to better understand each topic and also know the difference between different topics.

In practice, the different kinds of labels can be used together to allow users to browse topic models in a level-wise matter, as described in next section.

Topic 1 on SIGMOD proceeding dataset:

word label: *data analysis scientific set process analyze tool insight interest scenario*

phrase label: *data analysis ; data integration ; data set*

summary label: *The field of data analysis seek to extract value from data for either business or scientific benefit . ... Nowadays data analytic application are accessing more and more data from distributed data store , creating a large amount of data traffic on the network . ...these service will access data from different data source type and potentially need to aggregate data from different data source type with different data format ....Various data model will be discussed , including relational data , xml data , graph-structured data , data stream , and workflow ....*

Topic 2 on SIGMOD proceeding dataset:

word label: *user information attribute model privacy quality record result individual provide*

phrase label: *data set ; data analysis ; data integration*

summary label: *An essential element for privacy metric is the measure of how much adversaries can know about an individual ' sensitive attribute (sa) if they know the individual ' quasi-identifier (qi) ....We present an automated solution that elicit user preference on attribute and value , employing different disambiguation technique ranging from simple keyword matching , to more sophisticated probabilistic model ....Privgene need significantly less perturbation than previous method , and it achieve higher overall result quality , even for model fitting task where ga is not the first choice without privacy consideration ....*

5.2.5 Discussion of Practical Use

Although the summary labels produced by our method have higher relevance, coverage and discrimination than the word labels and the phrase labels, the summary labels have one obvious shortcoming of consuming more reading time of users, because the summaries are much longer than the words and phrases. The feedback from the human judges also reveals the above problem and all the three human judges said they need to take more than five times longer to read the summaries. Therefore, we want to find a better way to make use of the summary label in practice.

In order to consider both the shorter reading time of the phrase labels and the better quality of

the summary labels, we can use both of the two kinds of labels in the following hierarchical way:

For each topic, we first present only the phrase label to users, and if they can easily know about the topic after they read the phrase label, the summary label will not be shown to them. Whereas, if users cannot know well about the topic based on the phrase label, or they need more information about the topic, they may choose to read the summary label for better understanding the topic. Only the first 100 words of the summary label are shown to users, and the rest words will be shown upon request. In this way, the summary label is used as an important complement to the phrase label, and the burden of reading the longer summary label can be greatly alleviated.

6 Conclusions and Future Work

In this study, we addressed the problem of topic labeling by using text summaries. We propose a summarization algorithm based on submodular optimization to extract representative summaries for all the topics. Evaluation results demonstrate that the summaries produced by our proposed algorithm have high relevance, coverage and discrimination, and the use of summaries as labels has obvious advantages over the use of words and phrases.

In future work, we will explore to make use of all the three kinds of labels together to improve the users' experience when they want to browse, understand and leverage the topics.

In this study, we do not consider the coherence of the topic summaries because it is really very challenging to get a coherent summary by extracting different sentences from a large set of different documents. In future work, we will try to make the summary label more coherent by considering the discourse structure of the summary and leveraging sentence ordering techniques.

Abstract

In this paper, we propose a neural network model for graph-based dependency parsing which utilizes Bidirectional LSTM (BLSTM) to capture richer contextual information instead of using high-order factorization, and enable our model to use much fewer features than previous work. In addition, we propose an effective way to learn sentence segment embedding on sentence-level based on an extra forward LSTM network. Although our model uses only first-order factorization, experiments on English Peen Treebank and Chinese Penn Treebank show that our model could be competitive with previous higher-order graph-based dependency parsing models and state-of-the-art models.

1 Introduction

Dependency parsing is a fundamental task for language processing which has been investigated for decades. It has been applied in a wide range of applications such as information extraction and machine translation. Among a variety of dependency parsing models, graph-based models are attractive for their ability of scoring the parsing decisions on a whole-tree basis. Typical graph-based models factor the dependency tree into subgraphs, including single arcs (McDonald et al., 2005), sibling or grandparent arcs (McDonald and Pereira, 2006; Carreras, 2007) or higher-order substructures (Koo and Collins, 2010; Ma and Zhao, 2012) and then score the whole tree by summing scores of the subgraphs. In these models, subgraphs are usually represented as high-dimensional feature vectors which are then fed into a linear model to learn the feature weights.

However, conventional graph-based models heavily rely on feature engineering and their performance is restricted by the design of features. In addition, standard decoding algorithm (Eisner, 2000) only works for the first-order model which limits the scope of feature selection. To incorporate high-order features, Eisner algorithm must be somehow extended or modified, which is usually done at high cost in terms of efficiency. The fourth-order graph-based model (Ma and Zhao, 2012), which seems the highest-order model so far to our knowledge, requires $O(n^5)$ time and $O(n^4)$ space. Due to the high computational cost, high-order models are normally restricted to producing only unlabeled parses to avoid extra cost introduced by inclusion of arc-labels into the parse trees.

To alleviate the burden of feature engineering, Pei et al. (2015) presented an effective neural network model for graph-based dependency parsing. They only use atomic features such as word unigrams and POS tag unigrams and leave the model to automatically learn the feature combinations. However, their model requires many atomic features and still relies on high-order factorization strategy to further improve the accuracy.

Different from previous work, we propose an LSTM-based dependency parsing model in this paper and aim to use LSTM network to capture richer contextual information to support parsing decisions, instead of adopting a high-order factorization. The main advantages of our model are as follows:

- By introducing Bidirectional LSTM, our model shows strong ability to capture potential long range contextual information and exhibits improved accuracy in recovering long distance dependencies. It is different to previous work in which a similar effect is usually achieved by high-order factorization. More-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2306–2315,
Berlin, Germany, August 7-12, 2016.

over, our model also eliminates the need for setting feature selection windows and reduces the number of features to a minimum level.

- We propose an LSTM-based sentence segment embedding method named LSTM-Minus, in which distributed representation of sentence segment is learned by using subtraction between LSTM hidden vectors. Experiment shows this further enhances our model's ability to access to sentence-level information.

- Last but important, our model is a first-order model using standard Eisner algorithm for decoding, the computational cost remains at the lowest level among graph-based models. Our model does not trade-off efficiency for accuracy.

We evaluate our model on the English Penn Treebank and Chinese Penn Treebank, experiments show that our model achieves competitive parsing accuracy compared with conventional high-order models, however, with a much lower computational cost.

2 Graph-based dependency parsing

In dependency parsing, syntactic relationships are represented as directed arcs between head words and their modifier words. Each word in a sentence modifies exactly one head, but can have any number of modifiers itself. The whole sentence is rooted at a designated special symbol *ROOT*, thus the dependency graph for a sentence is constrained to be a rooted, directed tree.

For a sentence x, graph-based dependency parsing model searches for the highest-scoring tree of x:

$$y^*(x) = \arg\max_{\hat{y} \in Y(x)} Score(x, \hat{y}; \theta) \quad (1)$$

Here $y^*(x)$ is the tree with the highest score, $Y(x)$ is the set of all valid dependency trees for x and $Score(x, \hat{y}; \theta)$ measures how likely the tree $\hat{y}$ is the correct analysis of the sentence x, θ are the model parameters. However, the size of $Y(x)$ grows exponentially with respect to the length of the sentence, directly solving equation (1) is impractical.

The common strategy adopted in the graph-based model is to factor the dependency tree $\hat{y}$ into

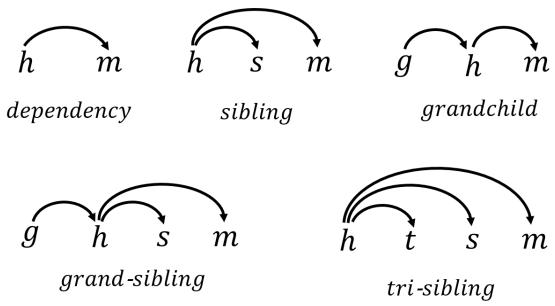

Figure 1: First-order, Second-order and Third-order factorization strategy. Here h stands for head word, m stands for modifier word, s and t stand for the sibling of m. g stands for the grandparent of m.

a set of subgraph c which can be scored in isolation, and score the whole tree $\hat{y}$ by summing score of each subgraph:

$$Score(x, \hat{y}; \theta) = \sum_{c \in \hat{y}} ScoreC(x, c; \theta) \quad (2)$$

Figure 1 shows several factorization strategies. The order of the factorization is defined according to the number of dependencies that subgraph contains. The simplest first-order factorization (McDonald et al., 2005) decomposes a dependency tree into single dependency arcs. Based on the first-order factorization, second-order factorization (McDonald and Pereira, 2006; Carreras, 2007) brings sibling and grandparent information into their model. Third-order factorization (Koo and Collins, 2010) further incorporates richer contextual information by utilizing grand-sibling and tri-sibling parts.

Conventional graph-based models (McDonald et al., 2005; McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010; Ma and Zhao, 2012) score subgraph by a linear model, which heavily depends on feature engineering. The neural network model proposed by Pei et al. (2015) alleviates the dependence on feature engineering to a large extent, but not completely. We follow Pei et al. (2015) to score dependency arcs using neural network model. However, different from their work, we introduce a Bidirectional LSTM to capture long range contextual information and an extra forward LSTM to better represent segments of the sentence separated by the head and modifier. These make our model more accurate in recovering long-distance dependencies and further decrease the number of atomic features.

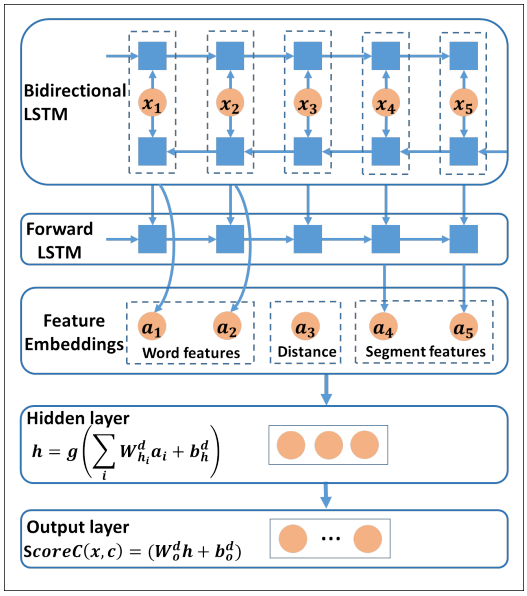

Figure 2: Architecture of the Neural Network. x_1 to x_5 stand for the input token of Bidirectional LSTM. a_1 to a_5 stand for the feature embeddings used in our model.

3 Neural Network Model

In this section, we describe the architecture of our neural network model in detail, which is summarized in Figure 2.

3.1 Input layer

In our neural network model, the words, POS tags are mapped into distributed embeddings. We represent each input token x_i which is the input of Bidirectional LSTM by concatenating POS tag embedding $e_{p_i} \in \mathbb{R}^{d_e}$ and word embedding $e_{w_i} \in \mathbb{R}^{d_e}$, d_e is the the dimensionality of embedding, then a linear transformation w_e is performed and passed though an element-wise activation function g:

$$x_i = g(w_e[e_{w_i}; e_{p_i}] + b_e) \tag{3}$$

where $x_i \in \mathbb{R}^{d_e}$, $w_e \in \mathbb{R}^{d_e \times 2d_e}$ is weight matrix, $b_e \in \mathbb{R}^{d_e}$ is bias term. the dimensionality of input token x_i is equal to the dimensionality of word and POS tag embeddings in our experiment, ReLU is used as our activation function g.

3.2 Bidirectional LSTM

Given an input sequence $x = (x_1, \ldots, x_n)$, where n stands for the number of words in a sentence, a standard LSTM recurrent network computes the hidden vector sequence $h = (h_1, \ldots, h_n)$ in one direction.

Bidirectional LSTM processes the data in both directions with two separate hidden layers, which are then fed to the same output layer. It computes the forward hidden sequence $\overrightarrow{h}$, the backward hidden sequence $\overleftarrow{h}$ and the output sequence v by iterating the forward layer from $t = 1$ to n, the backward layer from $t = n$ to 1 and then updating the output layer:

$$v_t = \overrightarrow{h}_t + \overleftarrow{h}_t \tag{4}$$

where $v_t \in \mathbb{R}^{d_l}$ is the output vector of Bidirectional LSTM for input x_t, $\overrightarrow{h}_t \in \mathbb{R}^{d_l}$, $\overleftarrow{h}_t \in \mathbb{R}^{d_l}$, d_l is the dimensionality of LSTM hidden vector. We simply add the forward hidden vector $\overrightarrow{h}_t$ and the backward hidden vector $\overleftarrow{h}_t$ together, which gets similar experiment result as concatenating them together with a faster speed.

The output vectors of Bidirectional LSTM are used as word feature embeddings. In addition, they are also fed into a forward LSTM network to learn segment embedding.

3.3 Segment Embedding

Contextual information of word pairs[1] has been widely utilized in previous work (McDonald et al., 2005; McDonald and Pereira, 2006; Pei et al., 2015). For a dependency pair (h, m), previous work divides a sentence into three parts (*prefix*, *infix* and *suffix*) by head word h and modifier word m. These parts which we call *segments* in our work make up the context of the dependency pair (h, m).

Due to the problem of data sparseness, conventional graph-based models can only capture contextual information of word pairs by using bigrams or tri-grams features. Unlike conventional models, Pei et al. (2015) use distributed representations obtained by averaging word embeddings in segments to represent contextual information of the word pair, which could capture richer syntactic and semantic information. However, their method is restricted to segment-level since their segment embedding only consider the word information within the segment. Besides, averaging operation simply treats all the words in segment equally. However, some words might carry more

[1] A word pair is limited to the dependency pair (h, m) in our work since we use only first-order factorization. In previous work, word pair could be any pair with particular relation (e.g., sibling pair (s, m) in Figure 1).

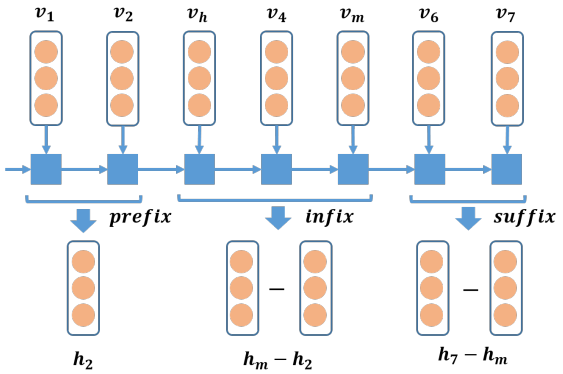

Figure 3: Illustration for learning segment embeddings based on an extra forward LSTM network, v_h, v_m and v_1 to v_7 indicate the output vectors of Bidirectional LSTM for head word h, modifier word m and other words in sentence, h_h, h_m and h_1 to h_7 indicate the hidden vectors of the forward LSTM corresponding to v_h, v_m and v_1 to v_7.

salient syntactic or semantic information and they are expected to be given more attention.

A useful property of forward LSTM is that it could keep previous useful information in their memory cell by exploiting input, output and forget gates to decide how to utilize and update the memory of previous information. Given an input sequence $v = (v_1, \ldots, v_n)$, previous work (Sutskever et al., 2014; Vinyals et al., 2014) often uses the last hidden vector h_n of the forward LSTM to represent the whole sequence. Each hidden vector h_t $(1 \leq t \leq n)$ can capture useful information before and including v_t.

Inspired by this, we propose a method named **LSTM-Minus** to learn segment embedding. We utilize subtraction between LSTM hidden vectors to represent segment's information. As illustrated in Figure 3, the segment *infix* can be described as $h_m - h_2$, h_m and h_2 are hidden vector of the forward LSTM network. The segment embedding of *suffix* can also be obtained by subtraction between the last LSTM hidden vector of the sequence (h_7) and the last LSTM hidden vector in *infix* (h_m). For *prefix*, we directly use the last LSTM hidden vector in *prefix* to represent it, which equals to subtract a zero embedding. When no *prefix* or *suffix* exists, the corresponding embedding is set to zero.

Specifically, we place an extra forward LSTM layer on top of the Bidirectional LSTM layer and learn segment embeddings using LSTM-Minus based on this forward LSTM. LSTM-minus enables our model to learn segment embeddings from information both outside and inside the segments and thus enhances our model's ability to access to sentence-level information.

3.4 Hidden layer and output layer

As illustrated in Figure 2, we map all the feature embeddings to a hidden layer. Following Pei et al. (2015), we use direction-specific transformation to model edge direction and tanh-cube as our activation function:

$$h = g\Big(\sum_i W^d_{h_i} a_i + b^d_h\Big) \tag{5}$$

where $a_i \in \mathbb{R}^{d_{a_i}}$ is the feature embedding, d_{a_i} indicates the dimensionality of feature embedding a_i, $W^d_{h_i} \in \mathbb{R}^{d_h \times d_{a_i}}$ is weight matrices which corresponding to a_i, d_h indicates the dimensionality of hidden layer vector, $b^d_h \in \mathbb{R}^{d_h}$ is bias term. $W^d_{h_i}$ and b^d_h are bound with index $d \in \{0, 1\}$ which indicates the direction between head and modifier.

A output layer is finally added on the top of the hidden layer for scoring dependency arcs:

$$ScoreC(x, c) = W^d_o h + b^d_o \tag{6}$$

Where $W^d_o \in \mathbb{R}^{L \times d_h}$ is weight matrices, $b^d_o \in \mathbb{R}^L$ is bias term, $ScoreC(x, c) \in \mathbb{R}^L$ is the output vector, L is the number of dependency types. Each dimension of the output vector is the score for each kind of dependency type of head-modifier pair.

3.5 Features in our model

Previous neural network models (Pei et al., 2015; Pei et al., 2014; Zheng et al., 2013) normally set context window around a word and extract atomic features within the window to represent the contextual information. However, context window limits their ability in detecting long-distance information. Simply increasing the context window size to get more contextual information puts their model in the risk of overfitting and heavily slows down the speed.

Unlike previous work, we apply Bidirectional LSTM to capture long range contextual information and eliminate the need for context windows, avoiding the limit of the window-based feature selection approach. Compared with Pei et al. (2015), the cancellation of the context window allows our model to use much fewer features. Moreover, by combining a word's atomic features (word form and POS tag) together, our model further decreases the number of features.

Pei et al. (2015)	$h_{-2}.w$, $h_{-1}.w$, $h.w$, $h_1.w$, $h_2.w$ $h_{-2}.p$, $h_{-1}.p$, $h.p$, $h_1.p$, $h_2.p$ $m_{-2}.w$, $m_{-1}.w$, $m.w$, $m_1.w$, $m_2.w$ $m_{-2}.p$, $m_{-1}.p$, $m.p$, $m_1.p$, $m_2.p$ *dis(h, m)*
Our basic model	v_h, v_m *dis(h, m)*

Table 1: Atomic features in our basic model and Pei's 1st-order atomic model. w is short for word and p for POS tag. h indicates head and m indicates modifier. The subscript represents the relative position to the center word. $dis(h, m)$ is the distance between head and modifier. v_h and v_m indicate the outputs of Bidirectional LSTM for head word and modifier word.

Table 1 lists the atomic features used in 1st-order atomic model of Pei et al. (2015) and atomic features used in our basic model. Our basic model only uses the outputs of Bidirectional LSTM for head word and modifier word, and the distance between them as features. Distance features are encoded as randomly initialized embeddings. As we can see, our basic model reduces the number of atomic features to a minimum level, making our model run with a faster speed. Based on our basic model, we incorporate additional segment information (*prefix*, *infix* and *suffix*), which further improves the effect of our model.

4 Neural Training

In this section, we provide details about training the neural network.

4.1 Max-Margin Training

We use the Max-Margin criterion to train our model. Given a training instance $(x^{(i)}, y^{(i)})$, we use $Y(x^{(i)})$ to denote the set of all possible dependency trees and $y^{(i)}$ is the correct dependency tree for sentence $x^{(i)}$. The goal of Max Margin training is to find parameters θ such that the difference in score of the correct tree $y^{(i)}$ from an incorrect tree $\hat{y} \in Y(x^{(i)})$ is at least $\triangle(y^{(i)}, \hat{y})$.

$$Score(x^{(i)},y^{(i)};\theta) \geq Score(x^{(i)},\hat{y};\theta)+\triangle(y^{(i)},\hat{y})$$

The structured margin loss $\triangle(y^{(i)}, \hat{y})$ is defined as:

$$\triangle(y^{(i)}, \hat{y}) = \sum_{j}^{n} \kappa \mathbf{1}\{h(y^{(i)}, x_j^{(i)}) \neq h(\hat{y}, x_j^{(i)})\}$$

where n is the length of sentence x, $h(y^{(i)}, x_j^{(i)})$ is the head (with type) for the j-th word of $x^{(i)}$ in tree $y^{(i)}$ and κ is a discount parameter. The loss is proportional to the number of word with an incorrect head and edge type in the proposed tree.

Given a training set with size m, The regularized objective function is the loss function $J(\theta)$ including a l_2-norm term:

$$\begin{aligned} J(\theta) &= \frac{1}{m}\sum_{i=1}^{m} l_i(\theta) + \frac{\lambda}{2}||\theta||^2 \\ l_i(\theta) &= \max_{\hat{y}\in Y(x^{(i)})} (Score(x^{(i)},\hat{y};\theta)+\triangle(y^{(i)},\hat{y})) \\ &\quad -Score(x^{(i)},y^{(i)};\theta) \end{aligned} \tag{7}$$

By minimizing this objective, the score of the correct tree is increased and score of the highest scoring incorrect tree is decreased.

4.2 Optimization Algorithm

Parameter optimization is performed with the diagonal variant of AdaGrad (Duchi et al., 2011) with minibatchs (batch size = 20) . The parameter update for the i-th parameter $\theta_{t,i}$ at time step t is as follows:

$$\theta_{t,i} = \theta_{t-1,i} - \frac{\alpha}{\sqrt{\sum_{\tau=1}^{t} g_{\tau,i}^2}} g_{t,i} \tag{8}$$

where α is the initial learning rate ($\alpha = 0.2$ in our experiment) and $g_\tau \in \mathbb{R}^{|\theta_i|}$ is the subgradient at time step τ for parameter θ_i.

To mitigate overfitting, dropout (Hinton et al., 2012) is used to regularize our model. we apply dropout on the hidden layer with 0.2 rate.

4.3 Model Initialization&Hyperparameters

The following hyper-parameters are used in all experiments: word embedding size = 100, POS tag embedding size = 100, hidden layer size = 200, LSTM hidden vector size = 100, Bidirectional LSTM layers = 2, regularization parameter $\lambda = 10^{-4}$.

We initialized the parameters using pretrained word embeddings. Following Dyer et al. (2015), we use a variant of the skip n-gram model introduced by Ling et al. (2015) on Gigaword corpus (Graff et al., 2003). We also experimented with randomly initialized embeddings, where embeddings are uniformly sampled from range $[-0.3, 0.3]$. All other parameters are uniformly sampled from range $[-0.05, 0.05]$.

	Models	UAS	LAS	Speed(sent/s)
First-order	MSTParser	91.60	90.39	20
	1st-order atomic (Pei et al., 2015)	92.14	90.92	55
	1st-order phrase (Pei et al., 2015)	92.59	91.37	26
	Our basic model	93.09	92.03	**61**
	Our basic model + segment	**93.51**	**92.45**	26
Second-order	MSTParser	92.30	91.06	14
	2nd-order phrase (Pei et al., 2015)	93.29	92.13	10
Third-order	(Koo and Collins, 2010)	93.04	N/A	N/A

Table 2: Comparison with previous graph-based models on Penn-YM.

5 Experiments

In this section, we present our experimental setup and the main result of our work.

5.1 Experiments Setup

We conduct our experiments on the English Penn Treebank (PTB) and the Chinese Penn Treebank (CTB) datasets.

For English, we follow the standard splits of PTB3. Using section 2-21 for training, section 22 as development set and 23 as test set. We conduct experiments on two different constituency-to-dependency-converted Penn Treebank data sets. The first one, **Penn-YM**, was created by the Penn2Malt tool[2] based on Yamada and Matsumoto (2003) head rules. The second one, **Penn-SD**, use Stanford Basic Dependencies (Marneffe et al., 2006) and was converted by version 3.3.0[3] of the Stanford parser. The Stanford POS Tagger (Toutanova et al., 2003) with ten-way jackknifing of the training data is used for assigning POS tags (accuracy $\approx$ 97.2%).

For Chinese, we adopt the same split of CTB5 as described in (Zhang and Clark, 2008). Following (Zhang and Clark, 2008; Dyer et al., 2015; Chen and Manning, 2014), we use gold segmentation and POS tags for the input.

5.2 Experiments Results

We first make comparisons with previous graph-based models of different orders as shown in Table 2. We use MSTParser [4] for conventional first-order model (McDonald et al., 2005) and second-order model (McDonald and Pereira, 2006). We also include the results of conventional high-order models (Koo and Collins, 2010; Ma and Zhao, 2012; Zhang and McDonald, 2012; Zhang et al., 2013; Zhang and McDonald, 2014) and the neural network model of Pei et al. (2015). Different from typical high-order models (Koo and Collins, 2010; Ma and Zhao, 2012), which need to extend their decoding algorithm to score new types of higher-order dependencies. Zhang and McDonald (2012) generalized the Eisner algorithm to handle arbitrary features over higher-order dependencies and controlled complexity via approximate decoding with cube pruning. They further improve their work by using perceptron update strategies for inexact hypergraph search (Zhang et al., 2013) and forcing inference to maintain both label and structural ambiguity through a secondary beam (Zhang and McDonald, 2014).

Following previous work, UAS (unlabeled attachment scores) and LAS (labeled attachment scores) are calculated by excluding punctuation[5]. The parsing speeds are measured on a workstation with Intel Xeon 3.4GHz CPU and 32GB RAM which is same to Pei et al. (2015). We measure the parsing speeds of Pei et al. (2015) according to their codes[6] and parameters.

On accuracy, as shown in table 2, our

Method	Penn-YM		Penn-SD		CTB5	
	UAS	LAS	UAS	LAS	UAS	LAS
(Zhang and Nivre, 2011)	92.9	91.8	-	-	86.0	84.4
(Bernd Bohnet, 2012)	93.39	92.38	-	-	87.5	85.9
(Zhang and McDonald, 2014)	**93.57**	**92.48**	93.01	90.64	**87.96**	**86.34**
(Dyer et al., 2015)	-	-	93.1	90.9	87.2	85.7
(Weiss et al., 2015)	-	-	93.99	**92.05**	-	-
Our basic model + segment	93.51	92.45	**94.08**	91.82	87.55	86.23

Table 3: Comparison with previous state-of-the-art models on Penn-YM, Penn-SD and CTB5.

basic model outperforms previous first-order graph-based models by a substantial margin, even outperforms Zhang and McDonald (2012)'s unlimited-order model. Moreover, incorporating segment information further improves our model's accuracy, which shows that segment embeddings do capture richer contextual information. By using segment embeddings, our improved model could be comparable to high-order graph-based models[7].

With regard to parsing speed, our model also shows advantage of efficiency. Our model uses only first-order factorization and requires $O(n^3)$ time to decode. Third-order model requires $O(n^4)$ time and fourth-order model requires $O(n^5)$ time. By using approximate decoding, the unlimited-order model of Zhang and McDonald (2012) requires $O(k \cdot log(k) \cdot n^3)$ time, where k is the beam size. The computational cost of our model is the lowest among graph-based models. Moreover, although using LSTM requires much computational cost. However, compared with Pei's 1st-order model, our model decreases the number of atomic features from 21 to 3, this allows our model to require a much smaller matrix computation in the scoring model, which cancels out the extra computation cost introduced by the LSTM computation. Our basic model is the fastest among first-order and second-order models. Incorporating segment information slows down the parsing speed while it is still slightly faster than conventional first-order model. To compare with conventional high-order models on practical parsing speed, we can make an indirect comparison according to Zhang and McDonald (2012). Conventional first-order model is about 10 times faster than Zhang and McDonald (2012)'s unlimited-order model and about 40 times faster than conventional third-order model, while our model is faster than conventional first-order model. Our model should be much faster than conventional high-order models.

[7]Note that our model can't be strictly comparable with third-order model (Koo and Collins, 2010) and fourth-order model (Ma and Zhao, 2012) since they are unlabeled model. However, our model is comparable with all the three unlimited-order models presented in (Zhang and McDonald, 2012), (Zhang et al., 2013) and (Zhang and McDonald, 2014), since they all are labeled models as ours.

Method	Peen-YM	Peen-SD	CTB5
Average	93.23	93.83	87.24
LSTM-Minus	**93.51**	**94.08**	**87.55**

Table 4: Model performance of different way to learn segment embeddings.

We further compare our model with previous state-of-the-art systems for English and Chinese. Table 3 lists the performances of our model as well as previous state-of-the-art systems on on Penn-YM, Penn-SD and CTB5. We compare to conventional state-of-the-art graph-based model (Zhang and McDonald, 2014), conventional state-of-the-art transition-based model using beam search (Zhang and Nivre, 2011), transition-based model combining graph-based approach (Bernd Bohnet, 2012) , transition-based neural network model using stack LSTM (Dyer et al., 2015) and transition-based neural network model using beam search (Weiss et al., 2015). Overall, our model achieves competitive accuracy on all three datasets. Although our model is slightly lower in accuarcy than unlimited-order double beam model (Zhang and McDonald, 2014) on Penn-YM and CTB5, our model outperforms their model on Penn-SD. It seems that our model performs better on data sets with larger label sets, given the number of labels used in Penn-SD data set is almost four times more than Penn-YM and CTB5 data sets.

To show the effectiveness of our segment embedding method LSTM-Minus, we compare with averaging method proposed by Pei et al. (2015). We get segment embeddings by averaging the output vectors of Bidirectional LSTM in segments.

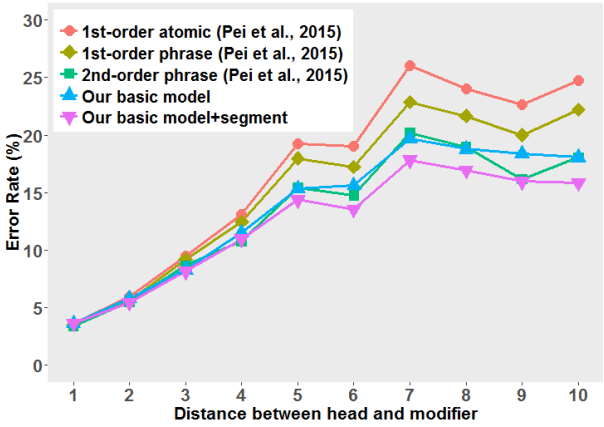

Figure 4: Error rates of different distance between head and modifier on Peen-YM.

To make comparison as fair as possible, we let two models have almost the same number parameters. Table 4 lists the UAS of two methods on test set. As we can see, LSTM-Minus shows better performance because our method further incorporates more sentence-level information into our model.

5.3 Impact of Network Structure

In this part, we investigate the impact of the components of our approach.

LSTM Recurrent Network

To evaluate the impact of LSTM, we make error analysis on Penn-YM. We compare our model with Pei et al. (2015) on error rates of different distance between head and modifier.

As we can see, the five models do not show much difference for short dependencies whose distance less than three. For long dependencies, both our two models show better performance compared with the 1st-order model of Pei et al. (2015), which proves that LSTM can effectively capture long-distance dependencies. Moreover, our models and Pei's 2nd-order phrase model both improve accuracy on long dependencies compared with Pei's 1st-order model, which is in line with our expectations. Using LSTM shows the same effect as high-order factorization strategy. Compared with 2nd-order phrase model of Pei et al. (2015), our basic model occasionally performs worse in recovering long distant dependencies. However, this should not be a surprise since higher order models are also motivated to recover long-distance dependencies. Nevertheless, with the introduction of LSTM-minus segment embeddings, our model consistently outperforms the 2nd-order phrase model of Pei et al. (2015) in accuracies of all long dependencies. We carried out significance test on the difference between our and Pei's models. Our basic model performs significantly better than all 1st-order models of Pei et al. (2015) (t-test with $p<0.001$) and our basic+segment model (still a 1st-order model) performs significantly better than their 2nd-order phrase model (t-test with $p<0.001$) in recovering long-distance dependencies.

Initialization of pre-trained word embeddings

We further analyze the influence of using pre-trained word embeddings for initialization. without using pretrained word embeddings, our improved model achieves 92.94% UAS / 91.83% LAS on Penn-YM, 93.46% UAS / 91.19% LAS on Penn-SD and 86.5% UAS / 85.0% LAS on CTB5. Using pre-trained word embeddings can obtain around 0.5%$\sim$1.0% improvement.

6 Related work

Dependency parsing has gained widespread interest in the computational linguistics community. There are a lot of approaches to solve it. Among them, we will mainly focus on graph-based dependency parsing model here. Dependency tree factorization and decoding algorithm are necessary for graph-based models. McDonald et al. (2005) proposed the first-order model which decomposes a dependency tree into its individual edges and use a effective dynamic programming algorithm (Eisner, 2000) to decode. Based on first-order model, higher-order models(McDonald and Pereira, 2006; Carreras, 2007; Koo and Collins, 2010; Ma and Zhao, 2012) factor a dependency tree into a set of high-order dependencies which bring interactions between head, modifier, siblings and (or) grandparent into their model. However, for above models, scoring new types of higher-order dependencies requires extensions of the underlying decoding algorithm, which also requires higher computational cost. Unlike above models, unlimited-order models (Zhang and McDonald, 2012; Zhang et al., 2013; Zhang and McDonald, 2014) could handle arbitrary features over higher-order dependencies by generalizing the Eisner algorithm.

In contrast to conventional methods, neural network model shows their ability to reduce the effort in feature engineering. Pei et al. (2015) proposed a model to automatically learn high-order feature

combinations via a novel activation function, allowing their model to use a set of atomic features instead of millions of hand-crafted features.

Different from previous work, which is sensitive to local state and accesses to larger context by higher-order factorization. Our model makes parsing decisions on a global perspective with first-order factorization, avoiding the expensive computational cost introduced by high-order factorization.

LSTM network is heavily utilized in our model. LSTM network has already been explored in transition-based dependency parsing. Dyer et al. (2015) presented stack LSTMs with push and pop operations and used them to implement a state-of-the-art transition-based dependency parser. Ballesteros et al. (2015) replaced lookup-based word representations with character-based representations obtained by Bidirectional LSTM in the continuous-state parser of Dyer et al. (2015), which was proved experimentally to be useful for morphologically rich languages.

7 Conclusion

In this paper, we propose an LSTM-based neural network model for graph-based dependency parsing. Utilizing Bidirectional LSTM and segment embeddings learned by LSTM-Minus allows our model access to sentence-level information, making our model more accurate in recovering long-distance dependencies with only first-order factorization. Experiments on PTB and CTB show that our model could be competitive with conventional high-order models with a faster speed.

Abstract

Recently, knowledge graph embedding, which projects symbolic entities and relations into continuous vector space, has become a new, hot topic in artificial intelligence. This paper proposes a novel generative model (**TransG**) to address the issue of **multiple relation semantics** that a relation may have multiple meanings revealed by the entity pairs associated with the corresponding triples. The new model can discover latent semantics for a relation and leverage a mixture of relation-specific component vectors to embed a fact triple. To the best of our knowledge, this is the first generative model for knowledge graph embedding, and at the first time, the issue of multiple relation semantics is formally discussed. Extensive experiments show that the proposed model achieves substantial improvements against the state-of-the-art baselines.

1 Introduction

Abstract or real-world knowledge is always a major topic in Artificial Intelligence. Knowledge bases such as Wordnet (Miller, 1995) and Freebase (Bollacker et al., 2008) have been shown very useful to AI tasks including question answering, knowledge inference, and so on. However, traditional knowledge bases are symbolic and logic, thus numerical machine learning methods cannot be leveraged to support the computation over the knowledge bases. To this end, knowledge graph embedding has been proposed to project entities and relations into continuous vector spaces. Among various embedding models, there is a line of translation-based models such as TransE (Bordes et al., 2013), TransH (Wang et al., 2014), TransR (Lin et al., 2015b), and other related models (He et al., 2015) (Lin et al., 2015a).

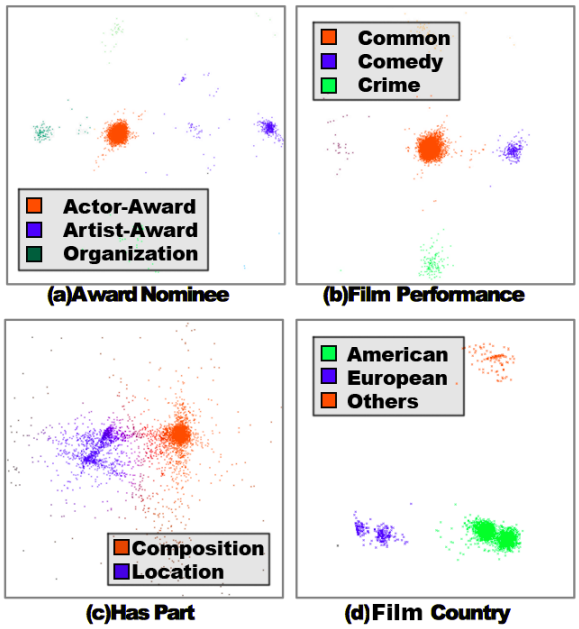

Figure 1: Visualization of TransE embedding vectors with PCA dimension reduction. Four relations (a $\sim$ d) are chosen from Freebase and Wordnet. A dot denotes a triple and its position is decided by the difference vector between tail and head entity ($\mathbf{t} - \mathbf{h}$). Since TransE adopts the principle of $\mathbf{t} - \mathbf{h} \approx \mathbf{r}$, there is supposed to be only one cluster whose centre is the relation vector $\mathbf{r}$. However, results show that there exist multiple clusters, which justifies our multiple relation semantics assumption.

A fact of knowledge base can usually be represented by a triple (h, r, t) where h, r, t indicate a head entity, a relation, and a tail entity, respectively. All translation-based models almost follow the same principle $\mathbf{h_r} + \mathbf{r} \approx \mathbf{t_r}$ where $\mathbf{h_r}, \mathbf{r}, \mathbf{t_r}$ in-

Berlin, Germany, August 7-12, 2016.

dicate the embedding vectors of triple (h, r, t), with the head and tail entity vector projected with respect to the relation space.

In spite of the success of these models, none of the previous models has formally discussed the issue of ***multiple relation semantics*** that a relation may have multiple meanings revealed by the entity pairs associated with the corresponding triples. As can be seen from Fig. 1, visualization results on embedding vectors obtained from TransE (Bordes et al., 2013) show that, there are different clusters for a specific relation, and different clusters indicate different latent semantics. For example, the relation HasPart has at least two latent semantics: composition-related as (Table, HasPart, Leg) and location-related as (Atlantics, HasPart, NewYorkBay). As one more example, in Freebase, (Jon Snow, birth place, Winter Fall) and (George R. R. Martin, birth place, U.S.) are mapped to schema /fictional_universe/fictional_character/place_of_birth and /people/person/place_of_birth respectively, indicating that *birth place* has different meanings. This phenomenon is quite common in knowledge bases for two reasons: artificial simplification and nature of knowledge. On one hand, knowledge base curators could not involve too many similar relations, so abstracting multiple similar relations into one specific relation is a common trick. On the other hand, both language and knowledge representations often involve ambiguous information. The ambiguity of knowledge means a semantic mixture. For example, when we mention "Expert", we may refer to scientist, businessman or writer, so the concept "Expert" may be ambiguous in a specific situation, or generally a semantic mixture of these cases.

However, since previous translation-based models adopt $\mathbf{h_r} + \mathbf{r} \approx \mathbf{t_r}$, they assign only one translation vector for one relation, and these models are not able to deal with the issue of multiple relation semantics. To illustrate more clearly, as showed in Fig.2, there is only one unique representation for relation $\mathrm{HasPart}$ in traditional models, thus the models made more errors when embedding the triples of the relation. Instead, in our proposed model, we leverage a Bayesian non-parametric infinite mixture model to handle multiple relation semantics by generating multiple translation components for a relation. Thus, different semantics are characterized by different components in our embedding model. For example, we can distinguish the two clusters $\mathrm{HasPart}.1$ or $\mathrm{HasPart}.2$, where the relation semantics are automatically clustered to represent the meaning of associated entity pairs.

To summarize, our contributions are as follows:

- We propose a new issue in knowledge graph embedding, ***multiple relation semantics*** that a relation in knowledge graph may have different meanings revealed by the associated entity pairs, which has never been studied previously.
- To address the above issue, we propose a novel Bayesian non-parametric infinite mixture embedding model, TransG. The model can automatically discover semantic clusters of a relation, and leverage a mixture of multiple relation components for translating an entity pair. Moreover, we present new insights from the generative perspective.
- Extensive experiments show that our proposed model obtains substantial improvements against the state-of-the-art baselines.

2 Related Work

Translation-Based Embedding. Existing translation-based embedding methods share the same translation principle $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$ and the score function is designed as:

$$f_r(h, t) = ||\mathbf{h_r} + \mathbf{r} - \mathbf{t_r}||_2^2$$

where $\mathbf{h_r}, \mathbf{t_r}$ are entity embedding vectors projected in the relation-specific space. **TransE** (Bordes et al., 2013), lays the entities in the original entity space: $\mathbf{h_r} = \mathbf{h}, \mathbf{t_r} = \mathbf{t}$. **TransH** (Wang et al., 2014) projects entities into a hyperplane for addressing the issue of complex relation embedding: $\mathbf{h_r} = \mathbf{h} - \mathbf{w_r}^\top \mathbf{h}\mathbf{w_r}, \mathbf{t_r} = \mathbf{t} - \mathbf{w_r}^\top \mathbf{t}\mathbf{w_r}$. To address the same issue, **TransR** (Lin et al., 2015b), transforms the entity embeddings by the same relation-specific matrix: $\mathbf{h_r} = \mathbf{M_r}\mathbf{h}, \mathbf{t_r} = \mathbf{M_r}\mathbf{t}$. TransR also proposes an ad-hoc clustering-based method, **CTransR**, where the entity pairs for a relation are clustered into different groups, and the pairs in the same group share the same relation vector. In comparison, our model is more elegant to address such an issue theoretically, and does not require a pre-process of clustering. Furthermore, our model has much better performance than CTransR, as expected. **TransM** (Fan et al.,

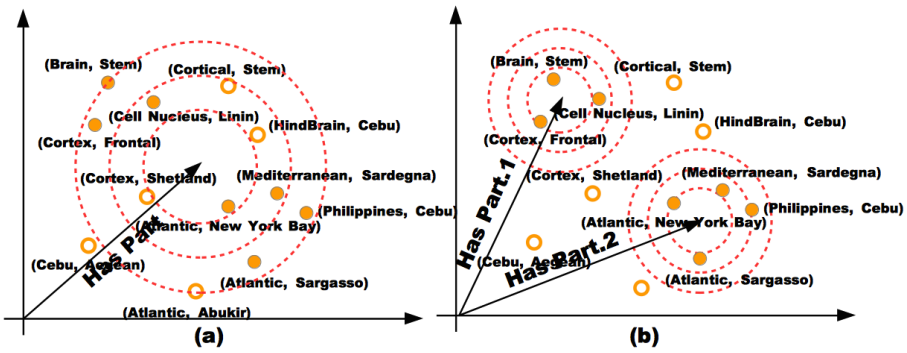

Figure 2: Visualization of multiple relation semantics. The data are selected from Wordnet. The dots are correct triples that belong to HasPart relation, while the circles are incorrect ones. The point coordinate is the difference vector between tail and head entity, which should be near to the centre. (a) The correct triples are hard to be distinguished from the incorrect ones. (b) By applying multiple semantic components, our proposed model could discriminate the correct triples from the wrong ones.

2014) leverages the structure of the knowledge graph via pre-calculating the distinct weight for each training triple to enhance embedding. **KG2E** (He et al., 2015) is a probabilistic embedding method for modeling the uncertainty in knowledge graph.

There are many works to improve translation-based methods by considering other information. For instance, (Guo et al., 2015) aims at discovering the geometric structure of the embedding space to make it semantically smooth. (Wang et al., 2014) focuses on bridging the gap between knowledge and texts, with a loss function for jointly modeling knowledge graph and text resources. (Wang et al., 2015) incorporates the rules that are related with relation types such as 1-N and N-1. **PTransE** (Lin et al., 2015a) takes into account path information in knowledge graph.

Since the previous models are point-wise modeling methods, **ManifoldE** (Xiao et al., 2016) proposes a novel manifold-based approach for knowledge graph embedding. In aid of kernel tricks, manifold-based methods can improve embedding performance substantially.

Structured & Unstructured Embedding. The structured embedding model (Bordes et al., 2011) transforms the entity space with the head-specific and tail-specific matrices. The score function is defined as $f_r(h,t) = ||\mathbf{M_{h,r}h} - \mathbf{M_{t,r}t}||$. According to (Socher et al., 2013), this model cannot capture the relationship between entities. Semantic Matching Energy (SME) (Bordes et al., 2012) (Bordes et al., 2014) can handle the correlations between entities and relations by matrix product and Hadamard product. The unstructured model (Bordes et al., 2012) may be a simplified version of TransE without considering any relation-related information. The score function is directly defined as $f_r(h,t) = ||\mathbf{h} - \mathbf{t}||_2^2$.

Neural Network based Embedding. Single Layer Model (SLM) (Socher et al., 2013) applies neural network to knowledge graph embedding. The score function is defined as $f_r(h,t) = \mathbf{u_r}^\top g(\mathbf{M_{r,1}h} + \mathbf{M_{r,2}t})$ where $\mathbf{M_{r,1}}, \mathbf{M_{r,2}}$ are relation-specific weight matrices. Neural Tensor Network (NTN) (Socher et al., 2013) defines a very expressive score function by applying tensor: $f_r(h,t) = \mathbf{u_r}^\top g(\mathbf{h}^\top \mathbf{W}_{\cdot\cdot\mathbf{r}}\mathbf{t} + \mathbf{M_{r,1}h} + \mathbf{M_{r,2}t} + \mathbf{b_r})$, where $\mathbf{u_r}$ is a relation-specific linear layer, $g(\cdot)$ is the $tanh$ function, $\mathbf{W} \in \mathbb{R}^{d\times d\times k}$ is a 3-way tensor.

Factor Models. The latent factor models (Jenatton et al., 2012) (Sutskever et al., 2009) attempt to capturing the second-order correlations between entities by a quadratic form. The score function is defined as $f_r(h,t) = \mathbf{h}^\top \mathbf{W_r t}$. RESCAL is a collective matrix factorization model which is also a common method in knowledge base embedding (Nickel et al., 2011) (Nickel et al., 2012).

3 Methods

3.1 TransG: A Generative Model for Embedding

As just mentioned, only one single translation vector for a relation may be insufficient to model multiple relation semantics. In this paper, we propose to use Bayesian non-parametric infinite mix-

ture embedding model (Griffiths and Ghahramani, 2011). The generative process of the model is as follows:

1. For an entity $e \in E$:
   (a) Draw each entity embedding mean vector from a standard normal distribution as a prior: $\mathbf{u_e} \backsim \mathcal{N}(\mathbf{0}, \mathbf{1})$.
2. For a triple $(h, r, t) \in \Delta$:
   (a) Draw a semantic component from Chinese Restaurant Process for this relation: $\pi_{r,m} \sim CRP(\beta)$.
   (b) Draw a head entity embedding vector from a normal distribution: $\mathbf{h} \backsim \mathcal{N}(\mathbf{u_h}, \sigma_h^2\mathbf{E})$.
   (c) Draw a tail entity embedding vector from a normal distribution: $\mathbf{t} \backsim \mathcal{N}(\mathbf{u_t}, \sigma_t^2\mathbf{E})$.
   (d) Draw a relation embedding vector for this semantics: $\mathbf{u_{r,m}} = \mathbf{t} - \mathbf{h} \backsim \mathcal{N}(\mathbf{u_t} - \mathbf{u_h}, (\sigma_h^2 + \sigma_t^2)\mathbf{E})$.

where $\mathbf{u_h}$ and $\mathbf{u_t}$ indicate the mean embedding vector for head and tail respectively, σ_h and σ_t indicate the variance of corresponding entity distribution respectively, and $\mathbf{u_{r,m}}$ is the m-th component translation vector of relation r. Chinese Restaurant Process (CRP) is a Dirichlet Process and it can automatically detect semantic components. In this setting, we obtain the score function as below:

$$\begin{aligned}\mathbb{P}\{(h,r,t)\} &\propto \sum_{m=1}^{M_r} \pi_{r,m}\mathbb{P}(\mathbf{u_{r,m}}|h,t) \\ &= \sum_{m=1}^{M_r} \pi_{r,m} e^{-\frac{||\mathbf{u_h}+\mathbf{u_{r,m}}-\mathbf{u_t}||_2^2}{\sigma_h^2+\sigma_t^2}} \quad (1)\end{aligned}$$

where $\pi_{r,m}$ is the mixing factor, indicating the weight of i-th component and M_r is the number of semantic components for the relation r, which is learned from the data automatically by the CRP.

Inspired by Fig.1, TransG leverages a mixture of relation component vectors for a specific relation. Each component represents a specific latent meaning. By this way, TransG could distinguish multiple relation semantics. Notably, the CRP could generate multiple semantic components when it is necessary and the relation semantic component number M_r is learned adaptively from the data.

Table 1: Statistics of datasets

Data	WN18	FB15K	WN11	FB13
#Rel	18	1,345	11	13
#Ent	40,943	14,951	38,696	75,043
#Train	141,442	483,142	112,581	316,232
#Valid	5,000	50,000	2,609	5,908
#Test	5,000	59,071	10,544	23,733

3.2 Explanation from the Geometry Perspective

Similar to previous studies, TransG has geometric explanations. In the previous methods, when the relation r of triple (h, r, t) is given, the geometric representations are fixed, as $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$. However, TransG generalizes this geometric principle to:

$$\begin{aligned}m^*_{(h,r,t)} = \underset{m=1...M_r}{\arg\max} &\left(\pi_{r,m} e^{-\frac{||\mathbf{u_h}+\mathbf{u_{r,m}}-\mathbf{u_t}||_2^2}{\sigma_h^2+\sigma_t^2}}\right) \\ &\mathbf{h} + \mathbf{u_{r,m^*_{(h,r,t)}}} \approx \mathbf{t} \quad (2)\end{aligned}$$

where $m^*_{(h,r,t)}$ is the index of primary component. Though all the components contribute to the model, the primary one contributes the most due to the exponential effect ($exp(\cdot)$). When a triple (h, r, t) is given, TransG works out the index of primary component then translates the head entity to the tail one with the primary translation vector.

For most triples, there should be only one component that have significant non-zero value as $\left(\pi_{r,m} e^{-\frac{||\mathbf{u_h}+\mathbf{u_{r,m}}-\mathbf{u_t}||_2^2}{\sigma_h^2+\sigma_t^2}}\right)$ and the others would be small enough, due to the exponential decay. This property reduces the noise from the other semantic components to better characterize multiple relation semantics. In detail, $(\mathbf{t} - \mathbf{h})$ is almost around only one translation vector $\mathbf{u_{r,m^*_{(h,r,t)}}}$ in TransG. Under the condition $m \neq m^*_{(h,r,t)}$, $\left(\frac{||\mathbf{u_h}+\mathbf{u_{r,m}}-\mathbf{u_t}||_2^2}{\sigma_h^2+\sigma_t^2}\right)$ is very large so that the exponential function value is very small. This is why the primary component could represent the corresponding semantics.

To summarize, previous studies make translation identically for all the triples of the same relation, but TransG automatically selects the best translation vector according to the specific semantics of a triple. Therefore, TransG could focus on the specific semantic embedding to avoid much noise from the other unrelated semantic components and result in promising improvements than existing methods. Note that, all the components in

Table 2: Evaluation results on link prediction

TransG have their own contributions, but the primary one makes the most.

3.3 Training Algorithm

The maximum data likelihood principle is applied for training. As to the non-parametric part, $\pi_{r,m}$ is generated from the CRP with Gibbs Sampling, similar to (He et al., 2015) and (Griffiths and Ghahramani, 2011). A new component is sampled for a triple (h,r,t) with the below probability:

$$\mathbb{P}(m_{r,new}) = \frac{\beta e^{-\frac{||\mathbf{h}-\mathbf{t}||_2^2}{\sigma_h^2+\sigma_t^2+2}}}{\beta e^{-\frac{||\mathbf{h}-\mathbf{t}||_2^2}{\sigma_h^2+\sigma_t^2+2}} + \mathbb{P}\{(h,r,t)\}} \quad (3)$$

where $\mathbb{P}\{(h,r,t)\}$ is the current posterior probability. As to other parts, in order to better distinguish the true triples from the false ones, we maximize the ratio of likelihood of the true triples to that of the false ones. Notably, the embedding vectors are initialized by (Glorot and Bengio, 2010). Putting all the other constraints together, the final objective function is obtained, as follows:

$$\min_{\mathbf{u_h},\mathbf{u_{r,m}},\mathbf{u_t}} \mathcal{L}$$

$$\mathcal{L} = -\sum_{(h,r,t)\in\Delta} ln\left(\sum_{m=1}^{M_r}\pi_{r,m}e^{-\frac{||\mathbf{u_h}+\mathbf{u_{r,m}}-\mathbf{u_t}||_2^2}{\sigma_h^2+\sigma_t^2}}\right)$$

$$+\sum_{(h',r',t')\in\Delta'} ln\left(\sum_{m=1}^{M_r}\pi_{r',m}e^{-\frac{||\mathbf{u_{h'}}+\mathbf{u_{r',m}}-\mathbf{u_{t'}}||_2^2}{\sigma_{h'}^2+\sigma_{t'}^2}}\right)$$

$$+C\left(\sum_{r\in R}\sum_{m=1}^{M_r}||\mathbf{u_{r,m}}||_2^2+\sum_{e\in E}||\mathbf{u_e}||_2^2\right) \quad (4)$$

where Δ is the set of golden triples and Δ' is the set of false triples. C controls the scaling degree. E is the set of entities and R is the set of relations. Noted that the mixing factors π and the variances σ are also learned jointly in the optimization.

SGD is applied to solve this optimization problem. In addition, we apply a trick to control the parameter updating process during training. For those very impossible triples, the update process is skipped. Hence, we introduce a similar condition as TransE (Bordes et al., 2013) adopts: the training algorithm will update the embedding vectors only if the below condition is satisfied:

$$\frac{\mathbb{P}\{(h,r,t)\}}{\mathbb{P}\{(h',r',t')\}} = \frac{\sum_{m=1}^{M_r}\pi_{r,m}e^{-\frac{||\mathbf{u_h}+\mathbf{u_{r,m}}-\mathbf{u_t}||_2^2}{\sigma_h^2+\sigma_t^2}}}{\sum_{m=1}^{M_{r'}}\pi_{r',m}e^{-\frac{||\mathbf{u_{h'}}+\mathbf{u_{r',m}}-\mathbf{u_{t'}}||_2^2}{\sigma_{h'}^2+\sigma_{t'}^2}}} \leq M_r e^{\gamma} \quad (5)$$

where $(h,r,t)\in\Delta$ and $(h',r',t')\in\Delta'$. γ controls the updating condition.

As to the efficiency, in theory, the time complexity of TransG is bounded by a small constant M compared to TransE, that is $O(\text{TransG}) = O(M \times O(\text{TransE}))$ where M is the number of semantic components in the model. Note that TransE is the fastest method among translation-based methods. The experiment of Link Prediction shows that TransG and TransE would converge at around 500 epochs, meaning there is also no significant difference in convergence speed. In experiment, TransG takes 4.8s for one iteration on FB15K while TransR costs 136.8s and PTransE

Table 3: Evaluation results on FB15K by mapping properties of relations(%)

Tasks	Predicting Head(HITS@10)				Predicting Tail(HITS@10)

costs 1200.0s on the same computer for the same dataset.

4 Experiments

Our experiments are conducted on four public benchmark datasets that are the subsets of Wordnet and Freebase, respectively. The statistics of these datasets are listed in Tab.1. Experiments are conducted on two tasks : Link Prediction and Triple Classification. To further demonstrate how the proposed model approaches multiple relation semantics, we present semantic component analysis at the end of this section.

4.1 Link Prediction

Link prediction concerns knowledge graph completion: when given an entity and a relation, the embedding models predict the other missing entity. More specifically, in this task, we predict t given $(h, r, *)$, or predict h given $(*, r, t)$. The WN18 and FB15K are two benchmark datasets for this task. Note that many AI tasks could be enhanced by Link Prediction such as relation extraction (Hoffmann et al., 2011).

Evaluation Protocol. We adopt the same protocol used in previous studies. For each testing triple (h, r, t), we corrupt it by replacing the tail t (or the head h) with every entity e in the knowledge graph and calculate a probabilistic score of this corrupted triple (h, r, e) (or (e, r, t)) with the score function $f_r(h, e)$. After ranking these scores in descending order, we obtain the rank of the original triple. There are two metrics for evaluation: the averaged rank (Mean Rank) and the proportion of testing triple whose rank is not larger than 10 (HITS@10). This is called "Raw" setting. When we filter out the corrupted triples that exist in the training, validation, or test datasets, this is the"Filter" setting. If a corrupted triple exists in the knowledge graph, ranking it ahead the original triple is also acceptable. To eliminate this case, the "Filter" setting is preferred. In both settings, a lower Mean Rank and a higher HITS@10 mean better performance.

Implementation. As the datasets are the same, we directly report the experimental results of several baselines from the literature, as in (Bordes et al., 2013), (Wang et al., 2014) and (Lin et al., 2015b). We have attempted several settings on the validation dataset to get the best configuration. For example, we have tried the dimensions of 100, 200, 300, 400. Under the "bern." sampling strategy, the optimal configurations are: learning rate $\alpha = 0.001$, the embedding dimension $k = 100$, $\gamma = 2.5$, $\beta = 0.05$ on WN18; $\alpha = 0.0015$, $k = 400$, $\gamma = 3.0$, $\beta = 0.1$ on FB15K. Note that all the symbols are introduced in "Methods". We train the model until it converges.

Results. Evaluation results on WN18 and FB15K are reported in Tab.2 and Tab.3[1]. We observe that:

1. TransG outperforms all the baselines obviously. Compared to TransR, TransG makes improvements by 2.9% on WN18 and 26.0% on FB15K, and the averaged semantic component number on WN18 is 5.67 and that on FB15K is 8.77. This result demonstrates capturing multiple relation semantics would benefit embedding.

[1]Note that correctly regularized TransE can produce much better performance than what were reported in the ogirinal paper, see (García-Durán et al., 2015).

Table 4: Different clusters in WN11 and FB13 relations.

Relation	Cluster	Triples (Head, Tail)
PartOf	Location	(Capital of Utah, Beehive State), (Hindustan, Bharat) ...
	Composition	(Monitor, Television), (Bush, Adult Body), (Cell Organ, Cell)...
Religion	Catholicism	(Cimabue, Catholicism), (St.Catald, Catholicism) ...
	Others	(Michal Czajkowsk, Islam), (Honinbo Sansa, Buddhism) ...
DomainRegion	Abstract	(Computer Science, Security System), (Computer Science, PL)..
	Specific	(Computer Science, Router), (Computer Science, Disk File) ...
Profession	Scientist	(Michael Woodruf, Surgeon), (El Lissitzky, Architect)...
	Businessman	(Enoch Pratt, Entrepreneur), (Charles Tennant, Magnate)...
	Writer	(Vlad. Gardin, Screen Writer), (John Huston, Screen Writer) ...

2. The model has a bad Mean Rank score on the WN18 dataset. Further analysis shows that there are 24 testing triples (0.5% of the testing set) whose ranks are more than 30,000, and these few cases would lead to about 150 mean rank loss. Among these triples, there are 23 triples whose tail or head entities have never been co-occurring with the corresponding relations in the training set. In one word, there is no sufficient training data for those relations and entities.

3. Compared to CTransR, TransG solves the multiple relation semantics problem much better for two reasons. Firstly, CTransR clusters the entity pairs for a specific relation and then performs embedding for each cluster, but TransG deals with embedding and multiple relation semantics simultaneously, where the two processes can be enhanced by each other. Secondly, CTransR models a triple by only one cluster, but TransG applies a mixture to refine the embedding.

Our model is almost insensitive to the dimension if that is sufficient. For the dimensions of $100, 200, 300, 400$, the HITS@10 of TransG on FB15 are $81.8\%, 84.0\%, 85.8\%, 88.2\%$, while those of TransE are $47.1\%, 48.5\%, 51.3\%, 49.2\%$.

4.2 Triple Classification

In order to testify the discriminative capability between true and false facts, triple classification is conducted. This is a classical task in knowledge base embedding, which aims at predicting whether a given triple (h, r, t) is correct or not. WN11 and FB13 are the benchmark datasets for this task. Note that evaluation of classification needs negative samples, and the datasets have already provided negative triples.

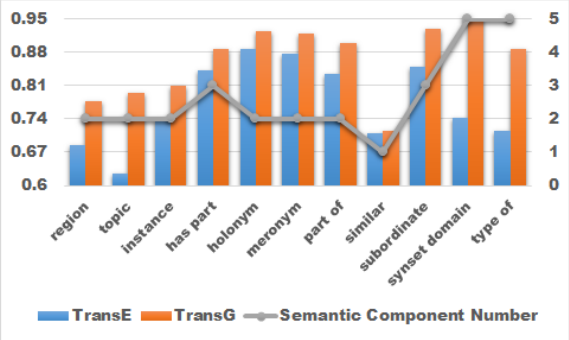

Figure 3: Accuracies of each relations in WN11 for triple classification. The right y-axis is the number of semantic components, corresponding to the lines.

Evaluation Protocol. The decision process is very simple as follows: for a triple (h, r, t), if $f_r(h, t)$ is below a threshold σ_r, then positive; otherwise negative. The thresholds $\{\sigma_r\}$ are determined on the validation dataset.

Table 5: Triple classification: accuracy(%) for different embedding methods.

Methods	WN11	FB13	AVG.
LFM	73.8	84.3	79.0
NTN	70.4	87.1	78.8
TransE	75.9	81.5	78.7
TransH	78.8	83.3	81.1
TransR	85.9	82.5	84.2
CTransR	85.7	N/A	N/A
KG2E	85.4	85.3	85.4
TransG	**87.4**	**87.3**	**87.4**

Implementation. As all methods use the same datasets, we directly re-use the results of different methods from the literature. We have attempted several settings on the validation dataset to find

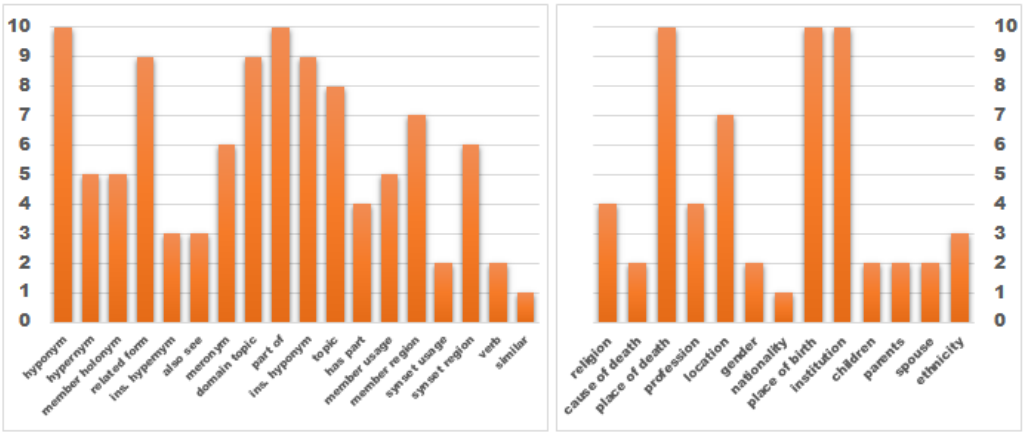

Figure 4: Semantic component number on WN18 (left) and FB13 (right).

the best configuration. The optimal configurations of TransG are as follows: "bern" sampling, learning rate $\alpha = 0.001$, $k = 50$, $\gamma = 6.0$, $\beta = 0.1$ on WN11, and "bern" sampling, $\alpha = 0.002$, $k = 400$, $\gamma = 3.0$, $\beta = 0.1$ on FB13.

Results. Accuracies are reported in Tab.5 and Fig.3. The following are our observations:

1. TransG outperforms all the baselines remarkably. Compared to TransR, TransG improves by 1.7% on WN11 and 5.8% on FB13, and the averaged semantic component number on WN11 is 2.63 and that on FB13 is 4.53. This result shows the benefit of capturing multiple relation semantics for a relation.

2. The relations, such as "Synset Domain" and "Type Of", which hold more semantic components, are improved much more. In comparison, the relation "Similar" holds only one semantic component and is almost not promoted. This further demonstrates that capturing multiple relation semantics can benefit embedding.

4.3 Semantic Component Analysis

In this subsection, we analyse the number of semantic components for different relations and list the component number on the dataset WN18 and FB13 in Fig.4.

Results. As Fig. 4 and Tab. 4 show, we have the following observations:

1. Multiple semantic components are indeed necessary for most relations. Except for relations such as "Also See", "Synset Usage" and "Gender", all other relations have more than one semantic component.

2. Different components indeed correspond to different semantics, justifying the theoretical analysis and effectiveness of TransG. For example, "Profession" has at least three semantics: scientist-related as $(\text{ElLissitzky}, \text{Architect})$, businessman-related as $(\text{EnochPratt}, \text{Entrepreneur})$ and writer-related as $(\text{Vlad.Gardin}, \text{ScreenWriter})$.

3. WN11 and WN18 are different subsets of Wordnet. As we know, the semantic component number is decided on the triples in the dataset. Therefore, It's reasonable that similar relations, such as "Synset Domain" and "Synset Usage" may hold different semantic numbers for WN11 and WN18.

5 Conclusion

In this paper, we propose a generative Bayesian non-parametric infinite mixture embedding model, TransG, to address a new issue, multiple relation semantics, which can be commonly seen in knowledge graph. TransG can discover the latent semantics of a relation automatically and leverage a mixture of relation components for embedding. Extensive experiments show our method achieves substantial improvements against the state-of-the-art baselines.

Abstract

Existing knowledge-based question answering systems often rely on small annotated training data. While shallow methods like relation extraction are robust to data scarcity, they are less expressive than the deep meaning representation methods like semantic parsing, thereby failing at answering questions involving multiple constraints. Here we alleviate this problem by empowering a relation extraction method with additional evidence from Wikipedia. We first present a neural network based relation extractor to retrieve the candidate answers from Freebase, and then infer over Wikipedia to validate these answers. Experiments on the WebQuestions question answering dataset show that our method achieves an F_1 of 53.3%, a substantial improvement over the state-of-the-art.

1 Introduction

Since the advent of large structured knowledge bases (KBs) like Freebase (Bollacker et al., 2008), YAGO (Suchanek et al., 2007) and DBpedia (Auer et al., 2007), answering natural language questions using those structured KBs, also known as KB-based question answering (or KB-QA), is attracting increasing research efforts from both natural language processing and information retrieval communities.

The state-of-the-art methods for this task can be roughly categorized into two streams. The first is based on semantic parsing (Berant et al., 2013; Kwiatkowski et al., 2013), which typically learns a grammar that can parse natural language to a sophisticated meaning representation language. But such sophistication requires a lot of annotated training examples that contains compositional structures, a practically impossible solution for large KBs such as Freebase. Furthermore, mismatches between grammar predicted structures and KB structure is also a common problem (Kwiatkowski et al., 2013; Berant and Liang, 2014; Reddy et al., 2014).

On the other hand, instead of building a formal meaning representation, information extraction methods retrieve a set of candidate answers from KB using relation extraction (Yao and Van Durme, 2014; Yih et al., 2014; Yao, 2015; Bast and Haussmann, 2015) or distributed representations (Bordes et al., 2014; Dong et al., 2015). Designing large training datasets for these methods is relatively easy (Yao and Van Durme, 2014; Bordes et al., 2015; Serban et al., 2016). These methods are often good at producing an answer irrespective of their correctness. However, handling compositional questions that involve multiple entities and relations, still remains a challenge. Consider the question *what mountain is the highest in north america*. Relation extraction methods typically answer with all the mountains in *North America* because of the lack of sophisticated representation for the mathematical function *highest*. To select the correct answer, one has to retrieve all the heights of the mountains, and sort them in descending order, and then pick the first entry. We propose a method based on textual evidence which can answer such questions without solving the mathematic functions implicitly.

Knowledge bases like Freebase capture real world facts, and Web resources like Wikipedia provide a large repository of sentences that validate or support these facts. For example, a sentence in Wikipedia says, *Denali (also known as Mount McKinley, its former official name) is the highest mountain peak in North America, with a summit elevation of 20,310 feet (6,190 m) above sea level.* To answer our example question against a KB using a relation extractor, we can use this sentence

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2326–2336,
Berlin, Germany, August 7-12, 2016.

as external evidence, filter out wrong answers and pick the correct one.

Using textual evidence not only mitigates representational issues in relation extraction, but also alleviates the data scarcity problem to some extent. Consider the question, *who was queen isabella's mother*. Answering this question involves predicting two constraints hidden in the word *mother*. One constraint is that the answer should be the *parent* of *Isabella*, and the other is that the answer's *gender* is *female*. Such words with multiple latent constraints have been a pain-in-the-neck for both semantic parsing and relation extraction, and requires larger training data (this phenomenon is coined as sub-lexical compositionality by Wang et al. (2015)). Most systems are good at triggering the *parent* constraint, but fail on the other, i.e., the answer entity should be *female*. Whereas the textual evidence from Wikipedia, *... her mother was Isabella of Barcelos ...*, can act as a further constraint to answer the question correctly.

We present a novel method for question answering which infers on both structured and unstructured resources. Our method consists of two main steps as outlined in §2. In the first step we extract answers for a given question using a structured KB (here Freebase) by jointly performing entity linking and relation extraction (§3). In the next step we validate these answers using an unstructured resource (here Wikipedia) to prune out the wrong answers and select the correct ones (§4). Our evaluation results on a benchmark dataset WebQuestions show that our method outperforms existing state-of-the-art models. Details of our experimental setup and results are presented in §5. Our code, data and results can be downloaded from `https://github.com/syxu828/QuestionAnsweringOverFB`.

2 Our Method

Figure 1 gives an overview of our method for the question "*who did shaq first play for*". We have two main steps: (1) inference on Freebase (*KB-QA* box); and (2) further inference on Wikipedia (*Answer Refinement* box). Let us take a close look into step 1. Here we perform *entity linking* to identify a topic entity in the question and its possible Freebase entities. We employ a *relation extractor* to predict the potential Freebase relations that could exist between the entities in the question and the answer entities. Later we perform a *joint inference* step over the entity linking and relation extraction

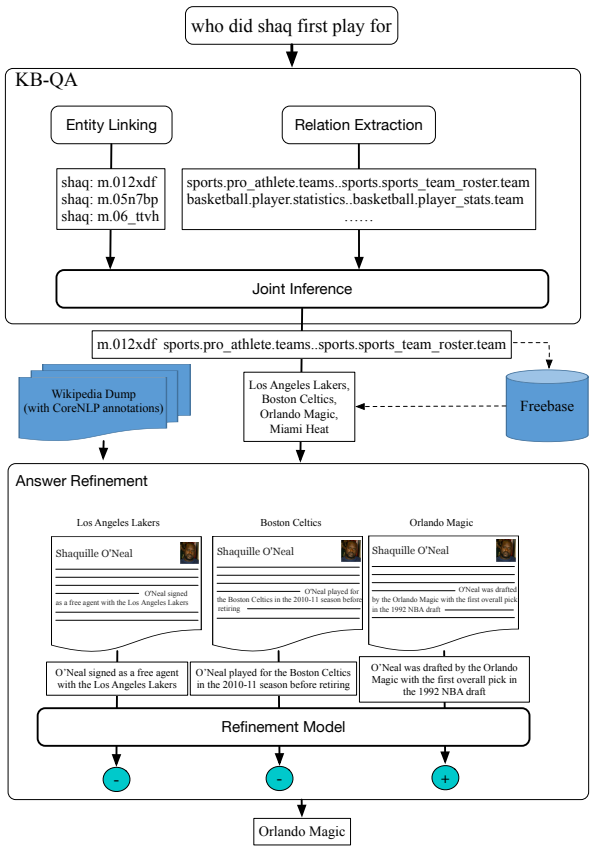

Figure 1: An illustration of our method to find answers for the given question *who did shaq first play for*.

results to find the best entity-relation configuration which will produce a list of candidate answer entities. In the step 2, we refine these candidate answers by applying an *answer refinement* model which takes the Wikipedia page of the topic entity into consideration to filter out the wrong answers and pick the correct ones.

While the overview in Figure 1 works for questions containing single Freebase relation, it also works for questions involving multiple Freebase relations. Consider the question *who plays anakin skywalker in star wars 1*. The actors who are the answers to this question should satisfy the following constraints: (1) the actor played *anakin skywalker*; and (2) the actor played in *star wars 1*. Inspired by Bao et al. (2014), we design a dependency tree-based method to handle such multi-relational questions. We first decompose the original question into a set of *sub-questions* using syntactic patterns which are listed in Appendix. The final answer set of the original question is obtained by intersecting the answer sets of all its sub-questions. For the

example question, the sub-questions are *who plays anakin skywalker* and *who plays in star wars 1*. These sub-questions are answered separately over Freebase and Wikipedia, and the intersection of their answers to these sub-questions is treated as the final answer.

3 Inference on Freebase

Given a sub-question, we assume the question word[1] that represents the answer has a distinct KB relation r with an entity e found in the question, and predict a single KB triple $(e, r, ?)$ for each sub-question (here ? stands for the answer entities). The QA problem is thus formulated as an information extraction problem that involves two sub-tasks, i.e., entity linking and relation extraction. We first introduce these two components, and then present a joint inference procedure which further boosts the overall performance.

3.1 Entity Linking

For each question, we use hand-built sequences of part-of-speech categories to identify all possible named entity mention spans, e.g., the sequence *NN* (*shaq*) may indicate an entity. For each mention span, we use the entity linking tool S-MART[2] (Yang and Chang, 2015) to retrieve the top 5 entities from Freebase. These entities are treated as candidate entities that will eventually be disambiguated in the joint inference step. For a given mention span, S-MART first retrieves all possible entities of Freebase by surface matching, and then ranks them using a statistical model, which is trained on the frequency counts with which the surface form occurs with the entity.

3.2 Relation Extraction

We now proceed to identify the relation between the answer and the entity in the question. Inspired by the recent success of neural network models in KB question-answering (Yih et al., 2015; Dong et al., 2015), and the success of syntactic dependencies for relation extraction (Liu et al., 2015; Xu et al., 2015), we propose a Multi-Channel Convolutional Neural Network (MCCNN) which could exploit both syntactic and sentential information for relation extraction.

[1] who, when, what, where, how, which, why, whom, whose.

[2] S-MART demo can be accessed at http://msre2edemo.azurewebsites.net/

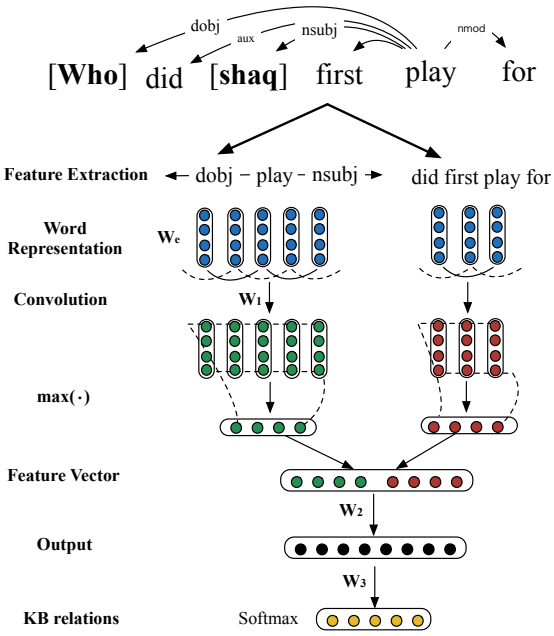

Figure 2: Overview of the multi-channel convolutional neural network for relation extraction. W_e is the word embedding matrix, W_1 is the convolution matrix, W_2 is the activation matrix and W_3 is the classification matrix.

3.2.1 MCCNNs for Relation Classification

In MCCNN, we use two channels, one for syntactic information and the other for sentential information. The network structure is illustrated in Figure 2. Convolution layer tackles an input of varying length returning a fixed length vector (we use max pooling) for each channel. These fixed length vectors are concatenated and then fed into a *softmax* classifier, the output dimension of which is equal to the number of predefined relation types. The value of each dimension indicates the confidence score of the corresponding relation.

Syntactic Features We use the shortest path between an entity mention and the question word in the dependency tree[3] as input to the first channel. Similar to Xu et al. (2015), we treat the path as a concatenation of vectors of words, dependency edge directions and dependency labels, and feed it to the convolution layer. Note that, the entity mention and the question word are excluded from the dependency path so as to learn a more general relation representation in syntactic level. As shown in Figure 2, the dependency path between *who* and *shaq* is $\leftarrow$ *dobj* – *play* – *nsubj* $\rightarrow$.

[3] We use Stanford CoreNLP dependency parser (Manning et al., 2014).

Sentential Features This channel takes the words in the sentence as input excluding the question word and the entity mention. As illustrated in Figure 2, the vectors for *did, first, play* and *for* are fed into this channel.

3.2.2 Objective Function and Learning

The model is learned using pairs of question and its corresponding gold relation from the training data. Given an input question x with an annotated entity mention, the network outputs a vector $o(x)$, where the entry $o_k(x)$ is the probability that there exists the *k*-th relation between the entity and the expected answer. We denote $t(x) \in \mathbb{R}^{K\times 1}$ as the target distribution vector, in which the value for the gold relation is set to 1, and others to 0. We compute the cross entropy error between $t(x)$ and $o(x)$, and further define the objective function over the training data as:

$$J(\theta) = -\sum_{x}\sum_{k=1}^{K} t_k(x)\log o_k(x) + \lambda||\theta||_2^2$$

where θ represents the weights, and λ the $L2$ regularization parameters. The weights θ can be efficiently computed via back-propagation through network structures. To minimize $J(\theta)$, we apply stochastic gradient descent (SGD) with AdaGrad (Duchi et al., 2011).

3.3 Joint Entity Linking & Relation Extraction

A pipeline of entity linking and relation extraction may suffer from error propagations. As we know, entities and relations have strong selectional preferences that certain entities do not appear with certain relations and vice versa. Locally optimized models could not exploit these implicit *bi-directional* preferences. Therefore, we use a joint model to find a globally optimal entity-relation assignment from local predictions. The key idea behind is to leverage various clues from the two local models and the KB to rank a correct entity-relation assignment higher than other combinations. We describe the learning procedure and the features below.

3.3.1 Learning

Suppose the pair (e_{gold}, r_{gold}) represents the gold entity/relation pair for a question q. We take all our entity and relation predictions for q, create a list of entity and relation pairs $\{(e_0, r_0), (e_1, r_1), ..., (e_n, r_n)\}$ from q and rank them using an SVM rank classifier (Joachims, 2006) which is trained to predict a rank for each pair. Ideally higher rank indicates the prediction is closer to the gold prediction. For training, SVM rank classifier requires a ranked or scored list of entity-relation pairs as input. We create the training data containing ranked input pairs as follows: if both $e_{pred} = e_{gold}$ and $r_{pred} = r_{gold}$, we assign it with a score of 3. If only the entity or relation equals to the gold one (i.e., $e_{pred} = e_{gold}$, $r_{pred} \neq r_{gold}$ or $e_{pred} \neq e_{gold}$, $r_{pred} = r_{gold}$), we assign a score of 2 (encouraging partial overlap). When both entity and relation assignments are wrong, we assign a score of 1.

3.3.2 Features

For a given entity-relation pair, we extract the following features which are passed as an input vector to the SVM ranker above:

Entity Clues. We use the score of the predicted entity returned by the entity linking system as a feature. The number of word overlaps between the entity mention and entity's Freebase name is also included as a feature. In Freebase, most entities have a relation *fb:description* which describes the entity. For instance, in the running example, *shaq* is linked to three potential entities *m.06_ttvh (Shaq Vs. Television Show)*, *m.05n7bp (Shaq Fu Video Game)* and *m.012xdf (Shaquille O'Neal)*. Interestingly, the word *play* only appears in the description of *Shaquille O'Neal* and it occurs three times. We count the content word overlap between the given question and the entity's description, and include it as a feature.

Relation Clues. The score of relation returned by the MCCNNs is used as a feature. Furthermore, we view each relation as a *document* which consists of the training questions that this relation is expressed in. For a given question, we use the sum of the *tf-idf* scores of its words with respect to the relation as a feature. A Freebase relation r is a concatenation of a series of fragments $r = r_1.r_2.r_3$. For instance, the three fragments of *people.person.parents* are *people*, *person* and *parents*. The first two fragments indicate the Freebase type of the subject of this relation, and the third fragment indicates the object type, in our case the answer type. We use an indicator feature to denote if the surface form of the third fragment (here *parents*) appears in the question.

Answer Clues. The above two feature classes indicate local features. From the entity-relation (e, r)

pair, we create the query triple $(e, r, ?)$ to retrieve the answers, and further extract features from the answers. These features are non-local since we require both e and r to retrieve the answer. One such feature is using the co-occurrence of the answer type and the question word based on the intuition that question words often indicate the answer type, e.g., the question word *when* usually indicates the answer type *type.datetime*. Another feature is the number of answer entities retrieved.

4 Inference on Wikipedia

We use the best ranked entity-relation pair from the above step to retrieve candidate answers from Freebase. In this step, we validate these answers using Wikipedia as our unstructured knowledge resource where most statements in it are verified for factuality by multiple people.

Our refinement model is inspired by the intuition of how people refine their answers. If you ask someone: *who did shaq first play for*, and give them four candidate answers (*Los Angeles Lakers*, *Boston Celtics*, *Orlando Magic* and *Miami Heat*), as well as access to Wikipedia, that person might first determine that the question is about *Shaquille O'Neal*, then go to *O'Neal*'s Wikipedia page, and search for the sentences that contain the candidate answers as evidence. By analyzing these sentences, one can figure out whether a candidate answer is correct or not.

4.1 Finding Evidence from Wikipedia

As mentioned above, we should first find the Wikipedia page corresponding to the *topic entity* in the given question. We use Freebase API to convert Freebase entity to Wikipedia page. We extract the content from the Wikipedia page and process it with *Wikifier* (Cheng and Roth, 2013) which recognizes Wikipedia entities, which can further be linked to Freebase entities using Freebase API. Additionally we use Stanford CoreNLP (Manning et al., 2014) for tokenization and entity co-reference resolution. We search for the sentences containing the candidate answer entities retrieved from Freebase. For example, the Wikipedia page of *O'Neal* contains a sentence "*O'Neal was drafted by the Orlando Magic with the first overall pick in the 1992 NBA draft*", which is taken into account by the *refinement model* (our inference model on Wikipedia) to discriminate whether *Orlando Magic* is the answer for the given question.

4.2 Refinement Model

We treat the refinement process as a binary classification task over the candidate answers, i.e., correct (positive) and incorrect (negative) answer. We prepare the training data for the refinement model as follows. On the training dataset, we first infer on Freebase to retrieve the candidate answers. Then we use the annotated gold answers of these questions and Wikipedia to create the training data. Specifically, we treat the sentences that contain correct/incorrect answers as positive/negative examples for the refinement model. We use LIBSVM (Chang and Lin, 2011) to learn the weights for classification.

Note that, in the Wikipedia page of the topic entity, we may collect more than one sentence that contain a candidate answer. However, not all sentences are relevant, therefore we consider the candidate answer as correct *if* at least there is one positive evidence. On the other hand, sometimes, we may not find any evidence for the candidate answer. In these cases, we fall back to the results of the KB-based approach.

4.3 Lexical Features

Regarding the features used in LIBSVM, we use the following lexical features extracted from the question and a Wikipedia sentence. Formally, given a question $q = <q_1, ... q_n>$ and an evidence sentence $s = <s_1, ... s_m>$, we denote the tokens of q and s by q_i and s_j, respectively. For each pair (q, s), we identify a set of all possible token pairs (q_i, s_j), the occurrences of which are used as features. As learning proceeds, we hope to learn a higher weight for a feature like (*first*, *drafted*) and a lower weight for (*first*, *played*).

5 Experiments

In this section we introduce the experimental setup, the main results and detailed analysis of our system.

5.1 Training and Evaluation Data

We use the WebQuestions (Berant et al., 2013) dataset, which contains 5,810 questions crawled via Google Suggest service, with answers annotated on Amazon Mechanical Turk. The questions are split into training and test sets, which contain 3,778 questions (65%) and 2,032 questions (35%), respectively. We further split the training questions into 80%/20% for development.

To train the MCCNNs and the joint inference model, we need the gold standard relations of the questions. Since this dataset contains only question-answer pairs and annotated topic entities, instead of relying on gold relations we rely on *surrogate* gold relations which produce answers that have the highest overlap with gold answers. Specifically, for a given question, we first locate the topic entity e in the Freebase graph, then select 1-hop and 2-hop relations connected to the topic entity as relation candidates. The 2-hop relations refer to the n-ary relations of Freebase, i.e., first hop from the subject to a mediator node, and the second from the mediator to the object node. For each relation candidate r, we issue the query (e, r, ?) to the KB, and label the relation that produces the answer with minimal F_1-loss against the gold answer, as the *surrogate* gold relation. From the training set, we collect 461 relations to train the MCCNN, and the target prediction during testing time is over these relations.

5.2 Experimental Settings

We have 6 dependency tree patterns based on Bao et al. (2014) to decompose the question into sub-questions (See Appendix). We initialize the word embeddings with Turian et al. (2010)'s word representations with dimensions set to 50. The hyper parameters in our model are tuned using the development set. The window size of MCCNN is set to 3. The sizes of the hidden layer 1 and the hidden layer 2 of the two MCCNN channels are set to 200 and 100, respectively. We use the Freebase version of Berant et al. (2013), containing 4M entities and 5,323 relations.

5.3 Results and Discussion

We use the average question-wise F_1 as our evaluation metric.[4] To give an idea of the impact of different configurations of our method, we compare the following with existing methods.

Structured. This method involves inference on Freebase only. First the entity linking (EL) system is run to predict the topic entity. Then we run the relation extraction (RE) system and select the best relation that can occur with the topic entity. We choose this entity-relation pair to predict the answer.

[4]We use the evaluation script available at `http://www-nlp.stanford.edu/software/sempre`.

Method	average F_1
Berant et al. (2013)	35.7
Yao and Van Durme (2014)	33.0

This work	
Structured	44.1
Structured + Joint	47.1
Structured + Unstructured	47.0
Structured + Joint + Unstructured	**53.3**

Table 1: Results on the test set.

Structured + Joint. In this method instead of the above pipeline, we perform joint EL and RE as described in §3.3.

Structured+Unstructured. We use the pipelined EL and RE along with inference on Wikipedia as described in §4.

Structured + Joint + Unstructured. This is our main model. We perform inference on Freebase using joint EL and RE, and then inference on Wikipedia to validate the results. Specifically, we treat the top two predictions of the joint inference model as the candidate subject and relation pairs, and extract the corresponding answers from each pair, take the union, and filter the answer set using Wikipedia.

Table 1 summarizes the results on the test data along with the results from the literature.[5] We can see that joint EL and RE performs better than the default pipelined approach, and outperforms most semantic parsing based models, except (Berant and Liang, 2015) which searches partial logical forms in strategic order by combining imitation learning and agenda-based parsing. In addition, inference on unstructured data helps the default model. The joint EL and RE combined with inference on unstructured data further improves the default pipelined model by 9.2% (from 44.1% to 53.3%), and achieves a new state-of-the-art result beating the previous reported best result of Yih et al. (2015) (with one-tailed t-test significance of $p < 0.05$).

[5]We use development data for all our ablation experiments. Similar trends are observed on both development and test results.

	Entity Linking Accuracy	Relation Extraction Accuracy
Isolated Model	79.8	45.9
Joint Inference	**83.2**	**55.3**

Table 2: Impact of the joint inference on the development set

Method	average F_1
Structured (syntactic)	38.1
Structured (sentential)	38.7
Structured (syntactic + sentential)	40.1
Structured + Joint (syntactic)	43.6
Structured + Joint (sentential)	44.1
Structured + Joint (syntactic + sentential)	**45.8**

Table 3: Impact of different MCCNN channels on the development set.

5.3.1 Impact of Joint EL & RE

From Table 1, we can see that the joint EL & RE gives a performance boost of 3% (from 44.1 to 47.1). We also analyze the impact of joint inference on the individual components of EL & RE.

We first evaluate the EL component using the gold entity annotations on the development set. As shown in Table 2, for 79.8% questions, our entity linker can correctly find the gold standard topic entities. The joint inference improves this result to 83.2%, a 3.4% improvement. Next we use the *surrogate* gold relations to evaluate the performance of the RE component on the development set. As shown in Table 2, the relation prediction accuracy increases by 9.4% (from 45.9% to 55.3%) when using the joint inference.

5.3.2 Impact of the Syntactic and the Sentential Channels

Table 3 presents the results on the impact of individual and joint channels on the end QA performance. When using a single-channel network, we tune the parameters of only one channel while switching off the other channel. As seen, the sentential features are found to be more important than syntactic features. We attribute this to the short and noisy nature of WebQuestions questions due to which syntactic parser wrongly parses or the shortest dependency path does not contain sufficient information to predict a relation. By using both the channels, we see further improvements than using any one of the channels.

Question & Answers
1. what is the largest nation in europe Before: Kazakhstan, Turkey, Russia, ... After: Russia
2. which country in europe has the largest land area Before: Georgia, France, Russia, ... After: Russian Empire, Russia
3. what year did ray allen join the nba Before: 2007, 2003, 1996, 1993, 2012 After: 1996
4. who is emma stone father Before: Jeff Stone, Krista Stone After: Jeff Stone
5. where did john steinbeck go to college Before: Salinas High School, Stanford University After: Stanford University

Table 4: Example questions and corresponding predicted answers before and after using unstructured inference. *Before* uses (*Structured* + *Joint*) model, and *After* uses *Structured* + *Joint* + *Unstructured* model for prediction. The colors *blue* and *red* indicate correct and wrong answers respectively.

5.3.3 Impact of the Inference on Unstructured Data

As shown in Table 1, when structured inference is augmented with the unstructured inference, we see an improvement of 2.9% (from 44.1% to 47.0%). And when *Structured* + *Joint* uses unstructured inference, the performance boosts by 6.2% (from 47.1% to 53.3%) achieving a new state-of-the-art result. For the latter, we manually analyzed the cases in which unstructured inference helps. Table 4 lists some of these questions and the corresponding answers before and after the unstructured inference. We observed the unstructured inference mainly helps for two classes of questions: (1) questions involving aggregation operations (Questions 1-3); (2) questions involving sub-lexical compositionally (Questions 4-5). Questions 1 and 2 contain the predicate $largest$ an aggregation operator. A semantic parsing method should explicitly handle this predicate to trigger $max(.)$ operator. For Question 3, structured inference predicts the Freebase relation *fb:teams..from* retrieving all the years in which *Ray Allen* has played basketball. Note that *Ray Allen* has joined *Connecticut University*'s team in *1993* and *NBA* from *1996*. To answer this question a semantic parsing system would require a *min*(·) operator along with an additional constraint that the year corresponds to the *NBA*'s term. Interestingly, without having to explicitly model these complex predicates, the unstructured inference helps in answering these questions more accurately. Questions 4-5 involve sub-lexical com-

positionally (Wang et al., 2015) predicates *father* and *college*. For example in Question 5, the user queries for the colleges that *John Steinbeck* attended. However, Freebase defines the relation *fb:education..institution* to describe a person's educational information without discriminating the specific periods such as high school or college. Inference using unstructured data helps in alleviating these representational issues.

5.3.4 Error analysis

We analyze the errors of *Structured + Joint + Unstructured* model. Around 15% of the errors are caused by incorrect entity linking, and around 50% of the errors are due to incorrect relation predictions. The errors in relation extraction are due to (i) insufficient context, e.g., in *what is duncan bannatyne*, neither the dependency path nor sentential context provides enough evidence for the MCCNN model; (ii) unbalanced distribution of relations (3022 training examples for 461 relations) heavily influences the performance of MCCNN model towards frequently seen relations. The remaining errors are the failure of unstructured inference due to insufficient evidence in Wikipedia or misclassification.

Entity Linking. In the entity linking component, we had handcrafted POS tag patterns to identify entity mentions, e.g., DT-JJ-NN (noun phrase), NN-IN-NN (prepositional phrase). These patterns are designed to have high recall. Around 80% of entity linking errors are due to incorrect entity prediction even when the correct mention span was found.

Question Decomposition. Around 136 questions (15%) of dev data contains compositional questions, leading to 292 sub-questions (around 2.1 subquestions for a compositional question). Since our question decomposition component is based on manual rules, one question of interest is how these rules perform on other datasets. By human evaluation, we found these rules achieves 95% on a more general but complex QA dataset QALD-5[6].

5.3.5 Limitations

While our unstructured inference alleviates representational issues to some extent, we still fail at modeling compositional questions such as *who is the mother of the father of prince william* involving multi-hop relations and the inter alia. Our current assumption that unstructured data could provide evidence for questions may work only for frequently typed queries or for popular domains like movies, politics and geography. We note these limitations and hope our result will foster further research in this area.

6 Related Work

Over time, the QA task has evolved into two main streams – QA on unstructured data, and QA on structured data. TREC QA evaluations (Voorhees and Tice, 1999) were a major boost to unstructured QA leading to richer datasets and sophisticated methods (Wang et al., 2007; Heilman and Smith, 2010; Yao et al., 2013; Yih et al., 2013; Yu et al., 2014; Yang et al., 2015; Hermann et al., 2015). While initial progress on structured QA started with small toy domains like GeoQuery (Zelle and Mooney, 1996), recent focus has shifted to large scale structured KBs like Freebase, DBPedia (Unger et al., 2012; Cai and Yates, 2013; Berant et al., 2013; Kwiatkowski et al., 2013; Xu et al., 2014), and on noisy KBs (Banko et al., 2007; Carlson et al., 2010; Krishnamurthy and Mitchell, 2012; Fader et al., 2013; Parikh et al., 2015). An exciting development in structured QA is to exploit multiple KBs (with different schemas) at the same time to answer questions jointly (Yahya et al., 2012; Fader et al., 2014; Zhang et al., 2016). QALD tasks and linked data initiatives are contributing to this trend.

Our model combines the best of both worlds by inferring over structured and unstructured data. Though earlier methods exploited unstructured data for KB-QA (Krishnamurthy and Mitchell, 2012; Berant et al., 2013; Yao and Van Durme, 2014; Reddy et al., 2014; Yih et al., 2015), these methods do not rely on unstructured data at test time. Our work is closely related to Joshi et al. (2014) who aim to answer noisy telegraphic queries using both structured and unstructured data. Their work is limited in answering single relation queries. Our work also has similarities to Sun et al. (2015) who does question answering on unstructured data but enrich it with Freebase, a reversal of our pipeline. Other line of very recent related work include Yahya et al. (2016) and Savenkov and Agichtein (2016).

Our work also intersects with relation extraction methods. While these methods aim to predict a relation between two entities in order to pop-

ulate KBs (Mintz et al., 2009; Hoffmann et al., 2011; Riedel et al., 2013), we work with sentence level relation extraction for question answering. Krishnamurthy and Mitchell (2012) and Fader et al. (2014) adopt open relation extraction methods for QA but they require hand-coded grammar for parsing queries. Closest to our extraction method is Yao and Van Durme (2014) and Yao (2015) who also uses sentence level relation extraction for QA. Unlike them, we can predict multiple relations per question, and our MCCNN architecture is more robust to unseen contexts compared to their logistic regression models.

Dong et al. (2015) were the first to use MCCNN for question answering. Yet our approach is very different in spirit to theirs. Dong et al. aim to maximize the similarity between the distributed representation of a question and its answer entities, whereas our network aims to predict Freebase relations. Our search space is several times smaller than theirs since we do not require potential answer entities beforehand (the number of relations is much smaller than the number of entities in Freebase). In addition, our method can explicitly handle compositional questions involving multiple relations, whereas Dong et al. learn latent representation of relation joins which is difficult to comprehend. Moreover, we outperform their method by 7 points even without unstructured inference.

7 Conclusion and Future Work

We have presented a method that could infer both on structured and unstructured data to answer natural language questions. Our experiments reveal that unstructured inference helps in mitigating representational issues in structured inference. We have also introduced a relation extraction method using MCCNN which is capable of exploiting syntax in addition to sentential features. Our main model which uses joint entity linking and relation extraction along with unstructured inference achieves the state-of-the-art results on WebQuestions dataset. A potential application of our method is to improve KB-question answering using the documents retrieved by a search engine.

Since we pipeline structured inference first and then unstructured inference, our method is limited by the coverage of Freebase. Our future work involves exploring other alternatives such as treating structured and unstructured data as two independent resources in order to overcome the knowledge gaps in either of the two resources.

Abstract

Semantic deficit is a symptom of language impairment in Alzheimer's disease (AD). We present a generalizable method for automatic generation of information content units (ICUs) for a picture used in a standard clinical task, achieving high recall, 96.8%, of human-supplied ICUs. We use the automatically generated topic model to extract semantic features, and train a random forest classifier to achieve an F-score of 0.74 in binary classification of controls versus people with AD using a set of only 12 features. This is comparable to results (0.72 F-score) with a set of 85 *manual* features. Adding semantic information to a set of standard lexicosyntactic and acoustic features improves F-score to 0.80. While control and dementia subjects discuss the same topics in the same contexts, controls are more informative per second of speech.

1 Introduction

Alzheimer's disease (AD) is the most common cause of neurodegenerative dementia, and affects more than 24.3 million people worldwide (Ballard et al., 2011). Importantly, early detection enables some therapeutic intervention and disease-modifying treatment (Sperling et al., 2011). Longitudinal studies of people with autopsy-confirmed AD indicate that linguistic changes are detectable in the prodromal stages of the disease; these include a decline in grammatical complexity, word-finding difficulties, and semantic content deficiencies, such as low idea density (i.e., the ratio of semantic units to the total number of words in a speech sample), and low efficiency (i.e., the rate of semantic units over the duration of the speech sample) (Bayles and Kaszniak, 1987; Snowdon et al., 1996; Le et al., 2011; Ahmed et al., 2013b). In the present study, we investigate methods of automatically assessing the semantic content of speech, and use it to distinguish people with AD from healthy older adults.

A standard clinical task for eliciting spontaneous speech, with high sensitivity to language in early AD, is picture description. In it, a participant is asked to provide a free-form verbal description of a visual stimulus (Goodglass and Kaplan, 1983; Bayles and Kaszniak, 1987). The picture is associated with a set of human-supplied information content units (**hsICUs**) representing components of the image, such as subjects, objects, locations, and actions (Croisile et al., 1996). The semantic content of the elicited speech can then be scored by counting the hsICUs present in the description. Previous studies found that, even in the earliest stages, descriptions by those with AD are less informative compared to those of healthy older adults, producing fewer information units out of a pre-defined list of units, and having less relevant content and lower efficiency (Hier et al., 1985; Croisile et al., 1996; Giles et al., 1996; Ahmed et al., 2013a).

Using a pre-defined list of annotated hsICUs is subject to several limitations: (i) it is *subjective* — different authors use a different number of hsICUs for the same picture (e.g., from 7 to 25 for *Cookie Theft* in the Boston Diagnostic Aphasia Examination (BDAE)) (Hier et al., 1985; Croisile et al., 1996; Forbes-McKay and Venneri, 2005; Lai et al., 2009); (ii) it *may not be optimal* for detecting linguistic impairment — the manually-annotated hsICUs are neither exhaustive of all details present in the picture, nor necessarily reflective of the content units which differ most across groups; (iii) it is *not generalizable* — hsICUs are specific to a particular picture, and new visual stimuli (e.g.,

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2337–2346,
Berlin, Germany, August 7-12, 2016.

required for longitudinal assessments) need to be annotated manually. In addition to requiring time and effort, this may result in inconsistencies, since the methodology for identifying hsICUs was never clearly defined in previous work.

Automatic scoring of semantic content in speech to detect cognitive impairment has so far required manual hsICUs. Hakkani-Tür et al. (2010) used unigram recall among hsICUs in the Western Aphasia Battery's *Picnic* picture (Kertesz, 1982) and obtained a correlation of 0.93 with manual hsICU counts. Pakhomov et al. (2010) counted N-grams ($N = 1, 2, 3, 4$) extracted from a list of hsICUs for the *Cookie Theft* picture to assess semantic content in the speech of patients with frontotemporal lobar degeneration. Fraser et al. (2016) counted instances of lexical tokens extracted from a list of hsICUs, using dependency parses of *Cookie Theft* picture descriptions, and combined them with other lexicosyntactic and acoustic features to obtain classification accuracy of 81.9% in identifying people with AD from controls. While those automated methods for scoring the information content in speech used manual hsICUs, we have found none that attempted to produce ICUs automatically.

In this paper, we present a generalizable method for automatically generating information content units for any given picture (or spontaneous speech task), using reference speech. Since clinical data can be sparse, we present a method for building word vector representations using a large general corpus, then augment it with local context windows from a smaller clinical corpus. We evaluate the generated ICUs by computing recall of hsICUs and use the constructed topic models to compare the speech of participants with and without dementia, and compute topic alignment. Second, we automatically score new picture descriptions by learning semantic features extracted from these generated ICU models, using a random forest classifier; we assess performance with recall, precision, and F-score. Third, we propose a set of clinically-relevant features for identifying AD based on differences in topic, topic context, idea density and idea efficiency.

2 Methodology

2.1 Data

DementiaBank is one of the largest public, longitudinal datasets of spontaneous speech from individuals with and without dementia. It was collected at the University of Pittsburgh (Becker et al., 1994) and contains verbal descriptions of the standard *Cookie Theft* picture (Goodglass and Kaplan, 1983), along with manual transcriptions.

In our study, we use 255 speech samples from participants diagnosed with probable or possible AD (collectively referred to as the 'AD' class), and 241 samples from healthy controls (collectively referred to as the 'CT' class), see Table 1. We remove all CHAT-format annotations (MacWhinney, 2015), filled pauses (e.g., '*ah*' and '*um*'), phonological fragments (e.g., '*b b boy*' becomes '*boy*'), repairs (e.g., '*in the in the kitchen*' becomes '*in the kitchen*'), non-standard forms (e.g., '*gonna*' becomes '*going to*'), and punctuation (e.g., commas are removed). These corrections are all provided in the database. We ignore transcripts of the investigator's speech, as irrelevant. Subject data were randomly partitioned into training, validation, and test sets using a 60-20-20 split.

Table 1: Distribution of dataset transcriptions.

Class	Subjects	Samples	Tokens
AD	168	255	24,753
CT	98	241	26,654
Total	266	496	51,407

2.2 Human-supplied ICUs (hsICUs)

We combine all hsICUs in previous work for the *Cookie Theft* picture (Hier et al., 1985; Croisile et al., 1996; Forbes-McKay and Venneri, 2005; Lai et al., 2009) with hsICUs obtained from a speech language pathologist (SLP) at the Toronto Rehabilitation Institute (TRI). The annotations of the SLP overlap completely with previously identified hsICUs, except for one (*apron*). The first three columns of Table 2 summarize these manually-produced hsICUs.

2.3 Automatic generation of ICUs

Our novel method of identifying ICUs is based on simple topic modelling using clusters of global word-vector representations from picture descriptions. First, we train a word-vector model on a large normative general-purpose corpus, allowing us to avoid sparsity in the clinical data's word-word co-occurrence matrix. Then, we extract the vector representations of words in the Dementia-

Table 2: Information units above the double line are human-supplied ICUs (hsICUs) found in previous work, except those marked with † which were annotated by an SLP for this study; those below are additionally analyzed. Over 1,000 clustering configurations based on word vectors extracted from *Control* and *Dementia* reference transcriptions, μ is the mean of the scaled distance (Eq. 1) of each hsICU to its closest cluster centroid, σ is the standard deviation, and $\delta = (\mu_{dementia} - \mu_{control})$. Statistical significance of δ was tested using an independent two-sample, two-tailed t-test; *** $= p < .001$, ** $= p < .01$, * $= p < .05$, ns = not significant.

Bank corpus, and optionally augment them with local context windows from the clinical dataset.

We use GloVe v1.2 (Pennington et al., 2014) to obtain embedded word representations and train on a combined corpus of Wikipedia 2014[1] + Gigaword 5[2]. The trained model consists of 400,000 word vectors, in 50 dimensions.

Transcriptions in DementiaBank are lowercased and tokenized using NLTK v3.1, and each word token is converted to its vector space representation using the trained GloVe model. There are a total of 26,654 word vectors (1,087 unique vectors) in the control data, and 24,753 (1,131 unique) in the dementia data. Since we aim to construct a model of semantic content, only nouns and verbs are retained prior to clustering. The resulting dataset consists of 9,330 word vectors (801 unique vectors) in the control data, and 8,021 (843 unique) in the dementia data.

We use k-means clustering with whitening, initialization with the Forgy method, and a distortion threshold of 10^{-5} as the stopping condition, where distortion is defined as the sum of the distances between each vector and its corresponding centroid. We train a *control cluster model* on the control training set (see Fig. 1 for a 2D projection of cluster vectors using principal component analysis), and a *dementia cluster model* on the dementia training set. Clusters represent topics, or groups of semantically related word vectors, discussed by the respective group of subjects. While prior work is based on hsICUs that are *expected* to be discussed by *healthy* speakers, we construct a separate cluster model for the control and dementia groups since it is unclear whether the topics discussed by both groups overlap. We vary k $(= 1, 5, 10, 15, 20, 30, 40, 50)$, completing 1,000 runs for each value, and use the Elbow method to select the optimal number of clusters on the respective validation set. The optimal setting, $k = 10$, optimizes the tradeoff between the percentage of variance explained by the clusters, and their total number. The resulting clusters represent topics that can be compared against hsICUs.

3 Experiments

3.1 Recall of hsICUs

In order to assess (i) how well the automatically generated clusters match clinical hsICUs for this

[1]http://dumps.wikimedia.org/enwiki/20140102/

[2]https://catalog.ldc.upenn.edu/LDC2011T07

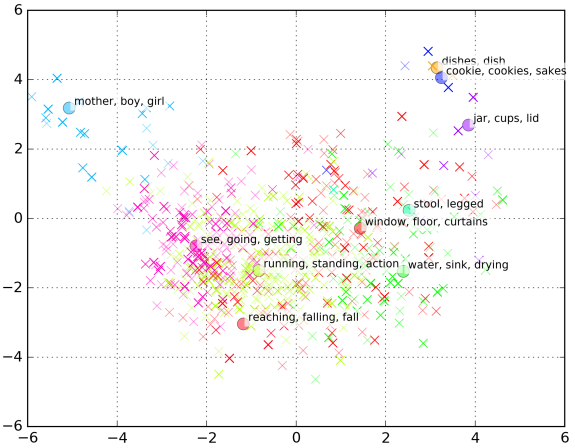

Figure 1: *Control* cluster model. The word vectors belonging to a given cluster are shown in the same colour. The most frequent words in each cluster are displayed.

image, and (ii) how much the two generated topic models differ, we analyze the vector space distance between each hsICU and its closest cluster centroid ($d_{Euclidean}$) in each of the *control* and *dementia* models. Since some clusters are more dispersed than others, we need to scale the distance appropriately. To do so, for each cluster in each model, we compute the mean distortion, μ_{cl}, of the vectors in the cluster, and the associated standard deviation σ_{cl}. For each hsICU vector, we compute the scaled distance between the vector and its closest cluster centroid in each generated model as follows:

$$d_{scaled} = \frac{(d_{Euclidean} - \mu_{cl})}{\sigma_{cl}} \quad (1)$$

The scaled distance is equivalent to the number of standard deviations above the mean — a value below zero indicates hsICUs which are very close to an automatically generated cluster centroid, while a large positive value indicates hsICUs that are far from a cluster centroid. To account for the fact that k-means is a stochastic algorithm, we perform clustering multiple times and average the results. Table 2 shows the mean, μ, and standard deviation, σ, of d_{scaled}, for each hsICU, over 1,000 cluster configurations for each model.

To quantify the recall of hsICUs using each generated cluster model, we consider hsICUs with $\mu \leq 3.0$ to be *recalled* (i.e., the distance to the assigned cluster centroid is not greater than those of 99.7% of the datapoints in the cluster, given a Gaussian distribution of distortion). The recall of

hsICUs, for both the control and dementia models, is 96.8%. Since the optimal number of generated clusters is $k = 10$, while the number of hsICUs is 31, multiple hsICUs can be grouped in related *themes* (e.g., one automatically generated cluster corresponds to the description of animate subjects in the picture, capturing four hsICUs: S1–S4). Both the control and dementia models do not recall hsICU O6, *dishcloth*, which suggests that it is a topic that neither study group discusses. All remaining hsICUs are recalled by both the control and dementia models, indicating that the hsICU topics are discussed by both groups.

However, to assess whether they are discussed to the same *extent*, i.e. to evaluate whether the two topic models differ, we conducted an independent two-sample two-tailed t-test to compare the mean scaled distance, μ, of each hsICU to its closest cluster centroid, in each cluster model (see δ in Table 2). As anticipated, since they involve inference of attention, the control model is better at accounting for the topics of the overflowing sink and the mother's indifference: *overflowing* ($t(1998) = -3.78$, $p < .001$); *sink* ($t(1998) = -9.85$, $p < .001$); *indifferent* ($t(1998) = -3.20$, $p < .01$). While there is no significant difference in the term *woman* between the two groups, the control model predicts the term *mother* better than the dementia model ($t(1998) = -30.05$, $p < .001$). To investigate whether healthy participants are more likely to identify relations between the subjects than participants with cognitive impairment, we repeated the recall experiment with the following new hsICUs: *brother*, *sister*, *son*, *daughter*. Interestingly, the dementia cluster model contains a cluster which aligns significantly more closely, than any in the control model, with all four of these relation words: *brother* ($t(1998) = 19.53$, $p < .001$); *sister* ($t(1998) = 8.93$, $p < .001$); *son* ($t(1998) = 18.78$, $p < .001$). While the control participants mention relation words as often as the participants with dementia[3], the generated cluster models show that the ratio of relation words to non-relation words is higher for the dementia group[4].

The new hsICU, *apron*, which was not identified in previous literature but was labelled by an SLP for this study, is significantly more likely to be discussed by the control population ($t(1998) = -12.46$, $p < .001$), suggesting at the importance of details for distinguishing cognitively impaired individuals. In a similar vein, control participants are significantly more likely to identify objects in the background of the scene, such as the *window* ($t(1998) = -26.04$, $p < .001$), *curtains* ($t(1998) = -24.54$, $p < .001$), *cupboard* ($t(1998) = -3.03$, $p < .01$), or *counter* ($t(1998) = -14.59$, $p < .001$).

3.2 Cluster model alignment

While prior work counted the *frequency* with which fixed topics are mentioned, our data-driven cluster models allow greater exploration of differences between the set of topics discussed by each subject group, and the alignment between them. Since prior work has found that subjects with cognitive impairment produce more irrelevant content, we quantify the amount of dispersion within each cluster through the standard deviation of its distortion and its type-to-token ratio (TTR), as shown in Table 3. Further, we compute directional alignment between pairs of clusters in each model. For each cluster in one model, alignment is determined by computing the closest cluster in the other model for each vector, and taking the majority assignment label (see a in Table 3). To quantify the alignment, the Euclidean distance of each vector to the assigned cluster in the other model is computed, scaled by the mean and standard deviation of the cluster distortion; the mean of the scaled distance, μ_a, is reported in Table 3.

To quantify the alignment of clusters in each model, we consider clusters to be *recalled* if their distance to the closest cluster in the other model is $\mu_a \leq 3$. Notably, all control clusters (C0-C9) are recalled by the dementia model, while one dementia cluster, D7, is not recalled by the control model. This exemplifies the fact that while the dementia group mentions all topics discussed by controls, they also mention a sufficient number of extraneous terms which constitute a new heterogeneous topic cluster, having the highest TTR.

[3] An independent two-sample two-tailed t-test of the effect of group on the *number of occurrences* of each relation word shows no statistical significance: *son* ($t(494) = 0.65$, $p > .05$), *daughter* ($t(494) = 0.63$, $p > .05$), *brother* ($t(494) = 0.97$, $p > .05$), *sister* ($t(494) = 1.65$, $p > .05$).

[4] An independent two-sample two-tailed t-test of the effect of group on this ratio shows a significant difference in the ratio of *sister* to *mother*, with the control group having a lower ratio ($t(494) = -4.10$, $p < .001$).

Table 3: Cluster statistics for control (C*) and dementia (D*) models, with computed cluster alignment. *Cluster words* are the 5 most frequently occurring words. f_{vec} is the fraction of all vectors which belong to the given cluster. μ_{cl} and σ_{cl} are the mean and standard deviation of the cluster distortion. f_n is the fraction of nouns among cluster vectors; $(1 - f_n)$ is the fraction of verbs. *TTR* is the type-to-token ratio. a is the ID of the aligned cluster, and μ_a is the mean scaled distance to the aligned cluster centroid.

	ID	Cluster words	f_{vec}	μ_{cl}	σ_{cl}	f_n	TTR	a	μ_a

3.3 Local context weighted vectors

Since there is significant overlap in the topics discussed between the control and dementia groups, we proceed by investigating whether the overlapping topics are discussed in the same contexts. To this end, we augment the word vector representations with local context windows from DementiaBank. Each word vector is constructed using a linear combination of its global vector from the trained GloVe model, and the vectors of the $\pm N$ surrounding context words, where each context word is weighted inversely to its distance from the central word:

$$\phi_w = v_w + \sum_{i=-N}^{-1} \alpha_i \times v_i + \sum_{i=1}^{N} \alpha_i \times v_i \qquad (2)$$

Here, ϕ_w is the local-context-weighted vector for word w, v_w is the GloVe vector for word w, v_i is the GloVe vector for word i within the context of w, and α_i is the weighting of word i, inversely and linearly proportional to the distance between context and central word. Following previous work (Fraser and Hirst, 2016), we use a context window of size $N = 3$. We extract local-context-weighted vectors for all control and dementia transcripts, and construct two topic models as before.

To quantify whether the dementia contexts differ significantly from the control contexts for the *same word*, we extract all word usages as local-context-weighted vectors, and find the centroid of the control usages, along with the mean and standard deviation of the control vectors from their centroids. Then, we compute the average scaled Euclidean distance, d_{scaled}, of the dementia vectors from the control centroid, as in Eq. 1. Words with $d_{scaled} > 3$ (i.e., where the dementia context vectors are further from the control centroid than the majority of control context vectors) are considered to have different context usage across the control and dementia groups.

Interestingly, all of the control cluster words are used in the *same contexts* by both healthy participants and those with dementia. However, the *average number of times* these words are used per transcript is significantly higher in the control group (1.07, $s.d. = 0.12$) than in the dementia group (0.77, $s.d. = 0.14$; $t(18) = 1.87$, $p < .05$).

While the two groups discuss the same topics generally and use the same words in the same contexts, not all participants in the dementia group identify all of the control topics or discuss them with the same frequency. A contextual analysis reveals that certain words are discussed in a distinct number of limited contexts, while others are discussed in more varied contexts. For in-

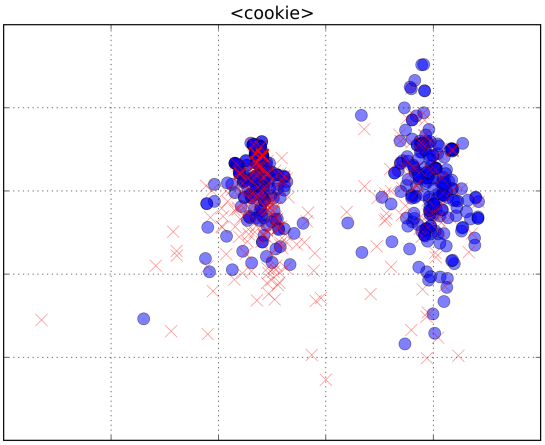

Figure 2: All usages of the word *cookie* in DementiaBank. Control usages are represented with blue circles; dementia with red crosses.

stance, while we identified a control cluster associated with the topic of the *cookie* in Section 3.2, there are two clearly distinct contexts in which this word is used, by both groups, as illustrated in Fig. 2. The two clusters in context space correspond to: (i) the usage of *cookie* in the compound noun phrase *cookie jar*, and (ii) referring to a single *cookie*, e.g. *reaching for a cookie*, *hand her a cookie*, *getting a cookie*.

3.4 Classification

To classify speakers as having AD or not, we extract the following types of features from our automatically-generated cluster models: (i) distance-based metrics for each of the control model clusters, C0–C9, (ii) distance-based metrics for each of the dementia model clusters, D0–D9, (iii) idea density, and (iv) idea efficiency. Given the vectors associated with a transcript's nouns and verbs, feature C_i (and equivalently, D_i) is computed by finding the average scaled distance, d_{scaled} (Eq. 1), of all vectors assigned to cluster C_i. A feature value below zero indicates that the transcript words assigned to the cluster are very well predicted by it (i.e., their distance from the cluster centroid is less than the average cluster distortion). Conversely, clusters which represent topics not discussed in the transcript have large positive feature values. We chose these distance-based metrics to evaluate topic recall in the transcript since a continuous measure is more appropriate for modelling the non-discrete nature of language and semantic similarity. We compute *idea density* as the number of expected topics mentioned[5] divided by the total number of words in the transcript, and *idea efficiency* as the number of expected topics mentioned divided by the total duration of the recording (in seconds). The expected topics used for computation of idea density and idea efficiency are the ICUs from the automatically-produced cluster models.

We perform classification using a random forest, whose parameters are optimized on the validation set, and performance reported on the test set. We vary the following experimental settings: *cluster model* (control; dementia; combined), *feature set* (distance-based; distance-based + idea density + idea efficiency), and *context* (no context; context with $N = 3$). A three-way ANOVA is conducted to examine the effects of these settings on average test F-score. There is a significant interaction between *feature set* and *context*, $F(1, 110) = 9.07$, $p < 0.01$. Simple main effect analysis shows that when using the extended feature set, vectors constructed without local context windows from the clinical dataset yield significantly better results than those with context ($p < 0.001$), but there is no effect when using only distance-based features ($p = 0.87$). There is no main effect of *cluster model* on test performance, $F(2, 117) = 2.30$, $p = 0.11$, which is expected since cluster alignment revealed significant overlap between the topics discussed by the control and dementia groups (Section 3.2). Notably, there is a significant effect of *feature set* on test performance, whereby adding the idea density and idea efficiency features results in significantly higher F-scores, both when using local context for vector construction ($p < 0.05$), and otherwise ($p < 0.001$).

As a baseline, we use a list of hsICUs extracted by Fraser et al. (2016) in a state-of-the-art automated method for separating AD and control speakers in DementiaBank. These features consist of (i) counts of lexical tokens representing hsICUs (e.g., *boy*, *son*, and *brother* are used to identify whether hsICU S1 (Table 2) was discussed, and (ii) Boolean values which indicate whether each hsICU was mentioned or not. Overall, this constitutes 85 features. Additionally, Fraser et al. (2016) identified a list of lexicosyntactic and acoustic (LS&A) features which are indicative of cognitive impairment. We compute the performance of each set of features independently, and then com-

[5] I.e., the number of word vectors in the transcript whose scaled distance is within 3 s.d.'s from the mean cluster distortion of at least one cluster.

Table 4: Binary classification (AD:CT) using a random forest classifier, with 10-fold cross-validation. All cluster models are trained on vectors with no local context. LS&A are lexicosyntactic and acoustic features as described by Fraser et al. (2016). The reported precision, recall, and F-score are a weighted average over the two classes.

Model	Features	Accuracy	Precision	Recall	F-score
Baseline	hsICUs	0.73	0.74	0.73	0.72
Baseline	LS&A	0.76	0.77	0.76	0.76
Baseline	hsICUs + LS&A	0.80	0.80	0.80	**0.80**
control	distance-based	0.68	0.69	0.68	0.68
dementia	distance-based	0.66	0.67	0.66	0.66
combined	distance-based	0.68	0.69	0.68	0.68
control	distance-based + idea density + idea efficiency	0.74	0.76	0.74	0.74
dementia	distance-based + idea density + idea efficiency	0.74	0.75	0.74	0.74
combined	distance-based + idea density + idea efficiency	0.74	0.75	0.74	0.74
control	distance-based + idea density + idea efficiency + LS&A	0.79	0.79	0.79	0.79
dementia	distance-based + idea density + idea efficiency + LS&A	0.77	0.78	0.77	0.77
combined	distance-based + idea density + idea efficiency + LS&A	0.80	0.80	0.80	**0.80**

bine them. Table 4 summarizes the results; the first column indicates the cluster model (e.g., *control* indicates a cluster model trained on the control transcriptions), and the second column specifies the feature set. Our 12 automatically generated features (i.e., the combined set of distance-based measures, idea density, and idea efficiency) result in higher F-scores (0.74) than using 85 manually generated hsICUs (0.72); a two-sample paired t-test shows no difference (using control cluster model: $t(9) = 1.10$, $p = 0.30$; using dementia cluster model: $t(9) = 0.74$, $p = 0.48$) indicating the similarity of our method to the manual gold standard. Furthermore, we match state-of-the-art results (F-score of 0.80) when we augment the set of LS&A features with our automatically generated semantic features.

4 Discussion

We demonstrated a method for generating topic models automatically within the context of clinical assessment, and confirmed that low idea density and low idea efficiency are salient indicators of cognitive impairment. In our data, we also found that speakers with and without Alzheimer's disease generally discuss the *same topics* and in the *same contexts*, although those with AD give more spurious descriptions, as exemplified by the irrelevant topic cluster D7 (Table 3).

Using a fully automated topic generation and feature extraction pipeline, we found a small set of features which perform as well as a large set of manually constructed hsICUs in binary classification experiments, achieving an F-score of 0.80 in 10-fold cross-validation on DementiaBank. The features which correlate most highly with class include: idea efficiency (Pearson's $r = -0.41$), which means that healthy individuals discuss more topics per unit time; distance from cluster C4 ($r = 0.34$), which indicates that speakers with AD focus less on the topic of the *three-legged stool*; and idea density ($r = -0.26$), which shows that healthy speakers need fewer words to express the same number of topics.

While we anticipated that combining a large normative corpus with local context windows from a clinical corpus would produce optimal vectors, using the former exclusively actually performs better. This phenomenon is being investigated. This implies that word-vector representations do not *need* to be adapted with context windows in specific clinical data in order to be effective.

A limitation of the current work is its requirement of high-quality transcriptions of speech, since high word-error rates (WERs) could compromise semantic information. We are therefore generating automatic transcriptions of the DementiaBank audio using the Kaldi speech recognition toolkit[6]. So far, a triphone model with the standard insertion penalty (0) and language model scale (20) on DementiaBank gives the best average WER of $36.7 \pm 3.6\%$ with 10-fold cross-validation. Continued optimization is the subject of ongoing research but preliminary experiments with these transcriptions indicate significantly lower perfor-

[6] http://kaldi.sourceforge.net/

mance of the baseline model (0.68 F-score; $t(9) = 3.52$, $p < 0.01$). While the eventual aim is a completely automatic system, our methodology overcomes several major challenges in the manual semantic annotation of clinical images for cognitive assessment, even with manual transcriptions. Specifically, our methodology is fully objective, sensitive to differences between groups, and generalizable to new stimuli which is especially important if longitudinal analysis is to avoid the so-called 'practice effect' by using multiple stimuli.

Across many domains, to extract useful semantic features (such as idea density and idea efficiency), one needs to first identify information content units in speech or text. Our method can be applied to any picture or contentful stimuli, given a sufficient amount of normative data, with no modification. Although we apply this generalizable method to a single (albeit important) image used in clinical practice in this work, we note that we obtain better accuracies with this completely automated method than a completely manual alternative.

Acknowledgments

The authors would like to thank Selvana Morcos, a speech language pathologist at the Toronto Rehabilitation Institute, for her generous help with providing professional annotations of information content units for the BDAE *Cookie Theft* picture.

Abstract

Part of the unique cultural heritage of China is the Chinese couplet. Given a sentence (namely an *antecedent clause*), people reply with another sentence (namely a *subsequent clause*) equal in length. Moreover, a special phenomenon is that corresponding characters from the same position in the two clauses match each other by following certain constraints on semantic and/or syntactic relatedness. Automatic couplet generation by computer is viewed as a difficult problem and has not been fully explored. In this paper, we formulate the task as a natural language generation problem using neural network structures. Given the issued antecedent clause, the system generates the subsequent clause via sequential language modeling. To satisfy special characteristics of couplets, we incorporate the attention mechanism and polishing schema into the encoding-decoding process. The couplet is generated incrementally and iteratively. A comprehensive evaluation, using perplexity and BLEU measurements as well as human judgments, has demonstrated the effectiveness of our proposed approach.

1 Introduction

Chinese antithetical couplets, (namely "对联"), form a special type of poetry composed of two clauses (i.e., sentences). The popularity of the game of Chinese couplet challenge manifests itself in many aspects of people's life, e.g., as a means of expressing personal emotion, political views, or communicating messages at festive occasions. Hence, Chinese couplets are considered an important cultural heritage. A couplet is often written in calligraphy on red banners during special occasions such as wedding ceremonies and the Chinese New Year. People also use couplets to celebrate birthdays, mark the openings of a business, and commemorate historical events. We illustrate a real couplet for Chinese New Year celebration in Figure 1, and translate the couplet into English character-by-character.

Usually in the couplet generation game, one person challenges the other person with a sentence (namely an *antecedent clause*). The other person then replies with another sentence (namely a *subsequent clause*) equal in length and term segmentation, in a way that corresponding characters from the same position in the two clauses match each other by obeying certain constraints on semantic and/or syntactic relatedness. We also illustrate the special phenomenon of Chinese couplet in Figure 1: "one" is paired with "two", "term" is associated with "character", "hundred" is mapped into "thousand", and "happiness" is coupled with "treasures". As opposed to free languages, couplets have unique poetic elegance, e.g., aestheticism and conciseness etc. Filling in the couplet is considered as a challenging task with a set of structural and semantic requirements. Only few best scholars are able to master the skill to manipulate and to organize terms.

The Chinese couplet generation given the antecedent clause can be viewed as a big challenge in the joint area of Artificial Intelligence and Natural Language Processing. With the fast development of computing techniques, we realize that computers might play an important role in helping people to create couplets: 1) it is rather convenient for computers to sort out appropriate term combinations from a large corpus, and 2) computer programs can take great advantages to recognize, to learn, and even to remember patterns or rules given the corpus. Although computers are no sub-

Berlin, Germany, August 7-12, 2016.

Figure 1: An example of a Chinese couplet for Chinese New Year. We mark the character-wise translation under each Chinese character of the couplet so as to illustrate that each character from the same position of the two clauses has the constraint of certain relatedness. Overall, the couplet can be translated as: the term of "peaceful and lucky" (i.e., 和顺) indicates countless happiness; the two characters "safe and sound" (a.k.a., 平 and 安) worth innumerable treasures.

stitute for human creativity, they can process very large text repositories of couplets. Furthermore, it is relatively straightforward for the machine to check whether a generated couplet conforms to constraint requirements. The above observations motivate automatic couplet generation using computational intelligence. Beyond the long-term goal of building an autonomous intelligent system capable of creating meaningful couplets eventually, there are potential short-term applications for augmented human expertise/experience to create couplets for entertainment or educational purposes.

To design the automatic couplet generator, we first need to empirically study the generation criteria. We discuss some of the general generation standards here. For example, the couplet generally have rigid formats with the same length for both clauses. Such a syntactic constraint is strict: both clauses have exactly the same length while the length is measured in Chinese characters. Each character from the same position of the two clauses have certain constraints. This constraint is less strict. Since Chinese language is flexible sometimes, synonyms and antonyms both indicate semantic relatedness. Also, semantic coherence is a critical feature in couplets. A well-written couplet is supposed to be semantically coherent among both clauses.

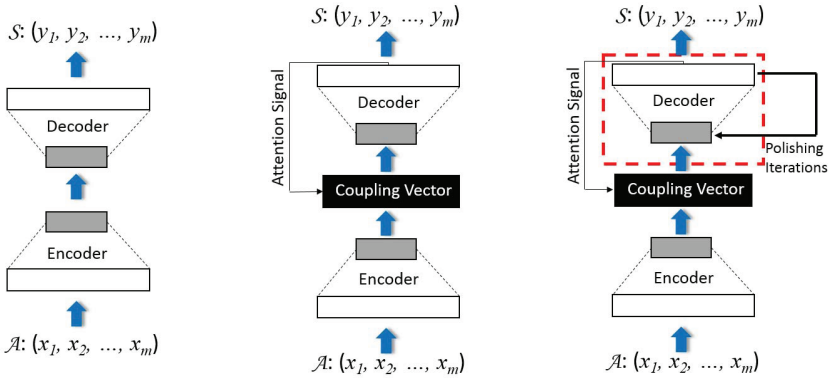
In this paper we are concerned with automatic couplet generation. We propose a neural couplet machine (NCM) based on neural network structures. Given a large collection of texts, we learn representations of individual characters, and their combinations within clauses as well as how they mutually reinforce and constrain each other. Given any specified antecedent clause, the system could generate a subsequent clause via sequential language modeling using encoding and decoding. To satisfy special characteristics of couplets, we incorporate the attention mechanism and polishing schema into the generation process. The couplet is generated incrementally and iteratively to refine wordings. Unlike the single-pass generation process, the hidden representations of the draft subsequent clause will be fed into the neural network structure to *polish* the next version of clause in our proposed system. In contrast to previous approaches, our generator makes utilizations of neighboring characters within the clause through an iterative polishing schema, which is novel.

To sum up, our contributions are as follows. For the first time, we propose a series of neural network-based couplet generation models. We formulate a new system framework to take in the antecedent clauses and to output the subsequent clauses in the couplet pairs. We tackle the special characteristics of couplets, such as corresponding characters paired in the two clauses, by incorporating the attention mechanism into the generation process. For the 1st time, we propose a novel polishing schema to iteratively refine the generated couplet using local pattern of neighboring characters. The draft subsequent clause from the last iteration will be used as additional information to generate a revised version of the subsequent clause.

The rest of the paper is organized as follows. In Section 2, we briefly summarize related work of couplet generation. Then Sections 3 and 4 show the overview of our approach paradigm and then detail the neural models. The experimental results and evaluation are reported in Section 5 and we draw conclusions Section 6.

2 Related Work

There are very few studies focused on Chinese couplet generation, based on templates (Zhang and Sun, 2009) or statistic translations (Jiang and Zhou, 2008). The Chinese couplet generation task can be viewed as a reduced form of 2-sentence poem generation (Jiang and Zhou, 2008). Given the first line of the poem, the generator ought to generate the second line accordingly, which is a similar process as couplet generation. We consider automatic Chinese poetry generation to be a closely re-



(a). Sequential couplet generation. (b). Couplet generation with attention (c). Couplet generation with polishing schema.

Figure 2: Three neural models for couplet generation. More details will be introduced in Section 4.

lated research area. Note that there are still some differences between couplet generation and poetry generation. The task of generating the subsequent clause to match the given antecedent clause is more well-defined than generating all sentences of a poem. Moreover, not all of the sentences in the poems need to follow couplet constraints.

There are some formal researches into the area of computer-assisted poetry generation. Scientists from different countries have studied the automatic poem composition in their own languages through different ways: 1) Genetic Algorithms. Manurung *et al.* (2004; 2011) propose to create poetic texts in English based on state search; 2) Statistical Machine Translation (SMT). Greene *et al.* (2010) propose a translation model to generation cross-lingual poetry, from Italian to English; 3) Rule-based Templates. Oliveira (2009; 2012) has proposed a system of poem generation platform based on semantic and grammar templates in Spanish. An interactive system has been proposed to reproduce the traditional Japanese poem named *Haiku* based on rule-based phrase search related to user queries (Tosa et al., 2008; Wu et al., 2009). Netzer *et al.* (2009) propose another way of Haiku generation using word association rules.

As to computer-assisted Chinese poetry generation. There are now several Chinese poetry generators available. The system named *Daoxiang*[1] basically relies on manual pattern selection. The system maintains a list of manually created terms related to pre-defined keywords, and inserts terms *randomly* into the selected template as a poem. The system is simple but random term selection leads to unnatural sentences.

[1] http://www.poeming.com/web/index.htm

Zhou *et al.* (2010) use a genetic algorithm for Chinese poetry generation by tonal codings and state search. He *et al.* (2012) extend the couplet machine translation paradigm (Jiang and Zhou, 2008) from a 2-line couplet to a 4-line poem by giving previous sentences sequentially, considering structural templates. Yan *et al.* (2013; 2016) proposed a summarization framework to generate poems. Recently, along with the prosperity of neural networks, a recurrent neural network based language generation is proposed (Zhang and Lapata, 2014): the generation is more or less a translation process. Given previous sentences, the system generates the next sentence of the poem.

We also briefly introduce deep neural networks, which contribute great improvements in NLP. A series of neural models are proposed, such as convolutional neural networks (CNN) (Kalchbrenner et al., 2014) and recurrent neural networks (RNN) (Mikolov et al., 2010) with or without gated recurrent units (GRU) (Cho et al., 2014) and long-short term memory (LSTM) units (Hochreiter and Schmidhuber, 1997). We conduct a pilot study to design neural network structures for couplet generation problems. For the first time, we propose a polishing schema for the couplet generation process, and combine it with the attention mechanism to satisfy the couplet constraints, which is novel.

3 Overview

The basic idea of the Chinese couplet generation is to build a hidden representation of the antecedent clause, and then generate the subsequent clause accordingly, shown in Figure 2. In this way, our system works in an encoding-decoding manner. The units of couplet generation are characters.

Problem formulation. We define the following

formulations:

• *Input.* Given the antecedent clause $\mathcal{A} = \{x_1, x_2, \ldots, x_m\}$, $x_i \in \mathcal{V}$, where x_i is a character and $\mathcal{V}$ is the vocabulary, we then learn an abstractive representation of the antecedent clause $\mathcal{A}$.

• *Output.* We generate a subsequent clause $\mathcal{S} = \{y_1, y_2, \ldots, y_m\}$ according to $\mathcal{A}$, which indicates semantic coherence. We have $y_i \in \mathcal{V}$. To be more specific, each character y_i in $\mathcal{S}$ is coordinated with the corresponding character x_i in $\mathcal{A}$, which is determined by the couplet constraint.

As mentioned, we encode the input clause as a hidden vector, and then decode the vector into an output clause so that the two clauses are actually a pair of couplets. Since we have special characteristics for couplet generation, we propose different neural models for different concerns. The proposed models are extended incrementally so that the final model would be able to tackle complicated issues for couplet generation. We first introduce these neural models from a high level description, and then elaborate them in more details.

Sequential Couplet Generation. The model accepts the input clause. We use a recurrent neural network (RNN) over characters to capture the meaning of the clause. Thus we obtain a single vector which represents the antecedent clause. We then use another RNN to decode the input vector into the subsequent clause by the character-wise generation. Basically, the process is a sequence-to-sequence generation via encoding and decoding, which is based on the global level of the clause. We show the diagram of sequential couplet generation in Figure 2(a).

Couplet Generation with Attention. There is a special phenomenon within a pair of couplets: the characters from the same position in the antecedent clause and subsequent clause, i.e., x_i and y_i, generally have some sort of relationships such as "coupling" or "pairing". Hence we ought to model such one-to-one correlation between x_i and y_i in the neural model for couplet generation. Recently, the attention mechanism is proposed to allow the decoder to dynamically select and linearly combine different parts of the input sequence with different weights. Basically, the attention mechanism models the alignment between positions between inputs and outputs, so it can be viewed as a local matching model. Moreover, the tonal coding issue can also be addressed by the pairwise attention mechanism. The extension of attention mechanism to the sequential couplet generation model is shown in Figure 2(b).

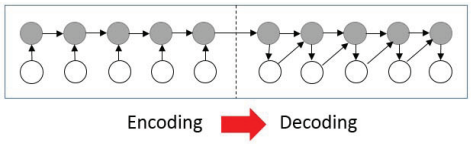


Figure 3: Couplet generation via sequential language modeling: plain neural couplet machine.

Polishing Schema for Generation. Couplet generation is a form of art, and art usually requires polishing. Unlike the traditional single-pass generation in previous neural models, our proposed couplet generator will be able to polish the generated couplets for one or more iterations to refine the wordings. The model is essentially the same as the sequential generation with attention except that the information representation of the previous generated clause draft will be again utilized as an input, serving as *additional* information for semantic coherence. The principle is illustrated in Figure 2(c): the generated draft from the previous iteration will be incorporated into the hidden state which generates the polished couplet pair in the next iteration.

To sum up, we introduce three neural models for Chinese couplet generation. Each revised model targets at tackling an issue for couplet generation so that the system could try to imitate a human couplet generator. We further elaborate these neural models incrementally in details in Section 4.

4 Neural Generation Models

4.1 Sequential Couplet Generation

The sequential couplet generation model is basically a sequence-to-sequence generation fashion (Sutskever et al., 2014) using encoding and decoding shown in Figure 3. We use a recurrent neural network (RNN) to iteratively pick up information over the character sequence $x_1, x_2, \ldots, x_m$ of the input antecedent clause $\mathcal{A}$. All characters are vectorized using their embeddings (Mikolov et al., 2013). For each character, the RNN allocates a hidden state $\boldsymbol{s_i}$, which is dependent on the current character's embedding $\boldsymbol{x}_i$ and the previous state $\boldsymbol{s}_{i-1}$. Since usually each clause in the couplet pair would not be quite long, it is sufficient to use a vanilla RNN with basic interactions.

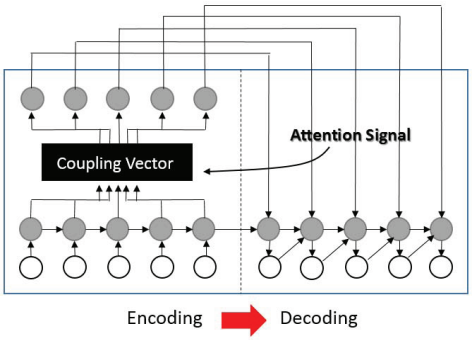

Figure 4: Couplet generation with attention mechanism, namely attention neural couplet machine. Attention signal is generated by both encoder and decoder, and then fed into the coupling vector. Calculation details are elaborated in Section 4.2.

The equation for encoding is as follows:

$$\boldsymbol{s}_i = f(W_h \boldsymbol{s}_{i-1} + W_x \boldsymbol{x}_i + b) \quad (1)$$

$\boldsymbol{x}$ is the vector representation (i.e., embedding) of the character. W and b are parameters for weights and bias. $f(\cdot)$ is the non-linear activation function and we use ReLU (Nair and Hinton, 2010) in this paper. As for the hidden state $\boldsymbol{h}_i$ in the decoding RNN, we have:

$$\boldsymbol{h}_i = f(W_x \boldsymbol{x}_{i-1} + W_h \boldsymbol{h}_{i-1}) \quad (2)$$

4.2 Couplet Generation with Attention

As mentioned, there is special phenomenon in the couplet pair that the characters from the same position in the antecedent clause and the subsequent clause comply with certain relatedness, so that two clauses may, to some extent, look "symmetric".

Hence we introduce the attention mechanism into the couplet generation model. The attention mechanism coordinates, either statically or dynamically, different positions of the input sequence (Shang et al., 2015). To this end, we introduce a hidden coupling vector $\boldsymbol{c}_i = \sum_{j=1}^{m} \alpha_{ij} \boldsymbol{s}_j$. The coupling vectors linearly combine all parts from the antecedent clause, and determine which part should be utilized to generate the characters in the subsequent clause. The attention signal α_{ij} can be calculated as $\alpha_{ij} = \sigma_{att}(\boldsymbol{s}_j, \boldsymbol{h}_{i-1})$ after a softmax function. The score is based on how well the inputs from position j and the output at position i match. $\sigma_{att}(\cdot)$ is parametrized as a neural network which is jointly trained with all the other components (Bahdanau et al., 2015; Hermann et al., 2015). This mechanism enjoys the advantage of adaptively focusing on the corresponding characters of the input text according to the generated characters in the subsequent clause. The mechanism is pictorially shown in Figure 4.

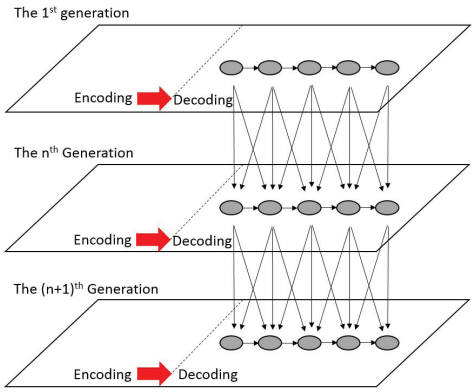

Figure 5: Couplet generation with the polishing schema, i.e., full neural couplet machine. Note that for conciseness, we only show the gist of this schema across polishing iterations. The shaded circles are the hidden vectors to generate characters in the subsequent clause. We omit the duplicated sequential and attention dependencies within each iteration as we have shown in Figures 3 & 4.

With the coupling vectors generated, we have the following equation for the decoding process with attention mechanism:

$$\boldsymbol{h}_i = f(W_x \boldsymbol{x}_{i-1} + W_h \boldsymbol{h}_{i-1} + W_c \boldsymbol{c}_i) \quad (3)$$

4.3 Polishing Schema for Generation

Inspired by the observation that a human couplet generator might recompose the clause for several times, we propose a polishing schema for the couplet generation. Specifically, after a single-pass generation, the couplet generator itself shall be aware of the generated clause as a *draft*, so that polishing each and every character of the clause becomes possible.

We hereby propose a convolutionary neural network (CNN) based polishing schema shown in Figure 5. The intuition for convolutionary structure is that this polishing schema guarantees better coherence: with the batch of neighboring characters, the couplet generator knows which character to generate during the revision process.

A convolutional neural network applies a fixed-size window to extract local (neighboring) patterns of successive characters. Suppose the window is of size t, the detected features at a certain position

$x_i, \cdots, x_{i+t-1}$ is given by

$$\boldsymbol{o}_i^{(n)} = f(W[\boldsymbol{h}_i^{(n)}; \cdots; \boldsymbol{h}_{i+t-1}^{(n)}] + \boldsymbol{b}) \quad (4)$$

Here $\boldsymbol{h}^{(n)}$ with the superscript n is the hidden vector representation from the n-th iteration. W and $\boldsymbol{b}$ are parameters for convolution. Semicolons refer to column vector concatenation. Also, $f(\cdot)$ is the non-linear activation function and we use ReLU (Nair and Hinton, 2010) as well. Note that we pad zero at the end of the term if a character does not have enough following characters to fill the slots in the convolution window. In this way, we obtain a set of detected features. Then a max-pooling layer aggregates information over different characters into a fixed-size vector.

Now the couplet generation with both attention mechanism and polishing schema becomes:

$$\begin{aligned}\boldsymbol{h}_i^{(n+1)} = f(&W_x \boldsymbol{x}_{i-1} + W_h \boldsymbol{h}_{i-1}^{(n+1)} \\ &+ W_c \boldsymbol{c}_i^{(n+1)} + W_o \boldsymbol{o}_i^{(n)})\end{aligned} \quad (5)$$

Note that in this way ,we feed the information from the n-th generation iteration into the (n+1)-th polishing iteration. For the iterations, we have the stopping criteria as follows.

• After each iteration process, we have the subsequent clause generated; we encode the clause as $\boldsymbol{h}$ using the RNN encoder using the calculation shown in Equation (1). We stop the algorithm iteration when the cosine similarity between the two $\boldsymbol{h}^{(n+1)}$ and $\boldsymbol{h}^{(n)}$ from two successive iterations exceeds a threshold Δ (Δ = 0.5 in this study).

• Ideally, we shall let the algorithm converge by itself. There will always be some long-tail cases. To be practical, it is necessary to apply a termination schedule when the generator polishes for many times. We stop the couplet generator after a fixed number of recomposition. Here we empirically set the threshold as 5 times of polishing, which means 6 iterations in all.

5 Experiments and Evaluations

5.1 Experimental Setups

Datasets. A large Chinese couplet corpus is necessary to learn the model for couplet generation. There is, however, no large-sized pure couplet collection available (Jiang and Zhou, 2008). As mentioned, generally people regard Chinese couplets as a reduced form of Chinese poetry and there are several large Chinese poem datasets publicly available, such as *Poems of Tang Dynasty* (i.e., Tang Poem) and *Poems of Song Dynasty* (i.e., Song Poem). It becomes a widely acceptable approximation to mine couplets out of existing poems, even though poems are not specifically intended for couplets[2] (Jiang and Zhou, 2008; Yan et al., 2013; He et al., 2012). We are able to mine such sentence pairs out of the poems and filtering those do not conform to couplet constraints, which is a similar process mentioned in (Jiang and Zhou, 2008). Moreover, we also crawl couplets from *couplet forums* where couplet fans discuss, practice and show couplet works. We performed standard Chinese segmentation into characters.

Table 1: Detailed information of the datasets. Each pair of couplets consist of two clauses.

	#Pairs	#Character
TANG Poem	26,833	6,358
SONG Poem	11,324	3,629
Couplet Forum	46,959	8,826

In all, we collect 85,116 couplets. We randomly choose 2,000 couplets for validation and 1,000 couplets for testing, other non-overlap ones for training. The details are shown in Table 1.

Hyperparameters and Setups. Word embeddings (Mikolov et al., 2013) are a standard apparatus in neural network-based text processing. A word is mapped to a low dimensional, real-valued vector. This process, known as vectorization, captures some underlying meanings. Given enough data, usage, and context, word embeddings can make highly accurate guesses about the meaning of a particular word. Embeddings can equivalently be viewed that a word is first represented as a one-hot vector and multiplied by a look-up table (Mikolov et al., 2013). In our model, we first vectorize all words using their embeddings. Here we used 128-dimensional word embeddings through vectorization, and they were initialized randomly and learned during training. We set the width of convolution filters as 3. The above parameters were chosen empirically.

Training. The objective for training is the cross entropy errors of the predicted character distribution and the actual character distribution in our

[2]For instance, in the 4-sentence poetry (namely *quatrain*, i.e., 绝句 in Chinese), the 3rd and 4th sentences are usually paired; in the 8-sentence poetry (namely *regulated verse*, i.e., 律诗 in Chinese), the 3rd-4th and 5th-6th sentences are generally form pairs which satisfy couplet constraints.

corpus. An ℓ_2 regularization term is also added to the objective. The model is trained with back propagation through time with the length being the time step. The objective is minimized by stochastic gradient descent with shuffled mini-batches (with a mini-batch size of 100) for optimization. During training, the cross entropy error of the output is back-propagated through all hidden layers. Initial learning rate was set to 0.8, and a multiplicative learning rate decay was applied. We used the validation set for early stopping. In practice, the training converges after a few epochs.

5.2 Evaluation Metrics

It is generally difficult to judge the effect of couplets generated by computers. We propose to evaluate results from 3 different evaluation metrics.

Perplexity. For most of the language generation research, language perplexity is a sanity check. Our first set of experiments involved intrinsic evaluation of the "perplexity" evaluation for the generated couplets. Perplexity is actually an entropy based evaluation. In this sense, the lower perplexity for the couplets generated, the better performance in purity for the generations, and the couplets are likely to be good. m denotes the length.

$$\text{pow}\left[2, -\frac{1}{m}\sum_{i=1}^{m}\log p(y_i)\right]$$

BLEU. The Bilingual Evaluation Understudy (BLEU) score-based evaluation is usually used for machine translation (Papineni et al., 2002): given the reference translation(s), the algorithm evaluates the quality of text which has been machine-translated from the reference translation as ground truth. We adapt the BLEU evaluation under the couplet generation scenario. Take a couplet from the dataset, we generate the computer authored subsequent clause given the antecedent clause, and compare it with the original subsequent clause written by humans. There is a concern for such an evaluation metric is that BLEU score can only reflect the partial capability of the models; there is (for most cases) only one ground truth for the generated couplet but actually there are more than one appropriate ways to generate a well-written couplet. The merit of BLEU evaluation is to examine how likely to approximate the computer generated couplet towards human authored ones.

Human Evaluation. We also include human judgments from 13 evaluators who are graduate students majoring in Chinese literature. Evaluators are requested to express an opinion over the automatically generated couplets. A clear criterion is necessary for human evaluation. We use the evaluation standards discussed in (Wang, 2002; Jiang and Zhou, 2008; He et al., 2012; Yan et al., 2013; Zhang and Lapata, 2014): "syntactic" and "semantic" satisfaction. For the syntactic side, evaluators consider whether the subsequent clauses conform the length restriction and word pairing between the two clauses. For a higher level of semantic side, evaluators then consider whether the two clauses are semantically meaningful and coherent. Evaluators assign 0-1 scores for both syntactic and semantic criteria ('0'-no, '1'- yes). The evaluation process is conducted as a blind-review[3]

5.3 Algorithms for Comparisons

We implemented several generation methods as baselines. For fairness, we conduct the same pre-generation process to all algorithms.

Standard SMT. We adapt the standard phrase-based statistical machine translation method (Koehn et al., 2003) for the couplet task, which regards the antecedent clause as the source language and the subsequent clause as the target language.

Couplet SMT. Based on SMT techniques, a phrase-based SMT system for Chinese couplet generation is proposed in (Jiang and Zhou, 2008), which incorporates extensive couplet-specific character filtering and re-rankings.

LSTM-RNN. We also include a sequence-to-sequence LSTM-RNN (Sutskever et al., 2014). LSTM-RNN is basically a RNN using the LSTM units, which consists of memory cells in order to store information for extended periods of time. For generation, we first use an LSTM-RNN to encode the given antecedent sequence to a vector space, and then use another LSTM-RNN to decode the vector into the output sequence.

Since Chinese couplet generation can be viewed as a reduced form of Chinese poetry generation, we also include some approaches designed for poetry generation as baselines.

iPoet. Given the antecedent clause, the *iPoet* method first retrieves relevant couplets from the

[3]We understand that acceptability is a gradable concept, especially for the less subjective tasks. Here from our experience, to grade the "yes"-"no" acceptability is more feasible for the human evaluators to judge (with good agreement). As to couplet evaluation, it might be more difficult for the evaluators to say "very acceptable" or "less acceptable". We will try to make scale-based evaluation as the future work.

Table 2: Overall performance comparison against baselines.

Algorithm	Perplexity	BLEU	Human Evaluation		
			Syntactic	Semantic	Overall
Standard SMT (Koehn et al., 2003)	128	21.68	0.563	0.248	0.811
Couplet SMT (Jiang and Zhou, 2008)	97	28.71	0.916	0.503	1.419
LSTM-RNN (Sutskever et al., 2014)	85	24.23	0.648	0.233	0.881
iPoet (Yan et al., 2013)	143	13.77	0.228	0.435	0.663
Poetry SMT (He et al., 2012)	121	23.11	0.802	0.516	1.318
RNNPG (Zhang and Lapata, 2014)	99	25.83	0.853	0.600	1.453
Neural Couplet Machine (NCM)	**68**	**32.62**	**0.925**	**0.631**	**1.556**

corpus, and then summarizes the retrieved couplets into a single clause based on a generative summarization framework (Yan et al., 2013).

Poetry SMT. He et al. (2012) extend the couplet SMT method into a poetry-oriented SMT approach, with different focus and different filtering for different applications from Couplet SMT.

RNNPG. The RNN-based poem generator (RNNPG) is proposed to generate a poem (Zhang and Lapata, 2014), and we adapt it into the couplet generation scenario. Given the antecedent clause, the subsequent clause is generated through the standard RNN process with contextual convolutions of the given antecedent clause.

Neural Couplet Machine (NCM). We propose the neural generation model particularly for couplets. Basically we have the RNN based encoding-decoding process with attention mechanism and polishing schema. We demonstrate with the best performance of all NCM variants proposed here.

5.4 Performance

In Table 2 we show the overall performance of our proposed NCM system compared with strong competing methods as described above. We see that, for perplexity, BLEU and human judgments, our system outperforms other baseline models.

The standard SMT method manipulates characters according to the dataset by standard translation but ignores all couplet characteristics in the model. The Couplet SMT especially established for couplet generation performs much better than the general SMT method since it incorporates several filtering with couplet constraints. As a strongly competitive baseline of the neural model LSTM-RNN, the perplexity performance gets boosted in the generation process, which indicates that neural models show strong ability for language generation. However, there is a major drawback that LSTM-RNN does not explicitly model the couplet constraints such as length restrictions and so on for couplet pairs. LSTM-RNN is not really a couplet-driven generation method and might not capture the corresponding patterns between the antecedent clause and subsequent clause well enough to get a high BLEU score.

For the group of algorithms originally proposed for poetry generation, we have summarization-based poetry method *iPoet*, translation-based poetry method *Poetry SMT* and a neural network based method *RNNPG*. In general, the summarization based poetry method iPoet does not perform well in either perplexity or BLEU evaluation: summarization is not an intuitive way to model and capture the pairwise relationship between the antecedent and subsequent clause within the couplet pair. Poetry SMT performs better, indicating the translation-based solution makes more sense for couplet generation than summarization methods. RNNPG is a strong baseline which applies both neural network structures, while the insufficiency lies in the lack of couplet-oriented constraints during the generation process. Note that all poetry-oriented methods show worse performance than the couplet SMT method, indicating that couplet constraints should be specially addressed.

We hence introduce the neural couplet machine based on neural network structures specially designed for couplet generation. We incorporate attention mechanism and polishing schema into the generation process. The attention mechanism strengthens the coupling characteristics between the antecedent and subsequent clause and the polishing schema enables the system to revise and refine the generated couplets, which leads to better performance in experimental evaluations.

For evaluations, the perplexity scores and BLEU scores show some consistency. Besides, we

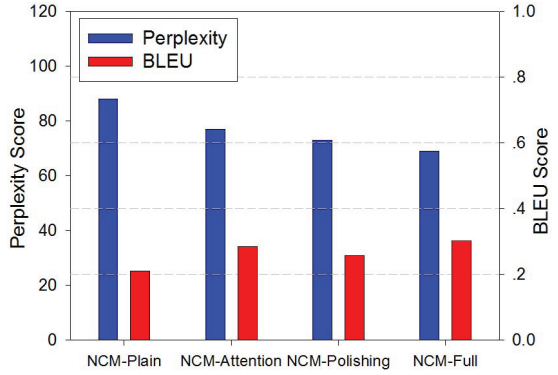

Figure 6: Performance comparison of all variants in the neural couplet machine family.

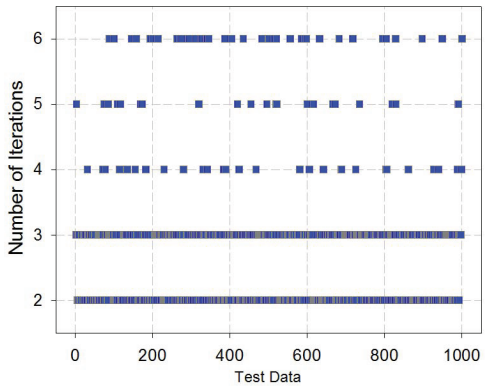

Figure 7: The distribution of stopping iteration counts for all test data. Note that 6 iterations of generation means 5 times of polishing.

observe that the BLEU scores are quite low for almost all methods. It is not surprising that these methods are not likely to generate the exactly same couplets as the ground truth, since that is not how the objective function works. BLEU can only partially calibrate the capability of couplet generation because there are many ways to create couplets which do not look like the ground truth but also make sense to people. Although quite subjective, the *human evaluations* in Table 2 can to some extent show the potentials of all couplet generators.

5.5 Analysis and Discussions

There are two special strategies in the proposed neural model for couplet generation: 1) attention mechanism and 2) polishing schema. We hence analyze the separate contributions of the two components in all the neural couplet machine variants. We have the *NCM-Plain* model with no attention or polishing strategy. We incrementally add the attention mechanism as *NCM-Attention*, and then add the polishing schema as *NCM-Full*. The three NCM variants correspond to the three models proposed in this paper. Besides, for a complete comparison, we also include the plain NCM integrated with polishing schema but without attention mechanism, namely *NCM-Polishing*.

The results are shown in Figure 6. We can see that NCM-Plain shows the weakest performance, with no strategy tailored for couplet generation. An interesting phenomenon is that *NCM-Attention* has better performance in BLEU score while *NCM-Polishing* performs better in terms of perplexity. We conclude that attention mechanism captures the pairing patterns between the two clauses, and the polishing schema enables better wordings of semantic coherence in the couplet after several revisions. The two strategies address different concerns for couplet generation, hence *NCM-Full* performs best.

We also take a closer look at the polishing schema proposed in this paper, which enables a multi-pass generation. The couplet generator can generate a subsequent clause utilizing additional information from the generated subsequent clause from the last iteration. It is a novel insight against previous methods. The effect and benefits of the polishing schema is demonstrated in Figure 6. We also examine the stopping criteria, shown in Figure 7. In general, most of the polishing process stops after 2-3 iterations.

6 Conclusions

The Chinese couplet generation is a difficult task in the field of natural language generation. We propose a novel neural couplet machine to tackle this problem based on neural network structures. Given an antecedent clause, we generate a subsequent clause to create a couplet pair using a sequential generation process. The two innovative insights are that 1) we adapt the attention mechanism for the couplet coupling constraint, and 2) we propose a novel polishing schema to refine the generated couplets using additional information.

We compare our approach with several baselines. We apply perplexity and BLEU to evaluate the performance of couplet generation as well as human judgments. We demonstrate that the neural couplet machine can generate rather good couplets and outperform baselines. Besides, both attention mechanism and polishing schema contribute to the better performance of the proposed approach.

A Thorough Examination of the CNN/Daily Mail Reading Comprehension Task

Danqi Chen and **Jason Bolton** and **Christopher D. Manning**
Computer Science Stanford University

Abstract

Enabling a computer to understand a document so that it can answer comprehension questions is a central, yet unsolved goal of NLP. A key factor impeding its solution by machine learned systems is the limited availability of human-annotated data. Hermann et al. (2015) seek to solve this problem by creating over a million training examples by pairing *CNN* and *Daily Mail* news articles with their summarized bullet points, and show that a neural network can then be trained to give good performance on this task. In this paper, we conduct a thorough examination of this new reading comprehension task. Our primary aim is to understand what depth of language understanding is required to do well on this task. We approach this from one side by doing a careful hand-analysis of a small subset of the problems and from the other by showing that simple, carefully designed systems can obtain accuracies of 72.4% and 75.8% on these two datasets, exceeding current state-of-the-art results by over 5% and approaching what we believe is the ceiling for performance on this task.[1]

1 Introduction

Reading comprehension (RC) is the ability to read text, process it, and understand its meaning.[2] How to endow computers with this capacity has been an elusive challenge and a long-standing goal of Artificial Intelligence (e.g., (Norvig, 1978)). Genuine reading comprehension involves interpretation of the text and making complex inferences. Human reading comprehension is often tested by asking questions that require interpretive understanding of a passage, and the same approach has been suggested for testing computers (Burges, 2013).

In recent years, there have been several strands of work which attempt to collect human-labeled data for this task – in the form of document, question and answer triples – and to learn machine learning models directly from it (Richardson et al., 2013; Berant et al., 2014; Wang et al., 2015). However, these datasets consist of only hundreds of documents, as the labeled examples usually require considerable expertise and neat design, making the annotation process quite expensive. The subsequent scarcity of labeled examples prevents us from training powerful statistical models, such as deep learning models, and would seem to prevent a system from learning complex textual reasoning capacities.

Recently, researchers at *DeepMind* (Hermann et al., 2015) had the appealing, original idea of exploiting the fact that the abundant news articles of *CNN* and *Daily Mail* are accompanied by bullet point summaries in order to heuristically create large-scale supervised training data for the reading comprehension task. Figure 1 gives an example. Their idea is that a bullet point usually summarizes one or several aspects of the article. If the computer understands the content of the article, it should be able to infer the missing entity in the bullet point.

This is a clever way of creating supervised data cheaply and holds promise for making progress on training RC models; however, it is unclear what level of reading comprehension is actually needed to solve this somewhat artificial task and, indeed, what statistical models that do reasonably well on this task have actually learned.

In this paper, our aim is to provide an in-depth and thoughtful analysis of this dataset and what level of natural language understanding is needed to

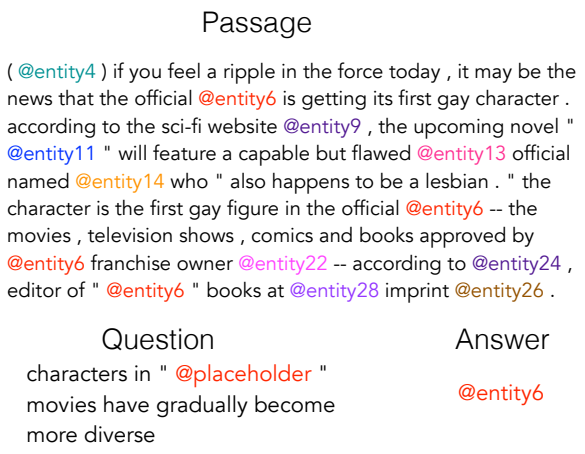

Figure 1: An example item from dataset *CNN*.

do well on it. We demonstrate that simple, carefully designed systems can obtain high, state-of-the-art accuracies of 72.4% and 75.8% on *CNN* and *Daily Mail* respectively. We do a careful hand-analysis of a small subset of the problems to provide data on their difficulty and what kinds of language understanding are needed to be successful and we try to diagnose what is learned by the systems that we have built. We conclude that: (i) this dataset is easier than previously realized, (ii) straightforward, conventional NLP systems can do much better on it than previously suggested, (iii) the distributed representations of deep learning systems are very effective at recognizing paraphrases, (iv) partly because of the nature of the questions, current systems much more have the nature of single-sentence relation extraction systems than larger-discourse-context text understanding systems, (v) the systems that we present here are close to the ceiling of performance for single-sentence and unambiguous cases of this dataset, and (vi) the prospects for getting the final 20% of questions correct appear poor, since most of them involve issues in the data preparation which undermine the chances of answering the question (coreference errors or anonymization of entities making understanding too difficult).

2 The Reading Comprehension Task

The RC datasets introduced in (Hermann et al., 2015) are made from articles on the news websites *CNN* and *Daily Mail*, utilizing articles and their bullet point summaries.[3] Figure 1 demonstrates an example[4]: it consists of a passage p, a question q and an answer a, where the passage is a news article, the question is a cloze-style task, in which one of the article's bullet points has had one entity replaced by a placeholder, and the answer is this questioned entity. The goal is to infer the missing entity (answer a) from all the possible entities which appear in the passage. A news article is usually associated with a few (e.g., 3–5) bullet points and each of them highlights one aspect of its content.

The text has been run through a Google NLP pipeline. It it tokenized, lowercased, and named entity recognition and coreference resolution have been run. For each coreference chain containing at least one named entity, all items in the chain are replaced by an @entity$n$ marker, for a distinct index n. Hermann et al. (2015) argue convincingly that such a strategy is necessary to ensure that systems approach this task by understanding the passage in front of them, rather than by using world knowledge or a language model to answer questions without needing to understand the passage. However, this also gives the task a somewhat artificial character. On the one hand, systems are greatly helped by entity recognition and coreference having already been performed; on the other, they suffer when either of these modules fail, as they do (in Figure 1, "the character" should probably be coreferent with @entity14; clearer examples of failure appear later on in our data analysis). Moreover, this inability to use world knowledge also makes it much more difficult for a human to do this task – occasionally it is very difficult or impossible for a human to determine the correct answer when presented with an item anonymized in this way.

The creation of the datasets benefits from the sheer volume of news articles available online, so they offer a large and realistic testing ground for statistical models. Table 1 provides some statistics on the two datasets: there are 380k and 879k training examples for *CNN* and *Daily Mail* respectively. The passages are around 30 sentences and 800 tokens on average, while each question contains around 12–14 tokens.

In the following sections, we seek to more deeply understand the nature of this dataset. We first build some straightforward systems in order to get a better idea of a lower-bound for the performance of current NLP systems. Then we turn to data analysis of a

sample of the items to examine their nature and an upper bound on performance.

3 Our Systems

In this section, we describe two systems we implemented – a conventional entity-centric classifier and an end-to-end neural network. While Hermann et al. (2015) do provide several baselines for performance on the RC task, we suspect that their baselines are not that strong. They attempt to use a frame-semantic parser, and we feel that the poor coverage of that parser undermines the results, and is not representative of what a straightforward NLP system – based on standard approaches to factoid question answering and relation extraction developed over the last 15 years – can achieve. Indeed, their frame-semantic model is markedly inferior to another baseline they provide, a heuristic word distance model. At present just two papers are available presenting results on this RC task, both presenting neural network approaches: (Hermann et al., 2015) and (Hill et al., 2016). While the latter is wrapped in the language of end-to-end memory networks, it actually presents a fairly simple window-based neural network classifier running on the CNN data. Its success again raises questions about the true nature and complexity of the RC task provided by this dataset, which we seek to clarify by building a simple attention-based neural net classifier.

Given the (passage, question, answer) triple (p, q, a), $p = \{p_1, \ldots, p_m\}$ and $q = \{q_1, \ldots, q_l\}$ are sequences of tokens for the passage and question sentence, with q containing exactly one "@placeholder" token. The goal is to infer the correct entity $a \in p \cap E$ that the placeholder corresponds to, where E is the set of all abstract entity markers. Note that the correct answer entity must appear in the passage p.

3.1 Entity-Centric Classifier

We first build a conventional feature-based classifier, aiming to explore what features are effective for this task. This is similar in spirit to (Wang et al., 2015), which at present has very competitive performance on the MCTest RC dataset (Richardson et al., 2013). The setup of this system is to design a feature vector $f_{p,q}(e)$ for each candidate entity e, and to learn a weight vector θ such that the correct answer a is expected to rank higher than all other candidate entities:

$$\theta^\intercal f_{p,q}(a) > \theta^\intercal f_{p,q}(e), \forall e \in E \cap p \setminus \{a\} \quad (1)$$

We employ the following feature templates:

1. Whether entity e occurs in the passage.
2. Whether entity e occurs in the question.
3. The frequency of entity e in the passage.
4. The first position of occurence of entity e in the passage.
5. n-gram exact match: whether there is an exact match between the text surrounding the placeholder and the text surrounding entity e. We have features for all combinations of matching left and/or right one or two words.
6. Word distance: we align the placeholder with each occurrence of entity e, and compute the average minimum distance of each non-stop question word from the entity in the passage.
7. Sentence co-occurrence: whether entity e co-occurs with another entity or verb that appears in the question, in some sentence of the passage.
8. Dependency parse match: we dependency parse both the question and all the sentences in the passage, and extract an indicator feature of whether $w \xrightarrow{r}$ @placeholder and $w \xrightarrow{r} e$ are both found; similar features are constructed for @placeholder $\xrightarrow{r} w$ and $e \xrightarrow{r} w$.

3.2 End-to-end Neural Network

Our neural network system is based on the *Attentive-Reader* model proposed by (Hermann et al., 2015). The framework can be described in the following three steps (see Figure 2):

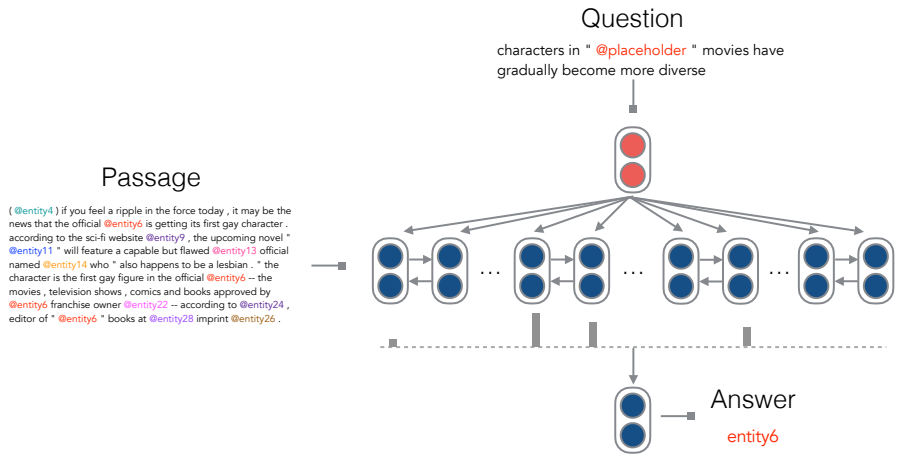

Figure 2: Our neural network architecture for the reading comprehension task.

Encoding: First, all the words are mapped to d-dimensional vectors via an embedding matrix $E \in \mathbb{R}^{d \times |\mathcal{V}|}$; therefore we have p: $\mathbf{p}_1, \ldots, \mathbf{p}_m \in R^d$ and $q : \mathbf{q}_1, \ldots, \mathbf{q}_l \in R^d$.

Next we use a shallow bi-directional LSTM with hidden size $\tilde{h}$ to encode contextual embeddings $\tilde{\mathbf{p}}_i$ of each word in the passage,

$$\overrightarrow{\mathbf{h}}_i = \text{LSTM}(\overrightarrow{\mathbf{h}}_{i-1}, \mathbf{p}_i), i = 1, \ldots, m$$
$$\overleftarrow{\mathbf{h}}_i = \text{LSTM}(\overleftarrow{\mathbf{h}}_{i+1}, \mathbf{p}_i), i = m, \ldots, 1$$

and $\tilde{\mathbf{p}}_i = \text{concat}(\overrightarrow{\mathbf{h}}_i, \overleftarrow{\mathbf{h}}_i) \in \mathbb{R}^h$, where $h = 2\tilde{h}$. Meanwhile, we use another bi-directional LSTM to map the question $\mathbf{q}_1, \ldots, \mathbf{q}_l$ to an embedding $\mathbf{q} \in \mathbb{R}^h$.

Attention: In this step, the goal is to compare the question embedding and all the contextual embeddings, and *select* the pieces of information that are relevant to the question. We compute a probability distribution α depending on the degree of relevance between word p_i (in its context) and the question q and then produce an output vector $\mathbf{o}$ which is a weighted combination of all contextual embeddings $\{\tilde{\mathbf{p}}_i\}$:

$$\alpha_i = \text{softmax}_i \, \mathbf{q}^\intercal \mathbf{W}_s \tilde{\mathbf{p}}_i \quad (2)$$
$$\mathbf{o} = \sum_i \alpha_i \tilde{\mathbf{p}}_i \quad (3)$$

$\mathbf{W_s} \in \mathbb{R}^{h \times h}$ is used in a bilinear term, which allows us to compute a similarity between $\mathbf{q}$ and $\tilde{\mathbf{p}}_i$ more flexibly than with just a dot product.

Prediction: Using the *output* vector $\mathbf{o}$, the system outputs the most likely answer using:

$$a = \arg\max_{a \in p \cap E} W_a^\intercal \mathbf{o} \quad (4)$$

Finally, the system adds a softmax function on top of $W_a^\intercal \mathbf{o}$ and adopts a negative log-likelihood objective for training.

Differences from (Hermann et al., 2015). Our model basically follows the *AttentiveReader*. However, to our surprise, our experiments observed nearly **8–10**% improvement over the original *AttentiveReader* results on *CNN* and *Daily Mail* datasets (discussed in Sec. 4). Concretely, our model has the following differences:

- We use a bilinear term, instead of a tanh layer to compute the relevance (attention) between question and contextual embeddings. The effectiveness of the simple bilinear attention function has been shown previously for neural machine translation by (Luong et al., 2015).
- After obtaining the weighted contextual embeddings $\mathbf{o}$, we use $\mathbf{o}$ for direct prediction. In contrast, the original model in (Hermann et al., 2015) combined $\mathbf{o}$ and the question embedding $\mathbf{q}$ via another non-linear layer before making final predictions. We found that we could remove this layer without harming performance. We believe it is sufficient for the model to learn to return the entity to which it maximally gives attention.
- The original model considers all the words from the vocabulary $\mathcal{V}$ in making predictions. We think this is unnecessary, and only predict among entities which appear in the passage.

Of these changes, only the first seems important; the other two just aim at keeping the model simple.

Window-based MemN2Ns (Hill et al., 2016). Another recent neural network approach proposed by (Hill et al., 2016) is based on a memory network architecture (Weston et al., 2015). We think it is highly similar in spirit. The biggest difference is their way of encoding passages: they demonstrate that it is most effective to only use a 5-word context window when evaluating a candidate entity and they use a positional unigram approach to encode the contextual embeddings: if a window consists of 5 words $x_1, \ldots, x_5$, then it is encoded as $\sum_{i=1}^{5} E_i(x_i)$, resulting in 5 separate embedding matrices to learn. They encode the 5-word window surrounding the placeholder in a similar way and all other words in the question text are ignored. In addition, they simply use a dot product to compute the "relevance" between the question and a contextual embedding. This simple model nevertheless works well, showing the extent to which this RC task can be done by very local context matching.

4 Experiments

4.1 Training Details

For training our conventional classifier, we use the implementation of *LambdaMART* (Wu et al., 2010) in the RankLib package.[5] We use this ranking algorithm since our problem is naturally a ranking problem and forests of boosted decision trees have been very successful lately (as seen, e.g., in many recent Kaggle competitions). We do not use all the features of *LambdaMART* since we are only scoring 1/0 loss on the first ranked proposal, rather than using an IR-style metric to score ranked results. We use Stanford's neural network dependency parser (Chen and Manning, 2014) to parse all our document and question text, and all other features can be extracted without additional tools.

For training our neural networks, we only keep the most frequent $|\mathcal{V}| = 50$k words (including entity and placeholder markers), and map all other words to an <*unk*> token. We choose word embedding size $d = 100$, and use the 100-dimensional pre-trained *GloVe* word embeddings (Pennington et al., 2014) for initialization. The attention and output parameters are initialized from a uniform distribution between $(-0.01, 0.01)$, and the LSTM weights are initialized from a Gaussian distribution $\mathcal{N}(0, 0.1)$.

We use hidden size $h = 128$ for *CNN* and 256 for *Daily Mail*. Optimization is carried out using vanilla stochastic gradient descent (SGD), with a fixed learning rate of 0.1. We sort all the examples by the length of its passage, and randomly sample a mini-batch of size 32 for each update. We also apply dropout with probability 0.2 to the embedding layer and gradient clipping when the norm of gradients exceeds 10.

All of our models are run on a single GPU (GeForce GTX TITAN X), with roughly a runtime of 6 hours per epoch for *CNN*, and 15 hours per epoch for *Daily Mail*. We run all the models up to 30 epochs and select the model that achieves the best accuracy on the development set.

4.2 Main Results

Table 2 presents our main results. The conventional feature-based classifier obtains 67.9% accuracy on the *CNN* test set. Not only does this significantly outperform any of the symbolic approaches reported in (Hermann et al., 2015), it also outperforms all the neural network systems from their paper and the best single-system result reported so far from (Hill et al., 2016). This suggests that the task might not be as difficult as suggested, and a simple feature set can cover many of the cases. Table 3 presents a feature ablation analysis of our entity-centric classifier on the development portion of the *CNN* dataset. It shows that n-gram match and frequency of entities are the two most important classes of features.

More dramatically, our single-model neural network surpasses the previous results by a large margin (over 5%), pushing up the state-of-the-art accuracies to 72.4% and 75.8% respectively. Due to resource constraints, we have not had a chance to investigate ensembles of models, which generally can bring further gains, as demonstrated in (Hill et al., 2016) and many other papers.

Concurrently with our paper, Kadlec et al. (2016) and Kobayashi et al. (2016) also experiment on these two datasets and report competitive results. However, our single model not only still outperforms theirs, but also appears to be structurally simpler. All these recent efforts converge to similar numbers, and we believe that they are approaching the ceiling performance of this task, as we will indicate in the next section.

5 Data Analysis

So far, we have good results via either of our systems. In this section, we aim to conduct an in-depth analysis and answer the following questions: (i) Since the

dataset was created in an automatic and heuristic way, how many of the questions are trivial to answer, and how many are noisy and not answerable? (ii) What have these models learned? What are the prospects for further improving them? To study this, we randomly sampled 100 examples from the dev portion of the *CNN* dataset for analysis (see more details in Appendix A).

5.1 Breakdown of the Examples

After carefully analyzing these 100 examples, we roughly classify them into the following categories (if an example satisfies more than one category, we classify it into the earliest one):

Exact match The nearest words around the placeholder are also found in the passage surrounding an entity marker; the answer is self-evident.

Sentence-level paraphrasing The question text is entailed/rephrased by *exactly* one sentence in the passage, so the answer can definitely be identified from that sentence.

Partial clue In many cases, even though we cannot find a complete semantic match between the question text and some sentence, we are still able to infer the answer through partial clues, such as some word/concept overlap.

Multiple sentences It requires processing multiple sentences to infer the correct answer.

Coreference errors It is unavoidable that there are many coreference errors in the dataset. This category includes those examples with critical coreference errors for the answer entity or key entities appearing in the question. Basically we treat this category as "not answerable".

Ambiguous or very hard This category includes examples for which we think humans are not able to obtain the correct answer (confidently).

Table 5 provides our estimate of the percentage for each category, and Table 4 presents one representative example from each category. To our surprise,

Category	Question	Passage
Exact Match	*it 's clear @entity0 is leaning toward* **@placeholder** , says an expert who monitors @entity0	. . . @entity116 , who follows @entity0 's operations and propaganda closely , recently told @entity3 , *it 's clear @entity0 is leaning toward* **@entity60** in terms of doctrine , ideology and an emphasis on holding territory after operations . . . .
Paraphrase	**@placeholder** says he understands why @entity0 wo n't play at his tournament	. . . @entity0 called me personally to let me know that he would n't be playing here at @entity23 , " **@entity3** said on his @entity21 event 's website . . . .
Partial clue	a tv movie based on @entity2 's book **@placeholder** casts a @entity76 actor as @entity5	. . . to @entity12 @entity2 professed that his **@entity11** is not a religious book . . . .
Multiple sent.	he 's doing a his - and - her duet all by himself , @entity6 said of **@placeholder**	. . . we got some groundbreaking performances , here too , tonight , @entity6 said . we got **@entity17** , who will be doing some musical performances . he 's doing a his - and - her duet all by himself . . . .
Coref. Error	rapper **@placeholder** " disgusted , " cancels upcoming show for @entity280	. . . with hip - hop star **@entity246** saying on @entity247 that he was canceling an upcoming show for the @entity249 . . . . (but @entity249 = @entity280 = SAEs)
Hard	pilot error and snow were reasons stated for **@placeholder** plane crash	. . . a small aircraft carrying **@entity5** , @entity6 and @entity7 the @entity12 @entity3 crashed a few miles from @entity9 , near @entity10 , @entity11 . . . .

Table 4: Some representative examples from each category.

No.	Category	(%)
1	Exact match	13
2	Paraphrasing	41
3	Partial clue	19
4	Multiple sentences	2
5	Coreference errors	8
6	Ambiguous / hard	17

Table 5: An estimate of the breakdown of the dataset into classes, based on the analysis of our sampled 100 examples from the *CNN* dataset.

Category	Classifier	Neural net
Exact match	13 (100.0%)	13 (100.0%)
Paraphrasing	32 (78.1%)	39 (95.1%)
Partial clue	14 (73.7%)	17 (89.5%)
Multiple sentences	1 (50.0%)	1 (50.0%)
Coreference errors	4 (50.0%)	3 (37.5%)
Ambiguous / hard	2 (11.8%)	1 (5.9%)
All	66 (66.0%)	74 (74.0%)

Table 6: The per-category performance of our two systems.

"coreference errors" and "ambiguous/hard" cases account for 25% of this sample set, based on our manual analysis, and this certainly will be a barrier for training models with an accuracy much above 75% (although, of course, a model can sometimes make a lucky guess). Additionally, only 2 examples require multiple sentences for inference – this is a lower rate than we expected and Hermann et al. (2015) suggest. Therefore, we hypothesize that in most of the "answerable" cases, the goal is to identify the most relevant (single) sentence, and then to infer the answer based upon it.

5.2 Per-category Performance

Now, we further analyze the predictions of our two systems, based on the above categorization.

As seen in Table 6, we have the following observations: (i) The exact-match cases are quite simple and both systems get 100% correct. (ii) For the ambiguous/hard and entity-linking-error cases,

meeting our expectations, both of the systems perform poorly. (iii) The two systems mainly differ in paraphrasing cases, and some of the "partial clue" cases. This clearly shows how neural networks are better capable of learning semantic matches involving paraphrasing or lexical variation between the two sentences. (iv) We believe that the neural-net system already achieves near-optimal performance on all the single-sentence and unambiguous cases. There does not seem to be much useful headroom for exploring more sophisticated natural language understanding approaches on this dataset.

6 Related Tasks

We briefly survey other tasks related to reading comprehension.

MCTest (Richardson et al., 2013) is an open-domain reading comprehension task, in the form of fictional short stories, accompanied by multiple-choice questions. It was carefully created using crowd sourcing, and aims at a 7-year-old reading comprehension level.

On the one hand, this dataset has a high demand on various reasoning capacities: over 50% of the questions require multiple sentences to answer and also the questions come in assorted categories (*what*, *why*, *how*, *whose*, *which*, etc). On the other hand, the full dataset has only 660 paragraphs in total (each paragraph is associated with 4 questions), which renders training statistical models (especially complex ones) very difficult.

Up to now, the best solutions (Sachan et al., 2015; Wang et al., 2015) are still heavily relying on manually curated syntactic/semantic features, with the aid of additional knowledge (e.g., word embeddings, lexical/paragraph databases).

Children Book Test (Hill et al., 2016) was developed in a similar spirit to the *CNN*/*Daily Mail* datasets. It takes any consecutive 21 sentences from a children's book – the first 20 sentences are used as the passage, and the goal is to infer a missing word in the 21st sentence (question and answer). The questions are also categorized by the type of the missing word: named entity, common noun, preposition or verb. According to the first study on this dataset (Hill et al., 2016), a language model (an n-gram model or a recurrent neural network) with local context is sufficient for predicting verbs or prepositions; however, for named entities or common nouns, it improves performance to scan through the whole paragraph to make predictions. So far, the best published results are reported by window-based memory networks.

bAbI (Weston et al., 2016) is a collection of artificial datasets, consisting of 20 different reasoning types. It encourages the development of models with the ability to chain reasoning, induction/deduction, etc., so that they can answer a question like "The football is in the *playground*" after reading a sequence of sentences "John is in the playground; Bob is in the office; John picked up the football; Bob went to the kitchen." Various types of memory networks (Sukhbaatar et al., 2015; Kumar et al., 2016) have been shown effective on these tasks, and Lee et al. (2016) show that vector space models based on extensive problem analysis can obtain near-perfect accuracies on all the categories. Despite these promising results, this dataset is limited to a small vocabulary (only 100–200 words) and simple language variations, so there is still a huge gap from real-world datasets that we need to fill in.

7 Conclusion

In this paper, we carefully examined the recent *CNN*/*Daily Mail* reading comprehension task. Our systems demonstrated state-of-the-art results, but more importantly, we performed a careful analysis of the dataset by hand.

Overall, we think the *CNN*/*Daily Mail* datasets are valuable datasets, which provide a promising avenue for training effective statistical models for reading comprehension tasks. Nevertheless, we argue that: (i) this dataset is still quite noisy due to its method of data creation and coreference errors; (ii) current neural networks have almost reached a performance ceiling on this dataset; and (iii) the required reasoning and inference level of this dataset is still quite simple.

As future work, we need to consider how we can utilize these datasets (and the models trained upon them) to help solve more complex RC reasoning tasks (with less annotated data).

A Samples and Labeled Categories from the *CNN* Dataset

For the analysis in Section 5, we uniformly sampled 100 examples from the development set of the *CNN* dataset. Table 8 provides a full index list of our samples and Table 7 presents our labeled categories.

Category	Sample IDs
Exact match (13)	8, 11, 23, 27, 28, 32, 43, 57, 63, 72, 86, 87, 99
Sentence-level paraphrasing (41)	0, 2, 7, 9, 12, 14, 16, 18, 19, 20, 29, 30, 31, 34, 36, 37, 39, 41, 42, 44, 47, 48, 52, 54, 58, 64, 65, 66, 69, 73, 74, 78, 80, 81, 82, 84, 85, 90, 92, 95, 96
Partial clues (19)	4, 17, 21, 24, 35, 38, 45, 53, 55, 56, 61, 62, 75, 83, 88, 89, 91, 97, 98
Multiple sentences (2)	5, 76
Coreference errors (8)	6, 22, 40, 46, 51, 60, 68, 94
Ambiguous or very hard (17)	1, 3, 10, 13, 15, 25, 26, 33, 49, 50, 59, 67, 70, 71, 77, 79, 93

Learning Language Games through Interaction

Sida I. Wang **Percy Liang** **Christopher D. Manning**
Computer Science Department
Stanford University
{sidaw,pliang,manning}@cs.stanford.edu

Abstract

We introduce a new language learning setting relevant to building adaptive natural language interfaces. It is inspired by Wittgenstein's language games: a human wishes to accomplish some task (e.g., achieving a certain configuration of blocks), but can only communicate with a computer, who performs the actual actions (e.g., removing all red blocks). The computer initially knows nothing about language and therefore must learn it from scratch through interaction, while the human adapts to the computer's capabilities. We created a game called SHRDLURN in a blocks world and collected interactions from 100 people playing it. First, we analyze the humans' strategies, showing that using compositionality and avoiding synonyms correlates positively with task performance. Second, we compare computer strategies, showing that modeling pragmatics on a semantic parsing model accelerates learning for more strategic players.

1 Introduction

Wittgenstein (1953) famously said that *language derives its meaning from use*, and introduced the concept of *language games* to illustrate the fluidity and purpose-orientedness of language. He described how a builder B and an assistant A can use a primitive language consisting of four words—*'block'*, *'pillar'*, *'slab'*, *'beam'*—to successfully communicate what block to pass from A to B. This is only one such language; many others would also work for accomplishing the cooperative goal.

This paper operationalizes and explores the idea of language games in a learning setting, which we call *interactive learning through language games*

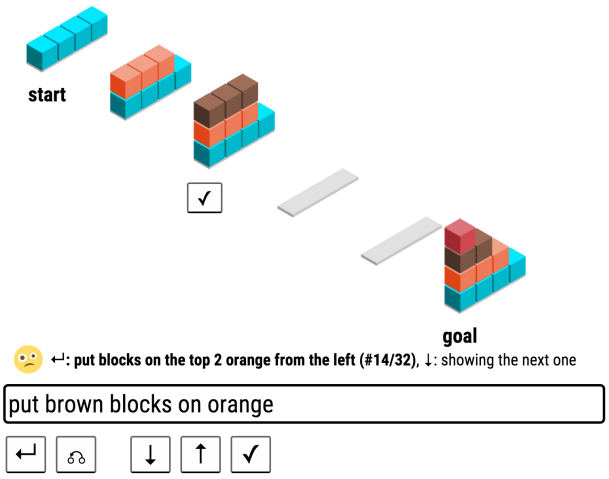

Figure 1: The SHRDLURN game: the objective is to transform the start state into the goal state. The human types in an utterance, and the computer (which does not know the goal state) tries to interpret the utterance and perform the corresponding action. The computer initially knows nothing about the language, but through the human's feedback, learns the human's language while making progress towards the game goal.

(ILLG). In the ILLG setting, the two parties do not initially speak a common language, but nonetheless need to collaboratively accomplish a goal. Specifically, we created a game called SHRDLURN,[1] in homage to the seminal work of Winograd (1972). As shown in Figure 1, the objective is to transform a start state into a goal state, but the only action the human can take is entering an utterance. The computer parses the utterance and produces a ranked list of possible interpretations according to its current model. The human scrolls through the list and chooses the intended one, simultaneously advancing the state of the blocks and providing feedback to the computer. Both the human and the computer wish to reach the goal state

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2368–2378,
Berlin, Germany, August 7-12, 2016.

(only known to the human) with as little scrolling as possible. For the computer to be successful, it has to learn the human's language quickly over the course of the game, so that the human can accomplish the goal more efficiently. Conversely, the human must also accommodate the computer, at least partially understanding what it can and cannot do.

We model the computer in the ILLG as a semantic parser (Section 3), which maps natural language utterances (e.g., *'remove red'*) into logical forms (e.g., `remove(with(red))`). The semantic parser has no seed lexicon and no annotated logical forms, so it just generates many candidate logical forms. Based on the human's feedback, it performs online gradient updates on the parameters corresponding to simple lexical features.

During development, it became evident that while the computer was eventually able to learn the language, it was learning less quickly than one might hope. For example, after learning that *'remove red'* maps to `remove(with(red))`, it would think that *'remove cyan'* also mapped to `remove(with(red))`, whereas a human would likely use mutual exclusivity to rule out that hypothesis (Markman and Wachtel, 1988). We therefore introduce a pragmatics model in which the computer explicitly reasons about the human, in the spirit of previous work on pragmatics (Golland et al., 2010; Frank and Goodman, 2012; Smith et al., 2013). To make the model suitable for our ILLG setting, we introduce a new online learning algorithm. Empirically, we show that our pragmatic model improves the online accuracy by 8% compared to our best non-pragmatic model on the 10 most successful players (Section 5.3).

What is special about the ILLG setting is the real-time nature of learning, in which the human also learns and adapts to the computer. While the human can teach the computer any language—English, Arabic, Polish, a custom programming language—a good human player will choose to use utterances that the computer is more likely to learn quickly. In the parlance of communication theory, the human *accommodates* the computer (Giles, 2008; Ireland et al., 2011). Using Amazon Mechanical Turk, we collected and analyzed around 10k utterances from 100 games of SHRDLURN. We show that successful players tend to use compositional utterances with a consistent vocabulary and syntax, which matches the inductive biases of the computer (Section 5.2). In addition, through this interaction, many players adapt to the computer by becoming more consistent, more precise, and more concise.

On the practical side, natural language systems are often trained once and deployed, and users must live with their imperfections. We believe that studying the ILLG setting will be integral for creating adaptive and customizable systems, especially for resource-poor languages and new domains where starting from close to scratch is unavoidable.

2 Setting

We now describe the interactive learning of language games (ILLG) setting formally. There are two players, the human and the computer. The game proceeds through a fixed number of levels. In each level, both players are presented with a starting state $s \in \mathcal{Y}$, but only the human sees the goal state $t \in \mathcal{Y}$. (e.g. in SHRDLURN, $\mathcal{Y}$ is the set of all configurations of blocks). The human transmits an utterance x (e.g., *'remove red'*) to the computer. The computer then constructs a ranked list of candidate actions $Z = [z_1, \ldots, z_K] \subseteq \mathcal{Z}$ (e.g., `remove(with(red))`, `add(with(orange))`, etc.), where $\mathcal{Z}$ is all possible actions. For each $z_i \in Z$, it computes $y_i = [\![z_i]\!]_s$, the successor state from executing action z_i on state s. The computer returns to the human the ordered list $Y = [y_1, \ldots, y_K]$ of successor states. The human then chooses y_i from the list Y (we say the computer is *correct* if $i = 1$). The state then updates to $s = y_i$. The level ends when $s = t$, and the players advance to the next level.

Since only the human knows the goal state t and only the computer can perform actions, the only way for the two to play the game successfully is for the human to somehow encode the desired action in the utterance x. However, we assume the two players do not have a shared language, so the human needs to pick a language and teach it to the computer. As an additional twist, the human does not know the exact set of actions $\mathcal{Z}$ (although they might have some preconception of the computer's capabilities).[2] Finally, the human only sees the outcomes of the computer's actions, not the actual logical actions themselves.

We expect the game to proceed as follows: In the beginning, the computer does not understand

[2]This is often the case when we try to interact with a new software system or service before reading the manual.

what the human is saying and performs arbitrary actions. As the computer obtains feedback and learns, the two should become more proficient at communicating and thus playing the game. Herein lies our key design principle: *language learning should be necessary for the players to achieve good game performance*.

SHRDLURN. Let us now describe the details of our specific game, SHRDLURN. Each state $s \in \mathcal{Y}$ consists of stacks of colored blocks arranged in a line (Figure 1), where each stack is a vertical column of blocks. The actions $\mathcal{Z}$ are defined compositionally via the grammar in Table 1. Each action either adds to or removes from a set of stacks, and a set of stacks is computed via various set operations and selecting by color. For example, the action `remove(leftmost(with(red)))` removes the top block from the leftmost stack whose topmost block is red. The compositionality of the actions gives the computer non-trivial capabilities. Of course, the human must teach a language to harness those capabilities, while not quite knowing the exact extent of the capabilities. The actual game proceeds according to a curriculum, where the earlier levels only need simpler actions with fewer predicates.

We designed SHRDLURN in this way for several reasons. First, visual block manipulations are intuitive and can be easily crowdsourced, and it can be fun as an actual game that people would play. Second, the action space is designed to be compositional, mirroring the structure of natural language. Third, many actions z lead to the same successor state $y = [\![z]\!]_s$; e.g., the *'leftmost stack'* might coincide with the *'stack with red blocks'* for some state s and therefore an action involving either one would result in the same outcome. Since the human only points out the correct y, the computer must grapple with this indirect supervision, a reflection of real language learning.

3 Semantic parsing model

Following Zettlemoyer and Collins (2005) and most recent work on semantic parsing, we use a log-linear model over logical forms (actions) $z \in \mathcal{Z}$ given an utterance x:

$$p_\theta(z \mid x) \propto \exp(\theta^\mathsf{T} \phi(x, z)), \tag{1}$$

where $\phi(x, z) \in \mathbb{R}^d$ is a feature vector and $\theta \in \mathbb{R}^d$ is a parameter vector. The denotation y (successor state) is obtained by executing z on a state s; formally, $y = [\![z]\!]_s$.

Features. Our features are n-grams (including skip-grams) conjoined with tree-grams on the logical form side. Specifically, on the utterance side (e.g., *'stack red on orange'*), we use unigrams (*'stack'*, $*$, $*$), bigrams (*'red'*, *'on'*, $*$), trigrams (*'red'*, *'on'*, *'orange'*), and skip-trigrams (*'stack'*, $*$, *'on'*). On the logical form side, features corresponds to the predicates in the logical forms and their arguments. For each predicate h, let $h.i$ be the i-th argument of h. Then, we define *tree-gram* features $\psi(h, d)$ for predicate h and depth $d = 0, 1, 2, 3$ recursively as follows:

$$\psi(h, 0) = \{h\},$$
$$\psi(h, d) = \{(h, i, \psi(h.i, d-1)) \mid i = 1, 2, 3\}.$$

The set of all features is just the cross product of utterance features and logical form features. For example, if $x =$ *'enlever tout'* and $z =$ `remove(all())`, then features include:

(*'enlever'*, `all`) (*'tout'*, `all`)
(*'enlever'*, `remove`) (*'tout'*, `remove`)
(*'enlever'*, (`remove`, 1, `all`))
(*'tout'*, (`remove`, 1, `all`))

Note that we do not model an explicit alignment or derivation compositionally connecting the utterance and the logical form, in contrast to most traditional work in semantic parsing (Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Liang et al., 2011; Kwiatkowski et al., 2010; Berant et al., 2013), instead following a looser model of semantics similar to (Pasupat and Liang, 2015). Modeling explicit alignments or derivations is only computationally feasible when we are learning from annotated logical forms or have a seed lexicon, since the number of derivations is much larger than the number of logical forms. In the ILLG setting, neither are available.

Generation/parsing. We generate logical forms from smallest to largest using beam search. Specifically, for each size $n = 1, \ldots, 8$, we construct a set of logical forms of size n (with exactly n predicates) by combining logical forms of smaller sizes according to the grammar rules in Table 1. For each n, we keep the 100 logical forms z with the highest score $\theta^\mathsf{T} \phi(x, z)$ according to the current model θ. Let Z be the set of logical forms on the final beam, which contains logical forms of all sizes n. During training, due to pruning at

Rule	Semantics	Description
Set	`all()`	all stacks
Color	`cyan|brown|red|orange`	primitive color
Color → Set	`with(`c`)`	stacks whose top block has color c
Set → Set	`not(`s`)`	all stacks except those in s
Set → Set	`leftmost|rightmost(`s`)`	leftmost/rightmost stack in s
Set Color → Act	`add(`s, c`)`	add block with color c on each stack in s
Set → Act	`remove(`s`)`	remove the topmost block of each stack in s

Table 1: The formal grammar defining the compositional action space $\mathcal{Z}$ for SHRDLURN. We use c to denote a Color, and s to denote a Set. For example, one action that we have in SHRDLURN is: *'add an orange block to all but the leftmost brown block'* $\mapsto$ `add(not(leftmost(with(brown))),orange)`.

intermediate sizes, Z is not guaranteed to contain the logical form that obtains the observed state y. To mitigate this effect, we use a curriculum so that only simple actions are needed in the initial levels, giving the human an opportunity to teach the computer about basic terms such as colors first before moving to larger composite actions.

The system executes all of the logical forms on the final beam Z, and orders the resulting denotations y by the maximum probability of any logical form that produced it.[3]

Learning. When the human provides feedback in the form of a particular y, the system forms the following loss function:

$$\ell(\theta, x, y) = -\log p_\theta(y \mid x, s) + \lambda||\theta||_1, \quad (2)$$

$$p_\theta(y \mid x, s) = \sum_{z:[\![z]\!]_s = y} p_\theta(z \mid x). \quad (3)$$

Then it makes a single gradient update using AdaGrad (Duchi et al., 2010), which maintains a per-feature step size.

4 Modeling pragmatics

In our initial experience with the semantic parsing model described in Section 3, we found that it was able to learn reasonably well, but lacked a reasoning ability that one finds in human learners. To illustrate the point, consider the beginning of a game when $\theta = 0$ in the log-linear model $p_\theta(z \mid x)$. Suppose that human utters *'remove red'* and then identifies $z_{\texttt{rm-red}} = \texttt{remove(with(red))}$ as the correct logical form. The computer then performs a gradient update on the loss function (2), upweighting features such as (*'remove'*, `remove`) and (*'remove'*, `red`).

Next, suppose the human utters *'remove cyan'*. Note that $z_{\texttt{rm-red}}$ will score higher than all other formulas since the (*'remove'*, `red`) feature will fire again. While statistically justified, this behavior fails to meet our intuitive expectations for a smart language learner. Moreover, this behavior is not specific to our model, but applies to any statistical model that simply tries to fit the data without additional prior knowledge about the specific language. While we would not expect the computer to magically guess *'remove cyan'* $\mapsto$ `remove(with(cyan))`, it should at least push down the probability of $z_{\texttt{rm-red}}$ because $z_{\texttt{rm-red}}$ intuitively is already well-explained by another utterance *'remove red'*.

This phenomenon, *mutual exclusivity*, was studied by Markman and Wachtel (1988). They found that children, during their language acquisition process, reject a second label for an object and treat it instead as a label for a novel object.

The pragmatic computer. To model mutual exclusivity formally, we turn to probabilistic models of pragmatics (Golland et al., 2010; Frank and Goodman, 2012; Smith et al., 2013; Goodman and Lassiter, 2015), which operationalize the ideas of Grice (1975). The central idea in these models is to treat language as a cooperative game between a speaker (human) and a listener (computer) as we are doing, but where the listener has an explicit model of the speaker's strategy, which in turn models the listener. Formally, let $S(x \mid z)$ be the speaker's strategy and $L(z \mid x)$ be the listener's

[3] We tried ordering based on the sum of the probabilities (which corresponds to marginalizing out the logical form), but this had the degenerate effect of assigning too much probability mass to y being the set of empty stacks, which can result from many actions.

	$z_{\texttt{rm-red}}$	$z_{\texttt{rm-cyan}}$	$z_3, z_4, \ldots$
	$p_\theta(z \mid x)$		
'remove red'	0.8	0.1	0.1
'remove cyan'	**0.6**	0.2	0.2
	$S(x \mid z)$		
'remove red'	0.57	0.33	0.33
'remove cyan'	0.43	0.67	0.67
	$L(z \mid x)$		
'remove red'	0.46	0.27	0.27
'remove cyan'	0.24	**0.38**	**0.38**

Table 2: Suppose the computer saw one example of *'remove red'* $\mapsto z_{\texttt{rm-red}}$, and then the human utters *'remove cyan'*. **top**: the literal listener, $p_\theta(z \mid x)$, mistakingly chooses $z_{\texttt{rm-red}}$ over $z_{\texttt{rm-cyan}}$. **middle**: the pragmatic speaker, $S(x \mid z)$, assigns a higher probability to *'remove cyan'* given $z_{\texttt{rm-cyan}}$; **bottom**: the pragmatic listener, $L(z \mid x)$ correctly assigns a lower probability to $z_{\texttt{rm-red}}$ where $p(z)$ is uniform.

strategy. The speaker takes into account the literal semantic parsing model $p_\theta(z \mid x)$ as well as a prior over utterances $p(x)$, while the listener considers the speaker $S(x \mid z)$ and a prior $p(z)$:

$$S(x \mid z) \propto \left(p_\theta(z \mid x)p(x)\right)^\beta, \quad (4)$$

$$L(z \mid x) \propto S(x \mid z)p(z), \quad (5)$$

where $\beta \geq 1$ is a hyperparameter that sharpens the distribution (Smith et al., 2013). The computer would then use $L(z \mid x)$ to rank candidates rather than p_θ. Note that our pragmatic model only affects the ranking of actions returned to the human and does not affect the gradient updates of the model p_θ.

Let us walk through a simple example to see the effect of modeling pragmatics. Table 2 shows that the literal listener $p_\theta(z \mid x)$ assigns high probability to $z_{\texttt{rm-red}}$ for both *'remove red'* and *'remove cyan'*. Assuming a uniform $p(x)$ and $\beta = 1$, the pragmatic speaker $S(x \mid z)$ corresponds to normalizing each column of p_θ. Note that if the pragmatic speaker wanted to convey $z_{\texttt{rm-cyan}}$, there is a decent chance that they would favor *'remove cyan'*. Next, assuming a uniform $p(z)$, the pragmatic listener $L(z \mid x)$ corresponds to normalizing each row of $S(x \mid z)$. The result is that conditioned on *'remove cyan'*, $z_{\texttt{rm-cyan}}$ is now more likely than $z_{\texttt{rm-red}}$, which is the desired effect.

The pragmatic listener models the speaker as a cooperative agent who behaves in a way to maximize communicative success. Certain speaker behaviors such as avoiding synonyms (e.g., not *'delete cardinal'*) and using a consistent word ordering (e.g, not *'red remove'*) fall out of the game theory.[4] For speakers that do not follow this strategy, our pragmatic model is incorrect, but as we get more data through game play, the literal listener $p_\theta(z \mid x)$ will sharpen, so that the literal listener and the pragmatic listener will coincide in the limit.

$\forall z, C(z) \leftarrow 0$
$\forall z, Q(z) \leftarrow \epsilon$
repeat
  receive utterance x from human
  $L(z \mid x) \propto \frac{P(z)}{Q(z)} p_\theta(z \mid x)^\beta$
  send human a list Y ranked by $L(z \mid x)$
  receive $y \in Y$ from human
  $\theta \leftarrow \theta - \eta \nabla_\theta \ell(\theta, x, y)$
  $Q(z) \leftarrow Q(z) + p_\theta(z \mid x)^\beta$
  $C(z) \leftarrow C(z) + p_\theta(z \mid x, [\![z]\!]_s = y)$
  $P(z) \leftarrow \frac{C(z)+\alpha}{\sum_{z':C(z')>0}\left(C(z')+\alpha\right)}$
until *game ends*

Algorithm 1: Online learning algorithm that updates the parameters of the semantic parser θ as well as counts C, Q required to perform pragmatic reasoning.

Online learning with pragmatics. To implement the pragmatic listener as defined in (5), we need to compute the speaker's normalization constant $\sum_x p_\theta(z \mid x)p(x)$ in order to compute $S(x \mid z)$ in (4). This requires parsing all utterances x based on $p_\theta(z \mid x)$. To avoid this heavy computation in an online setting, we propose Algorithm 1, where some approximations are used for the sake of efficiency. First, to approximate the intractable sum over all utterances x, we only use the examples that are seen to compute the normalization constant $\sum_x p_\theta(z \mid x)p(x) \approx \sum_i p_\theta(z \mid x_i)$. Then, in order to avoid parsing all previous examples again using the current parameters for each new example, we store $Q(z) = \sum_i p_{\theta_i}(z \mid x_i)^\beta$, where θ_i is the parameter after the model updates on the i^{th} example x_i. While θ_i is different from the current parameter θ, $p_\theta(z \mid x_i) \approx p_{\theta_i}(z \mid x_i)$ for the relevant example x_i, which is accounted for

[4] Of course, synonyms and variable word order occur in real language. We would need a more complex game compared to SHRDLURN to capture this effect.

by both θ_i and θ.

In Algorithm 1, the pragmatic listener $L(z \mid x)$ can be interpreted as an importance-weighted version of the sharpened literal listener p_θ^β, where it is downweighted by $Q(z)$, which reflects which z's the literal listener prefers, and upweighted by $P(z)$, which is just a smoothed estimate of the actual distribution over logical forms $p(z)$. By construction, Algorithm 1 is the same as (4) except that it uses the normalization constant Q based on stale parameters θ_i after seeing example, and it uses samples to compute the sum over x. Following (5), we also need $p(z)$, which is estimated by $P(z)$ using add-α smoothing on the counts $C(z)$. Note that $Q(z)$ and $C(z)$ are updated *after* the model parameters are updated for the current example.

Lastly, there is a small complication due to only observing the denotation y and not the logical form z. We simply give each consistent logical form $\{z \mid [\![z]\!]_s = y\}$ a pseudocount based on the model: $C(z) \leftarrow C(z) + p_\theta(z \mid x, [\![z]\!]_s = y)$ where $p_\theta(z \mid x, [\![z]\!]_s = y) \propto \exp(\theta^\mathsf{T}\phi(x, z))$ for $[\![z]\!]_s = y$ (0 otherwise).

Compared to prior work where the setting is specifically designed to require pragmatic inference, pragmatics arises naturally in ILLG. We think that this form of pragmatics is the most important during learning, and becomes less important if we had more data. Indeed, if we have a lot of data and a small number of possible zs, then $L(z|x) \approx p_\theta(z|x)$ as $\sum_x p_\theta(z|x)p(x) \to p(z)$ when $\beta = 1$.[5] However, for semantic parsing, we would not be in this regime even if we have a large amount of training data. In particular, we are nowhere near that regime in SHRDLURN, and most of our utterances / logical forms are seen only once, and the importance of modeling pragmatics remains.

5 Experiments

5.1 Setting

Data. Using Amazon Mechanical Turk (AMT), we paid 100 workers 3 dollars each to play SHRDLURN. In total, we have 10223 utterances along with their starting states s. Of these, 8874 utterances are labeled with their denotations y; the rest are unlabeled, since the player can try any utterance without accepting an action. 100 players completed the entire game under identical settings. We deliberately chose to start from scratch for every worker, so that we can study the diversity of strategies that different people used in a controlled setting.

Each game consists of 50 blocks tasks divided into 5 levels of 10 tasks each, in increasing complexity. Each level aims to reach an end goal given a start state. Each game took on average 89 utterances to complete.[6] It only took 6 hours to complete these 100 games on AMT and each game took around an hour on average according to AMT's *work time* tracker (which does not account for multi-tasking players). The players were provided minimal instructions on the game controls. Importantly, we gave no example utterances in order to avoid biasing their language use. Around 20 players were confused and told us that the instructions were not clear and gave us mostly spam utterances. Fortunately, most players understood the setting and some even enjoyed SHRDLURN as reflected by their optional comments:

- *That was probably the most fun thing I have ever done on mTurk.*
- *Wow this was one mind bending games [sic].*

Metrics. We use the *number of scrolls* as a measure of game performance for each player. For each example, the number of scrolls is the position in the list Y of the action selected by the player. It was possible to complete this version of SHRDLURN by scrolling (all actions can be found in the first 125 of Y)—22 of the 100 players failed to teach an actual language, and instead finished the game mostly by scrolling. Let us call them *spam players*, who usually typed single letters, random words, digits, or random phrases (e.g. *'how are you'*). Overall, spam players had to scroll a lot: 21.6 scrolls per utterance versus only 7.4 for the non-spam players.

5.2 Human strategies

Some example utterances can be found in Table 3. Most of the players used English, but vary in their adherence to conventions such as use of determiners, plurals, and proper word ordering. 5 players invented their own language, which are more precise, more consistent than general English. One player used Polish, and another used Polish notation (bottom of Table 3).

[5] Technically, we also need p_θ to be *well-specified*.

[6] This number is not 50 because some block tasks need multiple steps and players are also allowed to explore without reaching the goal.

Table 3: Example utterances, along with the average number of scrolls for that player in parentheses. Success is measured by the number of scrolls, where the more successful players need less scrolls. 1) The 20 most successful players tend to use consistent and concise language whose semantics is similar to our logical language. 2) Average players tend to be slightly more verbose and inconsistent (left and right), or significantly different from our logical langauge (middle). 3) Reasons for being unsuccessful vary. Left: no tokenization, middle: used a coordinate system and many conjunctions; right: confused in the beginning, and used a language very different from our logical language.

Overall, we find that many players adapt in ILLG by becoming more consistent, less verbose, and more precise, even if they used standard English at the beginning. For example, some players became more consistent over time (e.g. from using both *'remove'* and *'discard'* to only using *'remove'*). In terms of verbosity, removing function words like determiners as the game progresses is a common adaptation. In each of the following examples from different players, we compare an utterance that appeared early in the game to a similar utterance that appeared later: *'Remove the red ones'* **became** *'Remove red.'*; *'add brown on top of red'* **became** *'add orange on red'*; *'add red blocks to all red blocks'* **became** *'add red to red'*; *'dark red'* **became** *'red'*; one player used *'the'* in all of the first 20 utterances, and then never used *'the'* in the last 75 utterances.

Players also vary in precision, ranging from overspecified (e.g. *'remove the orange cube at the left'*, *'remove red blocks from top row'*) to underspecified or requiring context (e.g. *'change colors'*, *'add one blue'*, *'Build more blocus'*, *'Move the blocks fool'*,*'Add two red cubes'*). We found that some players became more precise over time, as they gain a better understanding of ILLG.

Most players use utterances that actually do not match our logical language in Table 1, even the successful players. In particular, numbers are often used. While some concepts always have the same effect in our blocks world (e.g. *'first block'* means `leftmost`), most are different. More concretely, of the top 10 players, 7 used numbers of some form and only 3 players matched our logical language. Some players who did not match the logical language performed quite well neverthe-

less. One possible explanation is because the action required is somewhat constrained by the logical language and some tokens can have unintended interpretations. For example, the computer can correctly interpret numerical positional references, as long as the player only refers to the leftmost and rightmost positions. So if the player says *'rem blk pos 4'* and *'rem blk pos 1'*, the computer can interpret *'pos'* as `rightmost` and interpret the bigram (*'pos'*, *'1'*) as `leftmost`. On the other hand, players who deviated significantly by describing the desired state declaratively (e.g. *'red orange red'*, *'246'*) rather than using actions, or a coordinate system (e.g. *'row two column two'*) performed poorly. Although players do not have to match our logical language exactly to perform well, being similar is definitely helpful.

Compositionality. As far as we can tell, all players used a compositional language; no one invented unrelated words for each action. Interestingly, 3 players did not put spaces between words. Since we assume monomorphemic words separated by spaces, they had to do a lot of scrolling as a result (e.g., 14.15 with utterances like *'orangeonorangerightmost'*).

5.3 Computer strategies

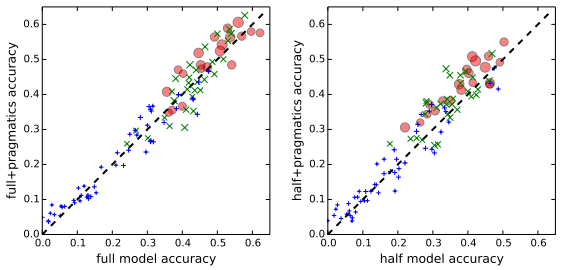
We now present quantitative results on how quickly the computer can learn, where our goal is to achieve high accuracy on new utterances as we make just a single pass over the data. The number of scrolls used to evaluate player is sensitive to outliers and not as intuitive as accuracy. Instead, we consider *online accuracy*, described as follows. Formally, if a player produced T utterances $x^{(j)}$ and labeled them $y^{(j)}$, then

$$\text{online accuracy} \stackrel{\text{def}}{=} \frac{1}{T}\sum_{j=1}^{T} \mathbb{I}\left[y^{(j)} = [\![z^{(j)}]\!]_{s^{(j)}}\right],$$

where $z^{(j)} = \arg\max_z p_{\theta^{(j-1)}}(z|x^{(j)})$ is the model prediction based on the previous parameter $\theta^{(j-1)}$. Note that the online accuracy is defined with respect to the player-reported labels, which only corresponds to the actual accuracy if the player is precise and honest. This is not true for most spam players.

Compositionality. To study the importance of compositionality, we consider two baselines. First, consider a non-compositional model (*memorize*) that just remembers pairs of complete utterance and logical forms. We implement this using indicator features on features (x, z), e.g., (*'remove all the red blocks'*, $z_{\texttt{rm-red}}$), and use a large learning rate. Second, we consider a model (*half*) that treats utterances compositionally with unigrams, bigrams, and skip-trigrams features, but the logical forms are regarded as non-compositional, so we have features such as (*'remove'*, $z_{\texttt{rm-red}}$), (*'red'*, $z_{\texttt{rm-red}}$), etc.

Table 4 shows that the full model (Section 3) significantly outperforms both the *memorize* and *half* baselines. The learning rate $\eta = 0.1$ is selected via cross validation, and we used $\alpha = 1$ and $\beta = 3$ following Smith et al. (2013).



(a) (b)

Figure 2: Pragmatics improve online accuracy. In these plots, each marker is a player. red o: players who ranked 1–20 in terms of minimizing number of scrolls, green x: players 20–50; blue +: lower than 50 (includes spam players). Marker sizes correspond to player rank, where better players are depicted with larger markers. **2a**: online accuracies with and without pragmatics on the full model; **2b**: same for the half model.

	players ranked by # of scrolls			
Method	top 10	top 20	top 50	all 100
memorize	25.4	24.5	22.5	17.6
half model	38.7	38.4	36.0	27.0
half + prag	43.7	42.7	39.7	29.4
full model	48.6	47.8	44.9	33.3
full + prag	52.8	49.8	45.8	33.8

Table 4: Average online accuracy under various settings. memorize: featurize entire utterance and logical form non-compositionally; half model: featurize the utterances with unigrams, bigrams, and skip-grams but conjoin with the entire logical form; full model: the model described in Section 3; +prag: the models above, with our online pragmatics algorithm described in Section 4. Both compositionality and pragmatics improve accuracy.

Pragmatics. Next, we study the effect of pragmatics on online accuracy. Figure 2 shows that modeling pragmatics helps successful players (e.g., top 10 by number of scrolls) who use precise and consistent languages. Interestingly, our pragmatics model did not help and can even hurt the less successful players who are less precise and consistent. This is expected behavior: the pragmatics model assumes that the human is cooperative and behaving rationally. For the bottom half of the players, this assumption is not true, in which case the pragmatics model is not useful.

6 Related Work and Discussion

Our work connects with a broad body of work on grounded language, in which language is used in some environment as a means towards some goal. Examples include playing games (Branavan et al., 2009, 2010; Reckman et al., 2010) interacting with robotics (Tellex et al., 2011, 2014), and following instructions (Vogel and Jurafsky, 2010; Chen and Mooney, 2011; Artzi and Zettlemoyer, 2013) Semantic parsing utterances to logical forms, which we leverage, plays an important role in these settings (Kollar et al., 2010; Matuszek et al., 2012; Artzi and Zettlemoyer, 2013).

What makes this work unique is our new interactive learning of language games (ILLG) setting, in which a model has to learn a language from *scratch* through interaction. While online gradient descent is frequently used, for example in semantic parsing (Zettlemoyer and Collins, 2007; Chen, 2012), we using it in a truly online setting, taking one pass over the data and measuring online accuracy (Cesa-Bianchi and Lugosi, 2006).

To speed up learning, we leverage computational models of pragmatics (Jäger, 2008; Golland et al., 2010; Frank and Goodman, 2012; Smith et al., 2013; Vogel et al., 2013). The main difference is these previous works use pragmatics with a trained base model, whereas we learn the model online. Monroe and Potts (2015) uses learning to improve the pragmatics model. In contrast, we use pragmatics to speed up the learning process by capturing phenomena like mutual exclusivity (Markman and Wachtel, 1988). We also differ from prior work in several details. First, we model pragmatics in the online learning setting where we use an online update for the pragmatics model. Second, unlikely the reference games where pragmatic effects plays an important role by design, SHRDLURN is not specifically designed to require pragmatics. The improvement we get is mainly due to players trying to be consistent in their language use. Finaly, we treat both the utterance and the logical forms as featurized compositional objects. Smith et al. (2013) treats utterances (i.e. words) and logical forms (i.e. objects) as categories; Monroe and Potts (2015) used features, but also over flat categories.

Looking forward, we believe that the ILLG setting is worth studying and has important implications for natural language interfaces. Today, these systems are trained once and deployed. If these systems could quickly adapt to user feedback in real-time as in this work, then we might be able to more readily create systems for resource-poor languages and new domains, that are customizable and improve through use.

Abstract

Arbitrariness of the sign—the notion that the forms of words are unrelated to their meanings—is an underlying assumption of many linguistic theories. Two lines of research have recently challenged this assumption, but they produce differing characterizations of non-arbitrariness in language. Behavioral and corpus studies have confirmed the validity of localized form-meaning patterns manifested in limited subsets of the lexicon. Meanwhile, global (lexicon-wide) statistical analyses instead find diffuse form-meaning systematicity across the lexicon as a whole.

We bridge the gap with an approach that can detect both local and global form-meaning systematicity in language. In the kernel regression formulation we introduce, form-meaning relationships can be used to predict words' distributional semantic vectors from their forms. Furthermore, we introduce a novel metric learning algorithm that can learn weighted edit distances that minimize kernel regression error. Our results suggest that the English lexicon exhibits far more global form-meaning systematicity than previously discovered, and that much of this systematicity is focused in localized form-meaning patterns.

1 Introduction

Arbitrariness of the sign refers to the notion that the phonetic/orthographic forms of words have no relationship to their meanings (de Saussure, 1916). It is a foundational assumption of many theories of language comprehension, production, acquisition, and evolution. For instance, Hockett's (1960) influential enumeration of the design features of human language ascribes a central role to arbitrariness in enabling the combination and recombination of phonemic units to create new words. Gasser (2004) uses simulations to show that for large vocabularies, arbitrary form-meaning mappings may provide an advantage in acquisition. Meanwhile, modular theories of language comprehension rely upon the duality of patterning to support the independence of the phonetic and semantic aspects of language comprehension (Levelt et al., 1999). Quantifying the extent to which the arbitrariness principle actually holds is important for understanding how language works.

Language researchers have long noted exceptions to arbitrariness. Most of these are patterns that occur in some relatively localized subset of the lexicon. These patterns are sub-morphemic because, unlike conventional morphemes, they cannot combine reliably to produce new words. *Phonaesthemes* (1930) are one example. A phonaestheme is a phonetic cluster that recurs in many words that have related meanings. One notable phonaestheme is the onset *gl-*, which occurs at the beginning of at least 38 English words relating to vision: *glow*, *glint*, *glaze*, *gleam*, etc. (Bergen, 2004). At least 46 candidate phonaesthemes have been posited in the linguistics literature, according to a list compiled by Hutchins (1998). *Iconicity* is another violation of arbitrariness that can lead to non-arbitrary local regularities. Iconicity occurs when the form of a word is transparently motivated by some perceptual aspect of its referent. Consequently, when several referents share perceptual features, their associated word-forms would tend to be similar as well (to the extent that they are iconic). For instance, Ohala (1984) conjectures that vowels with high acoustic frequency tend to associate with smaller items while vowels with low acoustic frequency

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2379–2388,
Berlin, Germany, August 7-12, 2016.

tend to associate with larger items, due to the experiential link between vocalizer size and frequency. Systematic iconicity is also manifested in sets of onomatopoeic words that echo similar sounds (e.g., *clink*, *clank*). Although these exceptions to non-arbitrariness differ, in each case, specific form-meaning relationships emerge in a subset of the lexicon. We will refer to all such specific localized form-meaning patterns as *phonosemantic sets*.

In recent decades, behavioral and corpus studies have empirically confirmed the psychological reality and statistical reliability of many phonosemantic sets that had previously been identified by intuition and observation. Various candidate phonaesthemes have significant effects on reaction times during language processing tasks (Hutchins, 1998; Magnus, 1998; Bergen, 2004). Sagi and Otis (2008) test the statistical significance of the 46 candidates in Hutchins's (1998) list, and find that 27 of them exhibit more within-category distributional semantic coherence than expected by chance. These results have been replicated using other corpora and distributional semantic models (Abramova et al., 2013). Klink (2000) shows that sound-symbolic attributes such as those proposed by Ohala (1984) are associated with human judgments about nonwords' semantic attributes, such as smallness or beauty. Using a statistical corpus analysis and WordNet semantic features, Monaghan et al. (2014a) examine a similar hypothesis space of sound-symbolic phonological and semantic attributes, and reach similar conclusions.

While these localized studies support the existence of some islands of non-arbitrariness in language, their results do not address how pervasive non-arbitrariness is at the global level—that is, in the lexicon of a language as a whole. After all, some seemingly non-arbitrary local patterns can be expected to emerge merely by chance. How can we measure whether local phonosemantic patterning translates into global *phonosemantic systematicity*–that is, strong, non-negligible lexicon-wide non-arbitrariness? Shillcock et al. (2001) introduce the idea of measuring phonosemantic systematicity by analyzing the correlation between phonological edit distances and distributional semantic distances. In a lexicon of monomorphemic and monosyllabic English words, they find a small but statistically significant correlation between these two distance measures. Monaghan et al. (2014b) elaborate on this methodology, showing that the statistical effect is robust to different choices of form-distance and semantic-distance metrics. They also look at the effect of leaving out each word in the lexicon on the overall correlation measure; from this, they derive a phonosemantic systematicity measure for each word. Interestingly, they find that systematicity is diffusely distributed across the words in English in a pattern indistinguishable from random chance. Hence, they conclude that "systematicity in the vocabulary is not a consequence of small clusters of sound symbolism." This line of work provides a proof-of-concept that it is possible to detect the phonosemantic systematicity of a language, and confirms that English exhibits significant phonosemantic systematicity.

Broadly speaking, both the localized tests of individual phonosemantic sets and the global analyses of phonosemantic systematicity challenge the arbitrariness of the sign. However, they attribute responsibility for non-arbitrariness differently. The local methods reveal dozens of specific phonosemantic sets that have strong, measurable behavioral effects and statistical signatures in corpora. Meanwhile, the global methods find small and diffuse systematicity. How can we reconcile this discrepancy?

Original Contributions. We attempt to bridge the gap with a new approach that builds off of previous lexicon-wide analyses, making two innovations. The first addresses the concern that the lexicon-wide methods currently in use may not be well suited to finding local regularities such as phonosemantic sets, because they make the assumption that systematicity exists only in the form of a global correlation between distances in form-space and distances in meaning-space. Instead, we model the problem using kernel regression, a non-parametric regression model. Crucially, in kernel regression the prediction for a point is based on the predictions of neighboring points; this enables us to conduct a global analysis while still capturing local, neighborhood effects. As in previous work, we represent word-forms by their orthographic strings, and word-meanings by their semantic vector representations as produced by a distributional semantic vector space model. The goal of the regression is then to learn a mapping from string-valued predictor variables to vector-valued target variables that minimizes regression

error in the vector space. Conveniently, our model allows us to produce predictions of the semantic vectors associated with both words and nonwords.

Previous work may also underestimate systematicity in that it weights all edits (substitutions, insertions, and deletions) equally in determining edit distance. A priori, there is no reason to believe this is the case—indeed, the work on individual phonosemantic sets suggests that some orthographic/phonetic attributes are more important than others for non-arbitrariness. To address this, we introduce String-Metric Learning for Kernel Regression (SMLKR), a metric-learning algorithm that is able to learn a weighted edit distance metric that minimizes the prediction error in kernel regression.

We find that SMLKR enables us to recover more systematicity from a lexicon of monomorphemic English words than reported in previous global analyses. Using SMLKR, we propose a new measure of per-word phonosemantic systematicity. Our analyses using this systematicity measure indicate that specific phonosemantic sets do contribute significantly to the global phonosemantic systematicity of English, in keeping with previous local-level analyses. Finally, we evaluate our systematicity measure against human judgments, and find that it accords with raters' intuitions about what makes a word's form well suited to its meaning.

2 Background & Related Work

2.1 Previous Approaches to Finding Lexicon-Wide Systematicity

Measuring Form, Meaning, and Systematicity. To our knowledge, all previous lexicon-level analyses of phonosemantic systematicity have used variations of the method of Shillcock et al. (2001). The inputs for this method are form-meaning tuples $(\mathbf{y}_i, s_i)$ for each word i in the lexicon, where $\mathbf{y}_i$ is the vector representation of the word in a distributional semantic model, and s_i is the string representation of the word (phonological, phonemic, or orthographic). Semantic distances are measured as cosine distances between the vectors of each pair of words. Shillcock et al. (Shillcock et al., 2001) and Monaghan et al. (Monaghan et al., 2014b) measure form-distances in terms of edit distance between each pair of strings. In addition Monaghan et al. (2014b) and Tamariz (2006) study distance measures based on a selected set binary phonological features, with similar results. Phonosemantic systematicity is then measured as the correlation between all the pairwise semantic distances and all the pairwise string distances.

Hypothesis Testing. In this line line of work, statistical significance of the results is assessed using the Mantel test, a permutation test of the correlation between two sets of pairwise distances (Mantel, 1967). The test involves randomly shuffling the assignments of semantic vectors to wordstrings in the lexicon. We can think of each form-meaning shuffle as a member of the set of all possible lexicons. Next, the correlation between the semantic distances and the string distances is computed under each reassignment. An empirical p-value for the true lexicon is then derived by performing many shufflings, and comparing the correlation coefficients measured under the shuffles to the correlation coefficient measured in the true lexicon. Under the null hypothesis that form-meaning assignments are arbitrary, the probability of observing a form-meaning correlation of at least the magnitude actually observed in the true lexicon is asymptotically equal to the proportion of reassignments that produce greater correlations than the true lexicon.

Previous Findings. Shillcock et al. (2001) find a statistically significant correlation between semantic and phonological edit distances in a lexicon of the 1733 most frequent monosyllabic monomorphemic words in the BNC. Tamariz (2008) extends these results to Spanish data, looking only at words with one of three consonant-vowel (CV) structures (CVCV, CVCCV, and CVCVCV). (2001), Monaghan et al. (2014b) derive a list of 5138 monomorphemic monosyllabic words and a list of 5604 monomorphemic polysyllabic from the CELEX database (Baayen et al., 1996), and find significant form-meaning correlations in both.

2.2 Kernel Regression

In contrast to previous studies, we study form-meaning systematicity using a kernel regression framework. Kernel regression is a nonparametric supervised learning technique that is able to learn highly nonlinear relationships between predictor variables and target variables. Rather than assuming any particular parametric relationship between the predictor and target variables, kernel regression assumes only that the value of the target vari-

able is a smooth function of the value of the predictors. In other words, given a new point in predictor space, the value of the target at that point can reasonably be estimated by the value of the targets at points that are nearby in the predictor space. In this way, kernel regression is analogous to an exemplar model. We performed kernel regression on our lexicon using the Nadaraya-Watson estimator (Nadaraya, 1964). Given a data set $\mathcal{D}$ of vector-valued predictor variables $\{\mathbf{x}_i\}_{i=1}^N$, and targets $\{\mathbf{y}_i\}_{i=1}^N$, the Nadaraya-Watson estimator of the target for sample i is

$$\hat{\mathbf{y}}_i = \hat{\mathbf{y}}(\mathbf{x}_i) = \frac{\sum_{j \neq i} k_{ij} \mathbf{y}_j}{\sum_{j \neq i} k_{ij}}, \quad (1)$$

where k_{ij} is the *kernel* between point i and point j. A commonly used kernel is the exponential kernel:

$$k_{ij} = k(\mathbf{x}_i, \mathbf{x}_j) = \exp(-d(\mathbf{x}_i, \mathbf{x}_j)/h),$$

where $d(\cdot, \cdot)$ is a distance metric and h is a *bandwidth* that determines the radius of the effective neighborhood around each point that contributes to its estimate. For our purposes we use the Levenshtein string edit distance metric (Levenshtein, 1966). The Levenshtein edit distance between two strings is the minimum number of edits needed to transform one string into the other, where an edit is defined as the insertion, deletion, or substitution of a single character. Using this edit distance and semantic vectors derived from a distributional semantic model, the Nadaraya-Watson estimator can estimate the position in the semantic vector space for each word in the lexicon. The exponential edit distance kernel has been useful for modeling behavior in many tasks involving word similarity and neighborhood effects; see, for example the Generalized Context Model (Nosofsky, 1986), which has been applied to word identification, recognition, and categorization, to inflectional morphology, and to artificial grammar learning (Bailey and Hahn, 2001).

2.3 Metric Learning for Kernel Regression

In kernel regression, the bandwidth h of the kernel function must be fine-tuned by testing out many different bandwidths. Moreover, for many tasks there is no reason to assume that all of the dimensions of a vector-valued predictor are equally important. This is problematic for conventional kernel regression, as the quality of its predictions is wholly reliant on the appropriateness of the given distance metric.

Weinberger and Tesauro (2007) introduce metric learning for kernel regression (MLKR), an algorithm that can learn a task-specific Mahalanobis (i.e., weighted Euclidean) distance metric over a real-vector-valued predictor space, in which small distances between two vectors imply similar target values. They note that this metric induces a kernel function whose parameters are set entirely from the data. Specifically, MLKR can learn a weight matrix W for a Mahalanobis metric that optimizes the leave-one out mean squared error of kernel regression (MSE), defined as:

$$\mathcal{L}(\mathcal{D}) = \frac{1}{N} \sum_{i=1}^{N} \mathcal{L}(\hat{\mathbf{y}}_i, \mathbf{y}_i) = \frac{1}{N} \sum_{i=1}^{N} \|\hat{\mathbf{y}}_i - \mathbf{y}_i\|_2^2,$$

where $\hat{\mathbf{y}}_i$ is estimated using $\hat{\mathbf{y}}_j$ for all $i \neq j$, as in Eq. 1.

In MLKR, the weighted distance metric is learned using stochastic gradient descent. As an added benefit, MLKR is implicitly able to learn an appropriate kernel bandwidth.

3 String-Metric Learning for Kernel Regression (SMLKR)

Our novel contribution is an extension of MLKR to situations where the predictor variables are not real-valued vectors, but strings, and the distance metric we wish to learn is a weighted Levenshtein edit distance. Vector-valued representations of the strings themselves would only approximately preserve edit distance. Fortunately, it turns out that we do not need vector-valued representations of the strings at all. Define the *minimum edit-distance path* as the smallest-length sequence of edits that is needed to transform one string into another. Observe that the weighted edit distance between two strings s_i and s_j can be represented as the weighted sum of all the edits that must take place to transform one string into the other along the minimum edit-distance path (Bellet et al., 2012). In turn, these edits can be represented by a vector $\boldsymbol{\nu}_{ij}$ constructed as in Fig 1, while the weights can be represented by a vector $\mathbf{w} = (w_1, ..., w_M)^T$:

$$d_{WL}(s_i, s_j) = \sum_{m=1}^{M} w_m \nu_{ijm} = \mathbf{w}^T \boldsymbol{\nu}_{ij}.$$

Figure 1: Each element in $\boldsymbol{\nu}_{ij}$ (the vector at left) represents a type of edit. The entry ν_{ijm} represents the number of edits of type m that occur as string s_i (*boot*) is transformed into string s_j (*bee*).

Each entry of $\boldsymbol{\nu}_{ij}$ corresponds to a particular type of edit operation (e.g., substitution of character a for character b). The value assigned to each entry is the count of the total number of times that the corresponding edit operation must be applied to achieve transformation of string i to string j along the minimum edit-distance path.

We note that $\boldsymbol{\nu}_{ij}$ does not admit a unique representation, since there are multiple ways to transform one string to another in the same number of edits, using different edit operations. However, we adopt the convention that some class of edit operations always takes priority over another—e.g., that deletions always occur before substitutions. This then enables us to specify $\boldsymbol{\nu}_{ij}$ uniquely. We also adopt the convention that the weights for edit operations are symmetric—e.g., that the weight for substituting character a for character b is the same as the weight for substituting character b for character a, so we represent every such pair of edit operations by a single entry in $\boldsymbol{\nu}_{ij}$.

As in MLKR, our goal is to minimize the leave-one-out MSE,[1] where $k_{ij} = e^{-\mathbf{w}^T\boldsymbol{\nu}_{ij}}$. The gradient of the regression error for MSE is

$$\frac{\partial\mathcal{L}(\mathcal{D})}{\partial\mathbf{w}} = \frac{2}{N}\sum_{i=1}^{N}(\mathbf{y}_i - \hat{\mathbf{y}}_i)\frac{\partial\hat{\mathbf{y}}_i}{\partial\mathbf{w}}$$

where

$$\frac{\partial\hat{\mathbf{y}}_i}{\partial\mathbf{w}} = \frac{\sum_{j\neq i}(\mathbf{y}_j - \hat{\mathbf{y}}_i)^T k_{ij}\boldsymbol{\nu}_{ij}}{\sum_{j\neq i}k_{ij}}.$$

Using this exact gradient, we can find the edit weights that minimize the loss function. We wish to constrain the weights to be non-negative, since weighted edit distance only makes sense with nonnegative weights. Thus, to minimize the loss we use the limited-memory Broyden–Fletcher–Goldfarb–Shanno algorithm for box constraints (L-BFGS-B) (Byrd et al., 1995), a quasi-Newton method that allows bounded optimization. We made a Python implementation of SMLKR available at `http://bit.ly/25Hidqg/`.

[1] We attained similar results minimizing mean cosine error. The gradient for mean cosine error is

$$\frac{\partial\mathcal{L}(\mathcal{D})}{\partial\mathbf{w}} = \frac{1}{N}\sum_{i=1}^{N}\frac{(\|\hat{\mathbf{y}}_i\|\mathbf{y}_i - \mathcal{L}(\mathbf{y}_i,\hat{\mathbf{y}}_i)\hat{\mathbf{y}}_i)}{\|\hat{\mathbf{y}}_i\|^2}\frac{\partial\hat{\mathbf{y}}_i}{\partial\mathbf{w}}.$$

4 Experimental Setup

4.1 Data

Lexicon. A principal concern is the possibility that our models may detect morphemes rather than sub-morphemic units. To minimize this concern, we adopted an approach similar to that of Shillcock et al. (2001), of training our model only on monomorphemic words. Monomorphemic words were selected by cross-referencing the morphemic analyses contained in the CELEX lexical database (Baayen et al., 1996) with the morphemic analyses contained in the etymologies of the Oxford English Dictionary Online (`http://www.oed.com`). Then, we went through the filtered list and removed any remaining polymorphemic words as well as place names, demonyms, spelling variants, and proper nouns. Finally, words that were not among the 40,000 most frequent non-filler word types in the corpus were excluded. The final lexicon was composed of 4,949 word types.

Corpus and Semantic Model. The corpus we used to train our semantic model is a concatenation of the UKWaC, BNC, and Wikipedia corpora (Ferraresi et al., 2008; BNC Consortium, 2007; Parker et al., 2011). We trained our vector-space model on this corpus using the Word2Vec (Mikolov et al., 2013), as instantiated in the GENSIM package (Řehůřek and Sojka, 2010) for Python using default parameters. We produced 100-dimensional word-embedding vectors using the SkipGram algorithm of Word2Vec and normalized the 100-dimensional vector for each word so that its Euclidean norm was equal to 1.

4.2 Training

We trained SMLKR on the 100-dimensional Word2Vec embeddings using L-BGFS-B, and placing non-negativity constraints on the weights $\mathbf{w}$. We let SMLKR run until convergence, as de-

termined by the following criterion:

$$\frac{|\mathcal{L}^{(k-1)} - \mathcal{L}^{(k)}|}{\max(|\mathcal{L}^{(k-1)}|, |\mathcal{L}^{(k)}|)} = \epsilon$$

where $\mathcal{L}^{(k)}$ is the loss at the k^{th} iteration of learning, and we set $\epsilon = 2 \times 10^{-8}$. We randomly initialized the L-BGFS-B algorithm 10 times to avoid poor local minima, and kept the solution with the lowest loss.

5 Experiments

5.1 Model Analysis

Weighted Edit Distance Reveals More Non-Arbitrariness. We first assessed whether the structure found by kernel regression could arise merely by arbitrary, random pairings of form and meaning (i.e., strings and semantic vectors). We adopt a Monte Carlo testing procedure similar to the Mantel test of §2.1. We first randomly shuffled the assignment of the semantic vectors of all the words in the lexicon. We then trained SMLKR on the shuffled lexicon just as we did on the true lexicon. We measured the mean squared error of the SMLKR prediction. Out of 1000 reassignments, none produced a prediction error as small as the prediction error in the true lexicon (i.e., empirical p-value of $p < .001$).

For comparison, we analyzed our corpus using the correlation method of Monaghan et al. (2014b). In our implementation, we measured the correlation between the pairwise cosine distances produced by Word2Vec and pairwise orthographic edit distances for all pairs of words in our lexicon. The correlation between the Word2Vec semantic distances and the orthographic edit distances in our corpus was $r = 0.0194$, similar to the correlation reported by Monaghan et al. of $r = 0.016$ between the phoneme edit distances and the semantic distances in the monomorphemic English lexicon. We also looked at the correlation between the weighted edit distances produced by SMLKR and the Word2Vec semantic distances. The correlation between these distances was $r = 0.0464$; thus, the weighted edit distance captures more than 5.7 times as much variance as the unweighted edit distance. Further, using the estimated semantic vectors produced by the SMLKR model, we can actually produce new estimates of the semantic distances between the words. The correlation between these estimated semantic distances and the true semantic distances was $r = 0.1028$, revealing much more systematicity than revealed by the simple linear correlation method. The Mantel test with 1,000 permutations produced significant empirical p-values for all correlations ($p < .001$).

Systematicity Not Evenly Distributed Across Lexicon. What could be accounting for the higher degree of systematicity detected with SMLKR? Applying a more expressive model could result in a better fit simply because incidental but inconsequential patterns are being captured. Conversely, SMLKR could be finding phonosemantic sets which the correlation method of Monaghan et al. (Monaghan et al., 2014b) is unable to detect. We investigated further by determining what was driving the better fit produced by SMLKR. Monaghan et al. measure per-word systematicity as the change in the lexicon-wide form-meaning correlation that results from removing the word from the lexicon. The more the correlation decreases from removing the word, the more systematic the word is, according to this measure. They compared the distribution of this systematicity measure across the words in the lexicon to the distribution of systematicity in lexicons with randomly shuffled form-meaning assignments, and found that the null hypothesis that the distributions were identical could not be rejected. From this, they conclude that the observed systematicity of the lexicon is not a consequence only of small pockets of sound symbolism, but is rather a feature of the mappings from sound to meaning across the lexicon as a whole. However, it is possible that their methods may not be sensitive enough to find localized phonosemantic sets.

We developed our own measure of per-word systematicity by measuring the per-word regression error of the SMLKR model. We presume words with lower regression errors to be more systematic. A list of the words with the lowest per-word regression error in our corpus can be found in Table 1. Notably, many of these words, such as *fluff*, *flutter*, and *flick*, exhibit word beginnings or word endings that have been previously identified as phonaesthemes (Hutchins, 1998; Otis and Sagi, 2008). Others exhibit regular onomatopoeia, such as *clang* and *croak*.

We decided to investigate the distribution of systematicity across two-letter word-beginnings in our lexicon using a permutation test. The goal of the permutation test is to estimate a p-value for the

SMLKR	Correlation	Random
gurgle	emu	tunic
tingle	nexus	decay
hoop	asylum	skirmish
chink	ethic	scroll
swirl	odd	silk
ladle	slime	prom
flick	snare	knob
wobble	scarlet	havoc
tangle	deem	irate
knuckle	balustrade	veer
glitter	envoy	wear
twig	scrape	phone
fluff	essay	surgeon
rasp	ambit	hiccup
quill	echo	bowel
flutter	onus	sack
whirl	exam	lens
croak	pirouette	hovel
squeal	kohl	challenge
clang	chandelier	box

likelihood that each set of words sharing a word beginning would exhibit the mean regression error it exhibits, if systematicity is randomly distributed across the lexicon. For each set $\mathcal{S}_\omega$ of words with word-beginning ω, we measured the mean SMLKR regression error of the words in $\mathcal{S}_\omega$. To get an empirical p-value for each $\mathcal{S}_\omega$ with cardinality greater than 5 (i.e., more than 5 word tokens), we randomly chose 10^5 sets of words in the lexicon with the same cardinality, and measured the mean SMLKR regression error for each of these random sets. If r of the randomly assembled sets had a lower mean regression error than $\mathcal{S}_\omega$ did, we assign an empirical p-value of $\frac{r}{10^5}$ to $\mathcal{S}_\omega$. A histogram of empirical p-values is in Fig. 2. From the figure, it seems clear that the p-values are not uniformly distributed; instead, an inordinate number of word-beginnings exhibit mean errors that are unlikely to occur if error is distributed arbitrarily across word-beginnings.

We can confirm this observation statistically. On the assumption that systematicity is arbitrarily distributed across word-beginnings, the empirical p-values of the permutation test should approximately conform to a Unif$(0, 1)$ distribution. We can test this hypothesis using a χ^2 test on the negative logarithms of the p-values (Fisher, 1932). Using this test, we reject the hypothesis that the p-values are uniformly distributed with $p < .0001$ ($\chi^2_{156} = 707.8$). The particular word-beginnings

with statistically significant empirical p-values ($p < .05$ after Benjamini-Hochberg (1995) correction for multiple comparisons) are in Table 2. Eight of these ten features are among the 18 two-letter onsets posited to be phonaesthemes by Hutchins (1998). For comparison, Otis and Sagi (2008) identified eight of Hutchins's 18 two-letter word-beginning candidate phonaesthemes (and 12 two-letter word-beginnings overall) as statistically significant, though they restricted their hypothesis space to only 50 pre-specified word-beginnings and word-endings. We are able to identify just as many candidate phonaesthemes, but with a much less restricted hypothesis space of candidates (225 rather than the 50 in Otis and Sagi's analysis) and with a general model not specifically attuned to finding phonaesthemes in particular, but rather systematicity in general.

5.2 Behavioral Evaluation of Systematicity Measure

We empirically tested whether the systematicity measure based on SMLKR regression error accords with naïve human judgments about how well-suited a word's form is to its meaning (its "phonosemantic feeling") (Stefanowitsch, 2002). We recruited 60 native English-speaking participants through Mechanical Turk, and asked them to judge the phonosemantic feeling of the 60 words in Table 1 on a sliding scale from 1 to 5.[2] We used Cronbach's α to measure inter-annotator reliability at $\alpha = 0.96$, indicating a high degree of inter-annotator reliability (Cronbach, 1951; George, 2000). The results showed that the words in the SMLKR list were rated higher for phonosemantic feeling than the words in the Correlation and Random lists. We fit a parametric linear mixed-effects model to the phonosemantic feeling judgments (Baayen et al., 2008), as implemented in the `lme4` library for R. As fixed effects, we entered the list identity (SMLKR, Correlation, Random), the word length, and the log frequency of the word in our corpus. Our random effects structure included a random intercept for word, and random subject slopes for all fixed effects, with all correlations allowed (a "maximal" random-effects structure (Barr et al., 2013)). Including list identity in the maximal mixed-effects model significantly improved model fit ($\chi^2_{11} = 126.08$, $p < 10^{-6}$). Post-hoc analysis revealed that the SMLKR list elicited average suitability judgments that were 0.49 points higher than the Random list ($p < 10^{-6}$) and 0.59 points higher than the Correlation list ($p < 10^{-6}$). Post-hoc analysis did not find a significant difference in suitability judgments between the Random and Correlation lists ($p > .16$).[3]

6 Conclusion

In this paper, we proposed SMLKR, a novel algorithm that can learn weighted string edit distances that minimize kernel regression error. We succeed in applying this algorithm to the problem of finding form-meaning systematicity in the monomorphemic English lexicon. Our algorithm offers improved global predictions of word-meaning given word-form at the lexicon-wide level. We show that this improvement seems related to localized pockets of form-meaning systematicity such as those previously uncovered in behavioral and corpus analyses. Unlike previous lexicon-wide analyses, we find that form-meaning systematicity is not randomly distributed throughout the English lexicon. Moreover, the measure of systematicity that we compute using SMLKR accords significantly with human raters' judgments about form-meaning correspondences in English.

Future work may investigate to what extent the SMLKR model can predict human intuitions about form-meaning systematicity in language. We do not know, for instance, if our model can predict human semantic judgments of novel words that have never been encountered. This is a question that has received attention in the market research literature, where new brand names are tested for the emotions they elicit (Klink, 2000). We would also like to investigate the degree to which our statistical model predicts the behavioral effects of phonosemantic systematicity during human semantic processing that have been reported in the psycholinguistics literature. Our model makes precise quantitative predictions that should allow us to address these questions.

While developing our model on preliminary versions of the monomorphemic lexicon, we noticed that the model detected high degrees of systematicity in words with suffixes such as *-ate* and *-tet* (e.g., *quintet*, *quartet*). We removed such words in the final analysis since they are polymorphemic, but this observation suggests that our algorithm may have applications in unsupervised morpheme discovery.

Finally, we would like to test our model using other representations of word-form and word-meaning. We chose to use orthographic rather than phonetic representations of words because of the variance in pronunciation present in the dialects of English that are manifested in our corpus. However, it would be interesting to verify our results in a phonological setting, perhaps using a monodialectal corpus. Moreover, previous local-level analyses suggest that systematicity seems to be concentrated in word-beginnings and word-

[2] Participants were given the following guidance: "Your job is to decide how well-suited each word is to what it means. This is known as the 'phonosemantic feeling.' Basically, most people feel like some of the words in their native language sound right, given what they mean." Full instructions and experiment available at `http://goo.gl/Z6Lzlp`

[3] Post hoc analyses were produced by comparing the items in only two of the lists at a time, and fitting the same mixed-effects model as above.

endings. Thus, it may be worthwhile to augment the representation of edit distance in our model by making it context-sensitive. Future work could also test whether a more interpretable meaning-space representation such as that provided by binary WordNet feature vectors reveals patterns of systematicity not found using a distributional semantic space.

Improving Hypernymy Detection with an Integrated Path-based and Distributional Method

Abstract

Detecting hypernymy relations is a key task in NLP, which is addressed in the literature using two complementary approaches. Distributional methods, whose supervised variants are the current best performers, and path-based methods, which received less research attention. We suggest an improved path-based algorithm, in which the dependency paths are encoded using a recurrent neural network, that achieves results comparable to distributional methods. We then extend the approach to integrate both path-based and distributional signals, significantly improving upon the state-of-the-art on this task.

1 Introduction

Hypernymy is an important lexical-semantic relation for NLP tasks. For instance, knowing that *Tom Cruise* is an *actor* can help a question answering system answer the question "which actors are involved in Scientology?". While semantic taxonomies, like WordNet (Fellbaum, 1998), define hypernymy relations between word types, they are limited in scope and domain. Therefore, automated methods have been developed to determine, for a given term-pair (x, y), whether y is an hypernym of x, based on their occurrences in a large corpus.

For a couple of decades, this task has been addressed by two types of approaches: distributional, and path-based. In distributional methods, the decision whether y is a hypernym of x is based on the distributional representations of these terms. Lately, with the popularity of word embeddings (Mikolov et al., 2013), most focus has shifted towards supervised distributional methods, in which each (x, y) term-pair is represented using some combination of the terms' embedding vectors.

In contrast to distributional methods, in which the decision is based on the *separate* contexts of x and y, path-based methods base the decision on the lexico-syntactic paths connecting the *joint* occurrences of x and y in a corpus. Hearst (1992) identified a small set of frequent paths that indicate hypernymy, e.g. *Y such as X*. Snow et al. (2004) represented each (x, y) term-pair as the multiset of dependency paths connecting their co-occurrences in a corpus, and trained a classifier to predict hypernymy, based on these features.

Using individual paths as features results in a huge, sparse feature space. While some paths are rare, they often consist of certain unimportant components. For instance, "Spelt is a species of wheat" and "Fantasy is a genre of fiction" yield two different paths: *X be species of Y* and *X be genre of Y*, while both indicating that X is-a Y. A possible solution is to generalize paths by replacing words along the path with their part-of-speech tags or with wild cards, as done in the PATTY system (Nakashole et al., 2012).

Overall, the state-of-the-art path-based methods perform worse than the distributional ones. This stems from a major limitation of path-based methods: they require that the terms of the pair occur together in the corpus, limiting the recall of these methods. While distributional methods have no such requirement, they are usually less precise in detecting a specific semantic relation like hypernymy, and perform best on detecting broad semantic similarity between terms. Though these approaches seem complementary, there has been rather little work on integrating them (Mirkin et al., 2006; Kaji and Kitsuregawa, 2008).

In this paper, we present HypeNET, an integrated path-based and distributional method for hypernymy detection. Inspired by recent progress

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2389–2398,
Berlin, Germany, August 7-12, 2016.

in relation classification, we use a long short-term memory (LSTM) network (Hochreiter and Schmidhuber, 1997) to encode dependency paths. In order to create enough training data for our network, we followed previous methodology of constructing a dataset based on knowledge resources.

We first show that our path-based approach, on its own, substantially improves performance over prior path-based methods, yielding performance comparable to state-of-the-art distributional methods. Our analysis suggests that the neural path representation enables better generalizations. While coarse-grained generalizations, such as replacing a word by its POS tag, capture mostly syntactic similarities between paths, HypeNET captures also semantic similarities.

We then show that we can easily integrate distributional signals in the network. The integration results confirm that the distributional and path-based signals indeed provide complementary information, with the combined model yielding an improvement of up to 14 F_1 points over each individual model.[1]

2 Background

We introduce the two main approaches for hypernymy detection: distributional (Section 2.1), and path-based (Section 2.2). We then discuss the recent use of recurrent neural networks in the related task of relation classification (Section 2.3).

2.1 Distributional Methods

Hypernymy detection is commonly addressed using distributional methods. In these methods, the decision whether y is a hypernym of x is based on the distributional representations of the two terms, i.e., the contexts with which each term occurs *separately* in the corpus.

Earlier methods developed unsupervised measures for hypernymy, starting with symmetric similarity measures (Lin, 1998), and followed by directional measures based on the distributional inclusion hypothesis (Weeds and Weir, 2003; Kotlerman et al., 2010). This hypothesis states that the contexts of a hyponym are expected to be largely included in those of its hypernym. More recent work (Santus et al., 2014; Rimell, 2014) introduce new measures, based on the assumption that the most typical linguistic contexts of a hypernym are less informative than those of its hyponyms.

More recently, the focus of the distributional approach shifted to supervised methods. In these methods, the (x, y) term-pair is represented by a feature vector, and a classifier is trained on these vectors to predict hypernymy. Several methods are used to represent term-pairs as a combination of each term's embeddings vector: concatenation $\vec{x} \oplus \vec{y}$ (Baroni et al., 2012), difference $\vec{y} - \vec{x}$ (Roller et al., 2014; Weeds et al., 2014), and dot-product $\vec{x} \cdot \vec{y}$. Using neural word embeddings (Mikolov et al., 2013; Pennington et al., 2014), these methods are easy to apply, and show good results (Baroni et al., 2012; Roller et al., 2014).

2.2 Path-based Methods

A different approach to detecting hypernymy between a pair of terms (x, y) considers the lexico-syntactic paths that connect the *joint* occurrences of x and y in a large corpus. Automatic acquisition of hypernyms from free text, based on such paths, was first proposed by Hearst (1992), who identified a small set of lexico-syntactic paths that indicate hypernymy relations (e.g. *Y such as X*, *X and other Y*).

In a later work, Snow et al. (2004) learned to detect hypernymy. Rather than searching for specific paths that indicate hypernymy, they represent each (x, y) term-pair as the multiset of all dependency paths that connect x and y in the corpus, and train a logistic regression classifier to predict whether y is a hypernym of x, based on these paths.

Paths that indicate hypernymy are those that were assigned high weights by the classifier. The paths identified by this method were shown to subsume those found by Hearst (1992), yielding improved performance. Variations of Snow et al.'s (2004) method were later used in tasks such as taxonomy construction (Snow et al., 2006; Kozareva and Hovy, 2010; Carlson et al., 2010; Riedel et al., 2013), analogy identification (Turney, 2006), and definition extraction (Borg et al., 2009; Navigli and Velardi, 2010).

A major limitation in relying on lexico-syntactic paths is the sparsity of the feature space. Since similar paths may somewhat vary at the lexical level, generalizing such variations into more abstract paths can increase recall. The PATTY algorithm (Nakashole et al., 2012) applied such generalizations for the purpose of acquiring a taxon-

[1] Our code and data are available in: https://github.com/vered1986/HypeNET

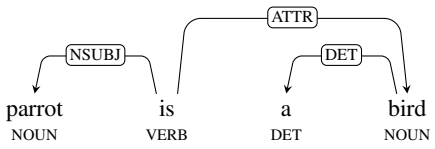

Figure 1: An example dependency tree of the sentence "parrot is a bird", with *x=parrot* and *y=bird*, represented in our notation as `X/NOUN/nsubj/< be/VERB/ROOT/-Y/NOUN/attr/>`.

omy of term relations from free text. For each path, they added generalized versions in which a subset of words along the path were replaced by either their POS tags, their ontological types or wild-cards. This generalization increased recall while maintaining the same level of precision.

2.3 RNNs for Relation Classification

Relation classification is a related task whose goal is to classify the relation that is expressed between two target terms in a given sentence to one of predefined relation classes. To illustrate, consider the following sentence, from the SemEval-2010 relation classification task dataset (Hendrickx et al., 2009): "The $[\text{apples}]_{e_1}$ are in the $[\text{basket}]_{e_2}$". Here, the relation expressed between the target entities is $Content - Container(e_1, e_2)$.

The shortest dependency paths between the target entities were shown to be informative for this task (Fundel et al., 2007). Recently, deep learning techniques showed good performance in capturing the indicative information in such paths.

In particular, several papers show improved performance using recurrent neural networks (RNN) that process a dependency path edge-by-edge. Xu et al. (2015; 2016) apply a separate long short-term memory (LSTM) network to each sequence of words, POS tags, dependency labels and WordNet hypernyms along the path. A max-pooling layer on the LSTM outputs is used as the input of a network that predicts the classification. Other papers suggest incorporating additional network architectures to further improve performance (Nguyen and Grishman, 2015; Liu et al., 2015).

While relation classification and hypernymy detection are both concerned with identifying semantic relations that hold for pairs of terms, they differ in a major respect. In relation classification the relation should be expressed in the given text, while in hypernymy detection, the goal is to recognize a generic lexical-semantic relation between terms that holds in many contexts. Accordingly, in relation classification a term-pair is represented by a single dependency path, while in hypernymy detection it is represented by the multiset of all dependency paths in which they co-occur in the corpus.

3 LSTM-based Hypernymy Detection

We present HypeNET, an LSTM-based method for hypernymy detection. We first focus on improving path representation (Section 3.1), and then integrate distributional signals into our network, resulting in a combined method (Section 3.2).

3.1 Path-based Network

Similarly to prior work, we represent each dependency path as a sequence of edges that leads from x to y in the dependency tree.[2] Each edge contains the lemma and part-of-speech tag of the source node, the dependency label, and the edge direction between two subsequent nodes. We denote each edge as $lemma/POS/dep/dir$. See figure 1 for an illustration.

Rather than treating an entire dependency path as a single feature, we encode the sequence of edges using a long short-term memory (LSTM) network. The vectors obtained for the different paths of a given (x, y) pair are pooled, and the resulting vector is used for classification. Figure 2 depicts the overall network structure, which is described below.

Edge Representation We represent each edge by the concatenation of its components' vectors:

$$\vec{v_e} = [\vec{v_l}, \vec{v_{pos}}, \vec{v_{dep}}, \vec{v_{dir}}]$$

where $\vec{v_l}, \vec{v_{pos}}, \vec{v_{dep}}, \vec{v_{dir}}$ represent the embedding vectors of the lemma, part-of-speech, dependency label and dependency direction (along the path from x to y), respectively.

Path Representation For a path p composed of edges $e_1, ..., e_k$, the edge vectors $\vec{v_{e_1}}, ..., \vec{v_{e_k}}$ are fed in order to an LSTM encoder, resulting in a vector $\vec{o_p}$ representing the entire path p. The LSTM architecture is effective at capturing temporal patterns in sequences. We expect the training procedure to drive the LSTM encoder to focus on parts of the path that are more informative for the classification task while ignoring others.

[2] Like Snow et al. (2004), we added for each path, additional paths containing single daughters of x or y not already contained in the path, referred by Snow et al. (2004) as "satellite edges". This enables including paths like *Such Y as X*, in which the word "such" is not in the path between x and y.

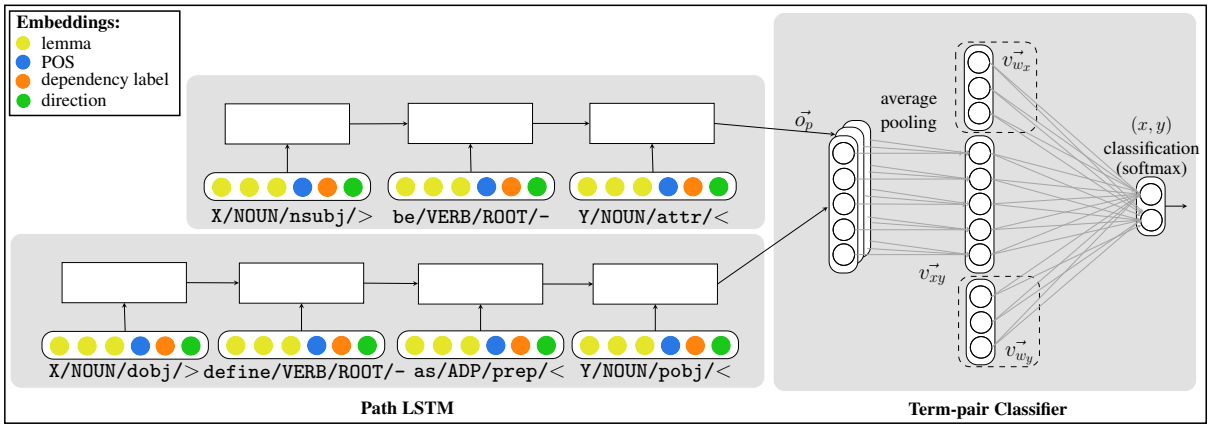

Figure 2: An illustration of term-pair classification. Each term-pair is represented by several paths. Each path is a sequence of edges, and each edge consists of four components: lemma, POS, dependency label and dependency direction. Each edge vector is fed in sequence into the LSTM, resulting in a path embedding vector $\vec{o_p}$. The averaged path vector becomes the term-pair's feature vector, used for classification. The dashed $\vec{v_{w_x}}, \vec{v_{w_y}}$ vectors refer to the integrated network described in Section 3.2.

Term-Pair Classification Each (x, y) term-pair is represented by the multiset of lexico-syntactic paths that connected x and y in the corpus, denoted as $paths(x, y)$, while the supervision is given for the term pairs. We represent each (x, y) term-pair as the weighted-average of its path vectors, by applying average pooling on its path vectors, as follows:

$$\vec{v_{xy}} = \vec{v}_{paths(x,y)} = \frac{\sum_{p \in paths(x,y)} f_{p,(x,y)} \cdot \vec{o_p}}{\sum_{p \in paths(x,y)} f_{p,(x,y)}} \quad (1)$$

where $f_{p,(x,y)}$ is the frequency of p in $paths(x, y)$. We then feed this path vector to a single-layer network that performs binary classification to decide whether y is a hypernym of x.

$$c = softmax(W \cdot \vec{v_{xy}}) \quad (2)$$

c is a 2-dimensional vector whose components sum to 1, and we classify a pair as positive if $c[1] > 0.5$.

Implementation Details To train the network, we used PyCNN.[3] We minimize the cross entropy loss using gradient-based optimization, with mini-batches of size 10 and the Adam update rule (Kingma and Ba, 2014). Regularization is applied by a dropout on each of the components' embeddings. We tuned the hyper-parameters (learning rate and dropout rate) on the validation set (see the appendix for the hyper-parameters values).

We initialized the lemma embeddings with the pre-trained GloVe word embeddings (Pennington et al., 2014), trained on Wikipedia. We tried both the 50-dimensional and 100-dimensional embedding vectors and selected the ones that yield better performance on the validation set.[4] The other embeddings, as well as out-of-vocabulary lemmas, are initialized randomly. We update all embedding vectors during training.

3.2 Integrated Network

The network presented in Section 3.1 classifies each (x, y) term-pair based on the paths that connect x and y in the corpus. Our goal was to improve upon previous path-based methods for hypernymy detection, and we show in Section 6 that our network indeed outperforms them. Yet, as path-based and distributional methods are considered complementary, we present a simple way to integrate distributional features in the network, yielding improved performance.

We extended the network to take into account distributional information on each term. Inspired by the supervised distributional concatenation method (Baroni et al., 2012), we simply concatenate x and y word embeddings to the (x, y) feature vector, redefining $\vec{v_{xy}}$:

$$\vec{v_{xy}} = [\vec{v_{w_x}}, \vec{v}_{paths(x,y)}, \vec{v_{w_y}}] \quad (3)$$

where $\vec{v_{w_x}}$ and $\vec{v_{w_y}}$ are x and y's word embeddings, respectively, and $\vec{v}_{paths(x,y)}$ is the averaged path vector defined in equation 1. This way, each (x, y) pair is represented using both the distributional features of x and y, and their path-based features.

4 Dataset

4.1 Creating Instances

Neural networks typically require a large amount of training data, whereas the existing hypernymy datasets, like BLESS (Baroni and Lenci, 2011), are relatively small. Therefore, we followed the common methodology of creating a dataset using distant supervision from knowledge resources (Snow et al., 2004; Riedel et al., 2013). Following Snow et al. (2004), who constructed their dataset based on WordNet hypernymy, and aiming to create a larger dataset, we extract hypernymy relations from several resources: WordNet (Fellbaum, 1998), DBPedia (Auer et al., 2007), Wikidata (Vrandečić, 2012) and Yago (Suchanek et al., 2007).

All instances in our dataset, both positive and negative, are pairs of terms that are directly related in at least one of the resources. These resources contain thousands of relations, some of which indicate hypernymy with varying degrees of certainty. To avoid including questionable relation types, we consider as denoting positive examples only indisputable hypernymy relations (Table 1), which we manually selected from the set of hypernymy indicating relations in Shwartz et al. (2015).

Term-pairs related by other relations (including hyponymy), are considered as negative instances. Using related rather than random term-pairs as negative instances tests our method's ability to distinguish between hypernymy and other kinds of semantic relatedness. We maintain a ratio of 1:4 positive to negative pairs in the dataset.

Like Snow et al. (2004), we include only term-pairs that have joint occurrences in the corpus, requiring at least two different dependency paths for each pair.

4.2 Random and Lexical Dataset Splits

As our primary dataset, we perform standard random splitting, with 70% train, 25% test and 5% validation sets.

As pointed out by Levy et al. (2015), supervised distributional lexical inference methods tend to perform "lexical memorization", i.e., instead of learning a relation between the two terms, they mostly learn an independent property of a single term in the pair: whether it is a "prototypical hypernym" or not. For instance, if the training set contains term-pairs such as *(dog, animal)*, *(cat, animal)*, and *(cow, animal)*, all annotated as positive examples, the algorithm may learn that *animal* is a prototypical hypernym, classifying any new *(x, animal)* pair as positive, regardless of the relation between x and *animal*. Levy et al. (2015) suggested to split the train and test sets such that each will contain a distinct vocabulary ("lexical split"), in order to prevent the model from overfitting by lexical memorization.

To investigate such behaviors, we present results also for a lexical split of our dataset. In this case, we split the train, test and validation sets such that each contains a distinct vocabulary. We note that this differs from Levy et al. (2015), who split only the train and the test sets, and dedicated a subset of the train for validation. We chose to deviate from Levy et al. (2015) because we noticed that when the validation set contains terms from the train set, the model is rewarded for lexical memorization when tuning the hyper-parameters, consequently yielding suboptimal performance on the lexically-distinct test set. When each set has a distinct vocabulary, the hyper-parameters are tuned to avoid lexical memorization and are likely to perform better on the test set. We tried to keep roughly the same 70/25/5 ratio in our lexical split.[5] The sizes of the two datasets are shown in Table 2.

Indeed, training a model on a lexically split dataset may result in a more general model, that can better handle pairs consisting of two unseen terms during inference. However, we argue that in the common applied scenario, the inference involves an unseen pair (x, y), in which x and/or y have already been observed separately. Models trained on a random split may introduce the model with a term's "prior probability" of being a hypernym or a hyponym, and this information can be exploited beneficially at inference time.

[5]The lexical split discards many pairs consisting of cross-set terms.

Table 3: Example generalizations of *X was established as Y*.

5 Baselines

We compare HypeNET with several state-of-the-art methods for hypernymy detection, as described in Section 2: path-based methods (Section 5.1), and distributional methods (Section 5.2). Due to different works using different datasets and corpora, we replicated the baselines rather than comparing to the reported results.

We use the Wikipedia dump from May 2015 as the underlying corpus of all the methods, and parse it using spaCy.[6] We perform model selection on the validation set to tune the hyper-parameters of each method.[7] The best hyper-parameters are reported in the appendix.

5.1 Path-based Methods

Snow We follow the original paper, and extract all shortest paths of four edges or less between terms in a dependency tree. Like Snow et al. (2004), we add paths with "satellite edges", i.e., single words not already contained in the dependency path, which are connected to either X or Y, allowing paths like *such Y as X*. The number of distinct paths was 324,578. We apply χ^2 feature selection to keep only the 100,000 most informative paths and train a logistic regression classifier.

Generalization We also compare our method to a baseline that uses generalized dependency paths. Following PATTY's approach to generalizing paths (Nakashole et al., 2012), we replace edges with their part-of-speech tags as well as with wild cards. We generate the powerset of all possible generalizations, including the original paths. See Table 3 for examples. The number of features after generalization went up to 2,093,220. Similarly to the first baseline, we apply feature selection, this time keeping the 1,000,000 most informative paths, and train a logistic regression classifier over the generalized paths.[8]

[6] https://spacy.io/

[7] We applied grid search for a range of values, and picked the ones that yield the highest F_1 score on the validation set.

[8] We also tried keeping the 100,000 most informative paths, but the performance was worse.

5.2 Distributional Methods

Unsupervised SLQS (Santus et al., 2014) is an entropy-based measure for hypernymy detection, reported to outperform previous state-of-the-art unsupervised methods (Weeds and Weir, 2003; Kotlerman et al., 2010). The original paper was evaluated on the BLESS dataset (Baroni and Lenci, 2011), which consists of mostly frequent words. Applying the vanilla settings of SLQS on our dataset, that contains also rare terms, resulted in low performance. Therefore, we received assistance from Enrico Santus, who kindly provided the results of SLQS on our dataset after tuning the system as follows.

The validation set was used to tune the threshold for classifying a pair as positive, as well as the maximum number of each term's most associated contexts (N). In contrast to the original paper, in which the number of each term's contexts is fixed to N, in this adaptation it was set to the minimum between the number of contexts with LMI score above zero and N. In addition, the SLQS scores were not multiplied by the cosine similarity scores between terms, and terms were lemmatized prior to computing the SLQS scores, significantly improving recall.

As our results suggest, while this method is state-of-the-art for unsupervised hypernymy detection, it is basically designed for classifying specificity level of related terms, rather than hypernymy in particular.

Supervised To represent term-pairs with distributional features, we tried several state-of-the-art methods: concatenation $\vec{x} \oplus \vec{y}$ (Baroni et al., 2012), difference $\vec{y} - \vec{x}$ (Roller et al., 2014; Weeds et al., 2014), and dot-product $\vec{x} \cdot \vec{y}$. We downloaded several pre-trained embeddings (Mikolov et al., 2013; Pennington et al., 2014) of different sizes, and trained a number of classifiers: logistic regression, SVM, and SVM with RBF kernel, which was reported by Levy et al. (2015) to perform best in this setting. We perform model selection on the validation set to select the best vectors, method and regularization factor (see the appendix).

Table 4: Performance scores of our method compared to the path-based baselines and the state-of-the-art distributional methods for hypernymy detection, on both variations of the dataset – with lexical and random split to train / test / validation.

6 Results

Table 4 displays performance scores of HypeNET and the baselines. *HypeNET Path-based* is our path-based recurrent neural network model (Section 3.1) and *HypeNET Integrated* is our combined method (Section 3.2). Comparing the path-based methods shows that generalizing paths improves recall while maintaining similar levels of precision, reassessing the behavior found in Nakashole et al. (2012). *HypeNET Path-based* outperforms both path-based baselines by a significant improvement in recall and with slightly lower precision. The recall boost is due to better path generalization, as demonstrated in Section 7.1.

Regarding distributional methods, the unsupervised SLQS baseline performed slightly worse on our dataset. The low precision stems from its inability to distinguish between hypernyms and meronyms, which are common in our dataset, causing many false positive pairs such as *(zabrze, poland)* and *(kibbutz, israel)*. We sampled 50 false positive pairs of each dataset split, and found that 38% of the false positive pairs in the random split and 48% of those in the lexical split were holonym-meronym pairs.

In accordance with previously reported results, the supervised embedding-based method is the best performing baseline on our dataset as well. *HypeNET Path-based* performs slightly better, achieving state-of-the-art results. Adding distributional features to our method shows that these two approaches are indeed complementary. On both dataset splits, the performance differences between *HypeNET Integrated* and *HypeNET Path-based*, as well as the supervised distributional method, are substantial, and statistically significant with p-value of 1% (paired t-test).

We also reassess that indeed supervised distributional methods perform worse on a lexical split (Levy et al., 2015). We further observe a similar reduction when using HypeNET, which is not a result of lexical memorization, but rather stems from over-generalization (Section 7.1).

7 Analysis

7.1 Qualitative Analysis of Learned Paths

We analyze HypeNET's ability to generalize over path structures, by comparing prominent indicative paths which were learned by each of the path-based methods. We do so by finding high-scoring paths that contributed to the classification of true-positive pairs in the dataset. In the path-based baselines, these are the highest-weighted features as learned by the logistic regression classifier. In the LSTM-based method, it is less straightforward to identify the most indicative paths. We assess the contribution of a certain path p to classification by regarding it as the only path that appeared for the term-pair, and compute its TRUE label score from the class distribution: $softmax(W \cdot \vec{v_{xy}})[1]$, setting $\vec{v_{xy}} = [\vec{0}, \vec{o_p}, \vec{0}]$.

A notable pattern is that Snow's method learns specific paths, like *X is Y from* (e.g. ***Megadeth** is an American thrash metal **band** from Los Angeles*). While Snow's method can only rely on verbatim paths, limiting its recall, the generalized version of Snow often makes coarse generalizations, such as *X VERB Y from*. Clearly, such a path is too general, and almost any verb assigned to it results in a non-indicative path (e.g. *X take Y from*). Efforts by the learning method to avoid such generalization, again, lower the recall. HypeNET provides a better midpoint, making fine-grained generalizations by learning additional semantically similar paths such as *X become Y from* and *X remain Y from*. See table 5 for additional example paths which illustrate these behaviors.

We also noticed that while on the random split our model learns a range of specific paths such as *X is Y published* (learned for e.g. *Y=magazine*) and *X is Y produced* (*Y=film*), in the lexical split it only learns the general *X is Y* path for these re-

hypernymy-like relations	21.03%
other relations	18.77%

Table 6: Distribution of relations holding between each pair of terms in the resources among false positive pairs.

lations. We note that *X is Y* is a rather "noisy" path, which may occur in ad-hoc contexts without indicating generic hypernymy relations (e.g. ***chocolate*** *is a big* ***problem*** in the context of children's health). While such a model may identify hypernymy relations between unseen terms, based on general paths, it is prone to over-generalization, hurting its performance, as seen in Table 4. As discussed in § 4.2, we suspect that this scenario, in which both terms are unseen, is usually not common enough to justify this limiting training setup.

7.2 Error Analysis

False Positives We categorized the false positive pairs on the random split according to the relation holding between each pair of terms in the resources used to construct the dataset. We grouped several semantic relations from different resources to broad categories, e.g. *synonym* includes also *alias* and *Wikipedia redirection*. Table 6 displays the distribution of semantic relations among false positive pairs.

More than 20% of the errors stem from confusing synonymy with hypernymy, which are known to be difficult to distinguish.

An additional 30% of the term-pairs are reversed hypernym-hyponym pairs (y is a hyponym of x). Examining a sample of these pairs suggests that they are usually near-synonyms, i.e., it is not that clear whether one term is truely more general than the other or not. For instance, *fiction* is annotated in WordNet as a hypernym of *story*, while our method classified *fiction* as its hyponym.

A possible future research direction might be to quite simply extend our network to classify term-pairs simultaneously to multiple semantic relations, as in Pavlick et al. (2015). Such a multi-class model can hopefully better distinguish between these similar semantic relations.

Another notable category is hypernymy-like relations: these are other relations in the resources that could also be considered as hypernymy, but were annotated as negative due to our restrictive selection of only indisputable hypernymy relations from the resources (see Section 4.1). These include instances like *(Goethe, occupation, novelist)* and *(Homo, subdivisionRanks, species)*.

Lastly, other errors made by the model often correspond to term-pairs that co-occur very few times in the corpus, e.g. $xebec$, a studio producing Anime, was falsely classified as a hyponym of *anime*.

False Negatives We sampled 50 term-pairs that were falsely annotated as negative, and analyzed the major (overlapping) types of errors (Table 7).

Most of these pairs had only few co-occurrences in the corpus. This is often either due to infrequent terms (e.g. *cbc.ca*), or a rare sense of x in which the hypernymy relation holds (e.g. *(night,*

	Error Type	%
1	low statistics	80%
2	infrequent term	36%
3	rare hyponym sense	16%
4	annotation error	8%

Table 7: (Overlapping) categories of false negative pairs: (1) x and y co-occurred less than 25 times (average co-occurrences for true positive pairs is 99.7). (2) Either x or y is infrequent. (3) The hypernymy relation holds for a rare sense of x. (4) (x, y) was incorrectly annotated as positive.

play) holding for "Night", a dramatic sketch by Harold Pinter). Such a term-pair may have too few hypernymy-indicating paths, leading to classifying it as negative.

8 Conclusion

We presented HypeNET: a neural-networks-based method for hypernymy detection. First, we focused on improving path representation using LSTM, resulting in a path-based model that performs significantly better than prior path-based methods, and matches the performance of the previously superior distributional methods. In particular, we demonstrated that the increase in recall is a result of generalizing semantically-similar paths, in contrast to prior methods, which either make no generalizations or over-generalize paths.

We then extended our network by integrating distributional signals, yielding an improvement of additional 14 F_1 points, and demonstrating that the path-based and the distributional approaches are indeed complementary.

Finally, our architecture seems straightforwardly applicable for multi-class classification, which, in future work, could be used to classify term-pairs to multiple semantic relations.

Acknowledgments

We would like to thank Omer Levy for his involvement and assistance in the early stage of this project and Enrico Santus for helping us by computing the results of SLQS (Santus et al., 2014) on our dataset.

This work was partially supported by an Intel ICRI-CI grant, the Israel Science Foundation grant 880/12, and the German Research Foundation through the German-Israeli Project Cooperation (DIP, grant DA 1600/1-1).

Abstract

We present an approach to improve statistical machine translation of image descriptions by multimodal pivots defined in visual space. The key idea is to perform image retrieval over a database of images that are captioned in the target language, and use the captions of the most similar images for crosslingual reranking of translation outputs. Our approach does not depend on the availability of large amounts of in-domain parallel data, but only relies on available large datasets of monolingually captioned images, and on state-of-the-art convolutional neural networks to compute image similarities. Our experimental evaluation shows improvements of 1 BLEU point over strong baselines.

1 Introduction

Multimodal data consisting of images and natural language descriptions (henceforth called *captions*) are an abundant source of information that has led to a recent surge in research integrating language and vision. Recently, the aspect of multilinguality has been added to multimodal language processing in a shared task at the WMT16 conference.[1] There is clearly also a practical demand for multilingual image captions, e.g., automatic translation of descriptions of art works would allow access to digitized art catalogues across language barriers and is thus of social and cultural interest; multilingual product descriptions are of high commercial interest since they would allow to widen e-commerce transactions automatically to international markets. However, while datasets of images and monolingual captions already include millions of tuples (Ferraro et al., 2015), the largest multilingual datasets of images and captions known to the authors contain 20,000 (Grubinger et al., 2006) or 30,000[2] triples of images with German and English descriptions.

In this paper, we want to address the problem of multilingual captioning from the perspective of statistical machine translation (SMT). In contrast to prior work on generating captions directly from images (Kulkarni et al. (2011), Karpathy and Fei-Fei (2015), Vinyals et al. (2015), *inter alia*), our goal is to integrate visual information into an SMT pipeline. Visual context provides orthogonal information that is free of the ambiguities of natural language, therefore it serves to disambiguate and to guide the translation process by grounding the translation of a source caption in the accompanying image. Since datasets consisting of source language captions, images, and target language captions are not available in large quantities, we would instead like to utilize large datasets of images and target-side monolingual captions to improve SMT models trained on modest amounts of parallel captions.

Let the task of *caption translation* be defined as follows: For production of a target caption e_i of an image i, a system may use as input an image caption for image i in the source language f_i, as well as the image i itself. The system may safely assume that f_i is relevant to i, i.e., the identification of relevant captions for i (Hodosh et al., 2013) is not itself part of the task of caption translation. In contrast to the inference problem of finding $\hat{e} = \text{argmax}_e\, p(e|f)$ in text-based SMT, multimodal caption translation allows to take into consideration i as well as f_i in finding $\hat{e}_i$:

$$\hat{e}_i = \underset{e_i}{\text{argmax}}\, p(e_i|f_i, i)$$

[1] http://www.statmt.org/wmt16/multimodal-task.html

[2] The dataset used at the WMT16 shared task is based on translations of Flickr30K captions (Rashtchian et al., 2010).

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2399–2409,
Berlin, Germany, August 7-12, 2016.

In this paper, we approach caption translation by a general crosslingual reranking framework where for a given pair of source caption and image, monolingual captions in the target language are used to rerank the output of the SMT system. We present two approaches to retrieve target language captions for reranking by pivoting on images that are similar to the input image. One approach calculates image similarity based deep convolutional neural network (CNN) representations. Another approach calculates similarity in visual space by comparing manually annotated object categories. We compare the multimodal pivot approaches to reranking approaches that are based on text only, and to standard SMT baselines trained on parallel data. Compared to a strong baseline trained on 29,000 parallel caption data, we find improvements of over 1 BLEU point for reranking based on visual pivots. Notably, our reranking approach does not rely on large amounts of in-domain parallel data which are not available in practical scenarios such as e-commerce localization. However, in such scenarios, monolingual product descriptions are naturally given in large amounts, thus our work is a promising pilot study towards real-world caption translation.

2 Related Work

Caption generation from images alone has only recently come into the scope of realistically solvable problems in image processing (Kulkarni et al. (2011), Karpathy and Fei-Fei (2015), Vinyals et al. (2015), *inter alia*). Recent approaches also employ reranking of image captions by measuring similarity between image and text using deep representations (Fang et al., 2015). The tool of choice in these works are neural networks whose deep representations have greatly increased the quality of feature representations of images, enabling robust and semantically salient analysis of image content. We rely on the CNN framework (Socher et al., 2014; Simonyan and Zisserman, 2015) to solve semantic classification and disambiguation tasks in NLP with the help of supervision signals from visual feedback. However, we consider image captioning as a different task than caption translation since it is not given the information of the source language string. Therefore we do not compare our work to caption generation models.

In the area of SMT, Wäschle and Riezler (2015) presented a framework for integrating a large, in-domain, target-side monolingual corpus into machine translation by making use of techniques from crosslingual information retrieval. The intuition behind their approach is to generate one or several translation hypotheses using an SMT system, which act as queries to find matching, semantically similar sentences in the target side corpus. These can in turn be used as templates for refinement of the translation hypotheses, with the overall effect of improving translation quality. Our work can be seen as an extension of this method, with visual similarity feedback as additional constraint on the crosslingual retrieval model. Calixto et al. (2012) suggest using images as supplementary context information for statistical machine translation. They cite examples from the news domain where visual context could potentially be helpful in the disambiguation aspect of SMT and discuss possible features and distance metrics for context images, but do not report experiments involving a full SMT pipeline using visual context. In parallel to our work, Elliott et al. (2015) addressed the problem of caption translation from the perspective of neural machine translation.[3] Their approach uses a model which is considerably more involved than ours and relies exclusively on the availability of parallel captions as training data. Both approaches crucially rely on neural networks, where they use a visually enriched neural encoder-decoder SMT approach, while we follow a retrieval paradigm for caption translation, using CNNs to compute similarity in visual space.

Integration of multimodal information into NLP problems has been another active area of recent research. For example, Silberer and Lapata (2014) show that distributional word embeddings grounded in visual representations outperform competitive baselines on term similarity scoring and word categorization tasks. The orthogonality of visual feedback has previously been exploited in a multilingual setting by Kiela et al. (2015) (relying on previous work by Bergsma and Van Durme (2011)), who induce a bilingual lexicon using term-specific multimodal representations obtained by querying the Google image

[3] We replicated the results of Elliott et al. (2015) on the IAPR TC-12 data. However, we decided to not include their model as baseline in this paper since we found our hierarchical phrase-based baselines to yield considerably better results on IAPR TC-12 as well as on MS COCO.

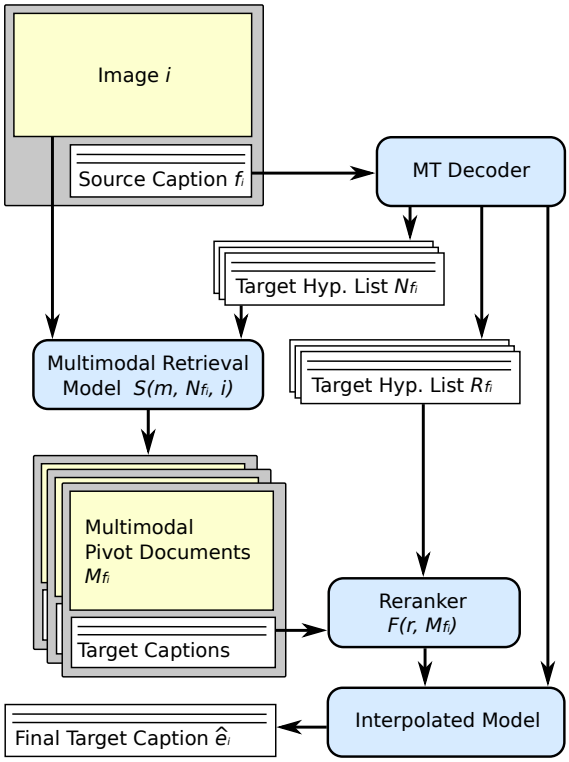

Figure 1: Overview of model architecture.

search engine.[4] Funaki and Nakayama (2015) use visual similarity for crosslingual document retrieval in a multimodal and bilingual vector space obtained by generalized canonical correlation analysis, greatly reducing the need for parallel training data. The common element is that CNN-based visual similarity information is used as a "hub" (Funaki and Nakayama, 2015) or pivot connecting corpora in two natural languages which lack direct parallelism, a strategy which we apply to the problem of caption translation.

3 Models

3.1 Overview

Following the basic approach set out by Wäschle and Riezler (2015), we use a crosslingual retrieval model to find sentences in a target language document collection C, and use these to rerank target language translations e of a source caption f.

The systems described in our work differ from that of Wäschle and Riezler (2015) in a number of aspects. Instead of a two-step architecture of coarse-grained and fine-grained retrieval, our system uses relevance scoring functions for retrieval of matches in the document collection C, and for reranking of translation candidates that are based on inverse document frequency of terms (Spärck Jones, 1972) and represent variants of the popular TF-IDF relevance measure.

A schematic overview of our approach is given in Figure 1. It consists of the following components:

Input: Source caption f_i, image i, target-side collection C of image-captions pairs

Translation: Generate unique list N_{f_i} of k_n-best translations, generate unique list R_{f_i} of k_r-best list of translations[5] using MT decoder

Multimodal retrieval: For list of translations N_{f_i}, find set M_{f_i} of k_m-most relevant pairs of images and captions in a target-side collection C, using a heuristic relevance scoring function $S(m, N_{f_i}, i), m \in C$

Crosslingual reranking: Use list M_{f_i} of image-caption pairs to rerank list of translations R_{f_i}, applying relevance scoring function $F(r, M_{f_i})$ to all $r \in R_{f_i}$

Output: Determine best translation hypothesis $\hat{e}_i$ by interpolating decoder score d_r for a hypothesis $r \in R_{f_i}$ with its relevance score $F(r, M_{f_i})$ with weight λ s.t.

$$\hat{e}_i = \underset{r \in R_{f_i}}{\operatorname{argmax}}\, d_r + \lambda \cdot F(r, M_{f_i})$$

The central concept is the scoring function $S(m, N_{f_i}, i)$ which defines three variants of target-side retrieval (TSR), all of which make use of the procedure outlined above. In the baseline text-based reranking model (TSR-TXT), we use relevance scoring function S_{TXT}. This function is purely text-based and does not make use of multimodal context information (as such, it comes closest to the models used for target-side retrieval in Wäschle and Riezler (2015)). In the retrieval model enhanced by visual information from a deep convolutional neural network (TSR-CNN), the scoring function S_{CNN} incorporates a textual relevance score with visual similarity information extracted from the neural network. Finally, we evaluate these models against a relevance score based on human object-category annotations (TSR-HCA), using the scoring function

[4] https://images.google.com/

[5] In practice, the first hypothesis list may be reused. We distinguish between the two hypothesis lists N_{f_i} and R_{f_i} for notational clarity since in general, the two hypothesis lists need not be of equal length.

S_{HCA}. This function makes use of the object annotations available for the MS COCO corpus (Lin et al., 2014) to give an indication of the effectiveness of our automatically extracted visual similarity metric. The three models are discussed in detail below.

3.2 Target Side Retrieval Models

Text-Based Target Side Retrieval. In the TSR-TXT retrieval scenario, a match candidate $m \in C$ is scored in the following way:

$$S_{TXT}(m, N_{f_i}) = Z_m \sum_{n \in N_{f_i}} \sum_{w_n \in tok(n)} \sum_{w_m \in typ(m)} \delta(w_m, w_n) idf(w_m),$$

where δ is the Kronecker δ-function, N_{f_i} is the set of the k_n-best translation hypotheses for a source caption f_i of image i by decoder score, $typ(a)$ is a function yielding the set of types (unique tokens) contained in a caption a,[6] $tok(a)$ is a function yielding the tokens of caption a, $idf(w)$ is the inverse document frequency (Spärck Jones, 1972) of term w, and $Z_m = \frac{1}{|typ(m)|}$ is a normalization term introduced in order to avoid biasing the system towards long match candidates containing many low-frequency terms. Term frequencies were computed on monolingual data from Europarl (Koehn, 2005) and the News Commentary and News Discussions English datasets provided for the WMT15 workshop.[7] Note that in this model, information from the image i is not used.

Multimodal Target Side Retrieval using CNNs. In the TSR-CNN scenario, we supplement the textual target-side TSR model with visual similarity information from a deep convolutional neural network. We formalize this by introduction of the positive-semidefinite distance function $v(i_x, i_y) \rightarrow [0, \infty)$ for images i_x, i_y (smaller values indicating more similar images). The relevance scoring function S_{CNN} used in this model takes the following form:

$$S_{CNN}(m, N_{f_i}, i) = \begin{cases} S_{TXT}(m, N_{f_i}) e^{-bv(i_m, i)}, & v(i_m, i) < d \\ 0 & otherwise, \end{cases}$$

where i_m is the image to which the caption m refers and d is a cutoff maximum distance, above which match candidates are considered irrelevant, and b is a weight term which controls the impact of the visual distance score $v(i_m, i)$ on the overall score.[8]

Our visual distance measure v was computed using the VGG16 deep convolutional model of Simonyan and Zisserman (2015), which was pretrained on ImageNet (Russakovsky et al., 2014). We extracted feature values for all input and reference images from the penultimate fully-connected layer (`fc7`) of the model and computed the Euclidean distance between feature vectors of images. If no neighboring images fell within distance d, the text-based retrieval procedure S_{TXT} was used as a fallback strategy, which occurred 47 out of 500 times on our test data.

Target Side Retrieval by Human Category Annotations. For contrastive purposes, we evaluated a TSR-HCA retrieval model which makes use of the human object category annotations for MS COCO. Each image in the MS COCO corpus is annotated with object polygons classified into 91 categories of common objects. In this scenario, a match candidate m is scored in the following way:

$$S_{HCA}(m, N_{f_i}, i) = \delta(cat(i_m), cat(i)) S_{TXT}(m, N_{f_i}),$$

where $cat(i)$ returns the set of object categories with which image i is annotated. The amounts to enforcing a strict match between the category annotations of i and the reference image i_m, thus pre-filtering the S_{TXT} scoring to captions for images with strict category match.[9] In cases where i was annotated with a unique set of object categories and thus no match candidates with nonzero scores were returned by S_{HCA}, S_{TXT} was used as a fallback strategy, which occurred 77 out of 500 times on our test data.

[6] The choice for per-type scoring of reference captions was primarily driven by performance considerations. Since captions rarely contain repetitions of low-frequency terms, this has very little effect in practice, other than to mitigate the influence of stopwords.

[7] `http://www.statmt.org/wmt15/translation-task.html`

[8] The value of $b = 0.01$ was found on development data and kept constant throughout the experiments.

[9] Attempts to relax this strict matching criterion led to strong performance degradation on the development test set.

3.3 Translation Candidate Re-scoring

The relevance score $F(r, M_{f_i})$ used in the reranking model was computed in the following way for all three models:

$$F(r, M_{f_i}) = Z_{M_{f_i}} \sum_{m \in M_{f_i}} \sum_{w_m \in typ(m)} \sum_{w_r \in tok(r)} \delta(w_m, w_r) idf(w_m)$$

with normalization term

$$Z_{M_{f_i}} = (\sum_{m \in M_{f_i}} |tok(m)|)^{-1},$$

where r is a translation candidate and M_{f_i} is a list of k_m-top target side retrieval matches. Because the model should return a score that is reflective of the relevance of r with respect to M_{f_i}, irrespective of the length of M_{f_i}, normalization with respect to the token count of M_{f_i} is necessary. The term $Z_{M_{f_i}}$ serves this purpose.

4 Experiments

4.1 Bilingual Image-Caption Data

We constructed a German-English parallel dataset based on the MS COCO image corpus (Lin et al., 2014). 1,000 images were selected at random from the 2014 training section[10] and, in a second step, one of their five English captions was chosen randomly. This caption was then translated into German by a native German speaker. Note that our experiments were performed with German as the source and English as the target language, therefore, our reference data was not produced by a single speaker but reflects the heterogeneity of the MS COCO dataset at large. The data was split into a development set of 250 captions, a development test set of 250 captions for testing work in progress, and a test set of 500 captions. For our retrieval experiments, we used only the images and captions that were not included in the development, development test or test data, a total of 81,822 images with 5 English captions per image. All data was tokenized and converted to lower case using the `cdec`[11] utilities `tokenized-anything.pl` and `lowercase.pl`. For the German data, we performed compound-splitting using the method described by Dyer (2009), as implemented by the `cdec` utility `compound-split.pl`. Table 1 gives an overview of the dataset. Our parallel development, development test and test data is publicly available.[12]

Section	Images	Captions	Languages
DEV	250	250	DE-EN
DEVTEST	250	250	DE-EN
TEST	500	500	DE-EN
RETRIEVAL (C)	81,822	409,110	EN

Table 1: Number of images and sentences in MS COCO image and caption data used in experiments.

4.2 Translation Baselines

We compare our approach to two baseline machine translation systems, one trained on out-of-domain data exclusively and one domain-adapted system. Table 2 gives an overview of the training data for the machine translation systems.

Out-of-Domain Baseline. Our baseline SMT framework is hierarchical phrase-based translation using synchronous context free grammars (Chiang, 2007), as implemented by the `cdec` decoder (Dyer et al., 2010). Data from the Europarl (Koehn, 2005), News Commentary and Common Crawl corpora (Smith et al., 2013) as provided for the WMT15 workshop was used to train the translation model, with German as source and English as target language.

Like the retrieval dataset, training, development and test data was tokenized and converted to lower case, using the same `cdec` tools. Sentences with lengths over 80 words in either the source or the target language were discarded before training. Source text compound splitting was performed using `compound-split.pl`. Alignments were extracted bidirectionally using the `fast-align` utility of `cdec` and symmetrized with the `atools` utility (also part of `cdec`) using the `grow-diag-final-and` symmetrization heuristic. The alignments were then used by the `cdec` grammar extractor to extract a synchronous context free grammar from the parallel data.

[10] We constructed our parallel dataset using only the training rather than the validation section of MS COCO so as to keep the latter pristine for future work based on this research.

News Discussions	57,803,684	EN	O/I
Flickr30k WMT16	29,000	EN	I

Table 2: Parallel and monolingual data used for training machine translation systems. Sentence counts are given for raw data without preprocessing. O/I: both out-of-domain and in-domain system, I: in-domain system only.

The target language model was trained on monolingual data from Europarl, as well as the News Crawl and News Discussions English datasets provided for the WMT15 workshop (the same data as was used for estimating term frequencies for the retrieval models) with the `KenLM` toolkit (Heafield et al., 2013; Heafield, 2011).[13]

We optimized the parameters of the translation system for translation quality as measured by IBM BLEU (Papineni et al., 2002) using the Margin Infused Relaxed Algorithm (MIRA) (Crammer and Singer, 2003). For tuning the translation models used for extraction of the hypothesis lists for final evaluation, MIRA was run for 20 iterations on the development set, and the best run was chosen for final testing.

In-Domain Baseline. We also compared our models to a domain-adapted machine translation system. The domain-adapted system was identical to the out-of-domain system, except that it was supplied with additional parallel training data from the image caption domain. For this purpose, we used 29,000 parallel German-English image captions as provided for the WMT16 shared task on multimodal machine translation. The English captions in this dataset belong to the Flickr30k corpus (Rashtchian et al., 2010) and are very similar to those of the MS COCO corpus. The German captions are expert translations. The English captions were also used as additional training data for the target-side language model. We generated k_n- and k_r-best lists of translation candidates using this in-domain baseline system.

[13] `https://kheafield.com/code/kenlm/`

Model	k_n	k_m	k_r	λ
TSR-TXT	300	500	5	$5 \cdot 10^4$
TSR-CNN	300	300	5	$70 \cdot 10^4$
TSR-HCA	300	500	5	$10 \cdot 10^4$

Table 3: Optimized hyperparameter values used in final evaluation.

4.3 Optimization of TSR Hyperparameters

For each of our retrieval models, we performed a step-wise exhaustive search of the hyperparameter space over the four system hyperparameters for IBM BLEU on the development set: The length of the k_n-best list the entries of which are used as queries for retrieval; the number of k_m-best-matching captions retrieved; the length of the final k_r-best list used in reranking; the interpolation weight λ of the relevance score F relative to the translation hypothesis log probability returned by the decoder. The parameter ranges to be explored were determined manually, by examining system output for prototypical examples. Table 3 gives an overview over the hyperparameter values obtained.

For TSR-CNN, we initially set the cutoff distance d to 90.0, after manually inspecting sets of nearest neighbors returned for various maximum distance values. After optimization of retrieval parameters, we performed an exhaustive search from $d = 80.0$ to $d = 100.0$, with step size 1.0 on the development set, while keeping all other hyperparameters fixed, which confirmed out initial choice of $d = 90.0$ as the optimal value.

Explored parameter spaces were identical for all models and each model was evaluated on the test set using its own optimal configuration of hyperparameters.

4.4 Significance Testing

Significance tests on the differences in translation quality were performed using the approximate randomization technique for measuring performance differences of machine translation systems described in Riezler and Maxwell (2005) and implemented by Clark et al. (2011) as part of the `Multeval` toolkit.[14]

TSR-TXT	45.8			0.12	0.00
TSR-CNN	**45.1**		0.03	0.00	0.00
TSR-HCA	**45.3**	0.34	0.02	0.00	0.00

Table 4: Metric scores for all systems and their significance levels as reported by Multeval. p_o-values are relative to the cdec out-of-domain baseline, p_d-values are relative to the cdec in-domain baseline, p_t-values are relative to TSR-TXT and p_c-values are relative to TSR-CNN. Best results are reported in **bold** face.[15]

4.5 Experimental Results

Table 4 summarizes the results for all models on an unseen test set of 500 captions. Domain adaptation led to a considerable improvement of +4.1 BLEU and large improvements in terms of METEOR and Translation Edit Rate (TER). We found that the target-side retrieval model enhanced with multimodal pivots from a deep convolutional neural network, TSR-CNN and TSR-HCA, consistently outperformed both the domain-adapted cdec baseline, as well as the text-based target side retrieval model TSR-TXT. These models therefore achieve a performance gain which goes beyond the effect of generic domain-adaptation. The gain in performance for TSR-CNN and TSR-HCA was significant at $p < 0.05$ for BLEU, METEOR, and TER. For all evaluation metrics, the difference between TSR-CNN and TSR-HCA was not significant, demonstrating that retrieval using our CNN-derived distance metric could match retrieval based the human object category annotations.

[15] A baseline for which a random hypothesis was chosen from the top-5 candidates of the in-domain system lies between the other two baseline systems: 27.5 / 33.3 / 47.7 (BLEU / METEOR / TER).

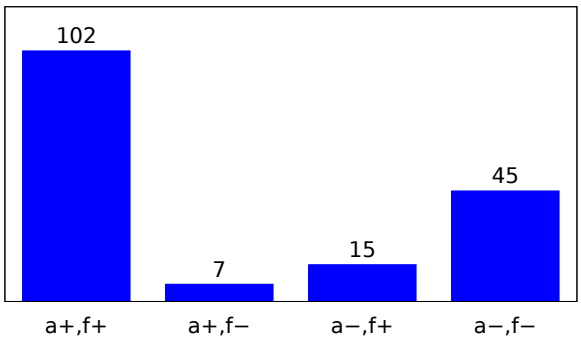

Figure 2: Results of the human pairwise preference ranking experiment, given as the joint distribution of both rankings: $a+$ denotes preference for TSR-CNN in terms of accuracy, $f+$ in terms of fluency; $a-$ denotes preference for the in-domain baseline in terms of accuracy, $f-$ in terms of fluency.

The text-based retrieval baseline TSR-TXT never significantly outperformed the in-domain cdec baseline, but there were slight nominal improvements in terms of BLEU, METEOR and TER. This finding is actually consistent with Wäschle and Riezler (2015) who report performance gains for text-based, target side retrieval models only on highly technical, narrow-domain corpora and even report performance degradation on medium-diversity corpora such as Europarl. Our experiments show that it is the addition of visual similarity information by incorporation of multimodal pivots into the image-enhanced models TSR-CNN and TSR-HCA which makes such techniques effective on MS COCO, thus upholding our hypothesis that visual information can be exploited for improvement of caption translation.

4.6 Human Evaluation

The in-domain baseline and TSR-CNN differed in their output in 169 out of 500 cases on the test set. These 169 cases were presented to a human judge alongside the German source captions in a double-blinded pairwise preference ranking experiment. The order of presentation was randomized for the two systems. The judge was asked to rank fluency and accuracy of the translations independently. The results are given in Figure 2. Overall, there was a clear preference for the output of TSR-CNN.

4.7 Examples

Table 5 shows example translations produced by both cdec baselines, TSR-TXT, TSR-CNN, and TSR-HCA, together with source caption, image, and reference translation. The visual information induced by target side captions of pivot images allows a disambiguation of translation alternatives such as "skirt" versus "rock (music)" for the German "Rock", "pole" versus "mast" for the German "Masten", and is able to repair mistranslations such as "foot" instead of "mouth" for the German "Maul".

5 Conclusions and Further Work

We demonstrated that the incorporation of multimodal pivots into a target-side retrieval model improved SMT performance compared to a strong in-domain baseline in terms of BLEU, METEOR and TER on our parallel dataset derived from MS COCO. The gain in performance was comparable between a distance metric based on a deep convolutional network and one based on human object category annotations, demonstrating the effectiveness of the CNN-derived distance measure. Using our approach, SMT can, in certain cases, profit from multimodal context information. Crucially, this is possible without using large amounts of in-domain parallel text data, but instead using large amounts of monolingual image captions that are more readily available.

Learning semantically informative distance metrics using deep learning techniques is an area under active investigation (Wu et al., 2013; Wang et al., 2014; Wang et al., 2015). Despite the fact that our simple distance metric performed comparably to human object annotations, using such high-level semantic distance metrics for caption translation by multimodal pivots is a promising avenue for further research.

The results were achieved on one language pair (German-English) and one corpus (MS COCO) only. As with all retrieval-based methods, generalized statements about the relative performance on corpora of various domains, sizes and qualities are difficult to substantiate. This problem is aggravated in the multimodal case, since the relevance of captions with respect to images varies greatly between different corpora (Hodosh et al., 2013). In future work, we plan to evaluate our approach in more naturalistic settings, such machine translation for captions in online multimedia repositories

such as Wikimedia Commons[16] and digitized art catalogues, as well as e-commerce localization.

A further avenue of future research is improving models such as that presented in Elliott et al. (2015) by crucial components of neural MT such as "attention mechanisms". For example, the attention mechanism of Bahdanau et al. (2015) serves as a soft alignment that helps to guide the translation process by influencing the sequence in which source tokens are translated. A similar mechanism is used in Xu et al. (2015) to decide which part of the image should influence which part of the generated caption. Combining these two types of attention mechanisms in a neural caption translation model is a natural next step in caption translation. While this is beyond the scope of this work, our models should provide an informative baseline against which to evaluate such methods.

Harnessing Deep Neural Networks with Logic Rules

Zhiting Hu, Xuezhe Ma, Zhengzhong Liu, Eduard Hovy, Eric P. Xing

Abstract

Combining deep neural networks with structured logic rules is desirable to harness flexibility and reduce uninterpretability of the neural models. We propose a general framework capable of enhancing various types of neural networks (e.g., CNNs and RNNs) with declarative first-order logic rules. Specifically, we develop an iterative distillation method that transfers the structured information of logic rules into the weights of neural networks. We deploy the framework on a CNN for sentiment analysis, and an RNN for named entity recognition. With a few highly intuitive rules, we obtain substantial improvements and achieve state-of-the-art or comparable results to previous best-performing systems.

1 Introduction

Deep neural networks provide a powerful mechanism for learning patterns from massive data, achieving new levels of performance on image classification (Krizhevsky et al., 2012), speech recognition (Hinton et al., 2012), machine translation (Bahdanau et al., 2014), playing strategic board games (Silver et al., 2016), and so forth.

Despite the impressive advances, the widely-used DNN methods still have limitations. The high predictive accuracy has heavily relied on large amounts of labeled data; and the purely data-driven learning can lead to uninterpretable and sometimes counter-intuitive results (Szegedy et al., 2014; Nguyen et al., 2015). It is also difficult to encode human intention to guide the models to capture desired patterns, without expensive direct supervision or ad-hoc initialization.

On the other hand, the cognitive process of human beings have indicated that people learn not only from concrete examples (as DNNs do) but also from different forms of general knowledge and rich experiences (Minksy, 1980; Lake et al., 2015). *Logic rules* provide a flexible declarative language for communicating high-level cognition and expressing structured knowledge. It is therefore desirable to integrate logic rules into DNNs, to transfer human intention and domain knowledge to neural models, and regulate the learning process.

In this paper, we present a framework capable of enhancing general types of neural networks, such as convolutional networks (CNNs) and recurrent networks (RNNs), on various tasks, with logic rule knowledge. Combining symbolic representations with neural methods have been considered in different contexts. Neural-symbolic systems (Garcez et al., 2012) construct a network from a given rule set to execute reasoning. To exploit *a priori* knowledge in general neural architectures, recent work augments each raw data instance with useful features (Collobert et al., 2011), while network training, however, is still limited to instance-label supervision and suffers from the same issues mentioned above. Besides, a large variety of structural knowledge cannot be naturally encoded in the feature-label form.

Our framework enables a neural network to learn simultaneously from labeled instances as well as logic rules, through an *iterative rule knowledge distillation* procedure that transfers the structured information encoded in the logic rules into the network parameters. Since the general logic rules are complementary to the specific data labels, a natural "side-product" of the integration is the support for semi-supervised learning where unlabeled data is used to better absorb the logical knowledge. Methodologically, our approach can be seen as a combination of the knowledge distillation (Hinton et al., 2015; Bucilu et al., 2006) and the posterior regularization (PR) method (Ganchev et al., 2010).

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2410–2420,
Berlin, Germany, August 7-12, 2016.

In particular, at each iteration we adapt the posterior constraint principle from PR to construct a rule-regularized *teacher*, and train the *student* network of interest to imitate the predictions of the teacher network. We leverage soft logic to support flexible rule encoding.

We apply the proposed framework on both CNN and RNN, and deploy on the task of sentiment analysis (SA) and named entity recognition (NER), respectively. With only a few (one or two) very intuitive rules, both the distilled networks and the joint teacher networks strongly improve over their basic forms (without rules), and achieve better or comparable performance to state-of-the-art models which typically have more parameters and complicated architectures.

To the best of our knowledge, this is the first work to integrate logic rules with general workhorse types of deep neural networks in a principled framework. The encouraging results indicate our method can be potentially useful for incorporating richer types of human knowledge, and improving other application domains.

2 Related Work

Combination of logic rules and neural networks has been considered in different contexts. Neural-symbolic systems (Garcez et al., 2012), such as KBANN (Towell et al., 1990) and CILP++ (França et al., 2014), construct network architectures from given rules to perform reasoning and knowledge acquisition. A related line of research, such as Markov logic networks (Richardson and Domingos, 2006), derives probabilistic graphical models (rather than neural networks) from the rule set.

With the recent success of deep neural networks in a vast variety of application domains, it is increasingly desirable to incorporate structured logic knowledge into general types of networks to harness flexibility and reduce uninterpretability. Recent work that trains on extra features from domain knowledge (Collobert et al., 2011), while producing improved results, does not go beyond the data-label paradigm. Kulkarni et al. (2015) uses a specialized training procedure with careful ordering of training instances to obtain an interpretable neural layer of an image network. Karaletsos et al. (2016) develops a generative model jointly over data-labels and similarity knowledge expressed in triplet format to learn improved disentangled representations.

Though there do exist general frameworks that allow encoding various structured constraints on latent variable models (Ganchev et al., 2010; Zhu et al., 2014; Liang et al., 2009), they either are not directly applicable to the NN case, or could yield inferior performance as in our empirical study. Liang et al. (2008) transfers predictive power of pre-trained structured models to unstructured ones in a pipelined fashion.

Our proposed approach is distinct in that we use an iterative rule distillation process to effectively transfer rich structured knowledge, expressed in the declarative first-order logic language, into parameters of general neural networks. We show that the proposed approach strongly outperforms an extensive array of other either ad-hoc or general integration methods.

3 Method

In this section we present our framework which encapsulates the logical structured knowledge into a neural network. This is achieved by forcing the network to emulate the predictions of a rule-regularized teacher, and evolving both models iteratively throughout training (section 3.2). The process is agnostic to the network architecture, and thus applicable to general types of neural models including CNNs and RNNs. We construct the teacher network in each iteration by adapting the posterior regularization principle in our logical constraint setting (section 3.3), where our formulation provides a closed-form solution. Figure 1 shows an overview of the proposed framework.

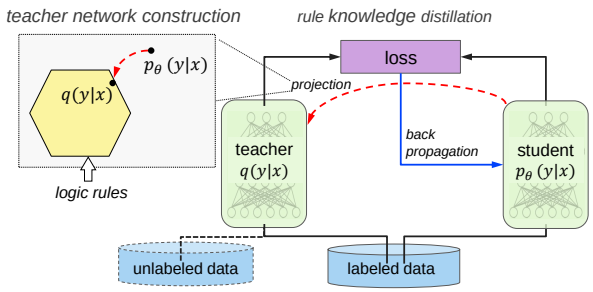

Figure 1: Framework Overview. At each iteration, the teacher network is obtained by projecting the student network to a rule-regularized subspace (red dashed arrow); and the student network is updated to balance between emulating the teacher's output and predicting the true labels (black/blue solid arrows).

3.1 Learning Resources: Instances and Rules

Our approach allows neural networks to learn from both specific examples and general rules. Here we give the settings of these "learning resources".

Assume we have input variable $\boldsymbol{x} \in \mathcal{X}$ and target variable $\boldsymbol{y} \in \mathcal{Y}$. For clarity, we focus on K-way classification, where $\mathcal{Y} = \Delta^K$ is the K-dimensional probability simplex and $\boldsymbol{y} \in \{0,1\}^K \subset \mathcal{Y}$ is a one-hot encoding of the class label. However, our method specification can straightforwardly be applied to other contexts such as regression and sequence learning (e.g., NER tagging, which is a sequence of classification decisions). The training data $\mathcal{D} = \{(\boldsymbol{x}_n, \boldsymbol{y}_n)\}_{n=1}^N$ is a set of instantiations of $(\boldsymbol{x}, \boldsymbol{y})$.

Further consider a set of first-order logic (FOL) rules with confidences, denoted as $\mathcal{R} = \{(R_l, \lambda_l)\}_{l=1}^L$, where R_l is the lth rule over the input-target space $(\mathcal{X}, \mathcal{Y})$, and $\lambda_l \in [0, \infty]$ is the confidence level with $\lambda_l = \infty$ indicating a hard rule, i.e., all groundings are required to be true (=1). Here a grounding is the logic expression with all variables being instantiated. Given a set of examples $(\boldsymbol{X}, \boldsymbol{Y}) \subset (\mathcal{X}, \mathcal{Y})$ (e.g., a minibatch from $\mathcal{D}$), the set of groundings of R_l are denoted as $\{r_{lg}(\boldsymbol{X}, \boldsymbol{Y})\}_{g=1}^{G_l}$. In practice a rule grounding is typically relevant to only a single or subset of examples, though here we give the most general form on the entire set.

We encode the FOL rules using soft logic (Bach et al., 2015) for flexible encoding and stable optimization. Specifically, soft logic allows continuous truth values from the interval $[0, 1]$ instead of $\{0, 1\}$, and the Boolean logic operators are reformulated as:

$$\begin{aligned} &A \& B = \max\{A + B - 1, 0\} \\ &A \vee B = \min\{A + B, 1\} \\ &A_1 \wedge \cdots \wedge A_N = \textstyle\sum_i A_i / N \\ &\neg A = 1 - A \end{aligned} \tag{1}$$

Here $\&$ and $\wedge$ are two different approximations to logical conjunction (Foulds et al., 2015): $\&$ is useful as a selection operator (e.g., $A \& B = B$ when $A = 1$, and $A \& B = 0$ when $A = 0$), while $\wedge$ is an averaging operator.

3.2 Rule Knowledge Distillation

A neural network defines a conditional probability $p_\theta(\boldsymbol{y}|\boldsymbol{x})$ by using a softmax output layer that produces a K-dimensional soft prediction vector denoted as $\boldsymbol{\sigma}_\theta(\boldsymbol{x})$. The network is parameterized by weights $\boldsymbol{\theta}$. Standard neural network training has been to iteratively update $\boldsymbol{\theta}$ to produce the correct labels of training instances. To integrate the information encoded in the rules, we propose to train the network to also imitate the outputs of a rule-regularized projection of $p_\theta(\boldsymbol{y}|\boldsymbol{x})$, denoted as $q(\boldsymbol{y}|\boldsymbol{x})$, which explicitly includes rule constraints as regularization terms. In each iteration q is constructed by projecting p_θ into a subspace constrained by the rules, and thus has desirable properties. We present the construction in the next section. The prediction behavior of q reveals the information of the regularized subspace and structured rules. Emulating the q outputs serves to transfer this knowledge into p_θ. The new objective is then formulated as a balancing between imitating the soft predictions of q and predicting the true hard labels:

$$\begin{aligned} \boldsymbol{\theta}^{(t+1)} = \arg\min_{\theta \in \Theta} \frac{1}{N} \sum_{n=1}^{N} &(1 - \pi) \ell(\boldsymbol{y}_n, \boldsymbol{\sigma}_\theta(\boldsymbol{x}_n)) \\ &+ \pi \ell(\boldsymbol{s}_n^{(t)}, \boldsymbol{\sigma}_\theta(\boldsymbol{x}_n)), \end{aligned} \tag{2}$$

where ℓ denotes the loss function selected according to specific applications (e.g., the cross entropy loss for classification); $\boldsymbol{s}_n^{(t)}$ is the soft prediction vector of q on $\boldsymbol{x}_n$ at iteration t; and π is the imitation parameter calibrating the relative importance of the two objectives.

A similar imitation procedure has been used in other settings such as model compression (Bucilu et al., 2006; Hinton et al., 2015) where the process is termed *distillation*. Following them we call $p_\theta(\boldsymbol{y}|\boldsymbol{x})$ the "student" and $q(\boldsymbol{y}|\boldsymbol{x})$ the "teacher", which can be intuitively explained in analogous to human education where a teacher is aware of systematic general rules and she instructs students by providing her solutions to particular questions (i.e., the soft predictions). An important difference from previous distillation work, where the teacher is obtained beforehand and the student is trained thereafter, is that our teacher and student are learned simultaneously during training.

Though it is possible to combine a neural network with rule constraints by projecting the network to the rule-regularized subspace after it is fully trained as before with only data-label instances, or by optimizing projected network directly, we found our iterative teacher-student distillation approach provides a much superior performance, as shown in the experiments. Moreover, since p_θ distills the rule information into the

weights $\boldsymbol{\theta}$ instead of relying on explicit rule representations, we can use p_θ for predicting new examples at test time when the rule assessment is expensive or even unavailable (i.e., the *privileged information* setting (Lopez-Paz et al., 2016)) while still enjoying the benefit of integration. Besides, the second loss term in Eq.(2) can be augmented with rich unlabeled data in addition to the labeled examples, which enables *semi-supervised* learning for better absorbing the rule knowledge.

3.3 Teacher Network Construction

We now proceed to construct the teacher network $q(\boldsymbol{y}|\boldsymbol{x})$ at each iteration from $p_\theta(\boldsymbol{y}|\boldsymbol{x})$. The iteration index t is omitted for clarity. We adapt the posterior regularization principle in our logic constraint setting. Our formulation ensures a closed-form solution for q and thus avoids any significant increases in computational overhead.

Recall the set of FOL rules $\mathcal{R} = \{(R_l, \lambda_l)\}_{l=1}^L$. Our goal is to find the optimal q that fits the rules while at the same time staying close to p_θ. For the first property, we apply a commonly-used strategy that imposes the rule constraints on q through an expectation operator. That is, for each rule (indexed by l) and each of its groundings (indexed by g) on $(\boldsymbol{X}, \boldsymbol{Y})$, we expect $\mathbb{E}_{q(\boldsymbol{Y}|\boldsymbol{X})}[r_{lg}(\boldsymbol{X}, \boldsymbol{Y})] = 1$, with confidence λ_l. The constraints define a rule-regularized space of all valid distributions. For the second property, we measure the closeness between q and p_θ with KL-divergence, and wish to minimize it. Combining the two factors together and further allowing slackness for the constraints, we finally get the following optimization problem:

$$\begin{aligned} \min_{q, \boldsymbol{\xi} \geq 0} \ & \mathrm{KL}(q(\boldsymbol{Y}|\boldsymbol{X}) \| p_\theta(\boldsymbol{Y}|\boldsymbol{X})) + C \sum\nolimits_{l, g_l} \xi_{l, g_l} \\ \text{s.t. } & \lambda_l (1 - \mathbb{E}_q[r_{l, g_l}(\boldsymbol{X}, \boldsymbol{Y})]) \leq \xi_{l, g_l} \\ & g_l = 1, \ldots, G_l, \ \ l = 1, \ldots, L, \end{aligned} \tag{3}$$

where $\xi_{l,g_l} \geq 0$ is the slack variable for respective logic constraint; and C is the regularization parameter. The problem can be seen as projecting p_θ into the constrained subspace. The problem is convex and can be efficiently solved in its dual form with closed-form solutions. We provide the detailed derivation in the supplementary materials and directly give the solution here:

$$q^*(\boldsymbol{Y}|\boldsymbol{X}) \propto p_\theta(\boldsymbol{Y}|\boldsymbol{X}) \exp\left\{ -\sum_{l, g_l} C \lambda_l (1 - r_{l, g_l}(\boldsymbol{X}, \boldsymbol{Y})) \right\} \tag{4}$$

Intuitively, a strong rule with large λ_l will lead to low probabilities of predictions that fail to meet the constraints. We discuss the computation of the normalization factor in section 3.4.

Our framework is related to the posterior regularization (PR) method (Ganchev et al., 2010) which places constraints over model posterior in unsupervised setting. In classification, our optimization procedure is analogous to the modified EM algorithm for PR, by using cross-entropy loss in Eq.(2) and evaluating the second loss term on unlabeled data differing from $\mathcal{D}$, so that Eq.(4) corresponds to the E-step and Eq.(2) is analogous to the M-step. This sheds light from another perspective on why our framework would work. However, we found in our experiments (section 5) that to produce strong performance it is crucial to use the same labeled data $\boldsymbol{x}_n$ in the two losses of Eq.(2) so as to form a direct trade-off between imitating soft predictions and predicting correct hard labels.

3.4 Implementations

The procedure of iterative distilling optimization of our framework is summarized in Algorithm 1.

During training we need to compute the soft predictions of q at each iteration, which is straightforward through direct enumeration if the rule constraints in Eq.(4) are factored in the same way as the base neural model p_θ (e.g., the "but"-rule of sentiment classification in section 4.1). If the constraints introduce additional dependencies, e.g., bigram dependency as the transition rule in the NER task (section 4.2), we can use dynamic programming for efficient computation. For higher-order constraints (e.g., the listing rule in NER), we approximate through Gibbs sampling that iteratively samples from $q(\boldsymbol{y}_i|\boldsymbol{y}_{-i}, \boldsymbol{x})$ for each position i. If the constraints span multiple instances, we group the relevant instances in minibatches for joint inference (and randomly break some dependencies when a group is too large). Note that calculating the soft predictions is efficient since only one NN forward pass is required to compute the base distribution $p_\theta(\boldsymbol{y}|\boldsymbol{x})$ (and few more, if needed, for calculating the truth values of relevant rules).

p v.s. q at Test Time At test time we can use either the distilled student network p, or the teacher network q after a final projection. Our empirical results show that both models substantially improve over the base network that is trained with only data-label instances. In general q performs better than p. Particularly, q is more suitable when the logic rules introduce additional dependencies (e.g., span-

Algorithm 1 Harnessing NN with Rules

Input: The training data $\mathcal{D} = \{(\boldsymbol{x}_n, \boldsymbol{y}_n)\}_{n=1}^{N}$,
The rule set $\mathcal{R} = \{(R_l, \lambda_l)\}_{l=1}^{L}$,
Parameters: π – imitation parameter
C – regularization strength

1: Initialize neural network parameter $\boldsymbol{\theta}$
2: **repeat**
3: Sample a minibatch $(\boldsymbol{X}, \boldsymbol{Y}) \subset \mathcal{D}$
4: Construct teacher network q with Eq.(4)
5: Transfer knowledge into p_θ by updating $\boldsymbol{\theta}$ with Eq.(2)
6: **until** convergence

Output: Distill student network p_θ and teacher network q

ning over multiple examples), requiring joint inference. In contrast, as mentioned above, p is more lightweight and efficient, and useful when rule evaluation is expensive or impossible at prediction time. Our experiments compare the performance of p and q extensively.

Imitation Strength π The imitation parameter π in Eq.(2) balances between emulating the teacher soft predictions and predicting the true hard labels. Since the teacher network is constructed from p_θ, which, at the beginning of training, would produce low-quality predictions, we thus favor predicting the true labels more at initial stage. As training goes on, we gradually bias towards emulating the teacher predictions to effectively distill the structured knowledge. Specifically, we define $\pi^{(t)} = \min\{\pi_0, 1 - \alpha^t\}$ at iteration $t \geq 0$, where $\alpha \leq 1$ specifies the speed of decay and $\pi_0 < 1$ is a lower bound.

4 Applications

We have presented our framework that is general enough to improve various types of neural networks with rules, and easy to use in that users are allowed to impose their knowledge and intentions through the declarative first-order logic. In this section we illustrate the versatility of our approach by applying it on two workhorse network architectures, i.e., convolutional network and recurrent network, on two representative applications, i.e., *sentence-level sentiment analysis* which is a classification problem, and *named entity recognition* which is a sequence learning problem.

For each task, we first briefly describe the base neural network. Since we are not focusing on tuning network architectures, we largely use the same or similar networks to previous successful neural models. We then design the linguistically-motivated rules to be integrated.

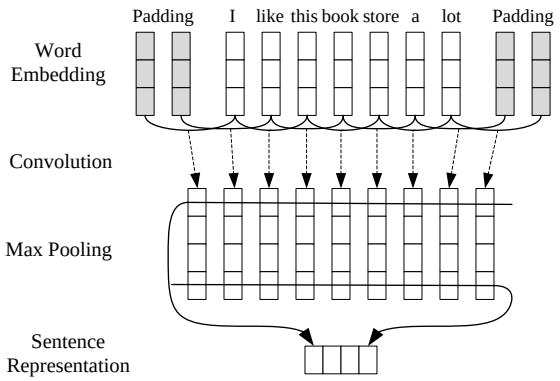

Figure 2: The CNN architecture for sentence-level sentiment analysis. The sentence representation vector is followed by a fully-connected layer with softmax output activation, to output sentiment predictions.

4.1 Sentiment Classification

Sentence-level sentiment analysis is to identify the sentiment (e.g., positive or negative) underlying an individual sentence. The task is crucial for many opinion mining applications. One challenging point of the task is to capture the contrastive sense (e.g., by conjunction "but") within a sentence.

Base Network We use the single-channel convolutional network proposed in (Kim, 2014). The simple model has achieved compelling performance on various sentiment classification benchmarks. The network contains a convolutional layer on top of word vectors of a given sentence, followed by a max-over-time pooling layer and then a fully-connected layer with softmax output activation. A convolution operation is to apply a filter to word windows. Multiple filters with varying window sizes are used to obtain multiple features. Figure 2 shows the network architecture.

Logic Rules One difficulty for the plain neural network is to identify contrastive sense in order to capture the dominant sentiment precisely. The conjunction word "but" is one of the strong indicators for such sentiment changes in a sentence, where the sentiment of clauses following "but" generally dominates. We thus consider sentences S with an "A-but-B" structure, and expect the sentiment of the whole sentence to be consistent with the sentiment of clause B. The logic rule is written as:

$$\begin{aligned} &\text{has-'A-but-B'-structure}(S) \Rightarrow \\ &(\mathbf{1}(y = +) \Rightarrow \boldsymbol{\sigma}_\theta(B)_+ \ \wedge \ \boldsymbol{\sigma}_\theta(B)_+ \Rightarrow \mathbf{1}(y = +)), \end{aligned} \tag{5}$$

where $\mathbf{1}(\cdot)$ is an indicator function that takes 1 when its argument is true, and 0 otherwise; class '+' represents 'positive'; and $\boldsymbol{\sigma}_\theta(B)_+$ is the element of $\boldsymbol{\sigma}_\theta(B)$ for class '+'. By Eq.(1), when S has the 'A-but-B' structure, the truth value of the above logic rule equals to $(1 + \boldsymbol{\sigma}_\theta(B)_+)/2$ when $y = +$, and $(2 - \boldsymbol{\sigma}_\theta(B)_+)/2$ otherwise [1]. Note that here we assume two-way classification (i.e., positive and negative), though it is straightforward to design rules for finer grained sentiment classification.

4.2 Named Entity Recognition

NER is to locate and classify elements in text into entity categories such as "persons" and "organizations". It is an essential first step for downstream language understanding applications. The task assigns to each word a named entity tag in an "X-Y" format where X is one of BIEOS (Beginning, Inside, End, Outside, and Singleton) and Y is the entity category. A valid tag sequence has to follow certain constraints by the definition of the tagging scheme. Besides, text with structures (e.g., lists) within or across sentences can usually expose some consistency patterns.

Base Network The base network has a similar architecture with the bi-directional LSTM recurrent network (called BLSTM-CNN) proposed in (Chiu and Nichols, 2015) for NER which has outperformed most of previous neural models. The model uses a CNN and pre-trained word vectors to capture character- and word-level information, respectively. These features are then fed into a bi-directional RNN with LSTM units for sequence tagging. Compared to (Chiu and Nichols, 2015) we omit the character type and capitalization features, as well as the additive transition matrix in the output layer. Figure 3 shows the network architecture.

Logic Rules The base network largely makes independent tagging decisions at each position, ignoring the constraints on successive labels for a valid tag sequence (e.g., I-ORG cannot follow B-PER). In contrast to recent work (Lample et al., 2016) which adds a conditional random field (CRF) to capture bi-gram dependencies between outputs, we instead apply logic rules which does not introduce extra parameters to learn. An example rule is:

$$\text{equal}(y_{i-1}, \text{I-ORG}) \Rightarrow \neg\, \text{equal}(y_i, \text{B-PER}) \qquad (6)$$

[1] Replacing $\wedge$ with & in Eq.(5) leads to a probably more intuitive rule which takes the value $\boldsymbol{\sigma}_\theta(B)_+$ when $y = +$, and $1 - \boldsymbol{\sigma}_\theta(B)_+$ otherwise.

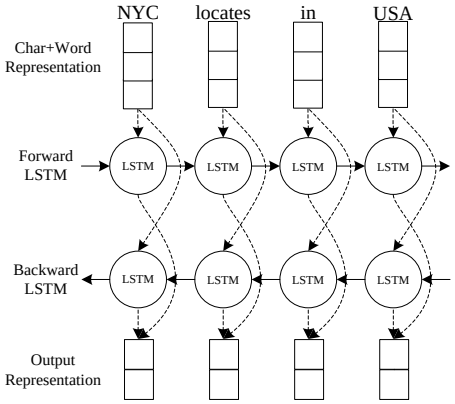

Figure 3: The architecture of the bidirectional LSTM recurrent network for NER. The CNN for extracting character representation is omitted.

The confidence levels are set to ∞ to prevent any violation.

We further leverage the *list* structures within and across sentences of the same documents. Specifically, named entities at corresponding positions in a list are likely to be in the same categories. For instance, in "1. Juventus, 2. Barcelona, 3. ..." we know "Barcelona" must be an organization rather than a location, since its counterpart entity "Juventus" is an organization. We describe our simple procedure for identifying lists and counterparts in the supplementary materials. The logic rule is encoded as:

$$\text{is-counterpart}(X, A) \Rightarrow 1 - \|c(\boldsymbol{e}_y) - c(\boldsymbol{\sigma}_\theta(A))\|_2, \quad (7)$$

where $\boldsymbol{e}_y$ is the one-hot encoding of y (the class prediction of X); $c(\cdot)$ collapses the probability mass on the labels with the same categories into a single probability, yielding a vector with length equaling to the number of categories. We use ℓ_2 distance as a measure for the closeness between predictions of X and its counterpart A. Note that the distance takes value in $[0, 1]$ which is a proper soft truth value. The list rule can span multiple sentences (within the same document). We found the teacher network q that enables explicit joint inference provides much better performance over the distilled student network p (section 5).

5 Experiments

We validate our framework by evaluating its applications of sentiment classification and named entity recognition on a variety of public benchmarks. By integrating the simple yet effective rules with

	Model	SST2	MR	CR
1	CNN (Kim, 2014)	87.2	81.3±0.1	84.3±0.2
2	CNN-Rule-p	88.8	81.6±0.1	85.0±0.3
3	CNN-Rule-q	89.3	**81.7±0.1**	**85.3±0.3**
4	MGNC-CNN (Zhang et al., 2016)	88.4	–	–
5	MVCNN (Yin and Schutze, 2015)	**89.4**	–	–
6	CNN-multichannel (Kim, 2014)	88.1	81.1	85.0
7	Paragraph-Vec (Le and Mikolov, 2014)	87.8	–	–
8	CRF-PR (Yang and Cardie, 2014)	–	–	82.7
9	RNTN (Socher et al., 2013)	85.4	–	–
10	G-Dropout (Wang and Manning, 2013)	–	79.0	82.1

Table 1: Accuracy (%) of Sentiment Classification. Row 1, CNN (Kim, 2014) is the base network corresponding to the "CNN-non-static" model in (Kim, 2014). Rows 2-3 are the networks enhanced by our framework: CNN-Rule-p is the student network and CNN-Rule-q is the teacher network. For MR and CR, we report the average accuracy±one standard deviation using 10-fold cross validation.

the base networks, we obtain substantial improvements on both tasks and achieve state-of-the-art or comparable results to previous best-performing systems. Comparison with a diverse set of other rule integration methods demonstrates the unique effectiveness of our framework. Our approach also shows promising potentials in the semi-supervised learning and sparse data context.

Throughout the experiments we set the regularization parameter to $C = 400$. In sentiment classification we set the imitation parameter to $\pi^{(t)} = 1 - 0.9^t$, while in NER $\pi^{(t)} = \min\{0.9, 1 - 0.9^t\}$ to downplay the noisy listing rule. The confidence levels of rules are set to $\lambda_l = 1$, except for hard constraints whose confidence is ∞. For neural network configuration, we largely followed the reference work, as specified in the following respective sections. All experiments were performed on a Linux machine with eight 4.0GHz CPU cores, one Tesla K40c GPU, and 32GB RAM. We implemented neural networks using Theano [2], a popular deep learning platform.

5.1 Sentiment Classification

5.1.1 Setup

We test our method on a number of commonly used benchmarks, including **1) SST2**, Stanford Sentiment Treebank (Socher et al., 2013) which contains 2 classes (negative and positive), and 6920/872/1821 sentences in the train/dev/test sets respectively. Following (Kim, 2014) we train models on both sentences and phrases since all labels are provided. **2) MR** (Pang and Lee, 2005), a set of 10,662 one-sentence movie reviews with negative or positive sentiment. **3) CR** (Hu and Liu, 2004), customer reviews of various products, containing 2 classes and 3,775 instances. For MR and CR, we use 10-fold cross validation as in previous work. In each of the three datasets, around 15% sentences contains the word "but".

For the base neural network we use the "non-static" version in (Kim, 2014) with the exact same configurations. Specifically, word vectors are initialized using word2vec (Mikolov et al., 2013) and fine-tuned throughout training, and the neural parameters are trained using SGD with the Adadelta update rule (Zeiler, 2012).

5.1.2 Results

Table 1 shows the sentiment classification performance. Rows 1-3 compare the base neural model with the models enhanced by our framework with the "but"-rule (Eq.(5)). We see that our method provides a strong boost on accuracy over all three datasets. The teacher network q further improves over the student network p, though the student network is more widely applicable in certain contexts as discussed in sections 3.2 and 3.4. Rows 4-10 show the accuracy of recent top-performing methods. On the MR and CR datasets, our model outperforms all the baselines. On SST2, MVCNN (Yin and Schutze, 2015) (Row 5) is the only system that shows a slightly better result than ours. Their neural network has combined diverse sets of pre-trained word embeddings (while we use only word2vec) and contained more neural layers and parameters than our model.

To further investigate the effectiveness of our framework in integrating structured rule knowledge, we compare with an extensive array of other

[2] http://deeplearning.net/software/theano

	Model	Accuracy (%)
1	CNN (Kim, 2014)	87.2
2	-but-clause	87.3
3	-ℓ_2-reg	87.5
4	-project	87.9
5	-opt-project	88.3
6	-pipeline	87.9
7	-Rule-p	88.8
8	-Rule-q	**89.3**

Table 2: Performance of different rule integration methods on SST2. 1) CNN is the base network; 2) "-but-clause" takes the clause after "but" as input; 3) "-ℓ_2-reg" imposes a regularization term $\gamma\|\boldsymbol{\sigma}_\theta(S) - \boldsymbol{\sigma}_\theta(Y)\|_2$ to the CNN objective, with the strength γ selected on dev set; 4) "-project" projects the trained base CNN to the rule-regularized subspace with Eq.(3); 5) "-opt-project" directly optimizes the projected CNN; 6) "-pipeline" distills the pre-trained "-opt-project" to a plain CNN; 7-8) "-Rule-p" and "-Rule-q" are our models with p being the distilled student network and q the teacher network. Note that "-but-clause" and "-ℓ_2-reg" are ad-hoc methods applicable specifically to the "but"-rule.

possible integration approaches. Table 2 lists these methods and their performance on the SST2 task. We see that: 1) Although all methods lead to different degrees of improvement, our framework outperforms all other competitors with a large margin. 2) In particular, compared to the pipelined method in Row 6 which is in analogous to the structure compilation work (Liang et al., 2008), our iterative distillation (section 3.2) provides better performance. Another advantage of our method is that we only train one set of neural parameters, as opposed to two separate sets as in the pipelined approach. 3) The distilled student network "-Rule-p" achieves much superior accuracy compared to the base CNN, as well as "-project" and "-opt-project" which explicitly project CNN to the rule-constrained subspace. This validates that our distillation procedure transfers the structured knowledge into the neural parameters effectively. The inferior accuracy of "-opt-project" can be partially attributed to the poor performance of its neural network part which achieves only 85.1% accuracy and leads to inaccurate evaluation of the "but"-rule in Eq.(5).

We next explore the performance of our framework with varying numbers of labeled instances as well as the effect of exploiting unlabeled data. Intuitively, with less labeled examples we expect the general rules would contribute more to the performance, and unlabeled data should help better learn from the rules. This can be a useful property especially when data are sparse and labels are expensive to obtain. Table 3 shows the results. The subsampling is conducted on the sentence level. That is, for instance, in "5%" we first selected 5% training sentences uniformly at random, then trained the models on these sentences as well as their phrases. The results verify our expectations. 1) Rows 1-3 give the accuracy of using only data-label subsets for training. In every setting our methods consistently outperform the base CNN. 2) "-Rule-q" provides higher improvement on 5% data (with margin 2.6%) than on larger data (e.g., 2.3% on 10% data, and 2.0% on 30% data), showing promising potential in the sparse data context. 3) By adding unlabeled instances for semi-supervised learning as in Rows 5-6, we get further improved accuracy. 4) Row 4, "-semi-PR" is the posterior regularization (Ganchev et al., 2010) which imposes the rule constraint through only unlabeled data during training. Our distillation framework consistently provides substantially better results.

	Data size	5%	10%	30%	100%
1	CNN	79.9	81.6	83.6	87.2
2	-Rule-p	81.5	83.2	84.5	88.8
3	-Rule-q	82.5	83.9	85.6	**89.3**
4	-semi-PR	81.5	83.1	84.6	–
5	-semi-Rule-p	81.7	83.3	84.7	–
6	-semi-Rule-q	**82.7**	**84.2**	**85.7**	–

Table 3: Accuracy (%) on SST2 with varying sizes of labeled data and semi-supervised learning. The header row is the percentage of labeled examples for training. Rows 1-3 use only the supervised data. Rows 4-6 use semi-supervised learning where the remaining training data are used as unlabeled examples. For "-semi-PR" we only report its projected solution (in analogous to q) which performs better than the non-projected one (in analogous to p).

5.2 Named Entity Recognition

5.2.1 Setup

We evaluate on the well-established CoNLL-2003 NER benchmark (Tjong Kim Sang and De Meulder, 2003), which contains 14,987/3,466/3,684 sentences and 204,567/51,578/46,666 tokens in train/dev/test sets, respectively. The dataset includes 4 categories, i.e., *person, location, organization*, and *misc*. BIOES tagging scheme is used.

	Model	F1
1	BLSTM	89.55
2	BLSTM-Rule-trans	p: 89.80, q: 91.11
3	BLSTM-Rules	p: 89.93, q: **91.18**
4	NN-lex (Collobert et al., 2011)	89.59
5	S-LSTM (Lample et al., 2016)	90.33
6	BLSTM-lex (Chiu and Nichols, 2015)	90.77
7	BLSTM-CRF$_1$ (Lample et al., 2016)	90.94
8	Joint-NER-EL (Luo et al., 2015)	91.20
9	BLSTM-CRF$_2$ (Ma and Hovy, 2016)	**91.21**

Table 4: Performance of NER on CoNLL-2003. Row 2, BLSTM-Rule-trans imposes the transition rules (Eq.(6)) on the base BLSTM. Row 3, BLSTM-Rules further incorporates the list rule (Eq.(7)). We report the performance of both the student model p and the teacher model q.

Around 1.7% named entities occur in lists.

We use the mostly same configurations for the base BLSTM network as in (Chiu and Nichols, 2015), except that, besides the slight architecture difference (section 4.2), we apply Adadelta for parameter updating. GloVe (Pennington et al., 2014) word vectors are used to initialize word features.

5.2.2 Results

Table 4 presents the performance on the NER task. By incorporating the bi-gram transition rules (Row 2), the joint teacher model q achieves 1.56 improvement in F1 score that outperforms most previous neural based methods (Rows 4-7), including the BLSTM-CRF model (Lample et al., 2016) which applies a conditional random field (CRF) on top of a BLSTM in order to capture the transition patterns and encourage valid sequences. In contrast, our method implements the desired constraints in a more straightforward way by using the declarative logic rule language, and at the same time does not introduce extra model parameters to learn. Further integration of the list rule (Row 3) provides a second boost in performance, achieving an F1 score very close to the best-performing systems including Joint-NER-EL (Luo et al., 2015) (Row 8), a probabilistic graphical model optimizing NER and entity linking jointly with massive external resources, and BLSTM-CRF (Ma and Hovy, 2016), a combination of BLSTM and CRF with more parameters than our rule-enhanced neural networks.

From the table we see that the accuracy gap between the joint teacher model q and the distilled student p is relatively larger than in the sentiment classification task (Table 1). This is because in the NER task we have used logic rules that introduce extra dependencies between adjacent tag positions as well as multiple instances, making the explicit joint inference of q useful for fulfilling these structured constraints.

6 Discussion and Future Work

We have developed a framework which combines deep neural networks with first-order logic rules to allow integrating human knowledge and intentions into the neural models. In particular, we proposed an iterative distillation procedure that transfers the structured information of logic rules into the weights of neural networks. The transferring is done via a teacher network constructed using the posterior regularization principle. Our framework is general and applicable to various types of neural architectures. With a few intuitive rules, our framework significantly improves base networks on sentiment analysis and named entity recognition, demonstrating the practical significance of our approach.

Though we have focused on first-order logic rules, we leveraged soft logic formulation which can be easily extended to general probabilistic models for expressing structured distributions and performing inference and reasoning (Lake et al., 2015). We plan to explore these diverse knowledge representations to guide the DNN learning. The proposed iterative distillation procedure also reveals connections to recent neural autoencoders (Kingma and Welling, 2014; Rezende et al., 2014) where generative models encode probabilistic structures and neural recognition models distill the information through iterative optimization (Rezende et al., 2016; Johnson et al., 2016; Karaletsos et al., 2016).

The encouraging empirical results indicate a strong potential of our approach for improving other application domains such as vision tasks, which we plan to explore in the future. Finally, we also would like to generalize our framework to automatically learn the confidence of different rules, and derive new rules from data.

Case and Cause in Icelandic: Reconstructing Causal Networks of Cascaded Language Changes

Abstract

Linguistic drift is a process that produces slow irreversible changes in the grammar and function of a language's constructions. Importantly, changes in a part of a language can have trickle down effects, triggering changes elsewhere in that language. Although such causally triggered chains of changes have long been hypothesized by historical linguists, no explicit demonstration of the actual causality has been provided. In this study, we use co-occurrence statistics and machine learning to demonstrate that the functions of morphological cases experience a slow, irreversible drift along history, even in a language as conservative as is Icelandic. Crucially, we then move on to demonstrate –using the notion of Granger-causality– that there are explicit *causal* connections between the changes in the functions of the different cases, which are consistent with documented processes in the history of Icelandic. Our technique provides a means for the quantitative reconstruction of connected networks of subtle linguistic changes.

1 Introduction

Sapir (1921/2014, p. 123) noticed that "Language moves down on a current of its own making. It has a *drift*" (emphasis added). In Sapir's view, the formation of different dialects requires that the small changes constantly being introduced by the speakers are not just plain white noise, but rather random walks in which minute changes accumulate over time. The very high dimensionality on which languages operate makes cumulative linguistic changes irreversible. Once a change has been effected there is very little chance that the language will ever return to its original state before the change, in the same way that a diffusion process in a very high dimensional space is never going to return to the exact same point in the space. Drift in language is in this respect reminiscent of random genetic drift from evolutionary biology (Wright, 1955). However, Sapir's idea of drift goes further in that he viewed it as a *directional* process, more similar to Wright's (1929) concept of a directional drift related to selectional pressures. In Sapir's view, "language has a 'slope"'; the small changes that accumulate in linguistic drift are not fully random, but rather they reflect the speakers' unconscious cognitive tendency to increase the consistency within their languages. This idea is currently challenged by some researchers (Croft, 2000; Lupyan and Dale, 2015), who are of the opinion that purely random drift –of the same type as that found in genetics–, when coupled with adequate selection mechanisms, is sufficient to account for the diachronic changes observed in the world's languages. Sapir motivated the need for directional change in what he saw as apparent causal chains in language change, which he illustrated with the progressive loss and functional shift of English oblique case markers, into an absolutive case-free system encoding animacy and position relative to the head noun.

'Chain reactions' along the history of a language are particularly well-studied in phonology. Chain shifts (Martinet, 1952) are processes by which the position in perceptual/articulatory space of a phoneme changes in response to the change in position of another phoneme (either moving away from the second phoneme, in a 'push' chain, or moving to occupy the space left void by the other, in a 'pull' chain). A famous example of a chain shift is the Great English Vowel Shift. In a similar fashion, one could think of functional chain shifts

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2421–2430,
Berlin, Germany, August 7-12, 2016.

in morphology, by which a certain morphological category takes over some of the functions of another, triggering a chain of 'push' and/or 'pull' movements in other categories. Such cascaded changes have often been reported in diachronic linguistics (Biberauer and Roberts, 2008; Fisiak, 1984; Lightfoot, 2002; Wittmann, 1983).

Icelandic is a famously conservative language. Compared to most other languages, its grammar has experienced remarkably little change since the high middle ages. For instance, Barðdal and Eythórsson (2003) argue that the changes it has experienced from its old phase (Old West Norse; mid XI century to mid XIV century) to its current phase are comparable to the slight changes occurring from early Modern English (late XV century into early XVIII century) into Modern English (from early XVIII century). In terms of inflectional morphology, change in Icelandic has been minimal. For instance, one finds that the nominal paradigms of Old West Norse, are mostly the same as those of Modern Icelandic. Notwithstanding the apparent formal stability of Icelandic cases, there is evidence that they are experiencing subtle changes in their *functions* (Barðdal, 2011; Barðdal and Eythórsson, 2003; Eythórsson, 2000). In particular, Barðdal argues that an accumulation of small syntatico-semantic shifts has finally resulted in a shift in the Icelandic dative's functions (i.e., 'dative sickness'), possibly triggered by earlier changes in nominatives and accusatives (e.g., 'nominative sickness').

In this study, we investigate whether one can reliably detect a drift in the functions of Icelandic case and –crucially– whether there is evidence for causal chain shifts in these functions. In Section 2, we describe the processing of a diachronic corpus of Icelandic to obtain co-occurrence representations of the functions of case types and tokens. Section 3 uses machine learning on the co-occurrence vectors of tokens to demonstrate that the usage of Icelandic cases has been subject to a constant drift along history, a drift that is distinguishable from the overall changes experienced by the language in this period. We then go on –in Section 4– to demonstrate using Granger-causality (Granger, 1969) that there are causal relations between the changes in the different cases, and it is possible to reconstruct a directed network of chain shifts, which is consistent with the directions of causality hypothesized by Barðdal (2011). Finally, in Section 5, we discuss the theoretical implications of our results for theories of language change, as well as the possibilities offered by the technical innovations presented here.

2 Corpus Processing

2.1 Corpus

We used the Icelandic Parsed Historical Corpus (Wallenberg et al., 2011), a sample of around one million word tokens of Icelandic texts that have been orthographically standardized, manually lemmatized, part-of-speech tagged, and parsed into context-free derivation trees. An example of the lemmatization and part-of-speech tagging for a sentence is shown in Fig. 1. The dating of the text samples ranges from 1,150 CE to 2,008 CE, covering most of the history of Icelandic (from its origins in Old West Norse, to the current official language of Iceland). The corpus is divided into 61 files of similar sizes (around 18,000 words per file), each file corresponding to a single document. The documents were chosen to cover the period in a roughly uniform manner, sampling from similar genres across the periods.

2.2 Preprocessing

We collapsed into a single file all documents that were dated on the same year. This left us with 44 files containing texts from distinct years. From each of the files, we discarded all tokens that contained anything but valid Icelandic alphabetic characters or the dollar sign (used for marking enclitic breaks within a word, such as the clitic determiner in *krossins* from the example in Fig. 1). All remaining word tokens were lower-cased, and the '$' character was removed from the stem elements of broken stem plus clitic pairs (e.g., *kross$* was changed into *kross*).

2.3 First Order Co-occurrence Vectors

Ideally, for constructing co-occurrence vectors, it is best to choose as features those words with highest overall informativity, which in fact tend to be those words with the highest occurrence frequencies (Bullinaria and Levy, 2007; Bullinaria and Levy, 2012; Lowe and McDonald, 2000). In our case, however, using plain token frequencies runs the risk of creating a representational space that is strongly uninformative about particular periods in the history of the language. Instead, we used document frequencies, as these still provide a measure

En	*armar*	*kross-*	*-ins*	*merkja*	*ást*	*við*	*Guð*	*og*	*menn*
en	*armur*	*krosur*	*hinn*	*merkja*	*ást*	*við*	*guð*	*og*	*maður*
CONJ	NS-N	N-G	D-G	VBP	N-A	P	NPR-A	CONJ	NS-A

Figure 1: Tagging and lemmatization of the Old West Norse sentence (number 819) from the *Íslensk Hómilíubók* ("Icelandic Book of Homilies"; late XII century): *En armar krossins merkja ást við Guð og menn.* ("But the arms of the cross mark the love of God and man.")

of word frequency (and therefore informativity), while at the same time ensuring that those words chosen as features are most representative across the history of the language. We selected as features all word types that occurred in at least 75% of the 44 by-year files, that is, all 529 distinct (unlemmatized) word forms that had a document frequency in the corpus of at least 33 documents.

For each (unlemmatized) word type (w) occurring at least three times in the whole corpus (17,741 distinct word types), we computed its co-occurrence frequency with each of the feature words (t). In this way, we obtained a matrix of 17,741 $\times$ 529 word by feature co-occurrence frequencies (f$[w, t]$) within a symmetrical window including the two preceding and following words.[1] The plain co-occurrence matrix was converted into a matrix of word-feature pointwise mutual informations $M = (m_{i,j})$, such that,

$$m_{i,j} = \log \frac{N \cdot \mathrm{f}[w_i, t_j]}{(W_1 - 1) \cdot \mathrm{f}[w_i] \cdot \mathrm{f}[t_j]},$$

where N = 899,763 tokens is the total number of tokens in the corpus, $W_1 = 5$ is the total sliding window size considered, and f$[w_i]$ and f$[t_j]$, are the overall corpus frequencies of words w_i and t_j, respectively. In this manner, the row $M_{i,\cdot} = (m_{i,1}, \ldots, m_{i,529})$ represents the contexts in which the word type w_i is found across the whole corpus.

2.4 Second Order Co-occurrence Vectors

The co-occurrence vectors computed above provide representations for the average contexts in which a given word type is found. In order to represent the specific context of each word token, we used second order co-occurrence vectors (Schütze and Pedersen, 1997). These provide important information about the aspects of a context that are relevant for inflectional morphology (Moscoso del Prado Martín, 2007). The second order vectors were computed by passing a symmetrical sliding window including, for each token, the immediately preceding and following word. The vector for each token was computed as the average between the first order vectors (of Subsection 2.3) of the preceding and following words. If no first order vector was available for either the preceding or the following word, the second order vector directly corresponded to the plain first order vector of the word for which there was a first order vector. We excluded those tokens for which we had first order vectors for neither the previous nor the following word type. We computed such second order vectors for all tokens in the corpus that had been tagged for grammatical case (a total of 419,910 vectors, on average 9,453 vectors per year, of which 38.14% were nominatives, 10.91% were genitives, 26.38% were accusatives, and 24.56% were datives).

2.5 Representation of the Case Prototypes

In order to represent the prototypical usages each grammatical case (i.e., nominative, genitive, accusative, and dative) in a given year, we used the first order co-occurrence technique. For each of the 44 distinct years –using the same features identified in Subsection 2.3– we computed first order co-occurrence vectors collapsing all word tokens in each grammatical case, and using a reduced window size including just the preceding and following words (i.e., $W_2 = 3$).[2] For each year (y) we obtained a 4×529 element matrix of co-occurrence frequencies (f$_y[c, t]$), indicating the number of times that each case (c)

[1] To avoid $\log 0$ values, all frequency counts in this paper were increased by one.

[2] The optimal window sizes for the first order co-occurrence vectors for words and for case prototypes were different because they were chosen to optimize different tasks. The window size for first order vectors for words were chosen to optimize the machine learning algorithm for identifying case identities of second order vectors (Section 3), whereas the first order vectors for case prototypes were optimized for clustering cases across the years (Section 4).

was found to co-occur (within the specified window) with feature (t). These matrices were transformed into case to feature pointwise mutual informations, resulting in a series of 44 matrices ($M[y] = (m[y]_{i,j})$ such that,

$$m[y]_{i,j} = \log \frac{N \cdot \mathrm{f}_y[c_i, t_j]}{(W_2 - 1) \cdot \mathrm{f}[c_i] \cdot \mathrm{f}[t_j]},$$

where N is the total number of tokens in the corpus, $\mathrm{f}[c_i]$ is the number of instances of case c_i, and $\mathrm{f}[t_j]$ denotes the number of instances of word t_j in the corpus. In this way, the rows of the $M[y]$ matrices provided a representation of the contexts in which each grammatical case was used in each year.

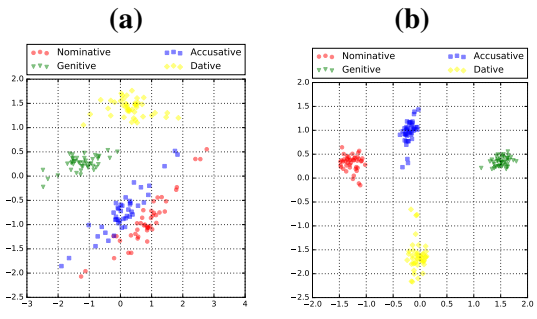

Figure 2: **(a)** Representation of the raw case vectors in SVD-reduced space (i.e., SVD dimension 1 vs. dimension 2). **(b)** Representation of the case vectors after discounting the average vector for each year (i.e., SVD dimension 1 vs. dimension 2).

Fig. 2a plots the spatial organization of the resulting vectors (after reducing to a bidimensional projection using Singular Value Decomposition; SVD). Notice that the prototypes for each case very naturally cluster together across the years. The scatter is however asymmetric, hinting at a process of change along the years common for all four cases. If we compute a yearly overall prototype vector as the average vector for the cases in each year, and we substract it from the corresponding case prototypes, we find that the case identities become clearly differentiated in space (see Fig. 2b), demonstrating that the case prototype vectors do indeed capture the contextual properties of all four cases, which are highly distinctive.

3 Functional Drift in Icelandic Cases

As was discussed in the Introduction, the inflectional paradigms marking case and number have barely –if at all– changed along the history of Icelandic. On the basis of this fact alone, one could conclude that the grammatical case system is not actually experiencing any linguistic drift, but has rather remained basically static throughout the last millennium. There is, however, another possibility. Linguistic drift could have been affecting the *functions* of grammatical cases in Icelandic. If this were the case, one would expect to observe a slow –constant rate– diachronic change in the contexts in which each of the four cases is used.

To investigate this latter possibility, for each of the 44 years documented in the corpus, we trained a basic logistic classifier in the task of assigning grammatical case to the second order co-occurrence vectors developed in Subsection 2.4. Once each of the classifiers had been trained, we tested the classifiers' performances on the vectors obtained from each of other 43 years on which they were not trained. On the one hand, if the functions of the cases have indeed remained constant along the history of the language, one would expect that the performance of a classifier tested on the data from a given year, should remain approximately constant when tested on vectors from all other years. If, on the other hand, the functions of Icelandic grammatical cases have been subject to linguistic drift, the irreversible and cumulative nature of the drift (Sapir, 1921/2014) implies that the classifier error should grow –if only so slightly– with each year passed. The reason for this is that the contexts in which one would use each case should be slightly different from year to year. One should then predict that the error of the classifier should depend on the temporal distance between the year of the testing vectors and that of the training ones. Furthermore, the change in error should be of a linear nature, with a very slight slope.

When tested on the same years in which they had been trained, the classifiers performed rather well in inferring the case to which each of the context vectors belonged (the distribution of errors across the 44 years was well approximated by a normal distribution with a mean error of 26.67%, a standard deviation of 1.99%, and best and worst classification errors of 22.17% and 30.39%, respectively).[3]

[3]Although we chose the best model among different learning algorithms, including multiple versions of Support Vector Machines, Classification Trees, and a Softmax Classifier, we have no doubt that the learning performance can be improved upon. For our purposes, however, it was sufficient

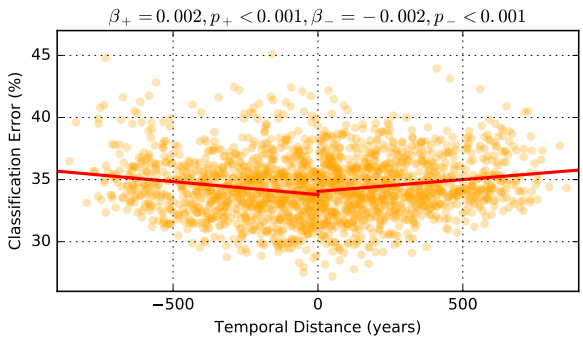

Figure 3: Correlation between the classifier error and the temporal distance from the year from which the training vectors were obtained to the year when the testing vectors were obtained. The solid lines plots a linear regressions.

We then tested the classifiers on the vectors obtained from different years. The results are plotted in Fig. 3. The scatter plots the difference in years (i.e., the difference values are positive when the classifier was tested on vectors obtained after those used for training, and negative when testing with vectors obtained before the training ones). When testing on data different from the training sets, there is a logical loss in performance (of about 8%) from the baseline of testing on the same training set. We fitted two linear regressions, one to the positive differences and another to the negative differences (plotted by the solid lines in Fig. 3). The first thing that stands out is that the performance of the classifier is remarkably good when tested on vectors obtained at considerable temporal distances from the time when the training vectors were obtained. While the error of the classifier is of about 34% when tested on vectors from the year after or before the training vectors, the error remains at 35% for vectors originating from texts that are five centuries apart. Once again, this speaks to the remarkable conservativeness of the Icelandic language. However, these small differences are in fact reliable: There are significant slopes in both regressions (positive differences: $R_+ = .161, p_+ < .001$; negative differences: $R_- = -.164, p_- < .001$). A second remarkable thing is that both regressions are substantially symmetrical, in fact their slopes are basically identical ($|\beta_+| = |\beta_-| = .002$). This indicates that the degree to which the usages of the cases at different

to have a classifier with a decent performance, as our goal was showing that the error is time-dependent.

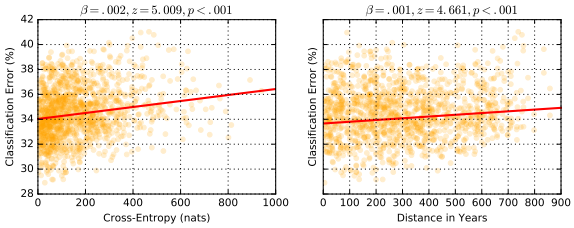

Figure 4: Independent effects of cross-entropy (left panel) and distance in years between the training and testing sets (right panel) as estimated by the linear mixed-effects regression model.

time points have diverged depends on the amount of time that has intervened, irrespective of whether it was the training or the testing set that was collected before.

One could argue that the slow drift observed may not be really due to changes in the functions of the grammatical cases themselves, but just to overall changes either in the overall language, or in the very topics that are addressed (e.g., one might guess that talk of swords, slaves, and longships was more frequent in XII century Norse than it is in Modern Icelandic). To investigate this possibility we used an information-theoretical measure of the prototypicality of a set of second order vectors for a particular year (based on that used in Moscoso del Prado Martín, 2007). From the vectors of each year, irrespective of their case, we fitted a 529-dimensional Gaussian distribution (by estimating the mean vector for that year, $\boldsymbol{\mu}_y$, and the covariance matrix, Σ_y). The average inadequacy of a given set of vectors $\{\mathbf{v}_1, \ldots, \mathbf{v}_n\}$ obtained in year z to the distribution fitted to the vectors obtained in year y is measured by the *cross-entropy*, a Monte Carlo estimator of which is given by,[4]

$$H(z, y) \approx K + \frac{1}{2}\log|\Sigma_y| + \frac{1}{2n}\sum_{i=1}^{n}(\mathbf{v}_i - \boldsymbol{\mu}_y)^T\Sigma_y^{-1}(\mathbf{v}_i - \boldsymbol{\mu}_y),$$

where K is a constant.[5] In addition, one should also take into account the fact that, for some years, the classifier might generalize better or worse than for others (due to irrelevant idiosyncrasies of one specific text used for training), which could lead to a distortion of the results.

To investigate whether, after discounting for the inadequacy of the vectors to the overall distribution of those in which the classifier was trained,

[4] Assuming Σ_y is definite positive so that its inverse exists.
[5] $K = \frac{529}{2}\log 2\pi$.

there was still evidence for drift in the functions of the cases, while also accounting for the different generalization powers of the classifiers, we fitted a linear mixed-effects model to the classifier errors, including fixed-effect predictors of the cross-entropy described above, and the absolute value of the difference in years between the training set and testing set dates (as indicated above, the effects were equivalent for positive and negative values in years), and the dating of the testing set as a random effect. As expected, we found that the cross-entropies had a significant positive effect ($\beta = .002, z = 5.009, p < .001$; left panel if Fig. 4), indicating that the performances of the models were indeed worse for less adequate sets of testing vectors, irrespective of any aspect of grammatical case. However –crucially– even after considering the effect of cross-entropy, there remained a significant positive effect of the temporal distance ($\beta = .001, z = 4.661, p < .001$; right panel if Fig. 4).[6] This result therefore supports the hypothesis that the function of grammatical case has been subject to a slight constant change during the history of the language: a functional drift.

4 Functional Chain Shifts in Case

In the previous section we have demonstrated that the functions of Icelandic cases have been subject to slow linguistic drift. The question now arises of whether this drift is purely random, or rather it has some degree of directionality arising from endogenous linguistic factors. It is possible that changes in the functions of some cases caused changes in the functions of others. We investigate this possibility using the notion of Granger-causality

4.1 Granger-causality

Granger-causality (Granger, 1969) is a powerful technique for assessing whether one time series can be said to be the cause of another one. The basic idea is that one time series $\mathbf{x}$ is said to *Granger-cause* another series $\mathbf{y}$ if the past of series $\mathbf{x}$ predicts the future of series $\mathbf{y}$ over and above any predictive power that can be found on $\mathbf{y}$'s own past. This idea has proven of great value to investigate the causal connections between economic variables, sequences of behavioral responses, neural spikes, or electroencephalographic potentials. Often, the technique is used to reconstruct directional networks of variables and processes that have causal connections.

If $\mathbf{x}$ and $\mathbf{y}$ are stationary time sequences on time (τ), in order to test whether $\mathbf{x}$ Granger-causes $\mathbf{y}$, one begins by fitting *autoregressive models* (AR) that predict the values of $\mathbf{y}$ from its own n values lagged into the past. This consists on finding values $a_1, a_2, \ldots, a_n$ that minimize the error ε in the equation,

$$y[\tau] = a_0 + \overbrace{a_1 y[\tau-1] + a_2 y[\tau-2] + \ldots + a_n y[\tau-n]}^{\text{past of } \mathbf{y}} + \varepsilon[\tau].$$

One then augments the autoregression by including m lagged values of $\mathbf{x}$, with additional parameters $b_1, \ldots, b_m$ to be fitted,

$$\begin{aligned} y[\tau] = & a_0 + \overbrace{a_1 y[\tau-1] + a_2 y[\tau-2] + \ldots + a_n y[\tau-n]}^{\text{past of } \mathbf{y}} + \\ & + \underbrace{b_1 x[\tau-1] + b_2 x[\tau-2] + \ldots + b_m x[\tau-m]}_{\text{past of } \mathbf{x}} + \varepsilon[\tau]. \end{aligned}$$

where the ε sequences are uncorrelated (white) gaussian noises, reflecting the fully random or chaotic part of the system, which cannot be predicted from its past (i.e., the error, that is termed by some the 'creativity' of the model). If the second regression is a significant improvement over the first, then it can be said that $\mathbf{x}$ *Granger-causes* $\mathbf{y}$, indicating that past values of $\mathbf{x}$ significantly predict future values of $\mathbf{y}$ over and above any predictive power of $\mathbf{y}$'s own past values. This is tested using an F-test, with the null hypothesis being that the second model does not improve on the first one. The selection of the autoregressive order parameters n and m is achieved by model comparisons using information criteria.

When one is interested in reconstructing a network of causal relations between multiple variables, one can use a mutivariate generalization of the AR model, the *vector autoregressive model* (VAR). The VAR model consists of mutiple AR equations (one for each variable in the model). If we consider an autoregressive order of one (i.e., $m = n = 1$), when we are simultaneously considering p variables $\mathcal{Y} = \{\mathbf{y}_1, \ldots, \mathbf{y}_p\}$, the VAR[1] model to be fitted can be expressed in matrix no-

[6] The estimated covariance matrices were not definite positive for two of the years, which were excluded from the analyses. In addition, in 552 out of the remaining 1,849 estimates, the cross-entropy took unusually large values, orders of magnitude larger than the rest (likely reflecting inadequacy of the multidimensional Gaussian approximation for these cases), which distorted the effect estimates. The analyses reported exclude these 552 points. However, keeping these outlying values in the regression, both key effects remained significant, but the slope estimates were less trustworthy.

tation as,

$$\begin{pmatrix} y_1[\tau] \\ \vdots \\ y_p[\tau] \end{pmatrix} = \begin{pmatrix} a_1 \\ \vdots \\ a_p \end{pmatrix} + \begin{pmatrix} A_{1,1} & \dots & A_{1,p} \\ \vdots & \ddots & \vdots \\ A_{p,1} & \dots & A_{p,p} \end{pmatrix} \begin{pmatrix} y_1[\tau-1] \\ \vdots \\ y_p[\tau-1] \end{pmatrix} + \begin{pmatrix} \varepsilon_1[\tau] \\ \vdots \\ \varepsilon_p[\tau] \end{pmatrix}.$$

This model enables testing for Granger-causality between any pair of variables $\mathbf{y}_i \in \mathcal{Y}$ and $\mathbf{y}_j \in \mathcal{Y}$, after partialling out the possible confounding effects of $\{\mathbf{y}_t,\, t \neq i, t \neq j, 1 \leq t \leq p\}$. $\mathbf{y}_j$ is said to Granger-cause $\mathbf{y}_i$ if the model coefficient $A_{i,j}$ is significantly different than zero, and the reverse holds if $A_{j,i}$ significantly different than zero (i.e., $\mathbf{y}_i$ Granger-causes $\mathbf{y}_j$).

4.2 Granger-causality in Case Drift

To investigate whether the pattern of change in one case triggers (i.e., Granger-cause) the pattern of change in another, we made use of the prototype vectors for the cases in each of the years developed in Subsection 2.5. As a measure of the amount of contextual change for a given case in a given year, we computed the city-block distances between the case prototypes from each year to the next available time point, which are plotted in Fig. 5a. Notice that there is an overall pattern of change equally affecting all cases, and the changes are therefore strongly correlated. This reflects the overall pattern of historical changes affecting Icelandic as a whole, as well as changes in the topics that would be discussed in the different time periods, as was documented in Subsection 2.5 and Section 3. Considering the changes in each case as a component in a four-dimensional vector, the modulus of this vector (plotted by the dashed orange line in Fig. 5a) gives the overall magnitude of the changes that are unspecific to the cases themselves. To remove this component from the changes, we fitted a linear regression to the sequence of changes in each case, using the overall pattern of change as a predictor. Fig. 5b plots the resulting residuals, indicating the amount of change that was specific to each case, over and above the overall pattern.[7]

A precondition for testing for Granger-causality is that the time series under consideration are stationary. In our case, the series depicted in Fig. 5b are significantly non-stationary; they exhibit, for instance, significant temporal trends. In order to remove the non-stationarities, the series were differentiated (i.e., we considered the difference between each two consecutive points). The result of this differentiation, plotted in Fig. 5c, removed the non-stationary trends from the original series.

Table 1: Results of the Granger-causality analyses. Causality directions that remained significant after FDR correction are highlighted in bold.

We fitted a VAR[n] model to the four differentiated time-series. The autoregressive order found to maximize Akaike's Information Criterion (Akaike, 1974) was $n = 1$.[8] The F statistics and significance values for the coefficients in the resulting VAR[1] model are given in Tab. 1. In order to reconstruct the causality network, we also need to consider that we started out with only very vague predictions on the possible directions of causality. As the model involved twelve separate p-value tests, the p-value estimates need to be corrected for multiple comparisons. This correction was done using the false discovery rate (FDR) method (Benjamini and Hochberg, 1995), resulting in the corrected p-value estimates listed in the last column of Tab. 1.

The Granger-causality analysis leads us to reconstruct the causality network depicted in Fig. 6. It appears that the drift in the functions of Icelandic case is not plainly random. Instead, we find evidence that changes in the functions of the accusatives and genitives have had a domino effect, triggering further changes in the functions of nominatives. Finally, changes in all other three cases result in changes in the functions of the dative. In summary, the changes observed are consistent with the idea discussed in the Introduction of a *functional chain shift* affecting the morphological case system of Icelandic.

5 Discussion

We have presented evidence for a steady drift –of the precise kind advocated by Sapir (1921/2014)– even in a language as remarkably conservative as is Icelandic. This supports the claim that human languages are in a state of 'perpetual motion' (Beckner et al., 2009; Dediu et al., 2013; Hawkins and Gell-Mann, 1992; Hopper, 1987;

[7] Negative values in this figure indicate changing less than the average, rather than 'negative change'.

[8] In fact $n = 1$ was also found to maximize both Akaike's Final Prediction Error and Hannan-Quinn Criteria.

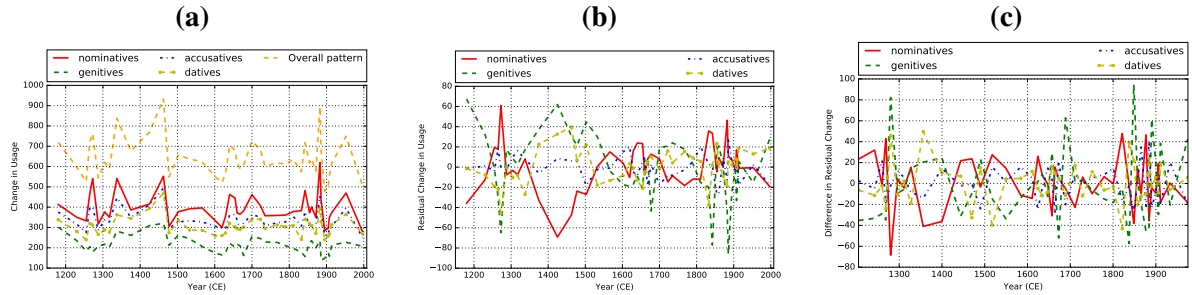

Figure 5: **(a)** Overall value of the city-block distances between the prototypical case vectors for consecutive years. **(b)** Residual value of the distances specific to each case after residualizing the overall pattern of change. **(c)** Differentiated values of the residualized distances, removing non-stationarities.

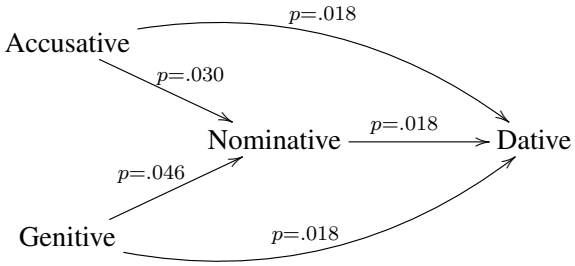

Figure 6: Reconstructed network of Granger-causal connections between diachronic changes in case functions. The p-values indicated on the causal arrows are FDR-corrected.

Larsen-Freeman and Cameron, 2007; Niyogi and Berwick, 1997). Although we have found that functional change in Icelandic case has proceeded at a constant rate, we do not think, as argued by Nettle (1999a, 1999b), that this rate of change needs to be constant across languages. There are strong arguments suggesting that in other languages such rates might be different (Wichmann, 2008; Wichmann and Holman, 2009).

The crucial innovation presented in this paper is the reconstruction of the causality network linking the changes in the four cases. Previous applications of the notion of Granger-causality to diachronic language change (Moscoso del Prado Martín, 2014) have focused on the macroscopic relation between sudden changes in syntax and morphology. Here, we have demonstrated that Granger-causality can also be used to reconstruct detailed networks of slow changes within the morphological system, at a more microscopic scale. The techniques developed offer a mechanism for investigating subtle changes in the functions of linguistic constructions, and the causal relations between them. Traditionally, historical linguists have focused on 'narrative' accounts of the the chains of change within a language. Although such type of accounts are extremely useful, the often very subtle changes in usage that can occur from one time-point to another cannot always be described with such clearcut patterns. Nevertheless, we have shown that those very small changes do accumulate in meaningful ways.

An important question addressed by this study is the presence of endogenous causal chains in language change. Lupyan and Dale (2015) argue that languages are constrained by their 'ecological niches', the communities in which they are spoken, and the extralinguistic properties of those niches can trigger exogenous change in the morphology of the languages. Following on Lupyan and Dale's ecosystem analogy, one should see that, as well as being part of ecosystems, languages are also ecosystems in themselves, in a nesting similar to that found in natural ecosystems (i.e., an animal is part of a particular ecosystem, and its body is an ecosystem in itself). Sounds, words and constructions have their own ecological niches within the language, and disturbances in the system can trigger cascaded changes, leading to readaptation (evolution) of the constructions. This contrasts with the view of changes in the function of Icelandic cases expressed by Eythórsson (2000). He showed that verbs whose arguments exhibit 'nominative sickness' and 'accusative sickness' tend to be clustered along certain syntactic and semantic lines. That it is in these particular niches that accusatives and datives ended up settling is not, however, the *cause* of the language changes. As we have shown, the case system was subject to a string of cascaded pressures. That the cases ended

up settling in new syntactico-semantic niches was the *result*, rather than the cause of the changes.

Abstract

The ability to compute an accurate reward function is essential for optimising a dialogue policy via reinforcement learning. In real-world applications, using explicit user feedback as the reward signal is often unreliable and costly to collect. This problem can be mitigated if the user's intent is known in advance or data is available to pre-train a task success predictor off-line. In practice neither of these apply for most real world applications. Here we propose an on-line learning framework whereby the dialogue policy is jointly trained alongside the reward model via active learning with a Gaussian process model. This Gaussian process operates on a continuous space dialogue representation generated in an unsupervised fashion using a recurrent neural network encoder-decoder. The experimental results demonstrate that the proposed framework is able to significantly reduce data annotation costs and mitigate noisy user feedback in dialogue policy learning.

1 Introduction

Spoken Dialogue Systems (SDS) allow human-computer interaction using natural speech. They can be broadly divided into two categories: chat-oriented systems which aim to converse with users and provide reasonable contextually relevant responses (Vinyals and Le, 2015; Serban et al., 2015), and task-oriented systems designed to assist users to achieve specific goals (e.g. find hotels, movies or bus schedules) (Daubigney et al., 2014; Young et al., 2013). The latter are typically designed according to a structured *ontology* (or a database *schema*), which defines the domain that the system can talk about. Teaching a system how to respond appropriately in a task-oriented SDS is non-trivial. This *dialogue management* task is often formulated as a manually defined dialogue flow that directly determines the quality of interaction. More recently, dialogue management has been formulated as a reinforcement learning (RL) problem which can be automatically optimised (Levin and Pieraccini, 1997; Roy et al., 2000; Williams and Young, 2007; Young et al., 2013). In this framework, the system learns by a *trial and error* process governed by a potentially delayed learning objective defined by a *reward function*.

TASK: Ask for an *expensive English* restaurant
Request its *phone number* and *address*

S: Hello, how may I help you?
U: I want an expensive place that serves English food.
S: Cote is a nice expensive restaurant with English food.
U: What is the phone number?
S: Its number is 01223 311053.
U: Thanks for the help, goodbye.
S: Thank you, goodbye!

S: System
U: User

EVALUATION:
- Objective Rating: Fail (*address* not mentioned)
- Subjective Rating: Success (get all info he asked)

Figure 1: An example of a task-oriented dialogue with a pre-defined task and the evaluation results.

A typical approach to defining the reward function in a task-oriented dialogue system is to apply a small per-turn penalty to encourage short dialogues and to give a large positive reward at the end of each successful interaction. Figure 1 is an example of a dialogue task which is typically set for users who are being paid to converse with the system. When users are primed with a specific task to complete, dialogue success can be determined from subjective user ratings (*Subj*), or

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 2431–2441,
Berlin, Germany, August 7-12, 2016.

an objective measure (*Obj*) based on whether or not the pre-specified task was completed (Walker et al., 1997; Gašić et al., 2013). However, prior knowledge of the user's goal is not normally available in real situations, making the objective reward estimation approach impractical.

Furthermore, objective ratings are inflexible and often fail as can be seen from Figure 1, if the user does not strictly follow the task. This results in a mismatch between the *Obj* and *Subj* ratings. However, relying on subjective ratings alone is also problematic since crowd-sourced subjects frequently give inaccurate responses and real users are often unwilling to extend the interaction in order to give feedback, resulting in unstable learning (Zhao et al., 2011; Gašić et al., 2011). In order to filter out incorrect user feedback, Gašić et al. (2013) used only dialogues for which $Obj = Subj$. Nonetheless, this is inefficient and not feasible anyway in most real-world tasks where the user's goal is generally unknown and difficult to infer.

In light of the above, Su et al. (2015a) proposed learning a neural network-based *Obj* estimator from off-line simulated dialogue data. This removes the need for the *Obj* check during on-line policy learning and the resulting policy is as effective as one trained with dialogues using the $Obj = Subj$ check. However, a user simulator will only provide a rough approximation of real user statistics and developing a user simulator is a costly process (Schatzmann et al., 2006).

To deal with the above issues, this paper describes an on-line active learning method in which users are asked to provide feedback on whether the dialogue was successful or not. However, active learning is used to limit requests for feedback to only those cases where the feedback would be useful, and also a noise model is introduced to compensate for cases where the user feedback is inaccurate. A Gaussian process classification (GPC) model is utilised to robustly model the uncertainty presented by the noisy user feedback. Since GPC operates on a fixed-length observation space and dialogues are of variable-length, a recurrent neural network (RNN)-based embedding function is used to provide fixed-length dialogue representations. In essence, the proposed method learns a dialogue policy and a reward estimator on-line from scratch, and is directly applicable to real-world applications.

The rest of the paper is organised as follows. The next section gives an overview of related work. The proposed framework is then described in §3. This consists of the policy learning algorithm, the creation of the dialogue embedding function and the active reward model trained from real user ratings. In §4, the proposed approach is evaluated in the context of an application providing restaurant information in Cambridge, UK. We first give an in-depth analysis of the dialogue embedding space. The results of the active reward model when it is trained together with a dialogue policy on-line with real users are then presented. Finally, our conclusions are presented in §5.

2 Related Work

Dialogue evaluation has been an active research area since late 90s. Walker et al. (1997) proposed the PARADISE framework, where a linear function of task completion and various dialogue features such as dialogue duration were used to infer user satisfaction. This measure was later used as a reward function for learning a dialogue policy (Rieser and Lemon, 2011). However, as noted, task completion is rarely available when the system is interacting with real users and also concerns have been raised regarding the theoretical validity of the model (Larsen, 2003).

Several approaches have been adopted for learning a dialogue reward model given a corpus of annotated dialogues. Yang et al. (2012) used collaborative filtering to infer user preferences. The use of reward shaping has also been investigated in (El Asri et al., 2014; Su et al., 2015b) to enrich the reward function in order to speed up dialogue policy learning. Also, Ultes and Minker (2015) demonstrated that there is a strong correlation between expert's user satisfaction ratings and dialogue success. However, all these methods assume the availability of reliable dialogue annotations such as expert ratings, which in practice are hard to obtain.

One effective way to mitigate the effects of annotator error is to obtain multiple ratings for the same data and several methods have been developed to guide the annotation process with uncertainty models (Dai et al., 2013; Lin et al., 2014). Active learning is particularly useful for determining when an annotation is needed (Settles, 2010; Zhang and Chaudhuri, 2015). It is often utilised using Bayesian optimisation approaches (Brochu et al., 2010). Based on this, Daniel et al. (2014)

exploited a pool-based active learning method for a robotics application. They queried the user for feedback on the most informative sample collected so far and showed the effectiveness of this method.

Rather than explicitly defining a reward function, inverse RL (IRL) aims to recover the underlying reward from demonstrations of good behaviour and then learn a policy which maximises the recovered reward (Russell, 1998). IRL was first introduced to SDS in (Paek and Pieraccini, 2008), where the reward was inferred from human-human dialogues to mimic the behaviour observed in a corpus. IRL has also been studied in a Wizard-of-Oz (WoZ) setting (Boularias et al., 2010; Rojas Barahona and Cerisara, 2014), where typically a human expert served as the dialogue manager to select each system reply based on the speech understanding output at different noise levels. However, this approach is costly and there is no reason to suppose that a human wizard is acting optimally, especially at high noise levels.

Since humans are better at giving relative judgements than absolute scores, another related line of research has focused on preference-based approaches to RL (Cheng et al., 2011). In (Sugiyama et al., 2012), users were asked to provide rankings between pairs of dialogues. However, this is also costly and does not scale well in real applications.

3 Proposed Framework

The proposed system framework is depicted in Figure 2. It is divided into three main parts: a dialogue policy, a dialogue embedding function, and an active reward model of user feedback. When each dialogue ends, a set of turn-level features $\mathbf{f_t}$ is extracted and fed into an embedding function σ to obtain a fixed-dimension dialogue representation $\mathbf{d}$ that serves as the input space of the reward model R. This reward is modelled as a Gaussian process which for every input point provides an estimate of task success along with a measure of the estimate uncertainty. Based on this uncertainty, R decides whether to query the user for feedback or not. It then returns a reinforcement signal to update the dialogue policy π, which is trained using the GP-SARSA algorithm (Gašić and Young, 2014). GP-SARSA also deploys Gaussian process estimation to provide an on-line sample-efficient reinforcement learning algorithm capable of bootstrapping estimates of sparse value functions from minimal numbers of samples (dialogues). The quality of each dialogue is defined by its cumulative reward, where each dialogue turn incurs a small negative reward (-1) and the final reward of either 0 or 20 depending on the estimate of task success are provided by the reward model.

Note that the key contribution here is to learn the noise robust reward model and the dialogue policy simultaneously on-line, using the user as a 'supervisor'. Active learning is not an essential component of the framework but highly desirable in practice to minimise the impact of the supervision burden on users. The use of a pre-trained embedding function is a sub-component of the proposed approach and is trained off-line on corpus data rather than manually designed here.

3.1 Unsupervised Dialogue Embeddings

In order to model user feedback over dialogues of varying length, an embedding function is used to map each dialogue into a fixed-dimensional continuous-space. The use of embedding functions has recently gained attention especially for word representations, and has boosted performance on several natural language processing tasks (Mikolov et al., 2013; Turian et al., 2010; Levy and Goldberg, 2014). Embedding has also been successfully applied to machine translation (MT) where it enables varying-length phrases to be mapped to fixed-length vectors using an RNN Encoder-Decoder (Cho et al., 2014). Similar to MT, dialogue embedding enables variable length sequences of utterances to be mapped into an appropriate fixed-length vector. Although embedding is used here to create a fixed-dimension input space for the GPC-based task success classifier, it should be noted that it potentially facilitates a variety of other downstream tasks which depend on classification or clustering.

The model structure of the embedding function is described on the left of Figure 2, where the episodic turn-level features $\mathbf{f_t}$ are extracted from a dialogue and serve as the input features to the encoder. In our proposed model, the encoder is a Bi-directional Long Short-Term Memory network (BLSTM) (Hochreiter and Schmidhuber, 1997; Graves et al., 2013). The LSTM is a Recurrent Neural Network (RNN) with gated recurrent units introduced to alleviate the vanishing gradient problem. The BLSTM encoder takes into account the sequential information from both directions of the input data, computing the *forward*

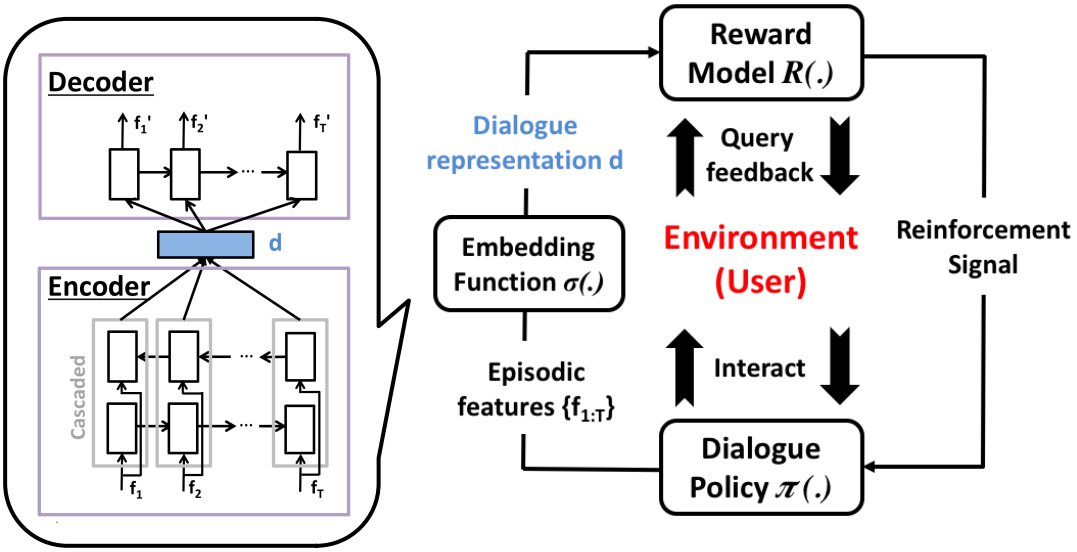

Figure 2: Schematic of the system framework. The three main system components dialogue policy, dialogue embedding creation, and reward modelling based on user feedback, are described in §3.

hidden sequences $\overrightarrow{\mathbf{h}}_{1:T}$ and the *backward* hidden sequences $\overleftarrow{\mathbf{h}}_{T:1}$ while iterating over all input features $\mathbf{f_t}$, $t = 1, ..., T$:

$$\overrightarrow{\mathbf{h_t}} = LSTM(\mathbf{f_t}, \overrightarrow{\mathbf{h}}_{t-1})$$
$$\overleftarrow{\mathbf{h_t}} = LSTM(\mathbf{f_t}, \overleftarrow{\mathbf{h}}_{t+1})$$

where $LSTM$ denotes the activation function. The dialogue representation $\mathbf{d}$ is then calculated as the average over all hidden sequences:

$$\mathbf{d} = \frac{1}{T}\sum_{t=1}^{T} \mathbf{h_t} \quad (1)$$

where $\mathbf{h_t} = [\overrightarrow{\mathbf{h_t}}; \overleftarrow{\mathbf{h_t}}]$ is the concatenation of the two directional hidden sequences.

Given the dialogue representation $\mathbf{d}$ output by the encoder, the decoder is a forward LSTM that takes $\mathbf{d}$ as its input for each turn t to produce the sequence of features $\mathbf{f'}_{1:T}$.

The training objective of the encoder-decoder minimises the mean-square-error (MSE) between the prediction $\mathbf{f'}_{1:T}$ and the output $\mathbf{f}_{1:T}$ (which is also the input):

$$MSE = \frac{1}{N}\sum_{i=1}^{N}\sum_{t=1}^{T} ||\mathbf{f}_t - \mathbf{f}'_t||^2 \quad (2)$$

where N is the number of training dialogues and $||\cdot||^2$ denotes the l^2-norm. Since all the functions used in the encoder and decoder are differentiable, stochastic gradient decent (SGD) can be used to train the model.

The dialogue representations generated by this LSTM-based unsupervised embedding function are then used as the observations for the reward model described in the next section 3.2.

3.2 Active Reward Learning

A Gaussian process is a Bayesian non-parametric model that can be used for regression or classification (Rasmussen and Williams, 2006). It is particularly appealing since it can learn from a small number of observations by exploiting the correlations defined by a *kernel function* and it provides a measure of uncertainty of its estimates. In the context of spoken dialogue systems it has been successfully used for RL policy optimisation (Gašić and Young, 2014; Casanueva et al., 2015) and IRL reward function regression (Kim et al., 2014).

Here we propose modelling dialogue success as a Gaussian process (GP). This involves estimating the probability $p(y|\mathbf{d}, \mathcal{D})$ that the task was successful given the current dialogue representation $\mathbf{d}$ and the pool $\mathcal{D}$ containing previously classified dialogues. We pose this as a classification problem where the rating is a binary observation $y \in \{-1, 1\}$ that defines failure or success. The observations y are considered to be drawn from a Bernoulli distribution with a success probability $p(y = 1|\mathbf{d}, \mathcal{D})$. The probability is related to a latent function $f(\mathbf{d}|\mathcal{D}) : \mathcal{R}^{dim(\mathbf{d})} \rightarrow \mathcal{R}$ that is mapped to a unit interval by a *probit* function $p(y = 1|\mathbf{d}, \mathcal{D}) = \phi(f(\mathbf{d}|\mathcal{D}))$, where ϕ denotes the cumulative density function of the standard Gaus-

sian distribution.

The latent function is given a GP prior: $f(\mathbf{d}) \sim \mathcal{GP}(m(\mathbf{d}), k(\mathbf{d}, \mathbf{d}'))$, where $m(\cdot)$ is the mean function and $k(\cdot, \cdot)$ the covariance function (kernel). Here the stationary squared exponential kernel k_{SE} is used. It is also combined with a white noise kernel k_{WN} in order to account for the "noise" in users' ratings:

$$k(\mathbf{d}, \mathbf{d}') = p^2 \exp(-\frac{||\mathbf{d} - \mathbf{d}'||^2}{2l^2}) + \sigma_n^2 \quad (3)$$

where the first term denotes k_{SE} and the second term k_{WN}.

The *hyper-parameters* p, l, σ_n can be adequately optimised by maximising the marginal likelihood using a gradient-based method (Chen et al., 2015). Since $\phi(\cdot)$ is not Gaussian, the resulting posterior probability $p(y = 1|\mathbf{d}, \mathcal{D})$ is analytically intractable. So instead an approximation method, expectation propagation (EP), was used (Nickisch and Rasmussen, 2008).

Querying the user for feedback is costly and may impact negatively on the user experience. This impact can be reduced by using active learning informed by the uncertainty estimate of the GP model (Kapoor et al., 2007). This ensures that user feedback is only sought when the model is uncertain about its current prediction. For the current application, an on-line (stream-based) version of active learning is required.

An illustration of a 1-dimensional example is shown in Figure 3. Given the labelled data $\mathcal{D}$, the predictive posterior mean μ_* and posterior variance σ_*^2 of the latent value $f(\mathbf{d}_*)$ for the current dialogue representation $\mathbf{d}_*$ can be calculated. Then a threshold interval $[1 - \lambda, \lambda]$ is set on the predictive success probability $p(y_* = 1|\mathbf{d}_*, \mathcal{D}) = \phi(\mu_*/\sqrt{1 + \sigma_*^2})$ to decide whether this dialogue should be labelled or not. The decision boundary implicitly considers both the posterior mean as well as the variance.

When deploying this reward model in the proposed framework, a GP with a zero-mean prior for f is initialised and $\mathcal{D} = \{\}$. After the dialogue policy π completes each episode with the user, the generated dialogue turns are transformed into the dialogue representation $\mathbf{d} = \sigma(\mathbf{f}_{1:T})$ using the dialogue embedding function σ. Given $\mathbf{d}$, the predictive mean and variance of $f(\mathbf{d}|\mathcal{D})$ are determined, and the reward model decides whether or not it should seek user feedback based on the threshold λ on $\phi(f(\mathbf{d}|\mathcal{D}))$. If the model is uncertain, the user's feedback on the current episode $\mathbf{d}$ is used to update the GP model and to generate the reinforcement signal for training the policy π; otherwise the predictive success rating from the reward model is used directly to update the policy. This process takes place after each dialogue.

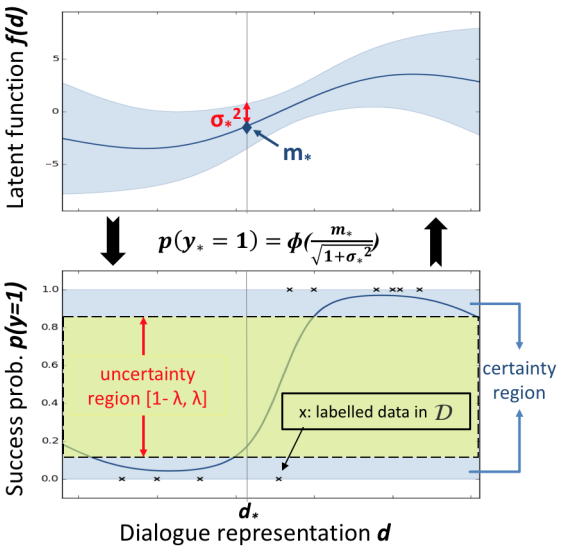

Figure 3: 1-dimensional example of the proposed GP active reward learning model.

4 Experimental results

The target application is a live telephone-based spoken dialogue system providing restaurant information for the Cambridge (UK) area. The domain consists of approximately 150 venues each having 6 slots (attributes) of which 3 can be used by the system to constrain the search (food-type, area and price-range) and the remaining 3 are informable properties (phone-number, address and postcode) available once a required database entity has been found.

The shared core components of the SDS common to all experiments comprise a HMM-based recogniser, a confusion network (CNet) semantic input decoder (Henderson et al., 2012), the BUDS belief state tracker (Thomson and Young, 2010) that factorises the dialogue state using a dynamic Bayesian network, and a template based natural language generator to map system semantic actions into natural language responses to the user. All policies were trained using the GP-SARSA algorithm and the summary action space of the RL policy contains 20 actions.

The reward given to each dialogue was set to $20 \times \mathbb{1}_{success} - N$, where N is the dialogue turn

number and $\mathbb{1}$ is the indicator function for dialogue success, which is determined by different methods as described in the following section. These rewards constitute the reinforcement signal used for policy learning.

4.1 Dialogue representations

The LSTM Encoder-Decoder model described in §3.1 was used to generate an embedding $\mathbf{d}$ for each dialogue. For each dialogue turn that contains a user's utterance and a system's response, a feature vector $\mathbf{f}$ of size 74 was extracted (Vandyke et al., 2015). This vector consists of the concatenation of the most likely user intention determined by the semantic decoder, the distribution over each concept of interest defined in the ontology, a one-hot encoding of the system's reply action, and the turn number normalised by the maximum number of turns (here 30). This feature vector was used as the input and the target for the LSTM Encoder-Decoder model, where the training objective was to minimise the MSE of the reconstruction loss.

The model was implemented using the Theano library (Bergstra et al., 2010; Bastien et al., 2012). A corpus consisting of 8565, 1199 and 650 real user dialogues in the Cambridge restaurant domain was used for training, validation and testing respectively. This corpus was collected via the Amazon Mechanical Turk (AMT) service, where paid subjects interacted with the dialogue system. The sizes of $\overrightarrow{\mathbf{h_t}}$ and $\overleftarrow{\mathbf{h_t}}$ in the encoder and the hidden layer in the decoder were all 32, resulting in $dim(\mathbf{h_t}) = dim(\mathbf{d}) = 64$. SGD per dialogue was used during backpropagation to train each model. In order to prevent over-fitting, *early stopping* was applied based on the held-out validation set.

In order to visualise the impact of the embeddings, the dialogue representations of all the 650 test dialogues were transformed by the embedding function in Figure 4 and reduced to two dimensions using t-SNE (Van der Maaten and Hinton, 2008). For each dialogue sample, the shape indicates whether or not the dialogue was successful, and the colour indicates the length of the dialogue (maximum 30 turns).

From the figure we can clearly see the colour gradient from the top left (shorter dialogues) to the bottom right (longer dialogues) for the positive *Subj* labels. This shows that dialogue length was one of the prominent features in the dialogue representation $\mathbf{d}$. It can also be seen that the longer

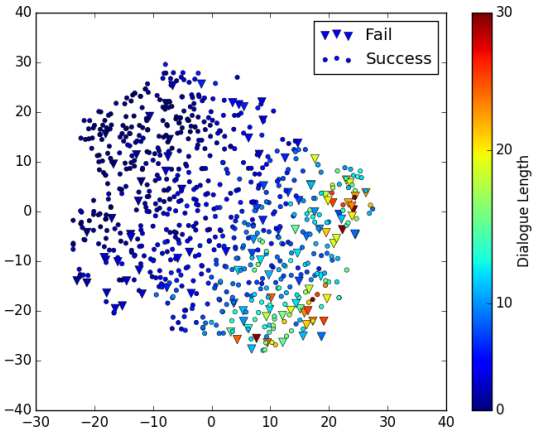

Figure 4: t-SNE visualisation on the unsupervised dialogue representation of the real user data in the Cambridge restaurant domain. Labels are the subjective ratings from the users.

failed dialogues (more than 15 turns) are located close to each other, mostly at the bottom right. On the other hand, there are other failed dialogues which are spread throughout the cluster. We can also see that the successful dialogues were on average shorter than 10 turns, which is consistent with the claim that users do not engage in longer dialogues with well-trained task-oriented systems.

This visualisation shows the potential of the unsupervised dialogue embedding since the transformed dialogue representations appear to be correlated with dialogue success in the majority of cases. For the purpose of GP reward modelling, this LSTM Encoder-Decoder embedding function appears therefore to be suitable for extracting an adequate fixed-dimension dialogue representation.

4.2 Dialogue Policy Learning

Given the well-trained dialogue embedding function, the proposed GP reward model operates on this input space. The system was implemented using the GPy library (Hensman et al., 2012). Given the predictive success probability of each newly seen dialogue, the threshold λ for the uncertainty region was initially set to 1 to encourage label querying and annealed to 0.85 for the first 50 collected dialogues and then set to 0.85 thereafter.

Initially, as each new dialogue was added to the training set, the hyper-parameters that defined the structure of the kernels mentioned in Eqn. 3 were optimised to minimise the negative log marginal likelihood using conjugate gradient as-

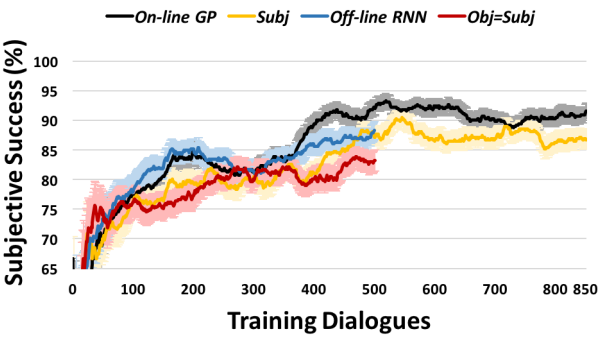

Figure 5: Learning curves showing subjective success as a function of the number of training dialogues used during on-line policy optimisation. The *on-line GP*, *Subj*, *off-line RNN* and *Obj=Subj* systems are shown as black, yellow, blue, and red lines. The light-coloured areas are one standard error intervals.

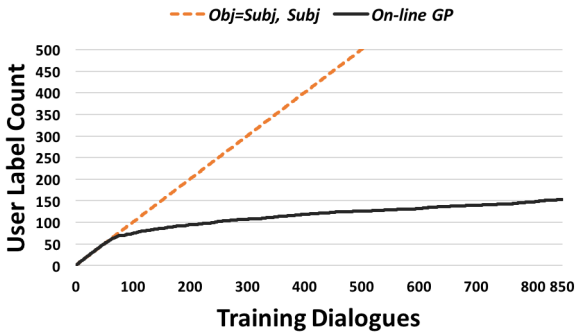

Figure 6: The number of times each system queries the user for feedback during on-line policy optimisation as a function of the number of training dialogues. The orange line represents both the *Obj=Subj* and *Subj* systems, and the black line represents the *on-line GP* system.

cent (Rasmussen and Williams, 2006). To prevent *overfitting*, after the first 40 dialogues, these hyper-parameters were only re-optimised after every batch of 20 dialogues.

To investigate the performance of the proposed *on-line GP* policy learning, three other contrasting systems were also tested. Note that the handcrafted system is not compared since it does not scale to larger domains and is sensitive to speech recognition errors. In each case, the only difference was the method used to compute the reward:

- the *Obj=Subj* system which uses prior knowledge of the task to only use training dialogues for which the user's subjective assessment of success is consistent with the objective assessment of success as in (Gašić et al., 2013).
- the *Subj* system which directly optimises the policy using only the user assessment of success whether accurate or not.
- the *off-line RNN* system that uses 1K simulated data and the corresponding *Obj* labels to train an RNN success estimator as in (Su et al., 2015a).

For the *Subj* system rating, in order to focus solely on the performance of the policy rather than other aspects of the system such as the fluency of the reply sentence, users were asked to rate dialogue success by answering the following question: *Did you find all the information you were looking for?*

All four of the above systems were trained with a total of 500 dialogues on-line by users recruited via the AMT service. Figure 5 shows the on-line learning curve of the subjective success rating when during training. For each system, the moving average was calculated using a window of 150 dialogues. In each case, three distinct policies were trained and the results were averaged to reduce noise.

As can be seen, all four systems perform better than 80 % subjective success rate after approximately 500 training dialogues. The *Obj=Subj* system is relatively poor compared to the others. This might be because users often report success even though the objective evaluation indicates failure. In such cases, the dialogue is discarded and not used for training. As a consequence, the *Obj=Subj* system required approximately 700 dialogues in order to obtain 500 which were useful, whereas all other systems made use of every dialogue.

To investigate learning behaviour over longer spans, training for the *on-line GP* and the *Subj* systems was extended to 850 dialogues. As can be seen, performance in both cases is broadly flat.

Similar to the conclusions drawn in (Gašić et al., 2011), the *Subj* system suffers from unreliable user feedback. Firstly, as in the *Obj=Subj* system, users forget the full requirements of the task and in particular, forget to ask for all required information. Secondly, users give inconsistent feedback due to a lack of proper care and attention. From Figure 5 it can be clearly seen that the *on-line GP* system consistently performed better than

Subj system, presumably, because its noise model mitigates the effect of inconsistency in user feedback. Of course, unlike crowd-sourced subjects, real users might provide more consistent feedback, but nevertheless, some inconsistency is inevitable and the noise model offers the needed robustness.

The advantage of the *on-line GP* system in reducing the number of times that the system requests user feedback (i.e. the label cost) can be seen in Figure 6. The black curve shows the number of active learning queries triggered in the *on-line GP* system averaged across the three policies. This system required only 150 user feedback requests to train a robust reward model. On the other hand, the *Obj=Subj* and *Subj* systems require user feedback for every training dialogue as shown by the dashed orange line.

Of course, the *off-line RNN* system required no user feedback at all when training the system on-line since it had the benefit of prior access to a user simulator. Its performance during training after the first 300 dialogues was, however, inferior to the *on-line GP* system.

4.3 Dialogue Policy Evaluation

In order to compare performance, the averaged results obtained between 400-500 training dialogues are shown in the first section of Table 1 along with one standard error. For the 400-500 interval, the *Subj*, *off-line RNN* and *on-line GP* systems achieved comparable results without statistical differences. The results of continuing training on the *Subj* and *on-line GP* systems from 500 to 850 training dialogues are also shown. As can be seen, the *on-line GP* system was significantly better presumably because it is more robust to erroneous user feedback compared to the *Subj* system.

4.4 Reward Model Evaluation

The above results verify the effectiveness of the proposed reward model for policy learning. Here we investigate further the accuracy of the model in predicting the subjective success rate. An evaluation of the *on-line GP* reward model between 1 and 850 training dialogues is presented in Table 2.

Since three reward models were learnt each with 850 dialogues, there were a total of 2550 training dialogues. Of these, the models queried the user for feedback a total of 454 times, leaving 2096 dialogues for which learning relied on the reward model's prediction. The results shown in the table are thus the average over 2096 dialogues.

Table 1: Subjective evaluation of the *Obj=Subj*, *off-line RNN*, *Subj* and *on-line GP* system during different stages of on-line policy learning. *Subjective*: user binary rating on dialogue success. Statistical significance was calculated using a two-tailed Students t-test with p-value of 0.05.

Dialogues	**Reward Model**	***Subjective*** *(%)*
400-500	*Obj=Subj*	85.0 ± 2.1
	off-line RNN	89.0 ± 1.8
	Subj	90.7 ± 1.7
	on-line GP	91.7 ± 1.6
500-850	*Subj*	87.1 ± 1.0
	on-line GP	$\mathbf{90.9 \pm 0.9}$*

$^* p < 0.05$

As can be seen, there was a significant imbalance between success and fail labels since the policy was improving along with the training dialogues. This lowered the recall on failed dialogue prediction as the model was biased to data with positive labels. Nevertheless, its precision scores well. On the other hand, the successful dialogues were accurately predicted by the proposed model.

Table 2: Statistical evaluation of the prediction of the *on-line GP* systems with respect to *Subj* rating.

Subj	**Prec.**	**Recall**	**F-measure**	**Number**
Fail	1.00	0.52	0.68	204
Suc.	0.95	1.00	0.97	1892
Total	0.96	0.95	0.95	2096

4.5 Example Dialogues

The key benefits of the *on-line GP* reward model compared to other models are its robustness to noise and efficient use of user supervision. Since the four systems compared above differ only in the design of reward model (learning objective), their on-line behaviours were broadly similar.

Two example dialogues between users and the *on-line GP* system are listed in Table 3 to illustrate how the system operates under different noise conditions. The user's subjective rating and the rating determined by the *on-line GP* reward model are also shown. The labels '*n*-th ASR' and '*n*-th SEM' indicate the n-th most likely hypotheses from speech recogniser and semantic decoder respectively.

Table 3: Example dialogues between on-line users and the proposed *on-line GP* system.

-Low noise condition- (User Subjective Evaluation: *Success***, on-line GP Evaluation:** *Success***)**	
Machine	: Hello, welcome to the Cambridge dialogue system, What kind of food would you like?
Human	: [Top ASR] Yeah I want to find a restaurant that serves European food.
	[Top SEM] inform(food=european,type=restaurant)
Machine	: Hotel du Vin and Bistro is a nice place. It serves European food.
Human	: [Top ASR] Uh what is the address and phone number?
	[Top SEM] request(phone,addr)
Machine	: Hotel du Vin and Bistro is a nice place. Their address is 15-19 Trumpington Street and their phone is 01223 227330.
Human	: [Top ASR] Thank you goodbye.
	[Top SEM] bye()
Machine	: Thank you for using this system.
-Higher noise condition- (User Subjective Evaluation: *Success***, on-line GP Evaluation:** *Success***)**	
Machine	: Hello, welcome to the Cambridge dialogue system, What kind of food would you like?
Human	: [Top ASR] And I want to find a expensive restaurant it should be in the south part of town.
	[Top SEM] inform(area=south,pricerange=expensive,type=restaurant)
Machine	: Gourmet burger kitchen is a nice place it is in the expensive price range.
Human	: [Top ASR] And do you have something else?
	[Top SEM] null()
	[2nd SEM] reqalts()
Machine	: Did you say you are looking for a venue in the area of south ?
Human	: [Top ASR] Yes.
	[Top SEM] affirm()
Machine	: Frankie and Benny's is a nice place, it is in the south part of town and it is in the expensive price range.
Human	: [Top ASR] Okay can I have the uh address phone number called for any.
	[Top SEM] request(addr)
	[2nd SEM] request(phone,addr)
Machine	: Frankie and Benny's is a nice place. Their address is Clifton Way and their phone number is 01223 412430.
Human	: [Top ASR] What is the pub called for free you any?
	...
	[5th ASR] What is the post code for free you any?
	[Top SEM] request(postcode)
Machine	: Frankie and Benny's is a nice place. Their postcode is C.B 1, 7 D.Y.
Human	: [Top ASR] Thank you goodbye.
	[Top SEM] bye()
Machine	: Thank you for using this system.

5 Conclusion

In this paper we have proposed an active reward learning model using Gaussian process classification and an unsupervised neural network-based dialogue embedding to enable truly on-line policy learning in spoken dialogue systems. The system enables stable policy optimisation by robustly modelling the inherent noise in real user feedback and uses active learning to minimise the number of feedback requests to the user. We found that the proposed model achieved efficient policy learning and better performance compared to other state-of-the-art methods in the Cambridge restaurant domain. A key advantage of this Bayesian model is that its uncertainty estimate allows active learning and noise handling in a natural way. The unsupervised dialogue embedding function required no labelled data to train whilst providing a compact and useful input to the reward predictor. Overall, the techniques developed in this paper enable for the first time a viable approach to on-line learning in deployed real-world dialogue systems which does not need a large corpus of manually annotated data or the construction of a user simulator.

Consistent with all of our previous work, the reward function studied here is focused primarily on task success. This may be too simplistic for many commercial applications and further work will be needed in conjunction with human interaction experts to identify and incorporate the extra dimensions of dialogue quality that will be needed to achieve the highest levels of user satisfaction.

Abstract

We introduce a globally normalized transition-based neural network model that achieves state-of-the-art part-of-speech tagging, dependency parsing and sentence compression results. Our model is a simple feed-forward neural network that operates on a task-specific transition system, yet achieves comparable or better accuracies than recurrent models. We discuss the importance of global as opposed to local normalization: a key insight is that the label bias problem implies that globally normalized models can be strictly more expressive than locally normalized models.

1 Introduction

Neural network approaches have taken the field of natural language processing (NLP) by storm. In particular, variants of long short-term memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) have produced impressive results on some of the classic NLP tasks such as part-of-speech tagging (Ling et al., 2015), syntactic parsing (Vinyals et al., 2015) and semantic role labeling (Zhou and Xu, 2015). One might speculate that it is the recurrent nature of these models that enables these results.

In this work we demonstrate that simple feed-forward networks without any recurrence can achieve comparable or better accuracies than LSTMs, as long as they are globally normalized. Our model, described in detail in Section 2, uses a transition system (Nivre, 2006) and feature embeddings as introduced by Chen and Manning (2014). We do not use any recurrence, but perform beam search for maintaining multiple hypotheses and introduce global normalization with a conditional random field (CRF) objective (Bottou et al., 1997; Le Cun et al., 1998; Lafferty et al., 2001; Collobert et al., 2011) to overcome the label bias problem that locally normalized models suffer from. Since we use beam inference, we approximate the partition function by summing over the elements in the beam, and use early updates (Collins and Roark, 2004; Zhou et al., 2015). We compute gradients based on this approximate global normalization and perform full backpropagation training of all neural network parameters based on the CRF loss.

In Section 3 we revisit the label bias problem and the implication that globally normalized models are strictly more expressive than locally normalized models. Lookahead features can partially mitigate this discrepancy, but cannot fully compensate for it—a point to which we return later. To empirically demonstrate the effectiveness of global normalization, we evaluate our model on part-of-speech tagging, syntactic dependency parsing and sentence compression (Section 4). Our model achieves state-of-the-art accuracy on all of these tasks, matching or outperforming LSTMs while being significantly faster. In particular for dependency parsing on the Wall Street Journal we achieve the best-ever published unlabeled attachment score of 94.61%.

As discussed in more detail in Section 5, we also outperform previous structured training approaches used for neural network transition-based parsing. Our ablation experiments show that we outperform Weiss et al. (2015) and Alberti et al. (2015) because we do global backpropagation training of all model parameters, while they fix the neural network parameters when training the global part of their model. We also outperform Zhou et al. (2015) despite using a smaller beam. To shed additional light on the label bias problem

Berlin, Germany, August 7-12, 2016.

in practice, we provide a sentence compression example where the local model completely fails. We then demonstrate that a globally normalized parsing model without any lookahead features is almost as accurate as our best model, while a locally normalized model loses more than 10% absolute in accuracy because it cannot effectively incorporate evidence as it becomes available.

Finally, we provide an open-source implementation of our method, called SyntaxNet,[1] which we have integrated into the popular TensorFlow[2] framework. We also provide a pre-trained, state-of-the art English dependency parser called "Parsey McParseface," which we tuned for a balance of speed, simplicity, and accuracy.

2 Model

At its core, our model is an incremental transition-based parser (Nivre, 2006). To apply it to different tasks we only need to adjust the transition system and the input features.

2.1 Transition System

Given an input x, most often a sentence, we define:

- A set of states $\mathcal{S}(x)$.
- A special start state $s^\dagger \in \mathcal{S}(x)$.
- A set of allowed decisions $\mathcal{A}(s, x)$ for all $s \in \mathcal{S}(x)$.
- A transition function $t(s, d, x)$ returning a new state s' for any decision $d \in \mathcal{A}(s, x)$.

We will use a function $\rho(s, d, x; \theta)$ to compute the score of decision d in state s for input x. The vector θ contains the model parameters and we assume that $\rho(s, d, x; \theta)$ is differentiable with respect to θ.

In this section, for brevity, we will drop the dependence of x in the functions given above, simply writing $\mathcal{S}$, $\mathcal{A}(s)$, $t(s, d)$, and $\rho(s, d; \theta)$.

Throughout this work we will use transition systems in which all complete structures for the same input x have the same number of decisions $n(x)$ (or n for brevity). In dependency parsing for example, this is true for both the *arc-standard* and *arc-eager* transition systems (Nivre, 2006), where for a sentence x of length m, the number of decisions for any complete parse is $n(x) = 2 \times m$.[3]

A complete structure is then a sequence of decision/state pairs $(s_1, d_1) \dots (s_n, d_n)$ such that $s_1 = s^\dagger$, $d_i \in \mathcal{S}(s_i)$ for $i = 1 \dots n$, and $s_{i+1} = t(s_i, d_i)$. We use the notation $d_{1:j}$ to refer to a decision sequence $d_1 \dots d_j$.

We assume that there is a one-to-one mapping between decision sequences $d_{1:j-1}$ and states s_j: that is, we essentially assume that a state encodes the entire history of decisions. Thus, each state can be reached by a unique decision sequence from $s^\dagger$.[4] We will use decision sequences $d_{1:j-1}$ and states interchangeably: in a slight abuse of notation, we define $\rho(d_{1:j-1}, d; \theta)$ to be equal to $\rho(s, d; \theta)$ where s is the state reached by the decision sequence $d_{1:j-1}$.

The scoring function $\rho(s, d; \theta)$ can be defined in a number of ways. In this work, following Chen and Manning (2014), Weiss et al. (2015), and Zhou et al. (2015), we define it via a feed-forward neural network as

$$\rho(s, d; \theta) = \phi(s; \theta^{(l)}) \cdot \theta^{(d)}.$$

Here $\theta^{(l)}$ are the parameters of the neural network, excluding the parameters at the final layer. $\theta^{(d)}$ are the final layer parameters for decision d. $\phi(s; \theta^{(l)})$ is the representation for state s computed by the neural network under parameters $\theta^{(l)}$. Note that the score is linear in the parameters $\theta^{(d)}$. We next describe how softmax-style normalization can be performed at the local or global level.

2.2 Global vs. Local Normalization

In the Chen and Manning (2014) style of greedy neural network parsing, the conditional probability distribution over decisions d_j given context $d_{1:j-1}$ is defined as

$$p(d_j | d_{1:j-1}; \theta) = \frac{\exp \rho(d_{1:j-1}, d_j; \theta)}{Z_L(d_{1:j-1}; \theta)}, \quad (1)$$

where

$$Z_L(d_{1:j-1}; \theta) = \sum_{d' \in \mathcal{A}(d_{1:j-1})} \exp \rho(d_{1:j-1}, d'; \theta).$$

[1] http://github.com/tensorflow/models/tree/master/syntaxnet

[2] http://www.tensorflow.org

[3] Note that this is not true for the *swap* transition system defined in Nivre (2009).

[4] It is straightforward to extend the approach to make use of dynamic programming in the case where the same state can be reached by multiple decision sequences.

Each $Z_L(d_{1:j-1};\theta)$ is a *local* normalization term. The probability of a sequence of decisions $d_{1:n}$ is

$$p_L(d_{1:n}) = \prod_{j=1}^{n} p(d_j|d_{1:j-1};\theta) = \frac{\exp\sum_{j=1}^{n}\rho(d_{1:j-1},d_j;\theta)}{\prod_{j=1}^{n} Z_L(d_{1:j-1};\theta)}. \quad (2)$$

Beam search can be used to attempt to find the maximum of Eq. (2) with respect to $d_{1:n}$. The additive scores used in beam search are the log-softmax of each decision, $\ln p(d_j|d_{1:j-1};\theta)$, not the raw scores $\rho(d_{1:j-1},d_j;\theta)$.

In contrast, a Conditional Random Field (CRF) defines a distribution $p_G(d_{1:n})$ as follows:

$$p_G(d_{1:n}) = \frac{\exp\sum_{j=1}^{n}\rho(d_{1:j-1},d_j;\theta)}{Z_G(\theta)}, \quad (3)$$

where

$$Z_G(\theta) = \sum_{d'_{1:n}\in\mathcal{D}_n} \exp\sum_{j=1}^{n}\rho(d'_{1:j-1},d'_j;\theta)$$

and $\mathcal{D}_n$ is the set of all valid sequences of decisions of length n. $Z_G(\theta)$ is a *global* normalization term. The inference problem is now to find

$$\operatorname*{argmax}_{d_{1:n}\in\mathcal{D}_n} p_G(d_{1:n}) = \operatorname*{argmax}_{d_{1:n}\in\mathcal{D}_n} \sum_{j=1}^{n}\rho(d_{1:j-1},d_j;\theta).$$

Beam search can again be used to approximately find the argmax.

2.3 Training

Training data consists of inputs x paired with gold decision sequences $d^*_{1:n}$. We use stochastic gradient descent on the negative log-likelihood of the data under the model. Under a locally normalized model, the negative log-likelihood is

$$L_{\text{local}}(d^*_{1:n};\theta) = -\ln p_L(d^*_{1:n};\theta) = \quad (4)$$
$$-\sum_{j=1}^{n}\rho(d^*_{1:j-1},d^*_j;\theta) + \sum_{j=1}^{n}\ln Z_L(d^*_{1:j-1};\theta),$$

whereas under a globally normalized model it is

$$L_{\text{global}}(d^*_{1:n};\theta) = -\ln p_G(d^*_{1:n};\theta) =$$
$$-\sum_{j=1}^{n}\rho(d^*_{1:j-1},d^*_j;\theta) + \ln Z_G(\theta). \quad (5)$$

A significant practical advantange of the locally normalized cost Eq. (4) is that the local partition function Z_L and its derivative can usually be computed efficiently. In contrast, the Z_G term in Eq. (5) contains a sum over $d'_{1:n} \in \mathcal{D}_n$ that is in many cases intractable.

To make learning tractable with the globally normalized model, we use beam search and early updates (Collins and Roark, 2004; Zhou et al., 2015). As the training sequence is being decoded, we keep track of the location of the gold path in the beam. If the gold path falls out of the beam at step j, a stochastic gradient step is taken on the following objective:

$$L_{\text{global-beam}}(d^*_{1:j};\theta) =$$
$$-\sum_{i=1}^{j}\rho(d^*_{1:i-1},d^*_i;\theta) + \ln\sum_{d'_{1:j}\in\mathcal{B}_j}\exp\sum_{i=1}^{j}\rho(d'_{1:i-1},d'_i;\theta). \quad (6)$$

Here the set $\mathcal{B}_j$ contains all paths in the beam at step j, together with the gold path prefix $d^*_{1:j}$. It is straightforward to derive gradients of the loss in Eq. (6) and to back-propagate gradients to all levels of a neural network defining the score $\rho(s,d;\theta)$. If the gold path remains in the beam throughout decoding, a gradient step is performed using $\mathcal{B}_n$, the beam at the end of decoding.

3 The Label Bias Problem

Intuitively, we would like the model to be able to revise an earlier decision made during search, when later evidence becomes available that rules out the earlier decision as incorrect. At first glance, it might appear that a locally normalized model used in conjunction with beam search or exact search is able to revise earlier decisions. However the label bias problem (see Bottou (1991), Collins (1999) pages 222-226, Lafferty et al. (2001), Bottou and LeCun (2005), Smith and Johnson (2007)) means that locally normalized models often have a very weak ability to revise earlier decisions.

This section gives a formal perspective on the label bias problem, through a proof that globally normalized models are strictly more expressive than locally normalized models. The theorem was originally proved[5] by Smith and Johnson (2007).

[5]More precisely Smith and Johnson (2007) prove the theorem for models with potential functions of the form $\rho(d_{i-1},d_i,x_i)$; the generalization to potential functions of the form $\rho(d_{1:i-1},d_i,x_{1:i})$ is straightforward.

The example underlying the proof gives a clear illustration of the label bias problem.[6]

Global Models can be Strictly More Expressive than Local Models Consider a tagging problem where the task is to map an input sequence $x_{1:n}$ to a decision sequence $d_{1:n}$. First, consider a locally normalized model where we restrict the scoring function to access only the first i input symbols $x_{1:i}$ when scoring decision d_i. We will return to this restriction soon. The scoring function ρ can be an otherwise arbitrary function of the tuple $\langle d_{1:i-1}, d_i, x_{1:i}\rangle$:

$$p_L(d_{1:n}|x_{1:n}) = \prod_{i=1}^{n} p_L(d_i|d_{1:i-1}, x_{1:i}) = \frac{\exp\sum_{i=1}^{n}\rho(d_{1:i-1}, d_i, x_{1:i})}{\prod_{i=1}^{n} Z_L(d_{1:i-1}, x_{1:i})}.$$

Second, consider a globally normalized model

$$p_G(d_{1:n}|x_{1:n}) = \frac{\exp\sum_{i=1}^{n}\rho(d_{1:i-1}, d_i, x_{1:i})}{Z_G(x_{1:n})}.$$

This model again makes use of a scoring function $\rho(d_{1:i-1}, d_i, x_{1:i})$ restricted to the first i input symbols when scoring decision d_i.

Define $\mathcal{P}_L$ to be the set of all possible distributions $p_L(d_{1:n}|x_{1:n})$ under the local model obtained as the scores ρ vary. Similarly, define $\mathcal{P}_G$ to be the set of all possible distributions $p_G(d_{1:n}|x_{1:n})$ under the global model. Here a "distribution" is a function from a pair $(x_{1:n}, d_{1:n})$ to a probability $p(d_{1:n}|x_{1:n})$. Our main result is the following:

Theorem 3.1 *See also Smith and Johnson (2007). $\mathcal{P}_L$ is a strict subset of $\mathcal{P}_G$, that is $\mathcal{P}_L \subsetneq \mathcal{P}_G$.*

To prove this we will first prove that $\mathcal{P}_L \subseteq \mathcal{P}_G$. This step is straightforward. We then show that $\mathcal{P}_G \not\subseteq \mathcal{P}_L$; that is, there are distributions in $\mathcal{P}_G$ that are not in $\mathcal{P}_L$. The proof that $\mathcal{P}_G \not\subseteq \mathcal{P}_L$ gives a clear illustration of the label bias problem.

Proof that $\mathcal{P}_L \subseteq \mathcal{P}_G$: We need to show that for any locally normalized distribution p_L, we can construct a globally normalized model p_G such that $p_G = p_L$. Consider a locally normalized model with scores $\rho(d_{1:i-1}, d_i, x_{1:i})$. Define a global model p_G with scores

$$\rho'(d_{1:i-1}, d_i, x_{1:i}) = \log p_L(d_i|d_{1:i-1}, x_{1:i}).$$

Then it is easily verified that

$$p_G(d_{1:n}|x_{1:n}) = p_L(d_{1:n}|x_{1:n})$$

for all $x_{1:n}, d_{1:n}$. □

In proving $\mathcal{P}_G \not\subseteq \mathcal{P}_L$ we will use a simple problem where every example seen in training or test data is one of the following two tagged sentences:

$$x_1x_2x_3 = \text{a b c}, \quad d_1d_2d_3 = \text{A B C}$$
$$x_1x_2x_3 = \text{a b e}, \quad d_1d_2d_3 = \text{A D E} \qquad (7)$$

Note that the input $x_2 = \text{b}$ is ambiguous: it can take tags B or D. This ambiguity is resolved when the next input symbol, c or e, is observed.

Now consider a globally normalized model, where the scores $\rho(d_{1:i-1}, d_i, x_{1:i})$ are defined as follows. Define $\mathcal{T}$ as the set $\{(A, B), (B, C), (A, D), (D, E)\}$ of bigram tag transitions seen in the data. Similarly, define $\mathcal{E}$ as the set $\{(a, A), (b, B), (c, C), (b, D), (e, E)\}$ of (word, tag) pairs seen in the data. We define

$$\rho(d_{1:i-1}, d_i, x_{1:i}) = \alpha \times [\![(d_{i-1}, d_i) \in \mathcal{T}]\!] + \alpha \times [\![(x_i, d_i) \in \mathcal{E}]\!] \qquad (8)$$

where α is the single scalar parameter of the model, and $[\![\pi]\!] = 1$ if π is true, 0 otherwise.

Proof that $\mathcal{P}_G \not\subseteq \mathcal{P}_L$: We will construct a globally normalized model p_G such that there is no locally normalized model such that $p_L = p_G$.

Under the definition in Eq. (8), it is straightforward to show that

$$\lim_{\alpha\to\infty} p_G(\text{A B C}|\text{a b c}) = \lim_{\alpha\to\infty} p_G(\text{A D E}|\text{a b e}) = 1.$$

In contrast, under *any* definition for $\rho(d_{1:i-1}, d_i, x_{1:i})$, we must have

$$p_L(\text{A B C}|\text{a b c}) + p_L(\text{A D E}|\text{a b e}) \leq 1 \qquad (9)$$

This follows because $p_L(\text{A B C}|\text{a b c}) = p_L(\text{A}|\text{a}) \times p_L(\text{B}|\text{A, a b}) \times p_L(\text{C}|\text{A B, a b c})$ and $p_L(\text{A D E}|\text{a b e}) = p_L(\text{A}|\text{a}) \times p_L(\text{D}|\text{A, a b}) \times p_L(\text{E}|\text{A D, a b e})$. The inequality $p_L(\text{B}|\text{A, a b}) + p_L(\text{D}|\text{A, a b}) \leq 1$ then immediately implies Eq. (9).

[6] Smith and Johnson (2007) cite Michael Collins as the source of the example underlying the proof. Note that the theorem refers to *conditional* models of the form $p(d_{1:n}|x_{1:n})$ with global or local normalization. Equivalence (or non-equivalence) results for *joint* models of the form $p(d_{1:n}, x_{1:n})$ are quite different: for example results from Chi (1999) and Abney et al. (1999) imply that weighted context-free grammars (a globally normalized joint model) and probabilistic context-free grammars (a locally normalized joint model) are equally expressive.

Parsey McParseface	-	97.52	94.24	96.45	-	-	-	-	-	-	-	-

Table 1: Final POS tagging test set results on English WSJ and Treebank Union as well as CoNLL'09. We also show the performance of our pre-trained open source model, "Parsey McParseface."

It follows that for sufficiently large values of α, we have $p_G(\text{A B C}|\text{a b c}) + p_G(\text{A D E}|\text{a b e}) > 1$, and given Eq. (9) it is impossible to define a locally normalized model with $p_L(\text{A B C}|\text{a b c}) = p_G(\text{A B C}|\text{a b c})$ and $p_L(\text{A D E}|\text{a b e}) = p_G(\text{A D E}|\text{a b e})$. □

Under the restriction that scores $\rho(d_{1:i-1}, d_i, x_{1:i})$ depend only on the first i input symbols, the globally normalized model is still able to model the data in Eq. (7), while the locally normalized model fails (see Eq. 9). The ambiguity at input symbol b is naturally resolved when the next symbol (c or e) is observed, but the locally normalized model is not able to revise its prediction.

It is easy to fix the locally normalized model for the example in Eq. (7) by allowing scores $\rho(d_{1:i-1}, d_i, x_{1:i+1})$ that take into account the input symbol x_{i+1}. More generally we can have a model of the form $\rho(d_{1:i-1}, d_i, x_{1:i+k})$ where the integer k specifies the amount of lookahead in the model. Such lookahead is common in practice, but insufficient in general. For every amount of lookahead k, we can construct examples that cannot be modeled with a locally normalized model by duplicating the middle input b in (7) $k+1$ times. Only a local model with scores $\rho(d_{1:i-1}, d_i, x_{1:n})$ that considers the entire input can capture any distribution $p(d_{1:n}|x_{1:n})$: in this case the decomposition $p_L(d_{1:n}|x_{1:n}) = \prod_{i=1}^{n} p_L(d_i|d_{1:i-1}, x_{1:n})$ makes no independence assumptions.

However, increasing the amount of context used as input comes at a cost, requiring more powerful learning algorithms, and potentially more training data. For a detailed analysis of the tradeoffs between structural features in CRFs and more powerful local classifiers without structural constraints, see Liang et al. (2008); in these experiments local classifiers are unable to reach the performance of CRFs on problems such as parsing and named entity recognition where structural constraints are important. Note that there is nothing to preclude an approach that makes use of both global normalization and more powerful scoring functions $\rho(d_{1:i-1}, d_i, x_{1:n})$, obtaining the best of both worlds. The experiments that follow make use of both.

4 Experiments

To demonstrate the flexibility and modeling power of our approach, we provide experimental results on a diverse set of structured prediction tasks. We apply our approach to POS tagging, syntactic dependency parsing, and sentence compression.

While directly optimizing the global model defined by Eq. (5) works well, we found that training the model in two steps achieves the same precision much faster: we first pretrain the network using the local objective given in Eq. (4), and then perform additional training steps using the global objective given in Eq. (6). We pretrain all layers except the softmax layer in this way. We purposefully abstain from complicated hand engineering of input features, which might improve performance further (Durrett and Klein, 2015).

We use the training recipe from Weiss et al. (2015) for each training stage of our model. Specifically, we use averaged stochastic gradient descent with momentum, and we tune the learning rate, learning rate schedule, momentum, and early stopping time using a separate held-out corpus for each task. We tune again with a different set of hyperparameters for training with the global objective.

4.1 Part of Speech Tagging

Part of speech (POS) tagging is a classic NLP task, where modeling the structure of the output is important for achieving state-of-the-art performance.

Data & Evaluation. We conducted experiments on a number of different datasets: (1) the English Wall Street Journal (WSJ) part of the Penn Treebank (Marcus et al., 1993) with standard POS tagging splits; (2) the English "Treebank Union" multi-domain corpus containing data from the OntoNotes corpus version 5 (Hovy et al., 2006), the English Web Treebank (Petrov and McDonald, 2012), and the updated and corrected Question Treebank (Judge et al., 2006) with identical setup to Weiss et al. (2015); and (3) the CoNLL '09 multi-lingual shared task (Hajič et al., 2009).

Model Configuration. Inspired by the integrated POS tagging and parsing transition system of Bohnet and Nivre (2012), we employ a simple transition system that uses only a SHIFT action and predicts the POS tag of the current word on the buffer as it gets shifted to the stack. We extract the following features on a window ± 3 tokens centered at the current focus token: word, cluster, character n-gram up to length 3. We also extract the tag predicted for the previous 4 tokens. The network in these experiments has a single hidden layer with 256 units on WSJ and Treebank Union and 64 on CoNLL'09.

Results. In Table 1 we compare our model to a linear CRF and to the compositional character-to-word LSTM model of Ling et al. (2015). The CRF is a first-order linear model with exact inference and the same emission features as our model. It additionally also has transition features of the word, cluster and character n-gram up to length 3 on both endpoints of the transition. The results for Ling et al. (2015) were solicited from the authors.

Our local model already compares favorably against these methods on average. Using beam search with a locally normalized model does not help, but with global normalization it leads to a 7% reduction in relative error, empirically demonstrating the effect of label bias. The set of character ngrams feature is very important, increasing average accuracy on the CoNLL'09 datasets by about 0.5% absolute. This shows that character-level modeling can also be done with a simple feed-forward network without recurrence.

4.2 Dependency Parsing

In dependency parsing the goal is to produce a directed tree representing the syntactic structure of the input sentence.

Data & Evaluation. We use the same corpora as in our POS tagging experiments, except that we use the standard parsing splits of the WSJ. To avoid over-fitting to the development set (Sec. 22), we use Sec. 24 for tuning the hyperparameters of our models. We convert the English constituency trees to Stanford style dependencies (De Marneffe et al., 2006) using version 3.3.0 of the converter. For English, we use predicted POS tags (the same POS tags are used for all models) and exclude punctuation from the evaluation, as is standard. For the CoNLL '09 datasets we follow standard practice and include all punctuation in the evaluation. We follow Alberti et al. (2015) and use our own predicted POS tags so that we can include a k-best tag feature (see below) but use the supplied predicted morphological features. We report unlabeled and labeled attachment scores (UAS/LAS).

Model Configuration. Our model configuration is basically the same as the one originally proposed by Chen and Manning (2014) and then refined by Weiss et al. (2015). In particular, we use the arc-standard transition system and extract the same set of features as prior work: words, part of speech tags, and dependency arcs and labels in the surrounding context of the state, as well as k-best tags as proposed by Alberti et al. (2015). We use two hidden layers of 1,024 dimensions each.

Results. Tables 2 and 3 show our final parsing results and a comparison to the best systems from the literature. We obtain the best ever published results on almost all datasets, including the WSJ. Our main results use the same pre-trained word embeddings as Weiss et al. (2015) and Alberti et al. (2015), but no tri-training. When we artificially restrict ourselves to not use pre-trained word embeddings, we observe only a modest drop of $\sim$0.5% UAS; for example, training only on the WSJ yields 94.08% UAS and 92.15% LAS for our global model with a beam of size 32.

Even though we do not use tri-training, our model compares favorably to the 94.26% LAS and 92.41% UAS reported by Weiss et al. (2015) with tri-training. As we show in Sec. 5, these gains can be attributed to the full backpropagation training that differentiates our approach from that of Weiss et al. (2015) and Alberti et al. (2015). Our results also significantly outperform the LSTM-based approaches of Dyer et al. (2015) and Ballesteros et al. (2015).

4.3 Sentence Compression

Our final structured prediction task is extractive sentence compression.

Data & Evaluation. We follow Filippova et al. (2015), where a large news collection is used to heuristically generate compression instances. Our final corpus contains about 2.3M compression instances: we use 2M examples for training, 130k for development and 160k for the final test. We report per-token F1 score and per-sentence accuracy (A), i.e. percentage of instances that fully match the golden compressions. Following Filippova et al. (2015) we also run a human evaluation on 200 sentences where we ask the raters to score compressions for *readability* (`read`) and *informativeness* (`info`) on a scale from 0 to 5.

Model Configuration. The transition system for sentence compression is similar to POS tagging: we scan sentences from left-to-right and label each token as *keep* or *drop*. We extract features from words, POS tags, and dependency labels from a window of tokens centered on the input, as well as features from the history of predictions. We use a single hidden layer of size 400.

Method	Generated corpus A	Generated corpus F1	Human eval read	Human eval info
Filippova et al. (2015)	**35.36**	**82.83**	4.66	4.03
Automatic	-	-	4.31	3.77
Our Local (B=1)	30.51	78.72	4.58	4.03
Our Local (B=8)	31.19	75.69	-	-
Our Global (B=8)	35.16	81.41	**4.67**	**4.07**

Table 4: Sentence compression results on News data. *Automatic* refers to application of the same automatic extraction rules used to generate the News training corpus.

Results. Table 4 shows our sentence compression results. Our globally normalized model again significantly outperforms the local model. Beam search with a locally normalized model suffers from severe label bias issues that we discuss on a concrete example in Section 5. We also compare to the sentence compression system from Filippova et al. (2015), a 3-layer stacked LSTM which uses dependency label information. The LSTM and our global model perform on par on both the automatic evaluation as well as the human ratings, but our model is roughly 100× faster. All compressions kept approximately 42% of the tokens on average and all the models are significantly better than the automatic extractions ($p < 0.05$).

5 Discussion

We derived a proof for the label bias problem and the advantages of global models. We then empririically verified this theoretical superiority by demonstrating state-of-the-art performance on three different tasks. In this section we situate and compare our model to previous work and provide two examples of the label bias problem in practice.

5.1 Related Neural CRF Work

Neural network models have been been combined with conditional random fields and globally normalized models before. Bottou et al. (1997) and Le Cun et al. (1998) describe global training of neural network models for structured prediction problems. Peng et al. (2009) add a non-linear neural network layer to a linear-chain CRF and Do and Artires (2010) apply a similar approach to more general Markov network structures. Yao et al. (2014) and Zheng et al. (2015) introduce recurrence into the model and Huang et al. (2015) finally combine CRFs and LSTMs. These neural CRF models are limited to sequence labeling tasks where exact inference is possible, while our model works well when exact inference is intractable.

5.2 Related Transition-Based Parsing Work

For early work on neural-networks for transition-based parsing, see Henderson (2003; 2004). Our work is closest to the work of Weiss et al. (2015), Zhou et al. (2015) and Watanabe and Sumita (2015); in these approaches global normalization is added to the local model of Chen and Manning (2014). Empirically, Weiss et al. (2015) achieves the best performance, even though their model keeps the parameters of the locally normalized neural network fixed and only trains a perceptron that uses the activations as features. Their model is therefore limited in its ability to revise the predictions of the locally normalized model. In Table 5 we show that full backpropagation training all the way to the word embeddings is very important and significantly contributes to the performance of our model. We also compared training under the CRF objective with a Perceptron-like hinge loss between the gold and best elements of the beam. When we limited the backpropagation depth to training only the top layer $\theta^{(d)}$, we found negligible differences in accuracy: 93.20% and 93.28% for the CRF objective and hinge loss respectively. However, when training with full backpropagation the CRF accuracy is 0.2% higher and training converged more than 4× faster.

Method	UAS	LAS
Local (B=1)	92.85	90.59
Local (B=16)	93.32	91.09
Global (B=16) $\{\theta^{(d)}\}$	93.45	91.21
Global (B=16) $\{W_2, \theta^{(d)}\}$	94.01	91.77
Global (B=16) $\{W_1, W_2, \theta^{(d)}\}$	94.09	91.81
Global (B=16) (full)	94.38	92.17

Table 5: WSJ dev set scores for successively deeper levels of backpropagation. The *full* parameter set corresponds to backpropagation all the way to the embeddings. W_i: hidden layer i weights.

Zhou et al. (2015) perform full backpropagation training like us, but even with a much larger beam, their performance is significantly lower than ours. We also apply our model to two additional tasks, while they experiment only with dependency parsing. Finally, Watanabe and Sumita (2015) introduce recurrent components and additional techniques like max-violation updates for a corresponding constituency parsing model. In contrast, our model does not require any recurrence or specialized training.

5.3 Label Bias in Practice

We observed several instances of severe label bias in the sentence compression task. Although using beam search with the local model outperforms greedy inference on average, beam search leads the local model to occasionally produce empty compressions (Table 6). It is important to note that these are *not* search errors: the empty compression has higher probability under p_L than the prediction from greedy inference. However, the more expressive globally normalized model does not suffer from this limitation, and correctly gives the empty compression almost zero probability.

We also present some empirical evidence that the label bias problem is severe in parsing. We trained models where the scoring functions in parsing at position i in the sentence are limited to considering only tokens $x_{1:i}$; hence unlike the full parsing model, there is no ability to look ahead in the sentence when making a decision.[7] The result for a greedy model under this constraint

[7]This setting may be important in some applications, where for example parse structures for sentence prefixes are required, or where the input is received one word at a time and online processing is beneficial.

Method	Predicted compression	p_L	p_G
Local (B=1)	In Pakistan, former leader Pervez Musharraf has appeared in court for the first time, on treason charges.	0.13	0.05
Local (B=8)	In Pakistan, former leader Pervez Musharraf has appeared in court for the first time, on treason charges.	0.16	$<10^{-4}$
Global (B=8)	In Pakistan, former leader Pervez Musharraf has appeared in court for the first time, on treason charges.	0.06	0.07

Table 6: Example sentence compressions where the label bias of the locally normalized model leads to a breakdown during beam search. The probability of each compression under the local (p_L) and global (p_G) models shows that only the global model can properly represent zero probability for the empty compression.

is 76.96% UAS; for a locally normalized model with beam search is 81.35%; and for a globally normalized model is 93.60%. Thus the globally normalized model gets very close to the performance of a model with full lookahead, while the locally normalized model with a beam gives dramatically lower performance. In our final experiments with full lookahead, the globally normalized model achieves 94.01% accuracy, compared to 93.07% accuracy for a local model with beam search. Thus adding lookahead allows the local model to close the gap in performance to the global model; however there is still a significant difference in accuracy, which may in large part be due to the label bias problem.

A number of authors have considered modified training procedures for greedy models, or for locally normalized models. Daumé III et al. (2009) introduce Searn, an algorithm that allows a classifier making greedy decisions to become more robust to errors made in previous decisions. Goldberg and Nivre (2013) describe improvements to a greedy parsing approach that makes use of methods from imitation learning (Ross et al., 2011) to augment the training set. Note that these methods are focused on greedy models: they are unlikely to solve the label bias problem when used in conjunction with beam search, given that the problem is one of expressivity of the underlying model. More recent work (Yazdani and Henderson, 2015; Vaswani and Sagae, 2016) has augmented locally normalized models with *correctness probabilities* or *error states*, effectively adding a step after every decision where the probability of correctness of the resulting structure is evaluated. This gives considerable gains over a locally normalized model, although performance is lower than our full globally normalized approach.

6 Conclusions

We presented a simple and yet powerful model architecture that produces state-of-the-art results for POS tagging, dependency parsing and sentence compression. Our model combines the flexibility of transition-based algorithms and the modeling power of neural networks. Our results demonstrate that feed-forward network without recurrence can outperform recurrent models such as LSTMs when they are trained with global normalization. We further support our empirical findings with a proof showing that global normalization helps the model overcome the label bias problem from which locally normalized models suffer.

Acknowledgements

We would like to thank Ling Wang for training his C2W part-of-speech tagger on our setup, and Emily Pitler, Ryan McDonald, Greg Coppola and Fernando Pereira for tremendously helpful discussions. Finally, we are grateful to all members of the Google Parsing Team.
