As Siamese CBOW directly averages word embeddings for sentences, we expect it to learn that words with little semantic impact have a low vector norm. Indeed, we find that the 10 words with lowest vector norm are *to*, *of*, *and*, *the*, *a*, *in*, *that*, *with*, *on*, and *as*. At the other side of the spectrum we find many personal pronouns: *had*, *they*, *we*, *me*, *my*, *he*, *her*, *you*, *she*, *I*, which is natural given that the corpus on which we train consists of fiction, which typically contains dialogues.

It is interesting to see what the differences in related words are between Siamese CBOW and word2vec when trained on the same corpus. For example, for a cosine similarity > 0.6, the words related to *her* in word2vec space are *she*, *his*, *my* and *hers*. For Siamese CBOW, the only closely related word is *she*. Similarly, for the word *me*, word2vec finds *him* as most closely related word, while Siamese CBOW comes up with *I* and *my*. It seems from these few examples that Siamese CBOW learns to be very strict in choosing which words to relate to each other.

From the results presented in this section we conclude that optimizing word embeddings for the task of being averaged across sentences with Siamese CBOW leads to embeddings that are effective in a large variety of settings. Furthermore, Siamese CBOW is robust to different parameter settings and its performance is stable across itera-

tions. Lastly, we show that Siamese CBOW is fast and efficient in computing sentence embeddings at prediction time.

5 Related Work

A distinction can be made between supervised approaches for obtaining representations of short texts, where a model is optimised for a specific scenario, given a labeled training set, and unsupervised methods, trained on unlabeled data, that aim to capture short text semantics that are robust across tasks. In the first setting, word vectors are typically used as features or network initialisations (Kenter and de Rijke, 2015; Hu et al., 2014; Severyn and Moschitti, 2015; Yin and Schütze, 2015). Our work can be classified in the latter category of unsupervised approaches.

Many models related to the one we present here are used in a multilingual setting (Hermann and Blunsom, 2014b; Hermann and Blunsom, 2014a; Lauly et al., 2014). The key difference between this work and ours is that in a multilingual setting the goal is to predict, from a distributed representation of an input sentence, the same sentence in a different language, whereas our goals is to predict surrounding sentences.

Wieting et al. (2016) apply a model similar to ours in a related but different setting where explicit semantic knowledge is leveraged. As in our setting, word embeddings are trained by averaging them. However, unlike in our proposal, a margin-based loss function is used, which involves a parameter that has to be tuned. Furthermore, to select negative examples, at every training step, a computationally expensive comparison is made between all sentences in the training batch. The most crucial difference is that a large set of phrase pairs explicitly marked for semantic similarity has to be available as training material. Obtaining such high-quality training material is non-trivial, expensive and limits an approach to settings for which such material is available. In our work, we leverage unlabeled training data, of which there is a virtually unlimited amount.

As detailed in §2, our network predicts a sentence from its neighbouring sentences. The notion of learning from context sentences is also applied in (Kiros et al., 2015), where a recurrent neural network is employed. Our way of averaging the vectors of words contained in a sentence is more similar to the CBOW architecture of word2vec (Mikolov et al., 2013a), in which all context word vectors are aggregated to predict the one omitted word. A crucial difference between our approach and the word2vec CBOW approach is that we compare sentence representations directly, rather than comparing a (partial) sentence representation to a word representation. Given the correspondence between word2vec's CBOW model and ours, we included it as a baseline in our experiments in §3. As the skip-gram architecture has proven to be a strong baseline too in many settings, we include it too.

Yih et al. (2011) also propose a siamese architecture. Short texts are represented by tf-idf vectors and a linear combination of input weights is learnt by a two-layer fully connected network, which is used to represent the input text. The cosine similarity between pairs of representations is computed, but unlike our proposal, the differences between similarities of a positive and negative sentence pair are combined in a logistic loss function.

Finally, independently from our work, Hill et al. (2016) also present a log-linear model. Rather than comparing sentence representations to each other, as we propose, words in one sentence are compared to the representation of another sentence. As both input and output vectors are learnt, while we tie the parameters across the entire model, Hill et al. (2016)'s model has twice as many parameters as ours. Most importantly, however, the cost function used in (Hill et al., 2016) is crucially different from ours. As words in surrounding sentences are being compared to a sentence representation, the final layer of their network produces a softmax over the entire vocabulary. This is fundamentally different from the final softmax over cosines between sentence representations that we propose. Furthermore, the softmax over the vocabulary is, obviously, of vocabulary size, and hence grows when bigger vocabularies are used, causing additional computational cost. In our case, the size of the softmax is the number of positive plus negative examples (see §2.1). When the vocabulary grows, this size is unaffected.

6 Conclusion

We have presented Siamese CBOW, a neural network architecture that efficiently learns word embeddings optimized for producing sentence representations. The model is trained using only unla-

beled text data. It predicts, from an input sentence representation, the preceding and following sentence.

We evaluated the model on 20 test sets and show that in a majority of cases, 14 out of 20, Siamese CBOW outperforms a word2vec baseline and a baseline based on the recently proposed skip-thought architecture. As further analysis on various choices of parameters show that the method is stable across settings, we conclude that Siamese CBOW provides a robust way of generating high-quality sentence representations.

Word and sentence embeddings are ubiquitous and many different ways of using them in supervised tasks have been proposed. It is beyond the scope of this paper to provide a comprehensive analysis of all supervised methods using word or sentence embeddings and the effect Siamese CBOW would have on them. However, it would be interesting to see how Siamese CBOW embeddings would affect results in supervised tasks.

Lastly, although we evaluated Siamese CBOW on sentence pairs, there is no theoretical limitation restricting it to sentences. It would be interesting to see how embeddings for larger pieces of texts, such as documents, would perform in document clustering or filtering tasks.

Abstract

Can we train a system that, on any new input, either says "don't know" or makes a prediction that is guaranteed to be correct? We answer the question in the affirmative provided our model family is well-specified. Specifically, we introduce the unanimity principle: only predict when all models consistent with the training data predict the same output. We operationalize this principle for semantic parsing, the task of mapping utterances to logical forms. We develop a simple, efficient method that reasons over the infinite set of all consistent models by only checking two of the models. We prove that our method obtains 100% precision even with a modest amount of training data from a possibly adversarial distribution. Empirically, we demonstrate the effectiveness of our approach on the standard GeoQuery dataset.

1 Introduction

If a user asks a system "*How many painkillers should I take?*", it is better for the system to say "don't know" rather than making a costly incorrect prediction. When the system is learned from data, uncertainty pervades, and we must manage this uncertainty properly to achieve our precision requirement. It is particularly challenging since training inputs might not be representative of test inputs due to limited data, covariate shift (Shimodaira, 2000), or adversarial filtering (Nelson et al., 2009; Mei and Zhu, 2015). In this unforgiving setting, can we still train a system that is *guaranteed* to either abstain or to make the correct prediction?

Our present work is motivated by the goal of building reliable question answering systems and natural language interfaces. Our goal is to learn a semantic mapping from examples of utterance-logical form pairs (Figure 1). More generally, we assume the input x is a bag (multiset) of source atoms (e.g., words $\{area, of, Ohio\}$), and the output y is a bag of target atoms (e.g., predicates $\{\texttt{area}, \texttt{OH}\}$). We consider learning mappings M that decompose according to the multiset sum: $M(x) = \uplus_{s \in x} M(s)$ (e.g., $M(\{Ohio\}) = \{\texttt{OH}\}$, $M(\{area,of,Ohio\}) = \{\texttt{area},\texttt{OH}\}$). The main challenge is that an individual training example (x, y) does not tell us which source atoms map to which target atoms.[1]

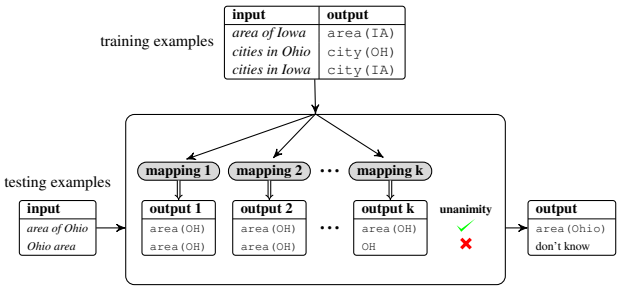

Figure 1: Given a set of training examples, we compute $\mathcal{C}$, the set of all mappings consistent with the training examples. On an input x, if all mappings in $\mathcal{C}$ unanimously predict the same output, we return that output; else we return "don't know".

How can a system be 100% sure about something if it has seen only a small number of possibly non-representative examples? Our approach is based on what we call the *unanimity* principle (Section 2.1). Let $\mathcal{M}$ be a model family that contains the true mapping from inputs to outputs. Let $\mathcal{C}$ be the subset of mappings that are consistent

[1] A semantic parser further requires modeling the context dependence of words and the logical form structure joining the predicates. Our framework handles these cases with a different choice of source and target atoms (see Section 4.2).

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 952–962,
Berlin, Germany, August 7-12, 2016.

with the training data. If all mappings $M \in \mathcal{C}$ unanimously predict the same output on a test input, then we return that output; else we return "don't know" (see Figure 1). The unanimity principle provides robustness to the particular input distribution, so that we can tolerate even adversaries (Mei and Zhu, 2015), provided the training outputs are still mostly correct.

To operationalize the unanimity principle, we need to be able to efficiently reason about the predictions of all consistent mappings $\mathcal{C}$. To this end, we represent a mapping as a matrix M, where M_{st} is number of times target atom t (e.g., `OH`) shows up for each occurrence of the source atom s (e.g., *Ohio*) in the input. We show that unanimous prediction can be performed by solving two integer linear programs. With a linear programming relaxation (Section 3), we further show that checking unanimity over $\mathcal{C}$ can be done very efficiently without any optimization but rather by checking the predictions of just two random mappings, while still guaranteeing 100% precision with probability 1 (Section 3.2).

We further relax the linear program to a linear system, which gives us a geometric view of the unanimity: We predict on a new input if it can be expressed as a "linear combination" of the training inputs. As an example, suppose we are given training data consisting of (CI) *cities in Iowa*, (CO) *cities in Ohio*, and (AI) *area of Iowa* (Figure 1). We can compute (AO) *area of Ohio* by analogy: (AO) = (CO) - (CI) + (AI). Other reasoning patterns fall out from more complex linear combinations.

We can handle noisy data (Section 3.4) by asking for unanimity over additional slack variables. We also show how the linear algebraic formulation enables other extensions such as learning from denotations (Section 5.1), active learning (Section 5.2), and paraphrasing (Section 5.3). We validate our methods in Section 4. On artificial data generated from an adversarial distribution with noise, we show that unanimous prediction obtains 100% precision, whereas point estimates fail. On GeoQuery (Zelle and Mooney, 1996), a standard semantic parsing dataset, where our model assumptions are violated, we still obtain 100% precision. We were able to reach 70% recall on recovering predicates and 59% on full logical forms.

source atoms	target atoms

Ohio → {`OH`}	*Ohio* → {`OH`}	*Ohio* → {`OH`}	*Ohio* → {`OH`}

Figure 2: Given the training examples in the top table, there are exactly four mappings consistent with these training examples.

2 Setup

We represent an input x (e.g., *area of Ohio*) as a bag (multiset) of *source atoms* and an output y (e.g., `area(OH)`) as a bag of *target atoms*. In the simplest case, *source atoms* are words and *target atoms* are predicates—see Figure 2(top) for an example.[2] We assume there is a true mapping M^* from a source atom s (e.g., *Ohio*) to a bag of target atoms $t = M^*(s)$ (e.g., $\{\texttt{OH}\}$). Note that M^* can also map a source atom s to no target atoms ($M^*(\textit{of}) = \{\}$) or multiple target atoms ($M^*(\textit{grandparent}) = \{\texttt{parent}, \texttt{parent}\}$). We extend M^* to bag of source atoms via multiset sum: $M^*(x) = \uplus_{s \in x} M^*(s)$.

Of course, we do not know M^* and must estimate it from training data. Our training examples are input-output pairs $D = \{(x_1, y_1), \ldots, (x_n, y_n)\}$. For now, we assume that there is no noise so that $y_i = M^*(x_i)$; Section 3.4 shows how to deal with noise. Our goal is to output a *mapping* $\hat{M}$ that maps each input x to either a bag of target atoms or "don't know." We say that $\hat{M}$ has 100% precision if $\hat{M}(x) = M^*(x)$ whenever $\hat{M}(x)$ is not "don't know." The chief difficulty is that the source atoms x_i and the target atoms y_i are unaligned. While we could try to infer the alignment, we will show that it is unnecessary for obtaining 100% precision.

2.1 Unanimity principle

Let $\mathcal{M}$ be the set of mappings (which contains the true mapping M^*). Let $\mathcal{C}$ be the subset of map-

[2] Our semantic parsing experiments (Section 4.2) use more complex source and target atoms to capture some context and structure.

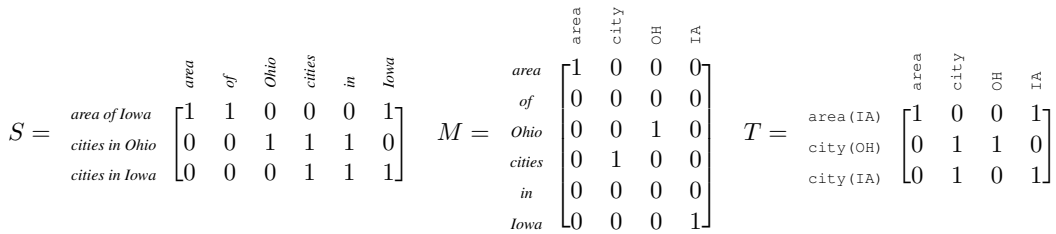

Figure 3: Our training data encodes a system of linear equations $SM = T$, where the rows of S are inputs, the rows of T are the corresponding outputs, and M specifies the mapping between source and target atoms.

pings consistent with the training examples.

$$\mathcal{C} \stackrel{\text{def}}{=} \{M \in \mathcal{M} \mid M(x_i) = y_i, \forall i = 1, \ldots, n\} \tag{1}$$

Figure 2 shows the four mappings consistent with the training set in our running example. Let $\mathcal{F}$ be the set of *safe inputs*, those on which all mappings in $\mathcal{C}$ agree:

$$\mathcal{F} \stackrel{\text{def}}{=} \{x : |\{M(x) : M \in \mathcal{C}\}| = 1\}. \tag{2}$$

The *unanimity principle* defines a mapping $\hat{M}$ that returns the unanimous output on $\mathcal{F}$ and "don't know" on its complement. This choice obtains the following strong guarantee:

Proposition 1. *For each safe input $x \in \mathcal{F}$, we have $\hat{M}(x) = M^*(x)$. In other words, M obtains 100% precision.*

Furthermore, $\hat{M}$ obtains the best possible recall given this model family subject to 100% precision, since for any $x \notin \mathcal{F}$ there are at least two possible outputs generated by consistent mappings, so we cannot safely guess one of them.

3 Linear algebraic formulation

To solve the learning problem laid out in the previous section, let us recast the problem in linear algebraic terms. Let n_s (n_t) be the number of source (target) atom types. First, we can represent the bag x (y) as a n_s-dimensional (n_t-dimensional) row vector of counts; for example, the vector form of "*area of Ohio*" is $\begin{matrix}\textit{area} & \textit{of} & \textit{Ohio} & \textit{cities} & \textit{in} & \textit{Iowa}\end{matrix}$ $[1 \quad 1 \quad 1 \quad 0 \quad 0 \quad 0]$.

We represent the mapping M as a non-negative integer-valued matrix, where M_{st} is the number of times target atom t appears in the bag that source atom s maps to (Figure 3). We also encode the n training examples as matrices: S is an $n \times n_\text{s}$ matrix where the i-th row is x_i; T as an $n \times n_\text{t}$ matrix where the i-th row is y_i. Given these matrices, we can rewrite the set of consistent mappings (2) as:

$$\mathcal{C} = \{M \in \mathbb{Z}_{\geq 0}^{n_\text{s} \times n_\text{t}} : SM = T\}. \tag{3}$$

See Figure 3 for the matrix formulation of S and T, along with one possible consistent mapping M for our running example.

3.1 Integer linear programming

Finding an element of $\mathcal{C}$ as defined in (3) corresponds to solving an integer linear program (ILP), which is NP-hard in the worst case, though there exist relatively effective off-the-shelf solvers such as Gurobi. However, *one* solution is not enough. To check whether an input x is in the safe set $\mathcal{F}$ (2), we need to check whether *all* mappings $M \in \mathcal{C}$ predict the same output on x; that is, xM is the same for all $M \in \mathcal{C}$.

Our insight is that we can check whether $x \in \mathcal{F}$ by solving just two ILPs. Recall that we want to know if the output vector xM can be different for different $M \in \mathcal{C}$. To do this, we pick a random vector $v \in \mathbb{R}^{n_\text{t}}$, and consider the scalar projection xMv. The first ILP maximizes this scalar and the second one minimizes it. If both ILPs return the same value, then with probability 1, we can conclude that xM is the same for all mappings $M \in \mathcal{C}$ and thus $x \in \mathcal{F}$. The following proposition formalizes this:

Proposition 2. *Let x be any input. Let $v \sim \mathcal{N}(0, I_{n_t \times n_t})$ be a random vector. Let $a = \min_{M \in \mathcal{C}} xMv$ and $b = \max_{M \in \mathcal{C}} xMv$. With probability 1, $a = b$ iff $x \in \mathcal{F}$.*

Proof. If $x \in \mathcal{F}$, there is only one output xM, so $a = b$. If $x \notin \mathcal{F}$, there exists two $M_1, M_2 \in \mathcal{C}$ for which $xM_1 \neq xM_2$. Then $w \stackrel{\text{def}}{=} x(M_1 -$

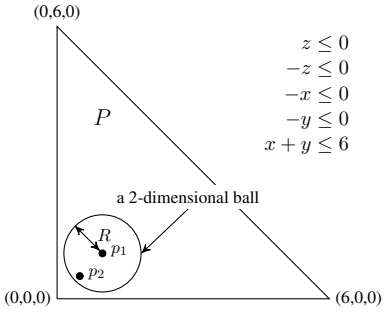

Figure 4: Our goal is to find two points p_1, p_2 in the relative interior of a polytope P defined by inequalities shown on the right. The inequalities $z \le 0$ and $-z \le 0$ are always active. Therefore, P is a 2-dimensional polytope. One solution to the LP (6) is $\alpha^* = 1, p^* = (1,1,0), \xi^{*\top} = [0,0,1,1,1]$, which results in $p_1 = (1,1,0)$ with $R = 1/\sqrt{2}$. The other point p_2 is chosen randomly from the ball of radius R.

$M_2) \in \mathbb{R}^{1 \times n_t}$ is nonzero. The probability of $wv = 0$ is zero because the space orthogonal to w is a $(n_t - 1)$-dimensional space while v is drawn from a n_t-dimensional space. Therefore, with probability 1, $xM_1v \neq xM_2v$. Without loss of generality, $a \le xM_1v < xM_2v \le b$, so $a \neq b$. □

3.2 Linear programming

Proposition 2 requires solving two non-trivial ILPs per input *at test time*. A natural step is to relax the integer constraint so that we solve two LPs instead.

$$\mathcal{C}_{\text{LP}} \stackrel{\text{def}}{=} \{M \in \mathbb{R}^{n_s \times n_t}_{\ge 0} \mid SM = T\} \quad (4)$$

$$\mathcal{F}_{\text{LP}} \stackrel{\text{def}}{=} \{x : |\{M(x) : M \in \mathcal{C}_{\text{LP}}\}| = 1\}. \quad (5)$$

The set of consistent mappings is larger ($\mathcal{C}_{\text{LP}} \supseteq \mathcal{C}$), so the set of safe inputs is smaller ($\mathcal{F}_{\text{LP}} \subseteq \mathcal{F}$). Therefore, if we predict only on $\mathcal{F}_{\text{LP}}$, we still maintain 100% precision, although the recall could be lower.

Now we will show how to exploit the convexity of $\mathcal{C}_{\text{LP}}$ (unlike $\mathcal{C}$) to avoid solving any LPs at test time at all. The basic idea is that if we choose two mappings $M_1, M_2 \in \mathcal{C}_{\text{LP}}$ "randomly enough", whether $xM_1 = xM_2$ is equivalent to unanimity over $\mathcal{C}_{\text{LP}}$. We could try to sample M_1, M_2 uniformly from $\mathcal{C}_{\text{LP}}$, but this is costly. We instead show that "less random" choice suffices. This is formalized as follows:

Proposition 3. *Let X be a finite set of test inputs. Let d be the dimension of $\mathcal{C}_{\text{LP}}$. Let M_1 be any mapping in $\mathcal{C}_{\text{LP}}$, and let vec(M_2) be sampled from a proper density over a d-dimensional ball lying in $\mathcal{C}_{\text{LP}}$ centered at vec(M_1). Then, with probability 1, for all $x \in X$, $xM_1 = xM_2$ implies $x \in \mathcal{F}_{\text{LP}}$.*

Proof. We will prove the contrapositive. If $x \notin \mathcal{F}_{\text{LP}}$, then xM is not the same for all $M \in \mathcal{C}_{\text{LP}}$. Without loss of generality, assume not all $M \in \mathcal{C}_{\text{LP}}$ agree on the i-th component of xM. Note that $(xM)_i = \text{tr}(Me_ix)$, which is the inner product of vec(M) and vec(e_ix). Since $(xM)_i$ is not the same for all $M \in \mathcal{C}_{\text{LP}}$ and $\mathcal{C}_{\text{LP}}$ is convex, the projection of $\mathcal{C}_{\text{LP}}$ onto vec(e_ix) must be a one-dimensional polytope. For both vec(M_1) and vec(M_2) to have the same projection on vec(e_ix), they would have to both lie in a $(d-1)$-dimensional polytope orthogonal to vec(e_ix). Since vec(M_2) is sampled from a proper density over a d-dimensional ball, this has probability 0. □

Algorithm. We now provide an algorithm to find two points p_1, p_2 inside a general d-dimensional polytope $P = \{p : Ap \le b\}$ satisfying the conditions of Proposition 3, where for clarity we have simplified the notation from vec(M_i) to p_i and $\mathcal{C}_{\text{LP}}$ to P.

We first find a point p_1 in the relative interior of P, which consists of points for which the fewest number of inequalities j are active (i.e., $a_jp = b_j$). We can achieve this by solving the following LP from Freund et al. (1985):

$$\max \mathbf{1}^\top \xi \text{ s.t. } Ap + \xi \le \alpha b, 0 \le \xi \le \mathbf{1}, \alpha \ge 1. \quad (6)$$

Here, ξ_j is a lower bound on the slack of inequality j, and α scales up the polytope so that all the ξ_j that can be positive are exactly 1 in the optimum solution. Importantly, if $\xi_j = 0$, constraint j is *always active* for all solutions $p \in P$. Let (p^*, ξ^*, α^*) be an optimal solution to the LP. Then define A_1 as the submatrix of A containing rows j for which $\xi^*_j = 1$, and A_0 consist of the remaining rows for which $\xi^*_j = 0$.

The above LP gives us $p_1 = p^*/\alpha^*$, which lies in the relative interior of P (see Figure 4). To obtain p_2, define a radius $R \stackrel{\text{def}}{=} (\alpha \max_{j:\xi^*_j=1} \|a_j\|_2)^{-1}$. Let the columns of matrix N form an orthonormal basis of the null space of A_0. Sample v from a unit d-dimensional ball centered at 0, and set $p_2 = p_1 + RNv$.

To show that $p_2 \in P$: First, p_2 satisfies the always-active constraints j, $a_j^\top(p_1 + RNv) = b_j$,

Algorithm 1 Our linear programming approach.

procedure TRAIN
Input: Training examples
Output: Generic mappings (M_1, M_2)
  Define $\mathcal{C}_{\text{LP}}$ as explained in (4).
  Compute M_1 and a radius R by solving an LP (6).
  Sample M_2 from a ball with radius R around M_1.
  return (M_1, M_2)
end procedure

procedure TEST
Input: input x, mappings (M_1, M_2)
Output: A guaranteed correct y or "don't know"
  Compute $y_1 = xM_1$ and $y_2 = xM_2$.
  if $y_1 = y_2$ **then return** y_1
  else return "don't know"
  end if
end procedure

by definition of null space. For non-active j, the LP ensures that $a_j^\top p_1 + \alpha^{-1} \leq b_j$, which implies $a_j^\top (p_1 + RNv) \leq b_j$.

Algorithm 1 summarizes our overall procedure: At training time, we solve a single LP (6) and draw a random vector to obtain M_1, M_2 satisfying Proposition 3. At test time, we simply apply M_1 and M_2, which scales only linearly with the number of source atoms in the input.

3.3 Linear system

To obtain additional intuition about the unanimity principle, let us relax $\mathcal{C}_{\text{LP}}$ (4) further by removing the non-negativity constraint, which results in a linear system. Define the relaxed set of consistent mappings to be all the solutions to the linear system and the relaxed safe set accordingly:

$$\mathcal{C}_{\text{LS}} \stackrel{\text{def}}{=} \{M \in \mathbb{R}^{n_{\text{s}} \times n_{\text{t}}} \mid SM = T\} \quad (7)$$

$$\mathcal{F}_{\text{LS}} \stackrel{\text{def}}{=} \{x : |\{M(x) : M \in \mathcal{C}_{\text{LS}}\}| = 1\}. \quad (8)$$

Note that $\mathcal{C}_{\text{LS}}$ is an affine subspace, so each $M \in \mathcal{C}_{\text{LS}}$ can be expressed as $M_0 + BA$, where M_0 is an arbitrary solution, B is a basis for the null space of S and A is an arbitrary matrix. Figure 5 presents the linear system for four training examples. In the rare case that S has full column rank (if we have many training examples), then the left inverse of S exists, and there is exactly one consistent mapping, the true one ($M^* = S^\dagger T$), but we do not require this.

Let's try to explore the linear algebraic structure in the problem. Intuitively, if we know *area of Ohio* maps to `area(OH)` and *Ohio* maps to `OH`, then we should conclude *area of* maps to `area` by subtracting the second example from the first. The following proposition formalizes and generalizes this intuition by characterizing the relaxed safe set:

Proposition 4. *The vector x is in row space of S iff $x \in \mathcal{F}_{\text{LS}}$.*

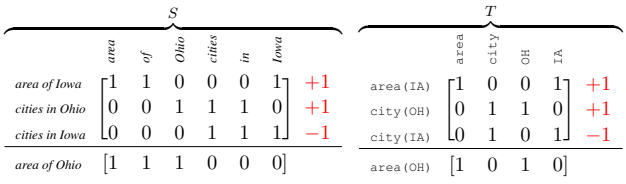

Figure 6: Under the linear system relaxation, we can predict the target atoms for the new input *area of Ohio* by adding and subtracting training examples (rows of S and T).

Proof. If x is in the row space of S, we can write x as a linear combination of S for some coefficients $\alpha \in \mathbb{R}^n$: $x = \alpha^\top S$. Then for all $M \in \mathcal{C}_{\text{LS}}$, we have $SM = T$, so $xM = \alpha^\top SM = \alpha^\top T$, which is the unique output[3] (See Figure 6). If $x \in \mathcal{F}_{\text{LS}}$ is safe, then there exists a y such that for all $M \in \mathcal{C}_{\text{LS}}$, $xM = y$. Recall that each element of $\mathcal{C}_{\text{LS}}$ can be decomposed into $M_0 + BA$. For $x(M_0 + BA)$ to be the same for each A, x should be orthogonal to each column of B, a basis for the null space of S. This means that x is in the row space of S. □

Intuitively, this proposition says that stitching new inputs together by adding and subtracting existing training examples (rows of S) gives you exactly the relaxed safe set $\mathcal{F}_{\text{LS}}$.

Note that relaxations increases the set of consistent mappings ($\mathcal{C}_{\text{LS}} \supseteq \mathcal{C}_{\text{LP}} \supseteq \mathcal{C}$), which has the contravariant effect of shrinking the safe set ($\mathcal{F}_{\text{LS}} \subseteq \mathcal{F}_{\text{LP}} \subseteq \mathcal{F}$). Therefore, using the relaxation (predicting when $x \in \mathcal{F}_{\text{LS}}$) still preserves 100% precision.

3.4 Handling noise

So far, we have assumed that our training examples are noiseless, so that we can directly add the

[3] There might be more than one set of coefficients (α_1, α_2) for writing x. However, they result to a same output: $\alpha_1^\top S = \alpha_2^\top S \implies \alpha_1^\top SM = \alpha_2^\top SM \implies \alpha_1^\top T = \alpha_2^\top T$.

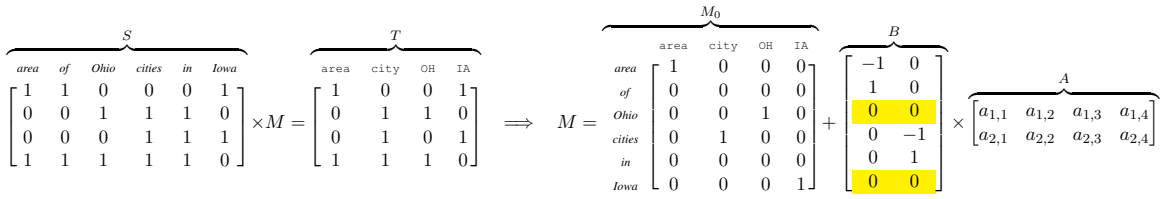

Figure 5: Under the linear system relaxation, all solutions M to $SM = T$ can be expressed as $M = M_0 + BA$, where B is the basis for the null space of S and A is arbitrary. Rows s of B which are zero (*Ohio* and *Iowa*) correspond to the safe source atoms (though not the only safe inputs).

constraint $SM = T$. Now assume that an adversary has made at most n_{mistakes} additions to and deletions of target atoms across the examples in T, but of course we do not know which examples have been tainted. Can we still guarantee 100% precision?

The answer is yes for the ILP formulation: we simply replace the exact match condition ($SM = T$) with a weaker one: $\|SM - T\|_1 \leq n_{\text{mistakes}}$ (*). The result is still an ILP, so the techniques from Section 3.1 readily apply. Note that as n_{mistakes} increases, the set of candidate mappings grows, which means that the safe set shrinks.

Unfortunately, this procedure is degenerate for linear programs. If the constraint (*) is not tight, then $M+E$ also satisfies the constraint for any matrix E of small enough norm. This means that the consistent mappings $\mathcal{C}_{\text{LP}}$ will be full-dimensional and certainly not be unanimous on any input.

Another strategy is to remove examples from the dataset if they could be potentially noisy. For each training example i, we run the ILP (*) on all but the i-th example. If the i-th example is not in the resulting safe set (2), we remove it. This procedure produces a noiseless dataset, on which we can apply the noiseless linear program or linear system from the previous sections.

4 Experiments

4.1 Artificial data

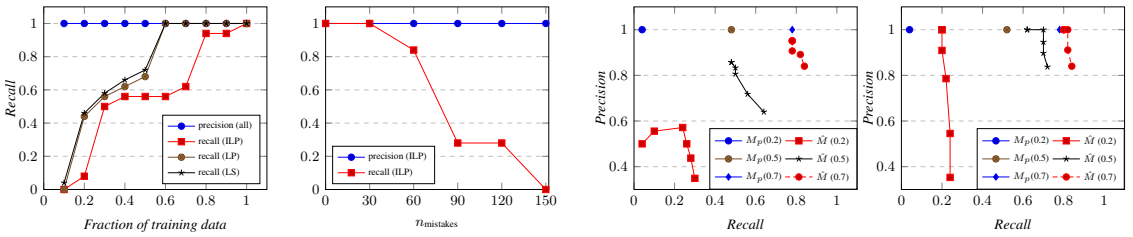
We generated a true mapping M^* from 50 source atoms to 20 target atoms so that each source atom maps to 0–2 target atoms. We then created 120 training examples and 50 test examples, where the length of every input is between 5 and 10. The source atoms are divided into 10 clusters, and each input only contains source atoms from one cluster.

Figure 7a shows the results for $\mathcal{F}$ (integer linear programming), $\mathcal{F}_{\text{LP}}$ (linear programming), and $\mathcal{F}_{\text{LS}}$ (linear system). All methods attain 100% precision, and as expected, relaxations lead to lower recall, though they all can reach 100% recall given enough data.

Comparison with point estimation. Recall that the unanimity principle $\hat{M}$ reasons over the entire set of consistent mappings, which allows us to be robust to changes in the input distribution, e.g., from training set attacks (Mei and Zhu, 2015). As an alternative, consider computing the point estimate M_p that minimizes $\|SM - T\|_2^2$ (the solution is given by $M_p = S^\dagger T$). The point estimate, by minimizing the average loss, implicitly assumes i.i.d. examples. To generate output for input x we compute $y = xM_p$ and round each coordinate y_t to the closest integer. To obtain a precision-recall tradeoff, we set a threshold ϵ and if for all target atoms t, the interval $[y_t - \epsilon, y_t + \epsilon)$ contains an integer, we set y_t to that integer; otherwise we report "don't know" for input x.

To compare unanimous prediction $\hat{M}$ and point estimation M_p, for each $f \in \{0.2, 0.5, 0.7\}$, we randomly generate 100 subsampled datasets consisting of an f fraction of the training examples. For M_p, we sweep ϵ across $\{0.0, 0.1, \ldots, 0.5\}$ to obtain a ROC curve. In Figure 7c(left/right), we select the distribution that results in the maximum/minimum difference between $F_1(\hat{M})$ and $F_1(M_p)$ respectively. As shown, $\hat{M}$ has always 100% precision, while M_p can obtain less 100% precision over its full ROC curve. An adversary can only hurt the recall of unanimous prediction.

Noise. As stated in Section 3.4, our algorithm has the ability to guarantee 100% precision even when the adversary can modify the outputs. As we increase the number of predicate additions/deletions (n_{mistakes}), Figure 7b shows that precision remains at 100%, while recall naturally decreases in response to being less confident about



(a) All the relaxations reach 100% recall; relaxation results in slightly slower convergence.

(b) Size of the safe set shrinks with increasing number of mistakes in the training data.

(c) Performance of the point estimate (M_p) and unanimous prediction ($\hat{M}$) when the inputs are chosen adversarially for M_p (left) and for $\hat{M}$ (right).

Figure 7: Our algorithm always obtains 100% precision with (a) different amounts of training examples and different relaxations, (b) existence of noise, and (c) adversarial input distributions.

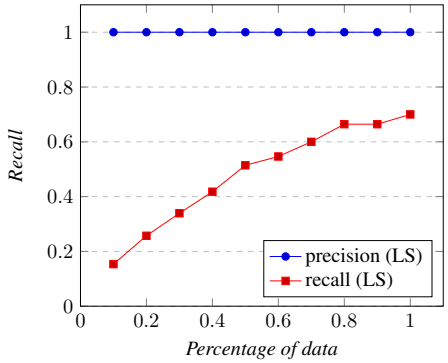


Figure 8: We maintain 100% precision while recall increases with the number of training examples.

the training outputs.

4.2 Semantic parsing on GeoQuery

We now evaluate our approach on the standard GeoQuery dataset (Zelle and Mooney, 1996), which contains 880 utterances and their corresponding logical forms. The utterances are questions related to the US geography, such as: "*what river runs through the most states*". We use the standard 600/280 train/test split (Zettlemoyer and Collins, 2005). After replacing entity names by their types[4] based on the standard entity lexicon, there are 172 different words and 57 different predicates in this dataset.

Handling context. Some words are polysemous in that they map to two predicates: in "*largest river*" and "*largest city*", the word *largest* maps to `longest` and `biggest`, respectively. Therefore, instead of using words as source atoms, we use bigrams, so that each source atom always maps to the same target atoms.

Reconstructing the logical form. We define target atoms to include more information than just the predicates, which enables us to reconstruct logical forms from the predicates. We use the variable-free functional logical forms (Kate et al., 2005), in which each target atom is a predicate conjoined with its argument order (e.g., `loc_1` or `loc_2`). Table 1 shows two different choices of target atoms. At test time, we search over all possible "compatible" ways of combining target atoms into logical forms. If there is exactly one, then we return that logical form and abstain otherwise. We call a predicate combination "compatible" if it appears in the training set.

We put a "null" word at the end of each sentence, and collapsed the `loc` and `traverse` predicates. To deal with noise, we minimized $\|SM - T\|_1$ over real-valued mappings and removed any example (row) with non-zero residual. We perform all experiments using the linear system relaxation. Training takes under 30 seconds.

Figure 8 shows precision and recall as a function of the number of the training examples. We obtain 70% recall over predicates on the test examples. 84% of these have a unique compatible way of combining target atoms into a logical form, which results in a 59% recall on logical forms.

Though our modeling assumptions are incorrect for real data, we were still able to get 100% precision for all training examples. Interestingly, the linear system (which allows negative mappings) helps model GeoQuery dataset better than the linear program (which has a non-negativity constraint). There exists a predicate `all:e` in GeoQuery that is in every sentence unless the ut-

[4]If an entity name has more than one type we replace it by concatenating all of its possible types.

utterances	logical form (A)	target atoms (A)	logical form (B)	target atoms (B)
cities traversed by the Columbia	`city(x),loc(x,Columbia)`	`city,loc,Columbia`	`city(loc_1(Columbia))`	`city,loc_1,Columbia`
cities of Texas	`city(x),loc(Texas,x)`	`city,loc,Texas`	`city(loc_2(Texas))`	`city,loc_2,Texas`

Table 1: Two different choices of target atoms: (A) shows predicates and (B) shows predicates conjoined with their argument position. (A) is sufficient for simply recovering the predicates, whereas (B) allows for logical form reconstruction.

terance contains a proper noun. With negative mappings, *null* maps to `all:e`, while each proper noun maps to its proper predicate *minus* `all:e`.

There is a lot of work in semantic parsing that tackles the GeoQuery dataset (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Kwiatkowski et al., 2010; Liang et al., 2011), and the state-of-the-art is 91.1% precision and recall (Liang et al., 2011). However, none of these methods can guarantee 100% precision, and they perform more feature engineering, so these numbers are not quite comparable. In practice, one could use our unanimous prediction approach in conjunction with others: For example, one could run a classic semantic parser and simply certify 59% of the examples to be correct with our approach. In critical applications, one could use our approach as a first-pass filter, and fall back to humans for the abstentions.

5 Extensions

5.1 Learning from denotations

Up until now, we have assumed that we have input-output pairs. For semantic parsing, this means annotating sentences with logical forms (e.g., *area of Ohio* to `area(OH)`) which is very expensive. This has motivated previous work to learn from question-answer pairs (e.g., *area of Ohio* to `44825`) (Liang et al., 2011). This provides weaker supervision: For example, `44825` is the area of Ohio (in squared miles), but it is also the zip code of Chatfield. So, the true output could be either `area(OH)` or `zipcode(Chatfield)`.

In this section, we show how to handle this form of weak supervision by asking for unanimity over additional selection variables. Formally, we have $D = \{(x_1, Y_1), \ldots, (x_n, Y_n)\}$ as a set of training examples, here each Y_i consists of k_i candidate outputs for x_i. In this case, the unknowns are the mapping M as before along with a selection vector π_i, which specifies which of the k_i outputs in Y_i is equal to $x_i M$. To implement the unanimity principle, we need to consider the set of all consistent solutions (M, π).

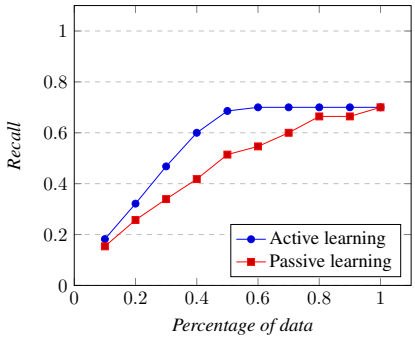

Figure 9: When we choose examples to be linearly independent, we only need half the number of examples to achieve the same performance.

We construct an integer linear program as follows: Each training example adds a constraint that the output of it should be exactly one of its candidate output. For the i-th example, we form a matrix $T_i \in \mathbb{R}^{k_i \times n_t}$ with all the k_i candidate outputs. Formally we want $x_i M = \pi_i T_i$. The entire ILP is:

$$\begin{aligned} &\forall i,\ x_i M = \pi_i T_i \\ &\forall i,\ \textstyle\sum_j \pi_{ij} = 1 \\ &\pi, M \geq 0 \end{aligned}$$

Given a new input x, we return the same output if xM is same for all consistent solutions (M, π). Note that we can effectively "marginalize out" π. We can also relax this ILP into an linear program following Section 3.2.

5.2 Active learning

A side benefit of the linear system relaxation (Section 3.3) is that it suggests an active learning procedure. The setting is that we are given a set of inputs (the matrix S), and we want to (adaptively) choose which inputs (rows of S) to obtain the output (corresponding row of T) for.

Proposition 4 states that under the linear system formulation, the set of safe inputs $\mathcal{F}_{\text{LS}}$ is exactly the same as the row space of S. Therefore, if we ask for an input that is already in the row space of S, this will not affect $\mathcal{F}_{\text{LS}}$ at all. The algo-

rithm is then simple: go through our training inputs $x_1, \ldots, x_n$ one by one and ask for the output only if it is not in the row space of the previously-added inputs $x_1, \ldots, x_{i-1}$.

Figure 9 shows the recall when we choose examples to be linearly independent in this way in comparison to when we choose examples randomly. The active learning scheme requires half as many labeled examples as the passive scheme to reach the same recall. In general, it takes $\text{rank}(S) \leq n$ examples to obtain the same recall as having labeled all n examples. Of course, the precision of both systems is 100%.

5.3 Paraphrasing

Another side benefit of the linear system relaxation (Section 3.3) is that we can easily partition the safe set $\mathcal{F}_{\text{LS}}$ (8) into subsets of utterances which are paraphrases of each other. Two utterances are paraphrase of each other if both map to the same logical form, e.g., "*Texas's capital*" and "*capital of Texas*". Given a sentence $x \in \mathcal{F}_{\text{LS}}$, our goal is to find all of its paraphrases in $\mathcal{F}_{\text{LS}}$.

As explained in Section 3.3, we can represent each input x as a linear combination of S for some coefficients $\alpha \in \mathbb{R}^n$: $x = \alpha^\top S$. We want to find all $x' \in \mathcal{F}_{\text{LS}}$ such that x' is guaranteed to map to the same output as x. We can represent $x' = \beta^\top S$ for some coefficients $\beta \in \mathbb{R}^n$. The outputs for x and x' are thus $\alpha^\top T$ and $\beta^\top T$, respectively. Thus we are interested in β's such that $\alpha^\top T = \beta^\top T$, or in other words, $\alpha - \beta$ is in the null space of $T^\top$. Let B be a basis for the null space of $T^\top$. We can then write $\alpha - \beta = Bv$ for some v. Therefore, the set of paraphrases of $x \in \mathcal{F}_{\text{LS}}$ are:

$$\text{Paraphrases}(x) \stackrel{\text{def}}{=} \{(\alpha - Bv)^\top S : v \in \mathbb{R}^n\}. \quad (9)$$

6 Discussion and related work

Our work is motivated by the semantic parsing task (though it can be applied to any set-to-set prediction task). Over the last decade, there has been much work on semantic parsing, mostly focusing on learning from weaker supervision (Liang et al., 2011; Goldwasser et al., 2011; Artzi and Zettlemoyer, 2011; Artzi and Zettlemoyer, 2013), scaling up beyond small databases (Cai and Yates, 2013; Berant et al., 2013; Pasupat and Liang, 2015), and applying semantic parsing to other tasks (Matuszek et al., 2012; Kushman and Barzilay, 2013; Artzi and Zettlemoyer, 2013). However, only Popescu et al. (2003) focuses on precision. They also obtain 100% precision, but with a hand-crafted system, whereas we *learn* a semantic mapping.

The idea of computing consistent hypotheses appears in the classic theory of version spaces for binary classification (Mitchell, 1977) and has been extended to more structured settings (Vanlehn and Ball, 1987; Lau et al., 2000). Our version space is used in the context of the unanimity principle, and we explore a novel linear algebraic structure. Our "safe set" of inputs appears in the literature as the complement of the disagreement region (Hanneke, 2007). They use this notion for active learning, whereas we use it to support unanimous prediction.

There is classic work on learning classifiers that can abstain (Chow, 1970; Tortorella, 2000; Balsubramani, 2016). This work, however, focuses on the classification setting, whereas we considered more structured output settings (e.g., for semantic parsing). Another difference is that we operate in a more adversarial setting by leaning on the unanimity principle.

Another avenue for providing user confidence is probabilistic calibration (Platt, 1999), which has been explored more recently for structured prediction (Kuleshov and Liang, 2015). However, these methods do not guarantee precision for *any* training set and test input.

In summary, we have presented the unanimity principle for guaranteeing 100% precision. For the task of learning semantic mappings, we leveraged the linear algebraic structure in our problem to make unanimous prediction efficient. We view our work as a first step in learning reliable semantic parsers. A natural next step is to explore our framework with additional modeling improvements—especially in dealing with context, structure, and noise.

Reproducibility. All code, data, and experiments for this paper are available on the CodaLab platform at `https://worksheets.codalab.org/worksheets/0x593676a278fc4e5abe2d8bac1e3df486/`.

Abstract

Dialogue topic tracking is a sequential labelling problem of recognizing the topic state at each time step in given dialogue sequences. This paper presents various artificial neural network models for dialogue topic tracking, including convolutional neural networks to account for semantics at each individual utterance, and recurrent neural networks to account for conversational contexts along multiple turns in the dialogue history. The experimental results demonstrate that our proposed models can significantly improve the tracking performances in human-human conversations.

1 Introduction

A human conversation often involves a series of multiple topics contextually related to each other. In this scenario, every participant in the conversation is required to understand the on-going topic discussed at each moment, detect any topic shift made by others, and make a decision to self-initiate a new topic. These human capabilities for handling topics are also expected from dialogue systems to achieve natural and human-like conversations.

Many studies have been conducted on multi-domain or multi-task dialogue systems by means of sentence-level topic identification as a sub-task of natural language understanding (Lin et al., 1999; Nakata et al., 2002; Lagus and Kuusisto, 2002; Adams and Martell, 2008; Ikeda et al., 2008; Celikyilmaz et al., 2011). In these approaches, a given user input at each turn is categorized into topic classes, each of which triggers the corresponding sub-system specializing in the particular topic. Despite many previous efforts, the sentence categorization methods still have the following limitations. Firstly, the effectiveness of the approaches is limited only in user-initiative conversations, because the categorization is performed mainly based on the user's input mentioned at a given turn. Secondly, no correlation between different topics is considered neither in the topic decision process nor in each topic-specific sub-system operated independently from the others. Lastly, the conversational coherence in a given dialogue history sequence has limited effects on determining the current topic.

Another direction for multi-topic dialogue systems has been towards utilizing human knowledge represented in domain models (Roy and Subramaniam, 2006) and agendas (Bohus and Rudnicky, 2003; Lee et al., 2008). The knowledge-based approaches make the system capable of having more control of dialogue flows including topic sequences. This aspect contributes to better decisions of topics in system-initiative cases, but it can adversely affect the flexibility to deal with unexpected inputs against the system's suggestions. Moreover, the high cost of building the required resources is another problem that these methods face from a practical point of view.

Recently, some researchers (Morchid et al., 2014a; Morchid et al., 2014b; Esteve et al., 2015) have worked on topic identification for analyzing human-human dialogues. Although they don't aim at building components in dialogue systems directly, the human behaviours learned from the conversations can suggest directions for further advancement of conversational agents. However, the problem defined in the studies is under the assumption that every dialogue session is assigned with just a single theme category, which means any topic shift occurred in a session is left out of consideration in the analyses.

On the other hand, we previously addressed the problem of detecting multiple topic transitions

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 963–973,
Berlin, Germany, August 7-12, 2016.

in mixed-initiative human-human conversations, which is called dialogue topic tracking (Kim et al., 2014a; Kim et al., 2014b). In these studies, the tracking task is formulated as a classification problem for each utterance-level, similar to the sentence categorization approaches. But the target of the classification is not just an individual topic category to which each input sentence belongs, but the decision whether a topic transition occurs at a given turn as well as what the most probable topic category will follow after the transition.

This paper presents our work also on dialogue topic tracking mainly focusing on the following issues. Firstly, in addition to transitions between dialogue segments from different topics, transitions between segments belonging to the same topic are also detected. This focuses the task more on detailed aspects of topic handling that are relevant to other subtasks such as natural language understanding and dialogue state tracking, rather than the conventional tracking of changes in topic categories only. Another contribution of this work is that we introduce a way to use convolutional neural networks in topic tracking to improve the classification performances with the learned convolutional features. In addition, we also propose the architectures based on recurrent neural networks to incorporate the temporal coherence that has not played an important role in previous approaches.

The remainder of this paper is structured as follows. We present a problem definition of dialog topic tracking in Section 2. We describe our proposed approaches to this task using convolutional and recurrent neural networks in Section 3. We report the evaluation result of the methods in Section 4 and conclude this paper in Section 5.

2 Dialogue Topic Tracking

Dialogue topic tracking is defined as a multi-class classification problem to categorize the topic state at each time step into the labels encoded in BIO tagging scheme (Ramshaw and Marcus, 1995) as follows:

$$f(t) = \begin{cases} \text{B-}\{c \in C\} & \text{if } u_t \text{ is at the beginning} \\ & \text{of a segment belongs to } c, \\ \text{I-}\{c \in C\} & \text{else if } u_t \text{ is inside a} \\ & \text{segment belongs to } c, \\ \text{O} & \text{otherwise,} \end{cases}$$

where u_t is the t-th utterance in a given dialogue session and C is a closed set of topic categories.

t	Speaker	Utterance (u_t)	$f(t)$
1	Guide	How can I help you?	B-OPEN
2	Tourist	Can you recommend some good places to visit in Singapore?	B-ATTR
3	Guide	Well if you like to visit an icon of Singapore, Merlion will be a nice place to visit.	I-ATTR
4	Tourist	Okay. But I'm particularly interested in amusement parks.	B-ATTR
5	Guide	Then, what about Universal Studio?	I-ATTR
6	Tourist	Good! How can I get there from Orchard Road by public transportation?	B-TRSP
7	Guide	You can take the red line train from Orchard and transfer to the purple line at Dhoby Ghaut. Then, you could reach HarbourFront where Sentosa Express departs.	I-TRSP
8	Tourist	How long does it take in total?	I-TRSP
9	Guide	It'll take around half an hour.	I-TRSP
10	Tourist	Alright.	I-TRSP
11	Guide	Or, you can use the shuttle bus service from the hotels in Orchard, which is free of charge.	B-TRSP
12	Tourist	Great! That would be definitely better.	I-TRSP
13	Guide	After visiting the park, you can enjoy some seafoods at the riverside on the way back.	B-FOOD
14	Tourist	What food do you have any recommendations to try there?	I-FOOD
15	Guide	If you like spicy foods, you must try chilli crab which is one of our favourite dishes.	I-FOOD
16	Tourist	Great! I'll try that.	I-FOOD

Figure 1: Examples of dialogue topic tracking on a tour guide dialogue labelled with BIO tags. ATTR, TRSP and FOOD denotes the topic categories of attraction, transportation, and food, respectively.

Figure 1 shows an example of topic tracking on a dialogue fragment between a tour guide and a tourist. Since each tag starting with 'B' should occur at the beginning of a new segment after a topic transition from its previous one, the label sequence indicates that this conversation is divided into six segments at $t = \{2, 4, 6, 11, 13\}$. The initiativity of each segment can be also found from who the speaker of the first utterance of the segment is. In this example, three of the cases are initiated by the tourist at $t = \{2, 4, 6\}$, but the others are leaded by the tour guide, which means it is a mixed-initiative type of conversation.

Different from the former studies (Kim et al., 2014a; Kim et al., 2014b) that were only focused on detecting transitions between different topic categories, this work subdivides each dialogue sequence which belongs to a single topic category, but discusses more than one subject that can be more specifically differentiated from each other. The above example also has two cases of transitions with no change of topic categories at $t = \{4, 11\}$: the first one is due to the tourist's request for an alternative attraction from the recommendation in the previous segment, and the other transition is triggered by the tour guide to suggest another option of transportation which is also available for the route discussed previously.

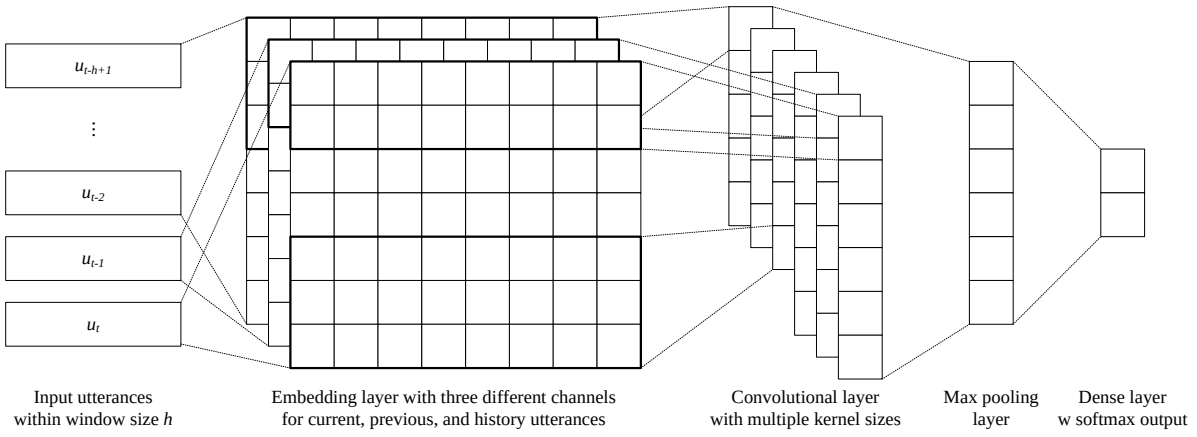

Figure 2: Convolutional neural network architecture for dialogue topic tracking.

3 Models

The classifier f can be built with supervised machine learning techniques, when a set of example dialogues manually annotated with gold standard labels are available as a training set. The earlier studies (Kim et al., 2014a; Kim et al., 2014b) also proposed supervised classification approaches particularly focusing on kernel methods to incorporate domain knowledge obtained from external resources into the linear vector space models based on bag-of-words features extracted from the training dialogues.

This work, on the other hand, aims at improving the classification capabilities only with the internal contents in given dialogues rather than making better uses of external knowledge. To overcome the limitations of the simple vector space models used in the previous work, we propose models based on convolutional and recurrent neural network architectures. These models are presented in the remainder of this section.

3.1 Convolutional Neural Networks

A convolutional neural network (CNN) automatically learns the filters in its convolutional layers which are applied to extract local features from inputs. Then, these lower-level features are combined into higher-level representations following a given network architecture. These aspects of CNNs make themselves a good fit to solve the problems which are invariant to the location where each feature is extracted on its input space and also depend on the compositional relationships between local and global features, which is the reason why CNNs have succeed in computer vision (LeCun et al., 1998). As implied by the successes of bag-of-words or bag-of-ngrams considering the existence of each linguistic unit independently and the important roles of compositional structures in linguistics, CNN models have recently achieved significant improvements also in some natural language processing tasks (Collobert et al., 2011; Shen et al., 2014; Yih et al., 2014; Kalchbrenner et al., 2014a; Kim, 2014).

The model for dialogue topic tracking (Figure 2) is basically based on the CNN architecture proposed by Collobert et al. (2011) and Kim (2014) for sentence classification tasks. In the architecture, a sentence of length n is represented as a matrix with the size of $n \times k$ concatenated with n rows each of which is the k-dimensional word vector $\vec{x}_i \in \mathbb{R}^k$ representing the i-th word in the sentence. This embedding layer can be learned from scratch with random initialization or fine-tuned from pre-trained word vectors (Mikolov et al., 2013) with back propagation during training the network.

Unlike other sentence classification tasks, dialogue topic tracking should consider not only a single sentence given at each time step, but also the other utterances previously mentioned. To incorporate the dependencies to the dialogue history into the topic tracking model, the input at the time step t is composed of three different channels each of which represents the current utterance u_t, the previous utterance u_{t-1}, and the other utterances $u_{t-h+1:t-2}$ within h time steps, respectively, where u_t is the t-th utterance in a session, $u_{i:j}$ is the concatenation of the utterances occurred from the i-th to the j-th time steps in the history, and h is the size of history window. The height of the $n \times k$ matrices of the first two channels for

the current and previous utterances is fixed to the length of the longest utterance in the whole training dataset, and then all the remaining rows after the end of each utterance are zero-padded to make all inputs same size. Since the other channel is made up by concatenating the utterances from the $(t-h+1)$-th to the $(t-2)$-th time steps, it has a matrix with the dimension of $((h-2)\cdot n)\times k$ where all the gaps between contiguous utterances in the matrix are filled with zero.

In the convolutional layer, each filter $\mathcal{F}\in\mathbb{R}^{km}$ which has the same width k as the input matrix and a given window size m as its height slides over from the first row to the $(n-m+1)$-th row of the input matrix. At the i-th position, the filter is applied to generate a feature $c_i = g\left(\mathcal{F}\cdot\vec{x}_{i:i+m-1}+b\right)$, where $\vec{x}_{i:j}$ is the subregion from the i-th row to the j-th row in the input, $b\in\mathbb{R}$ is a bias term, and g is a non-linear activation function such as rectified linear units. This series of convolution operations produces a feature map $\vec{c}=[c_1\cdots c_{n-m+1}]\in\mathbb{R}^{n-m+1}$ for the filter $\mathcal{F}$. Then, the maximum value $c'=\max(\vec{c})$ is selected from each feature map considered as the most important feature for the particular filter in the max-pooilng layer.

Every filter is shared across all the three different channels, but both the convolution and max-pooling operations are performed individually for each channel. Thus, the total number of feature values generated in the pooling layer is three times the number of filters. Finally, these values are forwarded to the fully-connected layer with softmax which generates the probabilistic distribution over the topic labels for a given input.

3.2 Recurrent Neural Networks

Dialogue topic tracking is conceptually performed on a sequence of interactions exchanged by the participants in a given session from its beginning to each turn. Thus, the contents discussed previously in the dialogue history are likely to have an important influence on tracking the current topic at a given turn, which is a fundamental difference from other text categorization problems that consider each input independently from all others.

To make use of the sequential dependencies in dialogue topic tracking, we propose the models based on recurrent neural networks (RNN) which learn the temporal dynamics by recurrent computations applied to every time step in a given input sequence. In a traditional RNN, hidden states connecting between input sequences and output labels are repeatedly updated with the operation $\vec{s_t}=g(Ux_t+Ws_{t-1})$, where x_t is the t-th element in a given input sequence, $\vec{s_t}\in\mathbb{R}^{|s|}$ is the hidden state at t with $|s|$ hidden units, and g is a non-linear activation function. The parameters U and W are shared all the time steps.

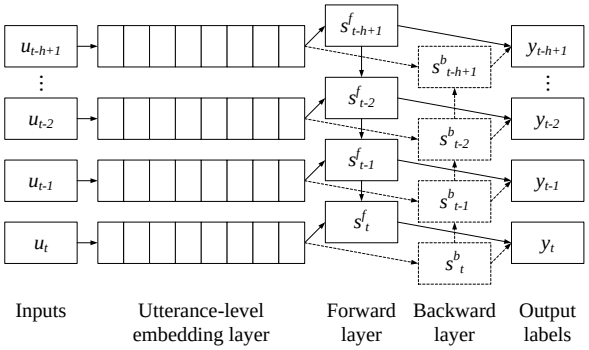

Figure 3: Recurrent neural network architecture for dialogue topic tracking. The backward layer with the dotted lines is enabled only with its bi-directional extension.

RNNs have been successfully applied to several natural language processing tasks including language modeling (Mikolov et al., 2010), text generation (Sutskever et al., 2011), and machine translation (Auli et al., 2013; Liu et al., 2014), all of which focus on dealing with variable length word sequences. On the other hand, an input sequence to be handled in dialogue topic tracking is composed of utterance-level units instead of words.

In our model (Figure 3), each utterance is represented by the k-dimensional vector $\vec{u}_t\in\mathbb{R}^k$ assigned with pre-trained sentence-level embeddings (Le and Mikolov, 2014). And then, a sequence of the utterance vectors within h time steps are connected in the recurrent layers. The default sequence of applying the recurrent operation is the ascending order from the former to the recent utterances, which is performed in the forward layer. But the opposite direction can be also considered in the backward layer which is stacked on top of the forward layer to build a bidirectional RNN (Schuster and Paliwal, 1997) which outputs the concatenation of both forward and backward states as an outcome of the recurrent operations. Then, these hidden states from the recurrent layers are passed to the fully-connected softmax layer to generate the output distributions for every time step in the sequence.

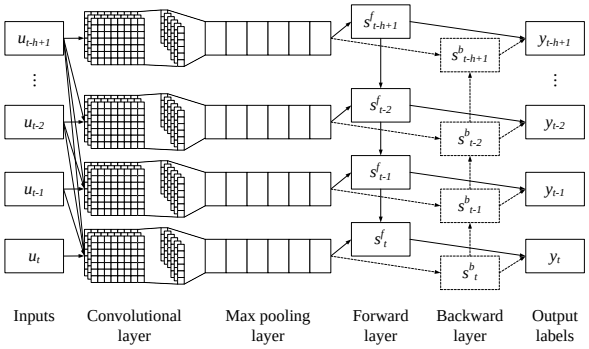

Figure 4: Recurrent convolutional network architecture for dialogue topic tracking. The backward layer is only for the bi-directional mode.

The output from the model at a given time step t is a label sequence $[y_{t-h+1}, \cdots, y_t]$ for the recent h utterances. Since the labels for the earlier utterances should have been already decided at the corresponding turns, only y_t is taken as the final outcome for the current time step. The hypothesis to be examined with this model is whether the other $h-1$ predictions that are not directly reflected to the results could help to improve the tracking performances by being considered together in the process of determining the current topic status.

3.3 Recurrent Convolutional Networks

The last approach proposed in this work aims at combining the two models described in the previous sections. In this model (Figure 4), each feature vector generated through the embedding, convolutional, and max pooling layers in the CNN network (Section 3.1) is connected to the recurrent layers in the RNN model (Section 3.2). This combination is expected to play a significant role in overcoming the limitations of the sentence-level embedding considered as a feature representation in the RNN model. While the previous approach depends only on a pre-trained and non-tunable embedding model, all the parameters in the combined network can be fine-tuned with back propagation by considering the convolutional features extracted at each time step and also the temporal dependencies occurred through multiple time steps in given dialogue sequences.

In computer vision, this kind of models connecting RNNs on top of CNNs is called recurrent convolutional neural networks (RCNN), which have been mostly used for exploring the dependencies between local convolutional features within a single image (Pinheiro and Collobert, 2014; Liang and Hu, 2015). Recently, they are also applied in video processing (Donahue et al., 2015) where visual features are extracted from the image at each frame using CNNs and the temporal aspects are learned with RNNs from the frame sequence of an input video. Our proposed model for dialogue topic tracking was originally motivated by this success of RCNNs particularly in video recognition considering that video and dialogue are analogous from the structural point of view. Each instance of a video and a dialogue consists of a temporal sequence of static units.

4 Evaluation

4.1 Data

To demonstrate the effectiveness of our proposed models, we performed experiments on TourSG corpus released for the fourth dialogue state tracking challenge (DSTC4) (Kim et al., 2016). The dataset consists of 35 dialogue sessions collected from human-human conversations about tourism in Singapore between tour guides and tourists. All the dialogues have been manually transcribed and annotated with the labels for the challenge tasks. For the multi-topic dialogue state tracking which is the main task of the challenge, each dialogue session is divided into sub-dialogues and each segment is assigned with its topic category. Since the task particularly focuses on filling out the topic-specific frame structure with the detailed information representing the dialogue states of a given segment, it has been performed under the assumption that the manual annotations for both segmentations and topic categories are provided as parts of every input. But, in this work for dialogue topic tracking, these labels are considered as the targets to be generated automatically by the models.

Every segment in the dataset belongs to one of eight topic categories. Following the nature of the tourism domain, the 'attraction' category accounts for the highest portion at 40.12% of the segments, which is followed by 'transportation', 'food', 'accommodation', 'shopping', 'closing' and 'opening' in order according to decreasing frequencies. The other 10.53% considered as beyond the scope of the task are annotated with 'other'.

Figure 5 shows the distributions of the segments by not only the topic categories, but also the transition types from two different points of views: the first one is which speaker initiates each segment, and the other is whether the segmentation causes

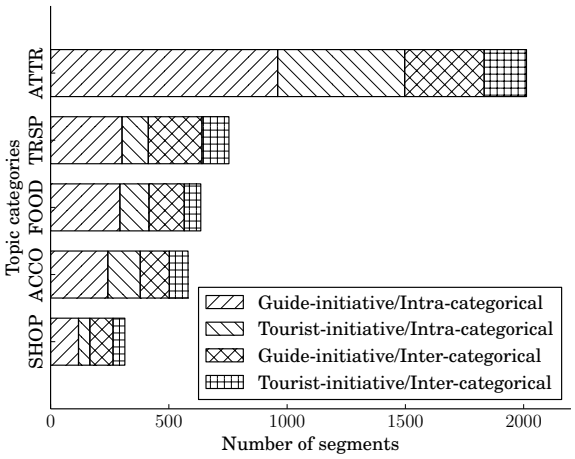

Figure 5: Distributions of the segments in TourSG corpus by topic categories and transition types. ATTR, TRSP, FOOD, ACCO and SHOP denotes the topic categories of attraction, transportation, food, accommodation, and shopping, respectively.

Table 1: Statistics of TourSG corpus. The whole dataset is divided into three subsets for training, development, and test purposes.

Set	# sessions	# segments	# utterances
Train	14	2,104	12,759
Dev	6	700	4,812
Test	15	2,210	13,463
Total	35	5,014	31,034

a topic category shift or not. The most frequent type found in the dataset is guide-initiative and intra-categorical transitions. 63.86% and 61.31% of the total segments are initiated by guides and segmented keeping topic categories, respectively.

For our experiments, all these segment-level annotations were converted into utterance-level BIO tags each of which belongs to one of 15 classes: $(\{\text{B-}, \text{I-}\} \times \{c : c \in C;$ and $c \neq$ 'other'$\}) \cup \{\text{O}\}$, where C consists of all the eight topic categories. The partition of the dataset (Table 1) have been kept the same as the one used for the state tracking task in DSTC4.

4.2 Models

Based on the dataset, we built 16 different models classified into the following five model families.

4.2.1 Baseline 1: Support Vector Machines

The first baseline uses support vector machine (SVM) (Cortes and Vapnik, 1995) models trained with the following features:

- BoN_t: bag of uni/bi/tri-grams in u_t weighted by tf-idf which is the product of term frequency in u_t and inverse document frequency across all the training utterances.
- BoN_{t-1}: bag of n-grams computed in the same way as BoN_t for the previous utterance.
- $\text{BoN}_{\text{history}} = \sum_{j=0}^{h} \left(\lambda^j \cdot \text{BoN}_j\right)$: weighted sum of n-gram vectors in the recent $h = 10$ utterances with a decay factor $\lambda = 0.9$.
- SPK_t, SPK_{t-1}: speakers of the current and the previous utterances.
- $\text{SPK}_{\{t-1,t\}}$: bi-gram of SPK_t and SPK_{t-1}.

Another variation replaces the bag of n-grams with the utterance-level neural embeddings inferred by the pre-trained 300 dimensional doc2vec (Le and Mikolov, 2014) model on 2.9M sentences with 37M words in 553k Singapore-related posts collected from travel forums. Then, the third model takes the concatenation of both bag of n-grams and doc2vec features.

All three baselines were implemented based on the one-against-all approach with the same number of binary classifiers as the total number of classes for multi-label classification. SVM^{light} (Joachims, 1999) was used for building each binary classfier with the linear kernel.

4.2.2 Baseline 2: Conditional Random Fields

To incorporate the temporal aspects also into the linear models, conditional random fields (CRFs) (Lafferty et al., 2001) which have been successfully applied for other sequential labelling problems were used for the second set of baselines. Similar to our proposed RNN architecture (Section 3.2), the recent utterances occurred within the window size of $h = 10$ composed the first-order linear-chain CRFs. Three CRF models were built using CRFsuite (Okazaki, 2007) with the same feature sets as in the SVM models.

4.2.3 CNN-based models

For the CNN architecture (Section 3.1), we compared two different models: the first one learned the word embeddings from scratch with random parameters, while the other was initialized with word2vec (Mikolov et al., 2013) trained on

the same dataset for the doc2vec model in Section 4.2.1. Both approaches generated a dense vector with a dimension of $k = 300$ for each word in utterances. Then, the embedded vectors were concatenated into three matrices representing the current, previous, and history utterances, respectively. While the first two channels for a single utterance, u_t or u_{t-1}, had a size of 65×300 according to the maximum number of words $n = 65$ in the training utterances, the number of rows in the other matrix was 520 which is eight times as large as the others to represent the history utterances from u_{t-9} to u_{t-2} where $h = 10$.

In the convolutional layer, 100 feature maps were learned for each of three different filter sizes $m = \{3, 4, 5\}$ by sliding them over the utterances, which produced 900 feature values in total after the max-pooling operations for all three channels. In addition to these learned features, SPK_t and SPK_{t-1} values introduced in Section 4.2.1 were appended to each feature vector to take the speaker information into account as in the baselines. Before the fully-connected layer, dropout was performed with the rate of 0.25 for regularization. And then, training was done with stochastic gradient descent (SGD) by minimizing categorical cross entropy loss on the training set.

All the neural network-based models in this work were implemented using Theano (Bergstra et al., 2010) with the parameters obtained from the grid search on the development set.

4.2.4 RNN and RCNN-based models

Each proposed recurrent network (Section 3.2 and 3.3) was implemented with four variations categorized by whether the backward layer is included in each model or not and also which architecture is used in the recurrent layers between traditional RNNs and long short-term memories (LSTMs) (Hochreiter and Schmidhuber, 1997). The RCNN models based on LSTMs are particularly called long-term recurrent convolutional networks (LRCN) (Donahue et al., 2015). All the RCNN-based models were initialized with the pre-trained word2vec model in the training phase.

The dimension of the hidden layers of the recurrent cells was chosen to be $|s| = 500$ based on the development set. And the other settings including the parameters, the training algorithm, and the loss fuction were the same as in Section 4.2.3.

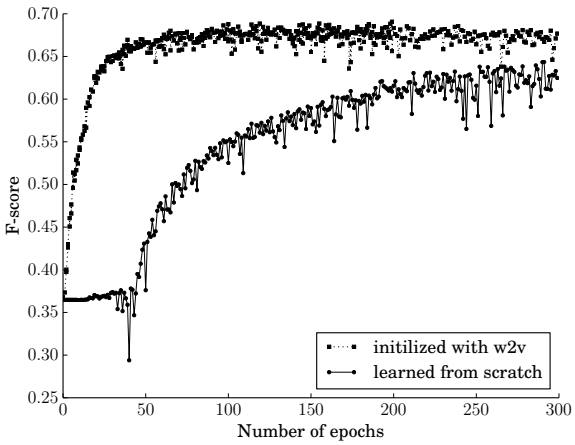

Figure 6: Comparisons of the topic tracking performances of the CNN models with different word embedding approaches according to the number of epochs for training in the development phase.

4.3 Results

Table 2 compares the performances of the models trained on the combination of the training and development sets and evaluated on the test set. The parameters for each model were decided in the development phase which built the models under various different settings only on the training set and validated them with the development set. The evaluations were performed with precision, recall, and F-measure to the manual annotations under three different schedules at tourist turns, guide turns, and all the turns. Then, the statistical significance for every pair was computed using approximate randomization (Yeh, 2000).

Comparing between two baseline families, the sequential extensions with the CRF models contributed to significant improvements ($p < 0.05$) from the SVM models in all the schedules. But in both SVM and CRF models, doc2vec features failed to achieve comparable performances to the simplest bag-of-ngrams features. Even the improvements by combining them to the word features were not statistically significant.

While these sentence-level embeddings trained in the unsupervised manner exposed the limitations in dialogue topic tracking performances, our proposed CNN-based models outperformed all these baselines. Especially, the CNN initialized with the pre-trained word2vec model achieved higher performances by 8.38%, 6.41%, and 7.21% in F-measure under each schedule, respectively, than the best baseline results.

Models	Schedule: Tourist Turns			Schedule: Guide Turns			Schedule: All

Uni-directional LRCN	69.37	71.45	70.40	**66.22**	67.41	66.81	67.50	69.04	68.26
Bi-directional LRCN	**69.85**	**72.56**	**71.18**	66.04	**67.62**	**66.82**	**67.60**	**69.62**	**68.59**

Table 2: Comparisons of the topic tracking performances with different models. D2V and W2V denote the vectors from doc2vec and word2vec, respectively.

Figure 6 presents the differences between two CNN models observed in the development phase. As the number of epochs increases, the performances of both models also increase up to certain points of saturation. But the model with random initialization required much longer time to be ready to gain scores in earlier iterations and its saturated performance was also lower than the other one learned on top of word2vec.

In contrast to the success of the CNN models, the proposed RNN architectures were not able to produce quality results, which was also caused by the limitations of doc2vec representations as already shown in the baseline results. Although some RNN models showed little performance gains over the SVM baselines only with doc2vec features, they were even worse than the CRF model with the same features.

On the other hand, the RCNN models connecting the results of CNNs to the RNNs contributed to performance improvements not only from the baselines, but also from the CNN models. While the uni-directional RNN was preferred in the RNN models only with doc2vec, the bi-directional LSTM showed better results in the RCNN architectures. As a result, the bi-directional LRCN model achieved the best performances against all the others, which were statistically significant ($p < 0.01$) compared to the second best results with bi-directional RCNN.

Table 3 shows the segmentation performances evaluated by considering only the beginning of each segment predicted by the best model of each architecture family. The proposed CNN and LRCN models demonstrated better capabilities of detecting topic transitions in both intra-categorical and inter-categorical conditions than the baselines. While the CNN model tended to have a higher coverage in segmentation than the others, the LRCN model produced more precise decisions to recognize the boundaries on the strength of the consideration of conversational coherences in dialogue history sequences.

However, the segmentation performances even with the best models were still very limited especially for inter-categorical transitions. And most of the models in the experiment had better performances in tourist turns than guide turns, as shown in Table 2. Considering the general characteristics of the target domain conversations that guide-driven and inter-categorical transitions are more likely to be dependent on human background knowledge than tourist-driven and intra-categorical cases, respectively, the current limitations are expected to be tackled by leveraging external resources into the models in future.

Finally, the generated errors from the models were categorized into the following error types:

Models	Intra-categorical			Inter-categorical			All		
	P	R	F	P	R	F	P	R	F
SVM (BoN+SPK+D2V)	40.22	30.19	34.49	8.68	28.14	13.26	18.65	29.51	22.85
CRF (BoN+SPK+D2V)	36.42	25.92	30.28	11.57	24.40	15.70	21.58	25.41	23.34
CNN (with W2V)	41.25	**41.50**	**41.37**	17.02	**40.87**	24.03	28.06	**41.29**	33.41
Bi-directional LRCN	**44.82**	38.28	41.29	**17.87**	40.72	**24.84**	**29.41**	39.09	**33.57**

Table 3: Comparisons of the segmentation performances with different models.

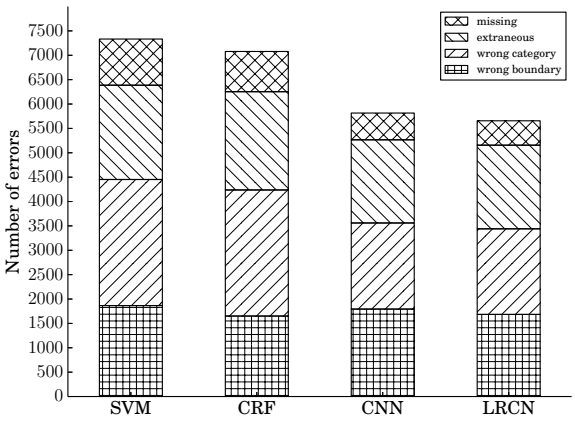

Figure 7: Distributions of errors generated from the best model of each architecture.

- Missing predictions: when the reference belongs to one of the labels other than 'O', but the model predicts it as 'O'.
- Extraneous labelling: when the reference belongs to 'O', but the model predicts it as another label.
- Wrong categorizations: when the reference belongs to a category other than 'O', but the model predicts it as another wrong category.
- Wrong boundary detections: when the model outputs the correct category, but with a wrong prediction from 'B' to 'I' or from 'I' to 'B'.

The error distributions in Figure 7 indicate that the significantly decreased numbers of wrong categories were the decisive factor in performance improvements by our proposed approaches from the baselines. Besides, the enhanced capabilities of the models in distinguishing between 'O' and other labels were demonstrated by the reduced numbers of missing and extraneous predictions. The sequential architectures in CRF and LRCN models also showed its effectiveness especially in boundary detection, as expected.

5 Conclusions

This paper presented various neural network architectures for dialogue topic tracking. Convolutional neural networks were proposed to capture the semantic aspects of utterances given at each moment, while recurrent neural networks were intended to incorporate temporal aspects in dialogue histories into tracking models. Experimental results showed that the proposed approaches helped to improve the topic tracking performance with respect to the linear baseline models.

Furthering this work, there would be still much room for improvement in future. Firstly, the architectures based on a single convolutional layer and a single bi-directional recurrent layer in the proposed models can be extended by adding more layers as well as utilizing more advanced components including hierarchical CNNs (Kalchbrenner et al., 2014b) to deal with utterance compositionalities or attention mechanisms (Denil et al., 2012) to focus on more important segments in dialogue sequences.

Secondly, the use of external knowledge could be a key to success in dialogue topic tracking, as proved in the previous studies. However, this work only takes internal dialogue information into account for making decisions. If we develop a good way of leveraging other useful resources into the neural network architectures, better performance can be expected especially for guide-driven and inter-categorical topic transitions that are considered to be more dependent on background knowledge of the speakers.

The other direction of our future work is to investigate joint models for tracking dialogue topics and states simultaneously. Although the previous multi-topic state tracking task has assumed that the topics should be given as inputs to state trackers, we expect that a joint approach can contribute to both problems by dealing with the bi-directional relationships between them.

Abstract

Lexico-semantic knowledge of our native language provides an initial foundation for second language learning. In this paper, we investigate whether and to what extent the lexico-semantic models of the native language (L1) are transferred to the second language (L2). Specifically, we focus on the problem of lexical choice and investigate it in the context of three typologically diverse languages: Russian, Spanish and English. We show that a statistical semantic model learned from L1 data improves automatic error detection in L2 for the speakers of the respective L1. Finally, we investigate whether the semantic model learned from a particular L1 is portable to other, typologically related languages.

1 Introduction

Lexico-semantic knowledge of our native language is one of the factors that underlie our ability to communicate and reason about the world. It is also the knowledge that guides us in the process of second language learning. Lexico-semantic variation across languages (Bach and Chao, 2008) makes lexical choice a challenging task for second language learners (Odlin, 1989). For instance, the meaning of the English expression *pull the trigger* is realised as **push the trigger* in Russian and Spanish, possibly leading to errors of lexical choice by Russian and Spanish speakers learning English. Our native language (L1) plays an essential role in the process of lexical choice. When choosing between several linguistic realisations in L2, non-native speakers may rely on the lexico-semantic information from L1 and select a translational equivalent that they deem to match their communicative intent best. For example, Russian speakers **do exceptions* and *offers* instead of *making* them, and **find decisions* instead of *finding solutions*, since in Russian *do* and *make* have a single translational equivalent (*delat'*), and so do *decision* and *solution* (*resheniye*). As a result, non-native speakers who tend to fall back to their L1 translate phrases word-for-word, violating English lexico-semantic conventions.

The effect of L1 interference on lexical choice in L2 has been pointed out in a number of studies (Chang et al., 2008; Rozovskaya, 2010; Rozovskaya, 2011; Dahlmeier and Ng, 2011). Some of these studies also demonstrated that using L1-specific properties, such as the error patterns of speakers of a given L1 or L1-induced paraphrases, improves the performance of automatic error correction in non-native writing. However, neither of the approaches has constructed a semantic model from L1 data and systematically studied the effects of its transfer onto L2. In addition, most previous work has focused on error correction, bypassing the task of error detection for lexical choice. Lexical choice is one of the most challenging tasks for both non-native speakers and automated error detection and correction (EDC) systems. The results of the most recent shared task on EDC, which spanned all error types including lexical choice, show that most teams either did not propose any algorithms for this type of errors or did not perform well on them (Ng, 2014).

In this paper, we experimentally investigate the influence of L1 on lexical choice in L2 and whether lexico-semantic models from L1 are transferred to L2 during language learning. For this purpose, we induce L1 and L2 semantic models from corpus statistics in each language independently, and then use the discrepancies between the two models to identify errors of lexical choice. We focus on two types of *verb–noun* combinations, VERB–DIRECT_OBJECT (*dobj*) and

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 974–983,
Berlin, Germany, August 7-12, 2016.

SUBJECT–VERB (*subj*), and consider two widely spoken L1s from different language families – Russian and Spanish. We conduct our experiments using the Cambridge Learner Corpus (Nicholls, 2003), containing writing samples of non-native speakers of English. Spanish speakers account for around 24.6% of the non-native speakers represented in this corpus and Russian speakers for 4%.

Our experiments test two hypotheses: (1) that L1 effects in the lexical choice in L2 reveal themselves in the difference of the word association strength in the L1 and L2; and (2) that L1 lexico-semantic models are portable to other, typologically related languages. To the best of our knowledge, our paper is the first one to experimentally investigate these questions. Our results demonstrate that L1-induced information improves automatic error detection for lexical choice, confirming the hypothesis that L1 speakers rely on semantic knowledge from their native language during L2 learning. We test the second hypothesis by verifying that Russian speakers exhibit similar trends in errors with the speakers of other Slavic languages, and Spanish speakers with the speakers of other Romance languages. We find that the L1-induced information from Russian and Spanish is effective in assessing lexical choice of the speakers of other languages for both language groups.

2 Related work

2.1 Error detection in content words

Early approaches to collocation error detection relied on manually created databases of correct and incorrect word combinations (Shei and Pain, 2000; Wible et al., 2003; Chang et al., 2008). Constructing such databases is expensive and time-consuming, and therefore, more recent research turned to the use of machine learning techniques.

Leacock et al. (2014) note that most approaches to detection and correction of collocation errors compare the writer's word choice to the set of alternatives using association strength measures and choose the combination with the highest score, reporting an error if this combination does not coincide with the original choice (Futagi et al., 2008; Östling and Knutsson, 2009; Liu et al., 2009). This strategy is expensive as it relies on comparison with a set of alternatives, limited in capacity as it depends on the quality of the alternatives generated and circular as the detection cannot be performed independently of the correction. Our approach alleviates these problems, since error detection depends on the original combination only.

Some previous approaches focused on correction only (Dahlmeier and Ng, 2011; Kochmar and Briscoe, 2015), and although they show promising results, they have not attempted to perform error detection in lexical choice. Kochmar and Briscoe (2014) focus on error detection, but their system addresses adjective–noun combinations and does not use L1-induced information.

2.2 L1 factors in L2 writing

The influence of an L1 on lexical choice in L2 and the resulting errors have been previously studied (Chang et al., 2008; Östling and Knutsson, 2009; Dahlmeier and Ng, 2011). These works focus on errors in particular L1s and use the translational equivalents directly to improve candidate selection and quality of corrections. Dahlmeier and Ng (2011) show that L1-induced paraphrases outperform approaches based on edit distance, homophones, and WordNet synonyms in selecting the appropriate corrections.

Rozovskaya and Roth (2010) show that an error correction system for prepositions benefits from restricting the set of possible corrections to those observed in the non-native data. Rozovskaya and Roth (2011) further demonstrate that the models perform better when they use knowledge about error patterns of the non-native writers. According to their results, an error correction algorithm that relies on a set of priors dependent on the writer's preposition and the writer's L1 outperforms other methods. Madnani et al. (2008) show promising results in whole-sentence grammatical error correction using round-trip translations from Google Translate via 8 different pivot languages.

The results of these studies suggest that L1 is a valuable source of information in EDC. However, all these works use isolated translational equivalents and focus on error correction only. In contrast, we construct holistic semantic models of L1 from L1 corpora and use these models to perform the more challenging task of error detection.

3 Data

We first use large monolingual corpora in Spanish, Russian and English to build word association models for each of the languages. We then apply the resulting models for error detection in the English learner data.

3.1 L1 Data

Spanish data The Spanish data was extracted from the Spanish Gigaword corpus (Mendonca et al., 2011), a one billion-word collection of news articles in Spanish. The corpus was parsed using the Spanish Malt parser (Nivre et al., 2007; Ballesteros et al., 2010). We extracted VERB–SUBJECT and VERB–DIRECT_OBJECT relations from the output of the parser, which we then used to build an L1 word association model for Spanish.

Russian data The Russian data was extracted from the RU-WaC corpus (Sharoff, 2006), a two billion-word representative collection of texts from the Russian Web. The corpus was parsed using Malt dependency parser for Russian (Sharoff and Nivre, 2011), and the VERB–SUBJECT and VERB–DIRECT_OBJECT relations were extracted from the parser output to create an L1 word association model for Russian.

Dictionaries and translation Once the L1 word associations have been computed for the verb–noun pairs, we identify possible translations for verbs and nouns (in each pair) in isolation, as a language learner might do. To create the translation dictionaries, we extracted translations from the English–Spanish and English–Russian editions of Wiktionary, both from the translation sections and the gloss sections if the latter contained single words as glosses. We focus on verb–noun pairs, therefore multi-word expressions were universally removed. We added inverse translations for every original translation. We then created separate translation dictionaries for each language and part-of-speech tag combination from the resulting collection of translations.

3.2 L2 data

To build the English word association model, we have used a combination of the British National Corpus (Burnard, 2007) and the UKWaC (Baroni et al., 2009). The corpora were parsed by the RASP parser (Briscoe et al., 2006) and VERB–SUBJECT and VERB–DIRECT_OBJECT relations were extracted from the parser output. Since the UKWaC is a Web corpus, we assume that the data contains a certain amount of noise, e.g. typographical errors, slang and non-words. We filter these out by checking that the verbs and nouns in the extracted relations are included in WordNet (Miller, 1995) with the appropriate part of speech.

3.3 Learner data

To extract the verb–noun combinations that have been used by non-native speakers in practice, we use the *Cambridge Learner Corpus* (CLC), which is a 52.5 million-word corpus of learner English collected by Cambridge University Press and Cambridge English Language Assessment since 1993 (Nicholls, 2003). It comprises English examination scripts written by learners of English with 148 different L1s, ranging across multiple examinations and covering all levels of language proficiency. A 25.5 million-word component of the CLC has been manually error-annotated.

We have preprocessed the CLC with the RASP parser (Briscoe et al., 2006), as it is robust when applied to ungrammatical sentences. We have then extracted all *dobj* and *subj* combinations: in total, we have extracted $187,109$ *dobj* and $225,716$ *subj* combinations. We have used the CLC error annotation to split the data into correct combinations and errors. We note that some verb–noun combinations are annotated both as being correct and as errors, depending on their wider context of use. To ensure that the annotation we use in our experiments is reliable and not context-dependent, we have empirically set a threshold to filter out ambiguously annotated instances. The set of correct word combinations includes only those word pairs that are used correctly in at least 70% of the cases they occur in the CLC; the set of errors includes only those that are used incorrectly at least 70% of the time.

3.4 Experimental datasets

We split the annotated CLC data by language and relation type. Table 1 presents the statistics on the datasets collected.[1] We extract the verb–noun combinations from the CLC texts written by native speakers of Russian (RU) and Spanish (ES) to test our first hypothesis, as well as by speakers of ALL L1s in the CLC to test our second hypothesis. We then filter the extracted relations using the translated verb–noun pairs from Russian and Spanish corpora.

We note that Russian and Spanish have comparable number of word combinations in L1-specific subsets – $10K$-$12K$ for *dobj* and *subj* combinations – and comparable error rates (ERR). We also note that the error rates in the *dobj* sub-

[1]The data is available at `http://www.cl.cam.ac.uk/~ek358/cross-ling-data.html`

Source	CLC	Total	ERR (%)	verbs	nouns
RU_{dobj}	RU	11,184	12.55	786	1,918
	ALL	62,923	14.02	1,387	4,168
RU_{subj}	RU	10,417	7.90	734	1,775
	ALL	63,649	9.49	1,403	4,374
ES_{dobj}	ES	11,959	14.66	705	1,926
	ALL	32,966	15.17	1,072	2,928
ES_{subj}	ES	9,899	8.09	573	1,733
	ALL	26,766	9.42	877	2,762

Table 1: Statistics on the datasets collected.

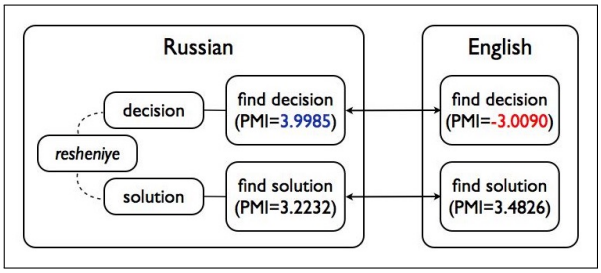

Figure 1: Russian to English interface for **find decision*.

sets are higher than in *subj* subsets, presumably, because VERB–SUBJECT combinations allow for more flexibility in lexical choice. We find a large number of translated word combinations in other L1s, and it is interesting to note that the error rates are higher across multiple languages than in the same L1s, which corroborates our second hypothesis that the lexico-semantic models from L1s transfer to L2. The last two columns of Table 1 show how diverse our datasets are in terms of verbs and nouns used in the constructions: for example, RU_{dobj} subset contains combinations with 786 different verbs and 1,918 different nouns.

4 Methods

Our approach to detecting lexico-semantic transfer errors relies on the intuition that a mismatch between the lexico-semantic models in two languages reveals itself in the difference in word association scores. We argue that a high association score of a *verb–noun* combination in L1 shows that it is a collocation in L1, but low association score of its translational equivalent in L2 signals an error in L2 stemming from the lexico-semantic transfer. Following previous research (Baldwin and Kim, 2010), we measure the strength of verb–noun association using pointwise mutual information (PMI). Figure 1 illustrates this intuition. In Russian, both **find decision* vs. *find solution* have a high PMI score. However, in English the latter has a high PMI while the former has a negative PMI. We expect such a discrepancy in word association to be an indicator of error of lexical choice, driven by the L1 semantics.

We treat the task of lexico-semantic transfer error detection as a binary classification problem and train a classifier for this task. The classifier uses a combination of L1 and L2 semantic features. If our hypothesis holds, we expect to see an improvement in the classifier's performance when adding L1 semantic features.

4.1 L2 lexico-semantic features

We experiment with two types of L2 features: lexico-semantic features and semantic vector space features.

Lexico-semantic features include:

- `pmi` in L2: we estimate the association strength between the noun and verb using the combined BNC and UKWaC corpus;
- `verb` and `noun`: the identity of the verb and the noun in the pair, encoded in a numerical form in the range of $(0, 1)$. The motivation behind that step is that certain words are more error-prone than others and converting them into numerical features helps the classifier to use this information.

Semantic vector space features Kochmar and Briscoe (2014) obtained state-of-the-art results in error detection by using the semantic component of the content word combinations. We reimplement these features and test their impact on our task. We extracted the noun and verb vectors from the publicly available `word2vec` dataset of word embeddings for 3 million words and phrases.[2] The 300-dimensional vectors have been trained on a part of Google News dataset (about 100 billion words) using `word2vec` (Mikolov et al., 2013). The *dobj* and *subj* vectors are then built using element-wise addition on the vectors (Mitchell and Lapata, 2008; Mikolov et al., 2013; Kochmar and Briscoe, 2014).

Once the compositional vectors are created, the method relies on the idea that correct combinations can be distinguished from the erroneous ones by certain vector properties (Vecchi et al., 2011; Kochmar and Briscoe, 2014). We implement a set of numerical features based on the following properties of the vectors:

[2] `code.google.com/archive/p/word2vec/`

- `length` of the additive (vn) vector
- $\texttt{cos}_{vn \wedge n}$ – cosine between the vn vector and the noun vector
- $\texttt{cos}_{vn \wedge v}$ – cosine between the vn vector and the verb vector
- $\texttt{dist}_{10}$ – distance to the 10 nearest neighbours of the vn vector
- `lex-overlap` – proportion of the 10 nearest neighbours of the vn vector containing the verb/noun
- `comp-overlap` – overlap between the 10 neighbours of the vn vector and 10 neighbours of the verb/noun vector
- $\texttt{cos}_{v \wedge n}$ – cosine between the verb and the noun vectors.

The 10 nearest neighbours are retrieved in the combined semantic space containing word embeddings and additive phrase vectors. All features, except for the last one, have been introduced in previous work and showed promising results (Vecchi et al., 2011; Kochmar and Briscoe, 2014). For example, it has been shown that the distance from the constructed word combination vector to its nearest neighbours is one of the discriminative features of the error detection classifier. Manual inspection of the vectors and nearest neighbours shows that the closest neighbour to **find decision* is *see decision* with the similarity of 0.8735 while the closest one to *find solution* is *discover solution* with the similarity of 0.9048.

We implement an additional $\text{cos}_{v \wedge n}$ feature based on the intuition that the distance between the verb and noun vectors themselves may indicate a semantic mismatch and thus help in detecting lexical choice errors.

4.2 L1 lexico-semantic features

We first quantified the strength of association between the L1 verbs and nouns in the original L1 data, using PMI. We then generated a set of possible translations for each verb–noun pair in L1 using the translation dictionaries. Each verb–noun pair in the CLC was then mapped to one of the translated L1 pairs and its L1 features. We used the following L1 features in classification:

- `pmi` in L1: we estimate the strength of association on the original L1 corpora;
- `difference` between the PMI of the verb–noun pair in L1 and in L2.

4.3 Classification

Classifier settings We treat the task as a binary classification problem and apply a linear SVM classifier using `scikit-learn LinearSVC` implementation.[3] The error rates in Table 1 show that we are dealing with a two-class problem where one class (*correct* word combinations) significantly outnumbers the other class (*errors*) by up to 11:1 (on RU_{subj}). To address the problem of class imbalance, we use subsampling: we randomly split the set of correct word combinations in n samples keeping the majority class baseline under 0.60, and run n experiments over the samples. We apply 10-fold cross-validation within each sample. The results reported in the following sections are averaged across the samples for each dataset.

Evaluation The goal of the classifier is to detect errors, therefore we primarily focus on its performance on the *error* class and, in addition to accuracy, report *precision* (P), *recall* (R) and F_1 on this class. Previous studies (Nagata and Nakatani, 2010) suggest that systems with high precision in detecting errors are more helpful for L2 learning than systems with high recall as non-native speakers find misidentified errors very misleading. In line with this research, we focus on maximising precision on the *error* class.

Baseline We compare the performance of our different feature sets to the baseline classifier which uses L2 co-occurrence frequency of the verb and noun in the pair as a single feature. Frequency sets a competitive baseline as it is often judged to be the measure of acceptability of an expression and many previous works relied on the frequency of occurrence as an evidence of acceptability (Shei and Pain, 2000; Futagi et al., 2008).

5 Experimental Results

To test our hypothesis that lexico-semantic models are transferred from L1 to L2, we first run the set of experiments on the L1 subsets of the CLC data, that is $\text{RU} \rightarrow \text{RU}_{CLC}$ and $\text{ES} \rightarrow \text{ES}_{CLC}$, where the left-hand side of the notation denotes the lexico-semantic model and the right-hand side the L1 of the speakers that produced the word pairs extracted from the CLC. We incrementally add the features, starting with the set of lexico-semantic

features in L2 that are readily available without reference to the L1, and later adding L1 semantic features, and measure their contribution.

5.1 L2 lexico-semantic features

The first system configuration we experiment with uses the set of lexico-semantic features from L2. Table 2 reports the results. Our experiments show that a classifier that uses L2 PMI ($\mathtt{pmi}_{En}$) as a single feature performs with relatively high accuracy: on all four datasets it outperforms the baseline classifier achieving an increase from 7.54% (on ES_{dobj}) up to 14.77% (on ES_{subj}) in accuracy.

Adding the `noun` as a feature decreases performance of the classifier and we do not further use this feature. The `verb` used as an additional feature consistently improves classifier performance.

5.2 L2 semantic vector space features

Next, we test the combination of the semantic vector space features (`sem`) and combine them with two L2 lexico-semantic features including $\mathtt{pmi}_{En}$ and `verb` (denoted as $\mathtt{ft}_{En}$ hereafter for brevity). Table 3 reports the results.

We note that the semantic vector space features on their own yield precision of $50\% - 52\%$ on the *error* class in *dobj* combinations and lower than 50% on *subj* combinations. This suggests that the classifier misidentifies correct combinations as errors more frequently than it correctly detects errors. Moreover, recall of this system configuration is also low on all datasets. Adding the semantic vector space features to the other L2 semantic features, however, improves the performance, as shown in Table 3. As both groups of features refer to the phenomena in L2, the results suggest that they complement each other.

L1	Features	Acc	$\mathbf{P}_e$	R_e	F_{1_e}

Table 4: System performance (in %) using L1 and L2 lexico-semantic features, L1 $\rightarrow$ L1$_{CLC}$.

5.3 L1 lexico-semantic features

Finally, we add the L1 lexico-semantic features to the well-performing L2 features (`pmi` and `verb`). The combination of L1 lexico-semantic features with the L2 lexico-semantic and semantic vector space features achieves lower results, therefore we do not report them here. The use of L1 `pmi` improves both the accuracy and the F-score of the *error* class (see Table 4). For the ease of comparison, we also include the results obtained using a combination of L1 lexico-semantic features (denoted $\mathtt{ft}_{En}$). The addition of the explicit `difference` feature between the two PMIs has not yielded further improvement. This is likely to be due to the fact that the classifier already implicitly captures the knowledge of this difference in the form of individual L1 and L2 PMIs.

We note that the system using a combination of L1 and L2 lexico-semantic features gains an absolute improvement in accuracy from 1.04% for RU_{subj} to 2.55% on ES_{dobj}. The performance on the *error* class improves in all but one case (P_e on RU_{dobj}), with an absolute increase in F_1 up to 7.66%. The system has both a higher coverage in error detection (a rise in recall) and a higher precision. The improvement in performance across all four datasets is statistically significant at 0.05 level. These results demonstrate the effect of lexico-semantic model transfer from L1 to L2.

6 Effect on different L1s

Next, we test our second hypothesis that a lexico-semantic model from one L1 is portable across several L1s, in particular, typologically related ones. We first experiment with the data representing all L1s in the CLC and then with the data representing a specific language group. We compare the performance of the baseline system using verb–noun co-occurrence frequency as a single feature, the system that uses L2 semantic features only and the system that combines both L2 and L1 semantic features.

6.1 Experiments on all L1s

Table 1 shows that using the translated verb–noun combinations from our L1s (RU and ES) we are able to find a large amount of both correct and erroneous combinations in different L1s in the CLC including RU and ES (see ALL). This gives us an initial confirmation that the lexico-semantic models may be shared across multiple languages.

We then experiment with error detection across all L1s represented in the CLC. The results are shown in Table 5. The baseline system achieves similar performance on RU $\rightarrow$ ALL$_{CLC}$ as on RU $\rightarrow$ RU$_{CLC}$, and better performance on ES $\rightarrow$ ALL$_{CLC}$ than on ES $\rightarrow$ ES$_{CLC}$. The results obtained with the L2 lexico-semantic features are also comparable: the system achieves an absolute increase in accuracy of up to 9.86% for the model transferred from RU$_{subj}$, reaching an accuracy of around $65 - 66\%$ with balanced performance in terms of precision and recall on *errors*.

When the L1 lexico-semantic features are added to the model, we observe an absolute increase in the accuracy ranging from 0.57% (for RU$_{subj}$) to 1.43% (for ES$_{dobj}$). The Spanish lexico-semantic model has a higher positive effect on all measures, including precision on the *error* class. Although the addition of the L1 lexico-semantic features does not have a significant effect on the accuracy and precision, the system achieves an absolute improvement in recall of up to 12.71% (on RU$_{dobj}$). That is, the system that uses L1 lexico-semantic features is able to find more errors in the data originating with a set of different L1s. Generally, the results of the Spanish model are more stable and comparable to the results in the previous Section, which may be explained by the fact that Spanish is more well-represented in the CLC.

L1	Features	Acc	P_e	R_e	F_{1_e}
RU$_{dobj}$	baseline	55.13	50.17	72.14	58.99
	ft$_{En}$	63.58	59.73	57.98	58.85
	+pmi$_{L1}$	64.60	58.81	70.69	64.20
RU$_{subj}$	baseline	54.56	47.95	71.10	56.71

	ft$_{En}$	65.57	58.32	64.09	61.06
	+pmi$_{L1}$	66.54	58.80	68.72	63.36

Table 5: System performance (in %) using L1 and L2 lexico-semantic features, L1 $\rightarrow$ all L1s.

6.2 Experiments on related L1s

The results on ALL L1s confirm our expectations: since we have extracted verb–noun combinations that originate with two particular L1s from the set of all different L1s in the CLC, and then used the L1 lexico-semantic features, the system is able to identify more errors thus we observe an improvement in recall. The precision, however, does not improve, possibly because the set of errors in ALL L1s is different from that in the two L1s we rely on to build the lexico-semantic models. The final question that we investigate is whether the lexico-semantic models of our L1s are directly portable to typologically related languages. If this is the case, we expect to see an effect on the precision of the classifier as well as on the recall.

We experiment with the following groups of related languages ordered by the number of verb–noun pairs we found in the CLC data:

- `Ru group`: Russian, Polish, Czech, Slovak, Serbian, Croatian, Bulgarian, Slovene;
- `Es group`: Spanish, Italian, Portuguese, French, Catalan, Romanian, Romansch.

In addition to investigating the effect of the L1 lexico-semantic model on the whole language group, we also consider its effects on individual languages. We chose Polish for the RU model, and Italian for the ES model as these two languages have the most data representing their native speakers in the CLC. Table 6 shows the number of verb–noun combinations and error rates for the language groups and these individual languages.

The results are presented in Tables 7 and 8. They exhibit similar trends in the change of the system performance on L1 $\rightarrow$ L1_GROUP as we

Source	Targets	Total	ERR

Table 7: System performance (in %) using L1 and L2 lexico-semantic features, L1 → L1_GROUP.

see for L1 → ALL L1s. Adding the L1 lexico-semantic features has only a minor effect on accuracy and precision, and a more pronounced effect on recall. On the contrary, when we test the system on one particular related L1 (Table 8) we observe the opposite effect: with the exception of ES$_{subj}$ data, precision and accuracy improve, suggesting that the error detection system using L1-induced information identifies errors more precisely.

Overall, the observed gains in performance indicate that L1 semantic models contribute information to lexical choice error detection in L2 for the speakers of typologically related languages. This in turn suggests that there may be less semantic variation within a language group than across different language groups.

7 Discussion and data analysis

The best accuracy achieved in our experiments is 71.19% on ES$_{subj}$ combinations. However, previous research suggests that error detection in lexical choice is a difficult task. For instance, Kochmar and Briscoe (2014) report that the agreement between human annotators on error detection in adjective–noun combinations is 86.50%.

We then qualitatively assessed the performance of our systems by analysing what types of errors

L1	Features	Acc	$\mathbf{P}_e$	R_e	F_{1_e}
RU$_{dobj}$	baseline	55.04	47.68	63.87	53.81
	ft$_{En}$	64.73	59.76	46.05	52.01
	+pmi$_{L1}$	65.15	60.63	45.77	52.16

	ft$_{En}$	62.71	58.80	43.09	49.69
	+pmi$_{L1}$	62.44	58.46	41.71	48.60

Table 8: System performance (in %) using L1 and L2 lexico-semantic features, L1 → REL_L1.

the classifiers reliably detect and what types of errors the classifiers miss across all runs over the samples. Some of the most reliably identified errors in both RU and ES datasets include:

- verbs *offer*, *propose* and *suggest* which are often confused with each other. Correctly identified errors include **offer plan* vs. *suggest plan*, **propose work* vs. *offer work* and **suggest cost* vs. *offer cost*;
- verbs *demonstrate* and *show* where *demonstrate* is often used instead of *show* as in **chart demonstrates*;
- verbs *say* and *tell* particularly well identified with the ES model. Examples include **say idea* instead of *tell idea* and **tell goodbye* instead of *say goodbye*.

These examples represent lexical choice errors when selecting among near-synonyms, and violations of verb subcategorization frames. The error in **find solution* discussed throughout the paper is also reliably identified by the classifier across all runs. It is interesting to note that in the pair of verbs *do* and *make*, which are often confused with each other by both Russian and Spanish L1 speakers, errors involving *make* are identified more reliably than errors involving *do*: for example, **make business* is correctly identified as an error, while **do joke* is missed by the classifier.

Many of the errors missed by the classifier are context-dependent. Some of the most problematic errors involve errors in combinations with verbs like *be* and *become*. Such errors do not result from an L1 lexico-semantic transfer and it is not surprising that the classifiers miss them.

8 Conclusion

We have investigated whether lexico-semantic models from the native language are transferred to the second language, and what effect this transfer has on lexical choice in L2. We focused on two typologically different L1s – Russian and Spanish, and experimentally confirmed the hypothesis that statistical semantic models learned from these L1s significantly improve automatic error detection in L2 data produced by the speakers of the respective L1s. We also investigated whether the semantic models learned from particular L1s are portable to other languages, and in particular to languages that are typologically close to the investigated L1s. Our results demonstrate that L1 models improve the coverage of the error detection system on a range of other L1s.

Abstract

Fill-in-the-blank items are commonly featured in computer-assisted language learning (CALL) systems. An item displays a sentence with a blank, and often proposes a number of choices for filling it. These choices should include one correct answer and several plausible distractors. We describe a system that, given an English corpus, automatically generates distractors to produce items for preposition usage.

We report a comprehensive evaluation on this system, involving both experts and learners. First, we analyze the difficulty levels of machine-generated carrier sentences and distractors, comparing several methods that exploit learner error and learner revision patterns. We show that the quality of machine-generated items approaches that of human-crafted ones. Further, we investigate the extent to which mismatched L1 between the user and the learner corpora affects the quality of distractors. Finally, we measure the system's impact on the user's language proficiency in both the short and the long term.

1 Introduction

Fill-in-the-blank items, also known as gap-fill or cloze items, are a common form of exercise in computer-assisted language learning (CALL) applications. Table 1 shows an example item designed for teaching English preposition usage. It contains a sentence, "The objective is to kick the ball into the opponent's goal", with the preposition "into" blanked out; this sentence serves as the *stem* (or *carrier sentence*). It is followed by four choices for the blank, one of which is the *key* (i.e., the correct answer), and the other three are distractors. These choices enable the CALL application to provide immediate and objective feedback to the learner.

A high-quality item must meet multiple requirements. It should have a stem that is fluent and matches the reading ability of the learner; a blank that is appropriate for the intended pedagogical goal; exactly one correct answer among the choices offered; and finally, a number of distractors that seem plausible to the learner, and yet would each yield an incorrect sentence. Relying on language teachers to author these items is time consuming. Automatic generation of these items would not only expedite item authoring, but also potentially provide personalized items to suit the needs of individual learners. This paper addresses two research topics:

- How do machine-generated items compare with human-crafted items in terms of their quality?
- Do these items help improve the users' language proficiency?

For the first question, we focus on automatic generation of preposition distractors, comparing three different methods for distractor generation. One is based on word co-occurrence in standard

The objective is to kick the ball _____ the opponent's goal. (A) in (B) into (C) to (D) with

Table 1: An automatically generated fill-in-the-blank item, where "into" is the key, and the other three choices are distractors.

Berlin, Germany, August 7-12, 2016.

corpora; a second leverages error annotations in learner corpora; the third, a novel method, exploits learners' revision behavior. Further, we investigate the effect of tailoring distractors to the user's native language (L1). For the second question, we measure users' performance in the short and in the long term, through an experiment involving ten subjects, in multiple sessions tailored to their proficiency and areas of weakness.

Although a previous study has shown that learner error statistics can produce competitive items for prepositions on a narrow domain (Lee and Seneff, 2007), a number of research questions still await further investigation. Through both expert and learner evaluation, we will compare the quality of carrier sentences and the plausibility of automatically generated distractors against human-crafted ones. Further, we will measure the effect of mismatched L1 between the user and the learner corpora, and the short- and long-term impact on the user's preposition proficiency. To the best of our knowledge, this paper offers the most detailed evaluation to-date covering all these aspects.

The rest of the paper is organized as follows. Section 2 reviews previous work. Section 3 outlines the algorithms for generating the fill-in-the-blank items. Section 4 gives details about the experimental setup and evaluation procedures. Section 5 analyzes the results. Section 6 concludes the paper.

2 Previous Work

2.1 Distractor generation

Most research effort on automatic generation of fill-in-the-blank items has focused on vocabulary learning. In these items, the key is typically from an open-class part-of-speech (POS), e.g., nouns, verbs, or adjectives.

To ensure that the distractor results in an incorrect sentence, the distractor must rarely, or never, collocate with other words in the carrier sentence (Liu et al., 2005). To ensure the plausibility of the distractor, most approaches require it to be semantically close to the key, as determined by a thesaurus (Sumita et al., 2005; Smith et al., 2010), an ontology (Karamanis et al., 2006), rules handcrafted by experts (Chen et al., 2006), or context-sensitive inference rules (Zesch and Melamud, 2014); or to have similar word frequency (Shei, 2001; Brown et al., 2005). Sakaguchi et al. (2013) applied machine learning methods to select verb distractors, and showed that they resulted in items that can better predict the user's English proficiency level.

Less attention has been paid to items for closed-class POS, such as articles, conjunctions and prepositions, which learners also often find difficult (Dahlmeier et al., 2013). For these POS, the standard algorithms based on semantic relatedness for open-class POS are not applicable. Lee and Seneff (2007) reported the only previous study on using learner corpora to generate items for a closed-class POS. They harvested the most frequent preposition errors in a corpus of Japanese learners of English (Izumi et al., 2003), but performed an empirical evaluation with native Chinese speakers on a narrow domain.

We expand on this study in several dimensions. First, carrier sentences, selected from the general domain rather than a specific one, will be analyzed in terms of their difficulty level. Second, distractor quality will be evaluated not only by learners but also by experts, who give scores based on their plausibility; in contrast to most previous studies, their quality will be compared with the human gold standard. Thirdly, the effect of mismatched L1 will also be measured.

2.2 Learner error correction

There has been much recent research on automatic correction of grammatical errors. Correction of preposition usage errors, in particular, has received much attention. Our task can be viewed as the inverse of error correction — ensuring that the distractor yields an incorrect sentence — with the additional requirement on the plausibility of the distractor.

Most approaches in automatic grammar correction can be classified as one of three types, according to the kind of statistics on which the system is trained. Some systems are trained on examples of correct usage (Tetreault and Chodorow, 2008; Felice and Pulman, 2009). Others are trained on examples of pairs of correct and incorrect usage, either retrieved from error-annotated learner corpora (Han et al., 2010; Dahlmeier et al., 2013) or simulated (Lee and Seneff, 2008; Foster and Andersen, 2009). More recently, a system has been trained on revision statistics from Wikipedia (Cahill et al., 2013). We build on all three paradigms, using standard English cor-

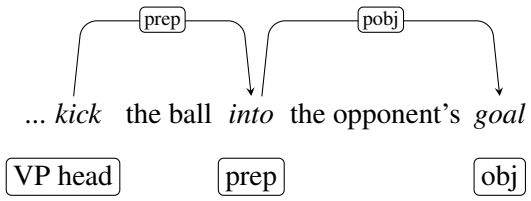

Figure 1: Parse tree for the carrier sentence in Table 1. Distractors are generated on the basis of the prepositional object ("obj") and the NP/VP head to which the prepositional phrase is attached (Section 3).

pora (Section 3.1), error-annotated learner corpora (Section 3.2) and learner revision corpora (Section 3.3) as resources to predict the most plausible distractors.

3 Item generation

The system assumes as input a set of English sentences, which are to serve as candidates for carrier sentences. In each candidate sentence, the system scans for prepositions, and extracts two features from the linguistic context of each preposition:

- The **prepositional object**. In Figure 1, for example, the word "goal" is the prepositional object of the key, "into".
- The head of the noun phrase or verb phrase (**NP/VP head**) to which the prepositional phrase (PP) is attached. In Figure 1, the PP "into the opponent's goal" is attached to the VP head "kick".

The system passes these two features to the following methods to generate distractors.[1] If all three methods are able to return a distractor, the preposition qualifies to serve as the key. If more than one key is found, the system randomly chooses one of them.

In the rest of this paper, we will sometimes abbreviate these three methods as the "Co-occur" (Section 3.1), "Error" (Section 3.2), and "Revision" (Section 3.3) methods, respectively.

3.1 Co-occurrence method

Proposed by Lee and Seneff (2007), this method requires co-occurrence statistics from a large corpus of well-formed English sentences.

[1]We do not consider errors where a preposition should be inserted or deleted.

Co-occurrence method ("Co-occur")
... *kicked* the chair *with* ...
... *kicked* the can *with* ...
... *with* the *goal* of ...
Learner error method ("Error")
... *kicked* it <error>*in*</error> the *goal*.
... *kick* the ball <error>*in*</error> the other team's *goal*.
Learner revision method ("Revision")
... *kick* the ball ~~to~~ into his own *goal*.
... *kick* the ball ~~to~~ towards his own *goal*.

Table 2: The Co-occurrence Method (Section 3.1) generates "with" as the distractor for the carrier sentence in Figure 1; the Learner Error Method (Section 3.2) generates "in"; the Learner Revision Method (Section 3.3) generates "to".

This method first retrieves all prepositions that co-occur with *both* the prepositional object and the NP/VP head in the carrier sentence. These prepositions are removed from consideration as distractors, since they would likely yield a correct sentence. The remaining candidates are those that co-occur with *either* the prepositional object *or* the NP/VP head, but not both. The more frequently the candidate co-occurs with either of these words, the more plausible it is expected to appear to a learner. Thus, the candidate with the highest co-occurrence frequency is chosen as the distractor. As shown in Table 2, this method generates the distractor "with" for the carrier sentence in Figure 1, since many instances of "kick ... with" and "with ... goal" are attested.

3.2 Learner error method

This method requires examples of English sentences from an error-annotated learner corpus. The corpus must mark wrong preposition usage, but does not need to provide corrections for the errors.

This method first retrieves all PPs that have the given prepositional object and are attached to the given NP/VP head. It then computes the frequency of prepositions that head these PPs and are marked as wrong. The one that is most frequently marked as wrong is chosen as the distractor. As shown in Table 2, this method generates the distractor "in" for the carrier sentence in Figure 1, since it is often marked as an error.

3.3 Learner revision method

It is expensive and time consuming to annotate learner errors. As an alternative, we exploit the revision behavior of learners in their English writing. This method requires draft versions of texts written by learners. In order to compute statistics on how often a preposition in an earlier draft ("draft n") is replaced with another one in the later draft ("draft $n + 1$"), the sentences in successive drafts must be sentence- and word-aligned.

This method scans for PPs that have the given prepositional object and are attached to the given NP/VP head. For all learner sentences in draft n that contain these PPs, it consults the sentences in draft $n+1$ to which they are aligned; it retains only those sentences whose prepositional object and the NP/VP head remain unchanged, but whose preposition has been replaced by another one. Among these sentences, the method selects the preposition that is most frequently edited between two drafts. Our assumption is that frequent editing implies a degree of uncertainty on the part of the learner as to which of these prepositions is in fact correct, thus suggesting that they may be effective distractors. As shown in Table 2, this method generates the distractor "to" for the carrier sentence in Figure 1, since it is most often edited in the given linguistic context. This study is the first to exploit a corpus of learner revision history for item generation.[2]

4 Experimental setup

In this section, we first describe our datasets (Section 4.1) and the procedure for item generation (Section 4.2). We then give details on the expert evaluation (Section 4.3) and the learner evaluation (Section 4.4).

4.1 Data

Carrier sentences. We used sentences in the English portion of the Wikicorpus (Reese et al., 2010) as carrier sentences. To avoid selecting stems with overly difficult vocabulary, we ranked the sentences in terms of their most difficult word. We measured the difficulty level of a word firstly with the graded English vocabulary lists compiled by the Hong Kong Education Bureau (EDB, 2012); and secondly, for words not occurring in any of these lists, with frequency counts derived from the Google Web Trillion Word Corpus.[3] In order to retrieve the prepositional object and the NP/VP head (cf. Section 3), we parsed the Wikicorpus, as well as the corpora mentioned below, with the Stanford parser (Manning et al., 2014).

Co-occurrence method ("Co-occur"). The statistics for the Co-occurrence method were also based on the English portion of Wikicorpus.

Learner Revision method ("Revision"). We used an 8-million-word corpus of essay drafts written by Chinese learners of English (Lee et al., 2015). This corpus contains over 4,000 essays, with an average of 2.7 drafts per essay. The sentences and words between successive drafts have been automatically aligned.

Learner Error method ("Error"). In addition to the corpus of essay drafts mentioned above, we used two other error-annotated learner corpora. The NUS Corpus of Learner English (NUCLE) contains one million words of academic writing by students at the National University of Singapore (Dahlmeier et al., 2013). The EF-Cambridge Open Language Database (EFCAMDAT) contains over 70 million words from 1.2 million assignments written by learners from a variety of linguistic background (Geertzen et al., 2013). A subset of the database has been error-annotated. We made use of the writings in this subset that were produced by students from China and Russia.

Human items ("Textbook"). To provide a comparison with human-authored items, we used the practise tests for preposition usage offered in an English exercise book designed for intermediate and advanced learners (Watcyn-Jones and Allsop, 2000). From the 50 tests in a variety of formats, we harvested 56 multiple-choice items, all of which had one key and three distractors.

4.2 Item generation procedure

We gathered three sets of 400 carrier sentences, for use in three evaluation sessions (see Section 4.4). Each sentence in Set 1 has one counterpart in Set 2 and one counterpart in Set 3 that have the same key, NP/VP head and prepositional object. We will refer to the items created from these counterpart carrier sentences as "similar" items. We will use these "similar" items to measure the learning impact on the subjects.

Each item has one key and distractors generated

[2] A similar approach, using revision statistics in Wikipedia, has been used for the purpose of correcting preposition errors (Cahill et al., 2013).

[3] http://norvig.com/ngrams/

by each of the three methods. For about half of the items, the three methods complemented one another to offer three distinct distractors. In the other half, two of the methods yielded the same distractor, resulting in only two distractors for those items. In Set 1, for control purposes, 56 of the items were replaced with the human items.

4.3 Expert evaluation procedure

Two professional English teachers (henceforth, the "experts") examined each of the 400 items in Set 1. They annotated each item, and each choice in the item, as follows.

For each item, the experts labeled its difficulty level in terms of the preposition usage being tested in the carrier sentence. They did not know whether the item was human-authored or machine-generated. Based on their experience in teaching English to native speakers of Chinese, they labeled each item as suitable for those in "Grades 1-3", "Grades 4-6", "Grades 7-9", "Grades 10-12", or ">Grade 12". We mapped these five categories to integers — 2, 5, 8, 11 and 13, respectively — for the purpose of calculating difficulty scores.

For each choice in the item, the experts judged whether it is correct or incorrect. They did not know whether each choice was the key or a distractor. They may judge one, multiple, or none of the choices as correct. For an incorrect choice, they further assessed its plausibility as a distractor, again from their experience in teaching English to native speakers of Chinese. They may label it as "Plausible", "Somewhat plausible", or "Obviously wrong".

4.4 Learner evaluation procedure

Ten university students (henceforth, the "learners") took part in the evaluation. They were all native Chinese speakers who did not major in English. The evaluation consisted of three one-hour sessions held on different days. At each session, the learner attempted 80 items on a browser-based application (Figure 2). The items were distributed in these sessions as follows.

Session 1. The 400 items in Set 1 were divided into 5 groups of 80 items, with 11 to 12 human items in each group. The items in each group had comparable difficulty levels as determined by the experts, with average scores ranging from 7.9 to 8.1. Each group was independently attempted by two learners. The system recorded the items to which the learner gave wrong answers; these will be referred to as the "wrong items". Among the items to which the learner gave correct answers, the system randomly set aside 10 items; these will be referred to as "control items".

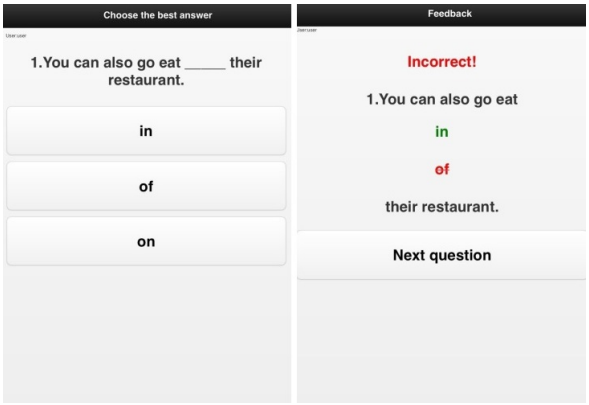

Figure 2: Interface for the learner evaluation. On the left, the learner selects a choice by tapping on it; on the right, the learner receives feedback.

Session 2. To measure the short-term impact, Session 2 was held on the day following Session 1. Each learner attempted 80 items, drawn from Set 2. These items were personalized according to the "wrong items" of the individual learner. For example, if a learner had 15 "wrong items" from Session 1, he or she then received 15 similar items[4] from Set 2. In addition, he or she also received ten items that were similar to the "control items" from Session 1. The remaining items were drawn randomly from Set 2. As in Session 1, the system noted the "wrong items" and set aside ten "control items".

Session 3. To test the long-term effect of these exercises, Session 3 was held two weeks after Session 2. Each learner attempted another 80 items, drawn from Set 3. These 80 items were chosen in the same manner as in Session 2.

5 Results

We first report inter-annotator agreement between the two experts on the difficulty levels of the carrier sentences and the distractors (Section 5.1). We then compare the difficulty levels of the human- and machine-generated items (Section 5.2). Next, we analyze the reliability and difficulty[5] of the

[4] See definition of "similar" in Section 4.2.

[5] Another metric, "validity", measures the ability of the distractor to discriminate between students of different proficiency levels. This metric is relevant for items intended for

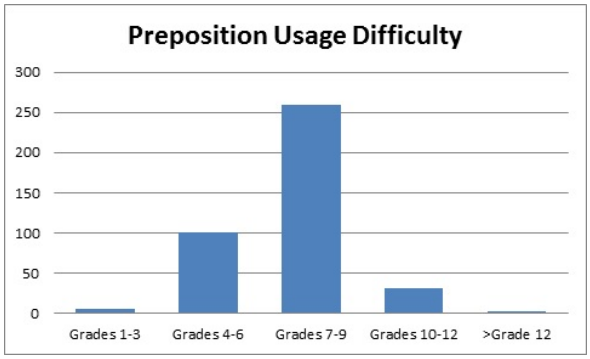

Figure 3: The difficulty level of the items in Set 1, as annotated by the experts.

automatically generated distractors (Sections 5.3 and 5.4), and the role of the native language (Section 5.5). Finally, we measure the impact on the learners' preposition proficiency (Section 5.6).

5.1 Inter-annotator agreement

For estimating the difficulty level of the preposition usage in the carrier sentences, the experts reached "substantial" agreement with kappa at 0.765 (Landis and Koch, 1977). In deciding whether a choice is correct or incorrect, the experts reached "almost perfect" agreement with kappa at 0.977. On the plausibility of the distractors, they reached "moderate" agreement with kappa at 0.537. The main confusion was between the categories "Obviously wrong" and "Somewhat plausible".

On the whole, expert judgment tended to correlate with actual behavior of the learners. For distractors considered "Plausible" by both experts, 63.6% were selected by the learners. In contrast, for those considered "Obviously wrong" by both experts, only 11.8% attracted any learner.

5.2 Carrier sentence difficulty

Figure 3 shows the distribution of difficulty level scores for the preposition usage in carrier sentences. Most items were rated as "Grades 7-9", with "Grades 4-6" being the second largest group.

A common concern over machine-generated items is whether the machine can create or select the kind of carrier sentences that illustrate challenging or advanced preposition usage, compared to those crafted by humans. In our system, the preposition errors and revisions in the learner corpora — as captured by the NP/VP head and the prepositional object — effectively served as the filter for selecting carrier sentences. Some of these errors and revisions may well be careless or trivial mistakes, and may not necessarily lead to the selection of appropriate carrier sentences.

To answer this question, we compared the difficulty levels of preposition usage in the machine-generated and human-crafted items. The average difficulty score for the human items was 8.7, meaning they were suitable for those in Grade 8. The average for the machine-generated items were lower, at 7.2. This result suggests that our system can select carrier sentences that illustrate challenging preposition usage, at a level that is only about 1.5 grade points below those designed by humans.

5.3 Distractor reliability

A second common concern over machine-generated items is whether their distractors might yield correct sentences. When taken out of context, a carrier sentence often admits multiple possible answers (Tetreault and Chodorow, 2008; Lee et al., 2009). In this section, we compare the performance of the automatic distractor generation methods against humans.

A distractor is called "reliable" if it yields an incorrect sentence. The Learner Revision method generated the most reliable distractors[6]; on average, 97.4% of the distractors were judged incorrect by both experts (Table 3). The Co-occurrence method ranked second at 96.1%, slightly better than those from the Learner Error method. Many distractors from the Learner Error method indeed led to incorrect sentences in their original contexts, but became acceptable when their carrier sentences were read in isolation. Items with unreliable distractors were excluded from the learner evaluation.

Surprisingly, both the Learner Revision and Co-occurrence methods outperformed the humans. Distractors in some of the human items did indeed yield sentences that were technically correct, and were therefore deemed "unreliable" by the experts. In many cases, however, these distractors were accompanied with keys that provided more natural choices. These items, therefore, remained valid.

assessment purposes (Brown et al., 2005; Sakaguchi et al., 2013) rather than self-learning.

[6]The difference with the Co-occurrence method is not statistically significant, in part due to the small sample size.

Method	Reliable distractor
Co-occur	96.1%
Error	95.6%
Revision	**97.4%**
Textbook	95.8%

Table 3: Distractors judged reliable by both experts.

5.4 Distractor difficulty

In the context of language learning, an item can be considered more useful if one of its distractors elicits a wrong choice from the learner, who would then receive corrective feedback. In this section, we compare the "difficulty" of the distractor generated by the various methods, in terms of their ability to attract the learners.

Expert evaluation. The two methods based on learner statistics produced the highest-quality distractors (Table 4). The Learner Error method had the highest rate of plausible distractors (51.2%) and the lowest rate of obviously wrong ones (22.0%). In terms of the number of distractors considered "Plausible", this method significantly outperformed the Learner Revision method.[7]

According to Table 4, all three automatic methods outperformed the humans in terms of the number of distractors rated "Plausible". This comparison, however, is not entirely fair, since the human items always supplied three distractors, whereas about half of the machine-generated items supplied only two, when two of the methods returned the same distractor.

An alternate metric is to compute the average number of distractors rated "Plausible" *per item*. On average, the human items had 0.91 plausible distractors; in comparison, the machine-generated items had 1.27. This result suggests that automatic generation of preposition distractors can perform at the human level.

Learner evaluation. The most direct way to evaluate the difficulty of a distractor is to measure how often a learner chose it. The contrast is less clear cut in this evaluation. Overall, the learners correctly answered 76.2% of the machine-generated items, and 75.5% of the human items, suggesting that the human distractors were more challenging. One must also take into account, however, the fact that the carrier sentences are more difficult in the human items than in the machine-generated ones. Broadly speaking, the machine-generated distractors were almost as successful as those authored by humans.

[7] $p < 0.05$ by McNemar's test, for both expert annotators.

Method	Plausible	Somewhat plausible	Obviously wrong
Co-occur	34.6%	31.5%	33.9%
Error	**51.2%**	**26.8%**	**22.0%**
Revision	45.4%	28.5%	26.1%
Textbook	31.4%	34.2%	34.5%

Table 4: Plausibility judgment of distractors by experts.

Consistent with the experts' opinion (Table 4), the Learner Error method was most successful among the three automatic methods (Table 5). The learner selection rate of its distractors was 13.5%, which was significantly higher[8] than its closest competitor, the Learner Revision method, at 9.5%. The Co-occurrence method ranked last, at 9.2%. It is unfortunately difficult to directly compare these rates with that of the human distractors, which they were offered in different carrier sentences.

5.5 Impact of L1

We now turn our attention to the relation between the native language (L1) of the user, and that of the learner corpora used for training the system. Specifically, we wish to measure the gain, if any, in matching the L1 of the user with the L1 of the learner corpora. To this end, for the Learner Error method, we generated distractors from the EF-Cambridge corpus with two sets of statistics: one harvested from the portion of the corpus with writings by Chinese students, the others from the portion by Russian students.

Expert evaluation. Table 6 contrasts the experts' plausibility judgment on distractors generated from these two sets. Chinese distractors were

[8] $p < 0.05$ by McNemar's test.

Method	Learner selection rate
Co-occur	9.2%
Error	**13.5%**
Revision	9.5%

Table 5: Percentage of distractors selected by learners.

Method	Plausible	Somewhat plausible	Obviously wrong
Chinese	**57.7%**	**24.0%**	**18.3%**
Russian	55.3%	22.0%	22.7%

Table 6: Plausibility judgment of distractors generated from the Chinese and Russian portions of the EF-Cambridge corpus, by experts.

Difficulty level	Retention rate
Below 6	74.0%
6-8	71.3%
9-11	60.0%
12 or above	25%

Table 7: Retention rate for items at different levels of difficulty.

slightly more likely to be rated "plausible" than the Russian ones, and less likely to be rated "obviously wrong".[9] The gap between the two sets of distractors was smaller than may be expected.

Learner evaluation. The difference was somewhat more pronounced in terms of the learners' behavior. The learners selected Chinese distractors, which matched their L1, 29.9% of the time over the three sessions. In contrast, they fell for the Russian distractors, which did not match their L1, only 25.1% of the time. This result confirms the intuition that matching L1 improves the plausibility of the distractors, but the difference was nonetheless relatively small. This result suggets that it might be worth paying the price for mismatched L1s, in return for a much larger pool of learner statistics.

5.6 Impact on learners

In this section, we consider the impact of these exercises on the learners. The performance of the learners was rather stable across all sessions; their average scores in the three sessions were 73.0%, 73.6% and 69.9%, respectively. It is difficult, however, to judge from these scores whether the learners benefited from the exercises, since the composition of the items differed for each session.

Instead, we measured how often the learners retain the system feedback. More specifically, if the learner chose a distractor and received feedback (cf. Figure 2), how likely would he or she succeed in choosing the key in a "similar"[10] item in a subsequent session.

We compared the learners' responses between Sessions 1 and 2 to measure the short-term impact, and between Sessions 2 and 3 to measure the long-term impact. In Session 2, when the learners attempted items that were "similar" to their "wrong items" from Session 1, they succeeded in choosing the key in 72.4% of the cases.[11] We refer to this figure as the "retention rate", in this case over the one-day period between the two sessions. The retention rate deteriorated over a longer term. In Session 3, when the learners attempted items that were "similar" to their "wrong items" from Session 2, which took place two weeks before, they succeeded only in 61.5% of the cases.[12]

Further, we analyzed whether the difficulty level of the items affected their retention rate. Statistics in Table 7 show that the rate varied widely according to the difficulty level of the "wrong items". Difficult items, at Grade 12 or beyond, proved hardest to learn, with a retention rate of only 25%. At the other end of the spectrum, those below Grade 6 were retained 74% of the time. This points to the need for the system to reinforce difficult items more frequently.

6 Conclusions

We have presented a computer-assisted language learning (CALL) system that automatically creates fill-in-the-blank items for prepositions. We found that the preposition usage tested in automatically selected carrier sentences were only slightly less challenging than those crafted by humans. We compared the performance of three methods for distractor generation, including a novel method that exploits learner revision statistics. The method based on learner error statistics yielded the most plausible distractors, followed by the one based on learner revision statistics. The items produced jointly by these automatic methods, in both expert and learner evaluations, rivalled the quality of human-authored items. Further, we evaluated the extent to which mismatched

[9] Data sparseness prevented us from generating both Chinese and Russian distractors for the same carrier sentences for evaluation. These statistics are therefore not controlled with regard to the difficulty level of the sentences.

[10] See definition of "similar" in Section 4.2.

[11] As a control, the retention rate for correctly answered items in Session 1 was 80% in Session 2.

[12] As a control, the retention rate for correctly answered items in Session 2 was 69.0% in Session 3.

native language (L1) affects distractor plausibility. Finally, in a study on the short- and long-term impact on the learners, we showed that difficult items had lower retention rate. In future work, we plan to conduct larger-scale evaluations to further validate these results, and to apply these methods on other common learner errors.

Acknowledgments

We thank NetDragon Websoft Holding Limited for their assistance with system evaluation, and the reviewers for their very helpful comments. This work was partially supported by an Applied Research Grant (Project no. 9667115) from City University of Hong Kong.

Abstract

We present persona-based models for handling the issue of speaker consistency in neural response generation. A speaker model encodes personas in distributed embeddings that capture individual characteristics such as background information and speaking style. A dyadic speaker-addressee model captures properties of interactions between two interlocutors. Our models yield qualitative performance improvements in both perplexity and BLEU scores over baseline sequence-to-sequence models, with similar gains in speaker consistency as measured by human judges.

1 Introduction

As conversational agents gain traction as user interfaces, there has been growing research interest in training naturalistic conversation systems from large volumes of human-to-human interactions (Ritter et al., 2011; Sordoni et al., 2015; Vinyals and Le, 2015; Li et al., 2016). One major issue for these data-driven systems is their propensity to select the response with greatest likelihood—in effect a consensus response of the humans represented in the training data. Outputs are frequently vague or non-committal (Li et al., 2016), and when not, they can be wildly inconsistent, as illustrated in Table 1.

message	Where do you live now?
response	I live in Los Angeles.
message	In which city do you live now?
response	I live in Madrid.
message	In which country do you live now?
response	England, you?
message	Where were you born?
response	I was born in Canada.
message	Where are you from?
response	England, you?
message	Where did you grow up?
response	I grew up in Texas.
message	How old are you?
response	16 and you?
message	What's your age?
response	18.
message	What is your major?
response	I'm majoring in psychology
message	What did you study in college?
response	English lit.

Table 1: Inconsistent responses generated by a 4-layer SEQ2SEQ model trained on 25 million Twitter conversation snippets.

In this paper, we address the challenge of consistency and how to endow data-driven systems with the coherent "persona" needed to model human-like behavior, whether as personal assistants, personalized avatar-like agents, or game characters.[1] For present purposes, we will define PERSONA as the character that an artificial agent, as actor, plays or performs during conversational interactions. A persona can be viewed as a composite of elements of identity (background facts or user profile), language behavior, and interaction style. A persona is also adaptive, since an agent may need to present different facets to different human interlocutors depending on the interaction.

Fortunately, neural models of conversation generation (Sordoni et al., 2015; Shang et al., 2015; Vinyals and Le, 2015; Li et al., 2016) provide a straightforward mechanism for incorporating personas as embeddings. We therefore explore two per-

* The entirety of this work was conducted at Microsoft.

[1](Vinyals and Le, 2015) suggest that the lack of a coherent personality makes it impossible for current systems to pass the Turing test.

sona models, a single-speaker SPEAKER MODEL and a dyadic SPEAKER-ADDRESSEE MODEL, within a sequence-to-sequence (SEQ2SEQ) framework (Sutskever et al., 2014). The Speaker Model integrates a speaker-level vector representation into the target part of the SEQ2SEQ model. Analogously, the Speaker-Addressee model encodes the interaction patterns of two interlocutors by constructing an interaction representation from their individual embeddings and incorporating it into the SEQ2SEQ model. These persona vectors are trained on human-human conversation data and used at test time to generate personalized responses. Our experiments on an open-domain corpus of Twitter conversations and dialog datasets comprising TV series scripts show that leveraging persona vectors can improve relative performance up to 20% in BLEU score and 12% in perplexity, with a commensurate gain in consistency as judged by human annotators.

2 Related Work

This work follows the line of investigation initiated by Ritter et al. (2011) who treat generation of conversational dialog as a statistical machine translation (SMT) problem. Ritter et al. (2011) represents a break with previous and contemporaneous dialog work that relies extensively on hand-coded rules, typically either building statistical models on top of heuristic rules or templates (Levin et al., 2000; Young et al., 2010; Walker et al., 2003; Pieraccini et al., 2009; Wang et al., 2011) or learning generation rules from a minimal set of authored rules or labels (Oh and Rudnicky, 2000; Ratnaparkhi, 2002; Banchs and Li, 2012; Ameixa et al., 2014; Nio et al., 2014; Chen et al., 2013). More recently (Wen et al., 2015) have used a Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) to learn from unaligned data in order to reduce the heuristic space of sentence planning and surface realization.

The SMT model proposed by Ritter et al., on the other hand, is end-to-end, purely data-driven, and contains no explicit model of dialog structure; the model learns to converse from human-to-human conversational corpora. Progress in SMT stemming from the use of neural language models (Sutskever et al., 2014; Gao et al., 2014; Bahdanau et al., 2015; Luong et al., 2015) has inspired efforts to extend these neural techniques to SMT-based conversational response generation. Sordoni et al. (2015) augments Ritter et al. (2011) by rescoring outputs using a SEQ2SEQ model conditioned on conversation history. Other researchers have recently used SEQ2SEQ to directly generate responses in an end-to-end fashion without relying on SMT phrase tables (Serban et al., 2015; Shang et al., 2015; Vinyals and Le, 2015). Serban et al. (2015) propose a hierarchical neural model aimed at capturing dependencies over an extended conversation history. Recent work by Li et al. (2016) measures mutual information between message and response in order to reduce the proportion of generic responses typical of SEQ2SEQ systems. Yao et al. (2015) employ an intention network to maintain the relevance of responses.

Modeling of users and speakers has been extensively studied within the standard dialog modeling framework (e.g., (Wahlster and Kobsa, 1989; Kobsa, 1990; Schatztnann et al., 2005; Lin and Walker, 2011)). Since generating meaningful responses in an open-domain scenario is intrinsically difficult in conventional dialog systems, existing models often focus on generalizing character style on the basis of qualitative statistical analysis (Walker et al., 2012; Walker et al., 2011). The present work, by contrast, is in the vein of the SEQ2SEQ models of Vinyals and Le (2015) and Li et al. (2016), enriching these models by training persona vectors directly from conversational data and relevant side-information, and incorporating these directly into the decoder.

3 Sequence-to-Sequence Models

Given a sequence of inputs $X = \{x_1, x_2, ..., x_{n_X}\}$, an LSTM associates each time step with an input gate, a memory gate and an output gate, respectively denoted as i_t, f_t and o_t. We distinguish e and h where e_t denotes the vector for an individual text unit (for example, a word or sentence) at time step t while h_t denotes the vector computed by the LSTM model at time t by combining e_t and h_{t-1}. c_t is the cell state vector at time t, and σ denotes the sigmoid function. Then, the vector representation h_t for each time step t is given by:

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ l_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} W \cdot \begin{bmatrix} h_{t-1} \\ e_t^s \end{bmatrix} \quad (1)$$

$$c_t = f_t \cdot c_{t-1} + i_t \cdot l_t \quad (2)$$

$$h_t^s = o_t \cdot \tanh(c_t) \quad (3)$$

where W_i, W_f, W_o, $W_l \in \mathbb{R}^{K \times 2K}$. In SEQ2SEQ generation tasks, each input X is paired with a sequence of outputs to predict: $Y = \{y_1, y_2, ..., y_{n_Y}\}$. The LSTM defines a distribution over outputs and sequentially predicts tokens using a softmax function:

$$p(Y|X) = \prod_{t=1}^{n_y} p(y_t|x_1, x_2, ..., x_t, y_1, y_2, ..., y_{t-1}) = \prod_{t=1}^{n_y} \frac{\exp(f(h_{t-1}, e_{y_t}))}{\sum_{y'} \exp(f(h_{t-1}, e_{y'}))}$$

where $f(h_{t-1}, e_{y_t})$ denotes the activation function between h_{t-1} and e_{y_t}. Each sentence terminates with a special end-of-sentence symbol *EOS*. In keeping with common practices, inputs and outputs use different LSTMs with separate parameters to capture different compositional patterns.

During decoding, the algorithm terminates when an *EOS* token is predicted. At each time step, either a greedy approach or beam search can be adopted for word prediction.

4 Personalized Response Generation

Our work introduces two persona-based models: the Speaker Model, which models the personality of the respondent, and the Speaker-Addressee Model which models the way the respondent adapts their speech to a given addressee — a linguistic phenomenon known as lexical entrainment (Deutsch and Pechmann, 1982).

4.1 Notation

For the response generation task, let M denote the input word sequence (message) $M = \{m_1, m_2, ..., m_I\}$. R denotes the word sequence in response to M, where $R = \{r_1, r_2, ..., r_J, \textit{EOS}\}$ and J is the length of the response (terminated by an *EOS* token). r_t denotes a word token that is associated with a K dimensional distinct word embedding e_t. V is the vocabulary size.

4.2 Speaker Model

Our first model is the Speaker Model, which models the respondent alone. This model represents each individual speaker as a vector or embedding, which encodes speaker-specific information (e.g., dialect, register, age, gender, personal information) that influences the content and style of her responses. Note that these attributes are not explicitly annotated, which would be tremendously expensive for our datasets. Instead, our model manages to cluster users along some of these traits (e.g., age, country of residence) based on the responses alone.

Figure 1 gives a brief illustration of the Speaker Model. Each speaker $i \in [1, N]$ is associated with a user-level representation $v_i \in \mathbb{R}^{K \times 1}$. As in standard SEQ2SEQ models, we first encode message S into a vector representation h_S using the source LSTM. Then for each step in the target side, hidden units are obtained by combining the representation produced by the target LSTM at the previous time step, the word representations at the current time step, and the speaker embedding v_i:

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ l_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} W \cdot \begin{bmatrix} h_{t-1} \\ e_t^s \\ v_i \end{bmatrix} \quad (4)$$

$$c_t = f_t \cdot c_{t-1} + i_t \cdot l_t \quad (5)$$

$$h_t^s = o_t \cdot \tanh(c_t) \quad (6)$$

where $W \in \mathbb{R}^{4K \times 3K}$. In this way, speaker information is encoded and injected into the hidden layer at each time step and thus helps predict personalized responses throughout the generation process. The Speaker embedding $\{v_i\}$ is shared across all conversations that involve speaker i. $\{v_i\}$ are learned by back propagating word prediction errors to each neural component during training.

Another useful property of this model is that it helps *infer* answers to questions even if the evidence is not readily present in the training set. This is important as the training data does not contain explicit information about every attribute of each user (e.g., gender, age, country of residence). The model learns speaker representations based on conversational content produced by different speakers, and speakers producing similar responses tend to have similar embeddings, occupying nearby positions in the vector space. This way, the training data of speakers nearby in vector space help increase the generalization capability of the speaker model. For example, consider two speakers i and j who sound distinctly British, and who are therefore close in speaker embedding space. Now, suppose that, in the training data, speaker i was asked *Where do you live?* and responded *in the UK*. Even if speaker j was never asked the same question, this answer can help influence a good response from speaker j, and this without explicitly labeled geo-location information.

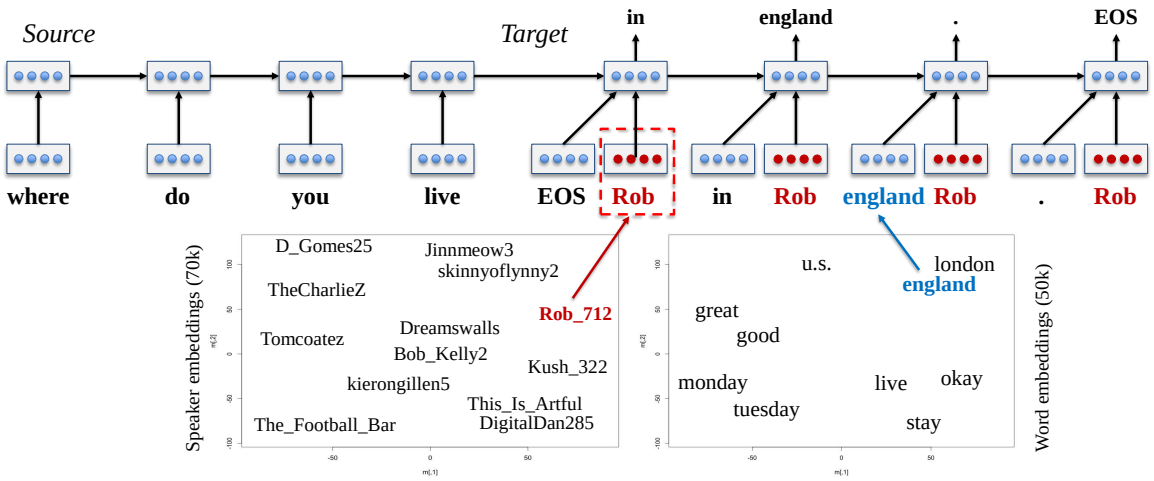

Figure 1: Illustrative example of the Speaker Model introduced in this work. Speaker IDs close in embedding space tend to respond in the same manner. These speaker embeddings are learned jointly with word embeddings and all other parameters of the neural model via backpropagation. In this example, say Rob is a speaker clustered with people who often mention England in the training data, then the generation of the token 'england' at time $t = 2$ would be much more likely than that of 'u.s.'. A non-persona model would prefer generating *in the u.s.* if 'u.s.' is more represented in the training data across all speakers.

4.3 Speaker-Addressee Model

A natural extension of the Speaker Model is a model that is sensitive to speaker-addressee interaction patterns within the conversation. Indeed, speaking style, register, and content does not vary only with the identity of the speaker, but also with that of the addressee. For example, in scripts for the TV series *Friends* used in some of our experiments, the character Ross often talks differently to his sister Monica than to Rachel, with whom he is engaged in an on-again off-again relationship throughout the series.

The proposed Speaker-Addressee Model operates as follows: We wish to predict how speaker i would respond to a message produced by speaker j. Similarly to the Speaker model, we associate each speaker with a K dimensional speaker-level representation, namely v_i for user i and v_j for user j. We obtain an interactive representation $V_{i,j} \in \mathbb{R}^{K\times 1}$ by linearly combining user vectors v_i and v_j in an attempt to model the interactive style of user i towards user j,

$$V_{i,j} = \tanh(W_1 \cdot v_i + W_2 \cdot v_2) \tag{7}$$

where $W_1, W_2 \in \mathbb{R}^{K\times K}$. $V_{i,j}$ is then linearly incorporated into LSTM models at each step in the target:

$$\begin{bmatrix} i_t \\ f_t \\ o_t \\ l_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} W \cdot \begin{bmatrix} h_{t-1} \\ e_t^s \\ V_{i,j} \end{bmatrix} \tag{8}$$

$$c_t = f_t \cdot c_{t-1} + i_t \cdot l_t \tag{9}$$

$$h_t^s = o_t \cdot \tanh(c_t) \tag{10}$$

$V_{i,j}$ depends on both speaker and addressee and the same speaker will thus respond differently to a message from different interlocutors. One potential issue with Speaker-Addressee modelling is the difficulty involved in collecting a large-scale training dataset in which each speaker is involved in conversation with a wide variety of people. Like the Speaker Model, however, the Speaker-Addressee Model derives generalization capabilities from speaker embeddings. Even if the two speakers at test time (i and j) were never involved in the same conversation in the training data, two speakers i' and j' who are respectively close in embeddings may have been, and this can help modelling how i should respond to j.

4.4 Decoding and Reranking

For decoding, the N-best lists are generated using the decoder with beam size $B = 200$. We set a maximum length of 20 for the generated candidates. Decoding operates as follows: At each time step, we first examine all $B \times B$ possible next-word candidates, and add all hypothesis ending with an *EOS* token to the N-best list. We then preserve the top-B unfinished hypotheses and move to the next word position.

To deal with the issue that SEQ2SEQ models tend to generate generic and commonplace responses such as *I don't know*, we follow Li et al. (2016) by reranking the generated N-best list using

a scoring function that linearly combines a length penalty and the log likelihood of the source given the target:

$$\log p(R|M, v) + \lambda \log p(M|R) + \gamma |R| \quad (11)$$

where $p(R|M, v)$ denotes the probability of the generated response given the message M and the respondent's speaker ID. $|R|$ denotes the length of the target and γ denotes the associated penalty weight. We optimize γ and λ on N-best lists of response candidates generated from the development set using MERT (Och, 2003) by optimizing BLEU. To compute $p(M|R)$, we train an inverse SEQ2SEQ model by swapping messages and responses. We trained standard SEQ2SEQ models for $p(M|R)$ with no speaker information considered.

5 Datasets

5.1 Twitter Persona Dataset

Data Collection Training data for the Speaker Model was extracted from the Twitter FireHose for the six-month period beginning January 1, 2012. We limited the sequences to those where the responders had engaged in at least 60 (and at most 300) 3-turn conversational interactions during the period, in other words, users who reasonably frequently engaged in conversation. This yielded a set of 74,003 users who took part in a minimum of 60 and a maximum of 164 conversational turns (average: 92.24, median: 90). The dataset extracted using responses by these "conversationalists" contained 24,725,711 3-turn sliding-window (context-message-response) conversational sequences.

In addition, we sampled 12000 3-turn conversations from the same user set from the Twitter FireHose for the three-month period beginning July 1, 2012, and set these aside as development, validation, and test sets (4000 conversational sequences each). Note that development, validation, and test sets for this data are single-reference, which is by design. Multiple reference responses would typically require acquiring responses from different people, which would confound different personas.

Training Protocols We trained four-layer SEQ2SEQ models on the Twitter corpus following the approach of (Sutskever et al., 2014). Details are as follows:

- 4 layer LSTM models with 1,000 hidden cells for each layer.
- Batch size is set to 128.
- Learning rate is set to 1.0.
- Parameters are initialized by sampling from the uniform distribution $[-0.1, 0.1]$.
- Gradients are clipped to avoid gradient explosion with a threshold of 5.
- Vocabulary size is limited to 50,000.
- Dropout rate is set to 0.2.

Source and target LSTMs use different sets of parameters. We ran 14 epochs, and training took roughly a month to finish on a Tesla K40 GPU machine.

As only speaker IDs of responses were specified when compiling the Twitter dataset, experiments on this dataset were limited to the Speaker Model.

5.2 Twitter Sordoni Dataset

The Twitter Persona Dataset was collected for this paper for experiments with speaker ID information. To obtain a point of comparison with prior state-of-the-art work (Sordoni et al., 2015; Li et al., 2016), we measure our baseline (non-persona) LSTM model against prior work on the dataset of (Sordoni et al., 2015), which we call the Twitter Sordoni Dataset. We only use its test-set portion, which contains responses for 2114 context and messages. It is important to note that the Sordoni dataset offers up to 10 references per message, while the Twitter Persona dataset has only 1 reference per message. Thus BLEU scores cannot be compared across the two Twitter datasets (BLEU scores on 10 references are generally much higher than with 1 reference). Details of this dataset are in (Sordoni et al., 2015).

5.3 Television Series Transcripts

Data Collection For the dyadic Speaker-Addressee Model we used scripts from the American television comedies *Friends*[2] and *The Big Bang Theory*,[3] available from Internet Movie Script Database (IMSDb).[4] We collected 13 main characters from the two series in a corpus of 69,565 turns. We split the corpus into training/development/testing sets, with development and testing sets each of about 2,000 turns.

Training Since the relatively small size of the dataset does not allow for training an open domain dialog model, we adopted a domain adaption strategy where we first trained a standard SEQ2SEQ

[2] https://en.wikipedia.org/wiki/Friends

[3] https://en.wikipedia.org/wiki/The_Big_Bang_Theory

[4] http://www.imsdb.com

System	BLEU
MT baseline (Ritter et al., 2011)	3.60%
Standard LSTM MMI (Li et al., 2016)	5.26%
Standard LSTM MMI (our system)	5.82%
Human	*6.08%*

Table 2: BLEU on the Twitter Sordoni dataset (10 references). We contrast our baseline against an SMT baseline (Ritter et al., 2011), and the best result (Li et al., 2016) on the established dataset of (Sordoni et al., 2015). The last result is for a human oracle, but it is not directly comparable as the oracle BLEU is computed in a leave-one-out fashion, having one less reference available. We nevertheless provide this result to give a sense that these BLEU scores of 5-6% are not unreasonable.

models using a much larger OpenSubtitles (OSDb) dataset (Tiedemann, 2009), and then adapting the pre-trained model to the TV series dataset.

The OSDb dataset is a large, noisy, open-domain dataset containing roughly 60M-70M scripted lines spoken by movie characters. This dataset does not specify which character speaks each subtitle line, which prevents us from inferring speaker turns. Following Vinyals et al. (2015), we make the simplifying assumption that each line of subtitle constitutes a full speaker turn.[5] We trained standard SEQ2SEQ models on OSDb dataset, following the protocols already described in Section 5.1. We run 10 iterations over the training set.

We initialize word embeddings and LSTM parameters in the Speaker Model and the Speaker-Addressee model using parameters learned from OpenSubtitles datasets. User embeddings are randomly initialized from $[-0.1, 0.1]$. We then ran 5 additional epochs until the perplexity on the development set stabilized.

6 Experiments

6.1 Evaluation

Following (Sordoni et al., 2015; Li et al., 2016) we used BLEU (Papineni et al., 2002) for parameter tuning and evaluation. BLEU has been shown to correlate well with human judgment on the response generation task, as demonstrated in (Galley et al., 2015). Besides BLEU scores, we also report perplexity as an indicator of model capability.

6.2 Baseline

Since our main experiments are with a new dataset (the Twitter Persona Dataset), we first show that our LSTM baseline is competitive with the state-of-the-art (Li et al., 2016) on an established dataset, the Twitter Sordoni Dataset (Sordoni et al., 2015). Our baseline is simply our implementation of the LSTM-MMI of (Li et al., 2016), so results should be relatively close to their reported results. Table 2 summarizes our results against prior work. We see that our system actually does better than (Li et al., 2016), and we attribute the improvement to a larger training corpus, the use of dropout during training, and possibly to the "conversationalist" nature of our corpus.

[5]This introduces a degree of noise as consecutive lines are not necessarily from the same scene or two different speakers.

Model	Standard LSTM	Speaker Model
Perplexity	47.2	42.2 (-10.6%)

Table 3: Perplexity for standard SEQ2SEQ and the Speaker model on the Twitter Persona development set.

Model	Objective	BLEU
Standard LSTM	MLE	0.92%
Speaker Model	MLE	1.12% (+21.7%)
Standard LSTM	MMI	1.41%
Speaker Model	MMI	1.66% (+11.7%)

Table 4: BLEU on the Twitter Persona dataset (1 reference), for the standard SEQ2SEQ model and the Speaker model using as objective either maximum likelihood (MLE) or maximum mutual information (MMI).

6.3 Results

We first report performance on the Twitter Persona dataset. Perplexity is reported in Table 3. We observe about a 10% decrease in perplexity for the Speaker model over the standard SEQ2SEQ model. In terms of BLEU scores (Table 4), a significant performance boost is observed for the Speaker model over the standard SEQ2SEQ model, yielding an increase of 21% in the maximum likelihood (MLE) setting and 11.7% for mutual information setting (MMI). In line with findings in (Li et al., 2016), we observe a consistent performance boost introduced by the MMI objective function over a standard SEQ2SEQ model based on the MLE objective function. It is worth noting that our persona models are more beneficial to the MLE models than to the MMI models. This result is intuitive as the persona models help make Standard LSTM MLE outputs more informative and less bland, and thus make the use of MMI less critical.

For the TV Series dataset, perplexity and BLEU scores are respectively reported in Table 5 and Table 6. As can be seen, the Speaker and Speaker-Addressee models respectively achieve perplexity values of 25.4 and 25.0 on the TV-series dataset,

Model	Standard LSTM	Speaker Model	Speaker-Addressee Model
Perplexity	27.3	25.4 (−7.0%)	25.0 (−8.4%)

Table 5: Perplexity for standard SEQ2SEQ and persona models on the TV series dataset.

Model	Standard LSTM	Speaker Model	Speaker-Addressee Model
MLE	1.60%	1.82% (+13.7%)	1.83% (+14.3%)
MMI	1.70%	1.90% (+10.6%)	1.88% (+10.9%)

Table 6: BLEU on the TV series dataset (1 reference), for the standard SEQ2SEQ and persona models.

7.0% and 8.4% percent lower than the correspondent standard SEQ2SEQ models. In terms of BLEU score, we observe a similar performance boost as on the Twitter dataset, in which the Speaker model and the Speaker-Addressee model outperform the standard SEQ2SEQ model by 13.7% and 10.6%. By comparing the Speaker-Addressee model against the Speaker model on the TV Series dataset, we do not observe a significant difference. We suspect that this is primarily due to the relatively small size of the dataset where the interactive patterns might not be fully captured. Smaller values of perplexity are observed for the Television Series dataset than the Twitter dataset, the perplexity of which is over 40, presumably due to the noisier nature of Twitter dialogues.

6.4 Qualitative Analysis

Diverse Responses by Different Speakers Table 7 represents responses generated by persona models in response to three different input questions. We randomly selected 10 speakers (without cherry-picking) from the original Twitter dataset. We collected their user level representations from a speaker look-up table and integrated them into the decoding models. The model tends to generate specific responses for different people in response to the factual questions.[6]

Table 8 shows responses generated from the *Speaker-Addressee Model* using the TV-series dataset. Interestingly, we regularly observe that this model is sensitive to the identity of the addressee, generating words specifically targeted at that addressee (e.g., her name). For example, the model produces *Of course, I love you, Emily* in response to an input from *Emily*. Also, the model generates *Of course I love you. (kisses him)*, where the pronoun "him" accurately identifies the gender of the addressee.

[6]There appears to be a population bias in the training set that favors British users.

message	Where is your hometown?
baseline	I was born in Canada.
user1	I'm from England.
user2	I'm from Manchester.
user3	I'm from Liverpool.
user4	England. You?

Table 7: Responses generated by the baseline (LSTM-MMI) and the Speaker Model for ten randomly selected users, without cherry picking. # indicates poor-quality responses produced by the system.

Human Evaluation We conducted a human evaluation of outputs from the Speaker Model, using a crowdsourcing service. Since we cannot expect crowdsourced human judges to know or attempt to learn the ground truth of Twitter users who are not well-known public figures, we designed our experiment to evaluate the consistency of outputs associated with the speaker IDs. To this end, we collected 24 pairs of questions for which we would expect

message	Do you love me?
baseline	Of course, I love you.
	addressee: Emily, speaker: Sheldon
response	Of course, I love you, Emily.
	addressee: Emily, speaker: Penny
response	Of course, I love you, Emily.
	addressee: Leonard, speaker: Penny
response	Of course, I love you, Leonard.
	addressee: Monica, speaker: Chandler
response	Of course I love you. I want to marry you.
	addressee: Rachel, speaker: Chandler
response	Of course I love you.
	addressee: Ross, speaker: Chandler
response	Of course I love you.
	addressee: Ross, speaker: Rachel
response	Of course I love you. (kisses him)
	addressee: Emily, speaker: Rachel
response	Of course I love you.

Table 8: Responses to *Do you love me?* from the *Speaker-Addressee* model on the TV-series dataset using different addressees and speakers.

responses to be consistent if the persona model is coherent. For example, responses to the questions *What country do you live in?* and *What city do you live in?* would be considered consistent if the answers were *England* and *London* respectively, but not if they were *UK* and *Chicago*. Similarly, the responses to *Are you vegan or vegetarian?* and *Do you eat beef?* are consistent if the answers generated are *vegan* and *absolutely not*, but not if they are *vegan* and *I love beef*. We collected 20 pairs of outputs for randomly-selected personas provided by the Speaker Model for each question pair (480 response pairs total). We also obtained the corresponding outputs from the baseline MMI-enhanced SEQ2SEQ system.

Since our purpose is to measure the gain in consistency over the baseline system, we presented the pairs of answers system-pairwise, i.e., 4 responses, 2 from each system, displayed on the screen, and asked judges to decide which of the two systems was more consistent. The position in which the system pairs were presented on the screen was randomized. The two systems were judged on 5-point zero-sum scale, assigning a score of 2 (-2) if one system was judged more (less) consistent than the other, and 1 (-1) if one was rated "somewhat" more (less) consistent. Ties were assigned a score of zero. Five judges rated each pair and their scores were averaged and remapped into 5 equal-width bins. After discarding ties, we found the persona model was judged either "more consistent" or "somewhat more consistent" in 56.7% of cases. If we ignore the "somewhat more consistent" judgments, the persona model wins in 6.1% of cases, compared with only 1.6% for the baseline model. It should be emphasized that the baseline model is a strong baseline, since it represents the consensus of all 70K Twitter users in the dataset[7].

response	I'm 16.

Table 9: Examples of speaker consistency and inconsistency generated by the Speaker Model

Table 9 illustrates how consistency is an emergent property of two arbitrarily selected users. The model is capable of discovering the relations between different categories of location such as London and the UK, Jakarta and Indonesia. However, the model also makes inconsistent response decisions, generating different answers in the second example in response to questions asking about age or major. Our proposed persona models integrate user embeddings into the LSTM, and thus can be viewed as encapsulating a trade-off between a persona-specific generation model and a general conversational model.

[7] *I'm not pregnant* is an excellent consensus answer to the question *Are you pregnant?*, while *I'm pregnant* is consistent as a response only in the case of someone who also answers the question *Are you a guy or a girl?* with something in the vein of *I'm a girl*.

7 Conclusions

We have presented two persona-based response generation models for open-domain conversation generation. There are many other dimensions of speaker behavior, such as mood and emotion, that are beyond the scope of the current paper and must be left to future work.

Although the gains presented by our new models are not spectacular, the systems outperform our baseline SEQ2SEQ systems in terms of BLEU, perplexity, and human judgments of speaker consistency. We have demonstrated that by encoding personas in distributed representations, we are able to capture personal characteristics such as speaking style and background information. In the Speaker-Addressee model, moreover, the evidence suggests that there is benefit in capturing dyadic interactions.

Our ultimate goal is to be able to take the profile of an arbitrary individual whose identity is not known in advance, and generate conversations that accurately emulate that individual's persona in terms of linguistic response behavior and other salient characteristics. Such a capability will dramatically change the ways in which we interact with dialog agents of all kinds, opening up rich new possibilities for user interfaces. Given a sufficiently large training corpus in which a sufficiently rich variety of speakers is represented, this objective does not seem too far-fetched.

Abstract

Deep Random Walk (DeepWalk) can learn a latent space representation for describing the topological structure of a network. However, for relational network classification, DeepWalk can be suboptimal as it lacks a mechanism to optimize the objective of the target task. In this paper, we present Discriminative Deep Random Walk (DDRW), a novel method for relational network classification. By solving a joint optimization problem, DDRW can learn the latent space representations that well capture the topological structure and meanwhile are discriminative for the network classification task. Our experimental results on several real social networks demonstrate that DDRW significantly outperforms DeepWalk on multi-label network classification tasks, while retaining the topological structure in the latent space. DDRW is stable and consistently outperforms the baseline methods by various percentages of labeled data. DDRW is also an online method that is scalable and can be naturally parallelized.

1 Introduction

Categorization is an important task in natural language processing, especially with the growing scale of documents in the Internet. As the documents are often not isolated, a large amount of the linguistic materials present a network structure such as citation, hyperlink and social networks. The large size of networks calls for scalable machine learning methods to analyze such data. Recent efforts have been made in developing statistical models for various network analysis tasks, such as network classification (Neville and Jensen, 2000), content recommendation (Fouss et al., 2007), link prediction (Adamic and Adar, 2003), and anomaly detection (Savage et al., 2014). One common challenge of statistical network models is to deal with the sparsity of networks, which may prevent a model from generalizing well.

One effective strategy to deal with network sparsity is to learn a latent space representation for the entities in a network (Hoff et al., 2002; Zhu, 2012; Tang and Liu, 2011; Tang et al., 2015). Among various approaches, DeepWalk (Perozzi et al., 2014) is a recent method that embeds all the entities into a continuous vector space using deep learning methods. DeepWalk captures entity features like neighborhood similarity and represents them by Euclidean distances (See Figure 1(b)). Furthermore, since entities that have closer relationships are more likely to share the same hobbies or belong to the same groups, such an embedding by DeepWalk can be useful for network classification, where the topological information is explored to encourage a globally consistent labeling.

Although DeepWalk is effective on learning embeddings of the topological structure, when dealing with a network classification task, it lacks a mechanism to optimize the objective of the target task and thus often leads to suboptimal embeddings. In particular, for our focus of relational network classification, we would like the embeddings to be both representing the topological structure of the network actors and discriminative in predicting the class labels of actors.

To address the above issues, we present Discriminative Deep Random Walk (DDRW) for relational network classification. DDRW extends DeepWalk by jointly optimizing the classification objective and the objective of embedding entities in a latent space that maintains the topological structure. Under this joint learning framework, DDRM manages to learn the latent representations

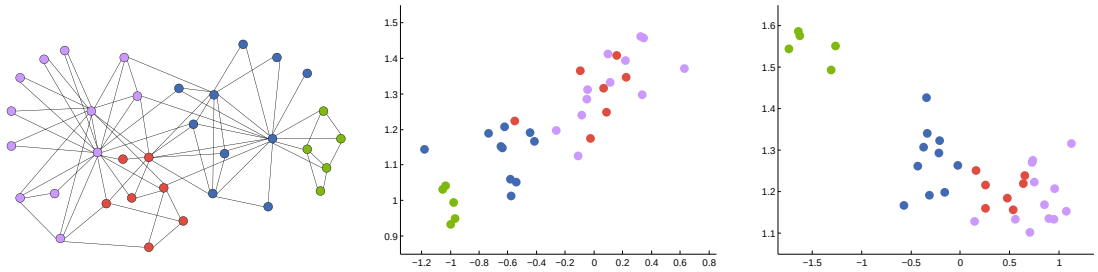
Berlin, Germany, August 7-12, 2016.



(a) Karate Graph (b) DeepWalk Embedding (c) DDRW Embedding

Figure 1: Different experimental results of embedding a network into a two dimensional real space. We use Karate Graph (Macskassy and Provost, 1977) for this example. Four different colors stand for the classes of the vertices. In (b), vertices which have stronger relations in the network are more likely to be closer in the embedding latent space. While in (c), besides the above-mentioned property, DDRW makes vertices in different classes more separated.

that are strongly associated with the class labels (See Figure 1(c)), making it easy to find a separating boundary between the classes, and the actors that are connected in the original network are still close to each other in the latent social space. This idea of combining task-specific and representation objectives has been widely explored in other regions such as MedLDA (Zhu et al., 2012) and Supervised Dictionary Learning (Mairal et al., 2009).

Technically, to capture the topological structure, we follow the similar idea of DeepWalk by running truncated random walks on the original network to extract sequences of actors, and then building a language model (i.e., Word2Vec (Mikolov et al., 2013b)) to project the actors into a latent space. To incorporate the supervising signal in network classification, we build a classifier based on the latent space representations. By sharing the same latent social space, the two objectives are strongly coupled and the latent social space is guided by both the network topology and class labels. DDRW optimizes the joint objective by using stochastic gradient descent, which is scalable and embarrassingly parallizable.

We evaluate the performance on several real-world social networks, including BlogCatalog, Flickr and YouTube. Our results demonstrate that DDRW significantly boosts the classification accuracy of DeepWalk in multi-label network classification tasks, while still retaining the topological structure in the learnt latent social space. We also show that DDRW is stable and consistently outperforms the baseline methods by various percentages of labeled data. Although the networks we use only bring topological information for clarity, DDRW is flexible to consider additional attributes (if any) of vertices. For example, DDRW can be naturally extended to classify documents/webpages, which are often represented as a network (e.g., citation/hyperlink network), by conjoining with a word2vec component to embed the documents/webpages into the same latent space, similar as previous work on extending DeepWalk to incorporate attributes (Yang et al., 2015).

2 Problem Definition

We consider the network classification problem, which classifies entities from a given network into one or more categories from a set $\mathcal{Y}$. Let $G = (V, E, Y)$ denote a network, where V is the set of vertices, representing the entities of the network; $E \subseteq (V \times V)$ is the set of edges, representing the relations between the entities; and $Y \subseteq \mathbb{R}^{|V|\times|\mathcal{Y}|}$ denotes the labels of entities. We also consider Y_U as a set of unknown labels in the same graph G. The target of the classification task is to learn a model from labeled data and generate a label set Y_P to be the prediction of Y_U. The difference between Y_P and Y_U indicates the classification quality.

When classifying elements $X \in \mathbb{R}^n$, traditional machine learning methods learn a weight matrix H to minimize the difference between $Y_P = \mathcal{F}(X, H)$ and Y_U, where $\mathcal{F}$ is any known fixed function. In network aspect, we will be able to utilize well-developed machine learning methods if adequate information of G is embedded into a corresponding form as X. By this motivation, relational learning (Getoor and Taskar, 2007; Neville and Jensen, 2000) methods are pop-

ularly employed. In network classification, the internal structure of a network is resolved to extract the neighboring features of the entities (Macskassy and Provost, 2007; Wang and Sukthankar, 2013). Accordingly, the core problem is how to describe the irregular networks within formal feature spaces. A variety of approaches have been proposed with the purpose of finding effective statistical information through the network (Gallagher and Eliassi-Rad, 2008; Henderson et al., 2011; Tang and Liu, 2011).

DeepWalk (Perozzi et al., 2014) is an outstanding method for network embedding, which uses truncated random walks to capture the explicit structure of the network and applies language models to learn the latent relationships between the actors. When applied to the network classification task, DeepWalk first learns X which describes the topological structure of G and then learns a subsequent classifier H. One obvious shortcoming of this two-step procedure is that the embedding step is unaware of the target class label information and likely to learn embeddings that are suboptimal for classification.

We present Discriminative Deep Random Walk (DDRW) to enhance the effect of DeepWalk by learning $X \in \mathbb{R}^{|V|\times d}$ and $H \in \mathbb{R}^{d\times|\mathcal{Y}|}$ jointly. By using topological and label information of a certain network simultaneously, we will show that DDRW improves the classification accuracy significantly compared with most recent related methods. Furthermore, we will also show that the embedded result X produced by DDRW is able to retain the structure of G well.

3 Discriminative Deep Random Walk

In this section, we present the details of Discriminative Deep Random Walk (DDRW). DDRW has both embedding and classification objectives. We optimize the two objectives jointly to learn latent representations that are strongly associated with the class labels in the latent space. We use stochastic gradient descent (Mikolov et al., 1991) as our optimization method.

3.1 Embedding Objective

Let $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \ldots, \boldsymbol{\theta}_{|V|})$ denote the embedded vectors in the latent space, and $\boldsymbol{\alpha}$ denote the topological structure of the graph. The embedding objective can be described as an optimization problem as follows:

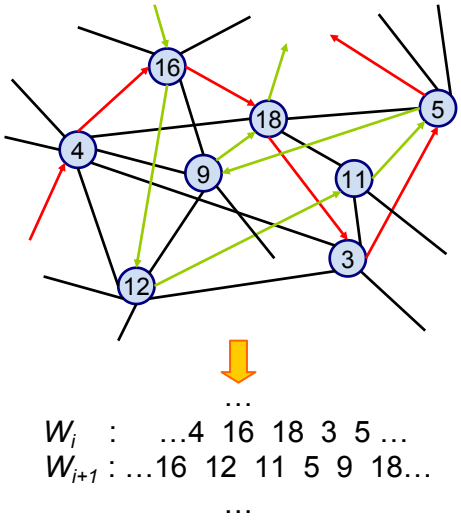


Figure 2: A part of Random Walk process in an undirected graph. Every time an adjacent vertex is chosen randomly (no matter visited or not) as the arrows indicate, until reaching the maximum length s.

$$\min_{\boldsymbol{\theta}} \ \mathcal{L}_r(\boldsymbol{\theta}, \boldsymbol{\alpha}), \tag{1}$$

where $\mathcal{L}_r$ indicates the difference between the embedded representations $\boldsymbol{\theta}$ and original topological structure $\boldsymbol{\alpha}$. For this objective, we use truncated random walks to capture the topological structure of the graph and the language model Word2Vec (Mikolov et al., 2013b) to learn the latent representations. Below, we explain each in turn.

3.1.1 Random Walk

Random Walk has been used in different regions in network analysis to capture the topological structure of graphs (Fouss et al., 2007; Andersen et al., 2006). As the name suggests, Random Walk chooses a certain vertex in the graph for the first step and then randomly migrates through the edges. Truncated random walk defines a maximum length s for all walk streams.

In our implementation, we shuffle the whole vertices V in the graph for τ times to build the sample set W. After each time of shuffling, we take the permutation list of vertices as the starting points of walks. Every time a walk stream starts at one element in order, randomly chooses an adjacent vertex to move, and ends when this stream reaches s vertices. By this procedure we get totally

$\tau|V|$ samples (i.e. walk streams) from the graph. Thus our sample set $W \in \mathbb{R}^{\tau|V| \times s}$ is obtained as the training materials.

3.1.2 Word2Vec

Existing work has shown that both the vertices in truncated random walks and the words in text articles follow similar power-law distributions in frequency, and then the idea of reshaping a social network into a form of corpus is very straightforward (Perozzi et al., 2014). Corresponding to linguistic analysis region, the objective is to find an embedding for a corpus to show the latent significances between the words. Words which have closer meanings are more likely to be embedded into near positions. Word2Vec (Mikolov et al., 2013b) is an appropriate tool for this problem. We use the Skip-gram (Mikolov et al., 2013a) strategy in Word2Vec, which uses the central word in a sliding window with radius R to predict other words in the window and make local optimizations. Specifically, let $\boldsymbol{\omega} = rw(\boldsymbol{\alpha})$ denote the full walk streams obtained from truncated random walks in Section 3.1.1. Then by Skip-gram we can get the objective function

$$\mathcal{L}_r(\boldsymbol{\theta}, \boldsymbol{\alpha}) = -\sum_{i=1}^{\tau} \frac{1}{s} \sum_{t=1}^{s} \sum_{-R \le j \le R, j \neq 0} \log p(\boldsymbol{\omega}_{i,t+j} | \boldsymbol{\omega}_{i,j}). \tag{2}$$

The standard Skip-gram method defines $p(\boldsymbol{\omega}_{i,t+j}|\boldsymbol{\omega}_{i,j})$ in Eq.(2) as follows:

$$p(\boldsymbol{\omega}_O|\boldsymbol{\omega}_I) = \frac{\exp(\boldsymbol{\theta}_{\boldsymbol{\omega}_O}^T \hat{\boldsymbol{\theta}}_{\boldsymbol{\omega}_I})}{\sum_{i=1}^{|V|} \exp(\boldsymbol{\theta}_i^T \hat{\boldsymbol{\theta}}_{\boldsymbol{\omega}_I})}, \tag{3}$$

where $\hat{\boldsymbol{\theta}}_i$ and $\boldsymbol{\theta}_i$ are the input and output representations of the ith vertex, respectively.

One shortcoming of the standard form is that the summation in Eq.(3) is very inefficient. To reduce the time consumption, we use the Hierarchical Softmax (Mnih and Hinton, 2009; Morin and Bengio, 2005) which is included in Word2Vec packages*. In Hierarchical Softmax, the Huffman binary tree is employed as an alternative representation for the vocabulary. The gradient descent step will be faster thanks to the Huffman tree structure which allows a reduction of output units necessarily evaluated.

*https://code.google.com/archive/p/word2vec/

3.2 Classification Objective

Let $\boldsymbol{y} = (\boldsymbol{y}_1, \boldsymbol{y}_2, \ldots, \boldsymbol{y}_{|V|})$ denote the labels, and $\boldsymbol{\beta}$ denote the subsequent classifier. The classification objective can be described as an optimization problem:

$$\min_{\boldsymbol{\theta}, \boldsymbol{\beta}} \ \mathcal{L}_c(\boldsymbol{\theta}, \boldsymbol{\beta}, \boldsymbol{y}). \tag{4}$$

In DDRW, we use existing classifiers and do not attempt to extend them. Although SVM^{multicalss} (Crammer and Singer, 2002) often shows good performance in multi-class tasks empirically, we choose the classifier being referred to as L2-regularized and L2-loss Support Vector Classification (Fan et al., 2008) to keep pace with the baseline methods to be mentioned in Section 4.

In L2-regularized and L2-loss SVC, the loss function is

$$\begin{aligned} &\mathcal{L}_c(\boldsymbol{\theta}, \boldsymbol{\beta}, \boldsymbol{y}) \\ =&C \sum_{i=1}^{|V|} (\sigma(1 - \boldsymbol{y}_i \boldsymbol{\beta}^T \boldsymbol{\theta}_i))^2 + \frac{1}{2} \boldsymbol{\beta}^T \boldsymbol{\beta}, \end{aligned} \tag{5}$$

where C is the regularization parameter, $\sigma(x) = x$ if $x > 0$ and $\sigma(x) = 0$ otherwise. Eq.(5) is for binary classification problems, and is extended to multi-class problems following the *one-against-rest* strategy (Fan et al., 2008).

3.3 Joint Learning

The main target of our method is to classify the unlabeled vertices in the given network. We achieve this target with the help of intermediate embeddings which latently represent the network structure. We simultaneously optimize two objectives in Section 3.1 and 3.2. Specifically, let $\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\beta}, \boldsymbol{\alpha}, \boldsymbol{y}) = \eta \mathcal{L}_r(\boldsymbol{\theta}, \boldsymbol{\alpha}) + \mathcal{L}_c(\boldsymbol{\theta}, \boldsymbol{\beta}, \boldsymbol{y})$, where η is a key parameter that balances the weights of the two objectives. We solve the joint optimization problem:

$$\min_{\boldsymbol{\theta}, \boldsymbol{\beta}} \ \mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\beta}, \boldsymbol{\alpha}, \boldsymbol{y}). \tag{6}$$

We use stochastic gradient descent (Mikolov et al., 1991) to solve the optimization problem in Eq.(6). In each gradient descent step, we have

$$\begin{aligned} \boldsymbol{\theta} &\leftarrow \boldsymbol{\theta} - \delta \frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}} = \boldsymbol{\theta} - \delta(\eta \frac{\partial \mathcal{L}_r}{\partial \boldsymbol{\theta}} + \frac{\partial \mathcal{L}_c}{\partial \boldsymbol{\theta}}), \\ \boldsymbol{\beta} &\leftarrow \boldsymbol{\beta} - \delta \frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \boldsymbol{\beta} - \delta \frac{\partial \mathcal{L}_c}{\partial \boldsymbol{\beta}}, \end{aligned} \tag{7}$$

where δ is the learning rate for stochastic gradient descent. In our implementation, δ is initially set to

0.025 and linearly decreased with the steps, same as the default setting of Word2Vec. The derivatives in Eq.(7) are estimated by local slopes.

In Eq.(7), the latent representations adjust themselves according to both topological information ($\partial\mathcal{L}_r/\partial\boldsymbol{\theta}$) and label information ($\partial\mathcal{L}_c/\partial\boldsymbol{\theta}$). This process intuitively makes vertices in the same class closer and those in different classes farther, and this is also proved by experiments (See Figure 1). Thus by joint learning, DDRW can learn the latent space representations that well capture the topological structure and meanwhile are discriminative for the network classification task.

We take each sample W_i from walk streams W to estimate the local derivatives of the loss function for a descent step. Stochastic gradient descent enables DDRW to be an online algorithm, and thus our method is easy to be parallelized. Besides, a vertex may repeatedly appear for numerous times in W produced by random walks. This repeat is superfluous for classifiers and there is a considerable possibility to arise overfitting. Inspired from DropOut (Hinton et al., 2012) ideas, we randomly ignore the label information to control the optimization process in an equilibrium state.

4 Experimental Setup

In this section we present an overview of the datasets and baseline methods which we will compare with in the experiments.

4.1 Datasets

We use three popular social networks, which are exactly same with those used in some of the baseline methods. Table 1 summarizes the statistics of the data.

- **BlogCatalog**: a network of social relationships provided by blog authors. The labels of this graph are the topics specified by the uploading users.
- **Flickr**: a network of the contacts between users of the Flickr photo sharing website. The labels of this graph represent the interests of users towards certain categories of photos.
- **YouTube**: a network between users of the Youtube video sharing website. The labels stand for the groups of the users interested in different types of videos.

Dataset	BlogCatalog	Flickr	YouTube
Actors $\|V\|$	10,312	80,513	1,138,499
Links $\|E\|$	333,983	5,899,882	2,990,443
Labels $\|\mathcal{Y}\|$	29	195	47
Sparsity	6.3×10^{-3}	1.8×10^{-3}	4.6×10^{-6}
Max Degree	3,992	5,706	28,754
Average Degree	65	146	5

Table 1: Statistics of the three networks. Sparsity indicates the ratio of the actual links and links in a complete graph.

4.2 Baseline Methods

We evaluate our proposed method by comparing it with some significantly related methods.

- **LINE** (Tang et al., 2015)[†]: This method takes the edges of a graph as samples to train the *first-order* and *second-order* proximity seprately and integrate the results as an embedding of the graph. This method can handle both graphs with unweighted and weighted and is especially efficient in large networks.
- **DeepWalk** (Perozzi et al., 2014): This method employs language models to learn latent relations between the vertices in the graph. The basic assumption is that the closer two vertices are in the embedding space, the deeper relationships they have and there is higher possibility that they are in the same categories.
- **SpectralClustering** (Tang and Liu, 2011): This method finds out that graph cuts are useful for the classification task. This idea is implemented by finding the eigenvectors of a normalized graph Laplacian of the original graph.
- **EdgeCluster** (Tang and Liu, 2009b): This method uses k-means clustering algorithm to segment the edges of the graph into pieces. Then it runs iterations on the small clusters to find the internal relationships separately. The core idea is to scale time-consuming work into tractable sizes.
- **Majority**: This baseline method simply chooses the most frequent labels. It does not use any structural information of the graph.

[†]Although LINE also uses networks from Flickr and YouTube in its experiments, the networks are different from this paper.

As the datasets are not only multi-class but also multi-label, we usually need a thresholding method to test the results. But literature gives a negative opinion of arbitrarily choosing thresholding methods because of the considerably different performances. To avoid this, we assume that the number of the labels is already known in all the test processes.

5 Experiments

In this section, we present the experimental results and analysis on both network classification and latent space learning. We thoroughly evaluate the performance on the three networks and analyze the sensitivity to key parameters.

5.1 Classification Task

We first represent the results on multi-class classification and compare with the baseline methods. To have a direct and fair comparison, we use the same data sets, experiment procedures and testing points as in the reports of our relevant baselines (Perozzi et al., 2014; Tang and Liu, 2011; Tang and Liu, 2009b). The training set of a specified graph consists of the vertices, the edges and the labels of a certain percentage of labeled vertices. The testing set consists of the rest of the labels. We employ Macro-F_1 and Micro-F_1 (Yang, 1999) as our measurements. Micro-F_1 computes F_1 score globally while Macro-F_1 caculates F_1 score locally and then average them globally. All the results reported are averaged from 10 repeated processes.

5.1.1 BlogCatalog

BlogCatalog is the smallest dataset among the three. In BlogCatalog we vary the percentage of labeled data from 10% to 90%. Our results are presented in Table 2. We can see that DDRW performs consistently better than all the baselines on both Macro-F_1 and Micro-F_1 with the increasing percentage of labeled data. When compared with DeepWalk, DDRW obtains larger improvement when the percentage of labeled nodes is high. This improvement demonstrates the significance of DDRW on learning discriminative latent embeddings that are good for classification tasks.

5.1.2 Flickr

Flickr is a larger dataset with quite a number of classes. In this experiment we vary the percentage of labeled data from 1% to 10%. Our results are presented in Table 3. We can see that DDRW still performs better than the baselines significantly on both Macro-F_1 and Micro-F_1, and the results are consistent with what in BlogCatalog.

5.1.3 YouTube

YouTube is an even larger dataset with fewer classes than Flickr. In YouTube we vary the percentage of labeled data from 1% to 10%. Our results are presented in Table 4. In YouTube, LINE shows its strength in large sparse networks, probably because the larger scale of samples reduces the discrepancy from actual distributions. But from a general view, DDRW still performs better at most of the test points thanks to the latent representations when links are not sufficient.

5.2 Parameter Sensitivity

We now present an analysis of the sensitivity with respect to several important parameters. We measure our method with changing parameters to evaluate its stability. Despite the parameters which are unilateral to classification performance, the two main bidirectional parameters are η and the dimension d of embedding space in different percentages of labeled data. We use BlogCatalog and Flickr networks for the experiments, and fix parameters of random walks ($\tau = 30, s = 40, R = 10$). We do not represent the effects of changing parameters of random walks because results usually show unilateral relationships with them.

5.2.1 Effect of η

The key parameter η in our algorithm adjusts the weights of two objectives (Section 3.3). We represent the effect of changing η in Figure 3(a) and 3(b). We fix $d = 128$ in these experiments. Although rapid gliding can be observed on either sides, there are still sufficient value range where DDRW keeps the good performance. These experiments also show that η is not very sensitive towards the percentage of labeled data.

5.2.2 Effect of Dimensionality

We represent the effect of changing dimension d of the embedding space in Figure 3(c) and 3(d). We fix $\eta = 1.0$ in these experiments. There is decline when the dimension is high, but this decrease is not very sharp. Besides, when the dimension is high, the percentage of labeled data has more effect on the performance.

5.3 Representation Efficiency

Finally, we examine the quality of the latent embeddings of entities discovered by DDRW. For network data, our major expectation is that the embedded social space should maintain the topological structure of the network. A visualization of the topological structure in a social space is showed in Figure 1. Besides, we examine the neighborhood structure of the vertices. Specifically, we check the top-K nearest vertices for each vertex in the embedded social space and calculate how many of the vertex pairs have edges between them in the observed network. We call this Adjacency Predict Accuracy. Table 5 shows the results, where DDRW with different percentages of labeled data, DeepWalk and Random are compared in BlogCatalog dataset. The baseline method Random maps all the vertices equably randomly into a fixed-size space. The experiments show that although DeepWalk outperforms on the whole, the performance of DDRW is approximate. DDRW is proved to inherit some important properties in latent representations of the network.

6 Related Work

Relational classification (Geman and Geman, 1984; Neville and Jensen, 2000; Getoor and Taskar, 2007) is a class of methods which involve the data item relation links during classification. A number of researchers have studied different methods for network relational learning. (Macskassy and Provost, 2003) present a simple weighted vote relational neighborhood classifier. (Xu et al., 2008) leverage the nonparametric infinite hidden relational model to analyze social networks. (Neville and Jensen, 2005) propose a latent group model for relational data, which discovers and exploits the hidden structures responsible for the observed autocorrelation among class labels. (Tang and Liu, 2009a) propose the latent social dimensions which are represented as continuous values and allow each node to involve at different dimensions in a flexible manner. (Gallagher et al., 2008) propose a method that learn sparsely labeled network data by adding ghost edges between neighbor vertices, and (Lin and Cohen, 2010) by using PageRank. (Wang and Sukthankar, 2013) extend the conventional relational classification to consider more additional features. (Gallagher and Eliassi-Rad, 2008) propose a complimentary approach to within-network classification based on the use of label-independent features. (Henderson et al., 2011) propose a regional feature generating method and demonstrate the usage of the regional feature in within-network and across-network classification. (Tang and Liu, 2009b) propose an edge-centric clustering scheme to extract sparse social dimensions for collective behavior prediction. (Tang and Liu, 2011) propose the concept of social dimensions to represent the latent affiliations of the entities. (Vishwanathan et al., 2010) propose Graph Kernels to use relational data during classification process and (Kang et al., 2012) propose a faster approximated method of Graph Kernels.

7 Conclusion

This paper presents Discriminative Deep Random Walk (DDRW), a novel approach for relational multi-class classification on social networks. By simultaneously optimizing embedding and classification objectives, DDRW gains significantly better performances in network classification tasks

than baseline methods. Experiments on different real-world datasets represent adequate stability of DDRW. Furthermore, the representations produced by DDRW is both an intermediate variable and a by-product. Same as other embedding methods like DeepWalk, DDRW can provide well-formed inputs for statistical analyses other than classification tasks. DDRW is also naturally an online algorithm and thus easy to parallel.

The future work has two main directions. One is semi-supervised learning. The low proportion of labeled vertices is a good platform for semi-supervised learning. Although DDRW has already combined supervised and unsupervised learning together, better performance can be expected after introducing well-developed methods. The other direction is to promote the random walk step. Literature has represented the good combination of random walk and language models, but this combination may be unsatisfactory for classification. It would be great if a better form of random walk is found.

Abstract

Automatically recognising medical concepts mentioned in social media messages (e.g. tweets) enables several applications for enhancing health quality of people in a community, e.g. real-time monitoring of infectious diseases in population. However, the discrepancy between the type of language used in social media and medical ontologies poses a major challenge. Existing studies deal with this challenge by employing techniques, such as lexical term matching and statistical machine translation. In this work, we handle the medical concept normalisation at the semantic level. We investigate the use of neural networks to learn the transition between layman's language used in social media messages and formal medical language used in the descriptions of medical concepts in a standard ontology. We evaluate our approaches using three different datasets, where social media texts are extracted from Twitter messages and blog posts. Our experimental results show that our proposed approaches significantly and consistently outperform existing effective baselines, which achieved state-of-the-art performance on several medical concept normalisation tasks, by up to 44%.

1 Introduction

Existing studies (O'Connor et al., 2014; Limsopatham and Collier, 2015a; Limsopatham and Collier, 2015b) have shown that data from social media (e.g. Twitter[1] and Facebook[2]) can be leveraged to improve the understanding of patients' experience in healthcare, such as the spread of infectious diseases and side-effects of drugs. However, the lexical and grammatical variability of the language used in social media poses a key challenge for extracting information (Baldwin et al., 2013; O'Connor et al., 2014). In particular, the frequent use of informal language, non-standard grammar and abbreviation forms, as well as typos in social media messages has to be taken into account by effective information extraction systems.

The task of medical concept normalisation for social media text, which aims to map a variable length social media message to a medical concept in some external coding system, is faced with a similar challenge (Limsopatham and Collier, 2015b). Traditional approaches, e.g. (Ristad and Yianilos, 1998; Aronson, 2001; Lu et al., 2011; McCallum et al., 2012), used proximity matching or heuristic string matching rules based on dictionary lookup when mapping texts to medical concepts. For example, Ristad and Yianilos (1998) incorporated edit-distance when mapping similar texts. The MetaMap system of Aronson (2001) applied a rule-based approach using pre-defined variants of terms when mapping texts to medical concepts in the UMLS Metathesaurus[3]. However, as shown in Table 1, existing string matching techniques may not be able to map the social media message "moon face and 30 lbs in 6 weeks" to the medical concept 'Weight Gain', or map "head spinning a little" to 'Dizziness', as no words in the social media messages and the description of the medical concepts correspond. Recent studies, e.g. (Leaman et al., 2013; Leaman and Lu, 2014; Limsopatham and Collier, 2015a), applied machine learning techniques to take into account relationships between different words (e.g. synonyms) when performing normal-

Social media message	Description of corresponding medical concept
lose my appetite	Loss of appetite
i don't hunger or thirst	Loss of Appetite
hungry	Hunger
moon face and 30 lbs in 6 weeks	Weight Gain
gained 7 lbs	Weight Gain
lose the 10 lbs	Body Weight Decreased
feeling dizzy ...	Dizziness
head spinning a little	Dizziness
terrible headache!!	Headache

Table 1: Examples of social media messages and their related medical concepts.

isation. For instance, the *DNorm* system of Leaman et al. (2013), which achieved state-of-the-art performance on several medical concept normalisation tasks for medical articles (Doğan et al., 2014) and patient records (Suominen et al., 2013), used a pairwise learning-to-rank technique to learn the similarity between different terms when performing concept normalisation. Limsopatham and Collier (2015a) leveraged translations between the informal language used in social media and the formal language used in the description of medical concepts in an ontology. However, we argue that effective concept normalisation requires a system to take into account the semantics of social media messages and medical concepts. For example, to be able to map from the social media message "i don't hunger or thirst" to the medical concept 'Loss of Appetite', a normalisation system has to take into account the semantics of the whole message; otherwise, "i don't hunger or thirst" may be mapped to the medical concept 'Hunger', because they contain the term "hunger" in common.

In this work, we go beyond string matching. We propose to learn and exploit the semantic similarity between texts from social media messages and medical concepts using deep neural networks. In particular, we investigate the use of techniques from two families of deep neural networks, i.e. a convolutional neural network (CNN) and a recurrent neural network (RNN), to learn the mapping between social media texts and medical concepts. We evaluate our approaches using three different datasets that contain messages from Twitter and blog posts. Our experimental results show that our proposed approaches significantly outperform existing strong baselines (e.g. DNorm) across all of the three datasets. The performance improvement is by up to 44%.

The main contributions of this paper are threefold:

1. We propose two novel approaches based on CNN and RNN for medical concept normalisation.

2. We introduce two datasets with the gold-standard mappings between medical concepts and social media texts extracted from tweets and blog posts, respectively.

3. We thoroughly evaluate our proposed approaches using these two datasets and an existing dataset of tweets related to the topic of adverse drug reactions (ADRs) (Limsopatham and Collier, 2015a).

The remainder of this paper is organised as follows. In Section 2, we discuss related work and position our paper in the literature. Section 3 introduces our neural network approaches for medical concept normalisation. We describe our experimental setup and empirically evaluate our proposed approaches in Sections 4 and 5, respectively. We provide further analysis and discussion of our approaches in Section 6. Finally, Section 7 provides concluding remarks.

2 Related Work

Existing techniques for concept normalisation are mostly based on string matching (e.g. (Tsuruoka et al., 2007; Ristad and Yianilos, 1998; Lu et al., 2011; McCallum et al., 2012). For example, McCallum et al. (2012) used conditional random field to learn edit distance between phrases. In the medical domain, Tsuruoka et al. (2007) learned mappings between phrases in medical documents and medical concepts by using string matching features, such as character bigrams and

common tokens. Meanwhile, Metke-Jimenez and Karimi (2015), and O'Connor et al. (2014) used term weighting techniques, such as TF-IDF and BM25 (Robertson and Zaragoza, 2009) to retrieve relevant concepts. We tackle the concept normalisation task in a different manner. In particular, we use deep neural networks to capture the similarity and/or dependency between terms and effectively represent a given social media message in a low dimensional vector representation, before mapping it to a medical concept.

Another research area related to this work is the exploitation of word embeddings (i.e. distributed vector representation of words). It has been empirically shown that word embeddings can capture semantic and syntactic similarities between words (Turian et al., 2010; Mikolov et al., 2013b; Pennington et al., 2014; Levy and Goldberg, 2014). The cosine similarity between vectors of words has a positive correlation with the semantic similarity between them (Mikolov et al., 2013b; Pennington et al., 2014). Importantly, word embeddings have been effectively used for several NLP tasks, such as named entity recognition (Passos et al., 2014), machine translation (Mikolov et al., 2013a) and part-of-speech tagging (Turian et al., 2010). In the context of concept normalisation, Limsopatham and Collier (2015a) showed that effective performance could be achieved by mapping the processed social media messages and medical concepts using the similarity of their embeddings. In this work, we use word embeddings as inputs of deep neural networks, which would allow an effective representation of words when learning the concept normalisation.

Neural networks, such as convolutional neural networks (CNN) and recurrent neural networks (RNN), have been effectively applied to NLP tasks, such as NER, sentiment classifications and machine translation (Collobert et al., 2011; Kim, 2014; Bahdanau et al., 2014). For example, Collobert et al. (2011) effectively used a multilayer neural network for chunking, part-of-speech tagging, NER and semantic role labelling. Kim (2014) effectively used CNN with pre-built word embeddings when performing sentence classifications. Kalchbrenner et al. (2014) learned representation of sentences by using CNN. Meanwhile, Bahdanau et al. (2014) used RNN to encode a sentence written in one language (e.g. French) into a fixed length vector before decoding it to a sentence in another language (e.g. English) for translation. Socher et al. used recursive neural networks to model sentences for different tasks, including paraphrase detection (Socher et al., 2011) and sentence classification (Socher et al., 2013). In this paper, we investigate only the use of CNN and RNN for medical concept normalisation, as recursive neural networks require parse trees of input sentences while grammatical rules are typically ignored in social media messages.

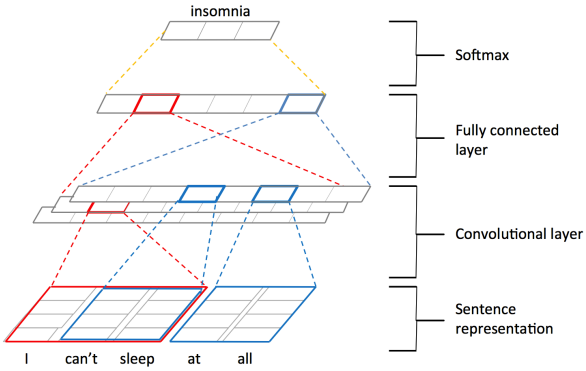

Figure 1: Our CNN architecture for medical concept normalisation.

3 Neural Networks for Concept Normalisation

Next, we introduce our medical concept normalisation approaches based on CNN and RNN in Sections 3.1 and 3.2, respectively.

3.1 CNN for Concept Normalisation

Our first approach uses CNN to learn the semantic representation of a social media message before mapping it to an appropriate medical concept. We use a CNN architecture with a single convolutional and pooling layer, as shown in Figure 1. Specifically, we firstly represent a given social media message of length l words (padded where necessary) using a sentence matrix $\mathbf{S} \in \mathbb{R}^{d \times l}$:

$$\mathbf{S} = \begin{bmatrix} | & | & | & | & \\ \mathbf{x}_1 & \mathbf{x}_2 & \mathbf{x}_3 & \dots & \mathbf{x}_l \\ | & | & | & | & \end{bmatrix} \quad (1)$$

where each column of $\mathbf{S}$ is the d-dimensional vector (i.e. embedding) $\mathbf{x}_i \in \mathbb{R}^d$ of each word in the social media message, which can be retrieved from pre-built word embeddings. This allows the model to take into account semantic features from the embeddings of each word.

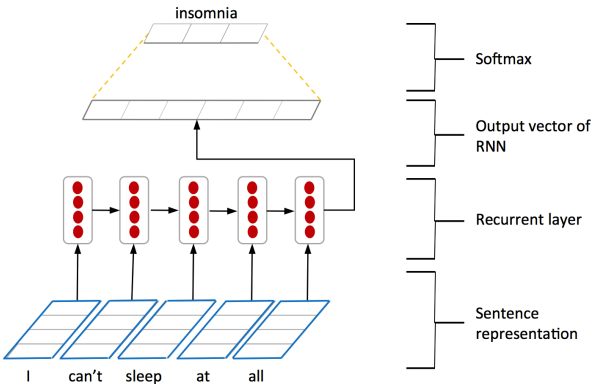

Figure 2: Our RNN architecture for medical concept normalisation.

We then apply a convolution operation using a filter $\mathbf{w} \in \mathbb{R}^{d \times h}$ to a window of h words. In particular, the filter $\mathbf{w}$ is convolved over the sequence of words in the sentence matrix $\mathbf{S}$ to create a feature matrix $\mathbf{C}$. Each feature c_i in $\mathbf{C}$ is extracted from a window of words $\mathbf{x}_{i:i+h-1}$, as follow:

$$c_i = f(\mathbf{w} \cdot \mathbf{x}_{i:i+h-1} + b) \quad (2)$$

where f is an activation function, such as sigmoid or tanh, and $b \in \mathbb{R}$ is a bias. Note that multiple filters (e.g. using different size h of window of words) can be used to extract multiple features.

This convolution operation enables the learning of dependencies between words from their semantic representation (i.e. word embeddings). In order to capture the most important features, max pooling (Collobert et al., 2011) is applied to take the maximum value of each row in the matrix $\mathbf{C}$:

$$\mathbf{c}_{max} = \begin{bmatrix} max(\mathbf{C}_{1,:}) \\ \vdots \\ max(\mathbf{C}_{d,:}) \end{bmatrix} \quad (3)$$

Finally, the fixed sized vector $\mathbf{c}_{max}$ forms a fully connected layer, which is used as inputs of softmax for multi-class classification. Indeed, the vector $\mathbf{c}_{max}$ provides a sentence representation that captures an extensional semantic information of the social media message for softmax to map to an appropriate medical concept.

3.2 RNN for Concept Normalisation

Our second approach uses RNN to capture the semantics of sequences of words in a social media message during normalisation. This approach is different from the CNN approach (introduced Section 3.1) in that instead of using the convolutional layer to learn the representation of social media messages (i.e. the vector representation at the fully connected layer), our RNN approach deploys a recurrent layer, as shown in Figure 2. Similar to the CNN approach, we initially represent a social media message of length l words using a sentence matrix $\mathbf{S} \in \mathbb{R}^{d \times l}$, as in Equation (1).

Then, the recurrent layer processes the vector $\mathbf{x}_i$ of each word in the social media message sequentially and produces a hidden state output $\mathbf{h}_i \in \mathbb{R}^k$, where $k \in \mathbb{Z}$ and $k > 0$. Importantly, when processing each input vector $\mathbf{x}_i$, the hidden state output $\mathbf{h}_{i-1}$ from the previous word is also recursively taken into account:

$$\mathbf{h}_i = f(\mathbf{h}_{i-1}, \mathbf{x}_i) \quad (4)$$

where f is a recurrent unit, such as long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and gated recurrent unit (GRU) (Cho et al., 2014).

Finally, the hidden state output $\mathbf{h}_l$, which is the output from processing the last word of the social media message, is used as an input of the softmax for identifying the appropriate concept, in the same manner as the vector at the fully connected layer of the CNN approach in Section 3.1.

	TwADR-S	TwADR-L	AskAPatient
$\|Q\|$	201	1,436	8,662
$\|V_Q\|$	488	995	2,872

$\|Q \mapsto C\|_{avg}$	3.4655	0.6428	8.3610
$\|Q \mapsto C\|_{SD}$	5.6264	3.3168	39.2009
$\|Q \mapsto C\|_{min}$	1	0	1
$\|Q \mapsto C\|_{max}$	35	58	1,073

Table 2: Statistics of the datasets used in the experiments. $|Q|$: Number of queries. $|V_Q|$: Vocabulary size of queries. $|C|$: Number of target concepts. $|V_C|$: Vocabulary size of definition of target concepts. $|Q \mapsto C|_{avg}$ and $|Q \mapsto C|_{SD}$: Average number of queries mapped to each target concept, and its standard deviation (SD). $|Q \mapsto C|_{min}$ and $|Q \mapsto C|_{max}$: Mininum and maximum number of queries mapped to a given target concept, respectively.

4 Experimental Setup

4.1 Datasets

To evaluate our proposed approaches, we use three different datasets (namely, *TwADR-S*, *TwADR-L*

and *AskAPatient*)[4], where the task is to map a social media phrase to a relevant medical concept. In these datasets, a given social media phrase is mapped to only one medical concept. Table 2 shows statistics for the three datasets. In particular, TwADR-S is the dataset provided by Limsopatham and Collier (2015a), which contains 201 Twitter phrases and their corresponding SNOMED-CT[5] concept. The total number of target concepts is 58, while on average a medical concept can be mapped by 3.47 queries with the standard deviation of 5.63.

The TwADR-L dataset is our new dataset that we constructed from a collection of three months of tweets (between July and November 2015), downloaded using the Twitter Streaming API[6] by filtering using the name of a pre-defined set of drugs, which have been used in the literature for ADR profiling (e.g. cognitive enhancers) (Bender et al., 2007). These tweets were sampled and then annotated by undergraduate-level linguists. This collection contains 1,436 Twitter phrases that can be mapped to one of 2,220 medical concepts from the SIDER 4 database of drug profiles[7]. Note that 1,947 from the 2,220 concepts are not relevant to any of the Twitter phrases.

For the AskAPatient dataset, we extracted the gold-standard mappings of social media messages and medical concepts from the ADR annotation collection of Karimi et al. (2015). Our AskAPatient dataset contains 8,662 phrases[8], each of which can be mapped to one of the 1,036 medical concepts from SNOMED-CT and AMT (the Australian Medicines Terminology). We expect this dataset to be less difficult than TwADR-S and TwADR-L, as the nature of blog posts is less informal and ambiguous than Twitter messages.

For each of the datasets, we randomly divide it into ten equally folds, so that our approaches and the baselines would be trained on the same sets of data. We evaluate our approaches based on the accuracy performance, averaged across the ten folds. The significant difference between the performance of our approaches and the baselines is measured using the paired t-test ($p < 0.05$).

[4]TwADR-L and AskAPatient datasets are available on Zenodo.org (DOI:http://dx.doi.org/10.5281/zenodo.55013).

4.2 Pre-trained Word Embeddings

As our CNN (Section 3.1) and RNN (Section 3.2) approaches require word vectors as inputs, we investigate the use of two different pre-trained word embeddings. The first word embeddings (denoted, *GNews*) are the publicly available 300-dimension embeddings (vocabulary size of 3M) that were induced from 100 billion words from Google News using word2vec (Mikolov et al., 2013b)[9], which has been shown to be effective for several tasks (Baroni et al., 2014; Kim, 2014). The second word embeddings (denoted, *BMC*) induced from 854M words of medical articles downloaded from BioMed Central[10] by using the skip-gram model from word2vec (with default parameters). The BMC embeddings also have 300 dimension. For the words that do not existing in any embeddings, we use a vector of random values sampled from $[-0.25, 0.25]$.

As an alternative, we also use randomly generated embeddings (denoted, *Rand*) with 300 dimensions, where a vector representation of each word is randomly sampled from $[-0.25, 0.25]$. This allows the investigation of the effectiveness of our approaches when the semantic information from pre-built embeddings is not available.

4.3 Parameters of Our CNN and RNN Approaches

For our CNN approach, we use the filter $\mathbf{w}$ with the window size h of 3, 4 and 5, each of which with 100 feature maps, which have shown to be effective for modelling sentences in sentiment analysis (Kim, 2014). For the RNN, we use gated recurrent unit (GRU) (Cho et al., 2014) and set the size k of the output vector of each recurrent unit to 100.

In addition, for both CNN and RNN, we use rectifier linear unit (ReLU) (Nair and Hinton, 2010) as activation functions. We also apply L_2 regularisation of the weight vectors. We train the models over a mini-batch of size 50 to minimise the negative log-likelihood of correct predictions. The stochastic gradient descent with back-propagation is performed using Adadelta update rule (Zeiler, 2012). We initially set the number of epochs for training both CNN and RNN approaches to be 100, and allow the models to update the input

[9]https://code.google.com/p/word2vec/

[10]http://www.biomedcentral.com/about/datamining

embeddings in the sentence matrix $\mathbf{S}$. Later, in Sections 6.2 and 6.3, we discuss the performance achieved as we vary the number of epochs used for training the models, and the performance achieves when we allow and do not allow the models to update the input embeddings, respectively.

4.4 Baselines

We consider five different baselines as follows:

1. *TF-IDF*: A traditional term matching-based approach, using the TF-IDF score.

2. *BM25*: A traditional term matching-based approach, using the BM25 score, which has shown to be effective for several text retrieval tasks (Robertson and Zaragoza, 2009)

3. *EmbSim*: The cosine similarity between the word vector representation of a social media phrase and the description of a medical concept. If the phrase (or the description) contains several words, we represent it by adding up the values of the same dimension of the embedding of each word.

4. *DNorm*: A machine learning-based approach that exploits the relationships between words (e.g. synonyms) learned from training data (Leaman and Lu, 2014). This approach achieved state-of-the-art performance for several medical concept normalisation tasks (Suominen et al., 2013; Doğan et al., 2014). Note that we customise the open-source version[11] of DNorm to enable the mapping to a specific set of the target concepts for each dataset.

5. *P-MT*: The concept normalisation approach that translates social media texts to a formal medical text before mapping to appropriate medical concepts using the cosine similarity of their embeddings (Limsopatham and Collier, 2015a). We use the variant where the top-5 translations are used to map the medical concepts by taking the ranked position into account. We calculate the cosine similarity using either the GNews or the BMC embeddings.

6. *LogisticRegression*: A variant of our proposed approaches where we concatenate embeddings of terms (padded where necessary) in each social media phrase into a fixed-size sentence vector, before using this vector as input features for a multi-class logistic regression classifier.

Another possible baseline is a word-sense disambiguation system, such as IMS (Zhong and Ng, 2010). Nevertheless, the results from our initial experiments using IMS showed that it could not perform effectively on the three datasets. This is because the performance of IMS depends heavily on the contexts (i.e. words surrounding the input phrase); however, such contexts are not available in any of the three datasets. Therefore, we do not report the performance of IMS in this paper.

Note that for the baselines that require training data (i.e. DNorm and P-MT) and our two proposed approaches, apart from the training data provides with each fold of the datasets, we also train them using the descriptions of the target medical concepts, as these data are also used by the non-supervised baselines (i.e. TF-IDF, BM25 and EmbSim).

5 Experimental Results

In this section, we compare the performance of our CNN and RNN approaches for medical concept normalisation against the six baselines, introduced in Section 4.4. Table 3 compares the performances of our proposed approaches with the baselines in terms of accuracy on the three datasets (i.e. TwADR-S, TwADR-L, AskAPatient). Overall, as expected, the accuracy performance achieved by our approaches and the baselines on the AskAPatient dataset is higher than the TwADR-L and TwADR-S. This is due to nature use of language in Twitter, which is more ambiguous and informal than blog posts. When comparing among the existing baseline approaches, we observe that *DNorm* and *P-MT* are the most effective baselines. In particular, *DNorm* outperforms the other baselines for the TwADR-S (accuracy 0.2983) and AskAPatient (accuracy 0.7339) datasets, while *P-MT* with GNews embeddings is the most effective baseline for the TwADR-L dataset (accuracy 0.3371). In addition, term matching-based approaches, i.e. *TF-IDF* (accuracy 0.1638, 0.2293 and 0.5547, respectively) and *BM25* (accuracy 0.1638, 0.2300 and 0.5546), achieve almost similar performances, which are also comparable to the performances of *EmbSim* baselines. When comparing the effectiveness of different

LogisticRegression	BMC	0.3036	0.3548	0.7752
CNN	Rand	0.3229$^{\bullet}$	0.4267$^{*\circ\bullet}$	0.8013$^{*\circ\bullet}$
CNN	GNews	**0.4174**$^{*\circ\bullet}$	**0.4478**$^{*\circ\bullet}$	**0.8141**$^{*\circ\bullet}$
CNN	BMC	0.3921$^{*\circ\bullet}$	0.4415$^{*\circ\bullet}$	0.8139$^{*\circ\bullet}$
RNN	Rand	0.2936$^{\bullet}$	0.3791$^{*\circ\bullet}$	0.7991$^{*\circ\bullet}$
RNN	GNews	**0.3529**$^{*\circ\bullet}$	**0.3882**$^{*\circ\bullet}$	**0.7998**$^{*\circ\bullet}$
RNN	BMC	0.3331$^{\bullet}$	0.3847$^{*\circ\bullet}$	0.7996$^{*\circ\bullet}$

Table 3: The accuracy performance of our proposed approaches and the baselines. Significant differences ($p < 0.05$, paired t-test) compared to the *DNorm*, *P-MT with GNews embeddings*, and *P-MT with BMC embeddings*, are denoted *, $^{\circ}$ and $^{\bullet}$, respectively.

pre-trained embeddings used in *EmbSim* and *P-MT*, we observe that GNews is more effective than BMC for both approaches, across all of the three datasets.

Next, we discuss the performance of our *CNN* and *RNN* approaches. From Table 3, we observe that both *CNN* and *RNN* markedly outperform all of the existing baselines for all of the three datasets. When compared with *DNorm* and *P-MT with GNews* baselines, which are the most effective existing baselines, we observe that both *CNN* and *RNN* significantly ($p < 0.05$, paired t-test) outperform the two baselines for all of the three datasets. Indeed, for the TwADR-L dataset, *CNN with GNews* (accuracy 0.4478) outperforms *DNorm* (accuracy 0.3099) by 44%. In addition, the choice of embeddings has a marked impact on the achieved performance. In particular, the GNews embeddings benefit both *CNN* and *RNN* more than the BMC embeddings, which is in line with the previous finding that GNews is more useful than BMC for the *EmbSim* and *P-MT* baselines. On the other than, the randomly generated embeddings (i.e. Rand) are less useful. These results show that the semantics captured in word embeddings are useful for both *CNN* and *RNN* approaches for medical concept normalisation. However, for both *CNN* and *RNN*, the choice of embeddings that are employed has less impact on the performance for the AskAPatient dataset, which has greater number of training data.

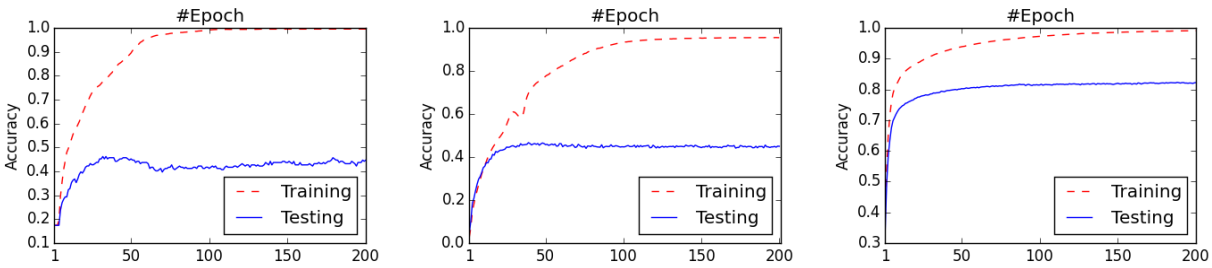
Furthermore, we observe that the *LogisticRegression* baseline, a variant of our proposed approach that uses the multi-class logistic regression instead of neural networks for identifying relevance concepts, also outperforms the all of the existing baselines. However, it performs worse than both *CNN* and *RNN* approaches. This shows that while logistic regression can exploit the semantics of embeddings of individual terms in social media texts (at the word level), it cannot learn the semantics of the whole phrase as effectively as CNN and RNN.

6 Analysis & Discussions

In this section, we further analyse the performance achieved by our proposed approaches. As the performance achieved by our CNN approach is better than that of our RNN approach, we discuss only our CNN approach in this section.

6.1 Failure Analysis

We first discuss the results achieved by the baselines and our CNN approach. As expected, we observe that all approaches perform very well for the social media phrases that lexically match with the definition of the medical concepts, e.g. the social media phrase "attention deficit disorder" is



(a) TwADR-S (b) TwADR-L (c) AskAPatient

Figure 3: The accuracy performance achieved by training with different numbers of epochs for the three datasets.

mapped to the medical concept 'Attention Deficit Disorder'. However, for a more complex phrases, such as "appetite on 10", "my appetite way up", "suppressed appetite", the baselines, including DNorm and P-MT, cannot effectively incorporate the modifiers of the word "appetite" in different phrases. For example, "appetite on 10", "my appetite way up" should be mapped to 'Increased Appetite', while "suppressed appetite" should be mapped to 'Loss of Appetite'. On the other hand, for social media phrases that do not have any terms in common with the definition of any medical concepts, all of the baselines performs poorly for most of the cases. For instance, even though DNorm can learn that the term "focusing" has some relationship with "concentration", it maps any phrases containing "focusing" to the 'Attention Concentration Difficulty' concept, including phrases, such as "focusing monster", which should be mapped to 'Consciousness Abnormal'. Our CNN approach could deal with most of these cases effectively, as it considers the semantic representation of the whole phrase during normalisation.

6.2 Impact of Number of Training Epochs

Next, we discuss the normalisation performance as we vary, between 1 and 200, the number of epochs used for training our CNN model. Figures 3(a), 3(b) and 3(c) show the performance in terms of accuracy achieved during training and testing for the TwADR-S, TWADR-L and AskAPatient datasets, respectively. We observe that training can be effectively achieved at around 60 - 70 epochs for the TwADR-S and TwADR-L datasets, and around 40 epochs for the AskAPatient dataset, before the performance becomes stable. We notice a gap between the performance achieved during training and testing, especially for the TwADR-S and TwADR-L datasets; however, this gap should be narrower if more training data are available.

Dataset	Accuracy	
	CNN with updated emb.	CNN with fixed emb.
TwADR-S	0.4174	**0.4369**
TwADR-L	0.4478	**0.4590**
AskAPatient	**0.8141**$^{\bullet}$	0.7869

Table 4: The accuracy performance of our CNN approach with the GNews embeddings, when allowing (*updated emb.*) and not allowing (*fixed emb.*) the model to update the input word embeddings. Significant difference ($p < 0.05$, paired t-test) between the performance achieved by the two variants, on each dataset, is denoted $^{\bullet}$.

6.3 Impact of Fixed Embeddings

In this section, we compare the performance of our CNN with GNews embeddings when we allow (*updated emb.*) and when we do not allow (*fixed emb.*) the input embeddings to be updated. Table 4 reports the accuracy performance of the two variants for the three datasets. We observe that for TwADR-S and TwADR-L datasets, which are smaller datasets (dataset size of 201 and 1,436, respectively), a better performance can be achieved if the model is not allowed to update the embeddings of the input phrases. In contrast, for the AskAPatient dataset (dataset size of 8,662), allowing the model to update the embeddings results in a significantly (paired t-test, $p < 0.05$) better performance. We observe the same trends of performance when using BMC embeddings. These results suggest that for small datasets, we should leverage semantics from pre-built word embeddings and do not allow the model to update the

embeddings. Meanwhile, for a larger dataset, further performance improvement can be achieved by allowing the model to update the embeddings.

7 Conclusions

We have motivated the importance of semantics when normalising medical concepts in social media messages. In particular, as social media messages are typically ambiguous, we argue that effective concept normalisation should deal with them at the semantic level. To do so, we introduced two neural network-based approaches for medical concept normalisation, which are based on convolutional and recurrent neural network architectures. Our experimental results evaluated on three different social media datasets showed that both of our approaches markedly and significantly outperformed several strong baselines, including an existing approach that achieved state-of-the-art performance on several medical concept normalisation tasks. From the analysis of the results, we found that while some existing approaches can capture synonyms of words, they could not leverage the semantic meaning of the social media message. Our approaches overcomes this by learning the semantic representation of the social media message before passing it to a classifier to match an appropriate concept.

Abstract

We introduce an agreement-based approach to learning parallel lexicons and phrases from non-parallel corpora. The basic idea is to encourage two asymmetric latent-variable translation models (i.e., source-to-target and target-to-source) to agree on identifying latent phrase and word alignments. The agreement is defined at both word and phrase levels. We develop a Viterbi EM algorithm for jointly training the two unidirectional models efficiently. Experiments on the Chinese-English dataset show that agreement-based learning significantly improves both alignment and translation performance.

1 Introduction

Parallel corpora, which are large collections of parallel texts, serve as an important resource for inducing translation correspondences, either at the level of words (Brown et al., 1993; Smadja and McKeown, 1994; Wu and Xia, 1994) or phrases (Kupiec, 1993; Melamed, 1997; Marcu and Wong, 2002; Koehn et al., 2003). However, the availability of large-scale, wide-coverage corpora still remains a challenge even in the era of big data: parallel corpora are usually only existent for resource-rich languages and restricted to limited domains such as government documents and news articles.

Therefore, intensive attention has been drawn to exploiting non-parallel corpora for acquiring translation correspondences. Most previous efforts have concentrated on learning parallel lexicons from non-parallel corpora, including parallel sentence and lexicon extraction via bootstrapping (Fung and Cheung, 2004), inducing parallel lexicons via canonical correlation analysis (Haghighi et al., 2008), training IBM models on monolingual corpora as decipherment (Ravi and Knight, 2011; Nuhn et al., 2012; Dou et al., 2014), and deriving parallel lexicons from bilingual word embeddings (Vulić and Moens, 2013; Mikolov et al., 2013; Vulić and Moens, 2015).

Recently, a number of authors have turned to a more challenging task: learning parallel phrases from non-parallel corpora (Zhang and Zong, 2013; Dong et al., 2015). Zhang and Zong (2013) present a method for retrieving parallel phrases from non-parallel corpora using a seed parallel lexicon. Dong et al. (2015) continue this line of research to further introduce an iterative approach to joint learning of parallel lexicons and phrases. They introduce a corpus-level latent-variable translation model in a non-parallel scenario and develop a training algorithm that alternates between (1) using a parallel lexicon to extract parallel phrases from non-parallel corpora and (2) using the extracted parallel phrases to enlarge the parallel lexicon. They show that starting from a small seed lexicon, their approach is capable of learning both new words and phrases gradually over time.

However, due to the structural divergence between natural languages as well as the presence of noisy data, only using asymmetric translation models might be insufficient to accurately identify parallel lexicons and phrases from non-parallel corpora. Dong et al. (2015) report that the accuracy on Chinese-English dataset is only around 40% after running for 70 iterations. In addition, their approach seems prone to be affected by noisy data in non-parallel corpora as the accuracy drops significantly with the increase of noise.

Since asymmetric word alignment and phrase alignment models are usually complementary, it is natural to combine them to make more accurate predictions. In this work, we propose to in-

Berlin, Germany, August 7-12, 2016.

troduce agreement-based learning (Liang et al., 2006; Liang et al., 2008) into extracting parallel lexicons and phrases from non-parallel corpora. Based on the latent-variable model proposed by Dong et al. (2015), we propose two kinds of loss functions to take into account the agreement between both phrase alignment and word alignment in two directions. As the inference is intractable, we resort to a Viterbi EM algorithm to train the two models efficiently. Experiments on the Chinese-English dataset show that agreement-based learning is more robust to noisy data and leads to substantial improvements in phrase alignment and machine translation evaluations.

2 Background

Given a monolingual corpus of source language phrases $E = \{\mathbf{e}^{(s)}\}_{s=1}^{S}$ and a monolingual corpus of target language phrases $F = \{\mathbf{f}^{(t)}\}_{t=1}^{T}$, we assume there exists a parallel corpus $D = \{\langle \mathbf{e}^{(s)}, \mathbf{f}^{(t)} \rangle | \mathbf{e}^{(s)} \leftrightarrow \mathbf{f}^{(t)}\}$, where $\mathbf{e}^{(s)} \leftrightarrow \mathbf{f}^{(t)}$ denotes that $\mathbf{e}^{(s)}$ and $\mathbf{f}^{(t)}$ are translations of each other.

As a long sentence in E is usually unlikely to have an translation in F and vise versa, most previous efforts build on the assumption that *phrases* are more likely to have translational equivalents on the other side (Munteanu and Marcu, 2006; Cettolo et al., 2010; Zhang and Zong, 2013; Dong et al., 2015). Such a set of phrases can be constructed by collecting either constituents of parsed sentences or strings with hyperlinks on webpages (e.g., Wikipedia). Therefore, we assume the two monolingual corpora are readily available and focus on how to extract D from E and F.

To address this problem, Dong et al. (2015) introduce a corpus-level latent-variable translation model in a non-parallel scenario:

$$P(F|E;\boldsymbol{\theta}) = \sum_{\mathbf{m}} \underbrace{P(F,\mathbf{m}|E;\boldsymbol{\theta})}_{\textit{phrase alignment}}, \quad (1)$$

where $\mathbf{m}$ is *phrase alignment* and $\boldsymbol{\theta}$ is a set of model parameters. Each target phrase $\mathbf{f}^{(t)}$ is restricted to connect to exactly one source phrase: $\mathbf{m} = (\mathbf{m}_1, \ldots, \mathbf{m}_t, \ldots \mathbf{m}_T)$, where $\mathbf{m}_t \in \{0, 1, \ldots, S\}$. For example, $\mathbf{m}_t = s$ denotes that $\mathbf{f}^{(t)}$ is aligned to $\mathbf{e}^{(s)}$. Note that $\mathbf{e}^{(0)}$ represents an empty source phrase.

They follow IBM Model 1 (Brown et al., 1993) to further decompose the model as

$$P(F,\mathbf{m}|E;\boldsymbol{\theta}) = \frac{p(T|S)}{(S+1)^T} \prod_{t=1}^{T} P(\mathbf{f}^{(t)}|\mathbf{e}^{(\mathbf{m}_t)};\boldsymbol{\theta}), \quad (2)$$

where $P(\mathbf{f}^{(t)}|\mathbf{e}^{(\mathbf{m}_t)};\boldsymbol{\theta})$ is a *phrase translation* model that can be further defined as

$$\begin{aligned} & P(\mathbf{f}^{(t)}|\mathbf{e}^{(\mathbf{m}_t)};\boldsymbol{\theta}) \\ &= \delta(\mathbf{m}_t, 0)\epsilon + \\ & \quad (1-\delta(\mathbf{m}_t,0)) \sum_{\mathbf{a}} \underbrace{P(\mathbf{f}^{(t)},\mathbf{a}|\mathbf{e}^{(\mathbf{m}_t)};\boldsymbol{\theta})}_{\textit{word alignment}}. \end{aligned} \quad (3)$$

Dong et al. (2015) distinguish between *empty* and *non-empty* phrase translations. If a target phrase $\mathbf{f}^{(t)}$ is aligned to the empty source phrase $\mathbf{e}^{(0)}$ (i.e., $\mathbf{m}_t = 0$), they set the phrase translation probability to a fixed number ϵ. Otherwise, conventional word alignment models such as IBM Model 1 can be used for non-empty phrase translation:

$$\begin{aligned} & P(\mathbf{f}^{(t)},\mathbf{a}|\mathbf{e}^{(\mathbf{m}_t)};\boldsymbol{\theta}) \\ &= \frac{p(J^{(t)}|I^{(\mathbf{m}_t)})}{(I^{(\mathbf{m}_t)}+1)^{J^{(t)}}} \prod_{j=1}^{J^{(t)}} p(\mathbf{f}_j^{(t)}|\mathbf{e}_{\mathbf{a}_j}^{(\mathbf{m}_t)}), \end{aligned} \quad (4)$$

where $p(J|I)$ is a *length* model and $p(f|e)$ is a *translation* model. We use $J^{(t)}$ to denote the length of $\mathbf{f}^{(t)}$.

Therefore, the latent-variable model involves two kinds of latent structures: (1) *phrase alignment* $\mathbf{m}$ between source and target phrases, (2) *word alignment* $\mathbf{a}$ between source and target words within phrases.

Given the two monolingual corpora E and F, the training objective is to maximize the likelihood of the training data:

$$\boldsymbol{\theta}^* = \operatorname*{argmax}_{\boldsymbol{\theta}} \Big\{ \mathcal{L}(\boldsymbol{\theta}) \Big\}, \quad (5)$$

where

$$\begin{aligned} \mathcal{L}(\boldsymbol{\theta}) = & \log P(F|E;\boldsymbol{\theta}) - \\ & \sum_I \lambda_I \Big(\sum_J p(J|I) - 1 \Big) - \\ & \sum_e \gamma_e \Big(\sum_f p(f|e) - 1 \Big) - \\ & \sum_f \sum_e \sigma(f,e,\mathbf{d}) \log \frac{\sigma(f,e,\mathbf{d})}{p(f|e)}. \end{aligned} \quad (6)$$

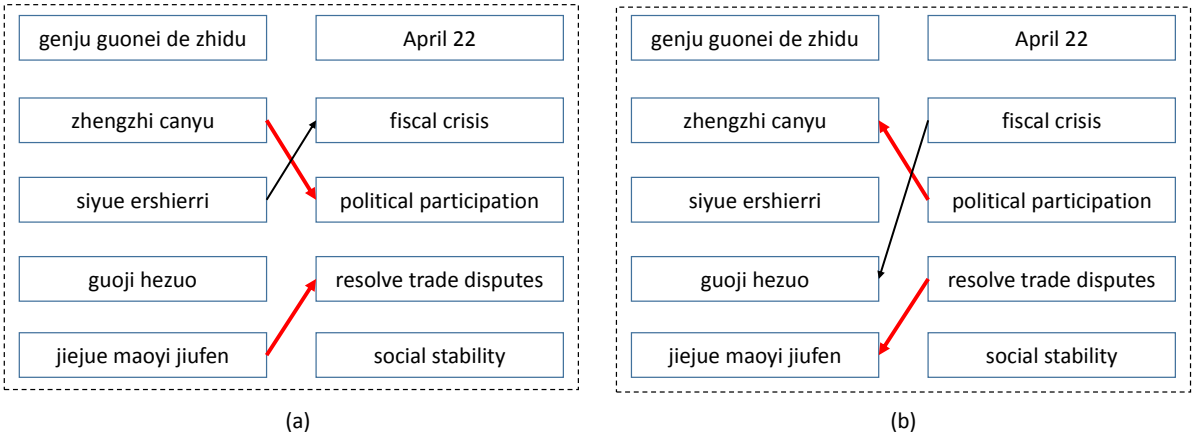

Figure 1: Agreement between (a) Chinese-to-English and (b) English-to-Chinese phrase alignments. The arrows indicate translation directions. The links on which two models agree are highlighted in bold red. The *outer agreement* loss function (see Eq. (14)) aims to encourage the agreement at the phrase level.

Note that $\mathbf{d}$ is a small seed parallel lexicon for initializing training [1] and $\sigma(f, e, \mathbf{d})$ checks whether an entry $\langle f, e \rangle$ exists in $\mathbf{d}$.

Given the monolingual corpora and the optimized model parameters, the Viterbi phrase alignment is calculated as

$$\mathbf{m}^* = \operatorname*{argmax}_{\mathbf{m}} \Big\{ P(F, \mathbf{m}|E; \boldsymbol{\theta}^*) \Big\} \quad (7)$$

$$= \operatorname*{argmax}_{\mathbf{m}} \Big\{ \prod_{t=1}^{T} P(\mathbf{f}^{(t)}|\mathbf{e}^{(\mathbf{m}_t)}; \boldsymbol{\theta}^*) \Big\}. \quad (8)$$

Finally, parallel lexicons can be derived from the translation probability table of IBM model 1 $\boldsymbol{\theta}^*$ and parallel phrases can be collected from the Viterbi phrase alignment $\mathbf{m}^*$. This process iterates and enlarges parallel lexicons and phrases gradually over time.

As it is very challenging to extract parallel phrases from non-parallel corpora, unidirectional models might only capture partial aspects of translation modeling on non-parallel corpora. Indeed, Dong et al. (2015) find that the accuracy of phrase alignment is only around 50% on the Chinese-English dataset. More importantly, their approach seems to be vulnerable to noise as the accuracy drops significantly with the increase of noise. As source-to-target and target-to-source translation models are usually complementary (Och and Ney, 2003; Koehn et al., 2003; Liang et al., 2006), it is appealing to combine them to improve alignment accuracy.

[1] Due to the difficulty of learning translation correspondences from non-parallel corpora, many authors have assumed that a small seed lexicon is readily available (Gaussier et al., 2004; Zhang and Zong, 2013; Vulić and Moens, 2013; Mikolov et al., 2013; Dong et al., 2015).

3 Approach

3.1 Agreement-based Learning

The basic idea of our work is to encourage the source-to-target and target-to-source translation models to agree on both phrase and word alignments.

For example, Figure 1 shows two example Chinese-to-English and English-to-Chinese phrase alignments on the same non-parallel data. As each model only captures partial aspects of translation modeling, our intuition is that the links on which two models agree (highlighted in red) are more likely to be correct.

More formally, let $P(F|E; \overrightarrow{\boldsymbol{\theta}})$ be a source-to-target translation model and $P(E|F; \overleftarrow{\boldsymbol{\theta}})$ be a target-to-source model, where $\overrightarrow{\boldsymbol{\theta}}$ and $\overleftarrow{\boldsymbol{\theta}}$ are corresponding model parameters. We use $\overrightarrow{\mathbf{m}} = (\overrightarrow{\mathbf{m}}_1, \ldots, \overrightarrow{\mathbf{m}}_t, \ldots, \overrightarrow{\mathbf{m}}_T)$ to denote source-to-target phrase alignment. Likewise, the target-to-source phrase alignment is denoted by $\overleftarrow{\mathbf{m}} = (\overleftarrow{\mathbf{m}}_1, \ldots, \overleftarrow{\mathbf{m}}_s, \ldots, \overleftarrow{\mathbf{m}}_S)$.

To ease the comparison between $\overrightarrow{\mathbf{m}}$ and $\overleftarrow{\mathbf{m}}$, we represent them as sets of non-empty links equivalently:

$$\overrightarrow{\mathbf{m}} = \Big\{ \langle \overrightarrow{\mathbf{m}}_t, t \rangle | \overrightarrow{\mathbf{m}}_t \neq 0 \Big\} \quad (9)$$

$$\overleftarrow{\mathbf{m}} = \Big\{ \langle s, \overleftarrow{\mathbf{m}}_s \rangle | \overleftarrow{\mathbf{m}}_s \neq 0 \Big\}. \quad (10)$$

For example, suppose the source-to-target and target-to-source phrase alignments are $\overrightarrow{\mathbf{m}} =$

1: **procedure** VITERBIEM(E, F, $\mathbf{d}$)
2: Initialize $\mathbf{\Theta}^{(0)}$
3: **for all** $k = 1, \ldots, K$ **do**
4: $\hat{\mathbf{m}}^{(k)} \leftarrow$ SEARCH($E, F, \mathbf{\Theta}^{(k-1)}$)
5: $\mathbf{\Theta}^{(k)} \leftarrow$ UPDATE($E, F, \mathbf{d}, \hat{\mathbf{m}}^{(k)}$)
6: **end for**
7: **return** $\hat{\mathbf{m}}^{(K)}, \mathbf{\Theta}^{(K)}$
8: **end procedure**

Figure 2: A Viterbi EM algorithm for agreement-based learning of parallel lexicons and phrases from non-parallel corpora. F and E are non-parallel corpora, $\mathbf{d}$ is a seed parallel lexicon, $\mathbf{\Theta}^{(k)}$ is the set of model parameters at the k-th iteration, $\hat{\mathbf{m}}^{(k)}$ is the Viterbi phrase alignment on which two models agree at the k-th iteration.

$(2, 3, 0, 0)$ and $\overleftarrow{\mathbf{m}} = (0, 1, 2)$. The equivalent link sets are $\overrightarrow{\mathbf{m}} = \{\langle 2, 1\rangle, \langle 3, 2\rangle\}$ and $\overleftarrow{\mathbf{m}} = \{\langle 2, 1\rangle, \langle 3, 2\rangle\}$. Therefore, $\overrightarrow{\mathbf{m}}$ is said to be *equal* to $\overleftarrow{\mathbf{m}}$ (i.e., $\delta(\overrightarrow{\mathbf{m}}, \overleftarrow{\mathbf{m}}) = 1$).

Following Liang et al. (2006), we introduce a new training objective that favors the agreement between two unidirectional models:

$$\begin{aligned}
&\mathcal{J}(\overrightarrow{\boldsymbol{\theta}}, \overleftarrow{\boldsymbol{\theta}}) \\
&= \log P(F|E; \overrightarrow{\boldsymbol{\theta}}) + \log P(E|F; \overleftarrow{\boldsymbol{\theta}}) - \\
&\quad \log \sum_{\overrightarrow{\mathbf{m}}, \overleftarrow{\mathbf{m}}} P(\overrightarrow{\mathbf{m}}|E, F; \overrightarrow{\boldsymbol{\theta}}) P(\overleftarrow{\mathbf{m}}|F, E; \overleftarrow{\boldsymbol{\theta}}) \\
&\qquad \times \Delta(E, F, \overrightarrow{\mathbf{m}}, \overleftarrow{\mathbf{m}}, \overrightarrow{\boldsymbol{\theta}}, \overleftarrow{\boldsymbol{\theta}}), \qquad (11)
\end{aligned}$$

where the posterior probabilities in two directions are defined as

$$P(\overrightarrow{\mathbf{m}}|E, F; \overrightarrow{\boldsymbol{\theta}}) = \prod_{t=1}^{T} \frac{P(\mathbf{f}^{(t)}|\mathbf{e}^{(\overrightarrow{\mathbf{m}}_t)}; \overrightarrow{\boldsymbol{\theta}})}{\sum_{s=0}^{S} P(\mathbf{f}^{(t)}|\mathbf{e}^{(s)}; \overrightarrow{\boldsymbol{\theta}})} \quad (12)$$

$$P(\overleftarrow{\mathbf{m}}|F, E; \overleftarrow{\boldsymbol{\theta}}) = \prod_{s=1}^{S} \frac{P(\mathbf{e}^{(s)}|\mathbf{f}^{(\overleftarrow{\mathbf{m}}_s)}; \overleftarrow{\boldsymbol{\theta}})}{\sum_{t=0}^{T} P(\mathbf{e}^{(s)}|\mathbf{f}^{(t)}; \overleftarrow{\boldsymbol{\theta}})}. \quad (13)$$

The *loss function* $\Delta(E, F, \overrightarrow{\mathbf{m}}, \overleftarrow{\mathbf{m}}, \overrightarrow{\boldsymbol{\theta}}, \overleftarrow{\boldsymbol{\theta}})$ measures the disagreement between the two models.

3.2 Outer Agreement

3.2.1 Definition

A straightforward loss function is to force the two models to generate identical phrase alignments:

$$\Delta_{\text{outer}}(E, F, \overrightarrow{\mathbf{m}}, \overleftarrow{\mathbf{m}}, \overrightarrow{\boldsymbol{\theta}}, \overleftarrow{\boldsymbol{\theta}}) = 1 - \delta(\overrightarrow{\mathbf{m}}, \overleftarrow{\mathbf{m}}). \quad (14)$$

We refer to Eq. (14) as *outer agreement* since it only considers phrase alignment and ignores the word alignment within aligned phrases.

3.2.2 Training Objective

Since the outer agreement forces two models to generate identical phrase alignments, the training objective can be written as

$$\begin{aligned}
&\mathcal{J}_{\text{outer}}(\overrightarrow{\boldsymbol{\theta}}, \overleftarrow{\boldsymbol{\theta}}) \\
&= \log P(F|E; \overrightarrow{\boldsymbol{\theta}}) + \log P(E|F; \overleftarrow{\boldsymbol{\theta}}) + \\
&\quad \log \sum_{\mathbf{m}} P(\mathbf{m}|E, F; \overrightarrow{\boldsymbol{\theta}}) P(\mathbf{m}|F, E; \overleftarrow{\boldsymbol{\theta}}), \qquad (15)
\end{aligned}$$

where $\mathbf{m}$ is a phrase alignment on which two models agree.

The partial derivatives of the training objective with respect to source-to-target model parameters $\overrightarrow{\boldsymbol{\theta}}$ are given by

$$\begin{aligned}
&\frac{\partial \mathcal{J}_{\text{outer}}(\overrightarrow{\boldsymbol{\theta}}, \overleftarrow{\boldsymbol{\theta}})}{\partial \overrightarrow{\boldsymbol{\theta}}} \\
&= \frac{\partial P(F|E; \overrightarrow{\boldsymbol{\theta}}) / \partial \overrightarrow{\boldsymbol{\theta}}}{P(F|E; \overrightarrow{\boldsymbol{\theta}})} + \\
&\quad \frac{\mathbb{E}_{\mathbf{m}|F,E;\overleftarrow{\boldsymbol{\theta}}} \left[\partial P(F|E; \overrightarrow{\boldsymbol{\theta}}) / \partial \overrightarrow{\boldsymbol{\theta}} \right]}{\sum_{\mathbf{m}} P(\mathbf{m}|E, F; \overrightarrow{\boldsymbol{\theta}}) P(\mathbf{m}|F, E; \overleftarrow{\boldsymbol{\theta}})}. \qquad (16)
\end{aligned}$$

The partial derivatives with respect to $\overleftarrow{\boldsymbol{\theta}}$ are defined likewise.

3.2.3 Training Algorithm

As the expectation in Eq. (16) is usually intractable to calculate due to the exponential search space of phrase alignment, we follow Dong et al. (2015) to use a Viterbi EM algorithm instead.

As shown in Figure 2, the algorithm takes a set of source phrases E, a set of target phrases F, and a seed parallel lexicon $\mathbf{d}$ as input (line 1). After initializing model parameters $\mathbf{\Theta} = \{\overrightarrow{\boldsymbol{\theta}}, \overleftarrow{\boldsymbol{\theta}}\}$ (line 2), the algorithm calls the procedure ALIGN($F, E, \mathbf{\Theta}$) to compute the Viterbi phrase alignment between E and F on which two models agree. Then, the algorithm updates the two models by normalizing counts collected from the Viterbi phrase alignment. The process iterates for K iterations and returns the final Viterbi phrase alignment and model parameters.

3.2.4 Computing Viterbi Phrase Alignments

The procedure ALIGN($F, E, \mathbf{\Theta}$) computes the Viterbi phrase alignment $\hat{\mathbf{m}}$ between E and F on which two models agree as follows:

$$\begin{aligned}
\hat{\mathbf{m}} = \operatorname*{argmax}_{\mathbf{m}} \Big\{ &P(\mathbf{m}|E, F; \overrightarrow{\boldsymbol{\theta}}) \times \\
&P(\mathbf{m}|F, E; \overleftarrow{\boldsymbol{\theta}}) \Big\}. \qquad (17)
\end{aligned}$$

Unfortunately, due to the exponential search space of phrase alignment, computing $\hat{\mathbf{m}}$ is also intractable. As a result, we approximate it as the intersection of two unidirectional Viterbi phrase alignments:

$$\hat{\mathbf{m}} \approx \overrightarrow{\mathbf{m}}^* \cap \overleftarrow{\mathbf{m}}^*, \tag{18}$$

where the unidirectional Viterbi phrase alignments are calculated as

$$\overrightarrow{\mathbf{m}}^* = \underset{\overrightarrow{\mathbf{m}}}{\text{argmax}} \left\{ \prod_{t=1}^{T} P(\mathbf{f}^{(t)} | \mathbf{e}^{(\overrightarrow{\mathbf{m}}_t)}; \overrightarrow{\boldsymbol{\theta}}) \right\} \tag{19}$$

$$\overleftarrow{\mathbf{m}}^* = \underset{\overleftarrow{\mathbf{m}}}{\text{argmax}} \left\{ \prod_{s=1}^{S} P(\mathbf{e}^{(s)} | \mathbf{f}^{(\overleftarrow{\mathbf{m}}_s)}; \overleftarrow{\boldsymbol{\theta}}) \right\}. \tag{20}$$

The source-to-target Viterbi phrase alignment is calculated as

$$\overrightarrow{\mathbf{m}}^* = \underset{\overrightarrow{\mathbf{m}}}{\text{argmax}} \left\{ P(\overrightarrow{\mathbf{m}} | E, F; \overrightarrow{\boldsymbol{\theta}}) \right\} \tag{21}$$

$$= \underset{\overrightarrow{\mathbf{m}}}{\text{argmax}} \left\{ \prod_{t=1}^{T} P(\mathbf{f}^{(t)} | \mathbf{e}^{(\mathbf{m}_t)}; \overrightarrow{\boldsymbol{\theta}}) \right\}. \tag{22}$$

Dong et al. (2015) indicate that computing the Viterbi alignment for individual target phrases is *independent* and only need to focus on finding the most probable source phrase for each target phrase:

$$\overrightarrow{\mathbf{m}}_t^* = \underset{s \in \{0,1,\ldots,S\}}{\text{argmax}} \left\{ P(\mathbf{f}^{(t)} | \mathbf{e}^{(s)}; \overrightarrow{\boldsymbol{\theta}}) \right\}. \tag{23}$$

This can be cast as a translation retrieval problem (Zhang and Zong, 2013; Dong et al., 2014). Please refer to (Dong et al., 2015) for more details. The target-to-source Viterbi phrase alignment can be calculated similarly.

3.2.5 Updating Model Parameters

Following Liang et al. (2006), we collect counts of model parameters only from the agreement term.[2]

Given the agreed Viterbi phrase alignment $\hat{\mathbf{m}}$, the count of the source-to-target length model $p(J|I)$ is given by

$$c(J|I; E, F) = \sum_{\langle s,t \rangle \in \hat{\mathbf{m}}} \delta(J^{(t)}, J) \delta(I^{(s)}, I). \tag{24}$$

The new length probabilities can be obtained by

$$p(J|I) = \frac{c(J|I; E, F)}{\sum_{J'} c(J'|I; E, F)}. \tag{25}$$

[2]We experimented with collecting counts from both the unidirectional and agreement terms but obtained much worse results than counting only from the agreement term.

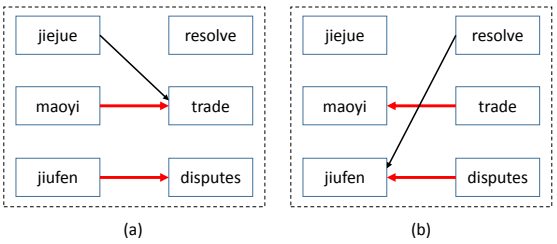

Figure 3: Agreement between (a) Chinese-to-English and (b) English-to-Chinese word alignments. The links on which two models agree are highlighted in red. The *inner agreement* loss function (see Eq. (28)) aims to encourage the agreement at both the phrase and word levels.

The count of the source-to-target translation model $p(f|e)$ is given by

$$\begin{aligned} & c(f|e; E, F) \\ = & \sum_{\langle s,t \rangle \in \hat{\mathbf{m}}} \frac{p(f|e)}{\sum_{i=0}^{I^{(s)}} p(f|\mathbf{e}_i^{(s)})} \times \\ & \sum_{j=1}^{J^{(t)}} \delta(f, \mathbf{f}_j^{(t)}) \sum_{i=0}^{I^{(s)}} \delta(e, \mathbf{e}_i^{(s)}) \\ & + \sigma(f, e, \mathbf{d}). \end{aligned} \tag{26}$$

The new translation probabilities can be obtained by

$$p(f|e) = \frac{c(f|e; E, F)}{\sum_{f'} c(f'|e; E, F)}. \tag{27}$$

Counts of target-to-source length and translation models can be calculated in a similar way.

3.3 Inner Agreement

3.3.1 Definition

As the outer agreement only considers the phrase alignment, the *inner agreement* takes both phrase alignment and word alignment into consideration:

$$\begin{aligned} & \Delta_{\text{inner}}(E, F, \overrightarrow{\mathbf{m}}, \overleftarrow{\mathbf{m}}, \overrightarrow{\boldsymbol{\theta}}, \overleftarrow{\boldsymbol{\theta}}) \\ = & -\delta(\overrightarrow{\mathbf{m}}, \overleftarrow{\mathbf{m}}) \times \\ & \sum_{\langle s,t \rangle \in \overrightarrow{\mathbf{m}}} \sum_{\overrightarrow{\mathbf{a}}, \overleftarrow{\mathbf{a}}} P(\overrightarrow{\mathbf{a}} | \mathbf{e}^{(s)}, \mathbf{f}^{(t)}; \overrightarrow{\boldsymbol{\theta}}) \times \\ & P(\overleftarrow{\mathbf{a}} | \mathbf{f}^{(t)}, \mathbf{e}^{(s)}; \overleftarrow{\boldsymbol{\theta}}) \times \\ & \delta(\overrightarrow{\mathbf{a}}, \overleftarrow{\mathbf{a}}). \end{aligned} \tag{28}$$

For example, Figure 3 shows two examples of Chinese-to-English and English-to-Chinese word alignments. The shared links are highlighted in

red. Our intuition is that a source phrase and a target phrase are more likely to be translations of each other if the two translation models also agree on word alignment within aligned phrases.

3.3.2 Training Objective and Algorithm

The training objective for inner agreement is given by

$$\begin{aligned}
&\mathcal{J}_{\text{inner}}(\overrightarrow{\boldsymbol{\theta}}, \overleftarrow{\boldsymbol{\theta}}) \\
= \;& \log P(F|E; \overrightarrow{\boldsymbol{\theta}}) + \log P(E|F; \overleftarrow{\boldsymbol{\theta}}) + \\
& \log \sum_{\mathbf{m}} P(\mathbf{m}|E, F; \overrightarrow{\boldsymbol{\theta}}) P(\mathbf{m}|F, E; \overleftarrow{\boldsymbol{\theta}}) \times \\
& \sum_{\langle s,t\rangle \in \mathbf{m}} \sum_{\mathbf{a}} P(\mathbf{a}|\mathbf{e}^{(s)}, \mathbf{f}^{(t)}; \overrightarrow{\boldsymbol{\theta}}) \times \\
& P(\mathbf{a}|\mathbf{f}^{(t)}, \mathbf{e}^{(s)}; \overleftarrow{\boldsymbol{\theta}}). \quad (29)
\end{aligned}$$

We still use the Viterbi EM algorithm as shown in Figure 2 for training the two models.

3.3.3 Computing Viterbi Phrase Alignments

The agreed Viterbi phrase alignment is defined as

$$\begin{aligned}
\hat{\mathbf{m}} = \operatorname*{argmax}_{\mathbf{m}} \Big\{ & P(\mathbf{m}|E, F; \overrightarrow{\boldsymbol{\theta}}) P(\mathbf{m}|F, E; \overleftarrow{\boldsymbol{\theta}}) \\
& \times \sum_{\langle s,t\rangle \in \mathbf{m}} \sum_{\mathbf{a}} P(\mathbf{a}|\mathbf{e}^{(s)}, \mathbf{f}^{(t)}; \overrightarrow{\boldsymbol{\theta}}) \\
& \times P(\mathbf{a}|\mathbf{f}^{(t)}, \mathbf{e}^{(s)}; \overleftarrow{\boldsymbol{\theta}}) \Big\}. \quad (30)
\end{aligned}$$

As computing $\hat{\mathbf{m}}$ is intractable, we still approximate it using the intersection of two unidirectional Viterbi phrase alignments (see Eq. (18)). The source-to-target Viterbi phrase alignment is calculated as

$$\begin{aligned}
\overrightarrow{\mathbf{m}}^* = \operatorname*{argmax}_{\overrightarrow{\mathbf{m}}} \Big\{ & P(\overrightarrow{\mathbf{m}}|E, F; \overrightarrow{\boldsymbol{\theta}}) \times \\
& \sum_{\langle s,t\rangle \in \overrightarrow{\mathbf{m}}} \sum_{j=1}^{J^{(t)}} \sum_{i=1}^{I^{(s)}} P(\langle i, j\rangle|\mathbf{e}^{(s)}, \mathbf{f}^{(t)}; \overrightarrow{\boldsymbol{\theta}}) \times \\
& P(\langle i, j\rangle|\mathbf{f}^{(t)}, \mathbf{e}^{(s)}; \overleftarrow{\boldsymbol{\theta}}) \Big\}, \quad (31)
\end{aligned}$$

where $P(\langle i, j\rangle|\mathbf{e}^{(s)}, \mathbf{f}^{(t)}; \overrightarrow{\boldsymbol{\theta}})$ is source-to-target link posterior probability of the link $\langle i, j\rangle$ being present (or absent) in the word alignment according to the source-to-target model, $P(\langle i, j\rangle|\mathbf{f}^{(t)}, \mathbf{e}^{(s)}; \overleftarrow{\boldsymbol{\theta}})$ is target-to-source link posterior probability. We follow Liang et al. (2006) to use the product of link posteriors to encourage the agreement at the level of word alignment.

We use a coarse-to-fine approach (Dong et al., 2015) to compute the Viterbi alignment: first retrieving a coarse set of candidate source phrases using translation probabilities and then selecting the candidate with the highest score according to Eq. (31). The target-to-source Viterbi phrase alignment can be calculated similarly.

3.3.4 Updating Model Parameters

Given the agreed Viterbi phrase alignment $\hat{\mathbf{m}}$, the count of the source-to-target length model $p(J|I)$ is still given by Eq. (24). The count of the translation model $p(f|e)$ is calculated as

$$\begin{aligned}
& c(f|e; E, F) \\
= \;& \sum_{\langle s,t\rangle \in \hat{\mathbf{m}}} \sum_{i=1}^{I^{(s)}} \sum_{j=1}^{J^{(t)}} P(\langle i, j\rangle|\mathbf{e}^{(s)}, \mathbf{f}^{(t)}; \overrightarrow{\boldsymbol{\theta}}) \times \\
& \qquad P(\langle i, j\rangle|\mathbf{f}^{(t)}, \mathbf{e}^{(s)}; \overleftarrow{\boldsymbol{\theta}}) \times \\
& \qquad \delta(f, \mathbf{f}^{(t)}) \delta(e, \mathbf{e}^{(s)}) \\
& + \sigma(f, e, \mathbf{d}). \quad (32)
\end{aligned}$$

Counts of target-to-source length and translation models can be calculated in a similar way.

4 Experiments

In this section, we evaluate our approach in two tasks: phrase alignment (Section 4.1) and machine translation (Section 4.2).

4.1 Alignment Evaluation

4.1.1 Evaluation Metrics

Given two monolingual corpora E and F, we suppose there exists a ground truth parallel corpus G and denote an extracted parallel corpus as D. The quality of an extracted parallel corpus can be measured by F1 $= 2|D \cap G|/(|D| + |G|)$.

4.1.2 Data Preparation

Although it is appealing to apply our approach to dealing with real-world non-parallel corpora, it is time-consuming and labor-intensive to manually construct a ground truth parallel corpus. Therefore, we follow Dong et al. (2015) to build synthetic E, F, and G to facilitate the evaluation.

We first extract a set of parallel phrases from a sentence-level parallel corpus using the state-of-the-art phrase-based translation system Moses (Koehn et al., 2007) and discard low-probability parallel phrases. Then, E and F can be constructed by corrupting the parallel phrase set by

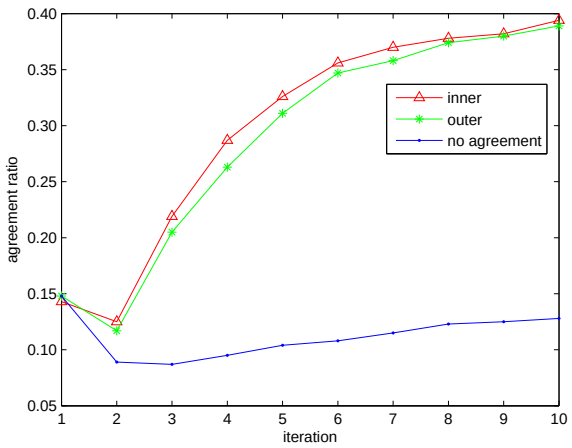

Figure 4: Comparison of agreement ratios on the development set.

seed	C → E	E → C	Outer	Inner
50	4.1	4.8	60.8	66.2
100	5.1	5.5	65.6	69.8
500	7.5	8.4	70.4	72.5
1,000	22.4	23.1	73.6	74.3

Table 1: Effect of seed lexicon size in terms of F1 on the development set.

adding irrelevant source and target phrases randomly. Note that the parallel phrase set can serve as the ground truth parallel corpus G. We refer to the non-parallel phrases in E and F as *noise*.

From LDC Chinese-English parallel corpora, we constructed a *development set* and a *test set*. The development set contains 20K parallel phrases, 20K noisy Chinese phrases, and 20K noisy English phrases. The test test contains 20K parallel phrases, 180K noisy Chinese phrases, and 180K noisy English phrases. The seed parallel lexicon contains 1K entries.

4.1.3 Comparison of Agreement Ratios

We introduce *agreement ratio* to measure to what extent two unidirectional models agree on phrase alignment:

$$\text{ratio} = \frac{2|\overrightarrow{\mathbf{m}}^* \cap \overleftarrow{\mathbf{m}}^*|}{|\overrightarrow{\mathbf{m}}^*| + |\overleftarrow{\mathbf{m}}^*|}. \quad (33)$$

Figure 4 shows the agreement ratios of independent training ("no agreement"), joint training with the outer agreement ("outer"), and joint training with the inner agreement ("inner"). We find that independently trained unidirectional models hardly agree on phrase alignment, suggesting that each model can only capture partial aspects of translation modeling on non-parallel corpora. In contrast, imposing the agreement term significantly increases the agreement ratios: after 10 iterations, about 40% of phrase alignment links are shared by two models.

noise		C → E	E → C	Outer	Inner
C	E				
0	0	58.5	61.2	86.5	86.1
0	10K	41.0	54.4	83.6	83.8
0	20K	28.3	48.3	80.1	81.2
10K	0	54.7	43.1	84.9	84.3
20K	0	50.4	31.4	83.8	83.6
10K	10K	34.9	34.4	80.0	79.7
20K	20K	22.4	23.1	73.6	74.3

Table 2: Effect of noise in terms of F1 on the development set.

4.1.4 Effect of Seed Lexicon Size

Table 1 shows the F1 scores of the Chinese-to-English model ("C → E"), the English-to-Chinese model ("E → C"), joint learning based on the outer agreement ("outer"), and jointing learning based on the inner agreement ("inner") over various sizes of seed lexicons on the development set.

We find that agreement-based learning obtains substantial improvements over independent learning across all sizes. More importantly, even with a seed lexicon containing only 50 entries, agreement-based learning is able to achieve F1 scores above 60%. The inner agreement performs better than the outer agreement by taking the consensus at the word level into account.

4.1.5 Effect of Noise

Table 2 demonstrates the effect of noise on the development set. In row 1, "0+0" denotes there is no noise, which can be seen as an upper bound. Adding noise, either on the Chinese side or on the English side, deteriorates the F1 scores for all methods. Adding noise on the English side makes predicting phrase alignment in the C → E direction more challenging due to the enlarged search space. The situation is similar in the reverse direction. It is clear that agreement-based learning is more robust to noise: while independent training suffers from a reduction of 40% in terms of F1 for the "20K + 20K" setting, agreement-based learning still achieves F1 scores over 70%.

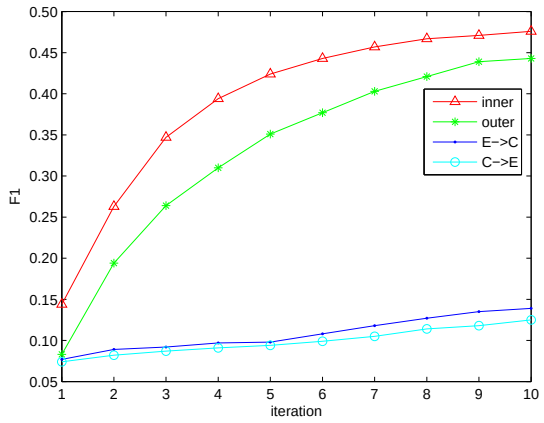

Figure 5: Comparison of F1 scores on the test set.

Chinese	*qianding bianjing maoyi xieding*
English	*signed border trade agreements*

Table 3: Example learned parallel lexicons and phrases. New words that are not included in the seed lexicon are highlighted in italic.

4.1.6 Results

Figure 5 gives the final results on the test set. We find that agreement-based training achieves significant improvements over independent training. By considering the consensus on both phrase and word alignments, the inner agreement significantly outperforms the outer agreement. Notice that Dong et al. (2015) only add noise on one side while we add noisy phrases on both sides, which makes phrase alignment more challenging.

Table 3 shows example learned parallel words and phrases. The lexicon is built from the translation table by retaining high-probability word pairs. Therefore, our approach is capable of learning both new words and new phrases unseen in the seed lexicon.

4.2 Translation Evaluation

Following Zhang and Zong (2013) and Dong et al. (2015), we evaluate our approach on domain adaptation for machine translation.

The data set consists of two in-domain non-parallel corpora and an out-domain parallel corpus. The in-domain non-parallel corpora consists of 2.65M Chinese phrases and 3.67M English phrases extracted from LDC news articles. We use a small out-domain parallel corpus extracted from financial news of FTChina which contains 10K phrase pairs. The task is to extract a parallel corpus from in-domain non-parallel corpora starting from a small out-domain parallel corpus.

We use the state-of-the-art translation system Moses (Koehn et al., 2007) and evaluate the performance on Chinese-English NIST datasets. The development set is NIST 2006 and the test set is NIST 2005. The evaluation metric is case-insensitive BLEU4 (Papineni et al., 2002). We use the SRILM toolkit (Stolcke, 2002) to train a 4-gram English language model on a monolingual corpus with 399M English words.

Table 4 shows the results. At iteration 0, only the out-domain corpus is used and the BLEU score is 5.61. All methods iteratively extract parallel phrases from non-parallel corpora and enlarge the extracted parallel corpus. We find that agreement-based learning achieves much higher BLEU scores while obtains a smaller parallel corpus as compared with independent learning. One possible reason is that the agreement-based learning rules out most unlikely phrase pairs by encouraging consensus between two models.

5 Conclusion

We have presented agreement-based training for learning parallel lexicons and phrases from non-parallel corpora. By modeling the agreement on both phrase alignment and word alignment, our approach achieves significant improvements in both alignment and translation evaluations.

In the future, we plan to apply our approach to real-world non-parallel corpora to further verify its effectiveness. It is also interesting to extend the phrase translation model to more sophisticated models such as IBM models 2-5 (Brown et al., 1993) and HMM (Vogel and Ney, 1996).

Deep Fusion LSTMs for Text Semantic Matching

Pengfei Liu, Xipeng Qiu*, Jifan Chen, Xuanjing Huang

Abstract

Recently, there is rising interest in modelling the interactions of text pair with deep neural networks. In this paper, we propose a model of deep fusion LSTMs (DF-LSTMs) to model the strong interaction of text pair in a recursive matching way. Specifically, DF-LSTMs consist of two interdependent LSTMs, each of which models a sequence under the influence of another. We also use external memory to increase the capacity of LSTMs, thereby possibly capturing more complicated matching patterns. Experiments on two very large datasets demonstrate the efficacy of our proposed architecture. Furthermore, we present an elaborate qualitative analysis of our models, giving an intuitive understanding how our model worked.

1 Introduction

Among many natural language processing (NLP) tasks, such as text classification, question answering and machine translation, a common problem is modelling the relevance/similarity of a pair of texts, which is also called text semantic matching. Due to the semantic gap problem, text semantic matching is still a challenging problem.

Recently, deep learning is rising a substantial interest in text semantic matching and has achieved some great progresses (Hu et al., 2014; Qiu and Huang, 2015; Wan et al., 2016). According to their interaction ways, previous models can be classified into three categories:

Weak interaction Models Some early works focus on sentence level interactions, such as ARC-I(Hu et al., 2014), CNTN(Qiu and Huang, 2015) and so on. These models first encode two sequences into continuous dense vectors by separated neural models, and then compute the matching score based on sentence encoding. In this paradigm, two sentences have no interaction until arriving final phase.

Semi-interaction Models Another kind of models use soft attention mechanism to obtain the representation of one sentence by depending on representation of another sentence, such as ABCNN (Yin et al., 2015), Attention LSTM (Rocktäschel et al., 2015; Hermann et al., 2015). These models can alleviate the weak interaction problem to some extent.

Strong Interaction Models Some models build the interaction at different granularity (word, phrase and sentence level), such as ARC-II (Hu et al., 2014), MultiGranCNN (Yin and Schütze, 2015), Multi-Perspective CNN (He et al., 2015), MV-LSTM (Wan et al., 2016), MatchPyramid (Pang et al., 2016). The final matching score depends on these different levels of interactions.

In this paper, we adopt a deep fusion strategy to model the strong interactions of two sentences. Given two texts $x_{1:m}$ and $y_{1:n}$, we define a matching vector $\mathbf{h}_{i,j}$ to represent the interaction of the subsequences $x_{1:i}$ and $y_{1:j}$. $\mathbf{h}_{i,j}$ depends on the matching vectors $\mathbf{h}_{s,t}$ on previous interactions $1 \leq s < i$ and $1 \leq t < j$. Thus, text matching can be regarded as modelling the interaction of two texts in a recursive matching way.

Following this idea, we propose deep fusion long short-term memory neural networks (DF-LSTMs) to model the interactions recursively. More concretely, DF-LSTMs consist of two interconnected conditional LSTMs, each of which models a piece of text under the influence of another. The output vector of DF-LSTMs is fed into a task-specific output layer to compute the match-

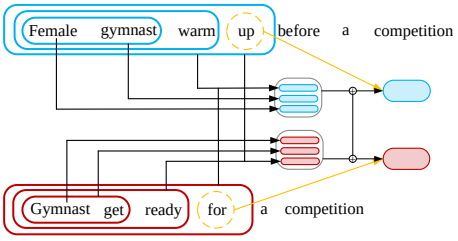

Figure 1: A motivated example to illustrate our recursive composition mechanism.

ing score.

The contributions of this paper can be summarized as follows.

1. Different with previous models, DF-LSTMs model the strong interactions of two texts in a recursive matching way, which consist of two inter- and intra-dependent LSTMs.

2. Compared to the previous works on text matching, we perform extensive empirical studies on two very large datasets. Experiment results demonstrate that our proposed architecture is more effective.

3. We present an elaborate qualitative analysis of our model, giving an intuitive understanding how our model worked.

2 Recursively Text Semantic Matching

To facilitate our model, we firstly give some definitions.

Given two sequences $X = x_1, x_2, \cdots, x_m$ and $Y = y_1, y_2, \cdots, y_n$, most deep neural models try to represent their semantic relevance by a **matching vector** $\mathbf{h}(X, Y)$, which is followed by a score function to calculate the matching score.

The weak interaction methods decompose matching vector by $\mathbf{h}(X, Y) = f(\mathbf{h}(X), \mathbf{h}(Y))$, where function $f(\cdot)$ may be one of some basic operations or the combination of them: concatenation, affine transformation, bilinear, and so on.

In this paper, we propose a strong interaction of two sequences to decompose matching vector $\mathbf{h}(X, Y)$ in a recursive way. We refer to the interaction of the subsequences $x_{1:i}$ and $y_{1:j}$ as $\mathbf{h}_{i,j}(X, Y)$, which depends on previous interactions $\mathbf{h}_{s,t}(X, Y)$ for $1 \leq s < i$ and $1 \leq t < j$.

Figure 1 gives an example to illustrate this. For sentence pair X ="`Female gymnast warm up before a competition`", Y="`Gymnast get ready for a competition`", considering the interaction ($\mathbf{h}_{4,4}$) between $x_{1:4}$ = "`Female gymnast warm up`" and $y_{1:4}$ = "`Gymnast get ready for`", which is composed by the interactions between their subsequences $(\mathbf{h}_{1,4}, \cdots, \mathbf{h}_{3,4}, \mathbf{h}_{4,1}, \cdots, \mathbf{h}_{4,3})$. We can see that a strong interaction between two sequences can be decomposed in recursive topology structure.

The matching vector $\mathbf{h}_{i,j}(X, Y)$ can be written as

$$\mathbf{h}_{i,j}(X, Y) = \mathbf{h}_{i,j}(X|Y) \oplus \mathbf{h}_{i,j}(Y|X), \quad (1)$$

where $\mathbf{h}_{i,j}(X|Y)$ refers to conditional encoding of subsequence $x_{1:i}$ influenced by $y_{1:j}$. Meanwhile, $\mathbf{h}_{i,j}(Y|X)$ is conditional encoding of subsequence $y_{1:j}$ influenced by subsequence $x_{1:i}$; $\oplus$ is concatenation operation.

These two conditional encodings depend on their history encodings. Based on this, we propose deep fusion LSTMs to model the matching of texts by recursive composition mechanism, which can better capture the complicated interaction of two sentences due to fully considering the interactions between subsequences.

3 Long Short-Term Memory Network

Long short-term memory neural network (LSTM) (Hochreiter and Schmidhuber, 1997) is a type of recurrent neural network (RNN) (Elman, 1990), and specifically addresses the issue of learning long-term dependencies. LSTM maintains a memory cell that updates and exposes its content only when deemed necessary.

While there are numerous LSTM variants, here we use the LSTM architecture used by (Jozefowicz et al., 2015), which is similar to the architecture of (Graves, 2013) but without peep-hole connections.

We define the LSTM *units* at each time step t to be a collection of vectors in $\mathbb{R}^d$: an *input gate* $\mathbf{i}_t$, a *forget gate* $\mathbf{f}_t$, an *output gate* $\mathbf{o}_t$, a *memory cell* $\mathbf{c}_t$ and a hidden state $\mathbf{h}_t$. d is the number of the LSTM units. The elements of the gating vectors $\mathbf{i}_t$, $\mathbf{f}_t$ and $\mathbf{o}_t$ are in $[0, 1]$.

The LSTM is precisely specified as follows.

$$\begin{bmatrix} \tilde{\mathbf{c}}_t \\ \mathbf{o}_t \\ \mathbf{i}_t \\ \mathbf{f}_t \end{bmatrix} = \begin{bmatrix} \tanh \\ \sigma \\ \sigma \\ \sigma \end{bmatrix} T_{\mathbf{A},\mathbf{b}} \begin{bmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{bmatrix}, \quad (2)$$

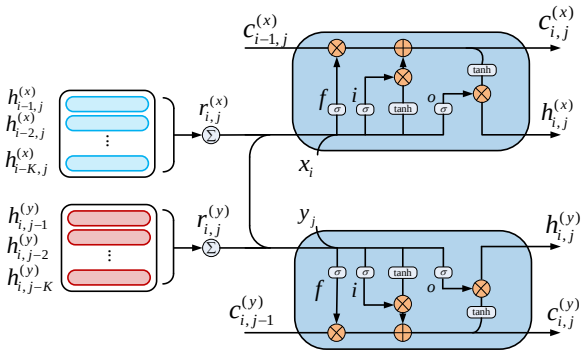

Figure 2: Illustration of DF-LSTMs unit.

$$\mathbf{c}_t = \tilde{\mathbf{c}}_t \odot \mathbf{i}_t + \mathbf{c}_{t-1} \odot \mathbf{f}_t, \quad (3)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t), \quad (4)$$

where $\mathbf{x}_t$ is the input at the current time step; $T_{\mathbf{A},\mathbf{b}}$ is an affine transformation which depends on parameters of the network $\mathbf{A}$ and $\mathbf{b}$. σ denotes the logistic sigmoid function and $\odot$ denotes elementwise multiplication. Intuitively, the forget gate controls the amount of which each unit of the memory cell is erased, the input gate controls how much each unit is updated, and the output gate controls the exposure of the internal memory state.

The update of each LSTM unit can be written precisely as

$$(\mathbf{h}_t, \mathbf{c}_t) = \mathbf{LSTM}(\mathbf{h}_{t-1}, \mathbf{c}_{t-1}, \mathbf{x}_t). \quad (5)$$

Here, the function $\mathbf{LSTM}(\cdot,\cdot,\cdot)$ is a shorthand for Eq. (2-4).

LSTM can map the input sequence of arbitrary length to a fixed-sized vector, and has been successfully applied to a wide range of NLP tasks, such as machine translation (Sutskever et al., 2014), language modelling (Sutskever et al., 2011), text matching (Rocktäschel et al., 2015) and text classification (Liu et al., 2015).

4 Deep Fusion LSTMs for Recursively Semantic Matching

To deal with two sentences, one straightforward method is to model them with two separate LSTMs. However, this method is difficult to model local interactions of two sentences.

Following the recursive matching strategy, we propose a neural model of deep fusion LSTMs (DF-LSTMs), which consists of two interdependent LSTMs to capture the inter- and intra-interactions between two sequences. Figure 2 gives an illustration of DF-LSTMs unit.

To facilitate our model, we firstly give some definitions. Given two sequences $X = x_1, x_2, \cdots, x_n$ and $Y = y_1, y_2, \cdots, y_m$, we let $\mathbf{x}_i \in \mathbb{R}^d$ denotes the embedded representation of the word x_i. The standard LSTM has one temporal dimension. When dealing with a sentence, LSTM regards the position as time step. At position i of sentence $x_{1:n}$, the output $\mathbf{h}_i$ reflects the meaning of subsequence $x_{1:i} = x_1, \cdots, x_i$.

To model the interaction of two sentences in a recursive way, we define $\mathbf{h}_{i,j}$ to represent the interaction of the subsequences $x_{1:i}$ and $y_{1:j}$, which is computed by

$$\mathbf{h}_{i,j} = \mathbf{h}^{(x)}_{i,j} \oplus \mathbf{h}^{(y)}_{i,j}, \quad (6)$$

where $\mathbf{h}^{(x)}_{i,j}$ denotes the encoding of subsequence $x_{1:i}$ in the first LSTM influenced by the output of the second LSTM on subsequence $y_{1:j}$; $\mathbf{h}^{(y)}_{i,j}$ is the encoding of subsequence $y_{1:j}$ in the second LSTM influenced by the output of the first LSTM on subsequence $x_{1:i}$.

More concretely,

$$(\mathbf{h}^{(x)}_{i,j}, \mathbf{c}^{(x)}_{i,j}) = \mathbf{LSTM}(\mathcal{H}_{i,j}, \mathbf{c}^{(x)}_{i-1,j}, \mathbf{x}_i), \quad (7)$$

$$(\mathbf{h}^{(y)}_{i,j}, \mathbf{c}^{(y)}_{i,j}) = \mathbf{LSTM}(\mathcal{H}_{i,j}, \mathbf{c}^{(y)}_{i,j-1}, \mathbf{x}_j), \quad (8)$$

where $\mathcal{H}_{i,j}$ is information consisting of history states before position (i, j).

The simplest setting is $\mathcal{H}_{i,j} = \mathbf{h}^{(x)}_{i-1,j} \oplus \mathbf{h}^{(y)}_{i,j-1}$. In this case, our model can be regarded as grid LSTMs (Kalchbrenner et al., 2015).

However, there are total $m \times n$ interactions in recursive matching process, LSTM could be stressed to keep these interactions in internal memory. Therefore, inspired by recent neural memory network, such as neural Turing machine(Graves et al., 2014) and memory network (Sukhbaatar et al., 2015), we introduce two external memories to keep the history information, which can relieve the pressure on low-capacity internal memory.

Following (Tran et al., 2016), we use external memory constructed by history hidden states, which is defined as

$$\mathbf{M}_t = \{\mathbf{h}_{t-K}, \ldots, \mathbf{h}_{t-1}\} \in \mathbb{R}^{K \times d}, \quad (9)$$

where K is the number of memory segments, which is generally instance-independent and predefined as hyper-parameter; d is the size of each segment; and $\mathbf{h}_t$ is the hidden state at time t emitted by LSTM.

At position i, j, two memory blocks $\mathbf{M}^{(x)}, \mathbf{M}^{(y)}$ are used to store contextual information of x and y respectively.

$$\mathbf{M}_{i,j}^{(x)} = \{\mathbf{h}_{i-K,j}^{(x)}, \ldots, \mathbf{h}_{i-1,j}^{(x)}\}, \quad (10)$$

$$\mathbf{M}_{i,j}^{(y)} = \{\mathbf{h}_{i,j-K}^{(y)}, \ldots, \mathbf{h}_{i,j-1}^{(y)}\}, \quad (11)$$

where $\mathbf{h}^{(x)}$ and $\mathbf{h}^{(x)}$ are outputs of two conditional LSTMs at different positions.

The history information can be read from these two memory blocks. We denote a read vector from external memories as $\mathbf{r}_{i,j} \in \mathbb{R}^d$, which can be computed by soft attention mechanisms.

$$\mathbf{r}_{i,j}^{(x)} = \mathbf{a}_{i,j}^{(x)} \mathbf{M}_{i,j}^{(x)}, \quad (12)$$

$$\mathbf{r}_{i,j}^{(y)} = \mathbf{a}_{i,j}^{(y)} \mathbf{M}_{i,j}^{(y)}, \quad (13)$$

where $\mathbf{a}_{i,j} \in \mathbb{R}^K$ represents attention distribution over the corresponding memory $\mathbf{M}_{i,j} \in \mathbb{R}^{K \times d}$.

More concretely, each scalar $a_{i,j,k}$ in attention distribution $\mathbf{a}_{i,j}$ can be obtained:

$$a_{i,j,k}^{(x)} = \text{softmax}(g(\mathbf{M}_{i,j,k}^{(x)}, \mathbf{r}_{i-1,j}^{(x)}, \mathbf{x}_i)), \quad (14)$$

$$a_{i,j,k}^{(y)} = \text{softmax}(g(\mathbf{M}_{i,j,k}^{(y)}, \mathbf{r}_{i,j-1}^{(y)}, \mathbf{y}_j)), \quad (15)$$

where $\mathbf{M}_{i,j,k} \in \mathbb{R}^d$ represents the k-th row memory vector at position (i, j), and $g(\cdot)$ is an align function defined by

$$g(\mathbf{x}, \mathbf{y}, \mathbf{z}) = \mathbf{v}^T \tanh(\mathbf{W}_a[\mathbf{x}; \mathbf{y}, \mathbf{z}]), \quad (16)$$

where $\mathbf{v} \in \mathbb{R}^d$ is a parameter vector and $\mathbf{W}_a \in \mathbb{R}^{d \times 3d}$ is a parameter matrix.

The history information $\mathcal{H}_{i,j}$ in Eq (7) and (8) is computed by

$$\mathcal{H}_{i,j} = \mathbf{r}_{i,j}^{(x)} \oplus \mathbf{r}_{i,j}^{(y)}. \quad (17)$$

By incorporating external memory blocks, DF-LSTMs allow network to re-read history interaction information, therefore it can more easily capture complicated and long-distance matching patterns. As shown in Figure 3, the forward pass of DF-LSTMs can be unfolded along two dimensional ordering.

4.1 Related Models

Our model is inspired by some recently proposed models based on recurrent neural network (RNN).

One kind of models is multi-dimensional recurrent neural network (MD-RNN) (Graves et al., 2007; Graves and Schmidhuber, 2009; Byeon et al., 2015) in machine learning and computer vision communities. As mentioned above, if we just use the neighbor states, our model can be regarded as grid LSTMs (Kalchbrenner et al., 2015).

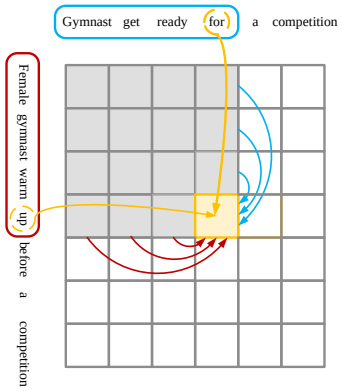

Figure 3: Illustration of unfolded DF-LSTMs.

What is different is the dependency relations between the current state and history states. Our model uses external memory to increase its memory capacity and therefore can store large useful interactions of subsequences. Thus, we can discover some matching patterns with long dependence.

Another kind of models is memory augmented RNN, such as long short-term memory-network (Cheng et al., 2016) and recurrent memory network (Tran et al., 2016), which extend memory network (Bahdanau et al., 2014) and equip the RNN with ability of re-reading the history information. While they focus on sequence modelling, our model concentrates more on modelling the interactions of sequence pair.

5 Training

5.1 Task Specific Output

There are two popular types of text matching tasks in NLP. One is ranking task, such as community question answering. Another is classification task, such as textual entailment.

We use different ways to calculate matching score for these two types of tasks.

1. For ranking task, the output is a scalar matching score, which is obtained by a linear transformation of the matching vector obtained by FD-LSTMs.

2. For classification task, the outputs are the probabilities of the different classes, which

is computed by a softmax function on the matching vector obtained by FD-LSTMs.

5.2 Loss Function

Accordingly, we use two loss functions to deal with different sentence matching tasks.

Max-Margin Loss for Ranking Task Given a positive sentence pair (X, Y) and its corresponding negative pair $(X, \hat{Y})$. The matching score $s(X, Y)$ should be larger than $s(X, \hat{Y})$.

For this task, we use the contrastive max-margin criterion (Bordes et al., 2013; Socher et al., 2013) to train our model on matching task.

The ranking-based loss is defined as

$$L(X, Y, \hat{Y}) = max(0, 1 - s(X, Y) + s(X, \hat{Y})). \quad (18)$$

where $s(X, Y)$ is predicted matching score for (X, Y).

Cross-entropy Loss for Classification Task Given a sentence pair (X, Y) and its label l. The output $\hat{l}$ of neural network is the probabilities of the different classes. The parameters of the network are trained to minimise the cross-entropy of the predicted and true label distributions.

$$L(X, Y; \boldsymbol{l}, \hat{\boldsymbol{l}}) = -\sum_{j=1}^{C} \boldsymbol{l}_j \log(\hat{\boldsymbol{l}}_j), \quad (19)$$

where $\boldsymbol{l}$ is one-hot representation of the ground-truth label l; $\hat{\boldsymbol{l}}$ is predicted probabilities of labels; C is the class number.

5.3 Optimizer

To minimize the objective, we use stochastic gradient descent with the diagonal variant of AdaGrad (Duchi et al., 2011).

To prevent exploding gradients, we perform gradient clipping by scaling the gradient when the norm exceeds a threshold (Graves, 2013).

5.4 Initialization and Hyperparameters

Orthogonal Initialization We use orthogonal initialization of our LSTMs, which allows neurons to react to the diverse patterns and is helpful to train a multi-layer network (Saxe et al., 2013).

Unsupervised Initialization The word embeddings for all of the models are initialized with the 100d GloVe vectors (840B token version, (Pennington et al., 2014)). The other parameters are initialized by randomly sampling from uniform distribution in $[-0.1, 0.1]$.

Hyper-parameters	MQA	RTE
K	9	9
Embedding size	100	100
Hidden layer size	50	100
Initial learning rate	0.05	0.005
Regularization	$5E{-}5$	$1E{-}5$

Table 1: Hyper-parameters for our model on two tasks.

Hyperparameters For each task, we used a stacked DF-LSTM and take the hyperparameters which achieve the best performance on the development set via an small grid search over combinations of the initial learning rate $[0.05, 0.0005, 0.0001]$, l_2 regularization $[0.0, 5E{-}5, 1E{-}5, 1E{-}6]$ and the values of K $[1, 3, 6, 9, 12]$. The final hyper-parameters are set as Table 1.

6 Experiment

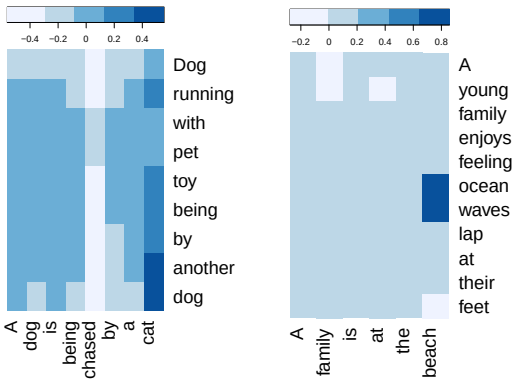
In this section, we investigate the empirical performances of our proposed model on two different text matching tasks: classification task (recognizing textual entailment) and ranking task (matching of question and answer).

6.1 Competitor Methods

- Neural bag-of-words (NBOW): Each sequence is represented as the sum of the embeddings of the words it contains, then they are concatenated and fed to a MLP.
- Single LSTM: Two sequences are encoded by a single LSTM, proposed by (Rocktäschel et al., 2015).
- Parallel LSTMs: Two sequences are first encoded by two LSTMs separately, then they are concatenated and fed to a MLP.
- Attention LSTMs: Two sequences are encoded by LSTMs with attention mechanism, proposed by (Rocktäschel et al., 2015).
- Word-by-word Attention LSTMs: An improved strategy of attention LSTMs, which introduces word-by-word attention mechanism and is proposed by (Rocktäschel et al., 2015).

Model	k	Train	Test
NBOW	100	77.9	75.1
single LSTM (Rocktäschel et al., 2015)	100	83.7	80.9
parallel LSTMs (Bowman et al., 2015)	100	84.8	77.6
Attention LSTM (Rocktäschel et al., 2015)	100	83.2	82.3
Attention(w-by-w) LSTM (Rocktäschel et al., 2015)	100	83.7	83.5
DF-LSTMs	100	85.2	**84.6**

Table 2: Accuracies of our proposed model against other neural models on SNLI corpus.



(a) 5-th neuron (b) 11-th neuron

Figure 4: Illustration of two interpretable neurons and some word-pairs captured by these neurons. The darker patches denote the corresponding activations are higher.

6.2 Experiment-I: Recognizing Textual Entailment

Recognizing textual entailment (RTE) is a task to determine the semantic relationship between two sentences. We use the Stanford Natural Language Inference Corpus (SNLI) (Bowman et al., 2015). This corpus contains 570K sentence pairs, and all of the sentences and labels stem from human annotators. SNLI is two orders of magnitude larger than all other existing RTE corpora. Therefore, the massive scale of SNLI allows us to train powerful neural networks such as our proposed architecture in this paper.

6.2.1 Results

Table 2 shows the evaluation results on SNLI. The 2nd column of the table gives the number of hidden states.

From experimental results, we have several experimental findings.

The results of DF-LSTMs outperform all the competitor models with the same number of hidden states while achieving comparable results to the state-of-the-art and using much fewer parameters, which indicate that it is effective to model the strong interactions of two texts in a recursive matching way.

All models outperform NBOW by a large margin, which indicate the importance of words order in semantic matching.

The strong interaction models surpass the weak interaction models, for example, compared with parallel LSTMs, DF-LSTMs obtain improvement by 7.0%.

6.2.2 Understanding Behaviors of Neurons in DF-LSTMs

To get an intuitive understanding of how the DF-LSTMs work on this problem, we examined the neuron activations in the last aggregation layer while evaluating the test set. We find that some cells are bound to certain roles.

We refer to $h_{i,j,k}$ as the activation of the k-th neuron at the position of (i, j), where $i \in \{1, \ldots, n\}$ and $j \in \{1, \ldots, m\}$. By visualizing the hidden state $\mathbf{h}_{i,j,k}$ and analyzing the maximum activation, we can find that there exist multiple interpretable neurons. For example, when some contextualized local perspectives are semantically related at point (i, j) of the sentence pair, the activation value of hidden neuron $h_{i,j,k}$ tends to be maximum, meaning that the model could capture some reasoning patterns.

Figure 4 illustrates this phenomenon. In Figure 4(a), a neuron shows its ability to monitor the word pairs with the property of describing different things of the same type.

The activation in the patch, containing the word pair "`(cat, dog)`", is much higher than others. This is an informative pattern for the relation prediction of these two sentences, whose ground truth is contradiction. An interesting thing is there are two "`dog`" in sentence "`Dog running with pet toy being by another dog`". Our model ignores the useless word, which indicates this neuron selectively captures pattern by contextual understanding, not just word level interaction.

In Figure 4(b), another neuron shows that it can capture the local contextual interactions, such as "`(ocean waves, beach)`". These patterns can be easily captured by final layer and provide a strong support for the final prediction.

Index of Cell	Word or Phrase Pairs	Explanation
5-th	(jeans, shirt), (dog, cat) (retriever, cat), (stand, sitting)	different entities or events of the same type
11-th	(pool, swimming), (street, outside) (animal, dog), (grass,outside)	word pair related to lexical entailment
20-th	(skateboard, skateboarding), (running, runs) (advertisement, ad), (grassy, grass)	words with different morphology
49-th	(blue, blue), (wearing black, wearing white), (green uniform, red uniform)	words related to color
55-th	(a man, two other men), (a man, two girls) (Two women, No one)	subjects with singular or plural forms

Table 3: Multiple interpretable neurons and the word-pairs/phrase-pairs captured by these neurons. The third column gives the explanations of corresponding neuron's behaviours.

Table 3 illustrates multiple interpretable neurons and some representative word or phrase pairs which can activate these neurons. These cases show that our model can capture contextual interactions beyond word level.

6.2.3 Case Study for Attention Addressing Mechanism

External memory with attention addressing mechanism enables the network explicitly to utilize the history information of two sentences simultaneously. As a by-product, the obtained attention distribution over history hidden states also help us interpret the network and discover underlying dependencies present in the data.

To this end, we randomly sample two good cases with entailment relation from test data and visualize attention distributions over external memory constructed by last 9 hidden states. As shown in Figure 5(a), For the first sentence pair, when the word pair "`(competition, competition)`" are processed, the model simultaneously selects "`warm, before`" from one sentence and "`gymnast,ready,for`" from the other, which are informative patterns and indicate our model has the capacity of capturing phrase-phrase pair.

Another case in Figure 5(b) also shows by attention mechanism, the network can sufficiently utilize the history information and the fusion approach allows two LSTMs to share the history information of each other.

6.2.4 Error Analysis

Although our model DF-LSTMs are more sensitive to the discrepancy of the semantic capacity between two sentences, some cases still can not be solved by our model. For example, our model gives a wrong prediction of the sentence pair "`A golden retriever nurses puppies/Puppies next to their mother`", whose ground truth is entailment. The model fails to realize "`nurses`" means "`next to`".

Besides, despite the large size of the training corpus, it's still very difficult to solve some cases, which depend on the combination of the world knowledge and context-sensitive inferences. For example, given an entailment pair "`Several women are playing volleyball/The women are hitting a ball with their arms`", all models predict "`neutral`".

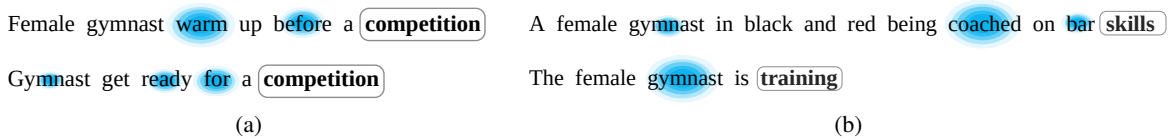
These analysis suggests that some architectural improvements or external world knowledge are necessary to eliminate all errors instead of simply scaling up the basic model.

6.3 Experiment-II: Matching Question and Answer

Matching question answering (MQA) is a typical task for semantic matching (Zhou et al., 2013). Given a question, we need select a correct answer from some candidate answers.

In this paper, we use the dataset collected from Yahoo! Answers with the getByCategory function provided in Yahoo! Answers API, which produces $963,072$ questions and corresponding best answers. We then select the pairs in which the length of questions and answers are both in the interval $[4, 30]$, thus obtaining $220,000$ question answer pairs to form the positive pairs.

For negative pairs, we first use each question's best answer as a query to retrieval top $1,000$ re-



(a) (b)

Figure 5: Examples of external memory positions attended when encoding the next word pair (bold and marked by a box)

Model	k	P@1(5)	P@1(10)
Random Guess	-	20.0	10.0
NBOW	50	63.9	47.6
single LSTM	50	68.2	53.9
parallel LSTMs	50	66.9	52.1
Attention LSTMs	50	73.5	62.0
Attention(w-by-w) LSTMs	50	75.1	64.0
DF-LSTMs	50	**76.5**	**65.0**

Table 4: Results of our proposed model against other neural models on Yahoo! question-answer pairs dataset.

sults from the whole answer set with Lucene, where 4 or 9 answers will be selected randomly to construct the negative pairs.

The whole dataset[1] is divided into training, validation and testing data with proportion $20:1:1$. Moreover, we give two test settings: selecting the best answer from 5 and 10 candidates respectively.

6.3.1 Results

Results of MQA are shown in the Table 4. we can see that the proposed model also shows its superiority on this task, which outperforms the state-of-the-arts methods on both metrics (P@1(5) and P@1(10)) with a large margin.

By analyzing the evaluation results of question-answer matching in Table 4, we can see strong interaction models (attention LSTMs, our DF-LSTMs) consistently outperform the weak interaction models (NBOW, parallel LSTMs) with a large margin, which suggests the importance of modelling strong interaction of two sentences.

7 Related Work

Our model can be regarded as a strong interaction model, which has been explored in previous methods.

One kind of methods is to compute similarities between all the words or phrases of the two sentences to model multiple-granularity interactions of two sentences, such as RAE (Socher et al., 2011), Arc-II (Hu et al., 2014),ABCNN (Yin et al., 2015),MultiGranCNN (Yin and Schütze, 2015), Multi-Perspective CNN (He et al., 2015), MV-LSTM (Wan et al., 2016).

Socher et al. (2011) firstly used this paradigm for paraphrase detection. The representations of words or phrases are learned based on recursive autoencoders.

Hu et al. (2014) proposed to an end-to-end architecture with convolutional neural network (Arc-II) to model multiple-granularity interactions of two sentences.

Wan et al. (2016) used LSTM to enhance the positional contextual interactions of the words or phrases between two sentences. The input of LSTM for one sentence does not involve another sentence.

Another kind of methods is to model the conditional encoding, in which the encoding of one sentence can be affected by another sentence. Rocktäschel et al. (2015) and Wang and Jiang (2015) used LSTM to read pairs of sequences to produce a final representation, which can be regarded as interaction of two sequences. By incorporating an attention mechanism, they got further improvements to the predictive abilities.

Different with these two kinds of methods, we model the interactions of two texts in a recursively matching way. Based on this idea, we propose a model of deep fusion LSTMs to accomplish recursive conditional encodings.

8 Conclusion and Future Work

In this paper, we propose a model of deep fusion LSTMs to capture the strong interaction for text semantic matching. Experiments on two large scale text matching tasks demonstrate the efficacy of our proposed model and its superiority to competitor models. Besides, our visualization analysis revealed that multiple interpretable neurons in our model can capture the contextual interactions of the words or phrases.

[1] http://nlp.fudan.edu.cn/data/.

In future work, we would like to investigate our model on more text matching tasks.

Abstract

We construct a humans-in-the-loop supervised learning framework that integrates crowdsourcing feedback and local knowledge to detect job-related tweets from individual and business accounts. Using data-driven ethnography, we examine discourse about work by fusing language-based analysis with temporal, geospatial, and labor statistics information.

1 Introduction

Work plays a major role in nearly every facet of our lives. Negative and positive experiences at work places can have significant social and personal impacts. Employment condition is an important social determinant of health. But how exactly do jobs influence our lives, particularly with respect to well-being? Many theories address this question (Archambault and Grudin, 2012; Schaufeli and Bakker, 2004), but they are hard to validate as well-being is influenced by many factors, including geography as well as social and institutional support.

Can computers help us understand the complex relationship between work and well-being? Both are broad concepts that are difficult to capture objectively (for instance, the unemployment rate as a statistic is continually redefined) and thus challenging subjects for computational research.

Our first contribution is to propose a classification framework for such broad concepts as work that alternates between humans-in-the-loop annotation and machine learning over multiple iterations to simultaneously clarify human understanding of these concepts and automatically determine whether or not posts from public social media sites are about work. Our framework balances the effectiveness of crowdsourced workers with local experience, evaluates the degree of subjectivity throughout the process, and uses an iterative post-hoc evaluation method to address the problem of discovering gold standard data. Our performance (on an open-domain problem) demonstrates the value of our humans-in-the-loop approach which may be of special relevance to those interested in discourse understanding, particularly settings characterized by high levels of subjectivity, where integrating human intelligence into active learning processes is essential.

Our second contribution is to use our classifiers to study job-related discourse on social media using data-driven ethnography. Language is fundamentally a social phenomenon, and social media gives us a lens through which to observe a very particular form of discourse in real time. We add depth to the NLP analysis by gathering data from specific geographical regions to study discourse along a broad spectrum of interacting social groups, using work as a framing device, and we fuse language-based analysis with temporal, geospatial and labor statistics dimensions.

2 Background and Related Work

Though not the first study of job-related social media, prior ones used data from large companies' internal sites, whose users were employees (De Choudhury and Counts, 2013; Yardi et al., 2008; Kolari et al., 2007; Brzozowski, 2009). An obvious limitation in that case is it excludes populations without access to such restricted networks. Moreover, workers may not disclose true feelings about their jobs on such sites, since their employ-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1044–1053,
Berlin, Germany, August 7-12, 2016.

ers can easily monitor them. On the other hand, we show that on Twitter, it is quite common for tweets to relate negative feelings about work ("*I don't wanna go to work today*"), unprofessional behavior ("*Got drunk as hell last night and still made it to work*"), or a desire to work elsewhere ("*I want to go work at Disney World so bad*").

Nonetheless, these studies inform our work. DeChoudhury et al. (2013) investigated the landscape of emotional expression of the employees via enterprise internal microblogging. Yardi et al. (2008) examined temporal aspects of blogging usage within corporate internal blogging community. Kolari et al. (2007) characterized comprehensively how behaviors expressed in posts impact a company's internal social networks. Brzozowski (2009) described a tool that aggregated shared internal social media which when combined with its enterprise directory added understanding the organization and employees connections.

From a theoretical perspective, the Job Demands-Resources Model (Schaufeli and Bakker, 2004) suggests that job demands (e.g., overworked, dissonance, and conflict) lead to burnout and disengagement while resources (e.g., appreciation, cohesion, and safety) often result in satisfaction and productivity. Although burnout and engagement have an inverse relationship, these states fluctuate and can vary over time. In 2014, more than two-thirds of U.S. workers were disengaged at work (Gallup, 2015a) and this disconnection costs the U.S. up to $398 billion annually in lost work and medical treatment (Gallup, 2015b). Indeed, job dissatisfaction poses serious health risks and has even been linked to suicide (Hazards Magazine, 2014). Thus, examining social media for job-related messages provides a novel opportunity to study job discourse and associated demands and resources. Moreover, the declarative and affective tone of these tweets may have important implications for understanding the relationship between burnout and engagement with such public health concerns as mental health.

3 Humans-in-the-Loop Classification

From July 2013 to June 2014 we collected over 7M geo-tagged tweets from around 85,000 public accounts in a 15-county around a midsized city using DataSift[1]. We removed punctuation and special characters, and used the Internet Slang Dictionary[2] to normalize nonstandard terms.

Figure 1 shows our humans-in-the-loop framework for learning classifiers to identify job-related posts. It consists of four rounds of machine classification – similar to that of Li et al. (2014) except that our rounds are not as uniform – where the classifier in each round acts as a filter on our training data, providing human annotators a sample of Twitter data to label and (except for the final round) using these labeled data to train the classifiers in later rounds.

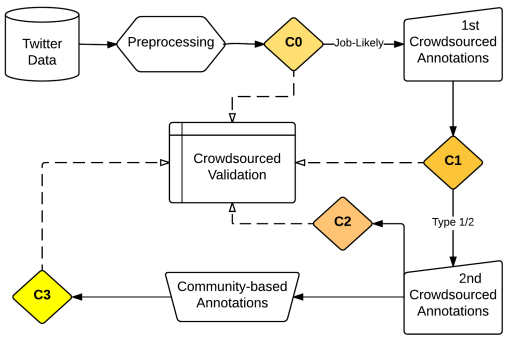

Figure 1: Flowchart of our humans-in-the-loop framework, laid out in Section 3.

The initial classifier C_0 is a simple term-matching filter; see Table 1 (number options were considered for some terms). The other classifiers (C_1, C_2, C_3) are SVMs that use a feature space of n-grams from the training set.

Include	job, jobless, manager, boss my/your/his/her/their/at work
Exclude	school, class, homework, student, course finals, good/nice/great job, boss ass[3]

Table 1: C_0 rules identifying *Job-Likely* tweets.

Round 1. We ran C_0 on our dataset. Approximately 40K tweets having at least five tokens passed this filter. We call them *Job-Likely tweets*. We randomly chose around 2,000 *Job-Likely* tweets and split them evenly into 50 AMT Human Intelligence Tasks (HITs), and further randomly duplicated five tweets in each HIT to evaluate each worker's consistency. Five crowdworkers assigned to each HIT[4] answered, for each tweet,

[1] http://datasift.com/

[2] http://www.noslang.com/dictionary

[3] Describe something awesome in a sense of utter dominance, magical superiority, or being ridiculously good.

[4] This is based on empirical insights for crowdsourced annotation tasks (Callison-Burch, 2009; Evanini et al., 2010).

the question: *Is this tweet about job or employment?* All crowdworkers lived in the U.S. and had an approval rating of 90% or better. They were paid $1.00 per HIT[5]. We assessed inter-annotator reliability among the five annotators in each HIT using Geertzen's tool (Geertzen, 2016).

This yielded 1,297 tweets where all 5 annotators agreed on the same label (Table 2). To balance our training data, we added 757 tweets chosen randomly from tweets outside the *Job-Likely* set that we labeled not job-related. C_1 trained on this set.

Round 2. Our goal was to collect 4,000 more labeled tweets that, when combined with the Round 1 training data, would yield a class-balanced set. Using C_1 to perform regression, we ranked the tweets in our dataset by the confidence score (Chang and Lin, 2011). We then spot-checked the tweets to estimate the frequency of job-related tweets as the confidence score increases. We discovered that among the top-ranked tweets about half, and near the separating hyperplane (i.e., where the confidence scores are near zero) almost none, are job-related.

Based on these estimates, we randomly sampled 2,400 tweets from those in the top 80th percentile of confidence scores (*Type-1*). We then randomly sampled about 800 tweets each from the first deciles of tweets greater and lesser than zero, respectively (*Type-2*).

The rationale for drawing from these two groups was that the false Type-1 tweets represent those on which the C_1 classifier most egregiously fails, and the Type-2 tweets are those closest to the feature vectors and those toward which the classifier is most sensitive.

Crowdworkers again annotated these tweets in the same fashion as in Round 1 (see Table 3), and cross-round comparisons are in Tables 2 and 4. We trained C_2 on all tweets from Round 1 and 2 with unanimous labels (bold in Table 2).

AMTs	job-related			not job-related		
	3	4	5	3	4	5
Round 1	104	389	**1027**	78	116	**270**
Round 2	140	287	**721**	66	216	**2568**

Table 2: Summary of both annotation rounds.

[5]We consulted with Turker Nation (`http://www.turkernation.com`) to ensure that the workers were treated and compensated fairly for their tasks. We also rewarded annotators based on the qualities of their work.

Round 2	job-related			not job-related		
	3	4	5	3	4	5
Type-1	129	280	713	50	149	1079
Type-2	11	7	8	16	67	1489

Table 3: Summary of tweet labels in Round 2 by confidence type (showing when 3/4/5 of 5 annotators agreed).

AMTs	Fleiss' kappa	Krippendorf's alpha
Round 1	0.62 ± 0.14	0.62 ± 0.14
Round 2	0.81 ± 0.09	0.81 ± 0.08

Table 4: Average $\pm$ stdev agreement from Round 1 and 2 are *Good*, *Very Good* (Altman, 1991).

Annotations	Sample Tweet
Y Y Y Y Y	Really bored....., no entertainment at work today
Y Y Y Y N	two more days of work then I finally get a day off.
Y Y Y N N	Leaving work at 430 and driving in this snow is going to be the death of me
Y Y N N N	Being a mommy is the hardest but most rewarding job a women can have #babyBliss #babybliss
Y N N N N	These refs need to DO THEIR FUCKING JOBS
N N N N N	One of the best Friday nights I've had in a while

Table 5: Inter-annotator agreement combinations with sample tweets. Y denotes job-related. Cases where the majority (not all) annotators agreed (3/4 out of 5) are underlined in bold.

Round 3. Two coauthors with prior experience from the local community reviewed instances from Round 1 and 2 on which crowdworkers disagreed (highlighted in Table 5) and provided labels. Cohen's kappa agreement was high: κ = 0.80. Combined with all labeled data from the previous rounds this yielded 2,670 gold-standard-labeled job-related and 3,250 not job-related tweets. We trained C_3 on this entire set. Since it is not strictly class-balanced, we grid-searched on a range of class weights and chose the estimator that optimized F1 score, using 10-fold cross validation[6]. Table 6 shows C_3's top-weighted features, which reflect the semantic field of work for the job-related class.

[6]These scores were determined respectively using the mean score over the cross-validation folds. The parameter settings that gave the best results on the left out data were a linear kernel with penalty parameter $C = 0.1$ and class weight ratio of 1:1.

job-related	weights	not job-related	weights
work	2.026	did	-0.714
job	1.930	amazing	-0.613
manager	1.714	nut	-0.600
jobs	1.633	hard	-0.571
managers	1.190	constr	-0.470
working	0.827	phone	-0.403
bosses	0.500	doing	-0.403
lovemyjob	0.500	since	-0.373
shift	0.487	brdg	-0.363
worked	0.410	play	-0.348
paid	0.374	its	-0.337
worries	0.369	think	-0.330
boss	0.369	thru	-0.329
seriously	0.368	hand	-0.321
money	0.319	awesome	-0.319

Table 6: Top 15 features for both classes of C_3.

Discovering Businesses. Manual examination of job-related tweets revealed patterns like: *Panera Bread: Baker – Night (#LOCATION) http://URL #Hospitality #VeteranJob #Job #Jobs #TweetMyJobs*. Nearly all tweets that contained at least one of these hashtags: *#veteranjob*, *#job*, *#jobs*, *#tweetmyjobs*, *#hiring*, *#retail*, *#realestate*, *#hr* also included a URL, which spot-checking revealed nearly always led to a recruitment website (see Table 7). This led to an effective heuristic to separate individual from business accounts only for posts that have first been classified as job-related: if an account had more job-related tweets with any of the above hashtags + URL patterns, we labeled it *business*; otherwise *individual*.

	hashtag only	hashtag + URL
#veteranjob	18,066	18,066
#job	79,362	79,327
#jobs	58,637	58,631
#tweetmyjobs	39,007	39,007
#hiring	148	147
#retail	17,037	17,035
#realestate	92	92
#hr	400	399

Table 7: Counts of hashtags queried, and counts of their subsets with hashtags coupled with URL.

4 Results and Discussion

Crowdsourced Validation The fundamental difficulty in open-domain classification problems such as this one is there is no gold-standard data to hold out at the beginning of the process. To address this, we adopted a post-hoc evaluation where we took balanced sets of labeled tweets from each classifier (C_0, C_1, C_2 and C_3) and asked AMT workers to label a total of 1,600 samples, taking the majority votes (where at least 3 out of 5 crowdworkers agreed) as reference labels. Our results (Table 8) show that C_3 performs the best, and significantly better than C_0 and C_1.

Estimating Effective Recall The two machine-labeled classes in our test data are roughly balanced, which is not the case in real-world scenarios. We estimated the effective recall under the assumption that the error rates in our test samples are representative of the entire dataset. Let y be the total number of the classifier-labeled "positive" elements in the entire dataset and n be the total of "negative" elements. Let y_t be the number of classifier-labeled "positive" tweets in our $1,600$-samples test set and let $n_t = 1,600 - y_t$. Then the estimated effective recall $\hat{R} = \frac{y \cdot n_t \cdot R}{y \cdot n_t \cdot R + n \cdot y_t \cdot (1-R)}$.

Model	Class	P	R	$\hat{\mathbf{R}}$	F1
C_0	job	0.72	0.33	0.01	0.45
	notjob	0.68	0.92	1.00	0.78
C_1	job	0.79	0.82	0.15	0.80
	notjob	0.88	0.86	0.99	0.87
C_2	job	0.82	0.95	0.41	0.88
	notjob	0.97	0.86	0.99	0.91
C_3	job	0.83	0.96	0.45	0.89
	notjob	0.97	0.87	0.99	0.92

Table 8: Crowdsourced validations of instances identified by 4 distinct models (1,600 total tweets).

Assessing Business Classifier For Table 8's tweets labeled by $C_0 - C_3$ as job-related, we asked AMT workers: *Is this tweet more likely from a personal or business account?* Table 9 shows that this method was quite accurate.

From	Class	P	R	F1
C_0	individual	0.86	1.00	0.92
	business	0.00	0.00	0.00
	avg/total	*0.74*	*0.86*	*0.79*
C_1	individual	1.00	0.97	0.98
	business	0.98	1.00	0.99
	avg/total	*0.99*	*0.99*	*0.99*
C_2	individual	1.00	0.98	0.99
	business	0.98	1.00	0.99
	avg/total	*0.99*	*0.99*	*0.99*
C_3	individual	1.00	0.99	0.99
	business	0.99	1.00	0.99
	avg/total	*0.99*	*0.99*	*0.99*

Table 9: Crowdsourced validations of individuals vs. businesses job-related tweets.

Our explanation for the strong performance of the business classifier is that the class of job-related tweets is relatively rare, and so by applying the classifier only to job-related tweets we sim-

plify the individual-or-business problem dramatically. Another, perhaps equally effective, simplification is that our tweets are geo-specific and so we automatically filter out business tweets from, e.g., national media.

Generalizability Tests Can our best model C_3 discover job-related tweets from other geographical regions, even though it was trained on data from one specific region? We repeated the tests above on 400 geo-tagged tweets from Detroit (balanced between job-related and not). Table 10 shows that C_3 and the business classifier generalize well to another region. This suggests the transferability of our humans-in-the-loop classification framework and of heuristic to separate individual from business accounts for tweets classified as job-related.

Model	Class	P	R	F1
C_3	job	0.85	0.99	0.92
	notjob	0.99	0.87	0.93
Heuristic	individual	1.00	0.96	0.98
	business	0.96	1.00	0.98
	avg/total	*0.98*	*0.98*	*0.98*

Table 10: Validations of C_3 and business classifier on Detroit data.

5 Understanding Job-Related Discourse

Using the job-related tweets – from both individual and business accounts – extracted by C_3 from the July 2013-June 2014 dataset (see Table 12), we conducted the following analyses.

C_3 Versus C_0 The fact that C_3 outperforms C_0 demonstrates our humans-in-the-loop framework is necessary and effective compared to an intuitive term-matching filter. We further examined the messages labeled as job-related by C_3, but not captured by C_0. More than 160,000 tweets fell into this *Difference* set, in which approximately 85,000 tweets are from individual accounts while the rest are from business accounts. Table 11 shows the top 3 most frequent uni-, bi-, and trigrams in the *Difference* dataset. These n-grams from the individual group suggest that people often talk about job-related topics while mentioning temporal information or announcing their working schedules. We neglected such time-related phrases when defining C_0. In contrast, the frequencies of the listed n-grams in the business group are much higher than those in the individual group. This indicates that our definitions of inclusion terms in C_0 did not capture a considerable amount of posts involving broad job-related topics, which is also reflected in Table 9: our business classifier did not find business accounts from the job-related tweets extracted by C_0.

Individual	Business
Unigrams	
day, 6989	ny, 83907
today, 5370	#job, 75178
good, 4245	#jobs, 55105
Bigrams	
last night, 359	#jobs #tweetmyjobs, 32165
getting ready, 354	#rochester ny, 22101
first day, 296	#job #jobs, 16923
Trigrams	
working hour shift, 51	#job #jobs #tweetmyjobs, 12004
first day back, 48	ny #jobs #tweetmyjobs, 4955
separate leader follower, 44	ny #retail #job, 4704

Table 11: Top 3 most frequent uni-, bi-, and trigrams with frequencies in the *Difference* set.

Hashtags Individuals posted 11,935 unique hashtags and businesses only 414. The top 250 hashtags from each group are shown in Figure 2.

Figure 2: Hashtags in job-related tweets: above – individual accounts; below – business accounts.

Individual users used an abbreviation for the name of the midsized city to mark their location,

and *fml*[7] to express personal embarrassing stories. *Work* and *job* are self-explanatory. *Money*, *motivation* relates to jobs. *Tired*, *exhausted*, *fuck*, *insomnia*, *bored*, *struggle* express negative conditions. Likewise, *lovemyjob*, *happy*, *awesome*, *excited*, *yay*, *tgif*[8] convey positive affects experienced from jobs. Business accounts exhibit distinct patterns. Besides the hashtags queried (Table 7), we saw local place names, like *corning*, *rochester*, *batavia*, *pittsford*, and regional ones like *syracuse*, *ithaca*. *Customerservice*, *nursing*, *accounting*, *engineering*, *hospitality*, *construction* record occupations, while *kellyjobs*, *familydollar*, *cintasjobs*, *cfgjobs*, *searsjobs* point to business agents. Unlike individual users, businesses do not use hashtags reflecting affective expressions.

Linguistic Differences We used the TweetNLP POS tagger (Gimpel et al., 2011). Figure 3 shows nine part-of-speech tag[9] frequencies for three subsets of tweets.

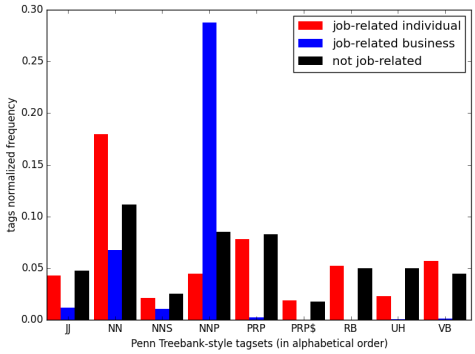

Figure 3: POS tag comparisons (normalized, averaged) among three subsets of tweets: job-related tweets from individual accounts (red), job-related tweets from business accounts (blue) and not job-related tweets (black).

Business accounts use NNPs more than individuals, perhaps because they often advertise job openings at specific locations, like *New York*, *Sears*. Individuals use NNPs less frequently and in a more casual way, e.g., *Jojo*, *galactica*, *Valli*. Also, individuals use JJ, NN, NNS, PRP, PRP$, RB, UH, and VB more regularly than business accounts do. Not job-related tweets have similar patterns to job-related ones from individual accounts, suggesting that individual users exhibit analogous language habits regardless of topic.

Temporal Patterns Our findings that individual users frequently used time-related n-grams (Table 11) prompted us to examine the temporal patterns of job discourse.

Figure 4a suggests that individuals talk about jobs the most in December and January (which also have the most tweets over other topics), and the least in the warmer months. July witnesses the busiest job-related tweeting from business and January the least. The user community is slightly less active in the warmer months, with fewer tweets then.

Figure 4b shows that job-related tweet volumes are higher on weekdays and lower on weekends, following the standard work week. Weekends see fewer business tweets than weekdays do. Sunday is the most – while Friday and Saturday are the least – active days from the not job-related perspective.

Figure 4c shows hourly trends. Job-related tweets from business accounts are most frequent during business hours, peaking at 11, and then taper off. Perhaps professionals are either getting their commercial tasks completed before lunch, or expecting others to check updates during lunch. Individuals post about jobs almost anytime awake and have a similar distribution to non-job-related tweets.

Measuring Affective Changes We examined positive affect (PA) and negative affect (NA) to measure diurnal changes in public mood (Figures 5 and 6), using two recognized lexicons, in job-related tweets from individual accounts (left), job-related tweets from business accounts (middle), and not job-related tweets (right).

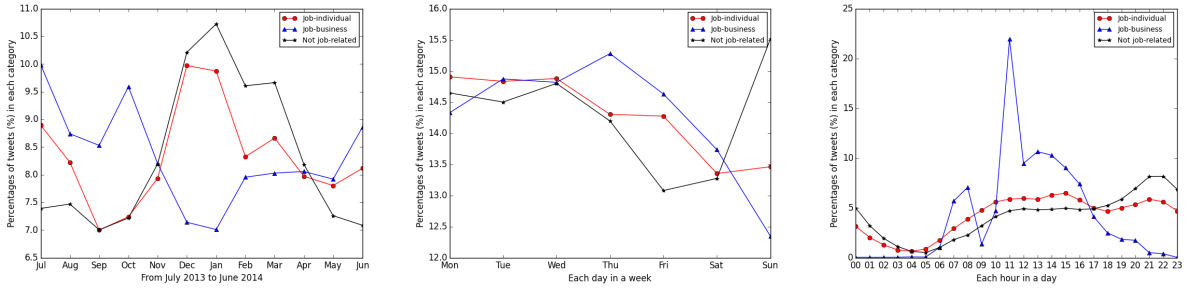
(1) Linguistic Inquiry and Word Count We used LIWC's *positive emotion* and *negative emotion* to represent PA and NA respectively (Pennebaker et al., 2001) because it is common in behavioral health studies, and used as a standard comparison in referenced work. Figure 5 shows the mean daily trends of PA and NA.[10] Panels 5a and 5b reveal contrasting job-related affective patterns, compared to prior trends from

[7] An acronym for *Fuck My Life*.

[8] An acronym for *Thank God It's Friday* to express the joy one feels in knowing that the work week has officially ended and that one has two days off which to enjoy.

[9] JJ – Adjective; NN – Noun (singular or mass); NNS – Noun (plural); NNP – Proper noun (singular); PRP – Personal pronoun; PRP$ – Possessive pronoun; RB – Adverb; UH – Interjection; VB – Verb (base form) (Santorini, 1990).

[10] Non-equal y-axes help show peak/valley patterns here and in Figure 6, also motivated by lexicon's unequal sizes.



(a) In each month (b) On each day of week (c) In each hour

Figure 4: Distributions of job-related tweets over time by job class. We converted timestamps from the Coordinated Universal Time standard (UTC) to local time zone with daylight saving time taken into account.

enterprise-wide micro-blog usage (De Choudhury and Counts, 2013), i.e., public social media exhibit gradual increase in PA while internal enterprise network decrease after business. This perhaps confirms our suspicion that people talk about work on public social media differently than on work-based media.

(2) Word-Emotion Association Lexicon We focused on the words from EmoLex's *positive* and *negative* categories, which represent sentiment polarities (Mohammad and Turney, 2013; Mohammad and Turney, 2010) and calculated the score for each tweet similarly as LIWC. The average daily positive and negative sentiment scores in Figure 6 display patterns analogous to Figure 5.

Labor Statistics We explored associations between Twitter temporal patterns, affect, and official labor statistics (Figure 8). These monthly statistics[11] include: labor force, employment, unemployment, and unemployment rate. We collected one more year of Twitter data from the same area, and applied C_3 to extract the job-related posts from individual and business accounts (Table 12 summarizes the basic statistics), then defined the following monthwise statistics for our two-year dataset: count of overall/job-individual/job-business/others tweets; percentage of job-individual/job-business/others tweets in overall tweets; average LIWC PA/NA scores of job-individual/job-business/others tweets[12].

Positive affect expressed in job-related discourse from both individual and business accounts correlate negatively with unemployment and unemployment rate. This is intuitive, as unemployment is generally believed to have a negative impact on individuals' lives. The counts of job-related tweets from individual and not job-related tweets are both positively correlated with unemployment and unemployment rate, suggesting that unemployment may lead to more activities in public social media. This correlation result shows that online textual disclosure themes and behaviors can reflect institutional survey data.

Inside vs. Outside City We compared tweets occurring within the city boundary to those lying outside (Table 13). The percentages of job-related tweets from individual accounts, either in urban or rural areas, remain relatively even. The proportion of job-related tweets from business accounts decreased sharply from urban to rural locations. This may be because business districts are usually centered in urban areas and individual tweets reflect more complex geospatial distributions.

Job-Life Cycle Model Based on hand inspection of a large number of job-related tweets and on models of the relationship between work and wellness found in behavioral studies (Archambault and Grudin, 2012; Schaufeli and Bakker, 2004), we tentatively propose a job-life model for job-related discourse from individual accounts (Figure 7). Each state in the model has three dimensions: the *point of view*, the *affect*, and the job-related *activity*, in terms of basic level of employment, expressed in the tweet.

We concatenated together all job-related tweets posted by each individual into a single document and performed latent Dirichlet allocation (LDA) (Blei et al., 2003) on this user-level corpus, using Gensim (Řehůřek and Sojka, 2010). We used 12

related discourse: 2 and 6 lean towards dissatisfaction and 5 toward satisfaction. 11 looks like a mixture. Topic 7 connects to coworkers. Many topics point to the importance of time (including leisure time in topic 4).

6 Conclusion

We used crowdsourcing and local expertise to power a humans-in-the-loop classification framework that iteratively improves identification of public job-related tweets. We separated business accounts from individual in job-related discourse. We also analyzed identified tweets integrating temporal, affective, geospatial, and statistical information. While jobs take up enormous amounts of most adults' time, job-related tweets are still rather infrequent. Examining affective changes reveals that PA and NA change independently; low NA appears to indicate the absence of negative feelings, not the presence of positive ones.

Our work is of social importance to working-age adults, especially for those who may struggle with job-related issues. Besides providing insights for discourse and its links to social science, our study could lead to practical applications, such as: aiding policy-makers with macro-level insights on job markets, connecting job-support resources to those in need, and facilitating the development of job recommendation systems.

This work has limitations. We did not study whether providing contextual information in our humans-in-the-loop framework would influence the model performance. This is left for future work. Additionally we recognize that the hashtag inventory used to discover business accounts from job-related topics might need to change over time, to achieve robust performance in the future. As another point, due to Twitter demographics, we are less likely to observe working seniors.

Achieving Open Vocabulary Neural Machine Translation with Hybrid Word-Character Models

Minh-Thang Luong and **Christopher D. Manning**
Computer Science Department, Stanford University, Stanford, CA 94305
{lmthang,manning}@stanford.edu

Abstract

Nearly all previous work on neural machine translation (NMT) has used quite restricted vocabularies, perhaps with a subsequent method to patch in unknown words. This paper presents a novel word-character solution to achieving open vocabulary NMT. We build hybrid systems that translate mostly at the *word* level and consult the *character* components for rare words. Our character-level recurrent neural networks compute source word representations and recover unknown target words when needed. The twofold advantage of such a hybrid approach is that it is much faster and easier to train than character-based ones; at the same time, it never produces unknown words as in the case of word-based models. On the WMT'15 English to Czech translation task, this hybrid approach offers an addition boost of +2.1−11.4 BLEU points over models that already handle unknown words. Our best system achieves a new state-of-the-art result with 20.7 BLEU score. We demonstrate that our character models can successfully learn to not only generate well-formed words for Czech, a highly-inflected language with a very complex vocabulary, but also build correct representations for English source words.

1 Introduction

Neural Machine Translation (NMT) is a simple new architecture for getting machines to translate. At its core, NMT is a single deep neural network that is trained end-to-end with several advantages such as simplicity and generalization. Despite being relatively new, NMT has already achieved state-of-the-art translation results for several language pairs such as English-French (Luong et al., 2015b), English-German (Jean et al., 2015a; Luong et al., 2015a; Luong and Manning, 2015), and English-Czech (Jean et al., 2015b).

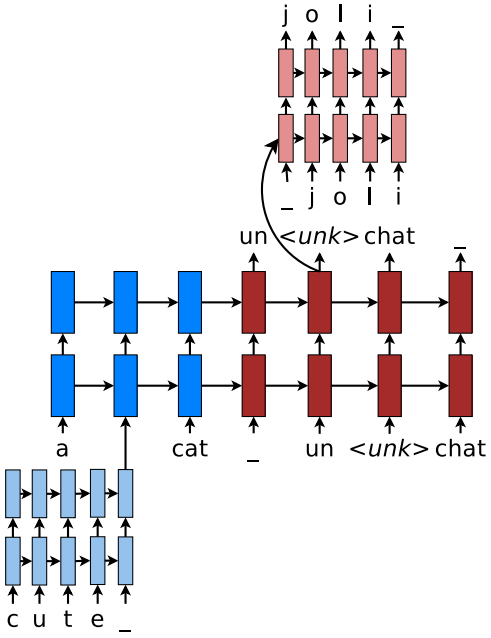

Figure 1: **Hybrid NMT** – example of a word-character model for translating "a cute cat" into "un joli chat". Hybrid NMT translates at the word level. For rare tokens, the character-level components build source representations and recover target <*unk*>. "_" marks sequence boundaries.

While NMT offers many advantages over traditional phrase-based approaches, such as small memory footprint and simple decoder implementation, nearly all previous work in NMT has used quite restricted vocabularies, crudely treating all other words the same with an <*unk*> symbol. Sometimes, a post-processing step that patches in unknown words is introduced to alleviate this problem. Luong et al. (2015b) propose to annotate

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1054–1063,
Berlin, Germany, August 7-12, 2016.

occurrences of target <*unk*> with positional information to track their alignments, after which simple word dictionary lookup or identity copy can be performed to replace <*unk*> in the translation. Jean et al. (2015a) approach the problem similarly but obtain the alignments for unknown words from the attention mechanism. We refer to these as the *unk replacement* technique.

Though simple, these approaches ignore several important properties of languages. First, *monolingually*, words are morphologically related; however, they are currently treated as independent entities. This is problematic as pointed out by Luong et al. (2013): neural networks can learn good representations for frequent words such as "distinct", but fail for rare-but-related words like "distinctiveness". Second, *crosslingually*, languages have different alphabets, so one cannot naïvely memorize all possible surface word translations such as name transliteration between "Christopher" (English) and "Kryštof" (Czech). See more on this problem in (Sennrich et al., 2016).

To overcome these shortcomings, we propose a novel *hybrid* architecture for NMT that translates mostly at the word level and consults the character components for rare words when necessary. As illustrated in Figure 1, our hybrid model consists of a word-based NMT that performs most of the translation job, except for the two (hypothetically) rare words, "cute" and "joli", that are handled separately. On the *source* side, representations for rare words, "cute", are computed on-the-fly using a deep recurrent neural network that operates at the character level. On the *target* side, we have a separate model that recovers the surface forms, "joli", of <*unk*> tokens character-by-character. These components are learned jointly end-to-end, removing the need for a separate unk replacement step as in current NMT practice.

Our hybrid NMT offers a twofold advantage: it is much faster and easier to train than character-based models; at the same time, it never produces unknown words as in the case of word-based ones. We demonstrate at scale that on the WMT'15 English to Czech translation task, such a hybrid approach provides an additional boost of +2.1−11.4 BLEU points over models that already handle unknown words. We achieve a new state-of-the-art result with 20.7 BLEU score. Our analysis demonstrates that our character models can successfully learn to not only generate well-formed words for Czech, a highly-inflected language with a very complex vocabulary, but also build correct representations for English source words.

We provide code, data, and models at `http://nlp.stanford.edu/projects/nmt`.

2 Related Work

There has been a recent line of work on end-to-end character-based neural models which achieve good results for part-of-speech tagging (dos Santos and Zadrozny, 2014; Ling et al., 2015a), dependency parsing (Ballesteros et al., 2015), text classification (Zhang et al., 2015), speech recognition (Chan et al., 2016; Bahdanau et al., 2016), and language modeling (Kim et al., 2016; Jozefowicz et al., 2016). However, success has not been shown for cross-lingual tasks such as machine translation.[1] Sennrich et al. (2016) propose to segment words into smaller units and translate just like at the word level, which does not learn to understand relationships among words.

Our work takes inspiration from (Luong et al., 2013) and (Li et al., 2015). Similar to the former, we build representations for rare words on-the-fly from subword units. However, we utilize recurrent neural networks with characters as the basic units; whereas Luong et al. (2013) use recursive neural networks with morphemes as units, which requires existence of a morphological analyzer. In comparison with (Li et al., 2015), our hybrid architecture is also a hierarchical sequence-to-sequence model, but operates at a different granularity level, word-character. In contrast, Li et al. (2015) build hierarchical models at the sentence-word level for paragraphs and documents.

3 Background & Our Models

Neural machine translation aims to directly model the conditional probability $p(y|x)$ of translating a source sentence, $x_1, \ldots, x_n$, to a target sentence, $y_1, \ldots, y_m$. It accomplishes this goal through an *encoder-decoder* framework (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014). The *encoder* computes a representation $\boldsymbol{s}$ for each source sentence. Based on that source

[1] Recently, Ling et al. (2015b) attempt character-level NMT; however, the experimental evidence is weak. The authors demonstrate only small improvements over word-level baselines and acknowledge that there are no differences of significance. Furthermore, only small datasets were used without comparable results from past NMT work.

representation, the *decoder* generates a translation, one target word at a time, and hence, decomposes the log conditional probability as:

$$\log p(y|x) = \sum_{t=1}^{m} \log p\left(y_t|y_{<t}, \boldsymbol{s}\right) \quad (1)$$

A natural model for sequential data is the recurrent neural network (RNN), used by most of the recent NMT work. Papers, however, differ in terms of: (a) architecture – from unidirectional, to bidirectional, and deep multi-layer RNNs; and (b) RNN type – which are long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and the gated recurrent unit (Cho et al., 2014). All our models utilize the *deep multi-layer* architecture with *LSTM* as the recurrent unit; detailed formulations are in (Zaremba et al., 2014).

Considering the top recurrent layer in a deep LSTM, with $\boldsymbol{h}_t$ being the current target hidden state as in Figure 2, one can compute the probability of decoding each target word y_t as:

$$p\left(y_t|y_{<t}, \boldsymbol{s}\right) = \text{softmax}\left(\boldsymbol{h}_t\right) \quad (2)$$

For a parallel corpus $\mathbb{D}$, we train our model by minimizing the below cross-entropy loss:

$$J = \sum_{(x,y)\in\mathbb{D}} -\log p(y|x) \quad (3)$$

Attention Mechanism – The early NMT approaches (Sutskever et al., 2014; Cho et al., 2014), which we have described above, use only the last encoder state to initialize the decoder, i.e., setting the input representation $\boldsymbol{s}$ in Eq. (1) to $[\bar{\boldsymbol{h}}_n]$. Recently, Bahdanau et al. (2015) propose an *attention mechanism*, a form of random access memory for NMT to cope with long input sequences. Luong et al. (2015a) further extend the attention mechanism to different scoring functions, used to compare source and target hidden states, as well as different strategies to place the attention. In all our models, we utilize the *global* attention mechanism and the *bilinear form* for the attention scoring function similar to (Luong et al., 2015a).

Specifically, we set $\boldsymbol{s}$ in Eq. (1) to the set of source hidden states at the top layer, $[\bar{\boldsymbol{h}}_1, \ldots, \bar{\boldsymbol{h}}_n]$. As illustrated in Figure 2, the attention mechanism consists of two stages: (a) *context vector* – the current hidden state $\boldsymbol{h}_t$ is compared with individual source hidden states in $\boldsymbol{s}$ to learn an alignment vector, which is then used to compute the context vector $\boldsymbol{c}_t$ as a weighted average of $\boldsymbol{s}$; and (b) *attentional hidden state* – the context vector $\boldsymbol{c}_t$ is then

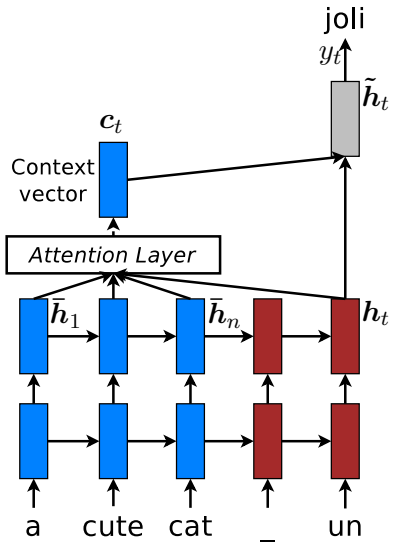

Figure 2: **Attention mechanism**.

used to derive a new attentional hidden state:

$$\tilde{\boldsymbol{h}}_t = \tanh(\boldsymbol{W}[\boldsymbol{c}_t; \boldsymbol{h}_t]) \quad (4)$$

The attentional vector $\tilde{\boldsymbol{h}}_t$ then replaces $\boldsymbol{h}_t$ in Eq. (2) in predicting the next word.

4 Hybrid Neural Machine Translation

Our hybrid architecture, illustrated in Figure 1, leverages the power of both words and characters to achieve the goal of open vocabulary NMT. The core of the design is a *word*-level NMT with the advantage of being fast and easy to train. The *character* components empower the word-level system with the abilities to compute any source word representation on the fly from characters and to recover character-by-character unknown target words originally produced as <*unk*>.

4.1 Word-based Translation as a Backbone

The core of our hybrid NMT is a deep LSTM encoder-decoder that translates at the *word* level as described in Section 3. We maintain a vocabulary of $|V|$ frequent words for each language. Other words not inside these lists are represented by a universal symbol <*unk*>, one per language. We translate just like a word-based NMT system with respect to these source and target vocabularies, except for cases that involve <*unk*> in the source input or the target output. These correspond to the character-level components illustrated in Figure 1.

A nice property of our hybrid approach is that by varying the vocabulary size, one can control

how much to blend the word- and character-based models; hence, taking the best of both worlds.

4.2 Source Character-based Representation

In regular word-based NMT, for all rare words outside the source vocabulary, one feeds the universal embedding representing <*unk*> as input to the encoder. This is problematic because it discards valuable information about the source word. To fix that, we learn a deep LSTM model over characters of source words. For example, in Figure 1, we run our deep character-based LSTM over 'c', 'u', 't', 'e', and '_' (the boundary symbol). The final hidden state at the top layer will be used as the on-the-fly representation for the current rare word.

The layers of the deep character-based LSTM are always initialized with *zero* states. One might propose to connect hidden states of the word-based LSTM to the character-based model; however, we chose this design for various reasons. First, it simplifies the architecture. Second, it allows for efficiency through *precomputation*: before each mini-batch, we can compute representations for rare source words all at once. All instances of the same word share the same embedding, so the computation is per *type*.[2]

4.3 Target Character-level Generation

General word-based NMT allows generation of <*unk*> in the target output. Afterwards, there is usually a post-processing step that handles these unknown tokens by utilizing the alignment information derived from the attention mechanism and then performing simple word dictionary lookup or identity copy (Luong et al., 2015a; Jean et al., 2015a). While this approach works, it suffers from various problems such as alphabet mismatches between the source and target vocabularies and multi-word alignments. Our goal is to address all these issues and create a coherent framework that handles an unlimited output vocabulary.

Our solution is to have a separate deep LSTM that "translates" at the character level given the current word-level state. We train our system such that whenever the word-level NMT produces an <*unk*>, we can consult this character-level decoder to recover the correct surface form of the unknown target word. This is illustrated in Figure 1.

[2]While Ling et al. (2015b) found that it is slow and difficult to train source character-level models and had to resort to pretraining, we demonstrate later that we can train our deep character-level LSTM perfectly fine in an end-to-end fashion.

The training objective in Eq. (3) now becomes:

$$J = J_w + \alpha J_c \tag{5}$$

Here, J_w refers to the usual loss of the word-level NMT; in our example, it is the sum of the negative log likelihood of generating {"un", "<*unk*>", "chat", "_"}. The remaining component J_c corresponds to the loss incurred by the character-level decoder when predicting characters, e.g., {'j', 'o', 'l', 'i', '_'}, of those rare words not in the target vocabulary.

Hidden-state Initialization Unlike the source character-based representations, which are context-independent, the target character-level generation requires the current word-level context to produce meaningful translation. This brings up an important question about what can best represent the current context so as to initialize the character-level decoder. We answer this question in the context of the attention mechanism (§3).

The final vector $\tilde{\boldsymbol{h}}_t$, just before the softmax as shown in Figure 2, seems to be a good candidate to initialize the character-level decoder. The reason is that $\tilde{\boldsymbol{h}}_t$ combines information from both the context vector $\boldsymbol{c}_t$ and the top-level recurrent state $\boldsymbol{h}_t$. We refer to it later in our experiments as the *same-path* target generation approach.

On the other hand, the same-path approach worries us because all vectors $\tilde{\boldsymbol{h}}_t$ used to seed the character-level decoder might have similar values, leading to the same character sequence being produced. The reason is because $\tilde{\boldsymbol{h}}_t$ is directly used in the softmax, Eq. (2), to predict the same <*unk*>. That might pose some challenges for the model to learn useful representations that can be used to accomplish two tasks at the same time, that is to predict <*unk*> and to generate character sequences. To address that concern, we propose another approach called the *separate-path* target generation.

Our separate-path target generation approach works as follows. We mimic the process described in Eq. (4) to create a counterpart vector $\breve{\boldsymbol{h}}_t$ that will be used to seed the character-level decoder:

$$\breve{\boldsymbol{h}}_t = \tanh(\breve{\boldsymbol{W}}[\boldsymbol{c}_t; \boldsymbol{h}_t]) \tag{6}$$

Here, $\breve{\boldsymbol{W}}$ is a new learnable parameter matrix, with which we hope to release $\boldsymbol{W}$ from the pressure of having to extract information relevant to both the word- and character-generation processes. Only the hidden state of the first layer

is initialized as discussed above. The other components in the character-level decoder such as the LSTM cells of all layers and the hidden states of higher layers, all start with zero values.

Implementation-wise, the computation in the character-level decoder is done per word *token* instead of per *type* as in the source character component (§4.2). This is because of the context-dependent nature of the decoder.

Word-Character Generation Strategy With the character-level decoder, we can view the final hidden states as representations for the surface forms of unknown tokens and could have fed these to the next time step. However, we chose not to do so for the efficiency reason explained next; instead, <*unk*> is fed to the word-level decoder "as is" using its corresponding word embedding.

During *training*, this design choice decouples all executions over <*unk*> instances of the character-level decoder as soon the word-level NMT completes. As such, the forward and backward passes of the character-level decoder over rare words can be invoked in batch mode. At *test* time, our strategy is to first run a beam search decoder at the word level to find the best translations given by the word-level NMT. Such translations contains <*unk*> tokens, so we utilize our character-level decoder with beam search to generate actual words for these <*unk*>.

5 Experiments

We evaluate the effectiveness of our models on the publicly available WMT'15 translation task from English into Czech with *newstest2013* (3000 sentences) as a development set and *newstest2015* (2656 sentences) as a test set. Two metrics are used: case-sensitive NIST BLEU (Papineni et al., 2002) and chrF$_3$ (Popović, 2015).[3] The latter measures the amounts of overlapping character n-grams and has been argued to be a better metric for translation tasks out of English.

5.1 Data

Among the available language pairs in WMT'15, all involving English, we choose *Czech* as a target language for several reasons. First and foremost, Czech is a Slavic language with not only rich and complex inflection, but also fusional morphology in which a single morpheme can encode multiple grammatical, syntactic, or semantic meanings. As a result, Czech possesses an enormously large vocabulary (about 1.5 to 2 times bigger than that of English according to statistics in Table 1) and is a challenging language to translate into. Furthermore, this language pair has a large amount of training data, so we can evaluate at scale. Lastly, though our techniques are language independent, it is easier for us to work with Czech since Czech uses the Latin alphabet with some diacritics.

	English		Czech	
	word	char	word	char
# Sents	15.8M			
# Tokens	254M	1,269M	224M	1,347M
# Types	1,172K	2003	1,760K	2053
200-char	98.1%		98.8%	

Table 1: **WMT'15 English-Czech data** – shown are various statistics of our training data such as *sentence*, *token* (word and character counts), as well as *type* (sizes of the word and character vocabularies). We show in addition the amount of words in a vocabulary expressed by a list of 200 characters found in frequent words.

In terms of preprocessing, we apply only the standard tokenization practice.[4] We choose for each language a list of 200 characters found in frequent words, which, as shown in Table 1, can represent more than 98% of the vocabulary.

5.2 Training Details

We train three types of systems, purely *word-based*, purely *character-based*, and *hybrid*. Common to these architectures is a word-based NMT since the character-based systems are essentially word-based ones with longer sequences and the core of hybrid models is also a word-based NMT.

In training word-based NMT, we follow Luong et al. (2015a) to use the global attention mechanism together with similar hyperparameters: (a) deep LSTM models, 4 layers, 1024 cells, and 1024-dimensional embeddings, (b) uniform initialization of parameters in $[-0.1, 0.1]$, (c) 6-epoch training with plain SGD and a simple learning rate schedule – start with a learning rate of 1.0; after 4 epochs, halve the learning rate every 0.5 epoch, (d) mini-batches are of size 128 and shuf-

[3]For NIST BLEU, we first run `detokenizer.pl` and then use `mteval-v13a` to compute the scores as per WMT guideline. For chrF$_3$, we utilize the implementation here `https://github.com/rsennrich/subword-nmt`.

[4]Use `tokenizer.perl` in Moses with default settings.

Table 2: **WMT'15 English-Czech results** – shown are the vocabulary sizes, perplexities, BLEU, and chrF$_3$ scores of various systems on *newstest2015*. Perplexities are listed under two categories, word (w) and character (c). **Best** and ***important*** results per metric are highlighed.

fled, (e) the gradient is rescaled whenever its norm exceeds 5, and (f) dropout is used with probability 0.2 according to (Pham et al., 2014). We now detail differences across the three architectures.

Word-based NMT – We constrain our source and target sequences to have a maximum length of 50 each; words that go past the boundary are ignored. The vocabularies are limited to the top $|V|$ most frequent words in both languages. Words not in these vocabularies are converted into <*unk*>. After translating, we will perform dictionary[5] lookup or identity copy for <*unk*> using the alignment information from the attention models. Such procedure is referred as the *unk replace* technique (Luong et al., 2015b; Jean et al., 2015a).

Character-based NMT – The source and target sequences at the character level are often about 5 times longer than their counterparts in the word-based models as we can infer from the statistics in Table 1. Due to memory constraint in GPUs, we limit our source and target sequences to a maximum length of 150 each, i.e., we backpropagate through at most 300 timesteps from the decoder to the encoder. With smaller 512-dimensional models, we can afford to have longer sequences with up to 600-step backpropagation.

Hybrid NMT – The *word*-level component uses the same settings as the purely word-based NMT. For the *character*-level source and target components, we experiment with both shallow and deep 1024-dimensional models of 1 and 2 LSTM layers. We set the weight α in Eq. (5) for our character-level loss to 1.0.

Training Time – It takes about 3 weeks to train a word-based model with $|V| = 50K$ and about 3 months to train a character-based model. Training and testing for the hybrid models are about 10-20% slower than those of the word-based models with the same vocabulary size.

5.3 Results

We compare our models with several strong systems. These include the winning entry in WMT'15, which was trained on a much larger amount of data, 52.6M parallel and 393.0M monolingual sentences (Bojar and Tamchyna, 2015).[6] In contrast, we merely use the provided parallel corpus of 15.8M sentences. For NMT, to the best

[5]Obtained from the alignment links produced by the Berkeley aligner (Liang et al., 2006) over the training corpus.

[6]This entry combines two independent systems, a phrase-based Moses model and a deep-syntactic transfer-based model. Additionally, there is an automatic post-editing system with hand-crafted rules to correct errors in morphological agreement and semantic meanings, e.g., loss of negation.

of our knowledge, (Jean et al., 2015b) has the best published performance on English-Czech.

As shown in Table 2, for a purely *word-based* approach, our single NMT model outperforms the best single model in (Jean et al., 2015b) by +1.8 points despite using a smaller vocabulary of only 50K words versus 200K words. Our ensemble system *(e)* slightly outperforms the best previous NMT system with 18.4 BLEU.

To our surprise, purely *character-based* models, though extremely slow to train and test, perform quite well. The 512-dimensional attention-based model *(g)* is best, surpassing the single word-based model in (Jean et al., 2015b) despite having much fewer parameters. It even outperforms most NMT systems on chrF$_3$ with 46.6 points. This indicates that this model translate words that closely but not exactly match the reference ones as evidenced in Section 6.3. We notice two interesting observations. First, attention is critical for character-based models to work as is obvious from the poor performance of the non-attentional model; this has also been shown in speech recognition (Chan et al., 2016). Second, long time-step backpropagation is more important as reflected by the fact that the larger 1024-dimensional model *(h)* with shorter backprogration is inferior to *(g)*.

Our *hybrid* models achieve the best results. At 10K words, we demonstrate that our *separate-path* strategy for the character-level target generation (§4.3) is effective, yielding an improvement of +1.5 BLEU points when comparing systems *(j)* vs. *(i)*. A *deeper* character-level architecture of 2 LSTM layers provides another significant boost of +2.1 BLEU. With 17.7 BLEU points, our hybrid system *(k)* has surpassed word-level NMT models.

When extending to 50K words, we further improve the translation quality. Our best single model, system *(l)* with 19.6 BLEU, is already better than all existing systems. Our ensemble model *(m)* further advances the SOTA result to ***20.7*** BLEU, outperforming the winning entry in the WMT'15 English-Czech translation task by a large margin of +1.9 points. Our ensemble model is also best in terms of chrF$_3$ with ***47.5*** points.

6 Analysis

This section first studies the effects of vocabulary sizes towards translation quality. We then analyze more carefully our character-level components by visualizing and evaluating rare word embeddings as well as examining sample translations.

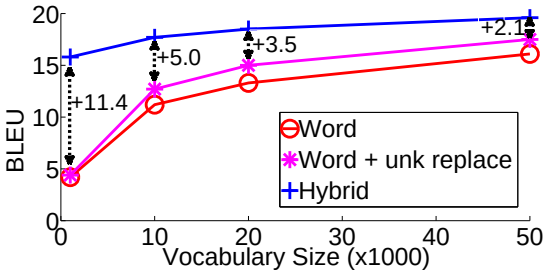

Figure 3: **Vocabulary size effect** – shown are the performances of different systems as we vary their vocabulary sizes. We highlight the improvements obtained by our hybrid models over word-based systems which already handle unknown words.

6.1 Effects of Vocabulary Sizes

As shown in Figure 3, our hybrid models offer large gains of +2.1-11.4 BLEU points over strong word-based systems which already handle unknown words. With only a small vocabulary, e.g., 1000 words, our hybrid approach can produce systems that are better than word-based models that possess much larger vocabularies. While it appears from the plot that gains diminish as we increase the vocabulary size, we argue that our hybrid models are still preferable since they understand word structures and can handle new complex words at test time as illustrated in Section 6.3.

6.2 Rare Word Embeddings

We evaluate the *source* character-level model by building representations for rare words and measuring how good these embeddings are.

Quantitatively, we follow Luong et al. (2013) in using the word similarity task, specifically on the *Rare Word* dataset, to judge the learned representations for complex words. The evaluation metric is the Spearman's correlation ρ between similarity scores assigned by a model and by human annotators. From the results in Table 3, we can see that source representations produced by our hybrid[7] models are significantly better than those of the word-based one. It is noteworthy that our deep recurrent character-level models can outperform the model of (Luong et al., 2013), which uses recursive neural networks and requires a complex morphological analyzer, by a large margin. Our performance is also competitive to the best Glove

[7]We look up the encoder embeddings for frequent words and build representations for rare word from characters.

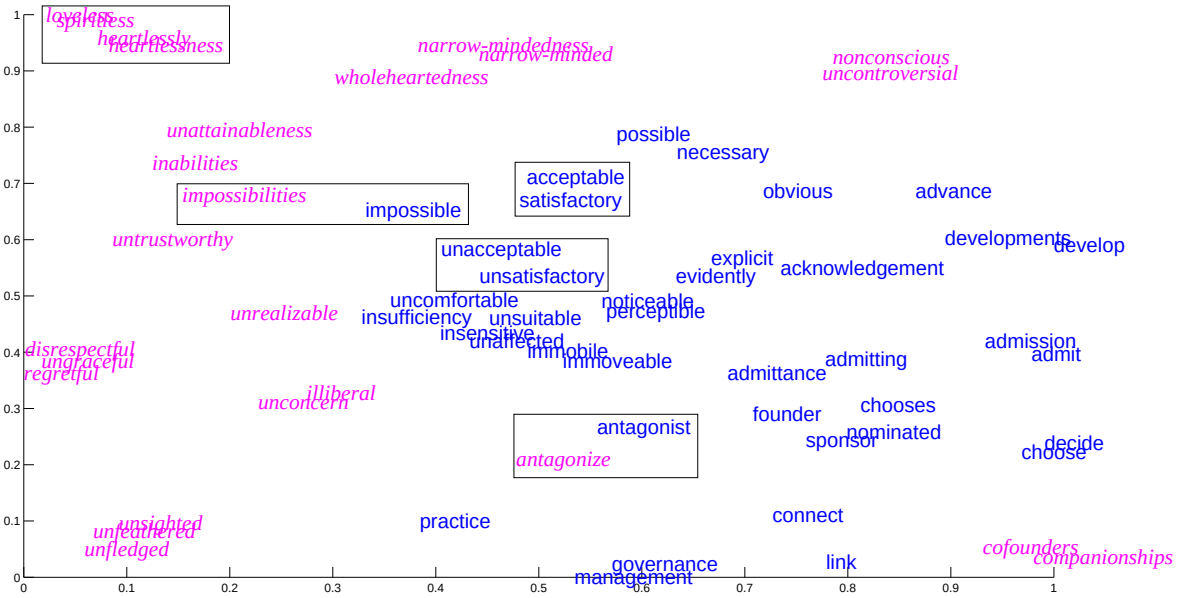

Figure 4: **Barnes-Hut-SNE visualization of source word representations** – shown are sample words from the *Rare Word* dataset. We differentiate two types of embeddings: frequent words in which encoder embeddings are looked up directly and *rare* words where we build representations from characters. Boxes highlight examples that we will discuss in the text. We use the hybrid model *(l)* in this visualization.

embeddings (Pennington et al., 2014) which were trained on a much larger dataset.

System		Size	$\|V\|$	ρ
(Luong et al., 2013)		1B	138K	34.4
Glove (Pennington et al., 2014)		6B	400K	38.1
		42B	400K	**47.8**
Our NMT models				
(d)	Word-based	0.3B	50K	20.4
(k)	Hybrid	0.3B	10K	42.4
(l)	Hybrid	0.3B	50K	***47.1***

Table 3: **Word similarity task** – shown are Spearman's correlation ρ on the *Rare Word* dataset of various models (with different vocab sizes $|V|$).

Qualitatively, we visualize embeddings produced by the hybrid model *(l)* for selected words in the Rare Word dataset. Figure 4 shows the two-dimensional representations of words computed by the Barnes-Hut-SNE algorithm (van der Maaten, 2013).[8] It is extremely interesting to observe that words are clustered together not only by the word structures but also by the meanings. For example, in the top-left box, the *character*-based representations for "loveless", "spiritless", "heartlessly", and "heartlessness" are nearby, but clearly separated into two groups. Similarly, in the center boxes, *word*-based embeddings of "acceptable", "satisfactory", "unacceptable", and "unsatisfactory", are close by but separated by meanings. Lastly, the remaining boxes demonstrate that our character-level models are able to build representations comparable to the word-based ones, e.g., "impossibilities" vs. "impossible" and "antagonize" vs. "antagonist". All of this evidence strongly supports that the source character-level models are useful and effective.

[8] We run Barnes-Hut-SNE algorithm over a set of 91 words, but filter out 27 words for displaying clarity.

6.3 Sample Translations

We show in Table 4 sample translations between various systems. In the first example, our hybrid model translates perfectly. The word-based model fails to translate "diagnosis" because the second <*unk*> was incorrectly aligned to the word "after". The character-based model, on the other hand, makes a mistake in translating names.

For the second example, the hybrid model surprises us when it can capture the long-distance reordering of "fifty years ago" and "před padesáti lety" while the other two models do not. The word-based model translates "Jr." inaccurately due to the incorrect alignment between the second <*unk*> and the word "said". The character-based model literally translates the name "King" into "král" which means "king".

Lastly, both the character-based and hybrid

		Její ***jedenáctiletá*** dcera , **Graham** Bart , řekla , že cítí " trochu divný " , [..] vrátila do školy .

Table 4: **Sample translations on newstest2015** – for each example, we show the *source*, *human* translation, and translations of the following NMT systems: *word* model *(d)*, *char* model *(g)*, and *hybrid* model *(k)*. We show the translations before replacing <*unk*> tokens (if any) for the word-based and hybrid models. The following formats are used to highlight ***correct***, **wrong**, and close translation segments.

models impress us by their ability to translate compound words exactly, e.g., "11-year-old" and "jedenáctiletá"; whereas the identity copy strategy of the word-based model fails. Of course, our hybrid model does make mistakes, e.g., it fails to translate the name "Shani Bart". Overall, these examples highlight how challenging translating into Czech is and that being able to translate at the character level helps improve the quality.

7 Conclusion

We have proposed a novel *hybrid* architecture that combines the strength of both word- and character-based models. Word-level models are fast to train and offer high-quality translation; whereas, character-level models help achieve the goal of open vocabulary NMT. We have demonstrated these two aspects through our experimental results and translation examples.

Our best hybrid model has surpassed the performance of both the best word-based NMT system and the best non-neural model to establish a new state-of-the-art result for English-Czech translation in WMT'15 with 20.7 BLEU. Moreover, we have succeeded in replacing the standard unk replacement technique in NMT with our character-level components, yielding an improvement of $+2.1-11.4$ BLEU points. Our analysis has shown that our model has the ability to not only generate well-formed words for Czech, a highly inflected language with an enormous and complex vocabulary, but also build accurate representations for English source words.

Additionally, we have demonstrated the potential of purely character-based models in producing good translations; they have outperformed past word-level NMT models. For future work, we hope to be able to improve the memory usage and speed of purely character-based models.

End-to-end Sequence Labeling via Bi-directional LSTM-CNNs-CRF

Abstract

State-of-the-art sequence labeling systems traditionally require large amounts of task-specific knowledge in the form of hand-crafted features and data pre-processing. In this paper, we introduce a novel neutral network architecture that benefits from both word- and character-level representations automatically, by using combination of bidirectional LSTM, CNN and CRF. Our system is truly end-to-end, requiring no feature engineering or data pre-processing, thus making it applicable to a wide range of sequence labeling tasks. We evaluate our system on two data sets for two sequence labeling tasks — Penn Treebank WSJ corpus for part-of-speech (POS) tagging and CoNLL 2003 corpus for named entity recognition (NER). We obtain state-of-the-art performance on both datasets — 97.55% accuracy for POS tagging and 91.21% F1 for NER.

1 Introduction

Linguistic sequence labeling, such as part-of-speech (POS) tagging and named entity recognition (NER), is one of the first stages in deep language understanding and its importance has been well recognized in the natural language processing community. Natural language processing (NLP) systems, like syntactic parsing (Nivre and Scholz, 2004; McDonald et al., 2005; Koo and Collins, 2010; Ma and Zhao, 2012a; Ma and Zhao, 2012b; Chen and Manning, 2014; Ma and Hovy, 2015) and entity coreference resolution (Ng, 2010; Ma et al., 2016), are becoming more sophisticated, in part because of utilizing output information of POS tagging or NER systems.

Most traditional high performance sequence labeling models are linear statistical models, including Hidden Markov Models (HMM) and Conditional Random Fields (CRF) (Ratinov and Roth, 2009; Passos et al., 2014; Luo et al., 2015), which rely heavily on hand-crafted features and task-specific resources. For example, English POS taggers benefit from carefully designed word spelling features; orthographic features and external resources such as gazetteers are widely used in NER. However, such task-specific knowledge is costly to develop (Ma and Xia, 2014), making sequence labeling models difficult to adapt to new tasks or new domains.

In the past few years, non-linear neural networks with as input distributed word representations, also known as word embeddings, have been broadly applied to NLP problems with great success. Collobert et al. (2011) proposed a simple but effective feed-forward neutral network that independently classifies labels for each word by using contexts within a window with fixed size. Recently, recurrent neural networks (RNN) (Goller and Kuchler, 1996), together with its variants such as long-short term memory (LSTM) (Hochreiter and Schmidhuber, 1997; Gers et al., 2000) and gated recurrent unit (GRU) (Cho et al., 2014), have shown great success in modeling sequential data. Several RNN-based neural network models have been proposed to solve sequence labeling tasks like speech recognition (Graves et al., 2013), POS tagging (Huang et al., 2015) and NER (Chiu and Nichols, 2015; Hu et al., 2016), achieving competitive performance against traditional models. However, even systems that have utilized distributed representations as inputs have used these to augment, rather than replace, hand-crafted features (e.g. word spelling and capitalization patterns). Their performance drops rapidly when the models solely depend on neural embeddings.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1064–1074,
Berlin, Germany, August 7-12, 2016.

In this paper, we propose a neural network architecture for sequence labeling. It is a truly end-to-end model requiring no task-specific resources, feature engineering, or data pre-processing beyond pre-trained word embeddings on unlabeled corpora. Thus, our model can be easily applied to a wide range of sequence labeling tasks on different languages and domains. We first use convolutional neural networks (CNNs) (LeCun et al., 1989) to encode character-level information of a word into its character-level representation. Then we combine character- and word-level representations and feed them into bi-directional LSTM (BLSTM) to model context information of each word. On top of BLSTM, we use a sequential CRF to jointly decode labels for the whole sentence. We evaluate our model on two linguistic sequence labeling tasks — POS tagging on Penn Treebank WSJ (Marcus et al., 1993), and NER on English data from the CoNLL 2003 shared task (Tjong Kim Sang and De Meulder, 2003). Our end-to-end model outperforms previous state-of-the-art systems, obtaining 97.55% accuracy for POS tagging and 91.21% F1 for NER. The contributions of this work are (i) proposing a novel neural network architecture for linguistic sequence labeling. (ii) giving empirical evaluations of this model on benchmark data sets for two classic NLP tasks. (iii) achieving state-of-the-art performance with this truly end-to-end system.

2 Neural Network Architecture

In this section, we describe the components (layers) of our neural network architecture. We introduce the neural layers in our neural network one-by-one from bottom to top.

2.1 CNN for Character-level Representation

Previous studies (Santos and Zadrozny, 2014; Chiu and Nichols, 2015) have shown that CNN is an effective approach to extract morphological information (like the prefix or suffix of a word) from characters of words and encode it into neural representations. Figure 1 shows the CNN we use to extract character-level representation of a given word. The CNN is similar to the one in Chiu and Nichols (2015), except that we use only character embeddings as the inputs to CNN, without character type features. A dropout layer (Srivastava et al., 2014) is applied before character embeddings are input to CNN.

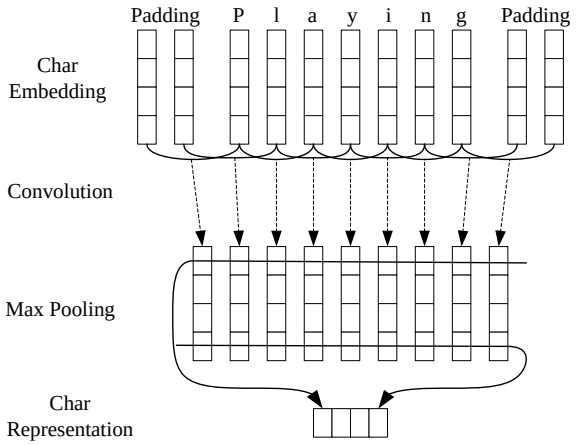

Figure 1: The convolution neural network for extracting character-level representations of words. Dashed arrows indicate a dropout layer applied before character embeddings are input to CNN.

2.2 Bi-directional LSTM

2.2.1 LSTM Unit

Recurrent neural networks (RNNs) are a powerful family of connectionist models that capture time dynamics via cycles in the graph. Though, in theory, RNNs are capable to capturing long-distance dependencies, in practice, they fail due to the gradient vanishing/exploding problems (Bengio et al., 1994; Pascanu et al., 2012).

LSTMs (Hochreiter and Schmidhuber, 1997) are variants of RNNs designed to cope with these gradient vanishing problems. Basically, a LSTM unit is composed of three multiplicative gates which control the proportions of information to forget and to pass on to the next time step. Figure 2 gives the basic structure of an LSTM unit.

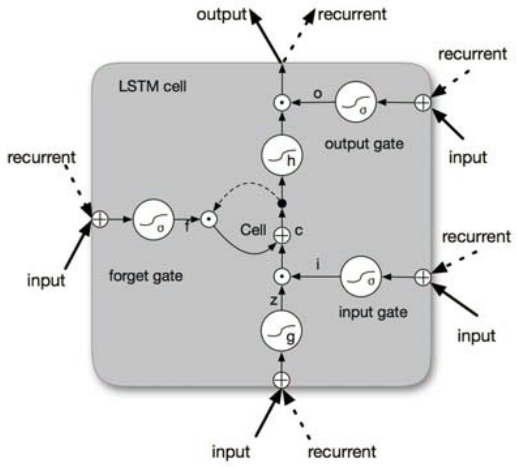

Figure 2: Schematic of LSTM unit.

Formally, the formulas to update an LSTM unit at time t are:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\boldsymbol{W}_i\mathbf{h}_{t-1} + \boldsymbol{U}_i\mathbf{x}_t + \boldsymbol{b}_i) \\
\mathbf{f}_t &= \sigma(\boldsymbol{W}_f\mathbf{h}_{t-1} + \boldsymbol{U}_f\mathbf{x}_t + \boldsymbol{b}_f) \\
\tilde{\mathbf{c}}_t &= \tanh(\boldsymbol{W}_c\mathbf{h}_{t-1} + \boldsymbol{U}_c\mathbf{x}_t + \boldsymbol{b}_c) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tilde{\mathbf{c}}_t \\
\mathbf{o}_t &= \sigma(\boldsymbol{W}_o\mathbf{h}_{t-1} + \boldsymbol{U}_o\mathbf{x}_t + \boldsymbol{b}_o) \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned}$$

where σ is the element-wise sigmoid function and $\odot$ is the element-wise product. $\mathbf{x}_t$ is the input vector (e.g. word embedding) at time t, and $\mathbf{h}_t$ is the hidden state (also called output) vector storing all the useful information at (and before) time t. $\boldsymbol{U}_i, \boldsymbol{U}_f, \boldsymbol{U}_c, \boldsymbol{U}_o$ denote the weight matrices of different gates for input $\mathbf{x}_t$, and $\boldsymbol{W}_i, \boldsymbol{W}_f, \boldsymbol{W}_c, \boldsymbol{W}_o$ are the weight matrices for hidden state $\mathbf{h}_t$. $\boldsymbol{b}_i, \boldsymbol{b}_f, \boldsymbol{b}_c, \boldsymbol{b}_o$ denote the bias vectors. It should be noted that we do not include peephole connections (Gers et al., 2003) in the our LSTM formulation.

2.2.2 BLSTM

For many sequence labeling tasks it is beneficial to have access to both past (left) and future (right) contexts. However, the LSTM's hidden state $\mathbf{h}_t$ takes information only from past, knowing nothing about the future. An elegant solution whose effectiveness has been proven by previous work (Dyer et al., 2015) is bi-directional LSTM (BLSTM). The basic idea is to present each sequence forwards and backwards to two separate hidden states to capture past and future information, respectively. Then the two hidden states are concatenated to form the final output.

2.3 CRF

For sequence labeling (or general structured prediction) tasks, it is beneficial to consider the correlations between labels in neighborhoods and jointly decode the best chain of labels for a given input sentence. For example, in POS tagging an adjective is more likely to be followed by a noun than a verb, and in NER with standard BIO2 annotation (Tjong Kim Sang and Veenstra, 1999) I-ORG cannot follow I-PER. Therefore, we model label sequence jointly using a conditional random field (CRF) (Lafferty et al., 2001), instead of decoding each label independently.

Formally, we use $\mathbf{z} = \{\mathbf{z}_1, \cdots, \mathbf{z}_n\}$ to represent a generic input sequence where $\mathbf{z}_i$ is the input vector of the ith word. $\boldsymbol{y} = \{y_1, \cdots, y_n\}$ represents a generic sequence of labels for $\mathbf{z}$. $\mathcal{Y}(\mathbf{z})$ denotes the set of possible label sequences for $\mathbf{z}$. The probabilistic model for sequence CRF defines a family of conditional probability $p(\boldsymbol{y}|\mathbf{z}; \mathbf{W}, \mathbf{b})$ over all possible label sequences $\boldsymbol{y}$ given $\mathbf{z}$ with the following form:

$$p(\boldsymbol{y}|\mathbf{z}; \mathbf{W}, \mathbf{b}) = \frac{\prod_{i=1}^{n} \psi_i(y_{i-1}, y_i, \mathbf{z})}{\sum_{y' \in \mathcal{Y}(\mathbf{z})} \prod_{i=1}^{n} \psi_i(y'_{i-1}, y'_i, \mathbf{z})}$$

where $\psi_i(y', y, \mathbf{z}) = \exp(\mathbf{W}_{y',y}^T \mathbf{z}_i + \mathbf{b}_{y',y})$ are potential functions, and $\mathbf{W}_{y',y}^T$ and $\mathbf{b}_{y',y}$ are the weight vector and bias corresponding to label pair (y', y), respectively.

For CRF training, we use the maximum conditional likelihood estimation. For a training set $\{(\mathbf{z}_i, \boldsymbol{y}_i)\}$, the logarithm of the likelihood (a.k.a. the log-likelihood) is given by:

$$L(\mathbf{W}, \mathbf{b}) = \sum_i \log p(\boldsymbol{y}|\mathbf{z}; \mathbf{W}, \mathbf{b})$$

Maximum likelihood training chooses parameters such that the log-likelihood $L(\mathbf{W}, \mathbf{b})$ is maximized.

Decoding is to search for the label sequence $\boldsymbol{y}^*$ with the highest conditional probability:

$$\boldsymbol{y}^* = \operatorname*{argmax}_{y \in \mathcal{Y}(\mathbf{z})} p(\boldsymbol{y}|\mathbf{z}; \mathbf{W}, \mathbf{b})$$

For a sequence CRF model (only interactions between two successive labels are considered), training and decoding can be solved efficiently by adopting the Viterbi algorithm.

2.4 BLSTM-CNNs-CRF

Finally, we construct our neural network model by feeding the output vectors of BLSTM into a CRF layer. Figure 3 illustrates the architecture of our network in detail.

For each word, the character-level representation is computed by the CNN in Figure 1 with character embeddings as inputs. Then the character-level representation vector is concatenated with the word embedding vector to feed into the BLSTM network. Finally, the output vectors of BLSTM are fed to the CRF layer to jointly decode the best label sequence. As shown in Figure 3, dropout layers are applied on both the input and output vectors of BLSTM. Experimental results show that using dropout significantly

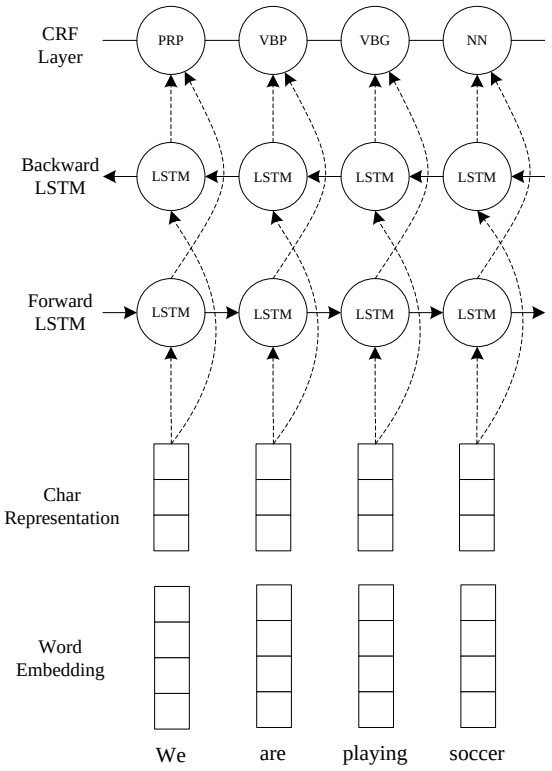

Figure 3: The main architecture of our neural network. The character representation for each word is computed by the CNN in Figure 1. Then the character representation vector is concatenated with the word embedding before feeding into the BLSTM network. Dashed arrows indicate dropout layers applied on both the input and output vectors of BLSTM.

improve the performance of our model (see Section 4.5 for details).

3 Network Training

In this section, we provide details about training the neural network. We implement the neural network using the Theano library (Bergstra et al., 2010). The computations for a single model are run on a GeForce GTX TITAN X GPU. Using the settings discussed in this section, the model training requires about 12 hours for POS tagging and 8 hours for NER.

3.1 Parameter Initialization

Word Embeddings. We use Stanford's publicly available GloVe 100-dimensional embeddings[1] trained on 6 billion words from Wikipedia and web text (Pennington et al., 2014)

We also run experiments on two other sets of published embeddings, namely Senna 50-dimensional embeddings[2] trained on Wikipedia and Reuters RCV-1 corpus (Collobert et al., 2011), and Google's Word2Vec 300-dimensional embeddings[3] trained on 100 billion words from Google News (Mikolov et al., 2013). To test the effectiveness of pretrained word embeddings, we experimented with randomly initialized embeddings with 100 dimensions, where embeddings are uniformly sampled from range $[-\sqrt{\frac{3}{dim}}, +\sqrt{\frac{3}{dim}}]$ where dim is the dimension of embeddings (He et al., 2015). The performance of different word embeddings is discussed in Section 4.4.

Character Embeddings. Character embeddings are initialized with uniform samples from $[-\sqrt{\frac{3}{dim}}, +\sqrt{\frac{3}{dim}}]$, where we set $dim = 30$.

Weight Matrices and Bias Vectors. Matrix parameters are randomly initialized with uniform samples from $[-\sqrt{\frac{6}{r+c}}, +\sqrt{\frac{6}{r+c}}]$, where r and c are the number of of rows and columns in the structure (Glorot and Bengio, 2010). Bias vectors are initialized to zero, except the bias $\mathbf{b}_f$ for the forget gate in LSTM , which is initialized to 1.0 (Jozefowicz et al., 2015).

3.2 Optimization Algorithm

Parameter optimization is performed with mini-batch stochastic gradient descent (SGD) with batch size 10 and momentum 0.9. We choose an initial learning rate of η_0 ($\eta_0 = 0.01$ for POS tagging, and 0.015 for NER, see Section 3.3.), and the learning rate is updated on each epoch of training as $\eta_t = \eta_0/(1 + \rho t)$, with decay rate $\rho = 0.05$ and t is the number of epoch completed. To reduce the effects of "gradient exploding", we use a gradient clipping of 5.0 (Pascanu et al., 2012). We explored other more sophisticated optimization algorithms such as AdaDelta (Zeiler, 2012), Adam (Kingma and Ba, 2014) or RMSProp (Dauphin et al., 2015), but none of them meaningfully improve upon SGD with momentum and gradient clipping in our preliminary experiments.

Early Stopping. We use early stopping (Giles, 2001; Graves et al., 2013) based on performance on validation sets. The "best" parameters appear at around 50 epochs, according to our experiments.

[3] https://code.google.com/archive/p/word2vec/

Layer	Hyper-parameter	POS	NER
CNN	window size	3	3
	number of filters	30	30
LSTM	state size	200	200
	initial state	0.0	0.0
	peepholes	no	no
Dropout	dropout rate	0.5	0.5
	batch size	10	10
	initial learning rate	0.01	0.015
	decay rate	0.05	0.05
	gradient clipping	5.0	5.0

Table 1: Hyper-parameters for all experiments.

Fine Tuning. For each of the embeddings, we fine-tune initial embeddings, modifying them during gradient updates of the neural network model by back-propagating gradients. The effectiveness of this method has been previously explored in sequential and structured prediction problems (Collobert et al., 2011; Peng and Dredze, 2015).

Dropout Training. To mitigate overfitting, we apply the dropout method (Srivastava et al., 2014) to regularize our model. As shown in Figure 1 and 3, we apply dropout on character embeddings before inputting to CNN, and on both the input and output vectors of BLSTM. We fix dropout rate at 0.5 for all dropout layers through all the experiments. We obtain significant improvements on model performance after using dropout (see Section 4.5).

3.3 Tuning Hyper-Parameters

Table 1 summarizes the chosen hyper-parameters for all experiments. We tune the hyper-parameters on the development sets by random search. Due to time constrains it is infeasible to do a random search across the full hyper-parameter space. Thus, for the tasks of POS tagging and NER we try to share as many hyper-parameters as possible. Note that the final hyper-parameters for these two tasks are almost the same, except the initial learning rate. We set the state size of LSTM to 200. Tuning this parameter did not significantly impact the performance of our model. For CNN, we use 30 filters with window length 3.

4 Experiments

4.1 Data Sets

As mentioned before, we evaluate our neural network model on two sequence labeling tasks: POS tagging and NER.

Dataset		WSJ	CoNLL2003
Train	SENT	38,219	14,987
	TOKEN	912,344	204,567
Dev	SENT	5,527	3,466
	TOKEN	131,768	51,578
Test	SENT	5,462	3,684
	TOKEN	129,654	46,666

Table 2: Corpora statistics. SENT and TOKEN refer to the number of sentences and tokens in each data set.

POS Tagging. For English POS tagging, we use the Wall Street Journal (WSJ) portion of Penn Treebank (PTB) (Marcus et al., 1993), which contains 45 different POS tags. In order to compare with previous work, we adopt the standard splits — section 0–18 as training data, section 19–21 as development data and section 22–24 as test data (Manning, 2011; Søgaard, 2011).

NER. For NER, We perform experiments on the English data from CoNLL 2003 shared task (Tjong Kim Sang and De Meulder, 2003). This data set contains four different types of named entities: *PERSON, LOCATION, ORGANIZATION*, and *MISC*. We use the BIOES tagging scheme instead of standard BIO2, as previous studies have reported meaningful improvement with this scheme (Ratinov and Roth, 2009; Dai et al., 2015; Lample et al., 2016).

The corpora statistics are shown in Table 2. We did not perform any pre-processing for data sets, leaving our system truly end-to-end.

4.2 Main Results

We first run experiments to dissect the effectiveness of each component (layer) of our neural network architecture by ablation studies. We compare the performance with three baseline systems — BRNN, the bi-direction RNN; BLSTM, the bi-direction LSTM, and BLSTM-CNNs, the combination of BLSTM with CNN to model character-level information. All these models are run using Stanford's GloVe 100 dimensional word embeddings and the same hyper-parameters as shown in Table 1. According to the results shown in Table 3, BLSTM obtains better performance than BRNN on all evaluation metrics of both the two tasks. BLSTM-CNN models significantly outperform the BLSTM model, showing that character-level representations are important for linguistic sequence labeling tasks. This is consistent with

	POS		NER					
	Dev	Test	Dev			Test		
Model	Acc.	Acc.	Prec.	Recall	F1	Prec.	Recall	F1

results reported by previous work (Santos and Zadrozny, 2014; Chiu and Nichols, 2015). Finally, by adding CRF layer for joint decoding we achieve significant improvements over BLSTM-CNN models for both POS tagging and NER on all metrics. This demonstrates that jointly decoding label sequences can significantly benefit the final performance of neural network models.

4.3 Comparison with Previous Work

4.3.1 POS Tagging

Table 4 illustrates the results of our model for POS tagging, together with seven previous top-performance systems for comparison. Our model significantly outperform Senna (Collobert et al., 2011), which is a feed-forward neural network model using capitalization and discrete suffix features, and data pre-processing. Moreover, our model achieves 0.23% improvements on accuracy over the "CharWNN" (Santos and Zadrozny, 2014), which is a neural network model based on Senna and also uses CNNs to model character-level representations. This demonstrates the effectiveness of BLSTM for modeling sequential data and the importance of joint decoding with structured prediction model.

Comparing with traditional statistical models, our system achieves state-of-the-art accuracy, obtaining 0.05% improvement over the previously best reported results by Søgaard (2011). It should be noted that Huang et al. (2015) also evaluated their BLSTM-CRF model for POS tagging on WSJ corpus. But they used a different splitting of the training/dev/test data sets. Thus, their results are not directly comparable with ours.

4.3.2 NER

Table 5 shows the F1 scores of previous models for NER on the test data set from CoNLL-2003 shared task. For the purpose of comparison, we list their results together with ours. Similar to the observations of POS tagging, our model achieves significant improvements over Senna and the other three neural models, namely the LSTM-CRF proposed by Huang et al. (2015), LSTM-CNNs pro-

Embedding	Dimension	POS	NER
Random	100	97.13	80.76
Senna	50	97.44	90.28
Word2Vec	300	97.40	84.91
GloVe	100	**97.55**	**91.21**

Table 6: Results with different choices of word embeddings on the two tasks (accuracy for POS tagging and F1 for NER).

posed by Chiu and Nichols (2015), and the LSTM-CRF by Lample et al. (2016). Huang et al. (2015) utilized discrete spelling, POS and context features, Chiu and Nichols (2015) used character-type, capitalization, and lexicon features, and all the three model used some task-specific data pre-processing, while our model does not require any carefully designed features or data pre-processing. We have to point out that the result (90.77%) reported by Chiu and Nichols (2015) is incomparable with ours, because their final model was trained on the combination of the training and development data sets[4].

To our knowledge, the previous best F1 score (91.20)[5] reported on CoNLL 2003 data set is by the joint NER and entity linking model (Luo et al., 2015). This model used many hand-crafted features including stemming and spelling features, POS and chunks tags, WordNet clusters, Brown Clusters, as well as external knowledge bases such as Freebase and Wikipedia. Our end-to-end model slightly improves this model by 0.01%, yielding a state-of-the-art performance.

4.4 Word Embeddings

As mentioned in Section 3.1, in order to test the importance of pretrained word embeddings, we performed experiments with different sets of publicly published word embeddings, as well as a random sampling method, to initialize our model. Table 6 gives the performance of three different word embeddings, as well as the randomly sampled one. According to the results in Table 6, models using pretrained word embeddings obtain a significant improvement as opposed to the ones using random embeddings. Comparing the two tasks, NER relies more heavily on pretrained embeddings than POS tagging. This is consistent with results reported by previous work (Collobert et al., 2011; Huang et al., 2015; Chiu and Nichols, 2015).

For different pretrained embeddings, Stanford's GloVe 100 dimensional embeddings achieve best results on both tasks, about 0.1% better on POS accuracy and 0.9% better on NER F1 score than the Senna 50 dimensional one. This is different from the results reported by Chiu and Nichols (2015), where Senna achieved slightly better performance on NER than other embeddings. Google's Word2Vec 300 dimensional embeddings obtain similar performance with Senna on POS tagging, still slightly behind GloVe. But for NER, the performance on Word2Vec is far behind GloVe and Senna. One possible reason that Word2Vec is not as good as the other two embeddings on NER is because of vocabulary mismatch — Word2Vec embeddings were trained in case-sensitive manner, excluding many common symbols such as punctuations and digits. Since we do not use any data pre-processing to deal with such common symbols or rare words, it might be an issue for using Word2Vec.

	POS			NER		
	Train	**Dev**	**Test**	**Train**	**Dev**	**Test**
No	98.46	97.06	97.11	99.97	93.51	89.25
Yes	97.86	97.46	97.55	99.63	94.74	91.21

OOTV	2,960	2,412	1,087	1,597
OOEV	659	588	44	8
OOBV	902	828	195	270

Table 8: Statistics of the partition on each corpus. It lists the number of tokens of each subset for POS tagging and the number of entities for NER.

4.5 Effect of Dropout

Table 7 compares the results with and without dropout layers for each data set. All other hyper-parameters remain the same as in Table 1. We observe a essential improvement for both the two tasks. It demonstrates the effectiveness of dropout in reducing overfitting.

[4]We run experiments using the same setting and get 91.37% F1 score.

[5]Numbers are taken from the Table 3 of the original paper (Luo et al., 2015). While there is clearly inconsistency among the precision (91.5%), recall (91.4%) and F1 scores (91.2%), it is unclear in which way they are incorrect.

	POS							
	Dev				Test			
	IV	OOTV	OOEV	OOBV	IV	OOTV	OOEV	OOBV

Table 9: Comparison of performance on different subsets of words (accuracy for POS and F1 for NER).

4.6 OOV Error Analysis

To better understand the behavior of our model, we perform error analysis on Out-of-Vocabulary words (OOV). Specifically, we partition each data set into four subsets — in-vocabulary words (IV), out-of-training-vocabulary words (OOTV), out-of-embedding-vocabulary words (OOEV) and out-of-both-vocabulary words (OOBV). A word is considered IV if it appears in both the training and embedding vocabulary, while OOBV if neither. OOTV words are the ones do not appear in training set but in embedding vocabulary, while OOEV are the ones do not appear in embedding vocabulary but in training set. For NER, an entity is considered as OOBV if there exists at lease one word not in training set and at least one word not in embedding vocabulary, and the other three subsets can be done in similar manner. Table 8 informs the statistics of the partition on each corpus. The embedding we used is Stanford's GloVe with dimension 100, the same as Section 4.2.

Table 9 illustrates the performance of our model on different subsets of words, together with the baseline LSTM-CNN model for comparison. The largest improvements appear on the OOBV subsets of both the two corpora. This demonstrates that by adding CRF for joint decoding, our model is more powerful on words that are out of both the training and embedding sets.

5 Related Work

In recent years, several different neural network architectures have been proposed and successfully applied to linguistic sequence labeling such as POS tagging, chunking and NER. Among these neural architectures, the three approaches most similar to our model are the BLSTM-CRF model proposed by Huang et al. (2015), the LSTM-CNNs model by Chiu and Nichols (2015) and the BLSTM-CRF by Lample et al. (2016).

Huang et al. (2015) used BLSTM for word-level representations and CRF for jointly label decoding, which is similar to our model. But there are two main differences between their model and ours. First, they did not employ CNNs to model character-level information. Second, they combined their neural network model with handcrafted features to improve their performance, making their model not an end-to-end system. Chiu and Nichols (2015) proposed a hybrid of BLSTM and CNNs to model both character- and word-level representations, which is similar to the first two layers in our model. They evaluated their model on NER and achieved competitive performance. Our model mainly differ from this model by using CRF for joint decoding. Moreover, their model is not truly end-to-end, either, as it utilizes external knowledge such as character-type, capitalization and lexicon features, and some data preprocessing specifically for NER (e.g. replacing all sequences of digits 0-9 with a single "0"). Recently, Lample et al. (2016) proposed a BLSTM-CRF model for NER, which utilized BLSTM to model both the character- and word-level information, and use data pre-processing the same as Chiu and Nichols (2015). Instead, we use CNN to model character-level information, achieving better NER performance without using any data preprocessing.

There are several other neural networks previously proposed for sequence labeling. Labeau et al. (2015) proposed a RNN-CNNs model for German POS tagging. This model is similar to the LSTM-CNNs model in Chiu and Nichols (2015), with the difference of using vanila RNN instead of LSTM. Another neural architecture employing

CNN to model character-level information is the "CharWNN" architecture (Santos and Zadrozny, 2014) which is inspired by the feed-forward network (Collobert et al., 2011). CharWNN obtained near state-of-the-art accuracy on English POS tagging (see Section 4.3 for details). A similar model has also been applied to Spanish and Portuguese NER (dos Santos et al., 2015) Ling et al. (2015) and Yang et al. (2016) also used BSLTM to compose character embeddings to word's representation, which is similar to Lample et al. (2016). Peng and Dredze (2016) Improved NER for Chinese Social Media with Word Segmentation.

6 Conclusion

In this paper, we proposed a neural network architecture for sequence labeling. It is a truly end-to-end model relying on no task-specific resources, feature engineering or data pre-processing. We achieved state-of-the-art performance on two linguistic sequence labeling tasks, comparing with previously state-of-the-art systems.

There are several potential directions for future work. First, our model can be further improved by exploring multi-task learning approaches to combine more useful and correlated information. For example, we can jointly train a neural network model with both the POS and NER tags to improve the intermediate representations learned in our network. Another interesting direction is to apply our model to data from other domains such as social media (Twitter and Weibo). Since our model does not require any domain- or task-specific knowledge, it might be effortless to apply it to these domains.

Abstract

Automatic spoken language assessment systems are becoming increasingly important to meet the demand for English second language learning. This is a challenging task due to the high error rates of, even state-of-the-art, non-native speech recognition. Consequently current systems primarily assess fluency and pronunciation. However, content assessment is essential for full automation. As a first stage it is important to judge whether the speaker responds on topic to test questions designed to elicit spontaneous speech. Standard approaches to off-topic response detection assess similarity between the response and question based on bag-of-words representations. An alternative framework based on Recurrent Neural Network Language Models (RNNLM) is proposed in this paper. The RNNLM is adapted to the topic of each test question. It learns to associate example responses to questions with points in a topic space constructed using these example responses. Classification is done by ranking the topic-conditional posterior probabilities of a response. The RNNLMs associate a broad range of responses with each topic, incorporate sequence information and scale better with additional training data, unlike standard methods. On experiments conducted on data from the Business Language Testing Service (BULATS) this approach outperforms standard approaches.

1 Introduction

As English has become the global *lingua franca*, there is growing demand worldwide for assessment of English as a second language (Seidlhofer, 2005). To assess spoken communication, spontaneous speech is typically elicited through a series of questions such as 'describe the photo' or 'plan a meeting'. Grades are awarded based on a candidate's responses.

Automatic assessment systems are becoming attractive as they allow second language assessment programmes to economically scale their operations while decreasing throughput time and provide testing on demand. Features for automatic graders are derived from the audio and from hypotheses produced by automatic speech recognition (ASR) systems. The latter is highly errorful due to the large variability in the input speech; disfluencies common to spontaneous speech, non-native accents and pronunciations. Current systems, such as ETS' *SpeechRater* (Zechner et al., 2009) and Pearson's *AZELLA* (Metallinou and Cheng, 2014), primarily assess pronunciation and fluency. Although these are clearly indicative of spoken language ability, full assessment of spoken communication requires judgement of high-level content and communication skills, such as response construction and relevance. The first stage of this is to assess whether the responses are off-topic, that is, has the candidate misunderstood the question and/or memorised a response.

While there has been little work done on detecting off-topic responses for spoken language assessment, detection of off-topic responses and content assessment has been studied for essay assessment. One approach for essay content assessment uses features based on semantic similarity metrics between vector space representations of responses. Common vector representations include lexical Vector Space Models and Latent Semantic Analysis (LSA) (Yannakoudakis, 2013). This approach was first applied to spoken assess-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1075–1084,
Berlin, Germany, August 7-12, 2016.

ment in (Xie et al., 2012) and then in (Evanini et al., 2013). Following this, (Yoon and Xie, 2014) investigated the detection of responses for which an automatic assessment system will have difficulty in assigning a valid score, of which off-topic responses are a specific type. A decision tree classifier is used with features based on cosine similarity between a test response and *tf-idf* vectors of both aggregate example responses and questions, as well as pronunciation and fluency. In (Evanini and Wang, 2014) text reuse and plagiarism in spoken responses are detected using a decision tree classifier based on vector similarity and lexical matching features which compare a response to a set of example 'source texts' . This task is similar to off-topic response detection in that it is based on comparing a test response to example responses. Thus, a standard approach to off-topic response detection would be based on measuring the similarity between vector representations of a spoken response and the test question. A major deficiency of this approach is that it is based on bag-of-words vector representations, which loses information about the sequential nature of speech, which is important to evaluating response construction and relevance. Additionally, adapting the approach to model a range of responses for each topic causes classification time to scale poorly with training data size and the number of questions.

To address these issues a general off-topic content detection framework based on topic adapted Recurrent Neural Network language models (RNNLM) has been developed and applied to off-topic response detection for spoken language assessment. This framework uses example responses to test questions in training of the language model and construction of the topic-space. The RNNLM learns to associate the example responses with points in the topic-space. Classification is done by ranking the topic-conditional posterior probabilities of a response. The advantage of this approach is that sequence information can be taken into account and broad ranges of responses can be associated with each topic without affecting classifcation speed. Two topic vector representations are investigated: Latent Dirichlet Allocation (LDA) (Blei et al., 2003; Griffiths and Steyvers, 2004) and Latent Semantic Analysis (LSA) (Landauer et al., 1998). They are compared to standard approaches on data from the Cambridge Business English (BULATS) exam.

The rest of this paper is structured as follows: Section 2 discusses the RNNLM adaptation and topic spaces; Section 3 discusses approaches to topic detection; Section 4 presents data sets and experimental infrastructure; Section 5 analyzes experimental results; Section 6 concludes the paper.

2 Topic Adapted RNNLMs

2.1 RNNLM Architecture

A statistical language model is used to model the semantic and syntactic information in text in the form of a probability distribution over word sequences. It assigns a probability to a word sequence $\mathbf{w} = \{w_0, w_1, \cdots, w_L\}$ as follows:

$$\mathtt{P}(w_i|w_{i-1}, \cdots, w_0) = \mathtt{P}(w_i|\mathbf{h}_0^{i-1}) \quad (1)$$

$$\mathtt{P}(\mathbf{w}) = \prod_{i=1}^{L} \mathtt{P}(w_i|\mathbf{h}_0^{i-1}) \quad (2)$$

where w_0 is the start of sentence symbol <s>. In this work a language model is trained to model example responses to questions on a spoken language assessment test. $\mathtt{P}(w_i|\mathbf{h}_0^{i-1})$ can be estimated by a number of approaches, most notably N-grams and Recurrent Neural Networks (Mikolov et al., 2010).

Recurrent Neural Network language models (RNNLMs) (Figure 1) (Mikolov, 2012) are a variable context length language model, capable of representing the entire context efficiently, unlike N-grams. RNNLMs represent the full untruncated history $\mathbf{h}_0^{i-1} = \{w_{i-1}, \cdots, w_0\}$ for word w_i as the hidden layer $\mathbf{s}_{i-1}$, a form of short-term memory, whose representation is learned from the data. Words and phrases are represented in a continuous space, which gives RNNLMs greater generalization abilities than other language models, such as N-grams.

RNNLMs can be adapted by adding a feature vector $\mathbf{f}$ which represents information absent from the RNN (Mikolov and Zweig, 2012). In this work, the vector representation of a spoken language test question topic $\mathbf{f}_q$ is used for the context vector $\mathbf{f}$. Architecturally, a context adapted RNNLM is described by equations 3-5. $\mathtt{e}(x)$ and $\mathtt{g}(x)$ are element-wise sigmoid and softmax acti-

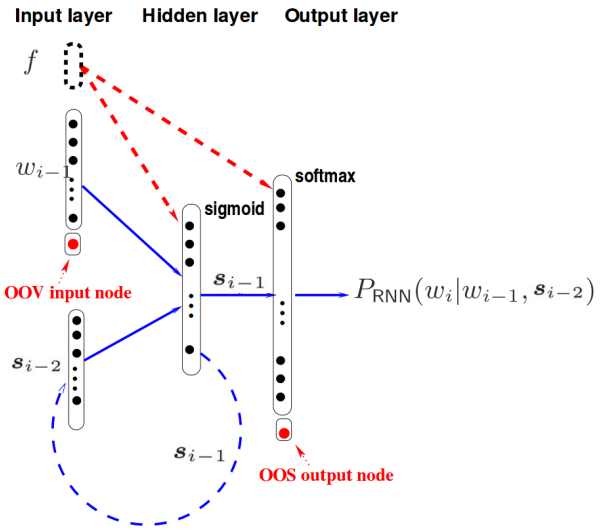

Figure 1: Context adapted RNN language model

vation functions.

$$\mathrm{P}(w_i|\mathbf{h}_0^{i-1}, \mathbf{f}) = \mathrm{P}_{\text{RNN}}(w_i|w_{i-1}, \mathbf{s}_{i-2}, \mathbf{f}) \quad (3)$$

$$\mathrm{P}_{\text{RNN}}(w_i|w_{i-1}, \mathbf{s}_{i-2}, \mathbf{f}) = \mathrm{g}(\mathbf{V}\mathbf{s}_{i-1} + \mathbf{H}\mathbf{f}) \quad (4)$$

$$\mathbf{s}_{i-1} = \mathrm{e}(\mathbf{U}w_{i-1} + \mathbf{W}\mathbf{s}_{i-2} + \mathbf{G}\mathbf{f}) \quad (5)$$

Through the process of adaptation the RNNLM learns to associate particular types of responses with particular topics, thereby becoming more discriminative. Thus, a sentence's topic-conditional probability $\mathrm{P}_{\text{RNN}}(\mathbf{w}|\mathbf{f}_q)$ will be higher if it corresponds to the topic q than if it does not.

2.2 Example Response Based Topic Space

In order for the topic vectors $\mathbf{f}_q$ to be informative they must span the space of all question topics in the test. Thus a topic space needs to be defined. Example responses, which are necessary to train the RNNLM, are used to define a topic space because typical responses to a question will be definitive of the question's topic. Multiple example responses to a particular question are merged into one aggregate response to capture a broad range of response variations and increase the robustness of the vector representation estimation.

By default a topic t is defined for each question q. However, multi-part questions are common, where candidates are given a scenario such as providing tourist information in which individual questions ask about food, hotels or sights. Since the underlying topic is related this can confuse a classifier. The responses for all these related questions could be merged to form a single aggregate vector, but the statistics of the responses to each question can be sufficiently different that less distinct topics are formed. Instead the aggregrate example responses for each question are assigned the same topic label. Thus, a mapping between questions and topics and its inverse is introduced:

$$\mathcal{M} : q \rightarrow t \quad (6)$$

$$\mathcal{M}_t^{-1} : \{q \in Q | \mathcal{M}(q) = t\} \quad (7)$$

A vector representation of a question topic is computed using the aggregate example responses. As mentioned in Section 1, two common representations are LDA and LSA; both are investigated in this work.

LDA is a generative model which allows documents to be modelled as distributions over latent topics $z \in Z$. Each latent topic z is described by a multinomial distribution over words $\mathrm{P}(w_i|z)$, and each word in a document is attributed to a particular latent topic (Blei et al., 2003). Thus, the adaptation vector $\mathbf{f}_\mathbf{w}$ represents a vector of posterior probabilities over latent topics for word sequence $\mathbf{w}$:

$$\mathbf{f}_\mathbf{w} = [\mathrm{P}(z = 1|\mathbf{w}), \cdots, \mathrm{P}(z = K|\mathbf{w})]^T \quad (8)$$

$$\mathrm{P}(z = k|\mathbf{w}) = \frac{\sum_{i=1}^{N} \delta(z_{w_i} = k)}{N} \quad (9)$$

LDA was found to perform better for RNNLM adaptation than other representations in (Mikolov and Zweig, 2012; Chen et al., 2015).

LSA (Landauer et al., 1998) is a popular representation for information retrieval tasks. A word-document matrix $\mathbf{F}$ is constructed using example responses and each word is weighted by its term frequency-inverse document frequency (TF-IDF). Then a low-rank approximation $\mathbf{F}_k$ is computed using Singular Value Decomposition (SVD):

$$\mathbf{F}_k = \mathbf{U}_k \mathbf{\Sigma}_k \mathbf{V}_k^T \quad (10)$$

$$\mathbf{F}_k = [\mathbf{f}_1, \cdots, \mathbf{f}_Q]^T \quad (11)$$

$$\mathbf{f}_\mathbf{w} = \Sigma_k^{-1} \mathbf{U}_k^T \mathbf{f}_{tfidf} \quad (12)$$

Only the k largest singular values of the singular value matrix Σ are kept. $\mathbf{F}_k$ is a representation of the data which retains only the k most significant factors of variation. Each row is a topic vector $\mathbf{f}_q$. New vectors $\mathbf{f}_\mathbf{w}$ for test responses can be projected into the LSA space via equation 12, where $\mathbf{f}_{tfidf}$ is the TF-IDF weighted bag-of-word representation of a test response.

3 Topic Detection and Features

This section discusses the standard, vector similarity feature-based, and the proposed topic adapted RNNLM approaches for topic detection.

3.1 Vector Similarity Features

The essence of the standard approach to topic detection is to assess the semantic distance $\mathtt{D}_{\mathtt{sem}}$ between the test response $\mathbf{w}$ and the aggregate example response $\mathbf{w}_q$ by approximating it using a vector distance metric $\mathtt{D}_{\mathtt{vec}}$ between vector representations of the response $\mathbf{f}_{\mathbf{w}}$ and the topic $\mathbf{f}_q$. Classification is done by selecting the topic closest to the test response:

$$\hat{t}_{\mathbf{w}} = \mathcal{M}\big(\arg\min_q \{\mathtt{D}_{\mathtt{sem}}(\mathbf{w}, \mathbf{w}_q)\}\big) \quad (13)$$

$$\mathtt{D}_{\mathtt{sem}}(\mathbf{w}, \mathbf{w}_q) \approx \mathtt{D}_{\mathtt{vec}}(\mathbf{f}_{\mathbf{w}}, \mathbf{f}_q) \quad (14)$$

The selection of an appropriate distance metric $\mathtt{D}_{\mathtt{vec}}(\mathbf{f}_{\mathbf{w}}, \mathbf{f}_q)$ can have a large effect on the classification outcome. A common metric used in topic classification and information retrieval is cosine similarity, which measures the cosine of the angle between two vectors. A distance metric based on this, *cosine distance*, can be defined as:

$$\mathtt{D}_{\mathtt{cos}}(\mathbf{f}_{\mathbf{w}}, \mathbf{f}_q) = 1 - \frac{\mathbf{f}_{\mathbf{w}}{}^{\mathsf{T}} \mathbf{f}_q}{|\mathbf{f}_{\mathbf{w}}||\mathbf{f}_q|} \quad (15)$$

While topics are robustly defined, this approach fails to capture the range of responses which can be given to a question. A different approach would be to maintain a separate point in this topic space for every example response. This retains the robust topic definition while allowing each topic to be represented by a cloud of points in topic space, thereby capturing a range of responses which can be given. A K-nearest neighbour (KNN) classifier can be used to detect the response topic by computing distances of the test response to each of the training points in topic space. However, classification may become impractical for large data sets, as the number of response points scales with the size of the training data. Low-cost distance measures, such as cosine distance, allow this approach to be used on large data sets before it becomes computationally infeasible. This approach is used as the baseline for comparison with the proposed RNNLM based method. For multi-part questions, topic vectors relating to the same overall topic are simply given the same topic label.

The classification rate can be improved by taking the top N $\hat{\mathbf{t}}_N = \{\hat{t}_1, \cdots, \hat{t}_N\}$ results into account. The KNN classifier can be modified to yield the N-best classification by removing all training points from the 1-best class from the KNN classifier and re-running the classification to get the 2-best results, and so on.

One of the main deficiencies of methods based on computing distances between vector representations is that commonly used representations, such as LSA and LDA, ignore word-order in documents, thereby throwing away information which is potentially useful for topic classification. Additionally, if any of the test or example response utterances are short, then their topic vector representations may not be robustly estimated.

3.2 Topic Adapted RNNLM Framework

The RNNLM based approach to topic detection is based on different principles. By combining equations 2 and 3 the log-probability $\mathtt{L}(q)$ of a response sentence given a particular topic vector $\mathtt{P}_{\mathtt{RNN}}(\mathbf{w}|\mathbf{f}_q)$ is computed. For each response $\mathbf{w}$ in the test set $\mathtt{L}(q)$ is computed (equation 16) for all topic vectors $\mathbf{f}_q$. $\mathtt{L}(q)$ is calculated using equation 17 for multi-part questions with responses $\mathbf{w}_p$ where $p \in t$. Classification is done by ranking log-probability $\mathtt{L}(q)$ for an utterance $\mathbf{w}$ and $\mathtt{L}(q)$ for all $q \in M_t^{-1}$ are averaged (equation 18).

$$\mathtt{L}(q) = \begin{cases} \log[\mathtt{P}_{\mathtt{RNN}}(\mathbf{w}|\mathbf{f}_q)] & (16) \\ \sum_p \frac{1}{N_p} \log[\mathtt{P}_{\mathtt{RNN}}(\mathbf{w}_p|\mathbf{f}_q)] & (17) \end{cases}$$

$$\hat{t}_{\mathbf{w}} = \arg\max_t \{ \frac{1}{|\mathcal{M}_t^{-1}|} \sum_{q \in M_t^{-1}} \mathtt{L}(q)\} \quad (18)$$

It is trivial to extend this approach to yield the N-best solutions by simply taking the top N outputs of equation 18.

The RNNLM approach has several benefits over standard approaches. Firstly, this approach explicitly takes account of word-order in determining the topical similarity of the response. Secondly, there is no need to explicitly select a distance metric. Thirdly, the problems of robustly estimating a vector representation $\mathbf{f}_{\mathbf{w}}$ of the test response are sidestepped. Furthermore, the RNNLM accounts for a broad range of responses because it is trained on individual response utterances which it associates with a question topic vector. This makes

it more scalable than the KNN approach because the number of comparisons which need to be made scales only with the number of questions, not the size of the training data. Thus, arbitrarily large data sets can be used to train the model without affecting classification time.

The RNNLM could be used in a KNN-style approach, where it associates each example response with its *individual* topic vector, using $\mathtt{L}(q)$ as a distance metric. However, this is computationally infeasible since computing $\mathtt{L}(q)$ is significantly more expensive than cosine distance and the previously mentioned scalability would be lost.

4 Data and Experimental Set-up

Data from the Business Language Testing Service (BULATS) English tests is used for training and testing. At test time, each response is recognised using an ASR system and the 1-best hypothesis is passed to the topic classifier. The topic detection system decides whether the candidate has spoken off topic by comparing the classifier output to the topic of the question being answered.

4.1 BULATS Test Format and Data

The BULATS Online Speaking Test has five sections (Chambers and Ingham, 2011):

A Candidates respond to eight simple questions about themselves and their work (e.g. what is your name, where do you come from?).

B Candidates read aloud six short texts appropriate to a work environment.

C Candidates talk about a work-related topic (e.g. the perfect office) with the help of prompts which appear on the screen.

D Candidates must describe a graph or chart such as a pie or a bar chart related to a business situation (e.g. company exports).

E Candidates are asked to respond to five open-ended questions related to a single context prompt. For example a set of five questions about organizing a stall at a trade fair.

Candidates are given a test consisting of 21 questions, however, only the last three sections, consisting of 7 questions, are spontaneously constructed responses to open ended question, and therefore of relevance to this work. Each unique set of 7 questions is a *question script*.

Training, development and evaluation data sets composed of predominantly Gujarati L1 candidates are used in these experiments. The data sets are designed to have an (approximately) even distribution over grades as well as over the different *question scripts*.

During operation the system will detect off-topic responses based on ASR transcriptions, so for the system to be matched it needs to be trained on ASR transcriptions as well. Thus, two training sets are made by using the ASR architecture described in section 4.2 to transcribe candidate responses. Each training set covers the same set of 282 unique topics. The first training set consists of data from 490 candidates, containing 9.9K responses, with an average of 35.1 responses per topic. The second, much larger, training set consists of data from 10004 candidates, containing 202K responses, with an average of 715.5 responses per topic.

Characteristic	Section				
	A	B	C	D	E
# Unique Topics	18	144	17	18	85
# Questions/Section	6	8	1	1	5
Av. # Words/Resp.	10	10	61	77	20

Table 1: Data Characteristics.

As Table 1 shows, the average response length varies across sections due to the nature of the sections. Shorter responses to questions are observed for sections A, B and E, with longer responses to C and D. Estimating topic representations for sections A, B and E questions based on individual responses would be problematic due to the short response lengths. However, by aggregating example responses across candidates, as described in section 2.2, the average length of responses in all sections is significantly longer, allowing the example-response topic space to be robustly defined.

Section E topics correspond to topics of sub-questions relating to an overall question, thus there are only 15 unique questions in section E. However, the sub-questions are sufficiently distinct to merit their own topic vectors. At classification time confusions between sub-questions of an overall section E question are not considered mistakes.

Held-out test sets are used for development, *DEV*, and evaluation, *EVAL*, composed of 84 and 223 candidates, respectively. ASR transcriptions are used for these test sets, as per the operating

scenario. A version of the DEV set with professionally produced transcriptions, *DEV REF*, is also used in training and development.

The publicly available Gibbs-LDA toolkit (Phan and Nguyen, 2007) is used to estimate LDA posterior topic vectors and the scikit-learn 17.0 toolkit (Pedregosa et al., 2011) to estimate LSA topic representations. The topic adapted RNNLM uses a 100-dimensional hidden layer. DEV REF is used as a validation set for early stopping to prevent over-fitting. The CUED RNNLM toolkit v0.1 (Chen et al., 2016) is used for RNNLM training, details of which can be found in (Chen et al., 2014; Mikolov et al., 2010)

4.2 ASR System

A hybrid deep neural network DNN-HMM system is used for ASR (Wang et al., 2015). The acoustic models are trained on 108.6 hours of BULATS test data (Gujarati L1 candidates) using an extended version of the HTK v3.4.1 toolkit (Young et al., 2009; Zhang and Woodland, 2015). A Kneser-Ney trigram LM is trained on 186K words of BULATs test data and interpolated with a general English LM trained on a large broadcast news corpus, using the SRILM toolkit (Stolcke, 2002). Lattices are re-scored with an interpolated trigram+RNN LM (Mikolov et al., 2010) by applying the 4-gram history approximation described in (Liu et al., 2014), where the RNNLM is trained using the CUED RNNLM toolkit (Chen et al., 2016). Interpolation weights are optimized on the DEV REF data set. Table 2 shows the word error rate (WER) on the DEV test set relative to the DEV REF references for each section and the combined spontaneous speech sections (C-E).

% WER					
A	B	C	D	E	C-E
30.6	23.2	32.0	29.9	32.3	31.5

5 Experiments

Two forms of experiment are conducted in order to assess the performance of the topic-adapted RNNLM. First, a topic classification experiment is run where the ability of the system to accurately recognize the topic of a response is evaluated. Second, a closed-set off-topic response detection experiment is done.

In the experimental configuration used here a response is classified into a topic and the accuracy is measured. The topic of the question being answered is known and all responses are actually on-topic. A label (on-topic/off-topic) is given for each response based on the output of the classifier relative to the question topic. Thus, results presented are in terms of false rejection (FR) and false acceptance (FA) rates rather than precision and recall.

Initial topic detection experiments were run using the DEV test set with both the reference transcriptions (REF) and recognition hypotheses (ASR) to compare different KNN and RNN systems. After this, performance is evaluated on the EVAL test set. The systems were trained using data sets of 490 and 10004 candidates, as described in section 4.1.

5.1 Topic Classification

Performance of the topic-adapted RNNLM is compared to the KNN classifier in Table 3. The RNN1 system outperforms the KNN system by 20-35 % using the LDA topic representation. Furthermore, the KNN system performs worse on section E than it does on section C, while RNN1 performance is better on section E by 7-10% than on section C. The LSA topic representation consistently yields much better performance than LDA by 25-50% for both systems. Thus, the LDA representation is not further investigated in any experiments.

When using the LSA representation the RNN1 system outperforms the KNN system only marginally, due to better performance on section E. Additionally, unlike the KNN-LDA system, the KNN-LSA system does not have a performance degradation on section E relative to section C. Notably, the RNN1 system performs better on section E by 5-13% than on section C. Clearly, section C questions are hardest to assess. Combining both representations through concatenation does not effect performance of the KNN system and slightly degrades RNN1 performance on section C. KNN and RNN1 systems with either topic representation perform comparably on REF and ASR. This suggests that the systems are quite robust to WER rates of 31.5% and the differences are mostly noise.

Training the RNN2 system on 20 times as much data leads to greatly improved performance over KNN and RNN1 systems, almost halving the over-

Topic Repn.	System	# Cands.	C		D		E		ALL (C-E)	
			REF	ASR	REF	ASR	REF	ASR	REF	ASR
LDA	KNN	490	75.0	81.0	37.0	42.0	91.8	91.1	68.0	71.4
	RNN1		61.9	58.3	28.4	25.9	48.8	51.2	46.6	45.4
LSA	KNN	490	32.1	28.6	2.5	3.7	31.3	33.3	22.0	21.9
	RNN1		29.8	31.0	4.9	6.2	23.8	23.8	19.7	20.5
	RNN2	10004	19.0	19.0	3.7	3.7	9.5	10.7	10.8	11.2
LDA +LSA	KNN	490	30.9	29.8	2.5	3.7	31.5	33.3	21.7	22.3
	RNN1		32.1	35.7	4.9	4.9	23.8	22.6	20.5	21.3
	RNN2	10004	25.0	22.6	4.9	4.9	10.7	10.7	13.7	12.9

Table 3: % False rejection in topic detection using KNN classifier with 6 nearest neighbour and distance weights and RNNLM classifier on the DEV test set. 280 dim. topic spaces for LDA and LSA, and 560 dim. for LDA+LSA.

all error rate. The KNN system could not be evaluated effectively in reasonable time using 20 times as many example responses and results are not shown, while RNN2 evaluation times are unaffected. Notably, RNN performance using the LSA representation scales with training data size better than with the LDA+LSA representation. Thus, we further investigate systems only with the LSA representation. Interestingly, section D performance is improved only marginally.

Performance on section D is always best, as section D questions relate to discussion of charts and graphs for different conditions for which the vocabulary is very specific. Section C and E questions are the less distinct because they have free-form answers to broad questions, leading to higher response variability. This makes the linking of topic from the training data to the test data more challenging, particularly for 1-best classification, leading to higher error rates.

Figure 2 shows the topic classification confusion matrix for the RNN1 LSA system. A similar matrix is observed for the KNN LSA system. Most confusions are with topics from the same section. This is because each section has a distinct style of questions and some questions within a section are similar. An example is shown below. Question SC-EX1 relates to personal local events in the workplace. SC-EX2, which relates to similar issues, is often confused with it. On the other hand, SC-EX3 is rarely confused with SC-EX1 as it is about non-personal events on a larger scale.

- SC-EX1: Talk about some advice from a colleague. You should say: what the advice was, how it helped you and whether you would give the same advice to another colleague.
- SC-EX2: Talk about a socially challenging day you had at work. You should say: what was the challenging situation, how you resolved it and why you found it challenging.
- SC-EX3: Talk about a company in your local town which you admire. You should say: what company it is, what they do, why you admire them, and how the company impacts life in your town.

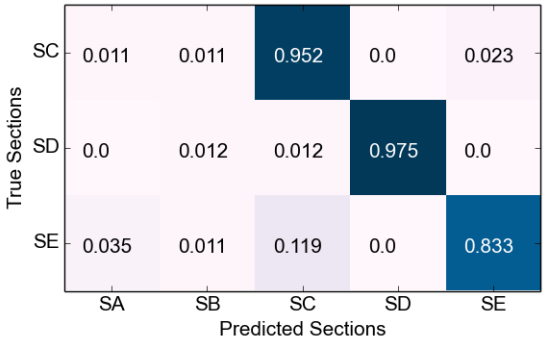

Figure 2: RNN1 LSA confusion matrix on DEV ASR.

System performance can be increased by considering N-best results, as described in Section 3. Results for systems trained on 490 and 10004 candidates are presented in Table 4. The error rate decreases as the value of N increases for all systems. However, performance scales better with N for the RNN systems than for KNN. Notably, for values of $N > 1$ performance of all systems on REF is better, which suggests that ASR errors do have a minor impact on system performance.

5.2 Off-topic response detection

In the second experiment off-topic response detection is investigated. Performance is measured

N	System	# Cands.	REF	ASR
1	KNN	490	22.1	21.9
	RNN1		19.7	20.5
	RNN2	10004	10.8	11.2
2	KNN	490	15.9	16.0
	RNN1		13.7	16.1
	RNN2	10004	6.8	7.6
3	KNN	490	13.5	14.3
	RNN1		10.4	11.2
	RNN2	10004	6.4	7.2
4	KNN	490	11.1	12.5
	RNN1		8.8	10.0
	RNN2	10004	5.2	6.4

Table 4: N-Best % false rejection performance of KNN and RNNLM classifiers with the LSA topic space on the DEV test set

in terms of the false acceptance (FA) probability of an off-topic response and false rejection (FR) probability of an on-topic response. The experiment is run on DEV and EVAL test sets. Since neither DEV nor EVAL contain real off-topic responses, a pool $\mathbf{W}_q$ of such responses is synthetically generated for each question by using valid responses to other questions in the data set. Off-topic responses are then selected from this pool. A selection strategy defines which responses are present in $\mathbf{W}_q$. Rather than using a single selection of off-topic responses, an expected performance over all possible off-topic response selections is estimated. The overall probability of falsely accepting an off-topic response can be expressed using equation 19.

$$\mathtt{P}(\mathtt{FA}) = \sum_{q=1}^{Q} \sum_{\mathbf{w} \in \mathbf{W}_q} \mathtt{P}(\mathtt{FA}|\mathbf{w}, q)\mathtt{P}(\mathbf{w}|q)\mathtt{P}(q) \quad (19)$$

In equation 19, the question q is selected with uniform probability from the set Q of possible questions. The candidate randomly selects with uniform probability $\mathtt{P}(\mathbf{w}|q)$ a response $\mathbf{w}$ from the pool $\mathbf{W}_q$. The correct response to the question is not present in the pool. The conditional probability of false accept $\mathtt{P}(\mathtt{FA}|\mathbf{w}, q) = 1$ if $\mathcal{M}(q) \in \hat{\mathbf{t}}_N$, and $\mathcal{M}(q)$ is not the real topic of the response $\mathbf{w}$, otherwise $\mathtt{P}(\mathtt{FA}|\mathbf{w}, q) = 0$.

As shown in Figure 2, the main confusions will occur if the response is from the same section as the question. Two strategies for selecting off-topic responses are considered based on this: `naive`, where an incorrect response can be selected from any section; and `directed`, where an incorrect response can only be selected from the same section as the question. The `naive` strategy represents candidates who have little knowledge of the system and memorise responses unrelated to the test, while the `directed` strategy represents those who are familiar with the test system and have access to real responses from previous tests.

Test Set	System	% Equal Error Rate	
		Directed	Naive
DEV	KNN	13.5	10.0
	RNN1	10.0	7.5
	RNN2	7.5	6.0
EVAL	KNN	12.5	9.0
	RNN1	8.0	6.0
	RNN2	5.0	4.5

Table 5: % Equal Error Rate for LSA topic space systems on the DEV and EVAL test sets.

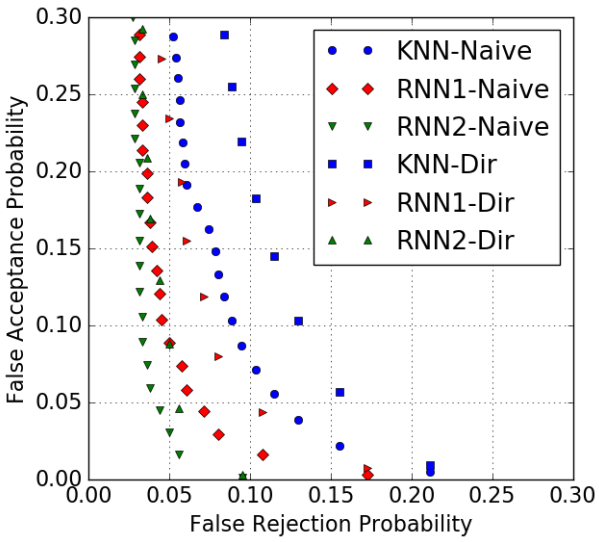

Figure 3: ROC curves of LSA topic space systems on the EVAL test set.

A Receiver Operating Characteristic (ROC) curve (Figure 3) can be constructed by plotting the FA and FR rates for a range of N. The RNN1 system performs better at all operating points than the KNN system for both selection strategies and evaluation test sets. Equal Error Rates (EER), where FA = FR, are given in Table 5. Results on EVAL are more representative of the difference between the KNN and RNN performance, as they are evaluated on nearly 3 times as many candidates. The

RNN2 system achieves the lowest EER. It is interesting that for better systems the difference in performance against the `naive` and `directed` strategies decreases. This indicates that the systems become increasingly better at discriminating between similar questions.

As expected, the equal error rate for the `directed` strategy is higher than for the `naive` strategy. In relation to the stated task of detecting when a test candidate is giving a memorized response, the `naive` strategy represents a lower-bound on realistic system performance, as students are not likely to respond with a valid response to a different question. Most likely they will fail to construct a valid response or will add completely unrelated phrases memorised beforehand, which, unlike responses from other sections, may not come from the same domain as the test (eg: Business for BULATs).

6 Conclusion and Future Work

In this work a novel off-topic content detection framework based on topic-adapted RNNLMs was developed. The system was evaluated on the task of detecting off-topic spoken responses on the BULATS test. The proposed approach achieves better topic classification and off-topic detection performance than the standard approaches.

A limitation of both the standard and proposed approach is that if a new question is created by the test-makers, then it will be necessary to collect example responses before it can be widely deployed. However, since the system can be trained on ASR transcriptions, the example responses do not need to be hand-transcribed. This is an attractive deployment scenario, as only a smaller hand-transcribed data set is needed to train an ASR system with which to cost-effectively transcribe a large number of candidate recordings.

Further exploration of different topic vector representations and their combinations is necessary in future work.

Abstract

Most machine translation systems construct translations from a closed vocabulary of target word forms, posing problems for translating into languages that have productive compounding processes. We present a simple and effective approach that deals with this problem in two phases. First, we build a classifier that identifies spans of the input text that can be translated into a single compound word in the target language. Then, for each identified span, we generate a pool of possible compounds which are added to the translation model as "synthetic" phrase translations. Experiments reveal that (i) we can effectively predict what spans can be compounded; (ii) our compound generation model produces good compounds; and (iii) modest improvements are possible in end-to-end English–German and English–Finnish translation tasks. We additionally introduce KomposEval, a new multi-reference dataset of English phrases and their translations into German compounds.

1 Introduction

Machine translation systems make a closed-vocabulary assumption: with the exception of basic rules for copying unknown word types from the input to the output, they can produce words in the target language only from a fixed, finite vocabulary. While this is always a naïve assumption given the long-tailed distributions that characterize natural language, it is particularly challenging in languages such as German and Finnish that have productive compounding processes.

In such languages, expressing compositions of basic concepts can require an unbounded number of words. For example, English multiword phrases like *market for bananas*, *market for pears*, and *market for plums* are expressed in German with single compound words (respectively, as *Bananenmarkt*, *Birnenmarkt*, and *Pflaumenmarkt*). Second, while they are individually rare, compound words are, on the whole, frequent in native texts (Baroni et al., 2002; Fritzinger and Fraser, 2010). Third, compounds are crucial for translation quality. Not only does generating them make the output seem more natural, but they are content-rich. Since each compound has, by definition, at least two stems, they are intuitively (at least) doubly important for translation adequacy.

Fortunately, compounding is a relatively regular process (as the above examples also illustrate), and it is amenable to modeling. In this paper we introduce a two-stage method (§2) to dynamically generate novel compound word forms given a source language input text and incorporate these as "synthetic rules" in a standard phrase-based translation system (Bhatia et al., 2014; Chahuneau et al., 2013; Tsvetkov et al., 2013). First, a binary classifier examines each source-language sentence and labels each span therein with whether that span could become a compound word when translated into the target language. Second, we transduce the identified phrase into the target language using a word-to-character translation model. This system makes a closed vocabulary assumption, albeit at the character (rather than word) level—thereby enabling new word forms to be generated. Training data for these models is extracted from automatically aligned and compound split parallel corpora (§3).

We evaluate our approach on both intrinsic and extrinsic metrics. Since German compounds are relatively rare, their impact on the standard MT evaluation metrics (e.g., BLEU) is minimal, as we

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1085–1094,
Berlin, Germany, August 7-12, 2016.

show with an oracle experiment, and we find that our synthetic phrase approach obtains only modest improvements in overall translation quality. To better assess its merits, we commissioned a new test set, which we dub KomposEval (from the German word for a compound word, *Komposita*), consisting of a set of 1090 English phrases and their translations as German compound words by a professional English–German translator. The translator was instructed to produce as many compound-word translations as were reasonable (§4). This dataset permits us to evaluate our compound generation component directly, and we show that (i) without mechanisms for generating compound words, MT systems cannot produce the long tail of compounds; and (ii) our method is an effective method for creating correct compounds.

2 Compound Generation via Rule Synthesis

Suppose we want to translate the sentence

the market for bananas has collapsed .

from English into German. In order to produce the following (good) translation,

der bananenmarkt ist abgestürzt .

a phrase-based translation system would need to contain a rule similar to *market for bananas* → *bananenmarkt*. While it is possible that such a rule would be learned from parallel corpora using standard rule extraction techniques, it is likely that such a rule would not exist (unless the system were trained on the translation examples from this paper).

We solve the compound translation problem by "filling in" such missing rule gaps in the phrase table. The process takes place in two parts: first, identifying spans in the input that appear to be translatable as compounds (§2.1), and second, generating candidate compounds for each positively identified span (§2.2). Since synthesized rules compete along side rules which are learned using standard rule extraction techniques (and which are often quite noisy), our rule synthesis system can *overgenerate* rule candidates, a fact which we exploit in both phases.

2.1 Phase I: Classifying Compoundable Spans

Given a source sentence, we classify each span therein (up to some maximum length) as either compoundable or non-compoundable using independent binary predictions. Rather than attempting to hand-engineer features to represent phrases, we use a bidirectional LSTM to learn a fixed-length vector representation $\mathbf{h}_{i,j}$ that is computed by composing representations of the tokens $(f_i, f_{i+1}, \ldots, f_j)$ in the input sentence. The probability that a span is compoundable is then modeled as:

$$p(\text{compoundable? } | f_i, f_{i+1}, \ldots, f_j) = \sigma\left(\mathbf{w}^\top \tanh(\mathbf{V}\mathbf{h}_{i,j} + \mathbf{b}) + a\right),$$

where σ is the logistic sigmoid function, and $\mathbf{w}$, $\mathbf{V}$, $\mathbf{b}$, and a are parameters.

To represent tokens that are inputs to the LSTM, we run a POS tagger (Toutanova et al., 2003), and for each token concatenate a learned embedding of the tag and word. Figure 1 shows the architecture.

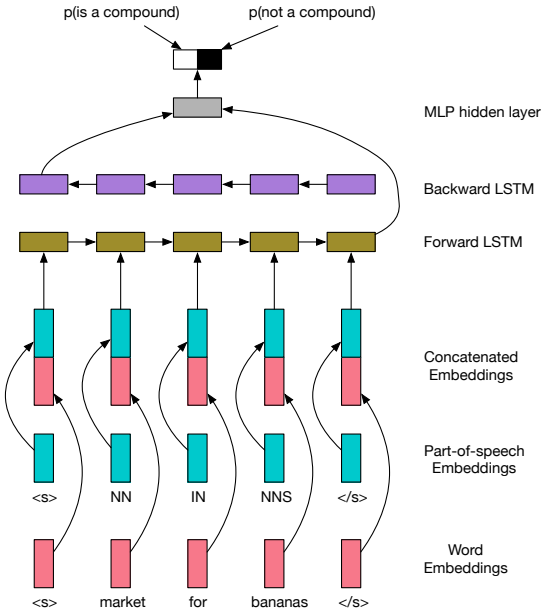

Figure 1: A graphical representation of the neural network used for classifying whether an input source phrase should or should not turn into a compound word in the target language

2.2 Phase II: Generating Compound Words

The second stage of our compound-generating pipeline is to generate hypothesis compound words for each source phrase that was identified as "compoundable" by the classifier just discussed. We do this by using a word-to-character–based machine translation system, which enables us to reuse a standard phrase-based decoder for compound generation.

2.2.1 Generation Model

The cornerstone of our generation approach is the forward and backward lexical translation tables learned by an unsupervised word aligner. We combine these two translation tables to create a word-to-character phrase table compatible with a standard decoder. This table allows our generator to know the correct translations of individual morphemes, but alone does not allow the generator to build full compound words.

To capture the small bits of "phonetic glue" (e.g., the *n* that occurs between *banane* and *markt* in the compound *bananenmarkt*) that may occur when generating compound words, we insert a special `SUF` symbol in between each pair of source words. This symbol will allow us to insert a small suffix in between the translations of source words.

Finally, we insert a special `END` symbol at the end of each source phrase. This symbol will allow the model to generate morphological variants due to suffixes indicating case, number, and agreement that only occur at the end of a whole compound word, but not in between the individual pieces. Some examples of all three types of rules are shown in Table 1.

2.2.2 Reordering and Word Dropping

We observe that in order to generate many compounds, including *bananenmarkts* from "market for bananas", a system must be able to both reorder and drop source words at will. Implemented naïvely, however, these allowances may produce invalid interleavings of source words and `SUF`/`END` tokens. For example, if we (correctly) drop the word "for" from our example, we might feed the decoder the sequence "market `SUF SUF` bananas `END`.

To disallow such bogus input sequences we disable all reordering inside the decoder, and instead encode all possible reorderings in the form of an input lattice (Dyer et al., 2008). Moreover, we allow the decoder to drop non-content words by skipping over them in the lattice. Each edge in our lattices contains a list of features, including the indices, lexical forms, and parts of speech of each word kept or dropped. Each possible sequence in the lattice also encodes features of the full path of source words kept, the full list of source words dropped, the parts of speech of the path and all dropped words, and the order of indices traversed.

With these constraints in place we can train the compound generator as though it were a normal MT system with no decode-time reordering.

3 Training

Our approach to generating compound word forms in translation has two stages. First, we build a classifier that chooses spans of source text that could produce target compounds. Second, we build a compound generator that outputs hypothesis word forms, given a source phrase. We will detail each of these steps in turn.

3.1 Extracting Compounds from Bitext

In order to learn to generate compound words we naturally require training data. Ideally we would like a large list of English phrases with their natural contexts and translations as German compounds. Of course virtually no such data exists, but it is possible to extract from parallel data, using a technique similar to that used by Tsvetkov and Wintner (2012).

To this end, we take our tokenized bitext and pass it through Dyer (2009)'s German compound splitter. We then align the segmented variant using the `fast_align` tool in both the forward and reverse directions, which produces both word alignments and lexical translation tables, which give the probability of a compound part given an English phrase. We then symmetrize the produced pair of alignments with the intersection heuristic. This results in a sparse alignment in which each target word is aligned to either 0 or 1 source words. We then undo any splits performed by the compound splitter, resulting in a corpus where the only words aligned many-to-one are precisely well-aligned compounds.

This process produces two crucially important data. First, a list of English phrase pairs that may become compound words in German on which we train our classifier. Second, the lexical translation tables, trained on compound split German data, which form the basis of our generation approach.

3.2 Training the Compoundability Classifier

The network is trained to maximize cross-entropy of its training data using the Adam optimizer (Kingma and Ba, 2014) until performance on a held-out dev set stops improving.

Due to the fact that we only need to represent the "compoundability" of each source-language word, and not its full semantics, we find that very small (10-dimensional) word and POS em-

Source	Target	Non-Zero Features
bananas	b a n a n e	$\phi_{fwd} = -0.495208$ $\phi_{rev} = -0.455368$
market	m a r k t	$\phi_{fwd} = -0.499118$ $\phi_{rev} = -0.269879$
SUF	n	$\phi_{fwd} = -3.718241$ $\phi_{\text{uses\_suf\_n}} = 1.0$
END	s	$\phi_{fwd} = -2.840721$ $\phi_{\text{uses\_end\_s}} = 1.0$

Table 1: A fragment of the word-to-character rules used in the compound generation system.

beddings work well. The recurrent part of the neural network uses two-layer LSTM (Hochreiter and Schmidhuber, 1997) cells with the hidden layer size set to 10. The final MLP's hidden layer size is also set to 10.

The training data is processed such that each span of length two to four is considered one training example, and is labeled as positive if it is well-aligned (Brown et al., 1993) to a single German compound word. Since most spans do not translate as compounds, we are faced with an extreme class imbalance problem (a ratio of about 300:1). We therefore experiment with down sampling the negative training examples to have an equal number of positive and negative examples.

3.3 Training the Compound Generation Model

As a translation model, there are two components to learning the translation system: learning the rule inventory and their features (§3.3.1) and learning the parameters of the generation model (§3.3.2).

3.3.1 Learning Word to Character Sequence Translation Rules

The possible translations of SUF and END are learned from the list of positive training examples extracted for our classifier. For each example, we find all the possible ways the source words could translate, in accordance with our translation table, into nonoverlapping substrings of the target word. Any left over letters in between pieces become possible translations of SUF, while extra letters at the end of the target string become possible translations of END. Probabilities for each translation are estimated by simply counting and normalizing the number of times each candidate was seen. See Figure 2 for an example of this splitting process.

3.3.2 Learning Generator Feature Weights

Since the generator model is encoded as a phrase-based machine translation system, we can train it using existing tools for this task. We choose to train using MIRA (Crammer and Singer, 2003), and use a 10-gram character-based language model trained on the target side of the positive training examples extracted for the classifier.

4 KomposEval Data Set

To evaluate our compound generator we needed a dataset containing English phrases that should be compounded along with their German translations. To the best of our knowledge, no substantial human-quality dataset existed, so we created one as part of this work.

We took our list of automatically extracted (English phrase, German compound) pairs and manually selected 1090 of them that should compound. We then asked a native German speaker to translate each English phrase into German compounds, and to list as many possibile compound translations as she could think of. The result is a test set consisting of 1090 English phrases, with between 1 and 5 possible German compound translations for each English phrase. This test set is published as supplementary material with this article. Some example translations are shown in Table 2.

Source phrase	Reference(s)
transitional period	Übergangsphase
	Übergangsperiode
	Übergangszeitraum
Chamber of deputies	Abgeordnetenhaus
	Abgeordnetenkammer
self-doubt	Selbstzweifel

Table 2: Examples of human-generated compounds from the KomposEval data set

5 Experiments

Before considering the problem of integrating our compound model with a full machine translation system, we perform an intrinsic evaluation of each of the two steps of our pipeline.

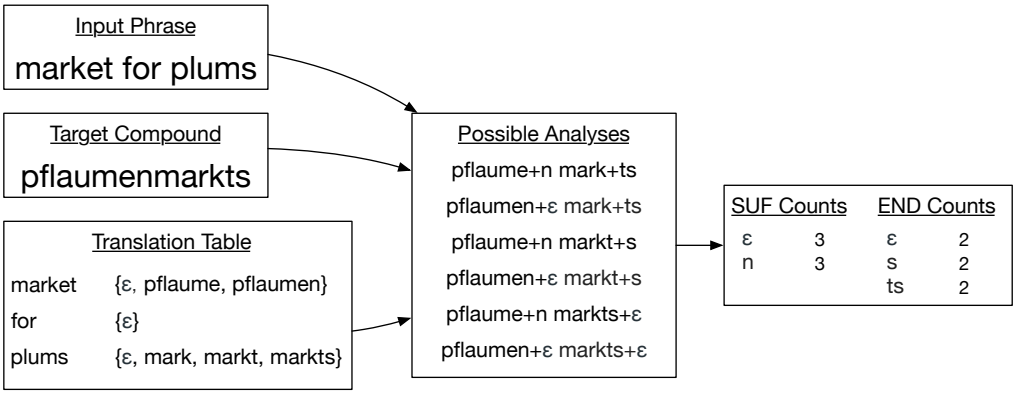

Figure 2: Decomposition of a target compound into possible analyses, given a source phrase and a morpheme-level translation table. This process allows us to learn the "phonetic glue" that can go in between morphemes, as well as the inflections that can attach to the end of a compound word.

5.1 Classifier Intrinsic Evaluation

We evaluate the effectiveness of our classifier, by measuring its precision and recall on the two held out test sets described in §2.1 taken from two language pairs: English–German and English–Finnish. Furthermore, we show results both with down-sampling (balanced data set) and without down-sampling (unbalanced data set).

Our classifier can freely trade off precision and recall by generalizing its requirement to call an example positive from $p(\text{compound} \mid \text{span}) > 0.5$ to $p(\text{compound} \mid \text{span}) > \tau$, for $\tau \in (0, 1)$, allowing us to report full precision-recall curves (Figure 3).

We find that our best results for the unbalanced cases come at $\tau = 0.24$ for German and $\tau = 0.29$ for Finnish, with F-scores of 20.1% and 67.8%, respectively. In the balanced case, we achieve 67.1% and 97.0% F-scores with $\tau = 0.04$ and $\tau = 0.57$ on German and Finnish respectively.

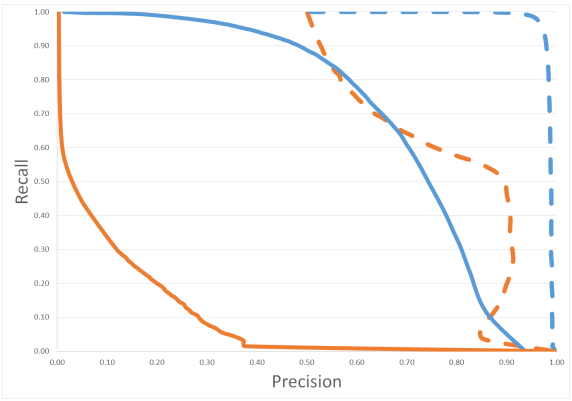

Figure 3: Precision-recall curves for our compound classifier for two languages: German (red) and Finnish (blue). Unbalanced test set results are shown with solid lines. Balanced test set results are shown with dashed lines.

5.2 Generator Instrinsic Evaluation

To evaluate our compound generator, we fed it the source side of our newly created KomposEval corpus and had it output a 100-best list of hypotheses translations for each English phrase. From this we are able to compute many intrinsic quality metrics. We report the following metrics:

- Mean reciprocal rank (MRR); which is one divided by the average over all segments of the position that the reference translation appears in our k-best list.
- Character error rate (CER), or the average number of character-level edits that are required to turn our 1-best hypothesis into the nearest of the reference translations.
- Precision at 1, 5, and 10, which indicate what percentage of the time a reference translation can be found in the top 1, 5, or 10 hypotheses of our k-best list, respectively.

These results can be found in Table 3. We compare to a naïve baseline that is just a standard English–German phrase-based translation system with no special handling of compound word forms. We immediately see that the baseline system is simply unable to generate most of the compound words in the test set, resulting in extraordinarily low metric scores across the board. Its one saving grace is its tolerable CER score, which shows that the system is capable of generating the correct morphemes, but is failing to correctly ad-

	MRR ↑	CER ↓	P@1 ↑	P@5 ↑	P@10 ↑
Baseline	<0.01	3.305	0%	0%	<0.01%
Our model	0.7004	2.506	61.38%	81.47%	84.31%

Table 3: Mean reciprocal rank, character error rate, and precision at K statistics of our baseline MT system and our compound generator.

join them and add the phonological glue required to produce a well-formed compound word. Our system, on the other hand, is capable of reaching at least one of the five references for every single sentence in the test set, and has a reference translation in the top 5 hypotheses in its k-best list over 80% of the time.

Qualitatively, the compounds generated by our model are remarkably good, and very understandable. Major error classes include incorrect word sense, non-compositional phrases, and special non- concatenative effects at word boundaries. An example of each of these errors, along with some examples of good compound generation can be found in Table 4.

5.3 Extrinsic Translation Evaluation

Finally, we use our compound generator as part of a larger machine translation pipeline. We run our compound span classifier on each of our translation system's tune and test sets, and extract our generator's top ten hypotheses for each of the postively identified spans. These English phrases are then added to a synthetic phrase table, along with their German compound translations, and two features: the compound generator's score, and an indicator feature simply showing that the rule represents a synthetic compound. Table 5 shows some example rules of this form. The weights of these features are learned, along with the standard translation system weights, by the MIRA algorithm as part of the MT training procedure.

The underlying translation system is a standard Hiero (Chiang et al., 2005) system using the cdec (Dyer et al., 2010) decoder, trained on all constrained-track WMT English–German data as of the 2014 translation task. Tokenization was done with `cdec`'s `tokenize-anything` script. The first character of each sentence was down cased if the unigram probability of the downcased version of the first word was higher than that of the original casing. Word alignment was performed using `cdec`'s `fast_align` tool,

		BLEU ↑	METR ↑	TER ↓	Len

and symmetrized using the `grow-diag` heuristic. Training is done using cdec's implementation of the MIRA algorithm. Evaluation was done using MultEval (Clark et al., 2011). A 4-gram language model was estimated using KenLM's `lmplz` tool (Heafield et al., 2013).

In addition to running our full end-to-end pipeline, we run an oracle experiment wherein we run the same pre-processing pipeline (compound splitting, bidirectionally aligning, intersecting, and de-splitting) on each test set to identify which spans do, in fact, turn into compounds, as well as their ideal translations. We then add grammar rules that allow precisely these source spans to translate into these oracle translations. This allows us to get an upper bound on the impact compound generation could have on translation quality.

The results, summarized in Table 6 and Table 7, show that adding these extra compounds has little effect on metric scores compared to our baseline system. Nevertheless, we believe that the qualitative improvements of our methods are more significant than the automatic metrics would indicate. Our method targets a very specific problem that pertains only to dense content-bearing target words that humans find very important. Moreover, BLEU is unable to reasonably evaluate improvements in these long tail phenomena, as it only captures exact lexical matches, and because we are purposely generating fewer target words than a standard translation system.

6 Related Work

Most prior work on compound generation has taken a different approach from the one advo-

cated here, first translating the source language into a morphologically analyzed and segmented variant of the target language, and then performing morphological generation on this sequence (Cap et al., 2014; Irvine and Callison-Burch, 2013; Denkowski et al., 2013; Clifton and Sarkar, 2011; Stymne and Cancedda, 2011).

Requesting multiple translations from a translator has been used in the past, most notably to create HyTER reference lattices (Dreyer and Marcu, 2012). However, in contrast to full-sentence translations the space of possible grammatical compounds is far smaller, substantially simplifying our task.

The splitting of German compound phrases for translation from German into English has been addressed by Koehn and Knight (2001) and Dyer (2009). They elegantly solve the problem of having a large, open vocabulary on the source side by splitting compound words into their constituent morphemes and translating German into English at the morpheme level. Their approach works excellently when translating *out* of a compounding language, but is unable to generate novel compound words in the target language without some sort of post processing.

Dynamic generation of compounds in a target language using such post processing has been examined in the past by Cap et al. (2014) and Clifton and Sarkar (2011). Both perform compound splitting on their parallel data, train a morpheme-based translation system, and then stitch compound words back together using different models. While effective, their approach runs into difficulties if the morphemes that should compound get separated by the reordering model during the translation process. Both address this using more complicated models, whereas our holistic approach handles this problem seamlessly.

Stymne (2012) gives an excellent taxonomy of compound types in Germanic languages, and discusses many different strategies that have been used to split and merge them for the purposes of machine translation. She identifies several difficulties with the split-translate-merge approach and points out some key subtleties, such as handling of bound morphemes that never occur outside of

compounds, that one must bear in mind when doing translation to or from compounding languages.

The idea of using entirely character-based translation systems was introduced by Vilar et al. (2007). While their letter-level translation system alone did not outperform standard phrase-based MT on a Spanish–Catalan task, they demonstrated substantial BLEU gains when combining phrase- and character-based translation models, particularly in low resource scenarios.

7 Conclusion

In this paper we have presented a technique for generating compound words for target languages with open vocabularies by dynamically introducing synthetic translation options that allow spans of source text to translate as a single compound word. Our method for generating such synthetic rules decomposes into two steps. First an RNN classifier detects compoundable spans in the source sentence. Second, a word-to-character machine translation system translates the span of text into a compound word.

By dynamically adding compound words to our translation grammars in this way we allow the decoder, which is in turn informed by the language model, to determine which, if any, of our hypothesized compounds look good in context. Our approach does away with the need for post processing, and avoids complications caused by reordering of morphemes in previous approaches. However, this technique relies heavily on a strong target language model. Therefore, one important extension of our work is to further study the interaction between our model and the underlying language model.

In addition to our generation technique we have presented a new human-quality data set that specifically targets compounding and use it to demonstrate tremendous improvements in our translation system's ability to correctly generalize from compound words found in parallel text to match human translations of unseen compoundable phrases.

Harnessing Cognitive Features for Sarcasm Detection

Abstract

In this paper, we propose a novel mechanism for enriching the feature vector, for the task of sarcasm detection, with cognitive features extracted from eye-movement patterns of human readers. Sarcasm detection has been a challenging research problem, and its importance for NLP applications such as review summarization, dialog systems and sentiment analysis is well recognized. Sarcasm can often be traced to *incongruity* that becomes apparent as the full sentence unfolds. This presence of incongruity- implicit or explicit- affects the way readers eyes move through the text. We observe the difference in the behaviour of the eye, while reading sarcastic and non sarcastic sentences. Motivated by this observation, we augment traditional linguistic and stylistic features for sarcasm detection with the cognitive features obtained from readers eye movement data. We perform statistical classification using the enhanced feature set so obtained. The augmented cognitive features improve sarcasm detection by 3.7% (in terms of F-score), over the performance of the best reported system.

1 Introduction

Sarcasm is an intensive, indirect and complex construct that is often intended to express contempt or ridicule [1]. Sarcasm, in speech, is multi-modal, involving tone, body-language and gestures along with linguistic artifacts used in speech. Sarcasm in text, on the other hand, is more restrictive when it comes to such non-linguistic modalities. This makes recognizing textual sarcasm more challenging for both humans and machines.

[1]The Free Dictionary

Sarcasm detection plays an indispensable role in applications like online review summarizers, dialog systems, recommendation systems and sentiment analyzers. This makes automatic detection of sarcasm an important problem. However, it has been quite difficult to solve such a problem with traditional NLP tools and techniques. This is apparent from the results reported by the survey from Joshi et al. (2016). The following discussion brings more insights into this.

Consider a scenario where an online reviewer gives a negative opinion about a movie through sarcasm: *"This is the kind of movie you see because the theater has air conditioning"*. It is difficult for an automatic sentiment analyzer to assign a rating to the movie and, in the absence of any other information, such a system may not be able to comprehend that *prioritizing the air-conditioning facilities of the theater over the movie experience indicates a negative sentiment towards the movie*. This gives an intuition to why, for sarcasm detection, it is necessary to go beyond textual analysis.

We aim to address this problem by exploiting the psycholinguistic side of sarcasm detection, using cognitive features extracted with the help of *eye-tracking*. A motivation to consider cognitive features comes from analyzing human eye-movement trajectories that supports the conjecture: *Reading sarcastic texts induces distinctive eye movement patterns, compared to literal texts.* The cognitive features, derived from human eye movement patterns observed during reading, include two primary feature types:

1. Eye movement characteristic features of readers while reading given text, comprising *gaze-fixaions* (*i.e,*longer stay of gaze on a visual object), forward and backward *saccades* (*i.e.,* quick jumping of gaze between two positions of rest).

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1095–1104,
Berlin, Germany, August 7-12, 2016.

2. Features constructed using the statistical and deeper structural information contained in *graph*, created by treating words as vertices and saccades between a pair of words as edges.

The cognitive features, along with textual features used in best available sarcasm detectors, are used to train binary classifiers against given sarcasm labels. Our experiments show significant improvement in classification accuracy over the state of the art, by performing such augmentation.

Feasibility of Our Approach

Since our method requires gaze data from human readers to be available, the methods practicability becomes questionable. We present our views on this below.

Availability of Mobile Eye-trackers

Availability of inexpensive embedded eye-trackers on hand-held devices has come close to reality now. This opens avenues to get eye-tracking data from inexpensive mobile devices from a huge population of online readers non-intrusively, and derive cognitive features to be used in predictive frameworks like ours. For instance, *Cogisen: (http://www.sencogi.com)* has a patent (ID: EP2833308-A1) on "eye-tracking using inexpensive mobile web-cams".

Applicability Scenario

We believe, mobile eye-tracking modules could be a part of mobile applications built for e-commerce, online learning, gaming *etc.* where automatic analysis of online reviews calls for better solutions to detect linguistic nuances like sarcasm. To give an example, let's say a book gets different reviews on Amazon. Our system could watch how readers read the review using mobile eye-trackers, and thereby, decide whether the text contains sarcasm or not. Such an application can horizontally scale across the web and will help in improving automatic classification of online reviews.

Since our approach seeks human mediation, one might be tempted to question the approach of relying upon eye-tracking, an indirect indicator, instead of directly obtaining man-made annotations. We believe, asking a large number of internet audience to annotate/give feedback on each and every sentence that they read online, following a set of annotation instructions, will be extremely intrusive and may not be responded well. Our system, on the other hand, can be seamlessly integrated into existing applications and as the eye-tracking process runs in the background, users will not be interrupted in the middle of the reading. This, thus, offers a more natural setting where human mediation can be availed without intervention.

Getting Users' Consent for Eye-tracking

Eye-tracking technology has already been utilized by leading mobile technology developers (like Samsung) to facilitate richer user experiences through services like *Smart-scroll* (where a user's eye movement determines whether a page has to be scrolled or not) and *Smart-lock* (where user's gaze position decides whether to lock the screen or not). The growing interest of users in using such services takes us to a promising situation where getting users' consent to record eye-movement patterns will not be difficult, though it is yet not the current state of affairs.

Disclaimer: In this work, we focus on detecting sarcasm in *non-contextual* and *short-text* settings prevalent in product reviews and social media. Moreover, our method requires eye-tracking data to be available in the test scenario.

2 Related Work

Sarcasm, in general, has been the focus of research for quite some time. In one of the pioneering works Jorgensen et al. (1984) explained how sarcasm arises when a figurative meaning is used opposite to the literal meaning of the utterance. In the word of Clark and Gerrig (1984), sarcasm processing involves canceling the indirectly negated message and replacing it with the implicated one. Giora (1995), on the other hand, define sarcasm as a mode of indirect negation that requires processing of both negated and implicated messages. Ivanko and Pexman (2003) define sarcasm as a six tuple entity consisting of *a speaker, a listener, Context, Utterance, Literal Proposition* and *Intended Proposition* and study the cognitive aspects of sarcasm processing.

Computational linguists have previously addressed this problem using rule based and statistical techniques, that make use of : **(a)** Unigrams and Pragmatic features (Carvalho et al., 2009; González-Ibánez et al., 2011; Barbieri et al., 2014; Joshi et al., 2015) **(b)** Stylistic patterns (Davidov et al., 2010) and patterns related to *situational disparity* (Riloff et al., 2013) and **(c)** Hastag

interpretations (Liebrecht et al., 2013; Maynard and Greenwood, 2014).

Most of the previously done work on sarcasm detection uses *distant supervision* based techniques (ex: leveraging *hashtags*) and stylistic/pragmatic features (emoticons, laughter expressions such as *"lol" etc*). But, detecting sarcasm in linguistically well-formed structures, in absence of explicit cues or information (like emoticons), proves to be hard using such linguistic/stylistic features alone.

With the advent of sophisticated eye-trackers and electro/magneto-encephalographic (EEG/MEG) devices, it has been possible to delve deep into the cognitive underpinnings of sarcasm understanding. Filik (2014), using a series of eye-tracking and EEG experiments try to show that for unfamiliar ironies, the literal interpretation would be computed first. They also show that a mismatch with context would lead to a re-interpretation of the statement, as being ironic. Camblin et al. (2007) show that in multi-sentence passages, discourse congruence has robust effects on eye movements. This also implies that disrupted processing occurs for discourse incongruent words, even though they are perfectly congruous at the sentence level. In our previous work (Mishra et al., 2016), we augment cognitive features, derived from eye-movement patterns of readers, with textual features to detect whether a human reader has realized the presence of sarcasm in text or not.

The recent advancements in the literature discussed above, motivate us to explore gaze-based cognition for sarcasm detection. As far as we know, our work is the first of its kind.

3 Eye-tracking Database for Sarcasm Analysis

Sarcasm often emanates from *incongruity* (Campbell and Katz, 2012), which enforces the brain to reanalyze it (Kutas and Hillyard, 1980). This, in turn, affects the way eyes move through the text. Hence, **distinctive eye-movement patterns may be observed in the case of successful processing of sarcasm in text in contrast to literal texts**. This hypothesis forms the crux of our method for sarcasm detection and we validate this using our previously released freely available sarcasm dataset[2] (Mishra et al., 2016) enriched with gaze information.

3.1 Document Description

The database consists of 1,000 short texts, each having 10-40 words. Out of these, 350 are sarcastic and are collected as follows: (a) 103 sentences are from two popular sarcastic quote websites[3], (b) 76 sarcastic short movie reviews are manually extracted from the *Amazon Movie Corpus* (Pang and Lee, 2004) by two linguists. (c) 171 tweets are downloaded using the hashtag *#sarcasm* from Twitter. The 650 non-sarcastic texts are either downloaded from Twitter or extracted from the Amazon Movie Review corpus. The sentences do not contain words/phrases that are *highly* topic or culture specific. The tweets were normalized to make them linguistically well formed to avoid difficulty in interpreting social media lingo. Every sentence in our dataset carries positive or negative opinion about specific "aspects". For example, the sentence *"The movie is extremely well cast"* has positive sentiment about the aspect "cast".

The annotators were seven graduate students with science and engineering background, and possess good English proficiency. They were given a set of instructions beforehand and are advised to seek clarifications before they proceed. The instructions mention the nature of the task, annotation input method, and necessity of head movement minimization during the experiment.

3.2 Task Description

The task assigned to annotators was to read sentences one at a time and label them with with binary labels indicating the polarity (*i.e.,* positive/negative). Note that, the participants were not

[3]http://www.sarcasmsociety.com, http://www.themarysue.com/funny-amazon-reviews

instructed to annotate whether a sentence is sarcastic or not., to rule out the *Priming Effect* (*i.e.,* if sarcasm is expected beforehand, processing incongruity becomes relatively easier (Gibbs, 1986)). The setup ensures its "ecological validity" in two ways: *(1)* Readers are not given any clue that they have to treat sarcasm with special attention. This is done by setting the task to polarity annotation (instead of sarcasm detection). *(2)* Sarcastic sentences are mixed with non sarcastic text, which does not give prior knowledge about whether the forthcoming text will be sarcastic or not.

The eye-tracking experiment is conducted by following the standard norms in eye-movement research (Holmqvist et al., 2011). At a time, one sentence is displayed to the reader along with the "aspect" with respect to which the annotation has to be provided. While reading, an SR-Research Eyelink-1000 eye-tracker (monocular remote mode, sampling rate 500Hz) records several eye-movement parameters like fixations (a long stay of gaze) and saccade (quick jumping of gaze between two positions of rest) and pupil size.

The accuracy of polarity annotation varies between 72%-91% for sarcastic texts and 75%-91% for non-sarcastic text, showing the inherent difficulty of sentiment annotation, when sarcasm is present in the text under consideration. Annotation errors may be attributed to: (a) lack of patience/attention while reading, (b) issues related to text comprehension, and (c) confusion/indecisiveness caused due to lack of context.

For our analysis, we do not discard the incorrect annotations present in the database. Since our system eventually aims to involve online readers for sarcasm detection, it will be hard to segregate readers who misinterpret the text. We make a rational assumption that, for a particular text, most of the readers, from a fairly large population, will be able to identify sarcasm. Under this assumption, the eye-movement parameters, averaged across all readers in our setting, may not be significantly distorted by a few readers who would have failed to identify sarcasm. This assumption is applicable for both regular and multi-instance based classifiers explained in section 6.

4 Analysis of Eye-movement Data

We observe distinct behavior during sarcasm reading, by analyzing the "fixation duration on the text" (also referred to as "dwell time" in the literature) and "scanpaths" of the readers.

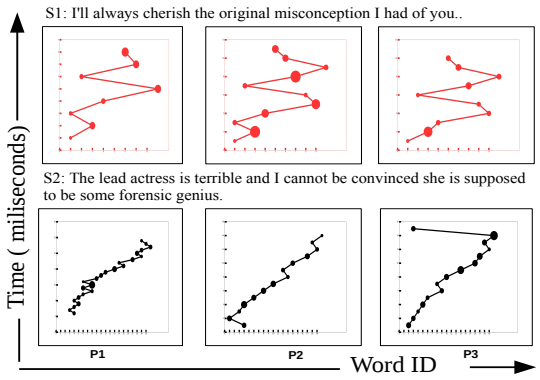

Figure 1: Scanpaths of three participants for two negatively polar sentences sentence *S1* and *S2*. Sentence *S1* is sarcastic but *S2* is not.

4.1 Variation in the Average Fixation Duration per Word

Since sarcasm in text can be expected to induce cognitive load, it is reasonable to believe that it would require more processing time (Ivanko and Pexman, 2003). Hence, fixation duration normalized over total word count should usually be higher for a sarcastic text than for a non-sarcastic one. We observe this for all participants in our dataset, with the *average fixation duration per word* for sarcastic texts being at least 1.5 times more than that of non-sarcastic texts. To test the statistical significance, we conduct a two-tailed t-test (assuming unequal variance) to compare the average fixation duration per word for sarcastic and non-sarcastic texts. The hypothesized mean difference is set to 0 and the error tolerance limit (α) is set to 0.05. The t-test analysis, presented in Table 1, shows that for all participants, a statistically significant difference exists between the average fixation duration per word for sarcasm (higher average fixation duration) and non-sarcasm (lower average fixation duration). This affirms that the presence of sarcasm affects the duration of fixation on words.

It is important to note that longer fixations may also be caused by other linguistic subtleties (such as difficult words, ambiguity and syntactically complex structures) causing delay in comprehension, or occulomotor control problems forcing readers to spend time adjusting eye-muscles. So, an elevated average fixation duration per word may not sufficiently indicate the presence of sarcasm. But we would also like to share that, for our

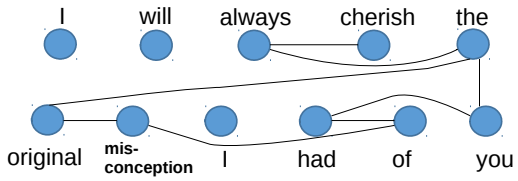

Figure 2: Saliency graph of participant *P1* for the sentence *I will always cherish the original misconception I had of you.*

dataset, when we considered *readability* (Flesch readability ease-score (Flesch, 1948)), *number of words in a sentence* and *average character per word* along with the *sarcasm label* as the predictors of average fixation duration following a linear mixed effect model (Barr et al., 2013), *sarcasm label* turned out to be the most significant predictor with a maximum slope. This indicates that average fixation duration per word has a strong connection with the text being sarcastic, at least in our dataset.

We now analyze *scanpaths* to gain more insights into the sarcasm comprehension process.

4.2 Analysis of Scanpaths

Scanpaths are line-graphs that contain fixations as nodes and saccades as edges; the radii of the nodes represent the fixation duration. A scanpath corresponds to a participant's eye-movement pattern while reading a particular sentence. Figure 1 presents scanpaths of three participants for the sarcastic sentence *S1* and the non-sarcastic sentence *S2*. The x-axis of the graph represents the sequence of words a reader reads, and the y-axis represents a temporal sequence in milliseconds.

Consider a sarcastic text containing incongruous phrases *A* and *B*. Our qualitative scanpath-analysis reveals that scanpaths with respect to sarcasm processing have two typical characteristics. Often, a long *regression* - a saccade that goes to a previously visited segment - is observed when a reader starts reading *B* after skimming through *A*. In a few cases, the fixation duration on *A* and *B* are significantly higher than the average fixation duration per word. In sentence *S1*, we see long and multiple regressions from the two incongruous phrases *"misconception"* and *"cherish"*, and a few instances where phrases *"always cherish"* and *"original misconception"* are fixated longer than usual. Such eye-movement behaviors are not seen for *S2*.

Though sarcasm induces distinctive scanpaths like the ones depicted in Figure 1 in the observed examples, presence of such patterns is not sufficient to guarantee sarcasm; such patterns may also possibly arise from literal texts. We believe that a combination of linguistic features, readability of text and features derived from scanpaths would help discriminative machine learning models learn sarcasm better.

5 Features for Sarcasm Detection

We describe the features used for sarcasm detection in Table 2. The features enlisted under *lexical*,*implicit incongruity* and *explicit incongruity* are borrowed from various literature (predominantly from Joshi et al. (2015)). These features are essential to separate sarcasm from other forms semantic incongruity in text (for example ambiguity arising from *semantic ambiguity* or from *metaphors*). Two additional *textual* features *viz. readability* and *word count* of the text are also taken under consideration. These features are used to reduce the effect of text hardness and text length on the eye-movement patterns.

5.1 Simple Gaze Based Features

Readers' eye-movement behavior, characterized by fixations, forward saccades, skips and regressions, can be directly quantified by simple statistical aggregation (*i.e.,* either computing features for individual participants and then averaging or performing a multi-instance based learning as explained in section 6). Since these eye-movement attributes relate to the cognitive process in reading (Rayner and Sereno, 1994), we consider these as features in our model. Some of these features have been reported by Mishra et al. (2016) for modeling sarcasm understandability of readers. However, as far as we know, these features are being introduced in NLP tasks like textual sarcasm detection for the first time. The values of these features are believed to increase with the increase in the degree of surprisal caused by incongruity in text (except *skip count*, which will decrease).

5.2 Complex Gaze Based Features

For these features, we rely on a graph structure, namely "saliency graphs", derived from eye-gaze information and word sequences in the text.

Constructing Saliency Graphs:

For each reader and each sentence, we construct a "saliency graph", representing the reader's atten-

Subcategory	Feature Name	Type	Intent
Category: Textual Sarcasm Features, Source: Joshi et. al.			
Lexical	Presence of Unigrams (UNI)	Boolean	Unigrams in the training corpus
	Punctuations (PUN)	Real	Count of punctuation marks
Implicit Incongruity	Implicit Incongruity (IMP)	Boolean	Incongruity of extracted implicit phrases (Rilof et.al, 2013)
Explicit Incongruity	Explicit Incongruity (EXP)	Integer	Number of times a word follows a word of opposite polarity
	Largest Pos/Neg Subsequence (LAR)	Integer	Length of the largest series of words with polarities unchanged
	Positive words (+VE)	Integer	Number of positive words
	Negative words (-VE)	Integer	Number of negative words
	Lexical Polarity (LP)	Integer	Sentence polarity found by supervised logistic regression
Category: Cognitive Features. We introduce these features for sarcasm detection.			
Textual	Readability (RED)	Real	Flesch Readability Ease (Flesch, 1948) score of the sentence
	Number of Words (LEN)	Integer	Number of words in the sentence
Simple Gaze Based	Avg. Fixation Duration (FDUR)	Real	Sum of fixation duration divided by word count
	Avg. Fixation Count (FC)	Real	Sum of fixation counts divided by word count
	Avg. Saccade Length (SL)	Real	Sum of saccade lengths (measured by number of words) divided by word count
	Regression Count (REG)	Real	Total number of gaze regressions
	Skip count (SKIP)	Real	Number of words skipped divided by total word count
	Count of regressions from second half to first half of the sentence (RSF)	Real	Number of regressions from second half of the sentence to the first half of the sentence (given the sentence is divided into two equal half of words)
	Largest Regression Position (LREG)	Real	Ratio of the absolute position of the word from which a regression with the largest amplitude (number of pixels) is observed, to the total word count of sentence
Complex Gaze Based	Edge density of the saliency gaze graph (ED)	Real	Ratio of the number of directed edges to vertices in the saliency gaze graph (SGG)
	Fixation Duration at Left/Source (F1H, F1S)	Real	Largest weighted degree (LWD) and second largest weighted degree (SWD) of the SGG considering the fixation duration of word i of edge E_{ij}
	Fixation Duration at Right/Target (F2H, F2S)	Real	LWD and SWD of the SGG considering the fixation duration of word j of edge E_{ij}
	Forward Saccade Word Count of Source (PSH, PSS)	Real	LWD and SWD of the SGG considering the number of forward saccades between words i and j of an edge E_{ij}
	Forward Saccade Word Count of Destination (PSDH, PSDS)	Real	LWD and SWD of the SGG considering the total distance (word count) of forward saccades between words i and j of an edge E_{ij}
	Regressive Saccade Word Count of Source (RSH, RSS)	Real	LWD and SWD of the SGG considering the number of regressive saccades between words i and j of an edge E_{ij}
	Regressive Saccade Word Count of Destination (RSDH, RSDS)	Real	LWD and SWD of the SGG considering the total distance (word count) of regressive saccades between words i and j of an edge E_{ij}

Table 2: The complete set of features used in our system.

tion characteristics. A saliency graph for a sentence S for a reader R, represented as $G = (V, E)$, is a graph with vertices (V) and edges (E) where each vertex $v \in V$ corresponds to a word in S (may not be unique) and there exists an edge $e \in E$ between vertices v_1 and v_2 if R performs at least one saccade between the words corresponding to $v1$ and $v2$.

Figure 2 shows an example of a saliency graph.A saliency graph may be weighted, but not necessarily connected, for a given text (as there may be words in the given text with no fixation on them). The "complex" gaze features derived from saliency graphs are also motivated by the theory of incongruity. For instance, *Edge Density* of a saliency graph increases with the number of distinct saccades, which could arise from the complexity caused by presence of sarcasm. Similarly, the highest weighted degree of a graph is expected to be higher, if the node corresponds to a phrase, incongruous to some other phrase in the text.

6 The Sarcasm Classifier

We interpret sarcasm detection as a binary classification problem. The training data constitutes

Features	P(1)	P(-1)	P(avg)	R(1)	R(-1)	R(avg)	F(1)	F(-1)	F(avg)	Kappa
Multi Layered Neural Network

Table 3: Classification results for different feature combinations. P→ Precision, R→ Recall, F→ F˙score, Kappa→ Kappa statistics show *agreement with the gold labels*. Subscripts 1 and -1 correspond to sarcasm and non-sarcasm classes respectively.

Sentence	Gold	Sarcasm	Gaze	Gaze+Sarcasm
1. I would like to live in Manchester, England. The transition between Manchester and death would be unnoticeable.	S	NS	S	S
2. Helped me a lot with my panic attacks. I took 6 mg a day for almost 20 years. Can't stop of course but it makes me feel very comfortable.	NS	S	NS	NS
3. Forgot to bring my headphones to the gym this morning, the music they play in this gym pumps me up so much!	S	S	NS	NS
4. Best show on satellite radio!! No doubt about it. The little doggy company has nothing even close.	NS	S	NS	S

Table 4: Example test-cases with *S* and *NS* representing labels for sarcastic and not-sarcastic respectively.

994 examples created using our eye-movement database for sarcasm detection. To check the effectiveness of our feature set, we observe the performance of multiple classification techniques on our dataset through a *stratified* 10-fold cross validation. We also compare the classification accuracy of our system and the best available systems proposed by Riloff et al. (2013) and Joshi et al. (2015) on our dataset. Using Weka (Hall et al., 2009) and LibSVM (Chang and Lin, 2011) APIs, we implement the following classifiers:

- Näive Bayes classifier
- Support Vector Machines (Cortes and Vapnik, 1995) with default hyper-paramaters
- Multilayer Feed Forward Neural Network
- Multi Instance Logistic Regression (MILR) (Xu and Frank, 2004)

6.1 Results

Table 3 shows the classification results considering various feature combinations for different classifiers and other systems. These are:

- *Unigram* (with principal components of unigram feature vectors),
- *Sarcasm* (the feature-set reported by Joshi et al. (2015) subsuming unigram features and features from other reported systems)
- *Gaze* (the simple and complex cognitive features we introduce, along with readability and word count features), and
- *Gaze+Sarcasm* (the complete set of features).

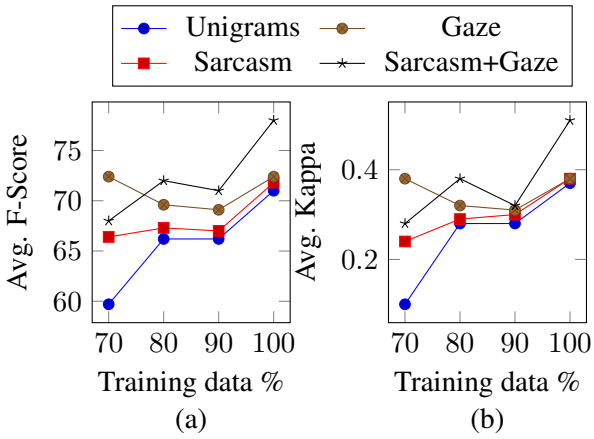

Figure 3: Effect of training data size on classification in terms of (a) F-score and (b) *Kappa* statistics

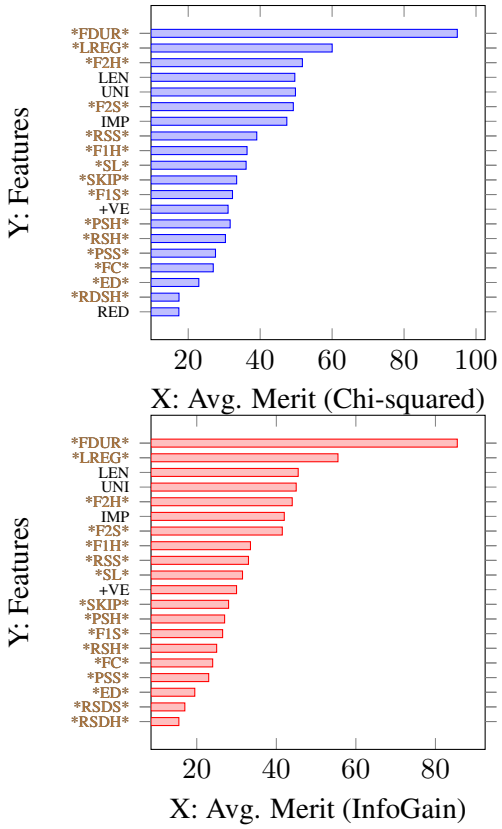

Figure 4: Significance of features observed by ranking the features using *Attribute Evaluation based on Information Gain* and *Attribute Evaluation based on Chi-squared test*. The length of the bar corresponds to the average merit of the feature. Features marked with * are gaze features.

For all regular classifiers, the gaze features are averaged across participants and augmented with linguistic and sarcasm related features. For the MILR classifier, the gaze features derived from each participant are augmented with linguistic features and thus, a multi instance "bag" of features is formed for each sentence in the training data. This multi-instance dataset is given to an MILR classifier, which follows the *standard multi instance assumption* to derive class-labels for each bag.

For all the classifiers, our feature combination outperforms the baselines (considering only unigram features) as well as (Joshi et al., 2015), with the MILR classifier getting an F-score improvement of **3.7%** and *Kappa* difference of **0.08**. We also achieve an improvement of **2%** over the baseline, using SVM classifier, when we employ our feature set. We also observe that the gaze features alone, also capture the differences between sarcasm and non-sarcasm classes with a high-precision but a low recall.

To see if the improvement obtained is statistically significant over the state-of-the art system with textual sarcasm features alone, we perform **McNemar test**. The output of the SVM classifier using only linguistic features used for sarcasm detection by Joshi et al. (2015) and the output of the MILR classifier with the complete set of features are compared, setting threshold $\alpha = 0.05$. There was a significant difference in the classifier's accuracy with **p(two-tailed) = 0.02** with an odds-ratio of **1.43**, showing that the classification accuracy improvement is unlikely to be observed by chance in 95% confidence interval.

6.2 Considering Reading Time as a Cognitive Feature along with Sarcasm Features

One may argue that, considering simple measures of reading effort like "reading time" as cognitive feature instead of the expensive eye-tracking features for sarcasm detection may be a cost-effective solution. To examine this, we repeated our experiments with "reading time" considered as the only cognitive feature, augmented with the textual features. The F-scores of all the classifiers turn out to be close to that of the classifiers considering sarcasm feature alone and the difference in the improvement is not statistically significant ($p > 0.05$). One the other hand, F-scores with gaze features are superior to the F-scores when reading time is considered as a cognitive feature.

6.3 How Effective are the Cognitive Features

We examine the effectiveness of cognitive features on the classification accuracy by varying the input training data size. To examine this, we create a

stratified (keeping the class ratio constant) random train-test split of 80%:20%. We train our classifier with 100%, 90%, 80% and 70% of the training data with our whole feature set, and the feature combination from Joshi et al. (2015). The goodness of our system is demonstrated by improvements in F-score and Kappa statistics, shown in Figure 3.

We further analyze the importance of features by ranking the features based on **(a)** Chi squared test, and **(b)** Information Gain test, using Weka's attribute selection module. Figure 4 shows the top 20 ranked features produced by both the tests. For both the cases, we observe 16 out of top 20 features to be gaze features. Further, in each of the cases, *Average Fixation Duration per Word* and *Largest Regression Position* are seen to be the two most significant features.

6.4 Example Cases

Table 4 shows a few example cases from the experiment with stratified 80%-20% train-test split.

- Example sentence 1 is sarcastic, and requires extra-linguistic knowledge (about poor living conditions at Manchester). Hence, the sarcasm detector relying only on textual features is unable to detect the underlying incongruity. However, our system predicts the label successfully, possibly helped by the gaze features.

- Similarly, for sentence 2, the false sense of presence of incongruity (due to phrases like "Helped me" and "Can't stop") affects the system with only linguistic features. Our system, though, performs well in this case also.

- Sentence 3 presents a false-negative case where it was hard for even humans to get the sarcasm. This is why our gaze features (and subsequently the complete set of features) account for erroneous prediction.

- In sentence 4, gaze features alone false-indicate presence of incongruity, whereas the system predicts correctly when gaze and linguistic features are taken together.

From these examples, it can be inferred that, only gaze features would not have sufficed to rule out the possibility of detecting other forms of incongruity that do not result in sarcasm.

6.5 Error Analysis

Errors committed by our system arise from multiple factors, starting from limitations of the eye-tracker hardware to errors committed by linguistic tools and resources. Also, aggregating various eye-tracking parameters to extract the cognitive features may have caused information loss in the regular classification setting.

7 Conclusion

In the current work, we created a novel framework to detect sarcasm, that derives insights from human cognition, that manifests over eye movement patterns. We hypothesized that distinctive eye-movement patterns, associated with reading sarcastic text, enables improved detection of sarcasm. We augmented traditional linguistic features with cognitive features obtained from readers' eye-movement data in the form of simple gaze-based features and complex features derived from a graph structure. This extended feature-set improved the success rate of the sarcasm detector by 3.7%, over the best available system. Using cognitive features in an NLP Processing system like ours is the first proposal of its kind.

Our general approach may be useful in other NLP sub-areas like sentiment and emotion analysis, text summarization and question answering, where considering textual clues alone does not prove to be sufficient. We propose to augment this work in future by exploring deeper graph and gaze features. We also propose to develop models for the purpose of learning complex gaze feature representation, that accounts for the power of individual eye movement patterns along with the aggregated patterns of eye movements.

Abstract

We present a novel end-to-end neural model to extract entities and relations between them. Our recurrent neural network based model captures both word sequence and dependency tree substructure information by stacking bidirectional tree-structured LSTM-RNNs on bidirectional sequential LSTM-RNNs. This allows our model to jointly represent both entities and relations with shared parameters in a single model. We further encourage detection of entities during training and use of entity information in relation extraction via entity pretraining and scheduled sampling. Our model improves over the state-of-the-art feature-based model on end-to-end relation extraction, achieving 12.1% and 5.7% relative error reductions in F1-score on ACE2005 and ACE2004, respectively. We also show that our LSTM-RNN based model compares favorably to the state-of-the-art CNN based model (in F1-score) on nominal relation classification (SemEval-2010 Task 8). Finally, we present an extensive ablation analysis of several model components.

1 Introduction

Extracting semantic relations between entities in text is an important and well-studied task in information extraction and natural language processing (NLP). Traditional systems treat this task as a pipeline of two separated tasks, i.e., named entity recognition (NER) (Nadeau and Sekine, 2007; Ratinov and Roth, 2009) and relation extraction (Zelenko et al., 2003; Zhou et al., 2005), but recent studies show that end-to-end (joint) modeling of entity and relation is important for high performance (Li and Ji, 2014; Miwa and Sasaki, 2014) since relations interact closely with entity information. For instance, to learn that *Toefting* and *Bolton* have an *Organization-Affiliation (ORG-AFF)* relation in the sentence *Toefting transferred to Bolton*, the entity information that *Toefting* and *Bolton* are *Person* and *Organization* entities is important. Extraction of these entities is in turn encouraged by the presence of the context words *transferred to*, which indicate an employment relation. Previous joint models have employed feature-based structured learning. An alternative approach to this end-to-end relation extraction task is to employ automatic feature learning via neural network (NN) based models.

There are two ways to represent relations between entities using neural networks: recurrent/recursive neural networks (RNNs) and convolutional neural networks (CNNs). Among these, RNNs can *directly* represent essential linguistic structures, i.e., word sequences (Hammerton, 2001) and constituent/dependency trees (Tai et al., 2015). Despite this representation ability, for relation classification tasks, the previously reported performance using long short-term memory (LSTM) based RNNs (Xu et al., 2015b; Li et al., 2015) is worse than one using CNNs (dos Santos et al., 2015). These previous LSTM-based systems mostly include limited linguistic structures and neural architectures, and do not model entities and relations jointly. We are able to achieve improvements over state-of-the-art models via end-to-end modeling of entities and relations based on richer LSTM-RNN architectures that incorporate complementary linguistic structures.

Word sequence and tree structure are known to be complementary information for extracting relations. For instance, dependencies between words

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1105–1116,
Berlin, Germany, August 7-12, 2016.

are not enough to predict that *source* and *U.S.* have an *ORG-AFF* relation in the sentence *"This is ...", one U.S. source said*, and the context word *said* is required for this prediction. Many traditional, feature-based relation classification models extract features from both sequences and parse trees (Zhou et al., 2005). However, previous RNN-based models focus on only one of these linguistic structures (Socher et al., 2012).

We present a novel end-to-end model to extract relations between entities on both word sequence and dependency tree structures. Our model allows joint modeling of entities and relations in a single model by using both bidirectional sequential (left-to-right and right-to-left) and bidirectional tree-structured (bottom-up and top-down) LSTM-RNNs. Our model first detects entities and then extracts relations between the detected entities using a single incrementally-decoded NN structure, and the NN parameters are jointly updated using both entity and relation labels. Unlike traditional incremental end-to-end relation extraction models, our model further incorporates two enhancements into training: entity pretraining, which pretrains the entity model, and scheduled sampling (Bengio et al., 2015), which replaces (unreliable) predicted labels with gold labels in a certain probability. These enhancements alleviate the problem of low-performance entity detection in early stages of training, as well as allow entity information to further help downstream relation classification.

On end-to-end relation extraction, we improve over the state-of-the-art feature-based model, with 12.1% (ACE2005) and 5.7% (ACE2004) relative error reductions in F1-score. On nominal relation classification (SemEval-2010 Task 8), our model compares favorably to the state-of-the-art CNN-based model in F1-score. Finally, we also ablate and compare our various model components, which leads to some key findings (both positive and negative) about the contribution and effectiveness of different RNN structures, input dependency relation structures, different parsing models, external resources, and joint learning settings.

2 Related Work

LSTM-RNNs have been widely used for sequential labeling, such as clause identification (Hammerton, 2001), phonetic labeling (Graves and Schmidhuber, 2005), and NER (Hammerton, 2003). Recently, Huang et al. (2015) showed that building a conditional random field (CRF) layer on top of bidirectional LSTM-RNNs performs comparably to the state-of-the-art methods in the part-of-speech (POS) tagging, chunking, and NER.

For relation classification, in addition to traditional feature/kernel-based approaches (Zelenko et al., 2003; Bunescu and Mooney, 2005), several neural models have been proposed in the SemEval-2010 Task 8 (Hendrickx et al., 2010), including embedding-based models (Hashimoto et al., 2015), CNN-based models (dos Santos et al., 2015), and RNN-based models (Socher et al., 2012). Recently, Xu et al. (2015a) and Xu et al. (2015b) showed that the shortest dependency paths between relation arguments, which were used in feature/kernel-based systems (Bunescu and Mooney, 2005), are also useful in NN-based models. Xu et al. (2015b) also showed that LSTM-RNNs are useful for relation classification, but the performance was worse than CNN-based models. Li et al. (2015) compared separate sequence-based and tree-structured LSTM-RNNs on relation classification, using basic RNN model structures.

Research on tree-structured LSTM-RNNs (Tai et al., 2015) fixes the direction of information propagation from bottom to top, and also cannot handle an arbitrary number of typed children as in a typed dependency tree. Furthermore, no RNN-based relation classification model simultaneously uses word sequence and dependency tree information. We propose several such novel model structures and training settings, investigating the simultaneous use of bidirectional sequential and bidirectional tree-structured LSTM-RNNs to jointly capture linear and dependency context for end-to-end extraction of relations between entities.

As for end-to-end (joint) extraction of relations between entities, all existing models are feature-based systems (and no NN-based model has been proposed). Such models include structured prediction (Li and Ji, 2014; Miwa and Sasaki, 2014), integer linear programming (Roth and Yih, 2007; Yang and Cardie, 2013), card-pyramid parsing (Kate and Mooney, 2010), and global probabilistic graphical models (Yu and Lam, 2010; Singh et al., 2013). Among these, structured prediction methods are state-of-the-art on several corpora. We present an improved, NN-based alternative for the end-to-end relation extraction.

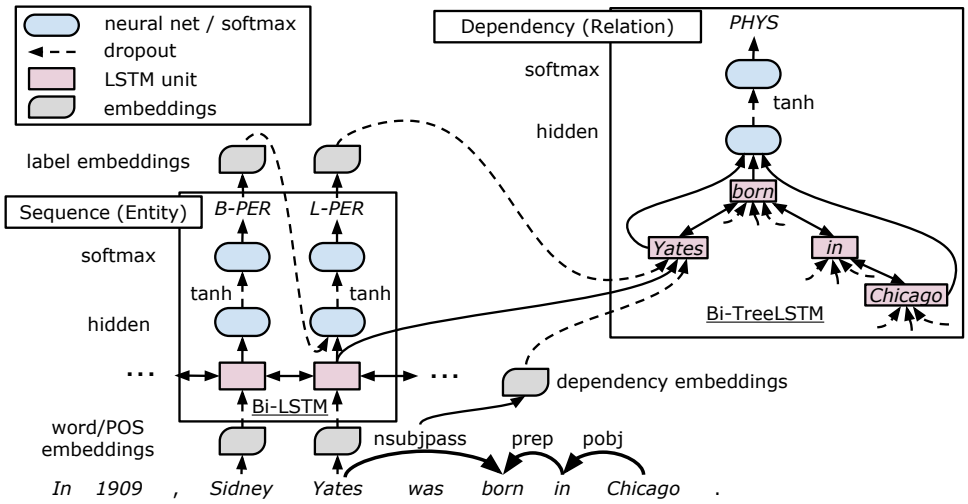

Fig. 1: Our incrementally-decoded end-to-end relation extraction model, with bidirectional sequential and bidirectional tree-structured LSTM-RNNs.

3 Model

We design our model with LSTM-RNNs that represent both word sequences and dependency tree structures, and perform end-to-end extraction of relations between entities on top of these RNNs. Fig. 1 illustrates the overview of the model. The model mainly consists of three representation layers: a word embeddings layer (embedding layer), a word sequence based LSTM-RNN layer (sequence layer), and finally a dependency subtree based LSTM-RNN layer (dependency layer). During decoding, we build greedy, left-to-right entity detection on the sequence layer and realize relation classification on the dependency layers, where each subtree based LSTM-RNN corresponds to a relation candidate between two detected entities. After decoding the entire model structure, we update the parameters simultaneously via backpropagation through time (BPTT) (Werbos, 1990). The dependency layers are stacked on the sequence layer, so the embedding and sequence layers are **shared** by both entity detection and relation classification, and the shared parameters are affected by both entity and relation labels.

3.1 Embedding Layer

The embedding layer handles embedding representations. n_w, n_p, n_d and n_e-dimensional vectors $v^{(w)}$, $v^{(p)}$, $v^{(d)}$ and $v^{(e)}$ are embedded to words, part-of-speech (POS) tags, dependency types, and entity labels, respectively.

3.2 Sequence Layer

The sequence layer represents words in a linear sequence using the representations from the embedding layer. This layer represents sentential context information and maintains entities, as shown in bottom-left part of Fig. 1.

We represent the word sequence in a sentence with bidirectional LSTM-RNNs (Graves et al., 2013). The LSTM unit at t-th word consists of a collection of n_{l_s}-dimensional vectors: an input gate i_t, a forget gate f_t, an output gate o_t, a memory cell c_t, and a hidden state h_t. The unit receives an n-dimensional input vector x_t, the previous hidden state h_{t-1}, and the memory cell c_{t-1}, and calculates the new vectors using the following equations:

$$
\begin{aligned}
i_t &= \sigma\left(W^{(i)}x_t + U^{(i)}h_{t-1} + b^{(i)}\right), \qquad (1)\\
f_t &= \sigma\left(W^{(f)}x_t + U^{(f)}h_{t-1} + b^{(f)}\right),\\
o_t &= \sigma\left(W^{(o)}x_t + U^{(o)}h_{t-1} + b^{(o)}\right),\\
u_t &= \tanh\left(W^{(u)}x_t + U^{(u)}h_{t-1} + b^{(u)}\right),\\
c_t &= i_t \odot u_t + f_t \odot c_{t-1},\\
h_t &= o_t \odot \tanh(c_t),
\end{aligned}
$$

where σ denotes the logistic function, $\odot$ denotes element-wise multiplication, W and U are weight matrices, and b are bias vectors. The LSTM unit at t-th word receives the concatenation of word and POS embeddings as its input vector: $x_t = \left[v_t^{(w)}; v_t^{(p)}\right]$. We also concatenate the hidden state vectors of the two directions' LSTM units corresponding to each word (denoted as $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$) as

its output vector, $s_t = \left[\overrightarrow{h_t}; \overleftarrow{h_t}\right]$, and pass it to the subsequent layers.

3.3 Entity Detection

We treat entity detection as a sequence labeling task. We assign an entity tag to each word using a commonly used encoding scheme BILOU (Begin, Inside, Last, Outside, Unit) (Ratinov and Roth, 2009), where each entity tag represents the entity type and the position of a word in the entity. For example, in Fig. 1, we assign *B-PER* and *L-PER* (which denote the beginning and last words of a person entity type, respectively) to each word in *Sidney Yates* to represent this phrase as a *PER* (person) entity type.

We perform entity detection on top of the sequence layer. We employ a two-layered NN with an n_{h_e}-dimensional hidden layer $h^{(e)}$ and a softmax output layer for entity detection.

$$h_t^{(e)} = \tanh\left(W^{(e_h)}[s_t; v_{t-1}^{(e)}] + b^{(e_h)}\right) \quad (2)$$

$$y_t = \text{softmax}\left(W^{(e_y)} h_t^{(e)} + b^{(e_y)}\right) \quad (3)$$

Here, W are weight matrices and b are bias vectors.

We assign entity labels to words in a greedy, left-to-right manner.[1] During this decoding, we use the predicted label of a word to predict the label of the next word so as to take label dependencies into account. The NN above receives the concatenation of its corresponding outputs in the sequence layer and the label embedding for its previous word (Fig. 1).

3.4 Dependency Layer

The dependency layer represents a relation between a pair of two target words (corresponding to a relation candidate in relation classification) in the dependency tree, and is in charge of relation-specific representations, as is shown in top-right part of Fig. 1. This layer mainly focuses on the *shortest path* between a pair of target words in the dependency tree (i.e., the path between the least common node and the two target words) since these paths are shown to be effective in relation classification (Xu et al., 2015a). For example, we show the shortest path between *Yates* and *Chicago* in the bottom of Fig. 1, and this path well captures the key phrase of their relation, i.e., *born in*.

[1] We also tried beam search but this did not show improvements in initial experiments.

We employ bidirectional tree-structured LSTM-RNNs (i.e., bottom-up and top-down) to represent a relation candidate by capturing the dependency structure around the target word pair. This bidirectional structure propagates to each node not only the information from the leaves but also information from the root. This is especially important for relation classification, which makes use of argument nodes near the bottom of the tree, and our top-down LSTM-RNN sends information from the top of the tree to such near-leaf nodes (unlike in standard bottom-up LSTM-RNNs).[2] Note that the two variants of tree-structured LSTM-RNNs by Tai et al. (2015) are not able to represent our target structures which have a variable number of typed children: the Child-Sum Tree-LSTM does not deal with types and the N-ary Tree assumes a fixed number of children. We thus propose a new variant of tree-structured LSTM-RNN that shares weight matrices Us for same-type children and also allows variable number of children. For this variant, we calculate n_{l_t}-dimensional vectors in the LSTM unit at t-th node with $C(t)$ children using following equations:

$$i_t = \sigma\left(W^{(i)}x_t + \sum_{l \in C(t)} U_{m(l)}^{(i)} h_{tl} + b^{(i)}\right), \quad (4)$$

$$f_{tk} = \sigma\left(W^{(f)}x_t + \sum_{l \in C(t)} U_{m(k)m(l)}^{(f)} h_{tl} + b^{(f)}\right),$$

$$o_t = \sigma\left(W^{(o)}x_t + \sum_{l \in C(t)} U_{m(l)}^{(o)} h_{tl} + b^{(o)}\right),$$

$$u_t = \tanh\left(W^{(u)}x_t + \sum_{l \in C(t)} U_{m(l)}^{(u)} h_{tl} + b^{(u)}\right),$$

$$c_t = i_t \odot u_t + \sum_{l \in C(t)} f_{tl} \odot c_{tl},$$

$$h_t = o_t \odot \tanh(c_t),$$

where $m(\cdot)$ is a type mapping function.

To investigate appropriate structures to represent relations between two target word pairs, we experiment with three structure options. We primarily employ the shortest path structure (**SP-Tree**), which captures the core dependency path between a target word pair and is widely used in relation classification models, e.g., (Bunescu and

[2] We also tried to use one LSTM-RNN by connecting the root (Paulus et al., 2014), but preparing two LSTM-RNNs showed slightly better performance in our initial experiments.

Mooney, 2005; Xu et al., 2015a). We also try two other dependency structures: **SubTree** and **FullTree**. SubTree is the subtree under the lowest common ancestor of the target word pair. This provides additional modifier information to the path and the word pair in SPTree. FullTree is the full dependency tree. This captures context from the entire sentence. While we use one node type for SPTree, we define two node types for SubTree and FullTree, i.e., one for nodes on shortest paths and one for all other nodes. We use the type mapping function $m(\cdot)$ to distinguish these two nodes types.

3.5 Stacking Sequence and Dependency Layers

We stack the dependency layers (corresponding to relation candidates) on top of the sequence layer to incorporate both word sequence and dependency tree structure information into the output. The dependency-layer LSTM unit at the t-th word receives as input $x_t = \left[s_t; v_t^{(d)}; v_t^{(e)}\right]$, i.e., the concatenation of its corresponding hidden state vectors s_t in the sequence layer, dependency type embedding $v_t^{(d)}$ (denotes the type of dependency to the parent[3]), and label embedding $v_t^{(e)}$ (corresponds to the predicted entity label).

3.6 Relation Classification

We incrementally build relation candidates using all possible combinations of the last words of detected entities, i.e., words with L or U labels in the BILOU scheme, during decoding. For instance, in Fig. 1, we build a relation candidate using *Yates* with an *L-PER* label and *Chicago* with an *U-LOC* label. For each relation candidate, we realize the dependency layer d_p (described above) corresponding to the path between the word pair p in the relation candidate, and the NN receives a relation candidate vector constructed from the output of the dependency tree layer, and predicts its relation label. We treat a pair as a negative relation when the detected entities are wrong or when the pair has no relation. We represent relation labels by type and direction, except for negative relations that have no direction.

The relation candidate vector is constructed as the concatenation $d_p = [\uparrow h_{p_A}; \downarrow h_{p_1}; \downarrow h_{p_2}]$, where $\uparrow h_{p_A}$ is the hidden state vector of the top LSTM unit in the bottom-up LSTM-RNN (representing the lowest common ancestor of the target word pair p), and $\downarrow h_{p_1}$, $\downarrow h_{p_2}$ are the hidden state vectors of the two LSTM units representing the first and second target words in the top-down LSTM-RNN.[4] All the corresponding arrows are shown in Fig. 1.

Similarly to the entity detection, we employ a two-layered NN with an n_{h_r}-dimensional hidden layer $h^{(r)}$ and a softmax output layer (with weight matrices W, bias vectors b).

$$h_p^{(r)} = \tanh\left(W^{(r_h)} d_p + b^{(r_h)}\right) \quad (5)$$

$$y_p = \text{softmax}\left(W^{(r_y)} h_t^{(r)} + b^{(r_y)}\right) \quad (6)$$

We construct the input d_p for relation classification from tree-structured LSTM-RNNs stacked on sequential LSTM-RNNs, so the contribution of sequence layer to the input is indirect. Furthermore, our model uses words for representing entities, so it cannot fully use the entity information. To alleviate these problems, we directly concatenate the average of hidden state vectors for each entity from the sequence layer to the input d_p to relation classification, i.e., $d'_p = \left[d_p; \frac{1}{|I_{p_1}|}\sum_{i\in I_{p_1}} s_i; \frac{1}{|I_{p_2}|}\sum_{i\in I_{p_2}} s_i\right]$ (**Pair**), where I_{p_1} and I_{p_2} represent sets of word indices in the first and second entities.[5]

Also, we assign two labels to each word pair in prediction since we consider both left-to-right and right-to-left directions. When the predicted labels are inconsistent, we select the positive and more confident label, similar to Xu et al. (2015a).

3.7 Training

We update the model parameters including weights, biases, and embeddings by BPTT and Adam (Kingma and Ba, 2015) with gradient clipping, parameter averaging, and L2-regularization (we regularize weights W and U, not the bias terms b). We also apply dropout (Srivastava et al., 2014) to the embedding layer and to the final hidden layers for entity detection and relation classification.

We employ two enhancements, **scheduled sampling** (Bengio et al., 2015) and **entity pretraining**, to alleviate the problem of unreliable prediction of entities in the early stage of training,

[3] We use the dependency to the parent since the number of children varies. Dependency types can also be incorporated into $m(\cdot)$, but this did not help in initial experiments.

[4] Note that the order of the target words corresponds to the direction of the relation, not the positions in the sentence.

[5] Note that we do not show this **Pair** in Fig.1 for simplicity.

and to encourage building positive relation instances from the detected entities. In scheduled sampling, we use gold labels as prediction in the probability of ϵ_i that depends on the number of epochs i during training if the gold labels are legal. As for ϵ_i, we choose the inverse sigmoid decay $\epsilon_i = k/(k + \exp(i/k))$, where $k(\geq 1)$ is a hyper-parameter that adjusts how often we use the gold labels as prediction. Entity pretraining is inspired by (Pentina et al., 2015), and we pretrain the entity detection model using the training data before training the entire model parameters.

4 Results and Discussion

4.1 Data and Task Settings

We evaluate on three datasets: ACE05 and ACE04 for end-to-end relation extraction, and SemEval-2010 Task 8 for relation classification. We use the first two datasets as our primary target, and use the last one to thoroughly analyze and ablate the relation classification part of our model.

ACE05 defines 7 coarse-grained entity types and 6 coarse-grained relation types between entities. We use the same data splits, preprocessing, and task settings as Li and Ji (2014). We report the primary micro F1-scores as well as micro precision and recall on both entity and relation extraction to better explain model performance. We treat an entity as correct when its type and the region of its head are correct. We treat a relation as correct when its type and argument entities are correct; we thus treat all non-negative relations on wrong entities as false positives.

ACE04 defines the same 7 coarse-grained entity types as ACE05 (Doddington et al., 2004), but defines 7 coarse-grained relation types. We follow the cross-validation setting of Chan and Roth (2011) and Li and Ji (2014), and the preprocessing and evaluation metrics of ACE05.

SemEval-2010 Task 8 defines 9 relation types between nominals and a tenth type *Other* when two nouns have none of these relations (Hendrickx et al., 2010). We treat this *Other* type as a negative relation type, and no direction is considered. The dataset consists of 8,000 training and 2,717 test sentences, and each sentence is annotated with a relation between two given nominals. We randomly selected 800 sentences from the training set as our development set. We followed the official task setting, and report the official macro-averaged F1-score (Macro-F1) on the 9 relation types.

For more details of the data and task settings, please refer to the supplementary material.

4.2 Experimental Settings

We implemented our model using the *cnn* library.[6] We parsed the texts using the Stanford neural dependency parser[7] (Chen and Manning, 2014) with the original Stanford Dependencies. Based on preliminary tuning, we fixed embedding dimensions n_w to 200, n_p, n_d, n_e to 25, and dimensions of intermediate layers (n_{l_s}, n_{l_t} of LSTM-RNNs and n_{h_e}, n_{h_r} of hidden layers) to 100. We initialized word vectors via word2vec (Mikolov et al., 2013) trained on Wikipedia[8] and randomly initialized all other parameters. We tuned hyper-parameters using development sets for ACE05 and SemEval-2010 Task 8 to achieve high primary (Micro- and Macro-) F1-scores.[9] For ACE04, we directly employed the best parameters for ACE05. The hyper-parameter settings are shown in the supplementary material. For SemEval-2010 Task 8, we also omitted the entity detection and label embeddings since only target nominals are annotated and the task defines no entity types. Our statistical significance results are based on the Approximate Randomization (AR) test (Noreen, 1989).

4.3 End-to-end Relation Extraction Results

Table 1 compares our model with the state-of-the-art feature-based model of Li and Ji (2014)[10] on final test sets, and shows that our model performs better than the state-of-the-art model.

To analyze the contributions and effects of the various components of our end-to-end relation extraction model, we perform ablation tests on the ACE05 development set (Table 2). The performance slightly degraded without scheduled sampling, and the performance significantly degraded when we removed entity pretraining or removed both ($p<0.05$). This is reasonable because the model can only create relation instances when both of the entities are found and, without these enhancements, it may get too late to find some relations. Removing label embeddings did not affect

Table 3: Comparison of LSTM-RNN structures on the ACE05 development dataset.

the entity detection performance, but this degraded the recall in relation classification. This indicates that entity label information is helpful in detecting relations.

We also show the performance without sharing parameters, i.e., embedding and sequence layers, for detecting entities and relations (−**Shared parameters**); we first train the entity detection model, detect entities with the model, and build a *separate* relation extraction model using the detected entities, i.e., without entity detection. This setting can be regarded as a pipeline model since two separate models are trained sequentially. Without the shared parameters, both the performance in entity detection and relation classification drops slightly, although the differences are not significant. When we removed all the enhancements, i.e., scheduled sampling, entity pretraining, label embedding, and shared parameters, the performance is significantly worse than SPTree ($p<0.01$), showing that these enhancements provide complementary benefits to end-to-end relation extraction.

Next, we show the performance with different LSTM-RNN structures in Table 3. We first compare the three input dependency structures (SPTree, SubTree, FullTree) for tree-structured LSTM-RNNs. Performances on these three structures are almost same when we distinguish the nodes in the shortest paths from other nodes, but when we do not distinguish them (-SP), the information outside of the shortest path, i.e.,

FullTree (-SP), significantly hurts performance ($p<0.05$). We then compare our tree-structured LSTM-RNN (SPTree) with the Child-Sum tree-structured LSTM-RNN on the shortest path of Tai et al. (2015). Child-Sum performs worse than our SPTree model, but not with as big of a decrease as above. This may be because the difference in the models appears only on nodes that have multiple children and all the nodes except for the least common node have one child.

We finally show results with two counterparts of sequence-based LSTM-RNNs using the shortest path (last two rows in Table 3). **SPSeq** is a bidirectional LSTM-RNN on the shortest path. The LSTM unit receives input from the sequence layer concatenated with embeddings for the surrounding dependency types and directions. We concatenate the outputs of the two RNNs for the relation candidate. **SPXu** is our adaptation of the shortest path LSTM-RNN proposed by Xu et al. (2015b) to match our sequence-layer based model.[11] This has two LSTM-RNNs for the left and right subpaths of the shortest path. We first calculate the max pooling of the LSTM units for each of these two RNNs, and then concatenate the outputs of the pooling for the relation candidate. The comparison with these sequence-based LSTM-RNNs indicates that a tree-structured LSTM-RNN is comparable to sequence-based ones in representing shortest paths.

Overall, the performance comparison of the LSTM-RNN structures in Table 3 show that for end-to-end relation extraction, *selecting the appropriate tree structure representation of the input (i.e., the shortest path) is more important than the choice of the LSTM-RNN structure on that input (i.e., sequential versus tree-based).*

4.4 Relation Classification Analysis Results

To thoroughly analyze the relation classification part alone, e.g., comparing different LSTM structures, architecture components such as hidden layers and input information, and classification task settings, we use the SemEval-2010 Task 8. This dataset, often used to evaluate NN models for relation classification, annotates only relation-related nominals (unlike ACE datasets), so we can focus cleanly on the relation classification part.

[11] This is different from the original one in that we use the sequence layer and we concatenate the embeddings for the input, while the original one prepared individual LSTM-RNNs for different inputs and concatenated their outputs.

Table 5: Comparison of LSTM-RNN structures on SemEval-2010 Task 8 development set.

We first report official test set results in Table 4. Our novel LSTM-RNN model is comparable to both the state-of-the-art CNN-based models on this task with or without external sources, i.e., WordNet, unlike the previous best LSTM-RNN model (Xu et al., 2015b).[12]

Next, we compare different LSTM-RNN structures in Table 5. As for the three input dependency structures (SPTree, SubTree, FullTree), FullTree performs significantly worse than other structures regardless of whether or not we distinguish the nodes in the shortest paths from the other nodes, which hints that the information outside of the shortest path significantly hurts the performance ($p<0.05$). We also compare our tree-structured LSTM-RNN (SPTree) with sequence-based LSTM-RNNs (SPSeq and SPXu) and tree-structured LSTM-RNNs (Child-Sum). All these LSTM-RNNs perform slightly worse than our SP-

[12] When incorporating WordNet information into our model, we prepared embeddings for WordNet hypernyms extracted by SuperSenseTagger (Ciaramita and Altun, 2006) and concatenated the embeddings to the input vector (the concatenation of word and POS embeddings) of the sequence LSTM. We tuned the dimension of the WordNet embeddings and set it to 15 using the development dataset.

Tree model, but the differences are small.

Overall, for relation classification, although the performance comparison of the LSTM-RNN structures in Table 5 produces different results on FullTree as compared to the results on ACE05 in Table 3, the trend still holds that selecting the appropriate tree structure representation of the input is more important than the choice of the LSTM-RNN structure on that input.

Finally, Table 6 summarizes the contribution of several model components and training settings on SemEval relation classification. We first remove the hidden layer by directly connecting the LSTM-RNN layers to the softmax layers, and found that this slightly degraded performance, but the difference was small. We then skip the sequence layer and directly use the word and POS embeddings for the dependency layer. Removing the sequence layer[13] or entity-related information from the sequence layer (−Pair) slightly degraded performance, and, on removing both, the performance dropped significantly ($p<0.05$). This indicates that the sequence layer is necessary but the last words of nominals are almost enough for expressing the relations in this task.

When we replace the Stanford neural dependency parser with the Stanford lexicalized PCFG parser (Stanford PCFG), the performance slightly dropped, but the difference was small. This indicates that the selection of parsing models is not critical. We also included WordNet, and this slightly improved the performance (+WordNet), but the difference was small. Lastly, for the generation of relation candidates, generating only left-to-right candidates slightly degraded the performance, but the difference was small and hence the creation of right-to-left candidates was not critical. Treating the inverse relation candidate as a negative instance (Negative sampling) also performed comparably to other generation methods in our model (unlike Xu et al. (2015a), which showed a significance improvement over generating only left-to-right candidates).

[13]Note that this setting still uses some sequence layer information since it uses the entity-related information (Pair).

5 Conclusion

We presented a novel end-to-end relation extraction model that represents both word sequence and dependency tree structures by using bidirectional sequential and bidirectional tree-structured LSTM-RNNs. This allowed us to represent both entities and relations in a single model, achieving gains over the state-of-the-art, feature-based system on end-to-end relation extraction (ACE04 and ACE05), and showing favorably comparable performance to recent state-of-the-art CNN-based models on nominal relation classification (SemEval-2010 Task 8).

Our evaluation and ablation led to three key findings. First, the use of both word sequence and dependency tree structures is effective. Second, training with the shared parameters improves relation extraction accuracy, especially when employed with entity pretraining, scheduled sampling, and label embeddings. Finally, the shortest path, which has been widely used in relation classification, is also appropriate for representing tree structures in neural LSTM models.

Acknowledgments

We thank Qi Li, Kevin Gimpel, and the anonymous reviewers for dataset details and helpful discussions.

A Supplemental Material

A.1 Data and Task Settings

ACE05 defines 7 coarse-grained entity types: Facility (*FAC*), Geo-Political Entities (*GPE*), Location (*LOC*), Organization (*ORG*), Person (*PER*), Vehicle (*VEH*) and Weapon (*WEA*), and 6 coarse-grained relation types between entities: Artifact (*ART*), Gen-Affiliation (*GEN-AFF*), Org-Affiliation (*ORG-AFF*), Part-Whole (*PART-WHOLE*), Person-Social (*PER-SOC*) and Physical (*PHYS*). We removed the *cts*, *un* subsets, and used a 351/80/80 train/dev/test split. We removed duplicated entities and relations, and resolved nested entities. We used head spans for entities. We follow the settings by (Li and Ji, 2014), and we did not use the full mention boundary unlike Lu and Roth (2015). We use *entities* and *relations* to refer to *entity mentions* and *relation mentions* in ACE for brevity.

ACE04 defines the same 7 coarse-grained entity types as ACE05 (Doddington et al., 2004), but defines 7 coarse-grained relation types: *PYS*, *PER-SOC*, Employment / Membership / Subsidiary (*EMP-ORG*), *ART*, *PER/ORG* affiliation (*Other-AFF*), *GPE* affiliation (*GPE-AFF*), and Discourse (*DISC*). We follow the cross-validation setting of Chan and Roth (2011) and Li and Ji (2014). We removed *DISC* and did 5-fold CV on *bnews* and *nwire* subsets (348 documents). We use the same preprocessing and evaluation metrics of ACE05.

SemEval-2010 Task 8 defines 9 relation types between nominals (*Cause-Effect*, *Instrument-Agency*, *Product-Producer*, *Content-Container*, *Entity-Origin*, *Entity-Destination*, *Component-Whole*, *Member-Collection* and *Message-Topic*), and a tenth type *Other* when two nouns have none of these relations (Hendrickx et al., 2010). We treat this *Other* type as a negative relation type, and no direction is considered. The dataset consists of 8,000 training and 2,717 test sentences, and each sentence is annotated with a relation between two given nominals. We randomly selected 800 sentences from the training set as our development set. We followed the official task setting, and report the official macro-averaged F1-score (Macro-F1) on the 9 relation types.

A.2 Hyper-parameter Settings

Here we show the hyper-parameters and the range tried for the hyper-parameters in parentheses. Hyper-parameters include the initial learning rate (5e-3, 2e-3, 1e-3, 5e-4, 2e-4, 1e-4), the regularization parameter (1e-4, 1e-5, 1e-6, 1e-7), dropout probabilities (0.0, 0.1, 0.2, 0.3, 0.4, 0.5), the size of gradient clipping (1, 5, 10, 50, 100), scheduled sampling parameter k (1, 5, 10, 50, 100), the number of epochs for training and entity pretraining ($\leq$ 100), and the embedding dimension of WordNet hypernym (5, 10, 15, 20, 25, 30).

A short proof that $\mathbf{O}_2$ is an MCFL

Mark-Jan Nederhof
School of Computer Science
University of St Andrews, UK

Abstract

We present a new proof that $\mathbf{O}_2$ is a multiple context-free language. It contrasts with a recent proof by Salvati (2015) in its avoidance of concepts that seem specific to two-dimensional geometry, such as the complex exponential function. Our simple proof creates realistic prospects of widening the results to higher dimensions. This finding is of central importance to the relation between extreme free word order and classes of grammars used to describe the syntax of natural language.

1 Introduction

The alphabet of the *MIX language* has three symbols, a, b and c. A string is in the language if and only if the number of a's, the number of b's, and the number of c's are all the same. A different way of defining the MIX language is as permutation closure of the regular language $(abc)^*$, as noted by Bach (1981); see also Pullum (1983).

If a, b and c represent, say, a transitive verb and its subject and its object, then a string in MIX represents a sentence with any number of triples of these constituents, in a hypothetical language with extreme free word order. This is admittedly rather unlike any actual natural language. Joshi (1985) argued that because of this, grammatical formalisms for describing natural languages should *not* be capable of generating MIX. He also conjectured that MIX was beyond the generative capacity of one particular formalism, namely the tree adjoining grammars. Several decades passed before Kanazawa and Salvati (2012) finally proved this conjecture.

MIX has been studied in the context of several other formalisms. Joshi et al. (1991) showed that MIX is generated by a generalization of tree adjoining grammars that decouples local domination for linear precedence. Boullier (1999) showed that MIX is generated by a range concatenation grammar. Negative results were addressed by Sorokin (2014) for well-nested multiple context-free grammars, and by Capelletti and Tamburini (2009) for a class of categorial grammars. The MIX language is also of interest outside of computational linguistics, e.g. in computational group theory (Gilman, 2005).

A considerable advance in the understanding of the MIX language is due to Salvati (2015), who showed that MIX is generated by a multiple context-free grammar (MCFG). The main part of the proof shows that the language $\mathbf{O}_2$ is generated by a MCFG. This language has four symbols, a, $\overline{a}$, b and $\overline{b}$. A string is in the language if and only if the number of a's equals the number of $\overline{a}$'s, and the number of b's equals the number of $\overline{b}$'s. MIX and $\mathbf{O}_2$ are rationally equivalent, which means that if one is generated by a multiple context-free grammar, then so is the other.

The proof by Salvati (2015) is remarkable, in that it is one of the few examples of geometry being used to prove a statement about formal languages. The proof has two related disadvantages however. The first is that a key element of the proof, that of the complex exponential function, is not immediately understood without background in geometry. The second is that this also seems to restrict the proof technique to two dimensions, and there is no obvious avenue to generalize the result to a variant of MIX with four or five symbols. We hope to remedy this by an alternative, self-contained proof that avoids the complex exponential function. The core idea is a straightforward normalization of paths in two dimensions, which allow simple arguments to lead to a proof by contradiction. We also sketch part of a possible proof in three dimensions.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1117–1126,
Berlin, Germany, August 7-12, 2016.

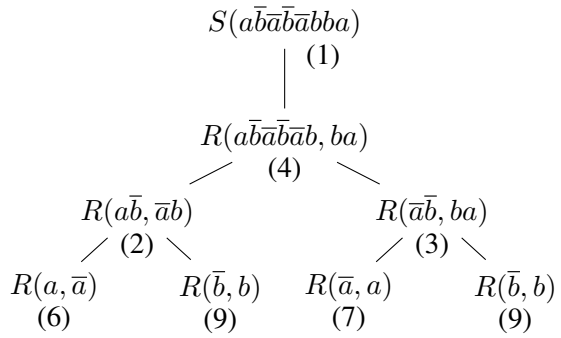

Figure 1: Derivation in G. The numbers indicate the rules that were used.

2 Initial problem

The MCFG G is defined as:

$$
\begin{aligned}
S(xy) &\leftarrow R(x,y) && (1)\\
R(xp,yq) &\leftarrow R(x,y)\ R(p,q) && (2)\\
R(xp,qy) &\leftarrow R(x,y)\ R(p,q) && (3)\\
R(xpy,q) &\leftarrow R(x,y)\ R(p,q) && (4)\\
R(p,xqy) &\leftarrow R(x,y)\ R(p,q) && (5)\\
R(a,\overline{a}) &\leftarrow && (6)\\
R(\overline{a},a) &\leftarrow && (7)\\
R(b,\overline{b}) &\leftarrow && (8)\\
R(\overline{b},b) &\leftarrow && (9)\\
R(\varepsilon,\varepsilon) &\leftarrow && (10)
\end{aligned}
$$

For the meaning of MCFGs in general, see Seki et al. (1991); for a closely related formalism, see Vijay-Shanker et al. (1987); see Kallmeyer (2010) for an overview of mildly context-sensitive grammar formalisms.

The reader unfamiliar with this literature is encouraged to interpret the rules of the grammar as logical implications, with S and R representing predicates. There is an implicit conjunction between the two occurrences of R in the right-hand side of each of the rules (2) — (5). The symbols x, y, p, q are string-valued variables, with implicit universal quantification that has scope over both left-hand side and right-hand side of a rule. The rules (6) — (10) act as axioms. The symbols a, $\overline{a}$, b, $\overline{b}$ are terminals, and ε denotes the empty string.

We can derive $S(x)$ for certain strings x, and $R(x,y)$ for certain strings x and y. Figure 1 presents an example of a derivation. The language generated by G is the set L of strings x such that $S(x)$ can be derived.

By induction on the depth of derivations, one can show that if $R(x,y)$, for strings x and y, then $xy \in \mathbf{O}_2$. Thereby, if $S(x)$ then $x \in \mathbf{O}_2$, which means $L \subseteq \mathbf{O}_2$. The task ahead is to prove that if $xy \in \mathbf{O}_2$, for some x and y, then $R(x,y)$. From this, $L = \mathbf{O}_2$ then follows.

Let $|x|$ denote the length of string x. For an inductive proof that $xy \in \mathbf{O}_2$ implies $R(x,y)$, the base cases are as follows. If $xy \in \mathbf{O}_2$ and $|x| \leq 1$ and $|y| \leq 1$, then trivially $R(x,y)$ by rules (6) — (10).

Furthermore, if we can prove that $xy \in \mathbf{O}_2$, $x \neq \varepsilon$ and $y \neq \varepsilon$ together imply $R(x,y)$, for $|xy| = m$, for some m, then we may also prove that $x'y' \in \mathbf{O}_2$ on its own implies $R(x',y')$ for $|x'y'| = m$. To see this, consider $m > 0$ and $z \in \mathbf{O}_2$ with $|z| = m$, and write it as $z = xy$ for some $x \neq \varepsilon$ and $y \neq \varepsilon$. If by assumption $R(x,y)$, then together with $R(\varepsilon,\varepsilon)$ and rule (4) or (5) we may derive $R(xy,\varepsilon)$ or $R(\varepsilon,xy)$, respectively. In the light of this, the inductive step merely needs to show that if for some x and y:

- $xy \in \mathbf{O}_2$, $|x| \geq 1$, $|y| \geq 1$ and $|xy| > 2$, and
- $pq \in \mathbf{O}_2$ and $|pq| < |xy|$ imply $R(p,q)$, for all p and q,

then also $R(x,y)$. One easy case is if $x \in \mathbf{O}_2$ (and thereby $y \in \mathbf{O}_2$) because then we can write $x = x_1x_2$ for some $x_1 \neq \varepsilon$ and $x_2 \neq \varepsilon$. The inductive hypothesis states that $R(x_1,x_2)$ and $R(\varepsilon,y)$, which imply $R(x,y)$ using rule (4).

A second easy case is if x or y has a proper prefix or proper suffix that is in $\mathbf{O}_2$. For example, assume there are $z_1 \neq \varepsilon$ and $z_2 \neq \varepsilon$ such that $x = z_1z_2$ and $z_1 \in \mathbf{O}_2$. Then we can use the inductive hypothesis on $R(z_1,\varepsilon)$ and $R(z_2,y)$, together with rule (2).

At this time, the reader may wish to read Figure 1 from the root downward. First, $a\overline{b}\overline{a}\overline{b}\overline{a}bba$ is divided into a pair of strings, namely $a\overline{b}\overline{a}\overline{b}\overline{a}b$ and ba. At each branching node in the derivation, a pair of strings is divided into four strings, which are grouped into two pairs of strings, using rules (2) — (5), read from left to right. Rules (2) and (3) divide each left-hand side argument into two parts. Rule (4) divides the first left-hand side argument into three parts, and rule (5) divides the second left-hand side argument into three parts.

What remains to show is that if $z_1z_2 \in \mathbf{O}_2$, $z_1 \notin \mathbf{O}_2$ and $|z_1z_2| > 2$, and no proper prefix or proper suffix of z_1 or of z_2 is in $\mathbf{O}_2$, then there is at least

one rule that allows us to divide z_1 and z_2 into four strings altogether, say x, y, p, q, of which at least three are non-empty, such that $xy \in \mathbf{O}_2$. This will then permit use of the inductive hypothesis on $R(x, y)$ and on $R(p, q)$.

We can in fact restrict our attention to $z_1'z_2' \in \mathbf{O}_2$, $|z_1'z_2'| > 2$, and no non-empty substring of z_1' or of z_2' is in $\mathbf{O}_2$, which can be justified as follows. Suppose we have z_1 and z_2 as in the previous paragraph, and suppose z_1' and z_2' result from z_1 and z_2 by exhaustively removing all non-empty substrings that are in $\mathbf{O}_2$; note that still $|z_1'z_2'| > 2$. If we can use a rule to divide z_1' and z_2' into x', y', p', q', of which at least three are non-empty, such that $x'y' \in \mathbf{O}_2$, then the same rule can be used to divide z_1 and z_2 into x, y, p, q with the required properties, which can be found from x', y', p', q' simply by reintroducing the removed substrings at corresponding positions.

3 Geometrical view

We may interpret a string x geometrically in two dimensions, as a path consisting of a series of line segments of length 1, starting in some point (i, j). Every symbol in x, from beginning to end, represents the next line segment in that path; an occurrence of a represents a line segment from the previous point (i, j) to the next point $(i + 1, j)$, $\overline{a}$ represents a line segment from (i, j) to $(i - 1, j)$, b represents a line segment from (i, j) to $(i, j+1)$, and $\overline{b}$ represents a line segment from (i, j) to $(i, j - 1)$. If $x \in \mathbf{O}_2$, then the path is *closed*, that is, the starting point and the ending point are the same. If we have two strings x and y such that $xy \in \mathbf{O}_2$ and $x \notin \mathbf{O}_2$, then this translates to two paths, connecting two distinct points, which together form a closed path. This is illustrated in Figure 2.

In the following, we assume a fixed choice of some x and y such that $xy \in \mathbf{O}_2$, $|xy| > 2$, and no non-empty substring of x or of y is in $\mathbf{O}_2$. If we follow the path of x starting in $P[0] = (0, 0)$, then the path ends in some point $P[1] = (i, j)$ such that i is the number of occurrences of a minus the number of occurrences of $\overline{a}$ and j is the number of occurrences of b minus the number of occurrences of $\overline{b}$. This path from $P[0]$ to $P[1]$ will be called $A[0]$. The path of y from $P[1]$ back to $P[0]$ will be called $B[1]$. We generalize this by defining for any integer k: $P[k]$ is the point $(k \cdot i, k \cdot j)$, $A[k]$ is the path of x from $P[k]$ to $P[k + 1]$ and $B[k]$ is the path of y from $P[k]$ to $P[k - 1]$. Where the starting points are irrelevant and only the shapes matter, we talk about paths A and B.

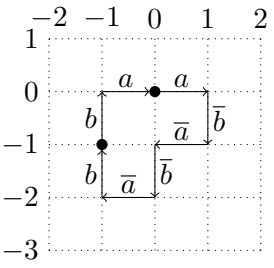

Figure 2: Two strings $x = a\overline{b}\overline{a}\overline{b}\overline{a}b$ and $y = ba$ together represent a closed path, consisting of a path from $(0, 0)$ to $(-1, -1)$ and a path from $(-1, -1)$ to $(0, 0)$.

Let C be a path, which can be either $A[k]$ or $B[k]$ for some k. We write $Q \in C$ to denote that Q is a point on C. Let $Q = (i, j) \in C$, not necessarily with i and j being integers. We define the path-distance $d_C(Q)$ of Q on C to be the length of the path along line segments of C to get from $P[k]$ to Q. In Figure 2, $(0, -1)$ has path-distance 3 on $A[0]$, as the path on $A[0]$ to reach $(0, -1)$ from $P[0] = (0, 0)$ consists of the line segments represented by the prefix $a\overline{b}\overline{a}$ of x. Similarly, $d_{A[0]}((0.5, -1)) = 2.5$.

Let C be a path as above and let points $Q_1, Q_2 \in C$ be such that $d_C(Q_1) \leq d_C(Q_2)$. We define the subpath $D = sub_C(Q_1, Q_2)$ to be such that $Q \in D$ if and only if $Q \in C$ and $d_C(Q_1) \leq Q \leq d_C(Q_2)$, and $d_D(Q) = d_C(Q) - d_C(Q_1)$ for every $Q \in D$. For two points Q_1 and Q_2, the line segment between Q_1 and Q_2 is denoted by $seg(Q_1, Q_2)$.

The task formulated at the end of Section 2 is accomplished if we can show that at least one of the following must hold:

- the angle in $P[0]$ between the beginning of $A[0]$ and that of $B[0]$ is 180° (Figure 3);
- there is a point $Q \notin \{P[0], P[1]\}$ such that $Q \in A[0]$ and $Q \in B[1]$ (Figure 4);
- there is a point $Q \neq P[1]$ such that $Q \in A[0]$, $Q \in A[1]$ and $d_{A[0]}(Q) > d_{A[1]}(Q)$ (Figure 5); or
- there is a point $Q \neq P[0]$ such that $Q \in B[0]$, $Q \in B[1]$ and $d_{B[1]}(Q) > d_{B[0]}(Q)$ (analogous to Figure 5).

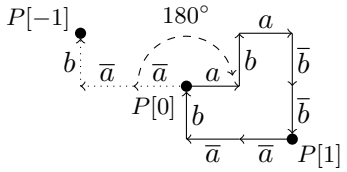

Figure 3: With $x = a\,b\,a\,\overline{b}\,\overline{b}$ and $y = \overline{a}\,\overline{a}\,b$, the beginning of path $A[0]$ and the beginning of (dotted) path $B[0]$ have an $180°$ angle in $P[0]$, which implies x and y start with complementing symbols (here a and $\overline{a}$; the other possibility is b and $\overline{b}$). By applying rule (2), two smaller closed paths result, one of which consists of these two complementing symbols.

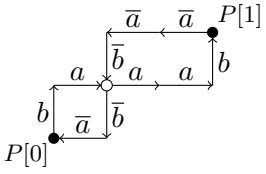

Figure 4: The paths $A[0]$ and $B[1]$ of $x = baaab$ and $y = \overline{a}\,\overline{a}\overline{b}\,\overline{b}\overline{a}$ have point $(1, 1)$ in common. Two smaller closed paths result by applying rule (3).

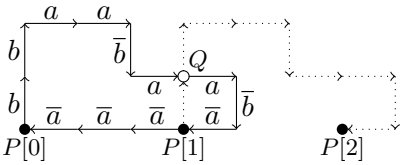

Figure 5: With $x = b\,b\,a\,a\,\overline{b}\,a\,a\,\overline{b}\,\overline{a}$ and $y = \overline{a}\,\overline{a}\,\overline{a}$, the path $A[0]$ and the (dotted) path $A[1]$ have point Q in common, with $d_{A[0]}(Q) = 6 > d_{A[1]}(Q) = 1$. By applying rule (4), two smaller closed paths result, one of which is formed by prefix b of length 1 and suffix $a\overline{b}\,\overline{a}$ of length $|x| - 6 = 3$ of x.

We will do this through a contradiction that results if we assume:

(i) the angle in $P[0]$ between the beginning of $A[0]$ and that of $B[0]$ is *not* $180°$;

(ii) $A[0] \cap B[1] = \{P[0], P[1]\}$;

(iii) there is no $Q \in (A[0] \cap A[1]) \setminus \{P[1]\}$ such that $d_{A[0]}(Q) > d_{A[1]}(Q)$; and

(iv) there is no $Q \in (B[0] \cap B[1]) \setminus \{P[0]\}$ such that $d_{B[1]}(Q) > d_{B[0]}(Q)$.

In the below, we will refer to these assumptions as the *four constraints*.

4 Continuous view

Whereas paths A and B were initially formed out of line segments of length 1 between points (i, j) with integers i and j, the proof becomes considerably easier if we allow i and j to be real numbers. The benefit lies in being able to make changes to the paths that preserve the four constraints, to obtain a convenient normal form for A and B. If we can prove a contradiction on the normal form, we will have shown that no A and B can exist that satisfy the four constraints.

We define, for each integer k, the line $\ell[k]$, which is perpendicular to the line through $P[k]$ and $P[k + 1]$, and lies exactly half-way between $P[k]$ and $P[k + 1]$. Much as before, we write $Q \in \ell[k]$ to denote that Q is a point on line $\ell[k]$. We will consistently draw points $\ldots, P[-1], P[0], P[1], \ldots$ in a straight line from left to right.

Let C be a path, which can be either $A[k']$ or $B[k']$, for some k', and let $Q \in C$. We write $\mathit{from\_right}_C(Q, \ell[k])$ to mean that path C is strictly to the right of $\ell[k]$ just before reaching Q, or formally, there is some $\delta > 0$ such that each $Q' \in C$ with $d_C(Q) - \delta < d_C(Q') < d_C(Q)$ lies strictly to the right of $\ell[k]$. The predicates $\mathit{from\_left}$, $\mathit{to\_right}$, $\mathit{to\_left}$ are similarly defined.

Let $Q_1, Q_2 \in C \cap \ell[k]$, for some k, such that $d_C(Q_1) \leq d_C(Q_2)$. We say that C has an *excursion from the right* between Q_1 and Q_2 at $\ell[k]$ if $\mathit{from\_right}_C(Q_1, \ell[k])$ and $\mathit{to\_right}_C(Q_2, \ell[k])$. This is illustrated in Figure 6: the path is strictly to the right of $\ell[k]$ just before reaching Q_1. From there on it may (but need not) cross over to the left of $\ell[k]$. Just after it reaches Q_2, it must again be strictly to the right of $\ell[k]$. The definition of *excursion from the left* is symmetric. Note that excursions may be nested; in Figure 6, $\mathit{sub}_C(Q_1, Q_2)$ has an excursion at $\ell[k]$ from the left below Q_2.

In Figure 6, the pair of points Q_1 and R_1 will be called a *crossing* of $\ell[k]$ from right to left, characterized by $Q_1, R_1 \in \ell[k]$, $\mathit{from\_right}_C(Q_1, \ell[k])$, $\mathit{to\_left}_C(R_1, \ell[k])$ and $\mathit{sub}_C(Q_1, R_1)$ being a line segment. The pair of points R_2 and Q_2 is a crossing of $\ell[k]$ from left to right, where the length of $\mathit{seg}(R_2, Q_2)$ happens to be 0. In much of the following we will simplify the discussion by assuming crossings consist of single points, as in the case of $R_2 = Q_2$. However, existence of crossings con-

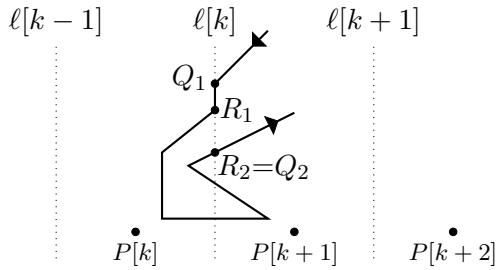

Figure 6: Excursion from the right at $\ell[k]$.

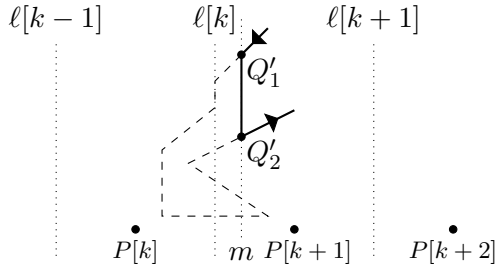

Figure 7: The excursion from Figure 6 truncated in Q'_1 and Q'_2 on line m.

sisting of line segments of non-zero length, as in the case of Q_1 and R_1, would not invalidate any of the arguments of the proof.

Excursions are the core obstacle that needs to be overcome for our proof. We can *truncate* an excursion at $\ell[k]$ by finding a suitable line m that is parallel to $\ell[k]$, some small distance away from it, between $\ell[k]$ and $P[k+1]$ for excursions from the right, and between $\ell[k]$ and $P[k]$ for excursions from the left. We further need to find points $Q'_1, Q'_2 \in C \cap m$, where $d_C(Q'_1) < d_C(Q_1)$ and $d_C(Q_2) < d_C(Q'_2)$. Because our coordinates no longer need to consist of integers, it is clear that m, Q'_1 and Q'_2 satisfying these requirements must exist.

The truncation consists in changing $sub_C(Q'_1, Q'_2)$ to become $seg(Q'_1, Q'_2)$, as illustrated by Figure 7. Note that if C is say $A[k']$, for some k', then changing the shape of C means changing the shape of $A[k'']$ for any other k'' as well; the difference between $A[k']$ and $A[k'']$ is only in the starting point $P[k']$ versus $P[k'']$.

At this time, we must allow for the possibility that for some excursions, no m, Q'_1 and Q'_2 can be found with which we can implement a truncation, if we also need to preserve the four constraints and preserve absence of self-intersections. There is a small number of possible causes. First,

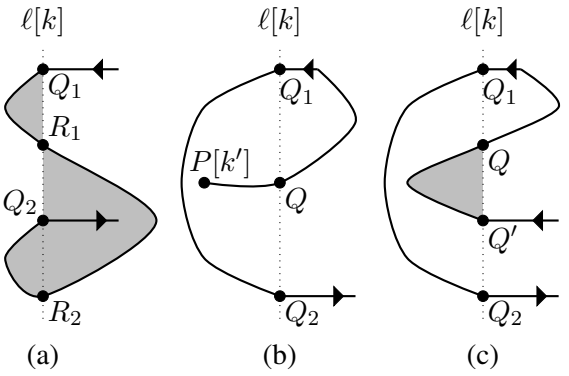

Figure 8: (a) Regions (shaded) of an excursion at $\ell[k]$; due to additional crossings in R_1 and R_2, three more excursions exist, each with a smaller area. (b) & (c) If truncation would introduce self-intersection, then either the excursion is filled, with some point $P[k']$ as in (b), or there is an excursion with smaller area, illustrated by shading in (c).

suppose that $C = A[k']$ and $B[k'+1]$ intersects with $seg(Q_1, Q_2)$. Then $B[k'+1]$ may intersect with $seg(Q'_1, Q'_2)$ for any choice of m, Q'_1 and Q'_2, and thereby no truncation is possible without violating constraint (ii). Similarly, a truncation may be blocked if $C = B[k'+1]$ and $A[k']$ intersects with $seg(Q_1, Q_2)$. Next, it could be that $C = A[k']$, while $d_{A[k']}(Q_1) > d_{A[k'+1]}(Q)$ holds for some $Q \in seg(Q_1, Q_2) \cap A[k'+1]$, or $d_{A[k'-1]}(Q) > d_{A[k']}(Q_2)$ holds for some $Q \in seg(Q_1, Q_2) \cap A[k'-1]$, either of which potentially blocks a truncation if constraint (iii) is to be preserved. Constraint (iv) has similar consequences. Furthermore, if we need to preserve absence of self-intersections, a truncation may be blocked if $d_C(Q) < d_C(Q_1)$ or $d_C(Q_2) < d_C(Q)$ for some $Q \in seg(Q_1, Q_2) \cap C$.

5 Normal form

The *regions* of an excursion of C between Q_1 and Q_2 at $\ell[k]$ are those that are enclosed by (subpaths of) $sub_C(Q_1, Q_2)$ and (subsegments of) $seg(Q_1, Q_2)$, as illustrated by Figure 8(a). The *area* of the excursion is the surface area of all regions together. We say an excursion is *filled* if any of its regions contains at least one point $P[k']$, for some integer k', otherwise it is said to be *unfilled*.

We say A and B are in *normal form* if no excursion can be truncated without violating the four constraints or introducing a self-intersection. Sup-

pose A and B are in normal form, while one or more excursions remain. Let us first consider the unfilled excursions. Among them choose one that has the smallest area. By assumption, one of the four constraints must be violated or a new self-intersection must be introduced, if we were to truncate that excursion. We will consider all relevant cases.

Each case will assume an unfilled excursion from the right (excursions from the left are symmetric) of a path C between Q_1 and Q_2 at $\ell[k]$. We may assume that $sub_C(Q_1, Q_2) \cap \ell[k] = \{Q_1, Q_2\}$, as additional crossings of $\ell[k]$ would mean that excursions exist with smaller areas (cf. Figure 8(a)), contrary to the assumptions. Now assume truncation is blocked due to $Q \in seg(Q_1, Q_2) \cap C$ such that $d_C(Q) < d_C(Q_1)$ (the case $d_C(Q_2) < d_C(Q)$ is symmetric), as we need to preserve absence of self-intersection. Suppose Q is the only such point, so that C crosses $seg(Q_1, Q_2)$ from left to right once without ever crossing it from right to left, until Q_1 is reached. Then C starts in the area of the excursion, or in other words, the excursion is filled, contrary to the assumptions (cf. Figure 8(b)). Now suppose there are points Q' and Q where C crosses $seg(Q_1, Q_2)$ from right to left and from left to right, respectively and $d_C(Q') < d_C(Q) < d_C(Q_1)$. If there are several choices, choose Q' and Q such that $sub_C(Q', Q) \cap \ell[k] = \{Q', Q\}$. This means the excursion between Q' and Q has an area smaller than the one between Q_1 and Q_2, contrary to the assumptions (cf. Figure 8(c)).

Note that excursions with zero area, that is, those that intersect with $\ell[k]$ without crossing over to the other side, can always be truncated. We can therefore further ignore non-crossing intersections.

Now suppose a truncation would violate constraint (ii), where $C = B[k'+1]$ and $D = A[k']$ crosses $seg(Q_1, Q_2)$. Then much as above, we may distinguish two cases. In the first, D has only one crossing of $seg(Q_1, Q_2)$ in some point Q, which means the excursion is filled with the starting or ending point of D, as in Figure 9(a). In the second, D has at least two consecutive crossings, say in Q and Q', from right to left and from left to right, respectively, which means the excursion between Q and Q' has smaller area than the one between Q_1 and Q_2, illustrated by shading in Figure 9(b). Both cases contradict the assumptions.

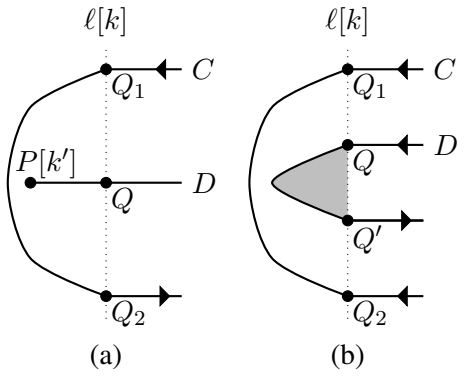

Figure 9: Truncating the excursion would introduce a violation of constraint (ii). The assumptions are contradicted in one of two ways.

For $C = A[k']$ and $D = B[k'+1]$, the reasoning is symmetric.

Next, suppose a truncation would violate constraint (iii), where $C = A[k']$ and $A[k'-1]$ crosses $seg(Q_1, Q_2)$ in Q, while $d_{A[k'-1]}(Q) > d_{A[k']}(Q_2)$. If the crossing in Q is from right to left, and there is an immediately next crossing in Q' from left to right, then we have the same situation as in Figure 9(b), involving an excursion with smaller area, contradicting the assumptions. If the crossing in Q is the only one, and it is from right to left, then we can use the fact that $sub_{A[k']}(Q_1, Q_2) \cap sub_{A[k'-1]}(Q, P[k']) = \emptyset$, as we assume the four constraints as yet hold. This means $P[k']$ must be contained in the area of the excursion, as illustrated in Figure 10(a), contradicting the assumption that the excursion is unfilled. If the crossing in Q is the only one, and it is from left to right, then we can use the fact that $sub_{A[k']}(Q_1, Q_2) \cap sub_{A[k'-1]}(Q'_2, Q) = \emptyset$, for the unique $Q'_2 \in A[k'-1] \cap \ell[k-1]$ such that $d_{A[k'-1]}(Q'_2) = d_{A[k']}(Q_2)$. This means the excursion contains Q'_2, which implies there is another unfilled excursion between points $R_1, R_2 \in A[k'] \cap \ell[k-1]$ with smaller area, as shaded in Figure 10(b), contrary to the assumptions.

Suppose a truncation would violate constraint (iii), where $C = A[k']$ and $A[k'+1]$ crosses $seg(Q_1, Q_2)$ in Q, while $d_{A[k']}(Q_1) > d_{A[k'+1]}(Q)$. The reasoning is now largely symmetric to the above, with the direction of the crossing reversed, except that the case analogous to Figure 10(b) is immediately excluded, as Q'_2 cannot be both to the left and to the right of $\ell[k]$. Constraint (iv) is symmetric to constraint (iii). All pos-

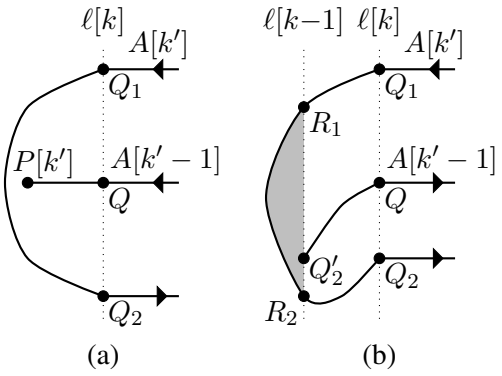

Figure 10: Truncating the excursion would introduce a violation of constraint (iii), where $d_{A[k'-1]}(Q) > d_{A[k']}(Q_2)$. The assumptions are contradicted in one of three ways, the first as in Figure 9(b), and the second and third as in (a) and (b) above.

sible cases have been shown to lead to contradictions, and therefore we conclude that there are no unfilled excursions if A and B are in normal form.

We now show that there cannot be any filled excursions either. For this, assume that $A[k']$ has a filled excursion between Q_1 and Q_2 at $\ell[k]$ from the right. This means $A[k'-1]$ has an identically shaped, filled excursion at $\ell[k-1]$ from the right, between corresponding points Q'_1 and Q'_2. Let us consider how path $A[k']$ proceeds after reaching Q_2. There are only three possibilities:

- it ends in $P[k+1]$, with $k' = k$, without further crossings of $\ell[k]$ or $\ell[k+1]$;
- it next crosses $\ell[k]$ leftward; or
- it next crosses $\ell[k+1]$ in some point Q_3.

The first of these can be excluded, in the light of $d_{A[k'-1]}(Q) \geq d_{A[k']}(Q_2)$ for each $Q \in sub_{A[k'-1]}(Q'_2, P[k'])$. Due to constraint (iii) therefore, this subpath of $A[k'-1]$ cannot intersect with the excursion of $A[k']$ to reach $P[k]$, and therefore $A[k']$ cannot reach $P[k+1]$. The second possibility is also excluded, as this would imply the existence of an unfilled excursion. For the remaining possibility, $Q_3 \in A[k'] \cap \ell[k+1]$ may be lower down than Q_2 (in the now familiar view of the points $P[0], P[1], \ldots$ being drawn from left to right along a horizontal line), or it may be higher up than Q_1. These two cases are drawn in Figures 11 and 12. The choice of Q_3 also determines a corresponding $Q'_3 \in A[k'-1] \cap \ell[k]$.

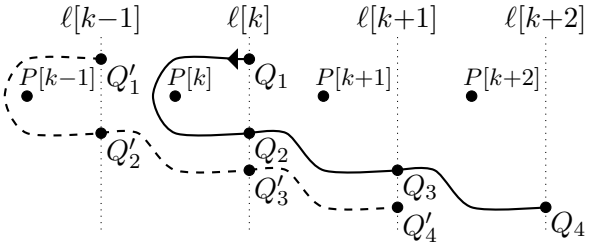

Figure 11: Continuing the (solid) path $A[k']$ after a filled excursion, restricted by the (dashed) path $A[k'-1]$, in the light of constraint (iii).

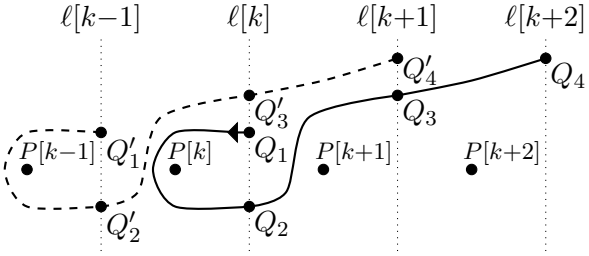

Figure 12: As in Figure 11 but Q_3 is chosen to be higher up than Q_1.

We now consider how $A[k']$ continues after Q_3 in the case of Figure 11. If it next crosses $\ell[k+1]$ leftward, this would imply the existence of an unfilled excursion. Further, $d_{A[k'-1]}(Q) \geq d_{A[k']}(Q_3)$ for each $Q \in sub_{A[k'-1]}(Q'_3, P[k'])$. Due to constraint (iii) therefore, this subpath of $A[k'-1]$ cannot intersect with $sub_{A[k']}(Q_2, Q_3)$, above which lies $P[k+1]$. Therefore, $A[k']$ must cross $\ell[k+2]$ in some Q_4, which is lower down than Q_3. This continues ad infinitum, and $A[k']$ will never reach its supposed end point $P[k'+1]$. The reasoning for Figure 12 is similar.

Filled excursions from the left are symmetric, but instead of investigating the path after Q_2, we must investigate the path *before* Q_1. The case of B is symmetric to that of A. We may now conclude no filled excursions exist.

6 The final contradiction

We have established that after A and B have been brought into normal form, there can be no remaining excursions. This means that $A[0]$ crosses $\ell[0]$ exactly once, in some point R_A, and $B[0]$ crosses $\ell[-1]$ exactly once, in some point L_B. Further, let L_A be the unique point where $A[-1]$ crosses $\ell[-1]$ and R_B the unique point where $B[1]$ crosses $\ell[0]$.

The region of the plane between $\ell[-1]$ and $\ell[0]$

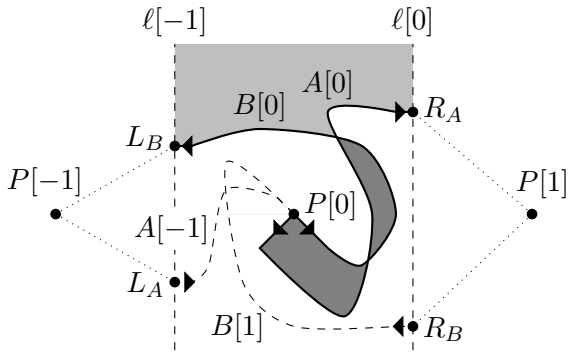

Figure 13: The region between $\ell[-1]$ and $\ell[0]$ is divided by $A[0]$ and $B[0]$ into a 'top' region (lightly shaded), a 'bottom' region (white), and areas enclosed by intersections of $A[0]$ and $B[0]$ (darkly shaded). Here $A[-1]$ and $B[1]$ are both in the 'bottom' region.

can now be partitioned into a 'top' region, a 'bottom' region, and zero or more enclosed regions. The 'top' region consists of those points that are reachable from any point between $\ell[-1]$ and $\ell[0]$ arbitrarily far above any point of $A[0]$ and $B[0]$, without intersecting with $A[0]$, $B[0]$, $\ell[-1]$ or $\ell[0]$. This is the lightly shaded region in Figure 13. The 'bottom' region is similarly defined, in terms of reachability from any point between $\ell[-1]$ and $\ell[0]$ arbitrarily far *below* any point of $A[0]$ and $B[0]$. The zero or more enclosed regions stem from possible intersections of $A[0]$ and $B[0]$; the two such enclosed regions in Figure 13 are darkly shaded. Note that the four constraints do *not* preclude intersections of $A[0]$ and $B[0]$.

However, constraint (ii) implies that, between $\ell[-1]$ and $\ell[0]$, $A[0]$ and $B[1]$ do not intersect other than in $P[0]$, and similarly, $A[-1]$ and $B[0]$ do not intersect other than in $P[0]$. Moreover, for any $Q \in sub_{A[-1]}(L_A, P[0])$ and any $Q' \in sub_{A[0]}(P[0], R_A)$ we have $d_{A[-1]}(Q) \geq d_{A[0]}(Q')$. By constraint (iii) this means $A[-1]$ and $A[0]$ do not intersect other than in $P[0]$. Similarly, $B[1]$ and $B[0]$ do not intersect other than in $P[0]$.

The angles in $P[0]$ between $A[0]$, $B[0]$, $A[-1]$ and $B[1]$ are multiples of $90°$. Because of constraint (i), which excludes a $180°$ angle between $A[0]$ and $B[0]$, it follows that either $sub_{A[-1]}(L_A, P[0])$ and $sub_{B[1]}(R_B, P[0])$ both lie entirely in the 'top' region, or both lie entirely in the 'bottom' region. The latter case is illustrated in Figure 13. In the former case, L_A and R_B are above L_B and R_A, respectively, and in the latter case L_A and R_B are below L_B and R_A. This is impossible, as L_A and R_A should be at the same height, these being corresponding points of $A[-1]$ and $A[0]$, which have the same shape, and similarly L_B and R_B should be at the same height.

This contradiction now leads back to the very beginning of our proof, and implies that the four constraints cannot all be true, and therefore that at least one rule is always applicable to allow use of the inductive hypothesis, and therefore that G generates $\mathbf{O}_2$.

7 Conclusions and outlook

We have presented a new proof that $\mathbf{O}_2$ is generated by a MCFG. It has at least superficial elements in common with the proof by Salvati (2015). Both proofs use essentially the same MCFG, both are geometric in nature, and both involve a continuous view of paths next to a discrete view. The major difference lies in the approach to tackling the myriad ways in which the paths can wind around each other and themselves. In the case of Salvati (2015), the key concept is that of the complex exponential function, which seems to restrict the proof technique to two-dimensional geometry. In our case, the key concepts are excursions and truncation thereof, and the identification of top and bottom regions.

At this time, no proof is within reach that generalizes the result to $\mathbf{O}_3$, i.e. the language of strings over an alphabet of six symbols, in which the number of a's equals the number of $\overline{a}$'s, the number of b's equals the number of $\overline{b}$'s, and the number of c's equals the number of $\overline{c}$'s; this language is rationally equivalent to MIX-4, which is defined analogously to MIX, but with four symbols. One may expect however that a proof would use three-dimensional geometry and generalize some of the arguments from this paper. Our aim here is to make this plausible, while emphasizing that an actual proof will require a novel framework at least as involved as that presented in the previous sections.

Omitting the start rule and the axioms, an obvious candidate MCFG to generate $\mathbf{O}_3$ would among others have the three rules:

$R(p_1q_1, p_2q_2, q_3p_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$
$R(p_1q_1, q_2p_2, p_3q_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$
$R(q_1p_1, p_2q_2, p_3q_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$

as well as the six rules:

$R(p_1q_1p_2, p_3q_2, q_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$
$R(p_1q_1p_2, q_2, p_3q_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$
$R(p_1q_1, p_2q_2p_3, q_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$
$R(p_1q_1, q_2, p_2q_3p_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$
$R(p_1, q_1p_2q_2, q_3p_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$
$R(p_1, q_1p_2, q_2p_3q_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$

Consider three strings x, y and z such that $xyz \in \mathbf{O}_3$. If we can use any of the above rules to divide these into six strings out of which we can select three, which concatenated together are a non-empty string in $\mathbf{O}_3$ shorter than xyz, then we can use the inductive hypothesis, much as in Section 2. For a proof by contradiction, therefore assume that no pair of prefixes of x and y and a suffix of z together form a non-empty string in $\mathbf{O}_3$ shorter than xyz, etc., in the light of the first three rules above, and assume that no 'short enough' prefix of x, a prefix of y and a 'short enough' suffix of x together form a non-empty string in $\mathbf{O}_3$, etc., in the light of the next six rules above.

For a geometric interpretation, consider the paths of x, y and z, leading from point $P_0 = (0, 0, 0)$ to points P_x, P_y and P_z, respectively. The concatenations of prefixes of x and y, and similarly those of x and z and those of y and z form three connecting surfaces, together forming one surface dividing the space around P_0 into an 'above' and a 'below'; cf. Figure 14. Our assumptions imply that the final parts of the paths of x, y and z from $-P_x$, $-P_y$ and $-P_z$, respectively, to P_0 should not intersect with this surface. In addition, no pair of strings from x, y and z should end on complementing symbols, i.e. a and $\overline{a}$, b and $\overline{b}$, or c and $\overline{c}$. This means that the three paths leading towards P_0 must all end in P_0 strictly 'above' or all strictly 'below' the surface.

This might lead to a contradiction, similar to that in Section 6, but only if one can ensure that none of the three paths to P_0 'sneak around' the surface. This is illustrated in Figure 15, where the path of z is 'entangled' with a copy of itself. It appears this can be achieved by adding three more rules, namely:

$R(p_1q_1p_2q_2, p_3, q_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$
$R(p_1, q_1p_2q_2p_3, q_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$
$R(p_1, q_1, q_2p_2q_3p_3) \leftarrow R(p_1, p_2, p_3)\ R(q_1, q_2, q_3)$

The physical interpretation of, say, the last rule seems to be that the path of z from $-P_z$ to P_0 can be iteratively shifted such that points other than its ending point coincide with P_0. At some stage

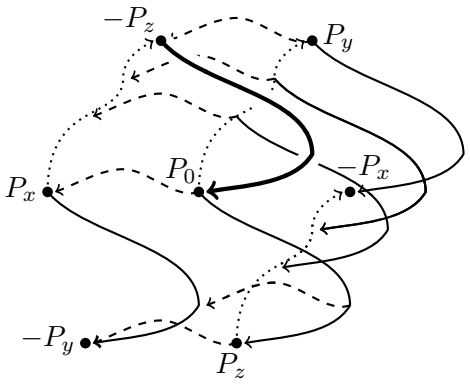

Figure 14: By taking prefixes of two strings from $\{x, y, z\}$ and concatenating them, we obtain a surface dividing the space around P_0 into 'above' and 'below'. Here the path of z from $-P_z$ to P_0 ends 'above', if our view is from above the surface.

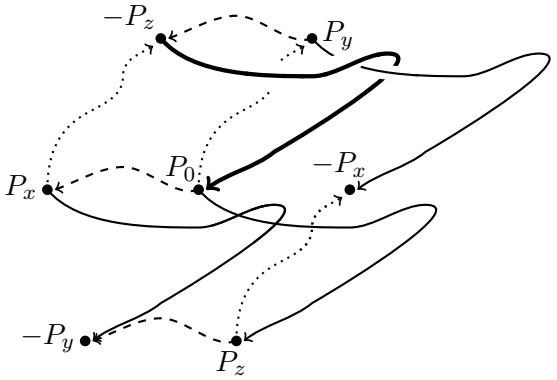

Figure 15: The path of z from $-P_z$ to P_0 is initially above the surface, but 'sneaks around' the path of z from P_y to $-P_x$, to end below.

the shifted path must intersect with the path of z from P_y to $-P_x$, before the entanglement of the two paths is broken.

The considerable challenges ahead involve finding a suitable definition of 'excursions' in three dimensions, and proving that these can be systematically truncated without violating appropriate constraints that preclude application of the above 12 rules.

Acknowledgements

This work came out of correspondence with Giorgio Satta. Gratefully acknowledged are also fruitful discussions with Sylvain Salvati, Vinodh Rajan, and Markus Pfeiffer. Much appreciated are anonymous referees and editors for their efforts and their courage to consider a theoretical paper for publication at this venue.

Abstract

Context is crucial for identifying argumentative relations in text, but many argument mining methods make little use of contextual features. This paper presents context-aware argumentative relation mining that uses features extracted from writing topics as well as from windows of context sentences. Experiments on student essays demonstrate that the proposed features improve predictive performance in two argumentative relation classification tasks.

1 Introduction

By supporting tasks such as automatically identifying *argument components*[1] (e.g., premises, claims) in text, and the *argumentative relations* (e.g., support, attack) between components, argument (argumentation) mining has been studied for applications in different research fields such as document summarization (Teufel and Moens, 2002), opinion mining (Boltužić and Šnajder, 2014), automated essay evaluation (Burstein et al., 2003), legal information systems (Palau and Moens, 2009), and policy modeling platforms (Florou et al., 2013).

Given a pair of argument components with one component as the *source* and the other as the *target*, *argumentative relation mining* involves determining whether a relation holds from the source to the target, and classifying the argumentative function of the relation (e.g., support vs. attack). Argumentative relation mining - beyond argument component mining - is perceived as an essential step towards more fully identifying the argumentative structure of a text (Peldszus and Stede, 2013; Sergeant, 2013; Stab et al., 2014). Consider the second paragraph shown in Figure 1. Only detecting the argument components (a claim in sentence 2 and two premises in sentences 3 and 4) does not give a complete picture of the argumentation. By looking for relations between these components, one can also see that the two premises together justify the claim. The argumentation structure of the text in Figure 1 is illustrated in Figure 2.

> **Essay 73**. Topic: Is image more powerful than the written word?
> ...(1)Hence, *I agree only to certain degree that in today's world, image serves as a more effective means of communication*$_{[MajorClaim]}$.
> (2)Firstly, **pictures can influence the way people think**$_{[Claim]}$. (3)For example, nowadays horrendous images are displayed on the cigarette boxes to illustrate the consequences of smoking$_{[Premise]}$. (4)As a result, statistics show a slight reduction in the number of smokers, indicating that they realize the effects of the negative habit$_{[Premise]}$...

Figure 1: Excerpt from a student persuasive essay (Stab and Gurevych, 2014a). Sentences are numbered and argument components are tagged.

Our current study proposes a novel approach for argumentative relation mining that makes use of contextual features extracted from surrounding sentences of *source* and *target* components as well as from topic information of the writings.

[1]There is no consensus yet on an annotation scheme for argument components, or on the minimal textual units to be annotated. We follow Peldszus and Stede (2013) and consider "*argument mining as the automatic discovery of an argumentative text portion, and the identification of the relevant components of the argument presented there.*" We also borrow their term "*argumentative discourse unit*" to refer to the textual units (e.g., text segment, sentence, clause) which are considered as argument components.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1127–1137,
Berlin, Germany, August 7-12, 2016.

Prior argumentative relation mining studies have often used features extracted from argument components to model different aspects of the relations between the components, e.g., relative distance, word pairs, semantic similarity, textual entailment (Cabrio and Villata, 2012; Stab and Gurevych, 2014b; Boltužić and Šnajder, 2014; Peldszus and Stede, 2015b). Features extracted from the text surrounding the components have been less explored, e.g., using words and their part-of-speech from adjacent sentences (Peldszus, 2014). The first hypothesis investigated in this paper is that the *discourse relations* of argument components with adjacent sentences (called *context windows* in this study, a formal definition is given in §5.3) can help characterize the argumentative relations that connect pairs of argument components. Reconsidering the example in Figure 1, without knowing the content "*horrendous images are displayed on the cigarette boxes*" in sentence 3, one cannot easily tell that "*reduction in the number of smokers*" in sentence 4 supports the "*pictures can influence*" claim in sentence 2. We expect that such content relatedness can be revealed from a discourse analysis, e.g., the appearance of a discourse connective "*As a result*".

While topic information in many writing genres (e.g., scientific publications, Wikipedia articles, student essays) has been used to create features for argument component mining (Teufel and Moens, 2002; Levy et al., 2014; Nguyen and Litman, 2015), topic-based features have been less explored for argumentative relation mining. The second hypothesis investigated in this paper is that features based on *topic context* also provide useful information for improving argumentative relation mining. In the excerpt below, knowing that '*online game*' and '*computer*' are topically related might help a model decide that the claim in sentence 1 supports the claim in sentence 2:

(1)**People who are addicted to games, especially online games, can eventually bear dangerous consequences**$_{[Claim]}$.

(2)Although it is undeniable that computer is a crucial part of human life$_{[Premise]}$, **it still has its bad side**$_{[MajorClaim]}$.[2]

Motivated by the discussion above, we propose *context-aware argumentative relation mining* – a novel approach that makes use of contextual features that are extracted by exploiting context sentence windows and writing topic to improve relation prediction. In particular, we derive features using *discourse relations* between argument components and windows of their surrounding sentences. We also derive features using an *argument and domain word lexicon* automatically created by post-processing an essay's topic model. Experimental results show that our proposed contextual features help significantly improve performance in two argumentative relation classification tasks.

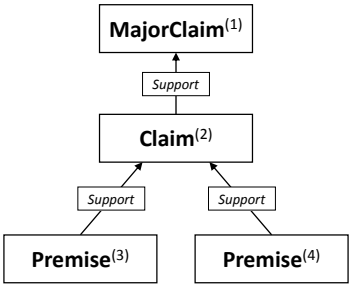

Figure 2: Structure of the argumentation in the excerpt. Relations are illustrated accordingly to the annotation provided in the corpus. Premises 3 and 4 were annotated for separate relations to Claim 2. Our visualization should not mislead that the two premises are linked or convergent.

2 Related Work

Unlike argument component identification where textual inputs are typically sentences or clauses (Moens et al., 2007; Stab and Gurevych, 2014b; Levy et al., 2014; Lippi and Torroni, 2015), textual inputs of argumentative relation mining vary from clauses (Stab and Gurevych, 2014b; Peldszus, 2014) to multiple-sentences (Biran and Rambow, 2011; Cabrio and Villata, 2012; Boltužić and Šnajder, 2014). Studying claim justification between user comments, Biran and Rambow (2011) proposed that the argumentation in justification of a claim can be characterized with discourse structure in the justification. They however only considered discourse markers but not discourse relations. Cabrio et al. (2013) conducted a corpus analysis and found certain similarity between Penn Discourse TreeBank relations (Prasad et al., 2008) and argumentation schemes (Walton et al., 2008). However they did not discuss how such similarity could be applied to argument mining.

Motivated by these findings, we propose to use features extracted from discourse relations be-

[2]In this excerpt, the Premise was annotated as an attack to the MajorClaim in sentence 2.

tween sentences for argumentative relation mining. Moreover, to enable discourse relation features when the textual inputs are only sentences/clauses, we group the inputs with their context sentences. Qazvinian and Radev (2010) used the term "context sentence" to refer to sentences surrounding a citation that contained information about the cited source but did not explicitly cite it. In our study, we only require that the context sentences of an argument component must be in the same paragraph and adjacent to the component.

Prior work in argumentative relation mining has used argument component labels to provide constraints during relation identification. For example, when an annotation scheme (e.g., (Peldszus and Stede, 2013; Stab and Gurevych, 2014a)) does not allow relations from claim to premise, no relations are inferred during relation mining for any argument component pair where the source is a claim and the target is a premise. In our work, we follow Stab and Gurevych (2014b) and use the predicted labels of argument components as features during argumentative relation mining. We, however, take advantage of an enhanced argument component model (Nguyen and Litman, 2016) to obtain more reliable argument component labels than in (Stab and Gurevych, 2014b).

Argument mining research has studied different data-driven approaches for separating organizational content (shell) from topical content to improve argument component identification, e.g., supervised sequence model (Madnani et al., 2012), unsupervised probabilistic topic models (Séaghdha and Teufel, 2014; Du et al., 2014). Nguyen and Litman (2015) post-processed LDA (Blei et al., 2003) output to extract a lexicon of argument and domain words from development data. Their semi-supervised approach exploits the topic context through essay titles to guide the extraction.

Finally, prior research has explored predicting different argumentative relationship labels between pairs of argument components, e.g., attachment (Peldszus and Stede, 2015a), support vs. non-support (Biran and Rambow, 2011; Cabrio and Villata, 2012; Stab and Gurevych, 2014b), {implicit, explicit}×{support, attack} (Boltužić and Šnajder, 2014), verifiability of support (Park and Cardie, 2014). Our experiments use two such argumentative relation classification tasks (Support vs. Non-support, Support vs. Attack) to evaluate the effectiveness of our proposed features.

3 Persuasive Essay Corpus

Stab and Gurevych (2014a) compiled the Persuasive Essay Corpus consisting of 90 student argumentative essays and made it publicly available.[3] Because the corpus has been utilized for different argument mining tasks (Stab and Gurevych, 2014b; Nguyen and Litman, 2015; Nguyen and Litman, 2016), we use this corpus to demonstrate our context-aware argumentative relation mining approach, and adapt the model developed by Stab and Gurevych (2014b) to serve as the baseline for evaluating our proposed approach.

Three experts identified possible argument components of three types within each sentence in the corpus (*MajorClaim* - writer's stance toward the writing topic, *Claim* - controversial statements that support or attack MajorClaim, and *Premise* - evidence used to underpin the validity of Claim), and also connected the argument components using two argumentative relations (*Support* and *Attack*). According to the annotation manual, each essay has exactly one MajorClaim. A sentence can have one or more argument components (*Argumentative* sentences). Sentences that do not contain any argument component are labeled *Non-argumentative*. Figure 1 shows an example essay with components annotated, and Figure 2 illustrates relations between those components. Argumentative relations are directed and can hold between a Premise and another Premise, a Premise and a (Major-) Claim, or a Claim and a MajorClaim. Except for the relation from Claim to MajorClaim, an argumentative relation does not cross paragraph boundaries. The three experts achieved inter-rater accuracy 0.88 for component labels and Krippendorff's α_U 0.72 for component boundaries. Given the annotated argument components, the three experts obtained Krippendorff's α 0.81 for relation labels. The number of relations are shown in Table 1.

4 Argumentative Relation Tasks

4.1 Task 1: Support vs. Non-support

Our first task follows (Stab and Gurevych, 2014b): given a pair of source and target argument components, identify whether the source argumentatively supports the target or not. Note that when a support relation does not hold, the source may attack or has no relation with the target compo-

Label	#instances
Within-paragraph constraint	
Support	989
Attack	103
No paragraph constraint	
Support	1312
Attack	161

Table 1: Data statistics of the corpus.

nent. For each of two argument components in the same paragraph[4], we form two pairs (i.e., reversing source and target). In total we obtain 6330 pairs, in which 989 (15.6%) have Support relation. Among 5341 Non-support pairs, 103 have Attack relation and 5238 are no-relation pairs.

Stab and Gurevych (2014b) split the corpus into an 80% training set and a 20% test set which have similar label distributions. We use this split to train and test our proposed models, and directly compare our models' performance to the reported performance in (Stab and Gurevych, 2014b).

4.2 Task 2: Support vs. Attack

To further evaluate the effectiveness of our approach, we conduct an additional task that classifies an argumentative relation as *Support* or *Attack*. For this task, we assume that the relation (i.e., attachment (Peldszus, 2014)) between two components is given, and aim at identifying the argumentative function of the relation. Because we remove the paragraph constraint in this task, we obtain more Support relations than in Task 1. As shown in Table 1, of the total 1473 relations, we have 1312 (89%) Support and 161 (11%) Attack relations. Because this task was not studied in (Stab and Gurevych, 2014b), we adapt Stab and Gurevych's model to use as the baseline.

5 Argumentative Relation Models

5.1 Baseline

We adapt (Stab and Gurevych, 2014b) to use as a baseline for evaluating our approach. Given a pair of argument components, we follow (Stab and Gurevych, 2014b) by first extracting 3 feature sets: structural (e.g., word counts, sentence position), lexical (e.g., word pairs, first words), and grammatical production rules (e.g., *S→NP,VP*).

[4]Allowing cross-paragraph relations exponentially increases the number of no-relation pairs, which makes the prediction data extremely skewed (Stab and Gurevych, 2014b).

Because a sentence may have more than one argument component, the relative component positions might provide useful information (Peldszus, 2014). Thus, we also include 8 new component position features: whether the source and target components are the whole sentences or the beginning/end components of the sentences; if the source is before or after the target component; and the absolute difference of their positions.

Stab and Gurevych (2014b) used a 55-discourse marker set to extract indicator features. We expand their discourse maker set by combining them with a 298-discourse marker set developed in (Biran and Rambow, 2011). We expect the expanded set of discourse markers will represent better possible discourse relations in the texts.

Stab and Gurevych (2014b) used predicted label of argument components as features for both training and testing their argumentation structure identification model.[5] As their predicted labels are not available to us, we adapt this feature set by using the argument component model in (Nguyen and Litman, 2016) which was shown to outperform the corresponding model of Stab and Gurevych.

For later presentation purposes, we name the set of all features from this section *except word pairs and production rules* as the **common features**. While word pairs and grammatical production rules were the most predictive features in (Stab and Gurevych, 2014b), we hypothesize that this large and sparse feature space may have negative impact on model robustness (Nguyen and Litman, 2015). Most of our proposed models replace word pairs and production rules with different combinations of new contextual features.

5.2 Topic-context Model

Our first proposed model (TOPIC) makes use of **Topic-context** features derived from a lexicon of argument and domain words for persuasive essays (Nguyen and Litman, 2015). Argument words (e.g., '*believe*', '*opinion*') signal the argumentative content and are commonly used across different topics. In contrast, domain words are specific terminologies commonly used within the topic (e.g., '*art*', '*education*'). The authors first use

[5]Stab and Gurevych (2014b) reported that including gold-standard labels of argument component in both training and testing phases yielded results close to human performance. Our preliminary experiment showed that including gold-standard argument component labels in training did not help when predicted labels were used in the test set.

topic prompts in development data of unannotated persuasive essays to semi-automatically collect argument and domain seed words. In particular, they used 10 argument seed words: *agree, disagree, reason, support, advantage, disadvantage, think, conclusion, result, opinion*. Domain seed words are those in the topic prompts but not argument seed words or stop words. The seeds words are then used to supervise an automated extraction of argument and domain words from output of LDA topic model (Blei et al., 2003) on the development data. The extracted lexicon consists of 263 (stemmed) argument words and 1806 (stemmed) domain words mapped to 36 LDA topics.[6] All argument words are from a single LDA topic while a domain word can map to multiple LDA topics (except the topic of argument words). Using the lexicon, we extract the following Topic-context features:

Argument word: from all word pairs extracted from the source and target components, we remove those that have at least one word not in the argument word list. Each argument word pair defines a boolean feature indicating its presence in the argument component pair. We also include each argument word of the source and target components as a boolean feature which is true if the word is present in the corresponding component. We count number of common argument words, the absolute difference in number of argument words between source and target components.

Domain word count: to measure the topic similarity between the source and target components, we calculate number of common domain words, number of pairs of two domain words that share an LDA topic, number of pairs that share no LDA topic, and the absolute difference in number of domain words between the two components.

Non-domain MainVerb-Subject dependency: we extract MainVerb-Subject dependency triples, e.g., *nsubj(belive, I)*, from the source and target components, and filter out triples that involve domain words. We model each extracted triple as a boolean feature which is true if the corresponding argument component has the triple.

Finally, we include the **common feature set**.

To illustrate the Topic-context features, consider the following source and target components. Argument words are in boldface, and domain words are in italic.

Essay 54. Topic: museum and art gallery will disappear soon?

Source: **more** and **more people can** *watch exhibitions* through *television* **or** *internet* at *home* **due to** *modern technology*$_{[Premise]}$

Target: **some people think** *museums* and *art galleries* **will** *disappear soon*$_{[Claim]}$

An argument word pair is **people-think**. There are 35 pairs of domain words. A pair of two domain words that share an LDA topic is *exhibitions-art*. A pair of two domain words that do not share any LDA topic is *internet-galleries*.

5.3 Window-context Model

Our second proposed model (WINDOW) extracts features from discourse relations and common words between context sentences in the *context windows* of the source and target components.

Definition. *Context window of an argument component is a text segment formed by neighboring sentences and the covering sentence of the component. The neighboring sentences are called context sentences, and must be in the same paragraph with the component.*

In this study, context windows are determined using *window-size* heuristics.[7] Given a window-size n, we form a context window by grouping the covering sentence with at most n adjacently preceding and n adjacently following sentences that must be in the same paragraph.

To minimize noise in feature space, we require that context windows of the source and target components must be mutually exclusive. Biran and Rambow (2011) observed that the relation between a source argument and a target argument is usually instantiated by some elaboration/justification provided in a support of the source argument. Therefore we prioritize the context window of source component when it overlaps with the target context window. Particularly, we keep overlapping context sentences in the source window, and remove them from the target window. For example, with window-size 1, context windows of the Claim in sentence 2 in Figure 1 and the Premise in sentence 4 overlap at sentence 3. When the Claim is set as source component, its

[6] An LDA topic is simply represented by a number, and should not be misunderstood with essay topics.

[7] Due to the paragraph constraint and window overlapping, window-size does not indicate the actual context window size. However, window-size tells what the maximum size a window can have.

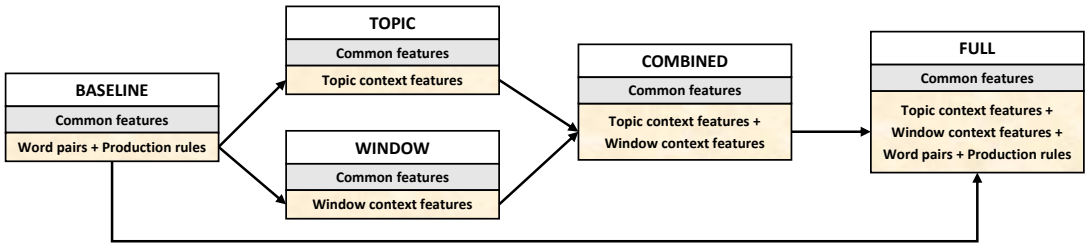

Figure 3: Features used in different models. Feature change across models are denoted by connectors.

context window includes sentences $\{2, 3\}$, and the Premise as a target has context window with only sentence 4. We extract three **Window-context** feature sets from the context windows:

Common word: as common word counts between adjacent sentences were shown useful for argument mining (Nguyen and Litman, 2016), we count common words between the covering sentence with preceding context sentences, and with following context sentences, for source and target components.

Discourse relation: for both source and target components, we extract discourse relations between context sentences, and within the covering sentence. We also extract discourse relations between each pair of source context sentence and target context sentence. Each relation defines a boolean feature. We extract both Penn Discourse Treebank (PDTB) relations (Prasad et al., 2008) and Rhetorical Structure Theory Discourse Treebank (RST-DTB) relations (Carlson et al., 2001) using publicly available discourse parsers (Ji and Eisenstein, 2014; Wang and Lan, 2015). Each PDTB relation has sense label defined in a 3-layered (class, type, subtype), e.g., *CONTINGENCY.Cause.result*. While there are only four semantic class labels at the class-level which may not cover well different aspects of argumentative relation, subtype-level output is not available given the discourse parser we use. Thus, we use relations at type-level as features. For RST-DTB relations, we use only relation labels, but ignore the nucleus and satellite labels of components as they do not provide more information given the component order in the pair. Because temporal relations were shown not helpful for argument mining tasks (Biran and Rambow, 2011; Stab and Gurevych, 2014b), we exclude them here.

Discourse marker: while the baseline model only considers discourse markers within the argument components, we define a boolean feature for each discourse marker classifying whether the marker is present before the covering sentence of the source and target components or not. This implementation aims to characterize the discourse of the preceding and following text segments of each argument component separately.

Finally, we include the **common feature set**.

5.4 Combined Model

While Window-context features are extracted from surrounding text of the argument components, which exploits the local context, the Topic-context features are an abstraction of topic-dependent information, e.g., domain words are defined within the context of topic domain (Nguyen and Litman, 2015), and thus make use of the global context of the topic domain. We believe that local and global context information represent complementary aspects of the relation between argument components. Thus, we expect to achieve the best performance by combining Window-context and Topic-context models.

5.5 Full Model

Finally, the FULL model includes all features in BASELINE and COMBINED models. That is, the FULL model is the COMBINED model plus word pairs and production rules. A summary of all models is shown in Figure 3.

6 Experiments

6.1 Task 1: Support vs. Non-support

Tuning Window-size Parameter

Because our WINDOW model uses a window-size parameter to form context windows of the source and target argument components, we investigate how the window-size of the context window impacts the prediction performance of the Window-context features. We set up a model with only Window-context features and determine the

	REPORTED	BASELINE	TOPIC	WINDOW	COMBINED	FULL
Accuracy	0.863	0.869	0.857	0.857	0.870	**0.877**
Kappa	–	0.445	0.407	0.449	**0.507***	0.481
Macro F1	0.722	0.722	0.703	0.724	**0.753***	0.739
Macro Precision	0.739	0.758	0.728	0.729	0.754	**0.777**
Macro Recall	0.705	0.699	0.685	0.720	**0.752***	0.715
F1:Support	0.519	0.519	0.488	0.533	**0.583***	0.550
F1:Non-support	0.920	0.925	0.917	0.916*	0.923	**0.929**

Table 2: Support vs. Non-support classification performances on test set. Best values are in bold. Values smaller than baseline are underlined. * indicates significantly different from the baseline ($p < 0.05$).

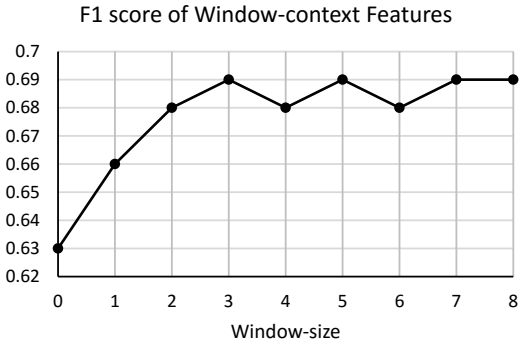

Figure 4: Performance of Window-context feature set by window-size.

window-size in range [0, 8][8] that yields the best F1 score in 10-fold cross validation. We use the training set as determined in (Stab and Gurevych, 2014b) to train/test[9] the models using LibLINEAR algorithm (Fan et al., 2008) without parameter or feature optimization. Cross-validations are conducted using Weka (Hall et al., 2009). We use Stanford parser (Klein and Manning, 2003) to perform text processing. As shown in Figure 4, while increasing the window-size from 2 to 3 improves performance (significantly), using window-sizes greater than 3 does not gain further improvement. We hypothesize that after a certain limit, larger context windows will produce more noise than helpful information for the prediction. Therefore, we set the window-size to 3 in all of our experiments involving Window-context model (all with a separate test set).

[8]Windows-size 0 means covering sentence is the only context sentence. We experimented with not using context sentence at all and obtained worse performance. Our data does not have context window with window-size 9 or larger.

[9]Note that via cross validation, in each fold some of our training set serves as a development set.

Performance on Test Set

We train all models using the training set and report their performances on the test set in Table 2. We also compare our baseline to the reported performance (REPORT) for Support vs. Non-support classification in (Stab and Gurevych, 2014b). The learning algorithm with parameters are kept the same as in the window-size tuning experiment. Given the skewed class distribution of this data, Accuracy and F1 of Non-support (the major class) are less important than Kappa, F1, and F1 of Support (the minor class). To conduct T-tests for performance significance, we split the test data into subsets by essays' ID, and record prediction performance for individual essays.

We first notice that the performances of our baseline model are better than (or equal to) REPORTED, except the Macro Recall. We reason that these performance disparities may be due to the differences in feature extractions between our implementation and Stab and Gurevych's, and also due to the minor set of new features (e.g., new predicted labels, expanded marker set, component position) that we added in our baseline.

Comparing proposed models with BASELINE, we see that WINDOW, COMBINED, and FULL models outperform BASELINE in important metrics: Kappa, F1, Recall, but TOPIC yields worse performances than BASELINE. However, the fact that COMBINED outperforms BASELINE, especially with significantly higher Kappa, F1, Recall, and F1:Support, has shown the value of Topic-context features. While Topic-context features alone are not effective, they help improve WINDOW model which supports our hypothesis that Topic-context and Window-context features are complementary aspects of context, and they together obtain better performance.

Comparing our proposed TOPIC, WINDOW,

	BASELINE	TOPIC	WINDOW	COMBINED	FULL
Accuracy	0.885	0.886	0.872	0.885	**0.887**
Kappa	0.245	0.305*	0.306*	**0.342***	0.274*
Macro F1	0.618	0.651*	0.652*	**0.670***	0.634*
Macro Precision	0.680	0.692	0.663	**0.697**	0.693
Macro Recall	0.595	0.628*	0.644*	**0.652***	0.609*
F1:Support	0.937	0.937	0.928*	0.936	**0.938**
F1:Attack	0.300	0.365*	0.376*	**0.404***	0.330*

Table 3: 5×10-fold cross validation performance of Support vs. Attack classification. * indicates significantly different from the baseline ($p < 0.01$).

COMBINED models with each other shows that COMBINED obtains the best performance while TOPIC performs the worst, which reveals that Topic-context feature set is less effective than Window-context set. While FULL model achieves the best Accuracy, Precision, and F1:Non-support, it has lower performance than COMBINED model in important metrics: Kappa, F1, F1:Support. We reason that the noise caused by word pairs and production rules even dominate the effectiveness of Topic-context and Window-context features, which degrades the overall performance.

Overall, by combining TOPIC and WINDOW models, we obtain the best performance. Most notably, we obtain the highest improvement in F1:Support, and have the best balance between Precision and Recall values among all models. These reveal that our contextual features not only dominate generic features like word pairs and production rules, but also are effective to predict minor positive class (i.e., Support).

6.2 Task 2: Support vs. Attack

To evaluate the robustness of our proposed models, we conduct an argumentative relation classification experiment that classifies a relation as Support or Attack. Because this task was not studied in (Stab and Gurevych, 2014b) and the training/test split for Support vs. Not task is not applicable here, we conduct 5×10-fold cross validation. We do not optimize the window-size parameter of the WINDOW model, and use the value 3 as set up before. Average prediction performance of all models are reported in Table 3.

Comparing our proposed models with the baseline shows that all of our proposed models significantly outperform the baseline in important metrics: Kappa, F1, F1:Attack. More notably than in the Support vs. Non-support classification, all of our proposed models predict the minor class (Attack) significantly more effectively than the baseline. The baseline achieves significantly higher F1:Support than WINDOW model. However, F1:Support of the baseline is in a tie with TOPIC, COMBINED, and FULL.

Comparing our proposed models, we see that TOPIC and WINDOW models reveal different behaviors. TOPIC model has significantly higher Precision and F1:Support, and significantly lower Recall and F1:Attack than WINDOW. Moreover, WINDOW model has slightly higher Kappa, F1, but significantly lower Accuracy. These comparisons indicate that Topic-context and Window-context features are equally effective but impact differently to the prediction. The different nature between these two feature sets is clearer than in the prior experiment, as now the classification involves classes that are more semantically different, i.e., Support vs. Attack. We recall that TOPIC model performs worse than WINDOW model in Support vs. Non-support task.

Our FULL model performs significantly worse than all of TOPIC, WINDOW, and COMBINED in Kappa, F1, Recall, and F1:Attack. Along with results from Support vs. Non-support task, this further suggests that word pairs and production rules are less effective and cannot be combined well with our contextual features.

Despite the fact that the Support vs. Attack task (Task 2) has smaller and more imbalanced data than the Support vs. Non-support (Task 1), our proposed contextual features seem to add even more value in Task 2 compared to Task 1. Using Kappa to roughly compare prediction performance across the two tasks, we observe a greater performance improvement from Baseline to Combined model in Task 2 than in Task 1. This is an evidence that our proposed context-aware features

work well even in a more imbalanced with smaller data classification task. The lower performance values of all models in Support vs. Attack than in Support vs. Non-support indirectly suggest that Support vs. Attack classification is a more difficult task. We hypothesize that the difference between support and attack exposes a deeper semantic relation than that between support and no-relation. We plan to extract textual text similarity and textual entailment features (Cabrio and Villata, 2012; Boltužić and Šnajder, 2014) to investigate this hypothesis in our future work.

7 Conclusions and Future Work

In this paper, we have presented *context-aware argumentative relation mining* that makes use of contextual features by exploiting information from topic context and context sentences. We have explored different ways to incorporate our proposed features with baseline features used in a prior study, and obtained insightful results about feature effectiveness. Experimental results show that Topic-context and Window-context features are both effective but impact predictive performance measures differently. In addition, predicting an argumentative relation will benefit most from combining these two set of features as they capture complementary aspects of context to better characterize the argumentation in justification.

The results obtained in this preliminary study are promising and encourage us to explore more directions to enable contextual features. Our next step will investigate uses of topic segmentation to identify context sentences and compare this linguistically-motivated approach to our current window-size heuristic. We plan to follow prior research on graph optimization to refine the argumentation structure and improve argumentative relation prediction. Also, we will apply our context-aware argumentative relation mining to different argument mining corpora to further evaluate its generality.

Leveraging Inflection Tables for Stemming and Lemmatization

Garrett Nicolai and **Grzegorz Kondrak**

University of Alberta
{nicolai,gkondrak}@ualberta.ca

Abstract

We present several methods for stemming and lemmatization based on discriminative string transduction. We exploit the paradigmatic regularity of semi-structured inflection tables to identify stems in an unsupervised manner with over 85% accuracy. Experiments on English, Dutch and German show that our stemmers substantially outperform Snowball and Morfessor, and approach the accuracy of a supervised model. Furthermore, the generated stems are more consistent than those annotated by experts. Our direct lemmatization model is more accurate than Morfette and Lemming on most datasets. Finally, we test our methods on the data from the shared task on morphological reinflection.

1 Introduction

Many languages contain multiple inflected forms that correspond to the same dictionary word. Inflection is a grammatical procedure that has little impact on the meaning of the word. For example, the German words in Table 1 all refer to the action of giving. When working with these languages, it is often beneficial to establish a consistent representation across a set of inflections. This is the task that we address here.

There are two principal approaches to inflectional simplification: stemming and lemmatization. Stemming aims at removing inflectional affixes from a word form. It can be viewed as a kind of word segmentation, in which the boundaries of the stem are identified within the word; no attempt is made to restore stem changes that may occur as part of the inflection process. The goal of lemmatization is to map any inflected form to its unique *lemma*, which is typically the word form that represents a set of related inflections in a dictionary. Unlike stemming, lemmatization must always produce an actual word form.

Word form	Meaning	Tag	Stem
geben	"to give"	INF	geb
gibt	"gives"	3SIE	gib
gab	"gave"	1SIA	gab
gegeben	"given"	PP	geb

Table 1: Examples of German word-forms corresponding to the lemma *geben*.

In this paper, we present a discriminative string transduction approach to both stemming and lemmatization. Supervised stemmers require morphologically annotated corpora, which are expensive to build. We remove this constraint by extracting stems from semi-structured inflection tables, such as the one shown in Table 2, in an unsupervised manner. We design two transduction models that are trained on such stems, and evaluate them on unseen forms against a supervised model. We then extend our stemming models to perform the lemmatization task, and to incorporate an unannotated corpus. We evaluate them on several datasets.Our best system improves the state of the art for Dutch, German, and Spanish. Finally, we test our methods on the data from the shared task on morphological reinflection.

This paper is organized as follows. In Section 2, we present an overview of prior work on inflectional simplification. In Section 3, we describe our stemming methodology, followed by three types of evaluation experiments in Section 4. In Section 5, we describe our approach to lemmatization, followed by both intrinsic and extrinsic experiments in Section 6. Section 7 concludes the paper.

Berlin, Germany, August 7-12, 2016.

2 Related Work

In this section, we review prior work on stemming and lemmatization.

2.1 Stemming and Segmentation

Stemming is a sub-task of the larger problem of morphological segmentation. Because of the scarcity of morphologically-annotated data, many segmentation algorithms are unsupervised or rule-based.

The Porter stemmer (Porter, 1980) and its derivatives, such as Snowball, apply hand-crafted context rules to strip affixes from a word. Creation of such rule-based programs requires significant effort and expert knowledge. We use structured inflection tables to create training data for a discriminative transducer.

Morfessor (Creutz and Lagus, 2002) and Linguistica (Goldsmith, 2001) are unsupervised word segmenters, which divide words into regularly occurring sub-sequences by applying the minimum description length (MDL) principle. While these methods are good at identifying common morphemes, they make no distinction between stems and affixes, and thus cannot be used for stemming. Morfessor Categories-MAP (Creutz and Lagus, 2004; Creutz and Lagus, 2005) distinguishes between stems and affixes, but not between derivational and inflectional affixes. We adapt a more recent version (Grönroos et al., 2014) to be used as an approximate stemmer.

Poon et al. (2009) abandons the generative model of Morfessor for a log-linear model that predicts segmentations in sequence. The discriminative approach allows for the incorporation of several priors that minimize over-segmentation. Their unsupervised model outperforms Morfessor, and they are also able to report semi- and fully-supervised results. We also approach the problem using a discriminative method, but by aligning structured inflection tables, we can take advantage of linguistic knowledge, without requiring costly annotation.

Ruokolainen et al. (2014) obtain further improvements by combining a structured perceptron CRF with letter successor variety (LSV), and the unsupervised features of Creutz and Lagus (2004). Their system is inherently supervised, while our stem annotations are derived in an unsupervised manner.

Cotterell et al. (2015) introduce Chipmunk, a fully-supervised system for labeled morphological segmentation. Extending the sequence-prediction models, Chipmunk makes use of data that is annotated not only for stem or affix, but also for inflectional role, effectively combining morphological segmentation and morphological analysis. While highly accurate, Chipmunk is limited in that it requires data that is fully-annotated for both segmentation and inflection. Our system has access to the morphological tags in inflection tables, but segmentation and tag alignment are performed in an unsupervised way.

	Singular			Plural
	1^{st}	2^{nd}	3^{rd}	1^{st}
Present	*doy*	*das*	*da*	*damos*
Imperfect	*daba*	*dabas*	*daba*	*dábamos*
Preterite	*di*	*diste*	*dio*	*dimos*
Future	*daré*	*darás*	*dará*	*daramos*

Table 2: A partial inflection table for the Spanish verb *dar* "to give".

2.2 Lemmatization

Unlike stemmers, which can be unsupervised, lemmatizers typically require annotated training data. In addition, some lemmatizers assume access to the morphological tag of the word, and/or the surrounding words in the text. Our focus is on context-free lemmatization, which could later be combined with a contextual disambiguation module.

Lemmatization is often part of the morphological analysis task, which aims at annotating each word-form with its lemma and morphological tag. Toutanova and Cherry (2009) learn a joint model for contextual lemmatization and part-of-speech prediction from a morphologically annotated lexicon. Their transduction model is tightly integrated with the POS information, which makes comparison difficult. However, in Section 6, we evaluate our approach against two other fully-supervised morphological analyzers: Morfette (Chrupała et al., 2008) and Lemming (Müller et al., 2015). Both of these systems perform lemmatization and morphological analysis in context, but can be trained to learn non-contextual models. Morfette requires morphological tags during training, while Lemming requires a morphological model constructed by its sister program, Marmot (Müller et al., 2013).

3 Stemming Methods

We approach stemming as a string transduction task. Stemming can be performed by inserting morpheme boundary markers between the stem and the affixes. For example, the German verb form *gegeben* is transduced into `ge+geb+en`, which induces the stem `geb`.

3.1 Character Alignment

The training of a transduction model requires a set of aligned pairs of source and target strings. The alignment involves every input and output character; the insertion and deletion operations are disallowed. Atomic character transformations are then extracted from the alignments.

We infer the alignment with a modified version of the M2M aligner of Jiampojamarn et al. (2007). The program applies the Expectation-Maximization algorithm with the objective to maximize the joint likelihood of its aligned source and target pairs. For our task, the source and target strings are nearly identical, except that the target includes stem-affix boundary markers. In order to account for every character in the target, which is usually longer than the source, we allow one-to-many alignment. This has the effect of tying the markers to the edge of a stem or affix. In order to encourage alignments between identical characters, we modify the aligner to generalize all identity transformations into a single match operation.

3.2 Supervised Transduction

Once we have aligned the source and target pairs, we proceed to train a *word-to-stem* transduction model for stemming unseen test instances. The word-to-stem model learns where to insert boundary markers. We refer to a model that is trained on annotated morphological segmentations as our supervised method.

We perform string transduction by adapting DIRECTL+, a tool originally designed for grapheme-to-phoneme conversion (Jiampojamarn et al., 2010). DIRECTL+ is a feature-rich, discriminative character transducer that searches for a model-optimal sequence of character transformation rules for its input. The core of the engine is a dynamic programming algorithm capable of transducing many consecutive characters in a single operation. Using a structured version of the MIRA algorithm (McDonald et al., 2005), training attempts to assign weights to each feature so that its linear model separates the gold-standard derivation from all others in its search space.

STEM|INF	**geb**|en	**setz**|en	**tu**|n
STEM|1SIA	gab|-	setz|te	tat|-
STEM|2SIE	gib|st	setz|t	tu|st
PP|STEM|PP	ge|geb|en	ge|setz|t	ge|ta|n

Table 3: Stemming of the training data based on the patterns of regularity in inflectional tables. Stemmas are shown in bold.

DIRECTL+ uses a number of feature templates to assess the quality of a rule: source context, target n-gram, and joint n-gram features. Context features conjoin the rule with indicators for all source character n-grams within a fixed window of where the rule is being applied. Target n-grams provide indicators on target character sequences, describing the shape of the target as it is being produced, and may also be conjoined with our source context features. Joint n-grams build indicators on rule sequences, combining source and target context, and memorizing frequently-used rule patterns.

Following Toutanova and Cherry (2009), we modify the out-of-the-box version of DIRECTL+ by implementing an abstract copy feature that indicates when a rule simply copies its source characters into the target, e.g. $b \rightarrow b$. The copy feature has the effect of biasing the transducer towards preserving the source characters during transduction.

3.3 Unsupervised Segmentation

In order to train a fully-supervised model for stemming, large lists of morphologically-segmented words are generally required. While such annotated corpora are rare, semi-structured, crowd-sourced inflection tables are available for many languages on websites such as Wiktionary (Table 2). In this section, we introduce an unsupervised method of inducing stems by leveraging paradigmatic regularity in inflection tables.

Sets of inflection tables often exhibit the same inflectional patterns, called paradigms, which are based on phonological, semantic, or morphological criteria (cf. Table 3). Each table consists of lists of word forms, including the lemma. The number of distinct stems, such as *'geb'* and *'gib'* for the verb *geben*, is typically very small, averaging slightly over two per German verb inflection table.

Source	g	i	b	t
Target	g	i	b	+t
Tags	STEM			3SIE
Joint	g	**e**	b	+3SIE

Table 4: Alignment of the various representations of the word *gibt*.

	Words	Noun	Verb	Adj
English	50,155	2	5	3
Dutch	101,667	2	9	3
German	96,038	8	27	48

Table 5: The number of words and distinct inflections for each language in the CELEX datasets.

The number of distinct affix forms corresponding to the same inflectional form across different lemmas is also small, averaging below three for German verbs. For example, the second person singular indicative present suffix is always either *-st*, *-est*, or *-t*.

We take advantage of this relative consistency to determine the boundaries between the stems and affixes of each word form in an unsupervised manner. We first associate each word form in the training data with an abstract tag sequence, which is typically composed of the `STEM` tag and a suffix tag representing a given inflection slot (Table 3). We then apply the unsupervised aligner to determine the most likely alignment between the character sequences and the tags, which are treated as indivisible units. The aligner simultaneously learns common representations for stems within a single inflection table, as well as common representations for each affix across multiple tables.

Some inflections, such as the German past participle (`PP` in Table 3) involve a *circumfix*, which can be analyzed as a prefix-suffix combination. Prior to the alignment, we associate all forms that belong to the inflection slots involving circumfixation with tag sequences composed of three tags. Occasionally, a word form will only have a suffix where one would normally expect a circumfix (e.g. *existiert*). In order to facilitate tag alignment in such cases, we prepend a dummy null character to each surface word form.

After the stem-affix boundaries have been identified, we proceed to train a *word-to-stem* transduction model as described in Section 3.2. We refer to this unsupervised approach as our basic method (cf. Figure 1).

3.4 Joint Stemming and Tagging

The method described in the previous section fails to make use of a key piece of information in the inflection table: the lemma. The stem of an inflected form is typically either identical or very similar to the stem of its lemma, or *stemma* (Table 3). Our joint method takes advantage of this similarity by transducing word-forms into stemmas with tags.

The format of the training data for the *word-to-stemma* model is different from the *word-to-stem* model. After the initial segmentation of the source word-forms into morphemes by the unsupervised aligner, as described in Section 3.3, the stems are replaced with the corresponding stemmas, and the affixes are replaced with the inflection tags. For example, the form *gibt* is paired with the sequence `geb+3SIE`, with the stem and stemma re-aligned at the character level as shown in Table 4.

Unlike the basic method, which simply inserts morpheme breaks into word-forms, the joint method uses the tags to identify the boundaries between stems and affixes. At test time, the input word-form is transduced into a stemma and tag sequence. The character string that has generated the tag is then stripped from the input word-form to obtain the stem. By making use of both the tags and the stemma, the *word-to-stemma* model jointly optimizes the stem and affix combination. We refer to this unsupervised approach as our joint method.

4 Stemming Experiments

Precise evaluation of stemming methods requires morphologically annotated lexicons, which are rare. Unlike lemmas, stems are abstract representations, rather than actual word forms. Unsurprisingly, annotators do not always agree on the segmentation of a word. In this section, we describe three experiments for evaluating stem extraction, intrinsic accuracy, and consistency.

We evaluate our methods against three systems that are based on very different principles. Snowball[1] is a rule-based program based on the methodology of the Porter Stemmer. Morfessor FlatCat (Grönroos et al., 2014) performs unsupervised morphological segmentation, and approximates stemming by distinguishing stems and af-

fixes.[2] Chipmunk (Cotterell et al., 2015), is a fully-supervised system that represents the current state of the art.

4.1 Data

We perform an evaluation of stemming on English (EN), Dutch (NL), and German (DE) lexicons from CELEX (Baayen et al., 1995). The three languages vary in terms of morphological complexity (Table 5). We use the morphological boundary annotations for testing all stemming systems, as well as for training our supervised system.

For both unsupervised systems, we could build training sets from any inflection tables that contain unsegmented word-forms. However, in order to perform a precise comparison between the supervised and unsupervised systems, we extract the inflection tables from CELEX, disregarding the segmentation information. Each system is represented by a single stemming model that works on nouns, verbs, and adjectives. Due to differences in representation, the number of training instances vary slightly between models, but the number of words is constant (Table 5).

In order to demonstrate that our unsupervised methods require no segmentation information, we create additional German training sets using the inflection tables extracted from Wiktionary by Durrett and DeNero (2013). The sets contain 18,912 noun forms and 43,929 verb forms. We derive separate models for verbs and nouns in order to compare the difficulty of stemming different parts of speech.

The test sets for both CELEX and Wiktionary data come from CELEX, and consist of 5252, 6155, and 9817 unique forms for English, Dutch, and German, respectively. The German test set contains 2620 nouns, 3837 verbs, and 3360 adjectives.

Chipmunk[3] requires training data in which every morpheme of a word is annotated for morphological function. Since this information is not included in CELEX, we train and test Chipmunk, as well as a version of our supervised model, on the data created by Cotterell et al. (2015), which is much smaller. The English and German segmentation datasets contain 1161 and 1266 training instances, and 816 and 952 test instances, respectively.

	EN	NL	DE
Supervised	98.5	96.0	91.2
Basic	82.3	89.1	80.9
Joint	94.6	93.2	86.0
Snowball	50.0	58.4	48.2
Morfessor	65.2	60.9	51.8

Table 7: Stemming accuracy of systems trained and tested on CELEX datasets.

4.2 Stem Extraction Evaluation

First, we evaluate our unsupervised segmentation approach, which serves as the basis for our basic and joint models, on the union of the training and development parts of the CELEX dataset. We are interested how often the stems induced by the method described in Section 3.3 match the stem annotations in the CELEX database.

The results are presented in Table 6. Our method is substantially more accurate than either Snowball or Morfessor. Snowball, despite being called a stemming algorithm, often eliminates derivational affixes; e.g. `able` in *unbearable*. Morfessor makes similar mistakes, although less often. Our method tends to prefer longer stems and shorter affixes. For example, it stems *verwandtestem*, as `verwandte`, while CELEX has `verwandt`.

4.3 Intrinsic Evaluation

The results of the intrinsic evaluation of the stemming accuracy on unseen forms in Tables 7-9 demonstrate the quality of our three models. The joint model performs better than the basic model, and approaches the accuracy of the supervised model. On the CELEX data, our unsupervised joint model substantially outperforms Snowball and Morfessor on all three languages (Table 7).[4]

[2] Morfessor is applied to the union of the training and test data.

[3] http://cistern.cis.lmu.de/chipmunk

[4] The decrease in Morfessor accuracy between Tables 6 and 7 can be attributed to a different POS distribution between training and testing.

	Noun	Verb
Basic	76.8	90.3
Joint	85.2	91.1
Snowball	55.5	39.8
Morfessor	61.9	34.9

Table 8: German stemming accuracy of systems trained on Wiktionary data, and tested on the CELEX data.

	EN	DE
Supervised	94.7	85.1
Chipmunk	94.9	87.4

Table 9: Stemming accuracy of systems trained and tested on the Chipmunk data.

These results are further confirmed on the German Wiktionary data (Table 8). Our supervised model performs almost as well as Chipmunk on its dataset (Table 9).

A major advantage of the joint model over the basic model is its tag awareness (cf. Table 4). Although the tags are not always correctly recovered on the test data, they often allow the model to select the right analysis. For example, the basic model erroneously segments the German form *erklärte* as `erklärt+e` because `+e` is a common verbal, adjectival and nominal suffix. The joint model, recognizing `er` as a verbal derivational prefix, predicts a verbal inflection tag (`+1SIA`), and the correct segmentation `erklär+te`. Verbal stems are unlikely to end in `ärt`, and `+te`, unlike `+e`, can only be a verbal suffix.

4.4 Consistency Evaluation

When stemming is used for inflectional simplification, it should ideally produce the same stem for all word-forms that correspond to a given lemma. In many cases, this is not an attainable goal because of internal stem changes (cf. Table 1). However, most inflected words follow regular paradigms, which involve no stem changes. For example, all forms of the Spanish verb *cantar* contain the substring `cant`, which is considered the common stem. We quantify the extent to which the various systems approximate this goal by calculating the average number of unique generated stems per inflection table in the CELEX test sets.[5]

	EN	NL	DE
Gold	1.10	1.17	1.30
Supervised	1.13	1.64	1.50
Basic	1.06	1.21	1.25
Joint	1.09	1.08	1.20
Snowball	1.03	1.45	2.02
Morfessor	1.11	1.68	3.27

Table 10: Average number of stems per lemma.

The results are presented in Table 10. The stems-per-table average tends to reflect the morphological complexity of a language. All systems achieve excellent consistency on English, but the Dutch and German results paint a different picture. The supervised system falls somewhat short of emulating the gold segmentations, which may be due to the confusion between different parts of speech. In terms of consistency, the stems generated by our unsupervised methods are superior to those of Snowball and Morfessor, and even to the gold stems. We attribute this surprising result to the fact that the EM-based alignment of the training data favors consistency in both stems and affixes, although this may not always result in the correct segmentation.

5 Lemmatization Methods

In this section, we present three supervised lemmatization methods, two of which incorporate the unsupervised stemming models described in Section 3. The different approaches are presented schematically in Figure 1, using the example of the German past participle *gedacht*.

5.1 Stem-based Lemmatization

Our stem-based lemmatization method is an extension of our basic stemming method. We compose the *word-to-stem* transduction model from Section 3 with a *stem-to-lemma* model that converts stems into lemmas. The latter is trained on character-aligned pairs of stems and lemmas, where stems are extracted from the inflection tables via the unsupervised method described in Section 3.3.

[5] Chipmunk is excluded from the consistency evaluation because its dataset is not composed of complete inflection tables.

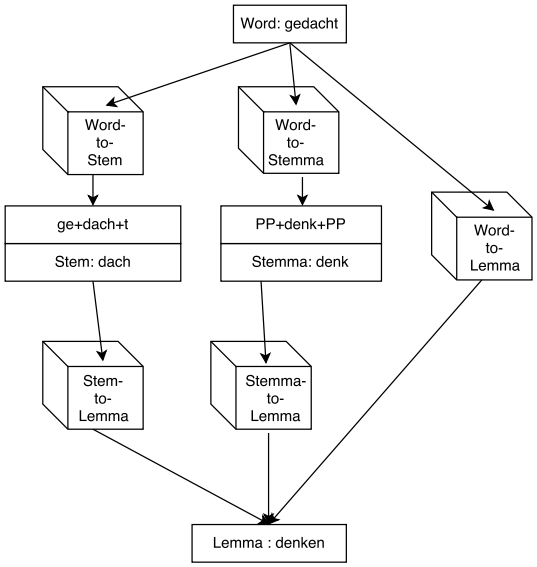

Figure 1: Three lemmatization methods.

5.2 Stemma-based Lemmatization

Our stemma-based lemmatization method is an extension of our joint stemming method. We compose the *word-to-stemma* transduction model described in Section 3.4 with a *stemma-to-lemma* model that converts stems into lemmas. The latter is trained on character-aligned pairs of stemmas and lemmas, where stemmas are extracted via the method described in Section 3.4. Typically, the model simply appends a lemmatic affix to the stemma, as all stem changes are handled by the *word-to-stemma* model.

5.3 Direct Lemmatization

Our final lemmatization method is a *word-to-lemma* transduction model that directly transforms word-forms into lemmas and tags. The model is trained on word-forms paired with their lemmas and inflectional tags, which are easily obtained from the inflection tables. A potential advantage of this method lies in removing the possibility of error propagation that is inherent in pipeline approaches. However, it involves a more complex transduction model that must simultaneously apply both stem changes, and transform inflectional affixes into lemmatic ones.

5.4 Re-ranking

Intuitively, lemmatization accuracy could be improved by leveraging large, unannotated corpora. After generating n-best lists of possible lemmas, we re-rank them using the method of Joachims (2002) implemented with the Liblinear SVM tool (Fan et al., 2008). We employ four features of the prediction:

1. normalized score from DIRECTL+,
2. rank in the n-best list
3. presence in the corpus,
4. normalized likelihood from a 4-gram character language model derived from the corpus.

6 Lemmatization Experiments

Unlike stemming, lemmatization is a completely consistent process: all word-forms within an inflection table correspond to the same lemma. In this section, we describe intrinsic and extrinsic experiments to evaluate the quality of the lemmas generated by our systems, and compare the results against the current state of the art.

6.1 Data

As in our stemming experiments, we extract complete English, Dutch, and German inflection tables from CELEX. We use the same data splits as in Section 4.1. We also evaluate our methods on Spanish verb inflection tables extracted from Wiktionary by Durrett and DeNero (2013), using the original data splits. Spanish is a Romance language, with a rich verbal morphology comprising 57 inflections for each lemma.

A different type of dataset comes from the CoNLL-2009 Shared Task (Hajič et al., 2009). Unlike the CELEX and Wiktionary datasets, they are extracted from an annotated text, and thus contain few complete inflection tables, with many lemmas represented by a small number of word-forms. We extract all appropriate parts-of-speech from the test section of the corpus for English, German, and Spanish. This results in a test set of 5165 unique forms for English, 6572 for German, and 2668 for Spanish.

For re-ranking, we make use of a word list constructed from the first one million lines of the appropriate Wikipedia dump.[6] A character language model is constructed using the CMU Statistical Language Modeling Toolkit.[7] 20% of the development set is reserved for the purpose of training a re-ranking model. For Lemming and Morfette, we provide a lexicon generated from the corpus.

Spanish marks unpredictable stress by marking a stressed vowel with an acute accent (e.g. *cantó*

[6] All dumps are from November 2, 2015.

vs. *canto*). In order to facilitate generalization, we perform a lossless pre-processing step that replaces all accented vowels with their unaccented equivalent followed by a special stress symbol (e.g. `canto'`). For consistency, this modification is applied to the data for each system.

6.2 Intrinsic Evaluation

We evaluate lemmatization using word accuracy. In cases where a surface word-form without a morphological tag may correspond to multiple lemmas, we judge the prediction as correct if it matches any of the lemmas. For example, both the noun *Schrei* and the verb *schreien* are considered to be correct lemmas for the German word *schreien*.[8]

The results without the use of a corpus are shown in Table 11. Thanks to its tag awareness, the stemma-based method is more accurate than the stem-based method, except on the verb-only Spanish Wiktionary dataset. However, our best method is the direct *word-to-lemma* model, which outperforms both Morfette and Lemming on most datasets.

We interpret the results as the evidence for the effectiveness of our discriminative string transduction approach. The direct model is superior to the stemma-based model because it avoids any information loss that may occur during an intermediate stemming step. However, it is still able to take advantage of the tag that it generates together with the target lemma. For example, Lemming incorrectly lemmatizes the German noun form *Verdienste* "earnings" as `verdien` because `+ste` is a superlative adjective suffix. Our direct model, however, considers `dien` to be an unlikely ending for an adjective, and instead produces the correct lemma *Verdienst*.

The results with the use of a corpus are shown in Table 12. We omit the results on Spanish Wiktionary and on both English datasets, which are almost identical to those in Table 11. We observe that both the stemma-based and direct methods achieve a substantial error rate reduction on the Dutch and German datasets, while Lemming improvements are minimal.[9] The Spanish CoNLL results are different: only the stem-based and stemma-based methods benefit noticeably from re-ranking.

	CELEX		CoNLL	
	NL	DE	DE	ES
Stem-based	82.3	76.9	71.9	90.6
Stemma-based	87.3	88.4	79.0	**93.3**
Direct	**92.4**	**90.0**	**81.3**	91.9
Lemming	86.9	88.5	77.9	90.6

Table 12: Lemmatization results boosted with a raw corpus.

Error analysis indicates that the re-ranker is able to filter non-existent lemmas, such as `wint` for *Winter*, and `endstadie` for *Endstadien*, instead of *Endstadium*. In general, the degree of improvement seems to depend on the set of randomly selected instances in the held-out set used for training the re-ranker. If a base model achieves a very high accuracy on the held-out set, the re-ranker tends to avoid correcting the predictions on the test set.

6.3 Extrinsic Evaluation

We perform our final evaluation experiment on the German dataset[10] from the SIGMORPHON shared task on morphological reinflection (Cot-

[8] The capitalization of German nouns is ignored.

[9] We were unable to obtain any corpus improvement with Morfette.

[10] http://sigmorphon.org/sharedtask

Stem-based	86.9	89.3
Stemma-based	84.0	89.5
Lemma-based	n/a	90.7
Source-Target	94.8	88.2

Table 13: Accuracy on the German dataset from the shared task on morphological reinflection.

terell et al., 2016).[11] The task of inflection generation (Task 1) is to produce a word-form given a lemma and an abstract inflectional tag. The task of unlabeled reinflection (Task 3) takes as input an unannotated inflected form instead of a lemma.

We evaluate four different methods that combine the models introduced in this paper. For Task 1, the stem-based method composes a *lemma-to-stem* and a *stem-to-word* models; the stemma-based method is similar, but pivots on stemmas instead; and the source-target method is a *lemma-to-word* model. For Task 3, a *word-to-lemma* model is added in front of both the stem-based and stemma-based methods; the lemma-based method composes a *word-to-lemma* and a *lemma-to-word* models; and the source-target method is a *word-to-word* model. In addition, we compare with a method that is similar to our *stem-based* method, but pivots on Chipmunk-generated stems instead. As a baseline, we run the transduction method provided by the task organizers.

The results are shown in Table 13. On Task 1, none of the stemming approaches is competitive with a direct *lemma-to-word* model. This is not surprising. First, the lemmatic suffixes provide information regarding part-of-speech. Second, the stemmers fail to take into account the fact that the source word-forms are lemmas. For example, the German word *überhitzend* "overheated" can either be an adjective, or the present participle of the verb *überhitzen*; if the word is a lemma, it is obviously the former.

The *lemma-based* method is the best performing one on Task 3. One advantage that it has over the *word-to-word* model lies in the ability to reduce the potentially quadratic number of transduction operations between various related word-forms to a linear number of transduction operations between the word-forms and their lemmas, and vice-versa.

[11] We use the development sets for this evaluation because the target sides of the test sets have not been publicly released.

7 Conclusion

We have presented novel methods that leverage readily available inflection tables to produce high-quality stems and lemmas. In the future, we plan to expand our method to predict morphological analyses, as well as to incorporate other information such as parts-of-speech.

Abstract

A key goal in natural language generation (NLG) is to enable fast generation even with large vocabularies, grammars and worlds. In this work, we build upon a recently proposed NLG system, Sentence Tree Realization with UCT (STRUCT). We describe four enhancements to this system: (i) pruning the grammar based on the world and the communicative goal, (ii) intelligently caching and pruning the combinatorial space of semantic bindings, (iii) reusing the lookahead search tree at different search depths, and (iv) learning and using a search control heuristic. We evaluate the resulting system on three datasets of increasing size and complexity, the largest of which has a vocabulary of about 10K words, a grammar of about 32K lexicalized trees and a world with about 11K entities and 23K relations between them. Our results show that the system has a median generation time of 8.5s and finds the best sentence on average within 25s. These results are based on a sequential, interpreted implementation and are significantly better than the state of the art for planning-based NLG systems.

1 Introduction and Related Work

We consider the restricted natural language generation (NLG) problem (Reiter and Dale, 1997): given a grammar, lexicon, world and a communicative goal, output a valid sentence that satisfies this goal. Though restricted, this problem is still challenging when the NLG system has to deal with the large probabilistic grammars of natural language, large knowledge bases representing realistic worlds with many entities and relations between them, and complex communicative goals.

Prior work has approach NLG from two directions. One strategy is over-generation and ranking, in which an intermediate structure generates many candidate sentences which are then ranked according to how well they match the goal. This includes systems built on chart parsers (Shieber, 1988; Kay, 1996; White and Baldridge, 2003), systems that use forest architectures such as HALogen/Nitrogen, (Langkilde-Geary, 2002), systems that use tree conditional random fields (Lu et al., 2009), and newer systems that use recurrent neural networks (Wen et al., 2015b; Wen et al., 2015a). Another strategy formalizes NLG as a goal-directed planning problem to be solved using an automated planner. This plan is then semantically enriched, followed by *surface realization* to turn it into natural language. This is often viewed as a *pipeline* generation process (Reiter and Dale, 1997).

An alternative to pipeline generation is *integrated generation*, in which the sentence planning and surface realization tasks happen simultaneously (Reiter and Dale, 1997). CRISP (Koller and Stone, 2007) and PCRISP (Bauer and Koller, 2010) are two such systems. These generators encode semantic components and grammar actions in PDDL (Fox and Long, 2003), the input format for many off-the-shelf planners such as Graphplan (Blum and Furst, 1997). During the planning process a semantically annotated parse is generated alongside the sentence, preventing ungrammatical sentences and structures that cannot be realized. PCRISP builds upon the CRISP system by incorporating grammar probabilities as costs in an off-the-shelf metric planner (Bauer and Koller, 2010). Our work builds upon the Sentence Tree Realization with UCT (STRUCT) system (McKinley and Ray, 2014), described further in the next section. STRUCT performs integrated generation by for-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1148–1157,
Berlin, Germany, August 7-12, 2016.

malizing the generation problem as planning in a Markov decision process (MDP), and using a probabilistic planner to solve it.

Results reported in previous work (McKinley and Ray, 2014) show that STRUCT is able to correctly generate sentences for a variety of communicative goals. Further, the system scaled better with grammar size (in terms of vocabulary) than CRISP. Nonetheless, these experiments were performed with toy grammars and worlds with artificial communicative goals written to test specific experimental variables in isolation. In this work, we consider the question: can we enable STRUCT to scale to realistic generation tasks? For example, we would like STRUCT to be able to generate any sentence from the Wall Street Journal (WSJ) corpus (Marcus et al., 1993). We describe four enhancements to the STRUCT system: (i) pruning the grammar based on the world and the communicative goal, (ii) intelligently caching and pruning the combinatorial space of semantic bindings, (iii) reusing the lookahead search tree at different search depths, and (iv) learning and using a search control heuristic. We call this enhanced version Scalable-STRUCT (S-STRUCT). In our experiments, we evaluate S-STRUCT on three datasets of increasing size and complexity derived from the WSJ corpus. Our results show that even with vocabularies, grammars and worlds containing tens of thousands of constituents, S-STRUCT has a median generation time of 8.5s and finds the best sentence on average within 25s, which is significantly better than the state of the art for planning-based NLG systems.

2 Background: LTAG and STRUCT

STRUCT uses an MDP (Puterman, 1994) to formalize the NLG process. The states of the MDP are semantically-annotated partial sentences. The actions of the MDP are defined by the rules of the grammar. STRUCT uses a probabilistic lexicalized tree adjoining grammar (PLTAG).

Tree Adjoining Grammars (TAGs) (Figure 1) consist of two sets of trees: initial trees and auxiliary (adjoining) trees. An initial tree can be applied to an existing sentence tree by replacing a leaf node whose label matches the initial tree's root label in an action called "substitution". Auxiliary trees have a special "foot" node whose label matches the label of its root, and uses this to encode recursive language structures. Given an existing sentence tree, an auxiliary tree can be applied in a three-step process called "adjunction". First, an adjunction site is selected from the sentence tree; that is, any node whose label matches that of the auxiliary tree's root and foot. Then, the subtree rooted by the adjunction site is removed from the sentence tree and substituted into the foot node of the auxiliary tree. Finally, the modified auxiliary tree is substituted back into the original adjunction location. LTAG is a variation of TAG in which each tree is associated with a lexical item known as an anchor (Joshi and Schabes, 1997). Semantics can be added to an LTAG by annotating each tree with compositional lambda semantics that are unified via β-reduction (Jurafsky and Martin, 2000). A PLTAG associates probabilities with every tree in the LTAG and includes probabilities for starting a derivation, probabilities for substituting into a specific node, and probabilities for adjoining at a node, or not adjoining.

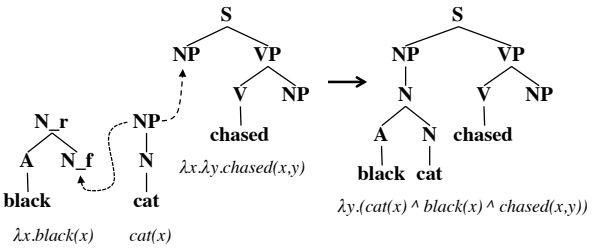

Figure 1: LTAG examples: initial tree (chased), substitution (cat), and adjunction (black)

The STRUCT reward function is a measure of progress towards the communicative goal as measured by the overlap with the semantics of a partial sentence. It gives positive reward to subgoals fulfilled and gives negative reward for unbound entities, unmet semantic constraints, sentence length, and ambiguous entities. Therefore, the best sentence for a given goal is the shortest unambiguous sentence which fulfills the communicative goal and all semantic constraints. The transition function of the STRUCT MDP assigns the total probability of selecting and applying an action in a state to transition to the next, given by the action's probability in the grammar. The final component of the MDP is the discount factor, which is set to 1. This is because with lexicalized actions, the state does not loop, and the algorithm may need to generate long sentences to match the communicative goal.

STRUCT uses a modified version of the probabilistic planner UCT (Kocsis and Szepesvári, 2006), which can generate near-optimal plans

with a time complexity independent of the state space size. UCT's online planning happens in two steps: for each action available, a lookahead search tree is constructed to estimate the action's utility. Then, the best available action is taken and the procedure is repeated. If there are any unexplored actions, UCT will choose one according to an "open action policy" which samples PLTAGs without replacement. If no unexplored actions remain, an action a is chosen in state s according to the "tree policy" which maximizes Equation 1.

$$P(s,a) = Q(s,a) + c\sqrt{\frac{lnN(s)}{N(s,a)}} \qquad (1)$$

Here $Q(s,a)$ is the estimated value of a, computed as the sum of expected future rewards after (s,a). $N(s,a)$ and $N(s)$ are the visit counts for s and (s,a) respectively. c is a constant term controlling the exploration/exploitation trade off. After an action is chosen, the policy is rolled out to depth D by repeatedly sampling actions from the PLTAG, thereby creating the lookahead tree.

UCT was originally used in an adversarial environment, so it selects actions leading to the best average reward; however, language generation is not adversarial, so STRUCT chooses actions leading to the best overall reward instead.

The modified STRUCT algorithm presented in this paper, which we call Scalable-STRUCT (S-STRUCT), is shown in Algorithm 1. If the changes described in the next section (lines marked with †) are removed, we recover the original STRUCT system.

3 Scaling the STRUCT system

In this section, we describe five enhancements to STRUCT that will allow it to scale to real world NLG tasks. Although the implementation details of these are specific to STRUCT, all but one (reuse of the UCT search tree) could theoretically be applied to any planning-based NLG system.

Algorithm 2 getAction (Algorithm 1, line 5)

Require: Search Tree $uctTree$, num trials N, lookahead depth D, grammar R

1: **for** N **do**
2: $\quad node \leftarrow uctTree$
3: $\quad$ **if** $node.state$ has unexplored actions **then**
4: $\quad\quad ^{\dagger}action \leftarrow$ pick with open action policy
5: $\quad$ **else**
6: $\quad\quad ^{\dagger}action \leftarrow$ pick with tree policy
7: $\quad$ **end if**
8: $\quad ^{\dagger}node \leftarrow applyAction(node, action)$
9: $\quad depth \leftarrow 1$
10: $\quad$ **while** $depth < D$ **do**
11: $\quad\quad action \leftarrow$ sample PLTAG from R
12: $\quad\quad ^{\dagger}node \leftarrow applyAction(node, action)$
13: $\quad\quad reward \leftarrow calcReward(node.state)$
14: $\quad\quad$ propagate $reward$ up $uctTree$
15: $\quad\quad depth \leftarrow depth + 1$
16: $\quad$ **end while**
17: **end for**
18: $uctTree \leftarrow$ best child of $uctTree$
19: **return** $uctTree$

3.1 Grammar Pruning

It is clear that for a given communicative goal, only a small percentage of the lexicalized trees in the grammar will be helpful in generating a sentence. Since these trees correspond to actions, if we prune the grammar suitably, we reduce the number of actions our planner has to consider.

Algorithm 3 pruneGrammar (Algorithm 1, line 1)

Require: Grammar R, World W, Goal G

1: $G' \leftarrow \emptyset$
2: **for** $e \in G$.entities **do**
3: $\quad G' \leftarrow G' \cup referringExpression(e, W)$
4: **end for**
5: $R' \leftarrow \emptyset$
6: **for** $tree \in R$ **do**
7: $\quad$ **if** $tree$ fulfills semantic constraints **or** $tree$.relations $\subseteq G'$.relations **then**
8: $\quad\quad R' \leftarrow R' \cup \{tree\}$
9: $\quad$ **end if**
10: **end for**
11: **return** R'

There are four cases in which an action is rele-

vant. First, the action could directly contribute to the goal semantics. Second, the action could satisfy a semantic constraint, such as mandatory determiner adjunction which would turn "cat" into "the cat" in Figure 1. Third, the action allows for additional beneficial actions later in the generation. An auxiliary tree anchored by "that", which introduces a relative clause, would not add any semantic content itself. However, it would add substitution locations that would let us go from "the cat" to "the cat that chased the rabbit" later in the generation process. Finally, the action could disambiguate entities in the communicative goal. In the most conservative approach, we cannot discard actions that introduce a relation sharing an entity with a goal entity (through any number of other relations), as it may be used in a referring expression (Jurafsky and Martin, 2000). However, we can optimize this by ensuring that we can find at least *one*, instead of *all*, referring expressions.

This grammar pruning is "lossless" in that, after pruning, the full communicative goal can still be reached, all semantic constraints can be met, and all entities can be disambiguated. However it is possible that the solution found will be longer than necessary. This can happen if we use two separate descriptors to disambiguate two entities where one would have sufficed. For example, we could generate the sentence "the black dog chased the red cat" where saying "the large dog chased the cat" would have sufficed (if "black", "red", and "large" were only included for disambiguation purposes).

We implement the pruning logic in the $pruneGrammar$ algorithm shown in Algorithm 3. First, an expanded goal G' is constructed by explicitly solving for a referring expression for each goal entity and adding it to the original goal. The algorithm is based on prior work (Bohnet and Dale, 2005) and uses an alternating greedy search, which chooses the relation that eliminates the most distractors, and a depth-first search to describe the entities. Then, we loop through the trees in the grammar and only keep those that can fulfill semantic constraints or can contribute to the goal. This includes trees introducing relative clauses.

3.2 Handling Semantic Bindings

As a part of the reward calculation in Algorithm 4, we must generate the valid bindings between the entities in the partial sentence and the entities in the world (line 2). We must have at least one valid binding, as this indicates that our partial sentence is factual (with respect to the world); however, more than one binding means that the sentence is ambiguous, so a penalty is applied. Unfortunately, computing the valid bindings is a combinatorial problem. If there are N world entities and K partial sentence entities, there are $\binom{N}{K}$ bindings between them that we must check for validity. This quickly becomes infeasible as the world size grows.

Algorithm 4 calcReward (Algorithm 2, line 13)

Require: Partial Sentence S, World W, Goal G

1: $score \leftarrow 0$
2: $^{\dagger}B \leftarrow getValidBindings(S, W)$
3: **if** $|B| > 0$ **then**
4: $\quad ^{\dagger}m \leftarrow getValidBinding(S, G)$
5: $\quad S \leftarrow$ apply m to S
6: $\quad score \mathrel{+}= C_1 \, |G.\text{relations} \cap S.\text{relations}|$
7: $\quad score \mathrel{-}= C_2 \, |G.\text{conds} - S.\text{conds}|$
8: $\quad score \mathrel{-}= C_3 \, |G.\text{entities} \ominus S.\text{entities}|$
9: $\quad score \mathrel{-}= C_4 \, |S.\text{sentence}|$
10: $\quad score \mathrel{/}= C_5 \, |B|$
11: **end if**
12: **return** $score$

Algorithm 5 getValidBindings (Alg. 4, line 2)

Require: Partial Sentence S, World W

1: $validBindings \leftarrow \emptyset$
2: $queue \leftarrow prevBindings$ **if exists else** $[\emptyset]$
3: **while** $|queue| > 0$ **do**
4: $\quad b \leftarrow queue$.pop()
5: $\quad S' \leftarrow$ apply binding b to S
6: $\quad$ **if** S', W consistent **and** S'.entities all bound **then**
7: $\quad\quad validBindings$.append(b)
8: $\quad$ **else if** S', W consistent **then**
9: $\quad\quad freeS \leftarrow$ unbound S'.entities
10: $\quad\quad freeW \leftarrow W$.entities not in b
11: $\quad\quad$ **for** $e_s, e_w \in freeS \times freeW$ **do**
12: $\quad\quad\quad queue$.push($b \cup \{e_s \rightarrow e_w\}$)
13: $\quad\quad$ **end for**
14: $\quad$ **end if**
15: **end while**
16: **return** $validBindings$

Instead of trying every binding, we use the procedure shown in Algorithm 5 to greatly reduce the number of bindings we must check. Starting with an initially empty binding, we repeatedly add a single $\{sentenceEntity \rightarrow worldEntity\}$ pair (line 12). If a binding contains all partial sentence

entities and the semantics are consistent with the world, the binding is valid (lines 6-7). If at any point, a binding yields partial sentence semantics that are *inconsistent* with the world, we no longer need to consider any bindings which it is a subset of (when condition on line 8 is false, no children expanded). The benefit of this bottom-up approach is that when an inconsistency is caused by adding a mapping of partial sentence entity e_1 and world entity e_2, *all* of the $\binom{N-1}{K-1}$ bindings containing $\{e_1 \rightarrow e_2\}$ are ruled out as well. This procedure is especially effective in worlds/goals with low ambiguity (such as real-world text).

We further note that many of the binding checks are repeated between action selections. Because our sentence semantics are conjunctive, entity specifications only get *more* specific with additional relations; therefore, bindings that were invalidated earlier in the search procedure can never again become valid. Thus, we can cache and reuse valid bindings from the previous partial sentence (line 2). For domains with very large worlds (where most relations have no bearing on the communicative goal), most of the possible bindings will be ruled out with the first few action applications, resulting in large computational savings.

3.3 Reusing the Search Tree

The STRUCT algorithm constructs a lookahead tree of depth D via policy rollout to estimate the value of each action. This tree is then discarded and the procedure repeated at the next state. But it may be that at the next state, many of the *useful* actions will already have been visited by prior iterations of the algorithm. For a lookahead depth D, some actions will have already been explored up to depth $D-1$.

For example if we have generated the partial sentence "the cat chased the rabbit" and S-STRUCT looks ahead to find that a greater reward is possible by introducing the relative clause "the rabbit that ate", when we transition to "the rabbit that", we do not need to re-explore "ate" and can directly try actions that result in "that ate grass", "that ate carrots", etc. Note that if there are still unexplored actions at an earlier depth, these will still be explored as well (action rollouts such as "that drank water" in this example).

Reusing the search tree is especially effective given that the tree policy causes us to favor areas of the search space with high value. Therefore, when we transition to the state with highest value, it is likely that many useful actions have already been explored. Reusing the search tree is reflected in Algorithms 1-2 by passing $uctTree$ back and forth to/from $getAction$ instead of starting a new search tree at each step. In $applyAction$, when a state/action already in the tree is chosen, S-STRUCT transitions to the next state without having to recompute the state or its reward.

3.4 Learning and Using Search Control

During the search procedure, a large number of actions are explored but relatively few of them are helpful. Ideally, we would know which actions would lead to valuable states without actually having to expand and evaluate the resultant states, which is an expensive operation. From prior knowledge, we know that if we have a partial sentence of "the sky is", we should try actions resulting in "the sky is blue" before those resulting in "the sky is yellow". This prior knowledge can be estimated through *learned* heuristics from previous runs of the planner (Yoon et al., 2008). To do this, a set of previously completed plans can be treated as a training set: for each (state, action) pair considered, a feature vector $\Phi(s,a)$ is emitted, along with either the distance to the goal state or a binary indicator of whether or not the state is on the path to the goal. A perceptron (or similar model) $H(s,a)$ is trained on the $(\Phi(s,a), target)$ pairs. $H(s,a)$ can be incorporated into the planning process to help guide future searches.

We apply this idea to our S-STRUCT system by tracking the (state, action) pairs visited in previous runs of the STRUCT system where STRUCT obtained at least 90% of the reward of the known best sentence and emit a feature vector for each, containing: global tree frequency, tree probability (as defined in Section 4.1), and the word correlation of the action's anchor with the two words on either side of the action location. We define the global tree frequency as the number of times the tree appeared in the corpus normalized by the number of trees in the corpus; this is different than the tree probability as it does not take any context into account (such as the parent tree and substitution location). Upon search completion, the feature vectors are annotated with a binary indicator label of whether or not the (state, action) pair was on the path to the best sentence. This training set is then used to train a perceptron $H(s,a)$.

Table 1: Summary statistics for test data sets

Test Set	Goals / Sentences	Vocab Size	Lex Trees / Actions	World Entities	World Relations	Avg. Goal Entities	Avg. Goal Relations	Max Depth
Small	50	130	395	77	135	1.54	2.70	0
Medium	500	1165	3734	741	1418	1.48	2.83	1
Large	5000	9872	31966	10998	23097	2.20	4.62	6

We use $H(s, a)$ to inform both the open action policy (Algorithm 2, line 4) and the tree policy (Algorithm 2, line 6). In the open action policy , we choose open actions according to their heuristic values, instead of just their tree probabilities. In the tree policy, we incorporate $H(s, a)$ into the reward estimation by using Equation 2 in place of Equation 1 in Algorithm 2 (Chaslot et al., 2008a):

$$P(s,a) = Q(s,a) + \lambda H(s,a) + c\sqrt{\frac{lnN(s)}{N(s,a)}}. \quad (2)$$

Here, $H(s, a)$ is a value prediction from prior knowledge and λ is a parameter controlling the trade-off between prior knowledge and estimated value on this goal.

4 Empirical Evaluation

In this section, we evaluate three hypotheses: (1) S-STRUCT can handle real-world datasets, as they scale in terms of (a) grammar size, (b) world size, (c) entities/relations in the goal, (d) lookahead required to generate sentences, (2) S-STRUCT scales better than STRUCT to such datasets and (3) Each of the enhancements above provides a positive contribution to STRUCT's scalability in isolation.

4.1 Datasets

We collected data in the form of grammars, worlds and goals for our experiments, starting from the WSJ corpus of the Penn TreeBank (Marcus et al., 1993). We parsed this with an LTAG parser to generate the best parse and derivation tree (Sarkar, 2000; XTAG Research Group, 2001). The parser generated valid parses for 18,159 of the WSJ sentences. To pick the *best* parse for a given sentence, we choose the parse which minimizes the PARSEVAL bracket-crossing metric against the gold-standard (Abney et al., 1991). This ensures that the major structures of the parse tree are retained. We then pick the 31 most frequently occurring XTAG trees (giving us 74% coverage of the parsed sentences) and annotate them with compositional semantics. The final result of this process was a corpus of semantically annotated WSJ sentences along with their parse and derivation trees [1].

To show the scalability of the improved STRUCT system, we extracted 3 datasets of increasing size and complexity from the semantically annotated WSJ corpus. We nominally refer to these datasets as Small, Medium, and Large. Summary statistics of the data sets are shown in Table 1. For each test set, we take the grammar to be all possible lexicalizations of the unlexicalized trees given the anchors of the test set. We set the world as the union of all communicative goals in the test set. The PLTAG probabilities are derived from the entire parseable portion of the WSJ. Due to the data sparsity issues (Bauer and Koller, 2010), we use unlexicalized probabilities.

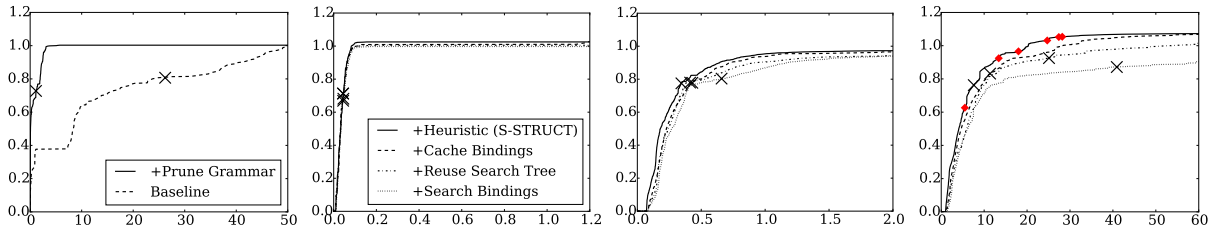
The reward function constants $\boldsymbol{C}$ were set to $[500, 100, 10, 10, 1]$. In the tree policy, c was set to 0.5. These are as in the original STRUCT system. λ was chosen as 100 after evaluating $\{0, 10, 100, 1000, 10000\}$ on a tuning set.

In addition to test sets, we extract an independent training set using 100 goals to learn the heuristic $H(s, a)$. We train a separate perceptron for each test set and incorporate this into the S-STRUCT algorithm as described in Section 3.4.

4.2 Results

For these experiments, S-STRUCT was implemented in Python 3.4. The experiments were run on a single core of a Intel(R) Xeon(R) CPU E5-2450 v2 processor clocked at 2.50GHz with access to 8GB of RAM. The times reported are from the start of the generation process instead of the start of the program execution to reduce variation caused by interpreter startup, input parsing, etc. In

[1] Not all of the covered trees were able to recursively derive their semantics, despite every constituent tree being semantically annotated. This is because β-reduction of the λ-semantics is not associative in many cases where the syntactic composition is associative, causing errors during semantic unification. Due to this and other issues, the number of usable parse trees/sentences was about 7500.



(a) Small Baseline (b) Small (c) Medium (d) Large

Figure 2: Avg. Best Normalized Reward (y-axis) vs. Time in Seconds (x-axis) for (a) Small Baseline, (b) Small, (c) Medium, (d) Large. Time when first grammatical sentence available marked as $\times$. Experiments are cumulative (a trial contains all improvements below it in the legend).

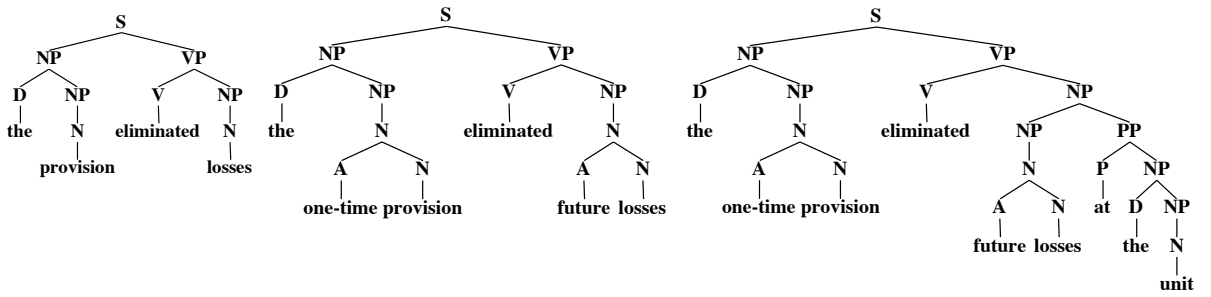


Figure 3: Best sentence available during S-STRUCT generation at 5.5 (s), 18.0 (s), and 28.2 (s)

all experiments, we normalize the reward of a sentence by the reward of the actual parse tree, which we take to be the gold standard. Note that this means that in some cases, S-STRUCT can produce solutions with *better* than this value, e.g. if there are multiple ways to achieve the semantic goal.

To investigate the first two hypotheses that S-STRUCT can handle the scale of real-world datasets and scales better than STRUCT, we plot the average best reward of all goals in the test set over time in Figure 2. The results show the cumulative effect of the enhancements; working up through the legend, each line represents "switching on" another option and includes the effects of all improvements listed below it. The addition of the heuristic represents the entire S-STRUCT system. On each line, $\times$ marks the time at which the first grammatically correct sentence was available.

The Baseline shown in Figure 2a is the original STRUCT system proposed in (McKinley and Ray, 2014). Due to the large number of actions that must be considered, the Baseline experiment's average first sentence is not available until 26.20 seconds, even on the Small dataset. In previous work, the experiments for both STRUCT and CRISP were on toy examples, with grammars having 6 unlexicalized trees and typically < 100 lexicalized trees (McKinley and Ray, 2014; Koller and Stone, 2007). In these experiments, STRUCT was shown to perform better than or as well as CRISP. Even in our smallest domain, however, the baseline STRUCT system is impractically slow. Further, prior work on PCRISP used a grammar that was extracted from the WSJ Penn TreeBank, however it was restricted to the 416 sentences in Section 0 with $<$16 words. With PCRISP's extracted grammar, the most successful realization experiment yielded a sentence in only 62% of the trials, the remainder having timed out after five minutes (Bauer and Koller, 2010). Thus it is clear that these systems do not scale to real NLG tasks.

Adding the grammar pruning to the Baseline allows S-STRUCT to find the first grammatically correct sentence in 1.3 seconds, even if the reward is still sub-optimal. For data sets larger than Small, the Baseline and Prune Grammar experiments could not be completed, as they still enumerated all semantic bindings. For even the medium world, a sentence with 4 entities would have to consider 1.2×10^{10} bindings. Therefore, the cumulative experiments start with Prune Grammar and Search Bindings turned on.

Figures 2b, 2c and 2d show the results for each enhancement above on the corresponding dataset. We observe that the improved binding search further improves performance on the Small task. The Small test set does not require any lookahead, so it is expected that there would be no benefit to

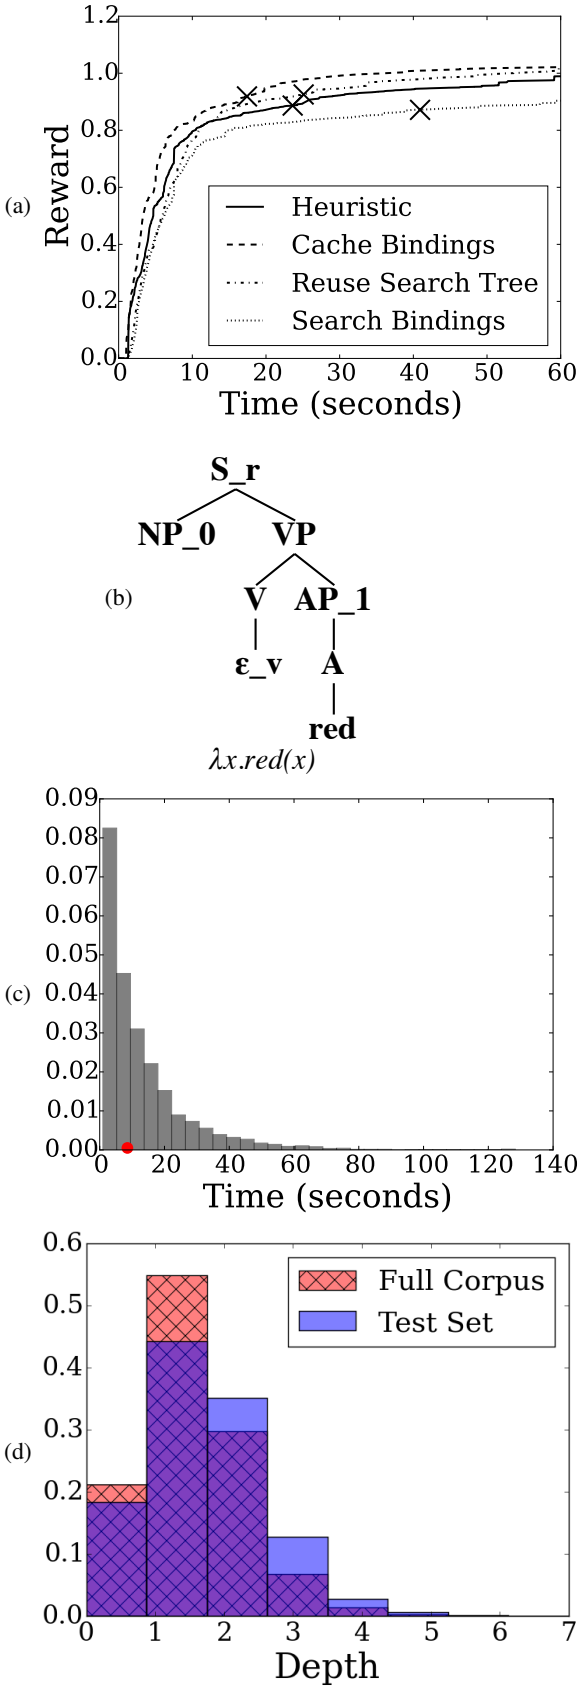

Figure 4: (a) Large Non-Cumulative Experiment (b) $\alpha nx0Ax1$ XTAG tree (c) Time to 90% Reward (d) Lookahead Required.

reusing the search tree, and little to no benefit from caching bindings or using a heuristic. In the Small domain, S-STRUCT is able to generate sentences very quickly; the first sentence is available by 44ms and the best sentence is available by 100ms. In the medium and large domains, the "Reuse Search Tree", "Cache Bindings", and "Heuristic" changes *do* improve upon the use of only "Search Bindings". The Medium domain is still extremely fast, with the first sentence available in 344ms and the best sentence available around 1s. The large domain slows down due to the larger lookahead required, the larger grammar, and the huge number of bindings that have to be considered. Even with this, S-STRUCT can generate a first sentence in 7.5s and the best sentence in 25s. In Figure 4c, we show a histogram of the generation time to 90% of the best reward. The median time is 8.55s (● symbol).

Additionally, histograms of the lookahead required for guaranteed optimal generation are shown for the entire parsable WSJ and our Large world in Figure 4d. The complexity of the entire WSJ does not exceed our Large world, thus we argue that our results are representative of S-STRUCT's performance on real-world tasks.

To investigate the third hypothesis that each improvement contributes positively to the scalability, the noncumulative impact of each improvement is shown in Figure 4a. All experiments still must have Prune Grammar and Search Bindings turned on in order to terminate. Therefore, we take this as a baseline to show that the other changes provide additional benefits. Looking at Figure 4a, we see that each of the changes improves the reward curve and the time to generate the first sentence.

4.3 Discussion, Limitations and Future Work

As an example of sentences available at a given time in the process, we annotate the Large Cumulative Heuristic Experiment with ♦ symbols for a specific trial of the Large dataset. Figure 3 shows the best sentence that was available at three different times. The first grammatically correct sentence was available 5.5 seconds into the generation process, reading "The provision eliminated losses". This sentence captured the major idea of the communicative goal, but missed some critical details. As the search procedure continued, S-STRUCT explored adjunction actions. By 18 seconds, additional semantic content was added to expand upon

the details of the provision and losses. S-STRUCT settled on the best sentence it could find at 28.2 seconds, able to match the entire communicative goal with the sentence "The one-time provision eliminated future losses at the unit".

In domains with large lookaheads required, reusing the Search Tree has a large effect on both the best reward at a given time and on the time to generate the first sentence. This is because S-STRUCT has already explored some actions from depth 1 to $D-1$. Additionally, in domains with a large world, the Cache Binding improvement is significant. The learned heuristic, which achieves the best reward and the shortest time to a complete sentence, tries to make S-STRUCT choose better actions at each step instead of allowing STRUCT to explore actions faster; this means that there is less overlap between the improvement of the heuristic and other strategies, allowing the *total* improvement to be higher.

One strength of the heuristic is in helping S-STRUCT to avoid "bad" actions. For example, the XTAG tree $\alpha nx0Ax1$ shown in Figure 4b is an initial tree lexicalized by an adjective. This tree would be used to say something like "The dog is red." S-STRUCT may choose this as an initial action to fulfill a subgoal; however, if the goal was to say that a red dog chased a cat, S-STRUCT will be shoehorned into a substantially worse goal down the line, when it can no longer use an initial tree that adds the "chase" semantics. Although the rollout process helps, some sentences can share the same reward up to the lookahead and only diverge later. The heuristic can help by biasing the search against such troublesome scenarios.

All of the results discussed above are without parallelization and other engineering optimizations (such as writing S-STRUCT in C), as it would make for an unfair comparison with the original system. The core UCT procedure used by STRUCT and S-STRUCT could easily be parallelized, as the sampling shown in Algorithm 2 can be done independently. This has been done in other domains in which UCT is used (Computer Go), to achieve a speedup factor of 14.9 using 16 processor threads (Chaslot et al., 2008b). Therefore, we believe these optimizations would result in a constant factor speedup.

Currently, the STRUCT and S-STRUCT systems only focuses on the domain of single sentence generation, rather than discourse-level planning. Additionally, neither system handles non-semantic feature unification, such as constraints on number, tense, or gender. While these represent practical concerns for a production system, we argue that their presence will not affect the system's scalability, as there is already feature unification happening in the λ-semantics. In fact, we believe that additional features could *improve* the scalability, as many available actions will be ruled out at each state.

5 Conclusion

In this paper we have presented S-STRUCT, which enhances the STRUCT system to enable better scaling to real generation tasks. We show via experiments that this system can scale to large worlds and generate complete sentences in real-world datasets with a median time of 8.5s. To our knowledge, these results and the scale of these NLG experiments (in terms of grammar size, world size, and lookahead complexity) represents the state-of-the-art for planning-based NLG systems. We conjecture that the parallelization of S-STRUCT could achieve the response times necessary for real-time applications such as dialog. S-STRUCT is available through Github upon request.

Abstract

Effective text classification requires experts to annotate data with labels; these training data are time-consuming and expensive to obtain. If you know what labels you want, active learning can reduce the number of labeled documents needed. However, establishing the label set remains difficult. Annotators often lack the global knowledge needed to induce a label set. We introduce ALTO: Active Learning with Topic Overviews, an interactive system to help humans annotate documents: topic models provide a global overview of what labels to create and active learning directs them to the right documents to label. Our forty-annotator user study shows that while active learning alone is best in extremely resource limited conditions, topic models (even by themselves) lead to better label sets, and ALTO's combination is best overall.

1 Introduction

Many fields depend on texts labeled by human experts; computational linguistics uses such annotation to determine word senses and sentiment (Kelly and Stone, 1975; Kim and Hovy, 2004); while social science uses "coding" to scale up and systemetize content analysis (Budge, 2001; Klingemann et al., 2006).

Classification takes these labeled data as a training set and labels new data automatically. Creating a broadly applicable and consistent label set that generalizes well is time-consuming and difficult, requiring expensive annotators to examine large swaths of the data. Effective NLP systems must measure (Hwa, 2004; Osborne and Baldridge, 2004; Ngai and Yarowsky, 2000) and reduce annotation cost (Tomanek et al., 2007). Annotation is hard because it requires both *global* and *local* knowledge of the entire dataset. Global knowledge is required to create the set of labels, and local knowledge is required to annotate the most useful examples to serve as a training set for an automatic classifier. The former's cost is often hidden in multiple rounds of refining annotation guidelines.

We create a single interface—ALTO (Active Learning with Topic Overviews)—to address both global and local challenges using two machine learning tools: *topic models* and *active learning* (we review both in Section 2). Topic models address the need for annotators to have a *global overview* of the data, exposing the broad themes of the corpus so annotators know what labels to create. Active learning *selects* documents that help the classifier understand the differences between labels and directs the user's attention *locally* to them. We provide users four experimental conditions to compare the usefulness of a topic model or a simple list of documents, with or without active learning suggestions (Section 3). We then describe our data and evaluation metrics (Section 4).

Through both synthetic experiments (Section 5) and a user study (Section 6) with forty participants, we evaluate ALTO and its constituent components by comparing results from the four conditions introduced above. We first examine user strategies for organizing documents, user satisfaction, and user efficiency. Finally, we evaluate the overall effectiveness of the label set in a post study crowdsourced task.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1158–1169,
Berlin, Germany, August 7-12, 2016.

Topic words	Document Title
metropolitan, carrier, rail, freight, passenger, driver, airport, traffic, transit, vehicles	A bill to improve the safety of motorcoaches, and for other purposes.
violence, sexual, criminal, assault, offense, victims, domestic, crime, abuse, trafficking	A bill to provide criminal penalties for stalking.
agricultural, farm, agriculture, rural, producer, dairy, crop, producers, commodity, nutrition	To amend the Federal Crop Insurance Act to extend certain supplemental agricultural disaster assistance programs through fiscal year 2017, and for other purposes.

Table 1: Given a dataset—in this case, the US congressional bills dataset—topics are automatically discovered sorted lists of terms that summarize segments of a document collection. Topics also are associated with documents. These topics give users a sense of documents' main themes and help users create high-quality labels.

2 Topic Overviews and Active Learning

ALTO,[1] a framework for assigning labels to documents that uses both global and local knowledge to help users create and assign document labels, has two main components: topic *overview* and active learning *selection*. We explain how ALTO uses topic models and active learning to aid label induction and document labeling.

Topic Models Topic models (Blei et al., 2003) automatically induce structure from a text corpus. Given a corpus and a constant K for the number of topics, topic models output (i) a distribution over words for each topic k ($\phi_{k,w}$) and (ii) a distribution over topics for each document ($\theta_{d,k}$). Each topic's most probable words and associated documents can help a user understand what the collection is about. Table 1 shows examples of topics and their highest associated documents from our corpus of US congressional bills.

Our hypothesis is that showing documents grouped by topics will be more effective than having the user wade through an undifferentiated list of random documents and *mentally sort the major themes themselves*.

Active Learning Active learning (Settles, 2012) directs users' attention to the examples that would be most useful to label when training a classifier. When user time is scarce, active learning builds a more effective training set than random labeling: uncertainty sampling (Lewis and Gale, 1994) or query by committee (Seung et al., 1992) direct users to the most useful documents to label.

In contrast to topic models, active learning provides local information: *this document* is the one you should pay attention to. Our hypothesis is that active learning directing users to documents most beneficial to label will not only be more effective than randomly selecting documents but will also *complement* the global information provided by topic models. Section 3.3 describes our approaches for directing user's local attention.

3 Study Conditions

Our goal is to characterize how local and global knowledge can aid users in annotating a dataset. This section describes our four experimental conditions and outlines the user's process for labeling documents.

3.1 Study Design

The study uses a 2×2 between-subjects design, with factors of document collection *overview* (two levels: topic model or list) and document *selection* (two levels: active or random). The four conditions, with the TA condition representing ALTO, are:

1. Topic model overview, active selection (TA)
2. Topic model overview, random selection (TR)
3. List overview, active selection (LA)
4. List overview, random selection (LR)

3.2 Document Collection Overview

The topic and list overviews offer different overall structure but the same basic elements for users to create, modify, and apply labels (Section 3.4). The topic overview (Figure 1a) builds on Hu et al. (2014): for each topic, the top twenty words are shown alongside twenty document titles. Topic words (w) are sized based on their probability $\phi_{k,w}$ in the topic k and the documents with the highest probability of that topic ($\theta_{d,k}$) are shown. The list overview, in contrast, presents documents as a simple, randomly ordered list of titles (Figure 1b). We display the same number of documents ($20K$, where K is the total number of topics) in both the topic model and list overviews, but the list overview provides no topic information.

[1]Code available at https://github.com/Foroughp/ALTO-ACL-2016

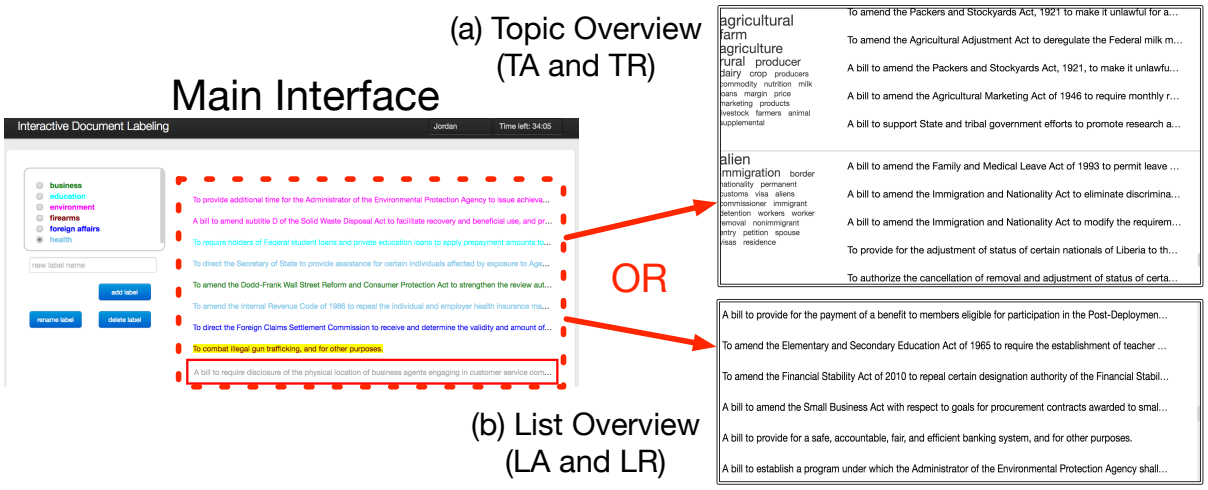

Figure 1: Our annotation system. Initially, the user sees lists of documents organized in either a list format or grouped into topics (only two topics are shown here; users can scroll to additional documents). The user can click on a document to label it.

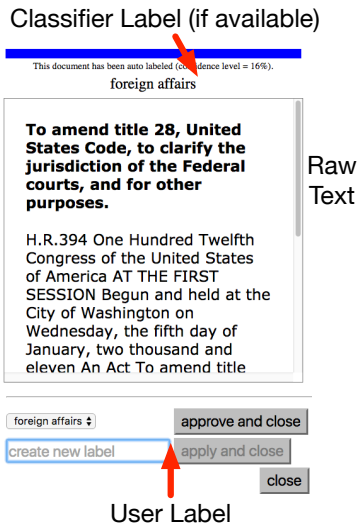

Figure 2: After clicking on a document from the list or topic overview, the user inspects the text and provides a label. If the classifier has a guess at the label, the user can confirm the guess.

3.3 Document Selection

We use a *preference function* U to direct users' attention to specific documents. To provide consistency across the four conditions, each condition will highlight the document that scores the highest for the condition's preference function. For the random selection conditions, TR and LR, document selection is random, within a topic or globally. We expect this to be less useful than active learning. The document preference functions are:

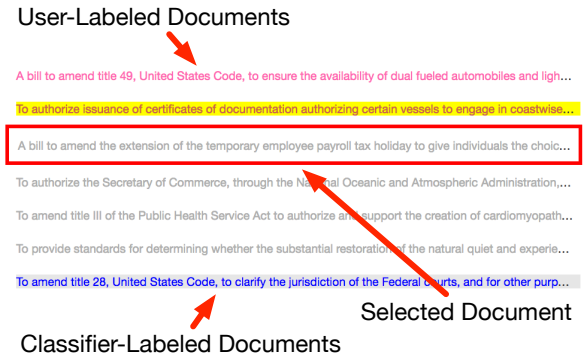

Figure 3: After the user has labeled some documents, the system can automatically label other documents and select which documents would be most helpful to annotate next. In the random selection setting, random documents are selected.

LA: LA uses traditional uncertainty sampling:

$$U_d^{\text{LA}} = \mathbb{H}_C\left[Y_d\right], \tag{1}$$

where $\mathbb{H}_C\left[y_d\right] = -\sum_i P(y_i|d) log P(y_i|d)$ is the classifier entropy. Entropy measures how confused (uncertain) classifier C is about its prediction of a document d's label y. Intuitively, it prefers documents the classifier suggests many labels instead of a single, confident prediction.

LR: LR's approach is the same as LA's except we replace $\mathbb{H}_C\left[y_d\right]$ with a uniform random number:

$$U_d^{\text{LR}} \sim \text{unif}(0, 1). \tag{2}$$

In contrast to LA, which suggests the most uncertain document, LR suggests a random document.

TA: Dasgupta and Hsu (2008) argue that clustering should inform active learning criteria, balancing coverage against classifier accuracy. We adapt their method to flat topic models—in contrast to their hierarchical cluster trees—by creating a composite measure of document uncertainty within a topic:

$$U_d^{\text{TA}} = \mathbb{H}_C\left[y_d\right]\theta_{d,k}, \tag{3}$$

where k is the prominent topic for document d. U_d^{TA} prefers documents that are *representative* of a topic (i.e., have a high value of $\theta_{d,k}$ for that topic) and are informative for the classifier.

TR: TR's approach is the same as TA's except we replace $\mathbb{H}_C\left[Y_d\right]$ with a uniformly random number:

$$U_d^{\text{TR}} = \text{unif}(0,1)\theta_{d,k}. \tag{4}$$

Similar to TA, U_d^{TR} prefers documents that are representative of a topic, but not any particular document in the topic. Incorporating the random component encourages covering different documents in diverse topics.

In LA and LR, the preference function directly chooses a document and directs the user to it. On the other hand, U_d^{TA} and U_d^{TR} are topic dependent. TA emphasizes documents that are both informative to the classifier and representative of a topic; if a document is not representative, the surrounding context of a topic will be less useful. Therefore, the factor $\theta_{d,k}$ appears in both. Thus, they require that a topic be chosen first and then the document with maximum preference, U, within that topic can be chosen. In TR, the topic is chosen randomly. In TA, the topic is chosen by

$$k^* = \arg\max_k(\text{median}_d(\mathbb{H}_C\left[y_d\right]\theta_{d,k}). \tag{5}$$

That is the topic with the maximum median U. Median encodes how "confusing" a topic is.[2] In other words, topic k^* is the topic that its documents confuse the classifier most.

3.4 User Labeling Process

The user's labeling process is the same in all four conditions. The *overview* (topic or list) allows users to examine individual documents (Figure 1). Clicking on a document opens a dialog box (Figure 2) with the text of the document and three options:

1. Create and assign a new label to the document.
2. Choose an existing label for the document.
3. Skip the document.

Once the user has labeled two documents with different labels, the displayed documents are replaced based on the preference function (Section 3.3), every time the user labels (or updates labels for) a document. In TA and TR, each topic's documents are replaced with the twenty highest ranked documents. In LA and LR, all documents are updated with the top $20K$ ranked documents.[3]

The system also suggests one document to consider by auto-scrolling to it and drawing a red box around its title (Figure 3). The user may ignore that document and click on any other document. After the user labels ten documents, the classifier runs and assigns labels to other documents.[4] For classifier-labeled documents, the user can either approve the label or assign a different label. The process continues until the user is satisfied or a time runs out (forty minutes in our user study, Section 6). We use time to control for the varying difficulty of assigning document labels: active learning will select more difficult documents to annotate, but they may be more useful; time is a more fair basis of comparison in real-world tasks.

4 Data and Evaluation Metrics

In this section, we describe our data, the machine learning techniques to learn classifiers from examples, and the evaluation metrics to know whether the final labeling of the complete documents collection was successful.

4.1 Datasets

Data Our experiments require corpora to compare user labels with gold standard labels. We experiment with two corpora: 20Newsgroups (Lang, 2007) and US congressional bills from GovTrack.[5]

For US congressional bills, GovTrack provides bill information such as the title and text, while the Congressional Bills Project (Adler and Wilkerson, 2006) provides labels and sub-labels for the bills. Examples of labels are agriculture and health, while sub-labels include agricultural trade and comprehensive health care reform. The twenty

[2] Outliers skew other measures (e.g., max or mean).

[3] In all conditions, the number of displayed unlabeled documents is adjusted based on the number of manually labeled documents. i.e. if the user has labeled n documents in topic k, n manually labeled documents followed by top $20 - n$ uncertain documents will be shown in topic k.

[4] To reduce user confusion, for each existing label, only the top 100 documents get a label assigned in the UI.

[5] `https://www.govtrack.us/`

top-level labels have been developed by consensus over many years by a team of top political scientists to create a reliable, robust dataset. We use the 112th Congress; after filtering,[6] this dataset has 5558 documents. We use this dataset in both the synthetic experiments (Section 5) and the user study (Section 6).

The 20 Newsgroups corpus has 19,997 documents grouped in twenty news groups that are further grouped into six more general topics. Examples are talk.politics.guns and sci.electronics, which belong to the general topics of politics and science. We use this dataset in synthetic experiments (Section 5).

4.2 Machine Learning Techniques

Topic Modeling To choose the number of topics (K), we calculate average topic coherence (Lau et al., 2014) on US Congressional Bills, between ten and forty topics and choose $K = 19$, as it has the maximum coherence score. For consistency, we use the same number of topics ($K = 19$) for 20 Newsgroups corpus. After filtering words based on TF-IDF, we use Mallet (McCallum, 2002) with default options to learn topics.

Features and Classification A logistic regression predicts labels for documents and provides the classification uncertainty for active learning. To make classification and active learning updates efficient, we use incremental learning (Carpenter, 2008, LingPipe). We update classification parameters using stochastic gradient descent, restarting with the previously learned parameters as new labeled documents become available.[7] We use cross validation, using argmax topics as surrogate labels, to set the parameters for learning the classifier.[8]

The features for classification include topic probabilities, unigrams, and the fraction of labeled documents in each document's prominent topic. The intuition behind adding this last feature is to allow active learning to suggest documents in a diverse range of topics if it finds this feature a useful indicator of uncertainty.[9]

4.3 Evaluation Metrics

Our goal is to create a system that allows users to quickly induce a high-quality label set. We compare the user-created label sets against the data's gold label sets. Comparing different clusterings is a difficult task, so we use three clustering evaluation metrics: purity (Zhao and Karypis, 2001), rand index (Rand, 1971, RI), and normalized mutual information (Strehl and Ghosh, 2003, NMI).[10]

Purity The documents labeled with a good user label should only have one (or a few) gold labels associated with them: this is measured by cluster purity. Given each user cluster, it measures what fraction of the documents in a user cluster belong to the most frequent gold label in that cluster:

$$\text{purity}(\mathbf{\Omega}, \mathbf{G}) = \frac{1}{N} \sum_l \max_j |\Omega_l \cap G_j|, \quad (6)$$

where L is the number of labels user creates, $\mathbf{\Omega} = \{\Omega_1, \Omega_2, \ldots, \Omega_L\}$ is the user clustering of documents, $\mathbf{G} = \{G_1, G_2, \ldots, G_J\}$ is gold clustering of documents, and N is the total number of documents. The user Ω_l and gold G_j labels are interpreted as sets containing all documents assigned to that label.

Rand index (RI) RI is a *pair counting* measure, where cluster evaluation is considered as a series of decisions. If two documents have the same gold label and the same user label (TP) or if they do not have the same gold label and are not assigned the same user label (TN), the decision is right. Otherwise, it is wrong (FP, FN). RI measures the percentage of decisions that are right:

$$\text{RI} = \frac{TP + TN}{TP + FP + TN + FN}. \quad (7)$$

Normalized mutual information (NMI) NMI is an *information theoretic* measure that measures the amount of information one gets about the gold clusters by knowing what the user clusters are:

$$\text{NMI}(\mathbf{\Omega}, \mathbf{G}) = \frac{2\mathbb{I}(\mathbf{\Omega}, \mathbf{G})}{\mathbb{H}_{\mathbf{\Omega}} + \mathbb{H}_{\mathbf{G}}}, \quad (8)$$

[6] We remove bills that have less than fifty words, no assigned gold label, duplicate titles, or have the gold label GOVERNMENT OPERATIONS or SOCIAL WELFARE, which are broad and difficult for users to label.

[7] Exceptions are when a new label is added, a document's label is deleted, or a label is deleted. In those cases, we train the classifier from scratch. Also, for final results in Section 6, we train a classifier from scratch.

[8] We use `blockSize=`$\frac{1}{\#\text{examples}}$ `minEpochs`=100, `learningRate`=0.1, `minImprovement`=0.01, `maxEpochs`=1000, and `rollingAverageSize`=5. The regression is unregularized.

[9] However, final classifier's coefficients suggested that this feature did not have a large effect.

[10] We avoided using adjusted rand index (Hubert and Arabie, 1985), because it can yield negative values, which is not consistent with purity and NMI. We also computed variation of information (Meilă, 2003) and normalized information distance (Vitányi et al., 2009) and observed consistent trends. We omit these results for the sake of space.

where $\mathbf{\Omega}$ and $\mathbf{G}$ are user and gold clusters, $\mathbb{H}$ is the entropy and $\mathbb{I}$ is mutual information (Bouma, 2009).

While purity, RI, and NMI are all normalized within $[0, 1]$ (higher is better), they measure different things. Purity measures the intersection between two clusterings, it is sensitive to the number of clusters, and it is not symmetric.

On the other hand, RI and NMI are less sensitive to the number of clusters and are symmetric. RI measures pairwise agreement in contrast to purity's emphasis on intersection. Moreover, NMI measures shared information between two clusterings.

None of these metrics are perfect: purity can be exploited by putting each document in its own label, RI does not distinguish separating similar documents with distinct labels from giving dissimilar documents the same label, and NMI's ability to compare different numbers of clusters means that it sometimes gives high scores for clusterings by chance. Given the diverse nature of these metrics, if a labeling does well in all three of them, we can be relatively confident that it is not a degenerate solution that games the system.

5 Synthetic Experiments

Before running a user study, we test our hypothesis that topic model overviews and active learning selection improve final cluster quality compared to standard baselines: list overview and random selection. We simulate the four conditions on Congressional Bills and 20 Newsgroups.

Since we believe annotators create more specific labels compared to the gold labels, we use sub-labels as simulated user labels and labels as gold labels (we give examples of labels and sub-labels in Section 4.1). We start with two randomly selected documents that have different sub-labels, assign the corresponding sub-labels, then add more labels based on each condition's preference function (Section 3.3). We follow the condition's preference function and incrementally add labels until 100 documents have been labeled (100 documents are representative of what a human can label in about an hour). Given these labels, we compute purity, RI, and NMI over time. This procedure is repeated fifteen times (to account for the randomness of initial document selections and the preference functions with randomness).[11]

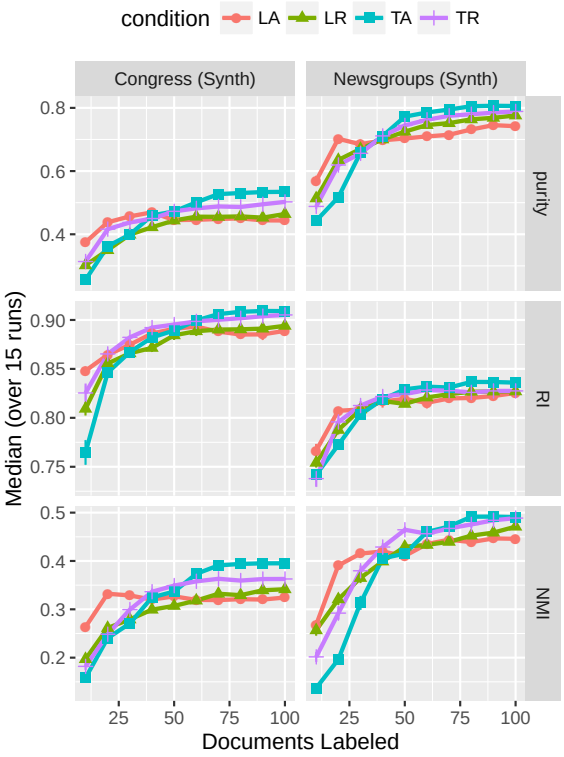

Figure 4: Synthetic results on US Congressional Bills and 20 Newsgroups data sets. Topic models help guide annotation attention to diverse segments of the data.

Synthetic results validate our hypothesis that topic overview and active learning selection can help label a corpus more efficiently (Figure 4). LA shows early gains, but tends to falter eventually compared to both topic overview and topic overview combined with active learning selection (TR and TA).

However, these experiments do not validate ALTO. Not all documents require the same time or effort to label, and active learning focuses on the hardest examples, which may confuse users. Thus, we need to evaluate how effectively actual users annotate a collection's documents.

6 User Study

Following the synthetic experiments, we conduct a user study with forty participants to evaluate ALTO (TA condition) against three alternatives that lack topic overview (LA), active learning selection (TR), or both (LR) (Sections 6.1 and 6.2). Then, we conduct a crowdsourced study to compare the overall

[11] Synthetic experiment data available at http://github.com/Pinafore/publications/tree/master/2016_acl_doclabel/data/synthetic_exp

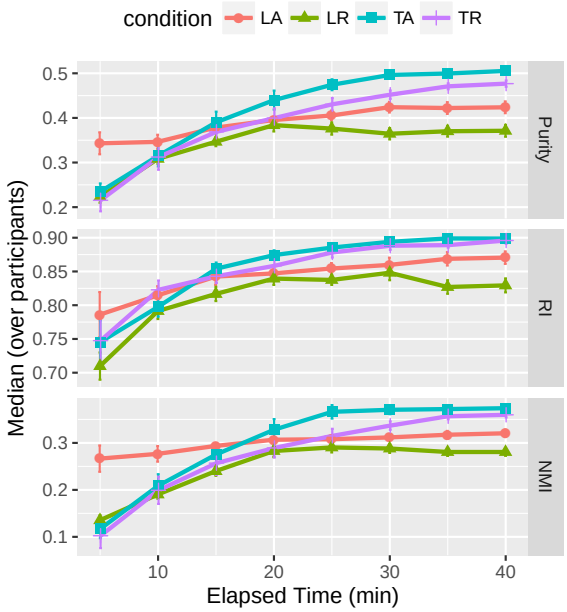

Figure 5: User study results on US Congressional Bills dataset. Active learning selection helps initially, but the combination of active learning selection and topic model overview has highest quality labels by the end of the task.

effectiveness of the label set generated by the participants in the four conditions (Section 6.3).

6.1 Method

We use the freelance marketplace Upwork to recruit online participants.[12] We require participants to have more than 90% job success on Upwork, English fluency, and US residency. Participants are randomly assigned to one of the four conditions and we recruited ten participants per condition.

Participants completed a demographic questionnaire, viewed a video of task instructions, and then interacted with the system and labeled documents until satisfied with the labels or forty minutes had elapsed.[13] The session ended with a survey, where participants rated mental, physical, and temporal demand, and performance, effort, and frustration on 20-point scales, using questions adapted from the NASA Task Load Index (Hart and Staveland, 1988, TLX). The survey also included 7-point scales for ease of coming up with labels, usefulness and satisfaction with the system, and—for TR and TA—topic information helpfulness. Each participant was paid fifteen dollars.[14]

For statistical analysis, we primarily use 2×2 (*overview* $\times$ *selection*) ANOVAs with Aligned Rank Transform (Wobbrock et al., 2011, ART), which is a non-parametric alternative to a standard ANOVA that is appropriate when data are not expected to meet the normality assumption of ANOVA.

	F		p	
	Overview	Selection	Overview	Selection
final purity	81.03	7.18	$< .001$	.011
final RI	39.89	6.28	$< .001$	.017
final NMI	70.92	9.87	$< .001$	.003

df(1,36) for all reported results

Table 2: Results from 2×2 ANOVA with ART analyses on the final purity, RI, and NMI metrics. Only main effects for the factors of *overview* and *selection* are shown; no interaction effects were statistically significant. Topics and active learning both had significant effects on quality scores.

6.2 Document Cluster Evaluation

We analyze the data by dividing the forty-minute labeling task into five minute intervals. If a participant stops before the time limit, we consider their final dataset to stay the same for any remaining intervals. Figure 5 shows the measures across study conditions, with similar trends for all three measures.

Topic model overview and active learning both significantly improve final dataset measures. The topic overview and active selection conditions significantly outperform the list overview and random selection, respectively, on the final label quality metrics. Table 2 shows the results of separate 2×2 ANOVAs with ART with each of final purity, RI, and NMI scores. There are significant main effects of *overview* and *selection* on all three metrics; no interaction effects were significant.

TR outperforms LA. Topic models by themselves outperform traditional active learning strategies (Figure 5). LA performs better than LR; while active learning was useful, it was not as useful as the topic model overview (TR and TA).

LA provides an initial benefit. Average purity, NMI and RI were highest with LA for the earliest labeling time intervals. Thus, when time is very

[12] http://Upwork.com

[13] Forty minutes of activity, excluding system time to classify and update documents. Participants nearly exhausted the time: 39.3 average minutes in TA, 38.8 in TR, 40.0 in LA, and 35.9 in LR.

[14] User study data available at http://github.com/Pinafore/publications/tree/master/2016_acl_doclabel/data/user_exp

	$M \pm SD\,[median]$		
	purity	RI	NMI
TA	$0.31 \pm 0.08\,[0.32]$	$0.80 \pm 0.05\,[0.80]$	$0.19 \pm 0.08\,[0.21]$
TR	$0.32 \pm 0.09\,[0.31]$	$0.82 \pm 0.04\,[0.82]$	$0.21 \pm 0.09\,[0.20]$
LA	$0.35 \pm 0.05\,[0.35]$	$0.82 \pm 0.04\,[0.81]$	$0.27 \pm 0.05\,[0.28]$
LR	$0.31 \pm 0.04\,[0.31]$	$0.79 \pm 0.04\,[0.79]$	$0.19 \pm 0.03\,[0.19]$

Table 3: Mean, standard deviation, and median purity, RI, and NMI after ten minutes. NMI in particular shows the benefit of LA over other conditions at early time intervals.

limited, using traditional active learning (LA) is preferable to topic overviews; users need time to explore the topics and a subset of documents within them. Table 3 shows the metrics after ten minutes. Separate 2×2 ANOVAs with ART on the means of purity, NMI and RI revealed a significant interaction effect between *overview* and *selection* on mean NMI ($F(1, 36) = 5.58$, p = .024), confirming the early performance trends seen in Figure 5 at least for NMI. No other main or interaction effects were significant, likely due to low statistical power.

Subjective ratings. Table 4 shows the average scores given for the six NASA-TLX questions in different conditions. Separate 2×2 ANOVA with ART for each of the measures revealed only one significant result: participants who used the topic model overview find the task to be significantly less frustrating ($M = 4.2$ and $median = 2$) than those who used the list overview ($M = 7.3$ and $median = 6.5$) on a scale from 1 (low frustration) to 20 (high frustration) ($F(1, 36) = 4.43$, $p = .042$), confirming that the topic overview helps users organize their thoughts and experience less stress during labeling.

Participants in the TA and TR conditions rate topic information to be useful in completing the task ($M = 5.0$ and $median = 5$) on a scale from 1 (not useful at all) to 7 (very useful). Overall, users are positive about their experience with the system. Participants in all conditions rate overall satisfaction with the interface positively ($M = 5.8$ and $median = 6$) on a scale from 1 (not satisfied at all) to 7 (very satisfied).

Discussion. One can argue that using topic overviews for labeling could have a negative effect: users may ignore the document content and focus on topics for labeling. We tried to avoid this issue by making it clear in the instructions that they need to focus on document content and use topics as a guidance. On average, the participants in TR create 1.96 labels per topic and the participants in TA created 2.26 labels per topic. This suggests that participants are going beyond what they see in topics for labeling, at least in the TA condition.

6.3 Label Evaluation Results

Section 6.2 compares clusters of documents in different conditions against the gold clusters but does not evaluate the quality of the labels themselves. Since one of the main contributions of ALTO is to accelerate inducing a high quality label set, we use crowdsourcing to assess how the final induced label sets compare in different conditions.

For completeness, we also compare labels against a fully automatic labeling method (Aletras and Stevenson, 2014) that does not require human intervention. We assign *automatic* labels to documents based on their most prominent topic.

We ask users on a crowdsourcing platform to *vote* for the "best" and "worst" label that describes the content of a US congressional bill (we use Crowdflower restricted to US contributors).

Five users label each document and we use the aggregated results generated by Crowdflower. The user gets $0.20 for each task.

We randomly choose 200 documents from our dataset (Section 4.1). For each chosen document, we randomly choose a participant from all four conditions (TA, TR, LA, LR). The labels assigned in different conditions and the automatic label of the document's prominent topic construct the candidate labels for the document.[15] Identical labels are merged into one label to avoid showing duplicate labels to users. If a merged label gets a "best" or "worst" vote, we split that vote across all the identical instances.[16] Figure 6 shows the average number of "best" and "worst" votes for each condition and the automatic method. ALTO (TA) receives the most "best" votes and the fewest "worst" votes. LR receives the most worst votes. The automatic labels, interestingly, appear to do at least as well as the list view labels, with a similar number of best votes and fewer worst votes. This indicates that automatic labels have reasonable quality compared to at least some manually generated labels. However, when users are provided with a topic model overview—

[15] Some participants had typos in the labels. We corrected all the typos using pyEnchant (`http://pythonhosted.org/pyenchant/`) spellchecker. If the corrected label was still wrong, we corrected it manually.

[16] Evaluation data available at `http://github.com/Pinafore/publications/tree/master/2016_acl_doclabel/data/label_eval`

Condition	Mental Demand	Physical Demand	Temporal Demand	Performance	Effort	Frustration
	$M \pm SD\,[median]$					
TA	$9.8 \pm 5.6\,[10]$	$2.9 \pm 3.4\,[2]$	$9 \pm 7.8\,[7]$	$5.5 \pm 5.8\,[1.5]$	$9.4 \pm 6.3\,[10]$	$4.5 \pm 5.5\,[1.5]$
TR	$10.6 \pm 4.5\,[11]$	$2.4 \pm 2.8\,[1]$	$7.4 \pm 4.1\,[9]$	$8.8 \pm 6.1\,[7.5]$	$9.8 \pm 3.7\,[10]$	$3.9 \pm 3.0\,[3.5]$
LA	$9.1 \pm 5.5\,[10]$	$1.7 \pm 1.3\,[1]$	$10.2 \pm 4.8\,[11]$	$8.6 \pm 5.3\,[10]$	$10.7 \pm 6.2\,[12.5]$	$6.7 \pm 5.1\,[5.5]$
LR	$9.8 \pm 6.1\,[10]$	$3.3 \pm 2.9\,[2]$	$9.3 \pm 5.7\,[10]$	$9.4 \pm 5.6\,[10]$	$9.4 \pm 6.2\,[10]$	$7.9 \pm 5.4\,[8]$

Table 4: Mean, standard deviation, and median results from NASA-TLX post-survey. All questions are scaled 1 (low)–20 (high), except performance, which is scaled 1 (good)–20 (poor). Users found topic model overview conditions, TR and TA, to be significantly less frustrating than the list overview conditions.

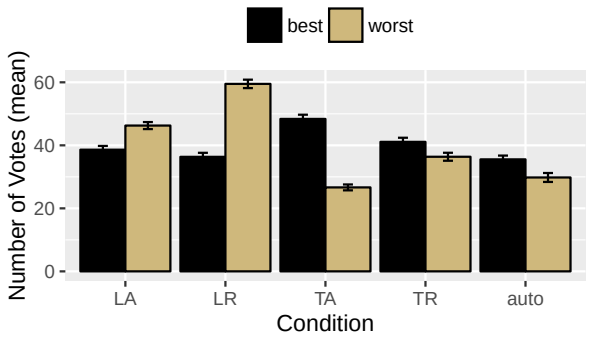

Figure 6: Best and worst votes for document labels. Error bars are standard error from bootstrap sample. ALTO (TA) gets the most best votes and the fewest worst votes.

with or without active learning selection—they can generate label sets that improve upon automatic labels and labels assigned without the topic model overview.

7 Related Work

Text classification—a ubiquitous machine learning tool for automatically labeling text (Zhang, 2010)—is a well-trodden area of NLP research. The difficulty is often creating the training data (Hwa, 2004; Osborne and Baldridge, 2004); coding theory is an entire subfield of social science devoted to creating, formulating, and applying labels to text data (Saldana, 2012; Musialek et al., 2016). Crowdsourcing (Snow et al., 2008) and active learning (Settles, 2012), can decrease the cost of annotation but only *after* a label set exists.

ALTO's corpus overviews aid text understanding, building on traditional interfaces for gaining both local and global information (Hearst and Pedersen, 1996). More elaborate interfaces (Eisenstein et al., 2012; Chaney and Blei, 2012; Roberts et al., 2014) provide richer information given a fixed topic model. Alternatively, because topic models are imperfect (Boyd-Graber et al., 2014), refining underlying topic models may also improve users' understanding of a corpus (Choo et al., 2013; Hoque and Carenini, 2015).

Summarizing document collections through discovered topics can happen through raw topics labeled manually by users (Talley et al., 2011), automatically (Lau et al., 2011), or by learning a mapping from labels to topics (Ramage et al., 2009). When there is not a direct correspondence between topics and labels, classifiers learn a mapping (Blei and McAuliffe, 2007; Zhu et al., 2009; Nguyen et al., 2015). Because we want topics to be consistent between users, we use a classifier with static topics in ALTO. Combining our interface with dynamic topics could improve overall labeling, perhaps at the cost of introducing confusion as topics change during the labeling process.

8 Conclusion and Future Work

We introduce ALTO, an interactive framework that combines both active learning *selection*s with topic model *overview*s to both help users induce a label set and assign labels to documents. We show that users can more effectively and efficiently induce a label set and create training data using ALTO in comparison with other conditions, which lack either topic *overview* or active *selection*.

We can further improve ALTO to help users gain better and faster understanding of text corpora. Our current system limits users to view only $20K$ documents at a time and allows for one label assignment per document. Moreover, the topics are static and do not adapt to better reflect users' labels. Users should have better support for browsing documents and assigning multiple labels.

Finally, with slight changes to what the system considers a document, we believe ALTO can be extended to NLP applications other than classification, such as named entity recognition or semantic role labeling, to reduce the annotation effort.

Abstract

Computationally modeling the evolution of science by tracking how scientific topics rise and fall over time has important implications for research funding and public policy. However, little is known about the mechanisms underlying topic growth and decline. We investigate the role of rhetorical framing: whether the rhetorical role or function that authors ascribe to topics (as methods, as goals, as results, etc.) relates to the historical trajectory of the topics. We train topic models and a rhetorical function classifier to map topic models onto their rhetorical roles in 2.4 million abstracts from the Web of Science from 1991-2010. We find that a topic's rhetorical function is highly predictive of its eventual growth or decline. For example, topics that are rhetorically described as results tend to be in decline, while topics that function as methods tend to be in early phases of growth.

1 Introduction

One of the most compelling research questions in the computational analysis of scientific literature is whether the vast collections of scientific text hold important clues about the dynamics involved in the evolution of science; clues that may help predict the rise and fall of scientific ideas, methods and even fields. Being able to predict scientific trends in advance could potentially revolutionize the way science is done, for instance, by enabling funding agencies to optimize allocation of resources towards promising research areas.

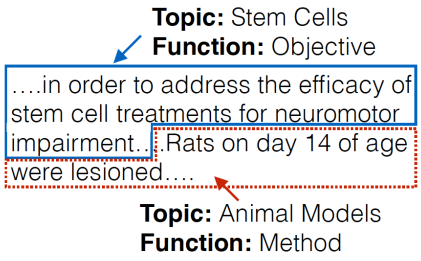

Figure 1: Example abstract snippet. The abstract rhetorically frames the *stem cells* topic as the OBJECTIVE of the research, while the *animal models* topic functions as the research METHOD.

Prior studies have often tracked scientific trends by applying topic modeling (Blei et al., 2003) based techniques to large corpora of scientific texts (Griffiths and Steyvers, 2004; Blei and Lafferty, 2006; Hall et al., 2008). They capture scientific ideas, methods, and fields in terms of *topics*, modeled as distributions over collection of words. These approaches usually adopt a decontextualized view of text and its usage, associating topics to documents based solely on word occurrences, disregarding where or how the words were employed. In reality, however, scientific abstracts often follow narrative structures (Crookes, 1986; Latour, 1987) that signal the specific *rhetorical roles* that different topics play within the research (Figure 1). The rhetorical role of a topic is the purpose or role it plays in the paper: as its background (scientific context), its objective/goal, the data employed, the design or method used (mode of inference), the results (what is found) or the conclusions (what they mean).

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1170–1180,
Berlin, Germany, August 7-12, 2016.

RATIONALE: Neonatal ibotenic acid lesion of the ventral hippocampus was proposed as a relevant animal model of schizophrenia reflecting positive as well as negative symptoms of this disease. Before and after reaching maturity, specific alterations in the animals' social behaviour were found. **OBJECTIVE:** In this study, social behaviour of ventral hippocampal lesioned rats was analysed. For comparison, rats lesioned either in the ventral hippocampus or the dorsal hippocampus at the age of 8 weeks were tested. **METHODS:** Rats on day 7 of age were lesioned with ibotenic acid in the ventral hippocampus and social behaviour was tested at the age of 13 weeks. For comparison, adult 8-week-old rats were lesioned either in the ventral or the dorsal hippocampus. Their social behaviour was tested at the age of 18 weeks. **RESULTS:** It was found that neonatal lesion resulted in significantly decreased time spent in social interaction and an enhanced level of aggressive behaviour. This shift is not due to anxiety because we could not find differences between control rats and lesioned rats in the elevated plus-maze. Lesion in the ventral and dorsal hippocampus, respectively, in 8-week-old rats did not affect social behaviour. **CONCLUSIONS:** The results of our study indicate that ibotenic acid-induced hippocampal damage per se is not related to the shift in social behaviour. We favour the hypothesis that these changes are due to lesion-induced impairments in neurodevelopmental processes at an early stage of ontogenesis.

Figure 2: An example of a self-annotated abstract.
Source: `http://www.ncbi.nlm.nih.gov/pubmed/10435405`.

Rhetorical functions that topics take part in could hold important clues about the stage or development of an intellectual movement they stand to represent. For example, a topic that shifts over time from being employed as a method to being mentioned as background may signal an increase in its maturity and perhaps a corresponding decrease in its popularity among new research.

In this paper, we introduce a new algorithm to determine the rhetorical functions of topics associated with an abstract. There is much work on annotating and automatically parsing the rhetorical functions or narrative structure of scientific writing (e.g., Teufel, 2000; Chung, 2009; Gupta and Manning, 2011; de Waard and Maat, 2012). We derive insights from this prior work, but since we desire to apply our analysis to a broad range of domains, we build our narrative structure model based on over 83,000 self-labeled abstracts extracted from a variety of domains in the Web of Science corpus. Figure 2 shows an example of an abstract in which the authors have labeled the different narrative sections explicitly and identified the rhetorical functions. We use our narrative structure model to assign rhetorical function labels to scientific topics and show that these labels offer important clues indicating whether topics will eventually grow or decline.

Contributions: The three main contributions of our paper are: 1) we introduce the notion of the rhetorical scholarly functions of scientific *topics*, extending previous work which tended to focus on the rhetorical functions of individual *sentences*. We present an algorithm to assign rhetorical function labels to a topic as used in an individual paper; 2) we derive a new narrative scheme for scientific abstracts from over 83,000 abstracts that are labeled with narrative structures by their authors themselves, and present a tagger trained on this data that can parse unseen abstracts with 87% accuracy; 3) we show that the rhetorical function distribution of a topic reflects its temporal trajectory, and that it is predictive of whether the topic will eventually rise or fall in popularity.

2 Related Work

Our work builds upon a wealth of previous literature in both topic modeling and scientific discourse analysis, which we discuss in this section. We also discuss how our work relates to prior work on analyzing scientific trends.

2.1 Topic Modeling

Topic modeling has a long history of applications to scientific literature, including studies of temporal scientific trends (Griffiths and Steyvers, 2004; Steyvers et al., 2004; Wang and McCallum, 2006), article recommendation (Wang and Blei, 2011), and impact prediction (Yogatama et al., 2011). For example, Hall et al. (2008) and Anderson et al. (2012) show how tracking topic popularities over time can produce a 'computational history' of a particular scientific field (in their case ACL, where they tracked the rise of statistical NLP, among other dramatic changes).

Technical advancements in these areas usually correspond to modifications or extensions of the topic modeling (i.e., LDA) framework itself, such as by incorporating citation (Nallapati et al., 2008) or co-authorship information (Mei et al., 2008) directly into the topic model; Nallapati et al. (2011) employ such an extension to estimate the temporal "lead" or "lag" of different scientific information outlets. We contribute to this line of work by showing how we can build off of the standard LDA

framework—by overlaying rhetorical roles—and how this allows us to not only detect the growth and decline of scientific topics but also to predict these trends based upon the rhetorical roles being employed. Since our framework is structured as a pipeline (Figure 3) and works with the output of a topic modeling system, it is compatible with the vast majority of these extended topic models.

2.2 Scientific Discourse Analysis

Scientific discourse analysis is an active area of research with many different proposed schema of analysis — Argument Zones (Teufel, 2000), Information Structure (Guo et al., 2010), Core Scientific Concepts (Liakata, 2010), Research Aspects (Gupta and Manning, 2011), Discourse Segments (de Waard and Maat, 2012), Relation Structures (Tateisi et al., 2014), and Rhetorical Roles (Chung, 2009) to name a few. Most studies in this area focus on improving automatic discourse parsing of scientific text, while some works also focus on the linguistic patterns and psychological effects of scientific argumentation (e.g., de Waard and Maat, 2012). A wide range of techniques have been used in prior work to parse scientific abstracts, from fully supervised techniques (Chung, 2009; Guo et al., 2010) to semi-supervised (Guo et al., 2011c; Guo et al., 2013) and unsupervised techniques (Kiela et al., 2015).

Scientific discourse parsing has also been applied to other downstream tasks within the biomedical domain, such as information retrieval from randomized controlled trials in evidence based medicine (Chung, 2009; Kim et al., 2011; Verbeke et al., 2012), cancer risk assessment (Guo et al., 2011b), summarization (Teufel and Moens, 2002; Contractor et al., 2012), and question answering (Guo et al., 2013). Our work also falls in this category in the sense that our goal is to apply the rhetorical function parser to better understand the link between rhetoric and the historical trajectory of scientific ideas.

2.3 Scientific Trends Analysis

There is also a large body of literature in bibliometrics and scientometrics on tracking scientific trends using various citation patterns. Researchers have attempted to detect emerging research fronts using topological measures of citation networks (Shibata et al., 2008) as well as co-citation clusters (Small, 2006; Shibata et al., 2009). Unlike this line of work, our focus is not on citation patterns, but on how scientific trends are reflected in the texts of scientific publications.

Prior studies have also analyzed text to detect scientific trends. Mane and Börner (2004) and Guo et al. (2011a) use word burst detection (Kleinberg, 2003) to map new and emerging scientific fields, while Small (2011) examined sentiments expressed in the text surrounding citations, showing *uncertainty* in interdisciplinary citations contrasted with *utility* in within-discipline citations. In contrast to this previous work, we analyze the rhetorical function of automatically extracted topics from abstract text, without access to the citation context in full text.

3 Corpus

We use the Thomson Reuters Web of Science Core Collection, which contains scientific abstracts from over 8,500 of leading scientific and technical journals across 150 disciplines. We limit our study to the subset of abstracts from 1991 to 2010, which forms the majority of articles. This subset (denoted WoS hereafter) contains over 25 million articles from around 250 fields.

4 Rhetorical Functions of Scientific Topics

We use the term *rhetorical function* to identify the purpose or role a scientific topic plays within a research paper. This function qualifies the association between a topic and a paper.

A topic could represent the general domain of the research or its main objective/goal. It could also correspond to the data used, the way the research is designed, or the methods used. A topic may serve one or more of these roles within the same paper. The same topic may also serve different roles in different papers. We are interested in finding the different rhetorical functions by which topics are associated with the papers in our corpus, as a tool for understanding the growth and decline of topics over time. Our focus is thus on the rhetorical functions that topics play across papers, in order to understand the 'rhetorical structure of science' (Latour, 1987), although these are cued by specific rhetorical structures in individual sentences of individual papers. (Our work on the function of *topics* thus differs somewhat from previous research focusing on the rhetorical role of individual *sentences* or segments in the structure of the paper.)

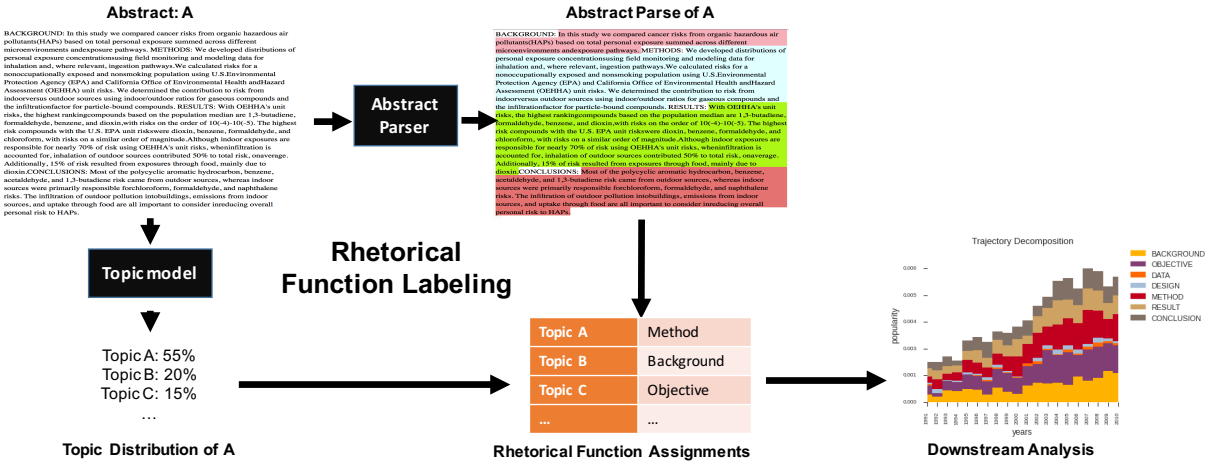

Figure 3: Rhetorical Function Labeling
The topic model (step a) assigns topic distributions to the abstract text (bottom left) and the abstract parser (step b) divides the text into discourse segments (top right). Rhetorical function labeling (step c) combines these two analyses to assign rhetorical functions to topics (bottom middle). These labels enrich the analysis of trends in topic popularity over decades (bottom right).

We follow a three-step process to assign rhetorical function labels to a large corpus of scientific abstracts. Figure 3 presents the pictorial representation of the procedure we follow — 1) obtain topic probabilities for each abstract, 2) parse the narrative structure of the abstracts in order to arrive at segments of text with different discourse intentions, and 3) superimpose the topic assignments and the abstract parse to arrive at the rhetorical function labels that capture how the topics are associated with the work presented in the abstract. We describe each of these steps in detail below.

a. Topic modeling: The core of our approach relies on the popular latent Dirichlet allocation (LDA) (Blei et al., 2003) algorithm. It probabilistically assigns both words and abstracts to different topics, in an unsupervised manner. Let $A = \{a_1, a_2, ...a_{|A|}\}$ be the set of abstracts within the field we are studying, and let $T = \{t_1, t_2, ...t_{|T|}\}$ be the set of different topics in the field. A topic model trained on A assigns $\theta_{a,t}$, the probability of topic t occurring in abstract a for all $a \in A$ and $t \in T$. The topic model also provides the $\phi_{t,w}$, the probability of word w occurring in topic t.

b. Abstract parsing: An abstract parser divides the abstract text into a sequence of discourse segments, with each segment assigned a specific label denoting its rhetorical purpose. Let $S(a) = (s_1, s_2, ...s_{|S(a)|})$ be the sequence of segments identified by the abstract parser, and let L denote the set of labels in the abstract parsing framework. The abstract parser assigns a label $l(s_i) \in L$, for each $s_i \in S(a)$.

c. Rhetorical Function Labeling: We tease apart the abstract-level topic distribution $\theta_{a,t}$ assigned by the topic model (step a) along the segments found by the abstract parser (step b), and find the topic weights on each label $\theta_{l,t}(a)$ by calculating topic weights for segments that are assigned label l, i.e., $\{s_i \in S(a) : l(s_i) = l\}$. We calculate the topic weights for each segment by aggregating the topic weights on each word derived from $\phi_{t,w}$ inferred by the topic model:

$$\theta_{l,t}(a) \propto \sum_{w_i \in s_i : l(s_i) = l} \phi_{t,w} \quad (1)$$

We first describe the abstract parsing system (step b) we built for this purpose in Section 5, before discussing the execution details of each of the above three steps in Section 6.

5 Abstract Parsing

Datasets with manual annotations for discourse structure of abstracts (e.g., Guo et al., 2010; Gupta and Manning, 2011) are few, small, and limited to specific domains. It is not clear how accurate an abstract parser trained on these datasets will perform on other domains. Since we want to obtain the structure of abstracts in a broad range of domains over different time-periods, a parser trained

on small datasets in specific domains may not be adequate for our purposes. Hence, we exploit the large number of abstracts in the WOS corpus in order to gather a dataset of self-labeled abstracts from a wide range of domains, over a period of two decades. By self-labeled abstracts, we refer to the abstracts where the authors have identified the discourse segments using explicit section labels.

5.1 Extracting Self-labeled Abstracts

In the first step, we extract all the patterns from the WOS corpus that could potentially be a segment label. For this, we look for a pattern that is commonly used by authors to label abstract segments — a capitalized phrase of one or more words occurring at the beginning of the abstract or preceded by a period, and followed by a ":". We obtained 455,972 matches for the above pattern, corresponding to 2,074 unique labels, majority of which were valid discourse segment labels. These include variations of the same labels (e.g., "OBJECTIVE" and "AIM", "CONCLUSION" and "CONCLUSIONS" etc.) and typos (e.g., "RESLUTS"). There were also instances where two common labels were combined (e.g., "DATA AND METHODS"). The extracted matches also contained a long tail of false positives (e.g., "BMI").

One of the challenges in using the set of abstracts we obtained above is that they do not follow a common labeling scheme. Hence, we manually analyzed the top 100 unique labels (which corresponds to labels with more than $\sim$50 instances) and mapped them into a unified labeling scheme, grouping together labels with similar intentions. This resulted in a typology of seven labels:

- BACKGROUND: The scientific context
- OBJECTIVE: The specific goal(s)
- DATA: The empirical dimension used
- DESIGN: The experimental setup
- METHOD: Means used to achieve the goal
- RESULT: What was found
- CONCLUSION: What was inferred

We use this mapping to obtain abstracts that are self-labeled. We exclude the abstracts that had combined labels, since they may add noise to the training data. We also exclude abstracts that contained only false positive matches. This preprocessing resulted in a dataset of 83,559 abstracts. We refer to this dataset as SL, hereafter. We divide the SL dataset into Train/Dev/Test subsets for our experiments (Table 1).

	Train	Dev	Test
# of abstracts	58,600	12,331	12,628
# of labeled segments	243,217	51,111	52,403
# of sentences	681,730	143,792	147,321

Table 1: Statistics of self-labeled abstracts

5.2 Automatic tagging of abstracts

We use the SL dataset to build a supervised learning system that can predict the abstract structure in unseen documents. We perform the prediction at the sentence level. We used the CRF algorithm to train the model, as it has been proven successful in similar tasks in prior work (Hirohata et al., 2008; Merity et al., 2009). In our preliminary experiments, we also tried using SVM, but CRF was faster and outperformed SVM by 4-5% points consistently. We use the following features:

1. Location: location of the sentence from the beginning or end of the abstract
2. Word ngrams: unigrams and bigrams of word lemmas
3. Part-of-speech ngrams: unigrams and bigrams of part-of-speech tags
4. Verb lemmas and part-of-speeches: lemmas of verbs, and their part-of-speech tags in order to identify the tense of verb usage
5. Verb classes: we looked up each verb in the VerbNet (Kipper-Schuler, 2005) index and added the VerbNet class to the feature set if the verb maps to a unique verb class.
6. Concreteness rating: we used the max, min, and mean concreteness ratings of words based on (Brysbaert et al., 2014).

Most of these features are commonly used in similar tasks, while the concreteness features are new (and significantly improved performance). We do not use parse features, however, since our pipeline emphasizes computational efficiency, and parse features showed minimal utility relative to their computational cost in prior work (Guo et al., 2010).

We evaluate the performance of our learned model in terms of overall accuracy as well as per-class precision, recall and F-measure of predicting the segment labels at the sentence level. We performed experiments on the Dev set to choose the best feature configuration (e.g., tuning for word and part-of-speech ngram length). Each feature set described in the previous paragraph were con-

	Precision	Recall	F-measure
BACKGROUND	74.6	77.2	75.8
OBJECTIVE	85.2	81.8	83.5
DATA	82.6	76.8	79.6
DESIGN	68.0	64.8	66.3
METHOD	80.4	80.1	80.2
RESULT	90.8	93.3	92.0
CONCLUSION	93.8	92.0	92.9
Accuracy		86.6	

Table 2: Results of parsing abstract structure

tributing features to the best performance obtained on the Dev set. The concreteness features we introduced significantly improved the overall accuracy by around 2%.

Table 2 shows the results obtained on testing the final classifier system on the Test subset of SL.[1] We obtain an overall high accuracy of 86.6% at the sentence level. While RESULT and CONCLUSION obtained F-measures above 90%, OBJECTIVE and METHOD reported reasonable F-measures above 80%. DESIGN obtained the lowest precision, recall and F-measure. Overall, the performance we obtain is in the range of other reported results in similar tasks (Guo et al., 2013).

6 Analysis Setup

In the rest of this paper, we apply the rhetorical function labeling system described in Section 4 to analyze the growth and decline of scientific topics. We chose four diverse fields from the WoS corpus with large numbers of abstracts for our analysis, which are: *Biochemistry & Molecular Biology* (BIO): 850,394 abstracts, *Applied Physics* (PHY): 558,934 abstracts, *Physical Chemistry* (CHM): 533,871 abstracts, and *Neurosciences* (NEU): 477,197 abstracts. We apply the steps (a), (b), and (c) of rhetorical function labeling as described in Section 4 to these fields as follows:

Topic Modeling: We use the LightLDA implementation (Yuan et al., 2015) of LDA. It employs a highly efficient and parallelized Metropolis-Hastings sampler that allows us to scale our approach to massive datasets (e.g., millions of abstracts in our case). For all our experiments, we ran the algorithm for 1000 iterations, as this was sufficient for convergence. We use 500 topics for all four fields, but otherwise use the default hyperparameter settings from the LightLDA package.[2]

Abstract Parsing We applied the 7-label abstract parsing system described in Section 5 on all abstracts in each of the four disciplines.

Rhetorical Function Labeling Once the steps (a) and (b) are completed, we applied the rhetorical function labeling step (c) from Section 4 in order to obtain topic weights for each segment. In addition, we calculate a rhetorical function label distribution (referred to as *label distribution* hereafter) for each topic associated with an abstract.

7 Dissecting Topic Trajectories

In this section, we investigate whether the label distribution of the topics (i.e., across the rhetorical function labels) sheds light on the kind of trajectories they follow; in particular, whether it can predict the up-trend vs. down-trend of topics. We formalize the problem as follows: given two sets of topics clustered based on their historical trajectories, do the label-distribution based features of a topic have predictive power to classify the topic to be in either set?

7.1 Tracking topic popularities

For each field, we first calculated the number of articles in which each topic occurred in at least one of the rhetorical functions for each year in the 20-year period 1991-2010. Since the fields themselves grow over the years, we divide this number by the number of articles within that field to obtain the popularity of each topic in any year:

$$popularity(t, y) = DocsWithTopic(t)/|A_y|,$$

where A_y denotes the subset of articles in year y.

7.2 Detecting growing vs. declining topics

We are interested in the set of topics in each field that are either growing or declining. Figure 4 shows example popularity trends for two such topics in neuroscience: stem cell research, which sees

[1] We report only the results obtained in unseen abstracts in the Test set due to lack of space. Similar performance was obtained in the Dev set as well.

[2] In preliminary experiments, we used 100, 500 and 1000 topics. Upon manual inspection, we found that 500 topics resulted in a granularity that better captures the scientific intellectual movements within fields.

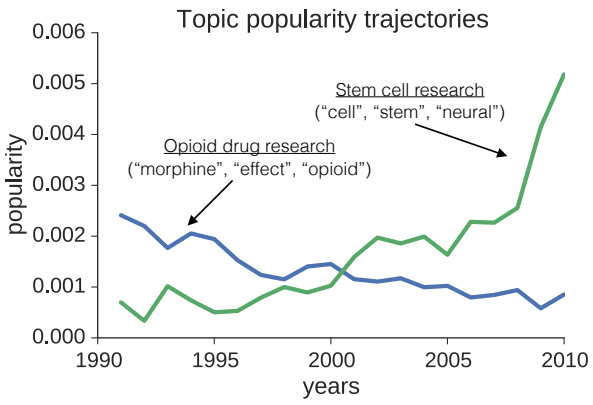

Figure 4: Example topic popularity curves from 1991 till 2010. Stem cell research (green) sees an increase in popularity over this time period, while Opioid research (blue) declines in popularity.

a dramatic increase in popularity from 1991-2010, and opioid[3] drug research, which declines in popularity during the same time-period.

Of course, topics do not always follow trajectories of pure growth or decline. A topic may have risen and subsequently fallen in popularity over the period of 20 years, or may stay more or less the same throughout (Griffiths and Steyvers, 2004). Hence, categorizing topics to be growing or declining solely based on the popularity at the beginning and end of the time period is problematic. We circumvent this issue and avoid manually-defined thresholds by discovering topical growth/decline curves in an unsupervised fashion. We use the K-Spectral Centroid (K-SC) algorithm (Yang and Leskovec, 2011), which groups different time-series into clusters, such that similar shapes get assigned to the same cluster, irrespective of scaling and translation (unlike other popular time series clustering algorithms such as Dynamic Time Warping). We run the clustering algorithm using $K = 3$, and choose the cluster with the upward trending centroid to be the set of growing topics and the cluster with the downward trending centroid to be the set of declining topics.[4] Figure 5 shows example centroids from Physical Chemistry, which clearly exhibit decreasing, increasing, and non-changing trends.

[3]Opioids are a popular class of analgesic (i.e., painkilling) drugs, including morphine.

[4]We also performed experiments using K = 5, 10 and 15 and grouped the clusters that are growing vs. declining. We obtained similar results in those experiments as well.

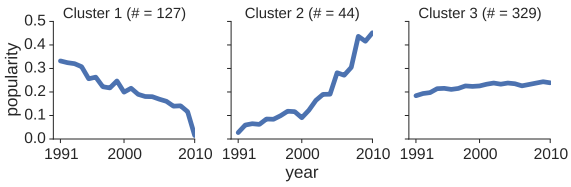

Figure 5: Cluster centroids in Physical Chemistry
Cluster 1: topics that declined in popularity;
Cluster 2: topics that grew in popularity;
Cluster 3: topics that stayed mostly the same.

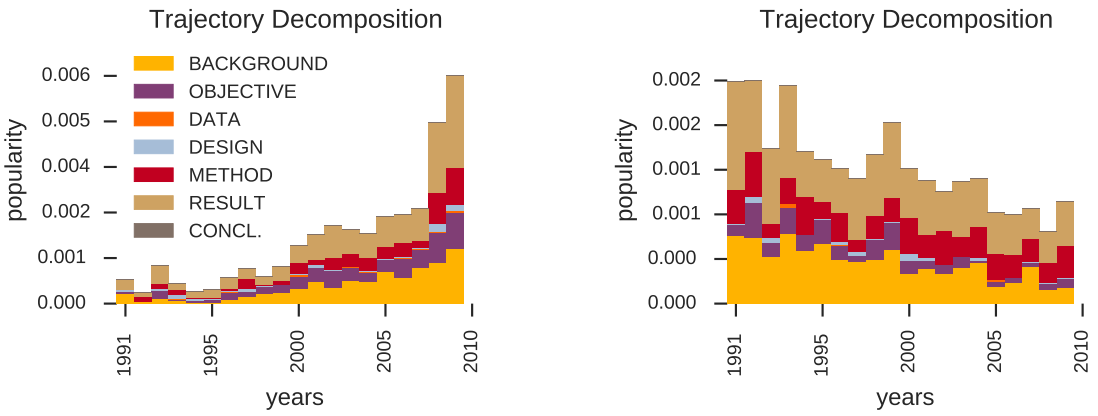
7.3 Characterizing topic growth vs. decline

We not only seek to detect growing vs. declining topics; our goal is to *characterize* these trajectories based upon the rhetorical functions that the topics are fulfilling during different points of their life-cycles. Figure 6 shows how the rhetorical function label distributions of the opioid and stem cell research topics shift from 1991 to 2010. The opioid research topic, which declines in popularity during this time-period, is frequently discussed in the RESULT and BACKGROUND roles during the early years. In contrast, the stem cell research topic, which is dramatically increasing in popularity, only begins to be discussed frequently in these roles towards the end of the time-period. Intuitively, these shifts make sense: topics become results-oriented and mentioned as background as they reach their peak; this peak is seen at the beginning of the time-period for opioid research, while stem cell research appears to be increasing towards a peak by the end of our data (i.e., 2010). These observations indicate that the rhetorical functions which a topic is fulfilling may be indicative of its current growth vs. decline.

7.4 Experiments

We perform two sets of experiments to quantify the qualitative insights noted above, i.e. that a topic's rhetorical function distribution is indicative of its eventual growth vs. decline. First, we show that a topic's rhetorical function distribution over the entire time-period can be used to *classify* the topic as either growing or declining. Next, we show that using only the first five years of data, we can *predict* whether a topic will eventually grow or decline. We use two sets of features:

- **label-distribution-percents (LD-%)**: seven features corresponding to the percentage of topics across the seven rhetorical function labels (e.g., % of time the topic is a *METHOD*)



(a) Stem cell topic.

(b) Opioid topic.

Figure 6: Examples of topics with changing rhetorical functions over time.

- **label-distribution-changes (LD-Δ)**: seven features that aggregate the mean change in this percentage over the years (e.g., is the % of being METHOD going up/down?).

These features are fed into a standard $L2$-regularized logistic regression classifier (with regularization parameter $C = 10$), which predicts whether a topic belongs to the growing or declining cluster.[5] We use random prediction and majority prediction as two uninformed baselines.

Classification task

System	ALL	BIO	PHY	CHM	NEU
Random	50.3	47.2	47.8	50.9	51.2
Majority	56.1	56.3	81.6	74.3	56.6
LR	74.2	81.0	83.3	81.9	74.8
LR - LD-R	71.3	77.7	81.6	73.1	70.5

Table 3: Results on classifying trajectories
LR: Logistic Regression using LD-%, LD-Δ, and LD-R.
LR - LD-R: Logistic Regression without using LD-R.

For the task of classifying a topic as either growing or declining, we compute the LD-% and LD-Δ features separately over the first and last five years of the data. This allows the model to analyze how the rhetorical functions are differentially expressed at the start vs. the end of the period under consideration. We also add a feature **label-distribution-ratio (LD-R)**, which is the ratio of the end to beginning LD-% values, so that the model has access to relative increases/decreases in the label distributions over the entire time-period.

[5]Similar performance was obtained with a linear SVM

Table 3 shows the performance of our model on this task. As expected a topic's label distribution over its entire life-time is very informative with respect to classifying the topic as growing or declining. We achieve a significant improvement over the baselines on the full dataset (32.3% relative improvement over majority prediction), and this trend holds across each field separately. The ratio feature proved to be extremely predictive in this task, i.e. relative increases/decreases in a topic being used in different functional roles are very predictive of the type of its trajectory.

Prediction task

We now turn to the more difficult task of *predicting* whether a topic will grow or decline, given access only to the first five years of its label distribution. The setup here is identical to the classification task, except that we now have access only to the LD-Δ and LD-% features aggregated over the first five years of data.

System	Accuracy on ALL
LD-% + LD-Δ	72.1
LD-% only	71.0
LD-Δ only	60.4

Table 4: Results on predicting trajectory

Table 4 shows the performance of our model on this task. (The baseline performances are the same as in the classification task). These results show that we can accurately predict whether a topic will grow or decline using only a small amount of data.

Label	BKGRND.	OBJ.	DATA	DESIGN	METHOD	RESULT	CONC.
LD-% Weight	-1.21	-0.10	6.38	1.21	3.82	-8.65	1.67
LD-Δ Weight	2.05	-0.01	2.20	-1.08	-1.63	-0.26	-1.27

Table 5: Logistic Regression feature weights for the prediction task on the full (ALL) dataset.

Moreover, we see that both percentage and delta features are necessary for this task.

7.5 Analysis

The feature weights of our learned linear model also provide insights into the dynamics of scientific trends. Table 5 contains the learned feature weights for the prediction task. Overall, these weights reinforce the conclusions drawn from the case study in Section 7.3. The strongest feature is the LD-% feature for the RESULT rhetorical function, which is highly negative. This indicates that topics that are currently being discussed as a result are likely at the peak of their popularity, and are thus likely to decrease in the future. Interestingly, the weights on the LD-% features for the methodological rhetorical functions (METHODS, DATA, and DESIGN) are all significantly positive. This suggests that topics occupying these functions may have reached a level of maturity where they are active areas of research and are being consumed by a large number of researchers, but that they have not yet peaked in their popularity. Finally, we see that the weights for the BACKGROUND and CONCLUSION roles have opposite trends: growing topics are more often mentioned as conclusions whereas dying topics, i.e. topics at the peak of their life-cycles, tend to be mentioned in background, or contextualizing, statements.

8 Conclusion

We introduce a novel framework for assigning rhetorical functions to associations between scientific topics and papers, and we show how these rhetorical functions are predictive of a topic's growth vs. decline.

Our analysis reveals important regularities with respect to how a topic's usage evolves over its life-cycle. We find that topics that are currently discussed as results tend to be in decline, whereas topics that are playing a methodological role tend to be in the early phases of growth. In some ways these results are counter-intuitive; for example, one might expect topics that are being discussed as results to be the focus of current cutting edge research, and that methodological topics might be more mundane and lacking in novelty. Instead our results suggest that results-oriented topics are at the peak of their life-cycle, while methodological topics still have room to grow. This result has important implications for research funding and public policy: the most promising topics—in terms of potential for future growth—are not those that are currently generating the most results, but are instead those that are active areas of methodological inquiry.

Our analysis does suffer from some limitations. Examining only 20 years of scientific progress prevents us from analyzing drastic scientific changes, e.g. paradigm shifts, that are only obvious over longer time-scales (Kuhn, 2012). Access to longer time-spans—along with varying data sources such as grants and patents—would also allow us to more completely model the trajectory of a topic as it moves from being active area of research to potentially impacting commercial industries and economic development. Nonetheless, we hope this work offers another step towards using computational tools to better understand the 'rhetorical structure of science' (Latour, 1987).

Abstract

In this paper, we present the first experiments using neural network models for the task of error detection in learner writing. We perform a systematic comparison of alternative compositional architectures and propose a framework for error detection based on bidirectional LSTMs. Experiments on the CoNLL-14 shared task dataset show the model is able to outperform other participants on detecting errors in learner writing. Finally, the model is integrated with a publicly deployed self-assessment system, leading to performance comparable to human annotators.

1 Introduction

Automated systems for detecting errors in learner writing are valuable tools for second language learning and assessment. Most work in recent years has focussed on error correction, with error detection performance measured as a byproduct of the correction output (Ng et al., 2013; Ng et al., 2014). However, this assumes that systems are able to propose a correction for every detected error, and accurate systems for correction might not be optimal for detection. While closed-class errors such as incorrect prepositions and determiners can be modeled with a supervised classification approach, content-content word errors are the 3rd most frequent error type and pose a serious challenge to error correction frameworks (Leacock et al., 2014; Kochmar and Briscoe, 2014). Evaluation of error correction is also highly subjective and human annotators have rather low agreement on gold-standard corrections (Bryant and Ng, 2015). Therefore, we treat error detection in learner writing as an independent task and propose a system for labeling each token as being correct or incorrect in context.

Common approaches to similar sequence labeling tasks involve learning weights or probabilities for context n-grams of varying sizes, or relying on previously extracted high-confidence context patterns. Both of these methods can suffer from data sparsity, as they treat words as independent units and miss out on potentially related patterns. In addition, they need to specify a fixed context size and are therefore often limited to using a small window near the target.

Neural network models aim to address these weaknesses and have achieved success in various NLP tasks such as language modeling (Bengio et al., 2003) and speech recognition (Dahl et al., 2012). Recent developments in machine translation have also shown that text of varying length can be represented as a fixed-size vector using convolutional networks (Kalchbrenner and Blunsom, 2013; Cho et al., 2014a) or recurrent neural networks (Cho et al., 2014b; Bahdanau et al., 2015).

In this paper, we present the first experiments using neural network models for the task of error detection in learner writing. We perform a systematic comparison of alternative compositional structures for constructing informative context representations. Based on the findings, we propose a novel framework for performing error detection in learner writing, which achieves state-of-the-art results on two datasets of error-annotated learner essays. The sequence labeling model creates a single variable-size network over the whole sentence, conditions each label on all the words, and predicts all labels together. The effects of different datasets on the overall performance are investigated by incrementally providing additional training data to the model. Finally, we integrate the error detection framework with a publicly deployed self-assessment system, leading

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1181–1191,
Berlin, Germany, August 7-12, 2016.

to performance comparable to human annotators.

2 Background and Related Work

The field of automatically detecting errors in learner text has a long and rich history. Most work has focussed on tackling specific types of errors, such as usage of incorrect prepositions (Tetreault and Chodorow, 2008; Chodorow et al., 2007), articles (Han et al., 2004; Han et al., 2006), verb forms (Lee and Seneff, 2008), and adjective-noun pairs (Kochmar and Briscoe, 2014).

However, there has been limited work on more general error detection systems that could handle all types of errors in learner text. Chodorow and Leacock (2000) proposed a method based on mutual information and the chi-square statistic to detect sequences of part-of-speech tags and function words that are likely to be ungrammatical in English. Gamon (2011) used Maximum Entropy Markov Models with a range of features, such as POS tags, string features, and outputs from a constituency parser. The pilot Helping Our Own shared task (Dale and Kilgarriff, 2011) also evaluated grammatical error detection of a number of different error types, though most systems were error-type specific and the best approach was heavily skewed towards article and preposition errors (Rozovskaya et al., 2011). We extend this line of research, working towards general error detection systems, and investigate the use of neural compositional models on this task.

The related area of grammatical error *correction* has also gained considerable momentum in the past years, with four recent shared tasks highlighting several emerging directions (Dale and Kilgarriff, 2011; Dale et al., 2012; Ng et al., 2013; Ng et al., 2014). The current state-of-the-art approaches can broadly be separated into two categories:

1. Phrase-based statistical machine translation techniques, essentially translating the incorrect source text into the corrected version (Felice et al., 2014; Junczys-Dowmunt and Grundkiewicz, 2014)

2. Averaged Perceptrons and Naive Bayes classifiers making use of native-language error correction priors (Rozovskaya et al., 2014; Rozovskaya et al., 2013).

Error correction systems require very specialised models, as they need to generate an improved version of the input text, whereas a wider range of tagging and classification models can be deployed on error detection. In addition, automated writing feedback systems that indicate the presence and location of errors may be better from a pedagogic point of view, rather than providing a panacea and correcting all errors in learner text. In Section 7 we evaluate a neural sequence tagging model on the latest shared task test data, and compare it to the top participating systems on the task of error detection.

3 Sequence Labeling Architectures

We construct a neural network sequence labeling framework for the task of error detection in learner writing. The model receives only a series of tokens as input, and outputs the probability of each token in the sentence being correct or incorrect in a given context. The architectures start with the vector representations of individual words, $[x_1, ..., x_T]$, where T is the length of the sentence. Different composition functions are then used to calculate a hidden vector representation of each token in context, $[h_1, ..., h_T]$. These representations are passed through a softmax layer, producing a probability distribution over the possible labels for every token in context:

$$p_t = softmax(W_o h_t) \quad (1)$$

where W_o is the weight matrix between the hidden vector h_t and the output layer.

We investigate six alternative neural network architectures for the task of error detection: convolutional, bidirectional recurrent, bidirectional LSTM, and multi-layer variants of each of them. In the **convolutional** neural network (CNN, Figure 1a) for token labeling, the hidden vector h_t is calculated based on a fixed-size context window. The convolution acts as a feedforward network, using surrounding context words as input, and therefore it will learn to detect the presence of different types of n-grams. The assumption behind the convolutional architecture is that memorising erroneous token sequences from the training data is sufficient for performing error detection.

The convolution uses d_w tokens on either side of the target token, and the vectors for these tokens are concatenated, preserving the ordering:

$$c_t = x_{t-d_w} : ... : x_{t+d_w} \quad (2)$$

where $x_1 : x_2$ is used as notation for vector concatenation of x_1 and x_2. The combined vector is

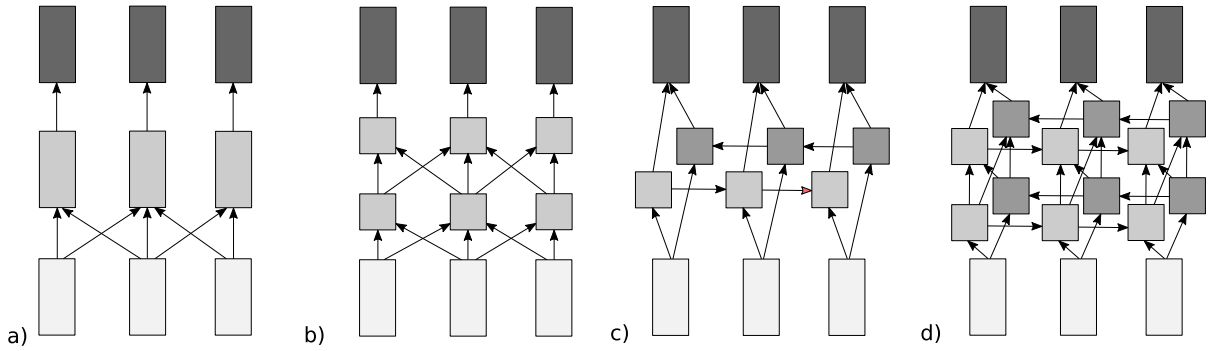

Figure 1: Alternative neural composition architectures for error detection. a) Convolutional network b) Deep convolutional network c) Recurrent bidirectional network d) Deep recurrent bidirectional network. The bottom layers are embeddings for individual tokens. The middle layers are context-dependent representations, built using different composition functions. The top layers are softmax output layers, predicting a label distribution for every input token.

then passed through a non-linear layer to produce the hidden representation:

$$h_t = tanh(W_c c_t) \tag{3}$$

The **deep convolutional** network (Figure 1b) adds an extra convolutional layer to the architecture, using the first layer as input. It creates convolutions of convolutions, thereby capturing more complex higher-order features from the dataset.

In a **recurrent** neural network (RNN), each hidden representation is calculated based on the current token embedding and the hidden vector at the previous time step:

$$h_t = f(Wx_t + Vh_{t-1}) \tag{4}$$

where $f(z)$ is a nonlinear function, such as the sigmoid function. Instead of a fixed context window, information is passed through the sentence using a recursive function and the network is able to learn which patterns to disregard or pass forward. This recurrent network structure is referred to as an Elman-type network, after Elman (1990).

The **bidirectional RNN** (Figure 1c) consists of two recurrent components, moving in opposite directions through the sentence. While the unidirectional version takes into account only context on the left of the target token, the bidirectional version recursively builds separate context representations from either side of the target token. The left and right context are then concatenated and used as the hidden representation:

$$h_t^{\rightarrow} = f(W_r x_t + V_r h_{t-1}^{\rightarrow}) \tag{5}$$

$$h_t^{\leftarrow} = f(W_l x_t + V_l h_{t+1}^{\leftarrow}) \tag{6}$$

$$h_t = h_t^{\rightarrow} : h_t^{\leftarrow} \tag{7}$$

Recurrent networks have been shown to perform well on the task of language modeling (Mikolov et al., 2011; Chelba et al., 2013), where they learn an incremental composition function for predicting the next token in the sequence. However, while language models can estimate the probability of each token, they are unable to differentiate between infrequent and incorrect token sequences. For error detection, the composition function needs to learn to identify semantic anomalies or ungrammatical combinations, independent of their frequency. The bidirectional model provides extra information, as it allows the network to use context on both sides of the target token.

Irsoy and Cardie (2014) created an extension of this architecture by connecting together multiple layers of bidirectional Elman-type recurrent network modules. This **deep bidirectional RNN** (Figure 1d) calculates a context-dependent representation for each token using a bidirectional RNN, and then uses this as input to another bidirectional RNN. The multi-layer structure allows the model to learn more complex higher-level features and effectively perform multiple recurrent passes through the sentence.

The long-short term memory (**LSTM**) (Hochreiter and Schmidhuber, 1997) is an advanced alternative to the Elman-type networks that has recently become increasingly popular. It uses

two separate hidden vectors to pass information between different time steps, and includes gating mechanisms for modulating its own output. LSTMs have been successfully applied to various tasks, such as speech recognition (Graves et al., 2013), machine translation (Luong et al., 2015), and natural language generation (Wen et al., 2015).

Two sets of gating values (referred to as the *input* and *forget* gates) are first calculated based on the previous states of the network:

$$i_t = \sigma(W_i x_t + U_i h_{t-1} + V_f c_{t-1} + b_i) \quad (8)$$

$$f_t = \sigma(W_f x_t + U_f h_{t-1} + V_f c_{t-1} + b_f) \quad (9)$$

where x_t is the current input, h_{t-1} is the previous hidden state, b_i and b_f are biases, c_{t-1} is the previous internal state (referred to as the *cell*), and σ is the logistic function. The new internal state is calculated based on the current input and the previous hidden state, and then interpolated with the previous internal state using f_t and i_t as weights:

$$\widetilde{c_t} = tanh(W_c x_t + U_c h_{t-1} + b_c) \quad (10)$$

$$c_t = f_t \odot c_{t-1} + i_t \odot \widetilde{c_t} \quad (11)$$

where $\odot$ is element-wise multiplication. Finally, the hidden state is calculated by passing the internal state through a $tanh$ nonlinearity, and weighting it with o_t. The values of o_t are conditioned on the new internal state (c_t), as opposed to the previous one (c_{t-1}):

$$o_t = \sigma(W_o x_t + U_o h_{t-1} + V_o c_t + b_o) \quad (12)$$

$$h_t = o_t \odot tanh(c_t) \quad (13)$$

Because of the linear combination in equation (11), the LSTM is less susceptible to vanishing gradients over time, thereby being able to make use of longer context when making predictions. In addition, the network learns to modulate itself, effectively using the gates to predict which operation is required at each time step, thereby incorporating higher-level features.

In order to use this architecture for error detection, we create a **bidirectional LSTM**, making use of the advanced features of LSTM and incorporating context on both sides of the target token. In addition, we experiment with a **deep bidirectional LSTM**, which includes two consecutive layers of bidirectional LSTMs, modeling even more complex features and performing multiple passes through the sentence.

For comparison with non-neural models, we also report results using **CRFs** (Lafferty et al., 2001), which are a popular choice for sequence labeling tasks. We trained the CRF++ [1] implementation on the same dataset, using as features unigrams, bigrams and trigrams in a 7-word window surrouding the target word (3 words before and after). The predicted label is also conditioned on the previous label in the sequence.

4 Experiments

We evaluate the alternative network structures on the publicly released First Certificate in English dataset (FCE-public, Yannakoudakis et al. (2011)). The dataset contains short texts, written by learners of English as an additional language in response to exam prompts eliciting free-text answers and assessing mastery of the upper-intermediate proficiency level. The texts have been manually error-annotated using a taxonomy of 77 error types. We use the released test set for evaluation, containing 2,720 sentences, leaving 30,953 sentences for training. We further separate 2,222 sentences from the training set for development and hyper-parameter tuning.

The dataset contains manually annotated error spans of various types of errors, together with their suggested corrections. We convert this to a token-level error detection task by labeling each token inside the error span as being incorrect. In order to capture errors involving missing words, the error label is assigned to the token immediately after the incorrect gap – this is motivated by the intuition that while this token is correct when considered in isolation, it is incorrect in the current context, as another token should have preceeded it.

As the main evaluation measure for error detection we use $F_{0.5}$, which was also the measure adopted in the CoNLL-14 shared task on error correction (Ng et al., 2014). It combines both precision and recall, while assigning twice as much weight to precision, since accurate feedback is often more important than coverage in error detection applications (Nagata and Nakatani, 2010). Following Chodorow et al. (2012), we also report raw counts for predicted and correct tokens. Related evaluation measures, such as the M^2-scorer (Ng et al., 2014) and the I-measure (Felice and

Briscoe, 2015), require the system to propose a correction and are therefore not directly applicable on the task of error detection.

During the experiments, the input text was lowercased and all tokens that occurred less than twice in the training data were represented as a single *unk* token. Word embeddings were set to size 300 and initialised using the publicly released pretrained Word2Vec vectors (Mikolov et al., 2013). The convolutional networks use window size 3 on either side of the target token and produce a 300-dimensional context-dependent vector. The recurrent networks use hidden layers of size 200 in either direction. We also added an extra hidden layer of size 50 between each of the composition functions and the output layer – this allows the network to learn a separate non-linear transformation and reduces the dimensionality of the compositional vectors. The parameters were optimised using gradient descent with initial learning rate 0.001, the ADAM algorithm (Kingma and Ba, 2015) for dynamically adapting the learning rate, and batch size of 64 sentences. $F_{0.5}$ on the development set was evaluated at each epoch, and the best model was used for final evaluations.

5 Results

Table 1 contains results for experiments comparing different composition architectures on the task of error detection. The CRF has the lowest $F_{0.5}$ score compared to any of the neural models. It memorises frequent error sequences with high precision, but does not generalise sufficiently, resulting in low recall. The ability to condition on the previous label also does not provide much help on this task – there are only two possible labels and the errors are relatively sparse.

The architecture using convolutional networks performs well and achieves the second-highest result on the test set. It is designed to detect error patterns from a fixed window of 7 words, which is large enough to not require the use of more advanced composition functions. In contrast, the performance of the bidirectional recurrent network (Bi-RNN) is somewhat lower, especially on the test set. In Elman-type recurrent networks, the context signal from distant words decreases fairly rapidly due to the sigmoid activation function and diminishing gradients. This is likely why the Bi-RNN achieves the highest precision of all systems – the predicted label is mostly influenced by the target token and its immediate neighbours, allowing the network to only detect short high-confidence error patterns. The convolutional network, which uses 7 context words with equal attention, is able to outperform the Bi-RNN despite the fixed-size context window.

The best overall result and highest $F_{0.5}$ is achieved by the bidirectional LSTM composition model (Bi-LSTM). This architecture makes use of the full sentence for building context vectors on both sides of the target token, but improves on Bi-RNN by utilising a more advanced composition function. Through the application of a linear update for the internal cell representation, the LSTM is able to capture dependencies over longer distances. In addition, the gating functions allow it to adaptively decide which information to include in the hidden representations or output for error detection.

We found that using multiple layers of compositional functions in a deeper network gave comparable or slightly lower results for all the composition architectures. This is in contrast to Ir-

Training data	Dev $F_{0.5}$	Test $F_{0.5}$

+FCE	57.2	61.1
+CPE	59.0	62.1
+CAE	**60.7**	**64.3**

Table 2: Results on the public FCE test set when incrementally providing more training data to the error detection model.

soy and Cardie (2014), who experimented with Elman-type networks and found some improvements using multiple layers of Bi-RNNs. The differences can be explained by their task benefiting from alternative features: the evaluation was performed on opinion mining where most target sequences are longer phrases that need to be identified based on their semantics, whereas many errors in learner writing are short and can only be identified by a contextual mismatch. In addition, our networks contain an extra hidden layer before the output, which allows the models to learn higher-level representations without adding complexity through an extra compositional layer.

6 Additional Training Data

There are essentially infinitely many ways of committing errors in text and introducing additional training data should alleviate some of the problems with data sparsity. We experimented with incrementally adding different error-tagged corpora into the training set and measured the resulting performance. This allows us to provide some context to the results obtained by using each of the datasets, and gives us an estimate of how much annotated data is required for optimal performance on error detection. The datasets we consider are as follows:

- FCE-public – the publicly released subset of FCE (Yannakoudakis et al., 2011), as described in Section 4.
- NUCLE – the NUS Corpus of Learner English (Dahlmeier et al., 2013), used as the main training set for CoNLL shared tasks on error correction.
- IELTS – a subset of the IELTS examination dataset extracted from the Cambridge Learner Corpus (CLC, Nicholls (2003)), containing 68,505 sentences from all proficiency levels, also used by Felice et al. (2014).
- FCE – a larger selection of FCE texts from the CLC, containing 323,192 sentences.
- CPE – essays from the proficient examination level in the CLC, containing 210,678 sentences.
- CAE – essays from the advanced examination level in the CLC, containing 219,953 sentences.

Table 2 contains results obtained by incrementally adding training data to the Bi-LSTM model. We found that incorporating the NUCLE dataset does not improve performance over using only the FCE-public dataset, which is likely due to the two corpora containing texts with different domains and writing styles. The texts in FCE are written by young intermediate students, in response to prompts eliciting letters, emails and reviews, whereas NUCLE contains mostly argumentative essays written by advanced adult learners. The differences in the datasets offset the benefits from additional training data, and the performance remains roughly the same.

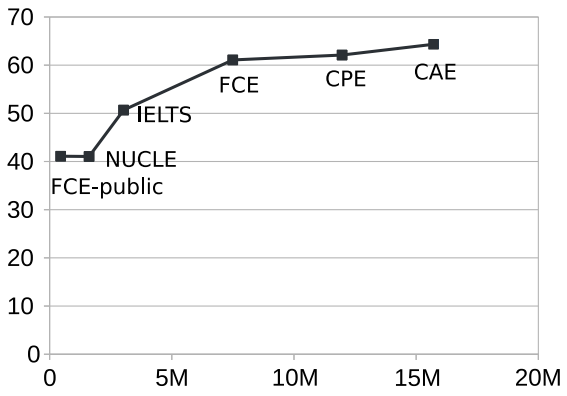

Figure 2: $F_{0.5}$ measure on the public FCE test set, as a function of the total number of tokens in the training set.

In contrast, substantial improvements are obtained when introducing the IELTS and FCE datasets, with each of them increasing the $F_{0.5}$ score by roughly 10%. The IELTS dataset contains essays from all proficiency levels, and FCE from mid-level English learners, which provides the model with a distribution of 'average' errors to learn from. Adding even more training data from

high-proficiency essays in CPE and CAE only provides minor further improvements.

Figure 2 also shows $F_{0.5}$ on the FCE-public test set as a function of the total number of tokens in the training data. The optimal trade-off between performance and data size is obtained at around 8 million tokens, after introducing the FCE dataset.

7 CoNLL-14 Shared Task

The CoNLL-14 shared task (Ng et al., 2014) focussed on automatically correcting errors in learner writing. The NUCLE dataset was provided as the main training dataset, but participants were allowed to include other annotated corpora and external resources. For evaluation, 25 students were recruited to each write two new essays, which were then annotated by two experts.

We used the same methods from Section 4 for converting the shared task annotation to a token-level labeling task in order to evaluate the models on error detection. In addition, the correction outputs of all the participating systems were made available online, therefore we are able to report their performance on this task. In order to convert their output to error detection labels, the corrected sentences were aligned with the original input using Levenshtein distance, and any changes proposed by the system resulted in the corresponding source words being labeled as errors.

The results on the two annotations of the shared task test data can be seen in Table 3. We first evaluated each of the human annotators with respect to the other, in order to estimate the upper bound on this task. The average $F_{0.5}$ of roughly 50% shows that the task is difficult and even human experts have a rather low agreement. It has been shown before that correcting grammatical errors is highly subjective (Bryant and Ng, 2015), but these results indicate that trained annotators can disagree even on the number and location of errors.

In the same table, we provide error detection results for the top 3 participants in the shared task: CAMB (Felice et al., 2014), CUUI (Rozovskaya et al., 2014), and AMU (Junczys-Dowmunt and Grundkiewicz, 2014). They each preserve their relative ranking also in the error detection evaluation. The CAMB system has a lower precision but the highest recall, also resulting in the highest $F_{0.5}$. CUUI and AMU are close in performance, with AMU having slightly higher precision.

After the official shared task, Susanto et al. (2014) published a system which combines several alternative models and outperforms the shared task participants when evaluated on error correction. However, on error detection it receives lower results, ranking 3rd and 4th when evaluated on $F_{0.5}$ (P1+P2+S1+S2 in Table 3). The system has detected a small number of errors with high precision, and does not reach the highest $F_{0.5}$.

Finally, we present results for the Bi-LSTM sequence labeling system for error detection. Using only FCE-public for training, the overall performance is rather low as the training set is very small and contains texts from a different domain. However, these results show that the model behaves as expected – since it has not seen similar language during training, it labels a very large portion of tokens as errors. This indicates that the network is trying to learn correct language constructions from the limited data and classifies unseen structures as errors, as opposed to simply memorising error sequences from the training data.

When trained on all the datasets from Section 6, the model achieves the highest $F_{0.5}$ of all systems on both of the CoNLL-14 shared task test annotations, with an absolute improvement of 3% over the previous best result. It is worth noting that the full Bi-LSTM has been trained on more data than the other CoNLL contestants. However, as the shared task systems were not restricted to the NUCLE training set, all the submissions also used differing amounts of training data from various sources. In addition, the CoNLL systems are mostly combinations of many alternative models: the CAMB system is a hybrid of machine translation, a rule-based system, and a language model re-ranker; CUUI consists of different classifiers for each individual error type; and P1+P2+S1+S2 is a combination of four different error correction systems. In contrast, the Bi-LSTM is a single model for detecting all error types, and therefore represents a more scalable data-driven approach.

8 Essay Scoring

In this section, we perform an extrinsic evaluation of the efficacy of the error detection system and examine the extent to which it generalises at higher levels of granularity on the task of automated essay scoring. More specifically, we replicate experiments using the *text-level* model described by Andersen et al. (2013), which is currently deployed in a self-assessment and tutoring system (SAT), an online automated writing feedback tool actively used by language learners.[2]

The SAT system predicts an overall score for a given text, which provides a holistic assessment of linguistic competence and language proficiency. The authors trained a supervised ranking perceptron model on the FCE-public dataset, using features such as error-rate estimates from a language model and various lexical and grammatical properties of text (e.g., word n-grams, part-of-speech n-grams and phrase-structure rules). We replicate this experiment and add the average probability of each token in the essay being correct, according to the error detection model, as an additional feature for the scoring framework. The system was then retrained on FCE-public and evaluated on correctly predicting the assigned essay score. Table 4 presents the experimental results.

The human performance on the test set is calculated as the average inter-annotator correlation on the same data, and the existing SAT system has demonstrated levels of performance that are very close to that of human assessors. Nevertheless, the Bi-LSTM model trained only on FCE-public complements the existing features, and the combined model achieves an absolute improvement of around 1% percent, corresponding to 20-31% relative error reduction with respect to the human performance. Even though the Bi-LSTM is trained on the same dataset and the SAT system already includes various linguistic features for capturing errors, our error detection model manages to further improve its performance.

	r	ρ
Human annotators	79.6	79.2
SAT	75.1	76.0
SAT + Bi-LSTM (FCE-public)	76.0	77.0
SAT + Bi-LSTM (full)	**78.0**	**79.9**

Table 4: Pearson's correlation r and Spearman's correlation ρ on the public FCE test set on the task of automated essay scoring.

When the Bi-LSTM is trained on all the available data from Section 6, the combination achieves further substantial improvements. The relative error reduction on Pearson's correlation is 64%, and the system actually outperforms human annotators on Spearman's correlation.

9 Conclusions

In this paper, we presented the first experiments using neural network models for the task of error detection in learner writing. Six alternative compositional network architectures for modeling context were evaluated. Based on the findings, we propose a novel error detection framework using token-level embeddings, bidirectional LSTMs for context representation, and a multi-layer architecture for learning more complex features. This structure allows the model to classify each token as being correct or incorrect, using the full sentence as context. The self-modulation architecture of LSTMs was also shown to be beneficial, as it allows the network to learn more advanced composition rules and remember dependencies over longer distances.

Substantial performance improvements were achieved by training the best model on additional

[2] http://www.cambridgeenglish.org/learning-english/free-resources/write-and-improve/

datasets. We found that the largest benefit was obtained from training on 8 million tokens of text from learners with varying levels of language proficiency. In contrast, including even more data from higher-proficiency learners gave marginal further improvements. As part of future work, it would be beneficial to investigate the effect of automatically generated training data for error detection (e.g., Rozovskaya and Roth (2010)).

We evaluated the performance of existing error correction systems from CoNLL-14 on the task of error detection. The experiments showed that success on error correction does not necessarily mean success on error detection, as the current best correction system (P1+P2+S1+S2) is not the same as the best shared task detection system (CAMB). In addition, the neural sequence tagging model, specialised for error detection, was able to outperform all other participating systems.

Finally, we performed an extrinsic evaluation by incorporating probabilities from the error detection system as features in an essay scoring model. Even without any additional data, the combination further improved performance which is already close to the results from human annotators. In addition, when the error detection model was trained on a larger training set, the essay scorer was able to exceed human-level performance.

Acknowledgments

We would like to thank Prof Ted Briscoe and the reviewers for providing useful feedback.

Abstract

This paper introduces a novel model for semantic role labeling that makes use of neural sequence modeling techniques. Our approach is motivated by the observation that complex syntactic structures and related phenomena, such as nested subordinations and nominal predicates, are not handled well by existing models. Our model treats such instances as subsequences of lexicalized dependency paths and learns suitable embedding representations. We experimentally demonstrate that such embeddings can improve results over previous state-of-the-art semantic role labelers, and showcase qualitative improvements obtained by our method.

1 Introduction

The goal of *semantic role labeling* (SRL) is to identify and label the arguments of semantic predicates in a sentence according to a set of predefined relations (e.g., "who" did "what" to "whom"). Semantic roles provide a layer of abstraction beyond syntactic dependency relations, such as *subject* and *object*, in that the provided labels are insensitive to syntactic alternations and can also be applied to nominal predicates. Previous work has shown that semantic roles are useful for a wide range of natural language processing tasks, with recent applications including statistical machine translation (Aziz et al., 2011; Xiong et al., 2012), plagiarism detection (Osman et al., 2012; Paul and Jamal, 2015), and multi-document abstractive summarization (Khan et al., 2015).

The task of semantic role labeling (SRL) was pioneered by Gildea and Jurafsky (2002). In their work, features based on syntactic constituent trees were identified as most valuable for labeling predicate-argument relationships. Later work confirmed the importance of syntactic parse features (Pradhan et al., 2005; Punyakanok et al., 2008) and found that dependency parse trees provide a better form of representation to assign role labels to arguments (Johansson and Nugues, 2008).

System	Analysis

This work	[He$_{A0}$] had trouble **raising** [funds$_{A1}$].

Table 1: Outputs of SRL systems for the sentence *He had trouble raising funds.* Arguments of **raise** are shown with predicted roles as defined in PropBank (A0: getter of money; A1: money). Asterisks mark flawed analyses that miss the argument *He*.

Most semantic role labeling approaches to date rely heavily on lexical and syntactic indicator features. Through the availability of large annotated resources, such as PropBank (Palmer et al., 2005), statistical models based on such features achieve high accuracy. However, results often fall short when the input to be labeled involves instances of linguistic phenomena that are relevant for the labeling decision but appear infrequently at training time. Examples include control and raising verbs, nested conjunctions or other recursive structures, as well as rare nominal predicates. The difficulty lies in that simple lexical and syntactic indicator features are not able to model interactions triggered by such phenomena. For instance, con-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1192–1202,
Berlin, Germany, August 7-12, 2016.

sider the sentence *He had trouble raising funds* and the analyses provided by four publicly available tools in Table 1 (mate-tools, Björkelund et al. (2010); mateplus, Roth and Woodsend (2014); TensorSRL, Lei et al. (2015); and easySRL, Lewis et al. (2015)). Despite all systems claiming state-of-the-art or competitive performance, none of them is able to correctly identify *He* as the agent argument of the predicate *raise*. Given the complex dependency path relation between the predicate and its argument, none of the systems actually identifies *He* as an argument at all.

In this paper, we develop a new neural network model that can be applied to the task of semantic role labeling. The goal of this model is to better handle control predicates and other phenomena that can be observed from the dependency structure of a sentence. In particular, we aim to model the semantic relationships between a predicate and its arguments by analyzing the dependency path between the predicate word and each argument head word. We consider lexicalized paths, which we decompose into sequences of individual items, namely the words and dependency relations on a path. We then apply long-short term memory networks (Hochreiter and Schmidhuber, 1997) to find a recurrent composition function that can reconstruct an appropriate representation of the full path from its individual parts (Section 2). To ensure that representations are indicative of semantic relationships, we use semantic roles as target labels in a supervised setting (Section 3).

By modeling dependency paths as sequences of words and dependencies, we implicitly address the data sparsity problem. This is the case because we use single words and individual dependency relations as the basic units of our model. In contrast, previous SRL work only considered full syntactic paths. Experiments on the CoNLL-2009 benchmark dataset show that our model is able to outperform the state-of-the-art in English (Section 4), and that it improves SRL performance in other languages, including Chinese, German and Spanish (Section 5).

2 Dependency Path Embeddings

In the context of neural networks, the term *embedding* refers to the output of a function f within the network, which transforms an arbitrary input into a real-valued vector output. Word embeddings, for instance, are typically computed by forwarding a one-hot word vector representation from the input layer of a neural network to its first hidden layer, usually by means of matrix multiplication and an optional non-linear function whose parameters are learned during neural network training.

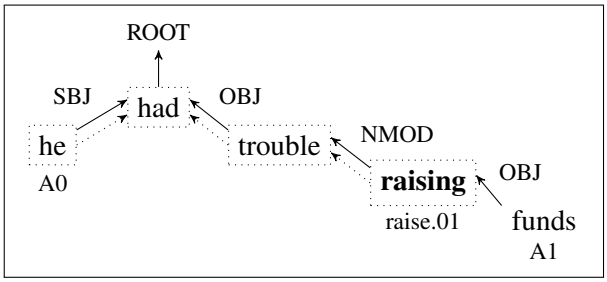

Figure 1: Dependency path (dotted) between the predicate *raising* and the argument *he*.

Here, we seek to compute real-valued vector representations for *dependency paths* between a pair of words $\langle w_i, w_j \rangle$. We define a dependency path to be the *sequence* of nodes (representing words) and edges (representing relations between words) to be traversed on a dependency parse tree to get from node w_i to node w_j. In the example in Figure 1, the dependency path from *raising* to *he* is $raising \xrightarrow{\text{NMOD}} trouble \xrightarrow{\text{OBJ}} had \xleftarrow{\text{SBJ}} he$.

Analogously to how word embeddings are computed, the simplest way to embed paths would be to represent each sequence as a one-hot vector. However, this is suboptimal for two reasons: Firstly, we expect only a subset of dependency paths to be attested frequently in our data and therefore many paths will be too sparse to learn reliable embeddings for them. Secondly, we hypothesize that dependency paths which share the same words, word categories or dependency relations should impact SRL decisions in similar ways. Thus, the words and relations on the path should drive representation learning, rather than the full path on its own. The following sections describe how we address representation learning by means of modeling dependency paths as sequences of items in a recurrent neural network.

2.1 Recurrent Neural Networks

The recurrent model we use in this work is a variant of the long-short term memory (LSTM) network. It takes a sequence of items $X = x_1, ..., x_n$ as input, recurrently processes each item $x_t \in X$ at a time, and finally returns one embedding state $\mathbf{e}_n$ for the complete input sequence. For each time

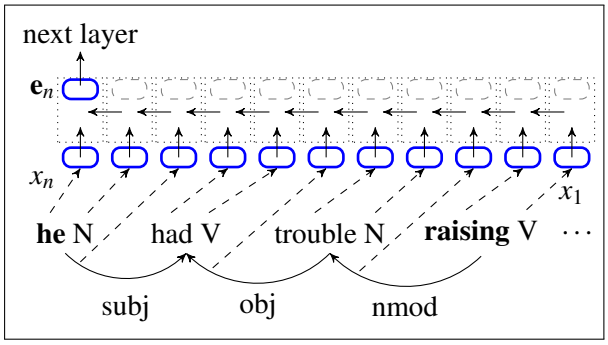

Figure 2: Example input and embedding computation for the path from *raising* to *he*, given the sentence *he had trouble raising funds*. LSTM time steps are displayed from right to left.

step t, the LSTM model updates an internal memory state $\mathbf{m}_t$ that depends on the current input as well as the previous memory state $\mathbf{m}_{t-1}$. In order to capture long-term dependencies, a so-called gating mechanism controls the extent to which each component of a memory cell state will be modified. In this work, we employ input gates $\mathbf{i}$, output gates $\mathbf{o}$ and (optional) forget gates $\mathbf{f}$. We formalize the state of the network at each time step t as follows:

$$\mathbf{i}_t = \sigma([\mathbf{W}^{\mathrm{mi}}\mathbf{m}_{t-1}] + \mathbf{W}^{\mathrm{xi}}x_t + \mathbf{b}^{\mathrm{i}}) \quad (1)$$

$$\mathbf{f}_t = \sigma([\mathbf{W}^{\mathrm{mf}}\mathbf{m}_{t-1}] + \mathbf{W}^{\mathrm{xf}}x_t + \mathbf{b}^{\mathrm{f}}) \quad (2)$$

$$\mathbf{m}_t = \mathbf{i}_t \odot (\mathbf{W}^{\mathrm{xm}}x_t) + \mathbf{f}_t \odot \mathbf{m}_{t-1} + \mathbf{b}^{\mathrm{m}} \quad (3)$$

$$\mathbf{o}_t = \sigma([\mathbf{W}^{\mathrm{mo}}\mathbf{m}_t] + \mathbf{W}^{\mathrm{xo}}x_t + \mathbf{b}^{\mathrm{o}}) \quad (4)$$

$$\mathbf{e}_t = \mathbf{o}_t \odot \sigma(\mathbf{m}_t) \quad (5)$$

In each equation, $\mathbf{W}$ describes a matrix of weights to project information between two layers, $\mathbf{b}$ is a layer-specific vector of bias terms, and σ is the logistic function. Superscripts indicate the corresponding layers or gates. Some models described in Section 3 do not make use of forget gates or memory-to-gate connections. In case no forget gate is used, we set $\mathbf{f}_t = \mathbf{1}$. If no memory-to-gate connections are used, the terms in square brackets in (1), (2), and (4) are replaced by zeros.

2.2 Embedding Dependency Paths

We define the *embedding of a dependency path* to be the final memory output state of a recurrent LSTM layer that takes a path as input, with each input step representing a binary indicator for a part-of-speech tag, a word form, or a dependency relation. In the context of semantic role labeling, we define each path as a sequence from a predicate to its potential argument.[1] Specifically, we define the first item x_1 to correspond to the part-of-speech tag of the predicate word w_i, followed by its actual word form, and the relation to the next word w_{i+1}. The embedding of a dependency path corresponds to the state $\mathbf{e}_n$ returned by the LSTM layer after the input of the last item, x_n, which corresponds to the word form of the argument head word w_j. An example is shown in Figure 2.

The main idea of this model and representation is that word forms, word categories and dependency relations can all influence role labeling decisions. The word category and word form of the predicate first determine which roles are plausible and what kinds of path configurations are to be expected. The relations and words seen on the path can then manipulate these expectations. In Figure 2, for instance, the verb *raising* complements the phrase *had trouble*, which makes it likely that the subject *he* is also the logical subject of *raising*.

By using word forms, categories and dependency relations as input items, we ensure that specific words (e.g., those which are part of complex predicates) as well as various relation types (e.g., subject and object) can appropriately influence the representation of a path. While learning corresponding interactions, the network is also able to determine which phrases and dependency relations might not influence a role assignment decision (e.g., coordinations).

2.3 Joint Embedding and Feature Learning

Our SRL model consists of four components depicted in Figure 3: (1) an LSTM component takes lexicalized dependency paths as input, (2) an additional input layer takes binary features as input, (3) a hidden layer combines dependency path embeddings and binary features using rectified linear units, and (4) a softmax classification layer produces output based on the hidden layer state as input. We therefore learn path embeddings jointly with feature detectors based on traditional, binary indicator features.

Given a dependency path X, with steps $x_k \in \{x_1, \ldots, x_n\}$, and a set of binary features B as input, we use the LSTM formalization from equations (1–5) to compute the embedding $\mathbf{e}_n$ at time

[1] We experimented with different sequential orders and found this to lead to the best validation set results.

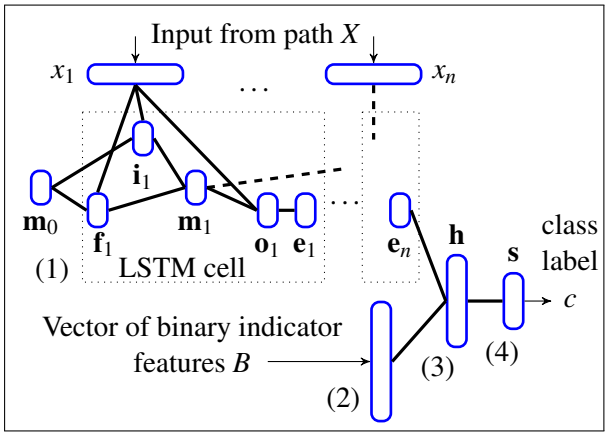

Figure 3: Neural model for joint learning of path embeddings and higher-order features: The path sequence $x_1 \ldots x_n$ is fed into a LSTM layer, a hidden layer $\mathbf{h}$ combines the final embedding $\mathbf{e}_n$ and binary input features B, and an output layer $\mathbf{s}$ assigns the highest probable class label c.

step n and formalize the state of the hidden layer $\mathbf{h}$ and softmax output $\mathbf{s}_c$ for each class category c as follows:

$$\mathbf{h} = \max(0, \mathbf{W}^{\text{Bh}} B + \mathbf{W}^{\text{eh}} \mathbf{e}_n + \mathbf{b}^{\text{h}}) \quad (6)$$

$$\mathbf{s}_c = \frac{\mathbf{W}_c^{\text{es}} \mathbf{e}_n + \mathbf{W}_c^{\text{hs}} \mathbf{h} + \mathbf{b}_c^{\text{s}}}{\Sigma_i (\mathbf{W}_i^{\text{es}} \mathbf{e}_n + \mathbf{W}_i^{\text{hs}} \mathbf{h} + \mathbf{b}_i^{\text{s}})} \quad (7)$$

3 System Architecture

The overall architecture of our SRL system closely follows that of previous work (Toutanova et al., 2008; Björkelund et al., 2009) and is depicted in Figure 4. We use a pipeline that consists of the following steps: predicate identification and disambiguation, argument identification, argument classification, and re-ranking. The neural-network components introduced in Section 2 are used in the last three steps. The following sub-sections describe all components in more detail.

3.1 Predicate Identification and Disambiguation

Given a syntactically analyzed sentence, the first two steps in an end-to-end SRL system are to identify and disambiguate the semantic predicates in the sentence. Here, we focus on verbal and nominal predicates but note that other syntactic categories have also been construed as predicates in the NLP literature (e.g., prepositions; Srikumar and Roth (2013)). For both identification and disambiguation steps, we apply the same logistic re-

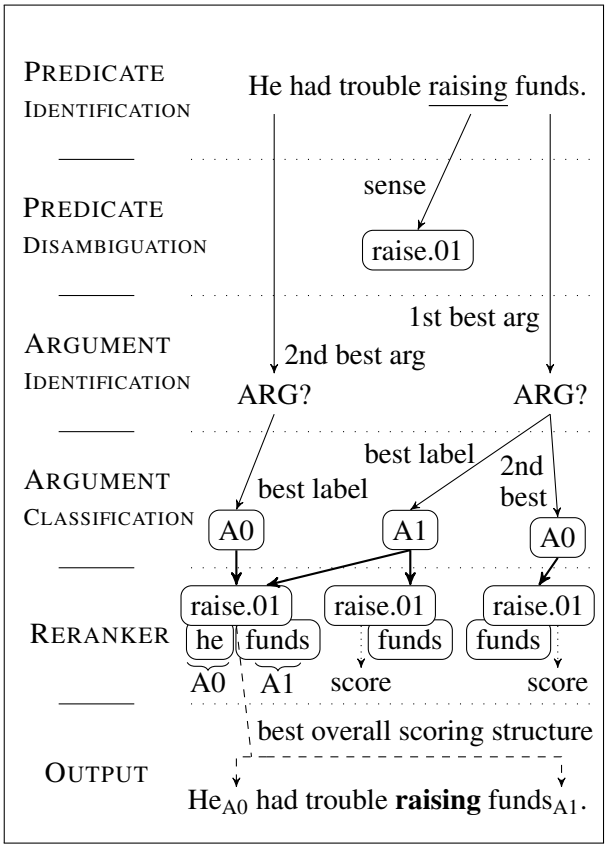

Figure 4: Pipeline architecture of our SRL system.

gression classifiers used in the SRL components of mate-tools (Björkelund et al., 2010). The classifiers for both tasks make use of a range of lexico-syntactic indicator features, including predicate word form, its predicted part-of-speech tag as well as dependency relations to all syntactic children.

3.2 Argument Identification and Classification

Given a sentence and a set of sense-disambiguated predicates in it, the next two steps of our SRL system are to identify all arguments of each predicate and to assign suitable role labels to them. For both steps, we train several LSTM-based neural network models as described in Section 2. In particular, we train separate networks for nominal and verbal predicates and for identification and classification. Following the findings of earlier work (Xue and Palmer, 2004), we assume that different feature sets are relevant for the respective tasks and hence different embedding representations should be learned. As binary input features, we use the following sets from the SRL literature (Björkelund et al., 2010).

Argument labeling step	forget gate	memory→gates	$\|e\|$	$\|h\|$	alpha	dropout rate
Identification (verb)	−	+	25	90	0.0006	0.42
Identification (noun)	−	+	16	125	0.0009	0.25
Classification (verb)	+	−	5	300	0.0155	0.50
Classification (noun)	−	−	88	500	0.0055	0.46

Table 2: Hyperparameters selected for best models and training procedures

Lexico-syntactic features Word form and word category of the predicate and candidate argument; dependency relations from predicate and argument to their respective syntactic heads; full dependency path sequence from predicate to argument.

Local context features Word forms and word categories of the candidate argument's and predicate's syntactic siblings and children words.

Other features Relative position of the candidate argument with respect to the predicate (left, self, right); sequence of part-of-speech tags of all words between the predicate and the argument.

3.3 Reranker

As all argument identification (and classification) decisions are independent of one another, we apply as the last step of our pipeline a global reranker. Given a predicate p, the reranker takes as input the n best sets of identified arguments as well as their n best label assignments and predicts the best overall argument structure. We implement the reranker as a logistic regression classifier, with hidden and embedding layer states of identified arguments as features, offset by the argument label, and a binary label as output (1: best predicted structure, 0: any other structure). At test time, we select the structure with the highest overall score, which we compute as the geometric mean of the global regression and all argument-specific scores.

4 Experiments

In this section, we demonstrate the usefulness of dependency path embeddings for semantic role labeling. Our hypotheses are that (1) modeling dependency paths as sequences will lead to better representations for the SRL task, thus increasing labeling precision overall, and that (2) embeddings will address the problem of data sparsity, leading to higher recall. To test both hypotheses, we experiment on the in-domain and out-of-domain test sets provided in the CoNLL-2009 shared task (Hajič et al., 2009) and compare results of our system, henceforth PathLSTM, with systems that do not involve path embeddings. We compute precision, recall and F_1-score using the official CoNLL-2009 scorer.[2] The code is available at `https://github.com/microth/PathLSTM`.

Model selection We train argument identification and classification models using the XLBP toolkit for neural networks (Monner and Reggia, 2012). The hyperparameters for each step were selected based on the CoNLL 2009 development set. For direct comparison with previous work, we use the same preprocessing models and predicate-specific SRL components as provided with mate-tools (Bohnet, 2010; Björkelund et al., 2010). The types and ranges of hyperparameters considered are as follows: learning rate $\alpha \in [0.00006, 0.3]$, dropout rate $d \in [0.0, 0.5]$, and hidden layer sizes $|e| \in [0, 100]$, $|h| \in [0, 500]$. In addition, we experimented with different gating mechanisms (with/without forget gate) and memory access settings (with/without connections between all gates and the memory layer, cf. Section 2). The best parameters were chosen using the Spearmint hyperparameter optimization toolkit (Snoek et al., 2012), applied for approx. 200 iterations, and are summarized in Table 2.

Results The results of our in- and out-of-domain experiments are summarized in Tables 3 and 5, respectively. We present results for different system configurations: 'local' systems make classification decisions independently, whereas 'global' systems include a reranker or other global inference mechanisms; 'single' refers to one model and 'ensemble' refers to combinations of multiple models.

In the in-domain setting, our PathLSTM model achieves 87.7% (single) and 87.9% (ensemble) F_1-score, outperforming previously published best re-

[2] Some recently proposed SRL models are only evaluated on the CoNLL 2005 and 2012 data sets, which lack nominal predicates or dependency annotations. We do not list any results from those models here.

System (local, single)	P	R	F_1
Björkelund et al. (2010)	87.1	84.5	85.8
Lei et al. (2015)	–	–	86.6

sults by 0.4 and 0.2 percentage points, respectively. At a F_1-score of 86.7%, our local model (using no reranker) reaches the same performance as state-of-the-art local models. Note that differences in results between systems might originate from the application of different preprocessing techniques as each system comes with its own syntactic components. For direct comparison, we evaluate against mate-tools, which use the same preprocessing techniques as PathLSTM. In comparison, we see improvements of +0.8–1.0 percentage points absolute in F_1-score.

In the out-of-domain setting, our system achieves new state-of-the-art results of 76.1% (single) and 76.5% (ensemble) F_1-score, outperforming the previous best system by Roth and Woodsend (2014) by 0.2 and 0.6 absolute points, respectively. In comparison to mate-tools, we observe absolute improvements in F_1-score of +0.4–0.8%.

Discussion To determine the sources of individual improvements, we test PathLSTM models without specific feature types and directly compare PathLSTM and mate-tools, both of which use

the same preprocessing methods. Table 4 presents in-domain test results for our system when specific feature types are omitted. The overall low results indicate that a combination of dependency path embeddings and binary features is required to identify and label arguments with high precision.

Figure 5 shows the effect of dependency path embeddings at mitigating sparsity: if the path between a predicate and its argument has not been observed at training time or only infrequently, conventional methods will often fail to assign a role. This is represented by the recall curve of mate-tools, which converges to zero for arguments with unseen paths. The higher recall curve for PathLSTM demonstrates that path embeddings can alleviate this problem to some extent. For unseen paths, we observe that PathLSTM improves over mate-tools by an order of magnitude, from 0.9% to 9.6%. The highest absolute gain, from 12.8% to 24.2% recall, can be observed for dependency paths that occurred between 1 and 10 times during training.

Figure 7 plots role labeling performance for sentences with varying number of words. There are two categories of sentences in which the improvements of PathLSTM are most noticeable: Firstly, it better handles short sentences that contain expletives and/or nominal predicates (+0.8% absolute in F_1-score). This is probably due to the fact that our learned dependency path representations are lexicalized, making it possible to model

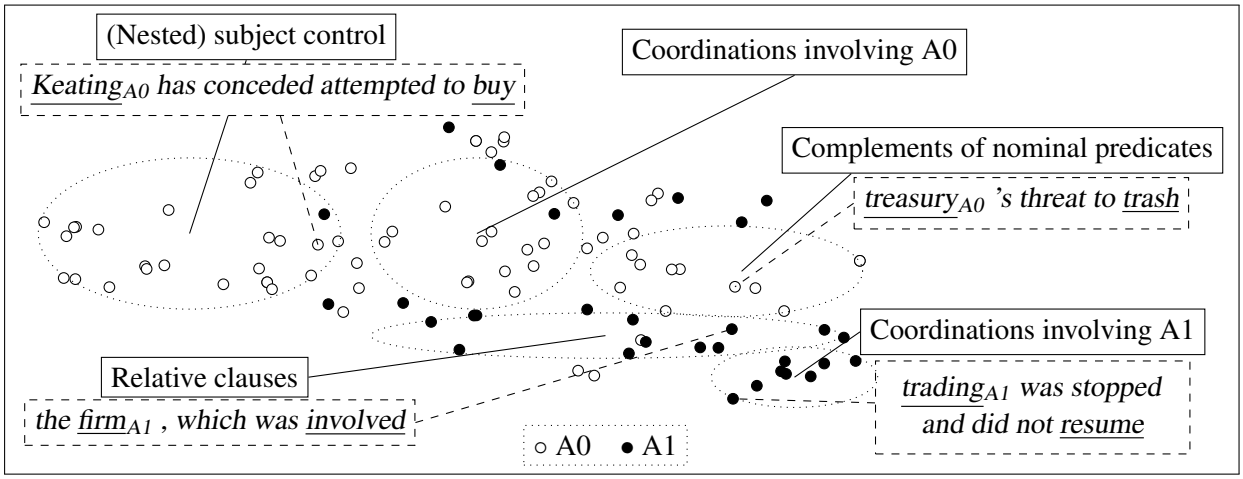

Figure 6: Dots correspond to the path representation of a predicate-argument instance in 2D space. White/black color indicates A0/A1 gold argument labels. Dotted ellipses denote instances exhibiting related syntactic phenomena (see rectangles for a description and dotted rectangles for linguistic examples). Example phrases show actual output produced by PathLSTM (underlined).

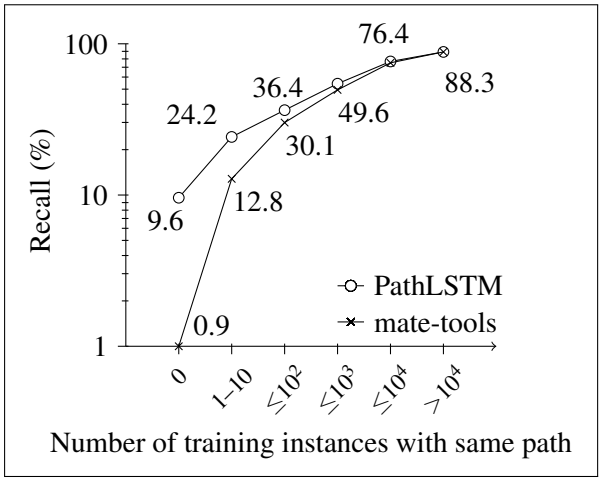

Figure 5: Results on in-domain test instances, grouped by the number of training instances that have an identical (unlexicalized) dependency path.

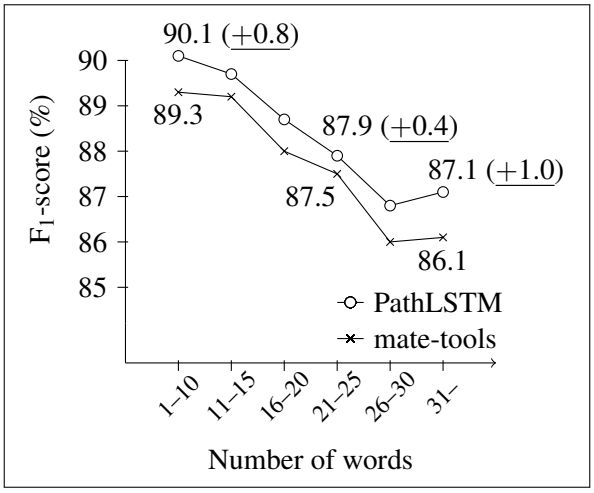

Figure 7: Results by sentence length. Improvements over mate-tools shown in parentheses.

argument structures of different nominals and distinguishing between expletive occurrences of 'it' and other subjects. Secondly, it improves performance on longer sentences (up to +1.0% absolute in F_1-score). This is mainly due to the handling of dependency paths that involve complex structures, such as coordinations, control verbs and nominal predicates.

We collect instances of different syntactic phenomena from the development set and plot the learned dependency path representations in the embedding space (see Figure 6). We obtain a projection onto two dimensions using t-SNE (Van der Maaten and Hinton, 2008). Interestingly, we can see that different syntactic configurations are clustered together in different parts of the space and that most instances of the PropBank roles A0 and A1 are separated. Example phrases in the figure highlight predicate-argument pairs that are correctly labeled by PathLSTM but not by mate-tools. Path embeddings are essential for handling these cases as indicator features do not generalize well enough.

Finally, Table 6 shows results for nominal and verbal predicates as well as for different (gold) role labels. In comparison to mate-tools, we can see that PathLSTM improves precision for all argument types of nominal predicates. For verbal predicates, improvements can be observed in

Predicate POS & Role Label	PathLSTM		Improvement over mate-tools	
	P (%)	R (%)	P (%)	R (%)
verb / A0	90.8	**89.2**	−0.4	+1.8
verb / A1	91.0	**91.9**	+0.0	+1.1
verb / A2	**84.3**	76.9	+1.5	+0.0
verb / AM	**82.2**	72.4	+2.9	−2.0
noun / A0	**86.9**	**78.2**	+0.8	+3.3
noun / A1	**87.5**	**84.4**	+2.6	+2.2
noun / A2	**82.4**	**76.8**	+1.0	+2.1
noun / AM	**79.5**	69.2	+0.9	−2.8

Table 6: Results by word category and role label.

terms of recall of proto-agent (A0) and proto-patient (A1) roles, with slight gains in precision for the A2 role. Overall, PathLSTM does slightly worse with respect to modifier roles, which it labels with higher precision but at the cost of recall.

5 Path Embeddings in other Languages

In this section, we report results from additional experiments on Chinese, German and Spanish data. The underlying question is to which extent the improvements of our SRL system for English also generalize to other languages. To answer this question, we train and test separate SRL models for each language, using the system architecture and hyperparameters discussed in Sections 3 and 4, respectively.

We train our models on data from the CoNLL-2009 shared task, relying on the same features as one of the participating systems (Björkelund et al., 2009), and evaluate with the official scorer. For direct comparison, we rely on the (automatic) syntactic preprocessing information provided with the CoNLL test data and compare our results with the best two systems for each language that make use of the same preprocessing information.

The results, summarized in Table 7, indicate that PathLSTM performs better than the system by Björkelund et al. (2009) in all cases. For German and Chinese, PathLSTM achieves the best overall F_1-scores of 80.1% and 79.4%, respectively.

Chinese	P	R	F_1
PathLSTM	**83.2**	**75.9**	**79.4**
Björkelund et al. (2009)	82.4	75.1	78.6

6 Related Work

Neural Networks for SRL Collobert et al. (2011) pioneered neural networks for the task of semantic role labeling. They developed a feed-forward network that uses a convolution function over windows of words to assign SRL labels. Apart from constituency boundaries, their system does not make use of any syntactic information. Foland and Martin (2015) extended their model and showcased significant improvements when including binary indicator features for dependency paths. Similar features were used by FitzGerald et al. (2015), who include role labeling predictions by neural networks as factors in a global model.

These approaches all make use of binary features derived from syntactic parses either to indicate constituency boundaries or to represent full dependency paths. An extreme alternative has been recently proposed in Zhou and Xu (2015), who model SRL decisions with a multi-layered LSTM network that takes word sequences as input but no syntactic parse information at all.

Our approach falls in between the two extremes: we rely on syntactic parse information but rather than solely making using of sparse binary features, we explicitly model dependency paths in a neural network architecture.

Other SRL approaches Within the SRL literature, recent alternatives to neural network architectures include sigmoid belief networks (Henderson et al., 2013) as well as low-rank tensor models (Lei et al., 2015). Whereas Lei et al. only make use of dependency paths as binary indicator features, Henderson et al. propose a joint model for syntactic and semantic parsing that learns and ap-

plies incremental dependency path representations to perform SRL decisions. The latter form of representation is closest to ours, however, we do not build syntactic parses incrementally. Instead, we take syntactically preprocessed text as input and focus on the SRL task only.

Apart from more powerful models, most recent progress in SRL can be attributed to novel features. For instance, Deschacht and Moens (2009) and Huang and Yates (2010) use latent variables, learned with a hidden markov model, as features for representing words and word sequences. Zapirain et al. (2013) propose different selection preference models in order to deal with the sparseness of lexical features. Roth and Woodsend (2014) address the same problem with word embeddings and compositions thereof. Roth and Lapata (2015) recently introduced features that model the influence of discourse on role labeling decisions.

Rather than coming up with completely new features, in this work we proposed to revisit some well-known features and represent them in a novel way that generalizes better. Our proposed model is inspired both by the necessity to overcome the problems of sparse lexico-syntactic features and by the recent success of SRL models based on neural networks.

Dependency-based embeddings The idea of embedding dependency structures has previously been applied to tasks such as relation classification and sentiment analysis. Xu et al. (2015) and Liu et al. (2015) use neural networks to embed dependency paths between entity pairs. To identify the relation that holds between two entities, their approaches make use of pooling layers that detect parts of a path that indicate a specific relation. In contrast, our work aims at modeling an individual path as a complete sequence, in which every item is of relevance. Tai et al. (2015) and Ma et al. (2015) learn embeddings of dependency structures representing full sentences, in a sentiment classification task. In our model, embeddings are learned jointly with other features, and as a result problems that may result from erroneous parse trees are mitigated.

7 Conclusions

We introduced a neural network architecture for semantic role labeling that jointly learns embeddings for dependency paths and feature combinations. Our experimental results indicate that our model substantially increases classification performance, leading to new state-of-the-art results. In a qualitive analysis, we found that our model is able to cover instances of various linguistic phenomena that are missed by other methods.

Beyond SRL, we expect dependency path embeddings to be useful in related tasks and downstream applications. For instance, our representations may be of direct benefit for semantic and discourse parsing tasks. The jointly learned feature space also makes our model a good starting point for cross-lingual transfer methods that rely on feature representation projection to induce new models (Kozhevnikov and Titov, 2014).

Abstract

Intelligent assistants on mobile devices, such as Siri, have recently gained considerable attention as novel applications of dialogue technologies. A tremendous amount of real users of intelligent assistants provide us with an opportunity to explore a novel task of predicting whether users will continually use their intelligent assistants in the future. We developed prediction models of prospective user engagement by using large-scale user logs obtained from a commercial intelligent assistant. Experiments demonstrated that our models can predict prospective user engagement reasonably well, and outperforms a strong baseline that makes prediction based past utterance frequency.

1 Introduction

Intelligent assistants on mobile devices, such as Siri,[1] have recently gained considerable attention as novel applications of dialogue technologies (Jiang et al., 2015). They receive instructions from users via voice control to execute a wide range of tasks (*e.g.*, searching the Web, setting alarms, making phone calls, and so on). Some are able to even chat or play games with users (Kobayashi et al., 2015).

Intelligent assistants possess a unique characteristic as an object of dialogue study. Popular intelligent assistants have thousands or even millions of real users, thanks to the prevalence of mobile devices. Some of those users continually use intelligent assistants for a long period of time, while others stop using them after a few trials. Such user behaviors are rarely observed in conventional experimental environments, where dialogue systems have only a small number of experimental participants who almost always continue to use the systems for the whole duration of the experiment.

This paper explores a novel task of predicting whether a user will continue to use intelligent assistants in the future (This task is referred to as *prospective user engagement prediction* and its definition is given in Section 3). We attempt to develop such a prediction model, which would contribute to enhancing intelligent assistants in many ways. For example, if users who are likely to stop using systems can be identified, intelligent assistants can take actions to gain or maintain their interest (*e.g.*, by sending push notifications).

This task is related to, but is significantly different from, user engagement detection, which has been extensively explored in prior dialogue studies (Wang and Hirschberg, 2011; Forbes-Riley et al., 2012; Forbes-Riley and Litman, 2013; Oertel and Salvi, 2013). The prior studies attempt to predict how strongly users are currently engaged in dialogues with systems. On the other hand, the goal of this study is to predict how strongly users will be engaged with intelligent assistants in the future. The largest difference lies in whether the prediction target is user engagement at present or in the future. Also, our definition of engagement is slightly different from the prior ones. In this study, engagement is considered as a sentiment as to whether users like intelligent assistants and feel like they want to use them continually.

To develop and evaluate models of prospective user engagement prediction, we exploit large-scale user logs obtained from a commercial intelligent assistant. Since monitoring users' long-term behaviors is considered crucial for precise prediction of their prospective engagement, we tailor various features by extracting usage patterns from a long history of user dialogues. The resulting features are contrastive to those previously used for user

[1] http://www.apple.com/ios/siri

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1203–1212,
Berlin, Germany, August 7-12, 2016.

engagement detection, in which features are basically extracted from a single user utterance.

Experimental results demonstrated that our models are able to predict prospective user engagement reasonably well and are overwhelmingly better than a strong baseline that makes predictions based on past utterance frequency. We also discuss the trade-off between prediction accuracy and instancy. Specifically, we investigate how the prediction performance improves as we wait for more user dialogues to be collected.

2 Yahoo! Voice Assist

This section summarizes *Yahoo! Voice Assist*[2] (hereafter Voice Assist), a commercial intelligent assistant that is investigated in this study. Although our investigation exclusively focused on this system, we will discuss how our findings can be generalized to other intelligent assistants in Section 5.5

Table 1 illustrates example dialogues of Voice Assist users.[3] As illustrated, Voice Assist offers a variety of functions to mobile users. They are largely categorized into two types:

device operation Voice Assist allows users to operate mobile devices through dialogue. This includes setting alarms, making phone calls, searching the Web, launching an app, and so on (*e.g.*, **V1**, **V3**, **V4**, and **V5**).

chat Voice Assist can give greetings to, have conversations with, and play games with users (*e.g.*, **V2** and **V6**). In contrast to device operations for accomplishing certain tasks, these functions are offered for fun or for facilitating smooth communication.

Voice Assist currently supports 66 functions (including setting alarms, the word chain game, etc.) and they can further be classified into fine-grained types, although a detailed description of them is beyond the scope of this paper.

Voice Assist users can register personal profile such as their home address and birthday, with which the system makes personalized responses. For example, the home address are used to estimate users' location when launching weather forecast apps (*i.e.*, response **V3**), while knowing birthdays allows Voice Assist to send greeting messages to users on their birthdays.

U1	Wake me up at 8 o'clock tomorrow.
V1	OK. Set the alarm to 8 am. (show the timer configuration)
U2	Good morning.
V2	Good morning. Thank you for talking to me.
U3	Check today's weather.
V3	Tokyo's weather will be fine today. (launch weather forecast app)
U4	From Tokyo to Kyoto.
V4	A rapid express is available at 9:30. (launch transit app to show timetable)
U5	What time will it arrive?
V5	It will arrive at Kyoto at 11:50. (show the timetable again)
U6	Let's play the word chain game.
V6	OK. Apple...

Table 1: Example dialogues of Voice Assist users. **U** and **V** indicate the user and Voice Assist, respectively. The notes in parentheses represent actions that Voice Assist takes after the responses.

3 Prospective User Engagement Prediction

This section specifies the task of prospective user engagement prediction. We first explain the user log data used in our experiments. We then describe two kinds of task settings.

3.1 User log data

We conducted an empirical study in which we examined Voice Assist user logs. We randomly sampled 348,295 users who used the system at least once from March 2015 to June 2015 (16 weeks) and extracted all their dialogue histories during that period. The log data included 7,472,915 utterances in total.

Table 2 illustrates examples of user logs. We used the following seven attributes: user ID, nickname, birthday, time stamp, user utterance, system response, and response type. Because it is not mandatory to register the personal profiles (including nicknames, birthdays, etc.), they are sometimes missing, as indicated by N/A in the table. The response type represents the 66 functions supported by Voice Assist. The time stamps were used to segment utterances into sessions, as rep-

[2] `http://v-assist.yahoo.co.jp` (in Japanese)

[3] Because Voice Assist supports only Japanese, all utterances are made in Japanese. In this paper, we present English translations rather than the original Japanese to facilitate non-Japanese readers' understanding.

ID	Nickname	Birthday	Time Stamp	Use Utterance	System Response	Type
A	John	2000-1-1	2015-3-1 23:50	Wake me up at 8 am tomorrow.	OK. Set the alarm to 8 am.	ALARM
			2015-3-2 08:10	Good morning.	Good morning.	CHAT
			2015-3-2 08:13	Check today's weather.	Tokyo's weather will be fine today.	WEATHER
B	N/A	2002-1-1	2015-3-1 08:00	From Tokyo to Kyoto.	A rapid express is available at 9:30.	TRANSIT
			2015-3-1 08:01	What time will it arrive?	It will arrive at Kyoto at 11:50.	TRANSIT
			2015-3-5 19:10	Let's play the word chain game.	OK. Apple...	WORD CHAIN

Table 2: User log examples. The dashed line represents the session boundary.

resented by dashed lines in the table. We follow (Jiang et al., 2015) to define sessions as utterance sequences in which the interval of two adjacent utterances does not exceed 30 minutes.

3.2 Task definition

We propose two types of prospective user engagement prediction tasks. In both tasks, we collect user dialogues from the first eight weeks of the user logs (referred to as *observation period*. We will discuss on length of observation period in Section 5.4), and then use those past dialogues to predict whether users are engaged with the intelligent assistant in the last eight weeks of the log data (referred to as *prediction period*).[4] We specifically explored two prediction tasks as follows.

Dropout prediction The first task is to predict whether a given user will not at all use the system in the prediction period. This task is referred to as *dropout prediction* and is formulated as a binary classification problem. The model of dropout prediction would allow intelligent assistants to take proactive actions against users who are likely to stop using the system. There are 71,330 dropout users, who does not at all use the system in the prediction period, among 275,630 in our data set.

Engagement level prediction The second task aims at predicting how frequently the system will be used in the prediction period by a given user. Because there are outliers, or heavy users, who use the system extremely frequently (one user used the system as many as 1,099 times in the eight weeks), we do not attempt to directly predict the number of utterances or sessions. Instead, we define engagement levels as detailed below, and aim at predicting those values.

The engagement levels are defined as follows. First, users are sorted in the ascending order of the number of sessions they made in the prediction period. We then split users into four equally-sized groups. The engagement levels of users in the four groups are defined as 1, 2, 3, and 4, respectively (Table 3). Note that a larger value of the engagement level means that the users are more engaged with the intelligent assistants. This task is referred to as *engagement level prediction* and is formulated as a regression problem.

Level	# of sessions	# of users
1	0	71,330
2	1–3	66,626
3	4–13	69,551
4	14–	68,123

Table 3: User distribution over the four engagement levels. The second column represents intervals of the number of sessions corresponding to the four levels.

The engagement level prediction has different applications from the dropout prediction. For example, it would allow us to detect in advance that a user's engagement level will change from four to three in the near future. It is beyond the scope of dropout prediction task to foresee such a change.

4 Features

The dropout prediction is performed using linear support vector machine (SVM) (Fan et al., 2008), while the engagement level prediction is performed using support vector regression (SVR) (Smola and Schölkopf, 2004) on the same feature set. Here, we divide the features into four categories by their function: utterance frequency features, response frequency features, time interval features, and user profile features. Table 4 lists these features.

4.1 Utterance frequency features

Here, we describe the features related to utterance frequency. These features attempt to capture our

[4] We removed users from the log data if the number of sessions was only once in the observation period, because such data lack a sufficient amount of dialogue histories for making a reliable prediction.

#Features	Name	Definition
1	**Utterance**	The number of utterances
7	**Utterance**w**Weeks**	The number of utterances in recent w weeks
1	**LongUtterance**	The number of lengthy utterances
1	**UrgedUtterance**	The number of utterances made in response to push notifications
1	**Restatement**	The number of restatement utterances
100	**UtteranceTopic**i	The number of utterances including words in the i-th cluster
1	**Session**	The number of sessions
7	**Session**w**Weeks**	The number of sessions in recent w weeks
7	**SessionByDay**	The number of sessions during each day of the week
66	**Response**(t)	The number of responses with response type t
66	**FirstResponse**(t)	**Response**(t) computed by using only the first responses in sessions
1	**LongResponse**	The number of lengthy responses
1	**ErrorMessage**	The number of error messages
1	**MaxInterval**	Max days between adjacent utterances
1	**MinInterval**	Min days between adjacent utterances
1	**AvgInterval**	Average days between adjacent utterances
1	**InactivePeriod**	Days from the last utterance date
66	**InactivePeriod**(t)	**InactivePeriod** computed for each type of the last response
1	**Nickname**	Whether or not a user has provided nickname information
1	**Birthday**	Whether or not a user has provided birthday information
6	**Age**	User's age category

Table 4: List of features. The utterance frequency features, response frequency features, and time interval features are all scaled.

intuition that users who frequently use intelligent assistants are likely to be engaged with them.

Utterance The number of utterances in the observation period. For scaling purposes, the value of this feature is set to $\log_{10}(x+1)$, where x is the number of utterances. The same scaling is performed on all features but user profile features.

Utterance$w$**Weeks** The number of utterances in the last w $(1 \leq w < 8)$ weeks of the observation period.

LongUtterance The number of lengthy utterances (more than 20 characters long). Jiang et al. (2015) pointed out that long utterances are prone to cause ASR errors. Since ASR errors are a factor that decreases user engagement, users who are prone to make long utterances are likely to be disengaged.

UrgedUtterance The number of utterances made in response to push notifications sent from the system. We expect that engaged users tend to react to push notifications.

Restatement The number of restatements made by users. Jiang et al. (2015) found that users tend to repeat previous utterances in case of ASR errors. An utterance is regarded as a restatement of the previous one if their normalized edit distance (Li and Liu, 2007) is below 0.5.

UtteranceTopic$i$ The number of utterances including a keyword belonging to i-th word cluster. To induce the word clusters, 100-dimensional word embeddings are first learned from the log data using WORD2VEC (Mikolov et al., 2013)[5], and then K-means clustering (K=100) is performed (MacQueen, 1967). All options of WORD2VEC are set to the default values. These features aim at capturing topics on utterances or speech acts. Table 5 illustrates example words in the clusters. For example, utterances including words in the cluster ID 36 and 63 are considered to be greeting acts and sports-related conversations, respectively.

[5] https://code.google.com/archive/p/word2vec

Cluster ID	Example words
14 (Weather)	pollen, typhoon, temperature
23 (Curse)	die, stupid, shit, shurrup, dorf
36 (Greeting)	thanks, good morning, hello
48 (Sentiment)	funny, cute, good, awesome
63 (Sports)	World cup, Nishikori, Yankees

Table 5: Example words in the clusters. Cluster names (presented in parentheses) are manually provided by the authors to help readers understand the word clusters.

Session The number of sessions in the observation period.

Session$w$Weeks The number of sessions in the last w $(1 \leq w < 8)$ weeks of the observation period.

SessionByDay The number of sessions in each day of week. There are seven different features of this type.

4.2 Response frequency features

Here, we describe the features of the response frequency.

Response(t) The number of system responses with response type t.

FirstResponse(t) **Response(t)** features that are computed by using only the first responses in sessions. Our hypothesis is that first responses in sessions crucially affect user engagement.

LongResponse The number of lengthy responses (more than 50 characters long). Because longer responses require a longer reading time, they are prone to irritate users and consequently decrease user engagement.

ErrorMessage The number of error messages. Voice Assist returns error messages (*Sorry, I don't know.*) when it fails to find appropriate responses to the user's utterances. We consider that these error messages decrease user engagement.

4.3 Time interval features

Here, we describe the features related to the session interval times.

MaxInterval The maximum interval (in days) between adjacent sessions in the observation period.

MinInterval The minimum interval (in days) between adjacent sessions in the observation period.

AvgInterval The average interval (in days) between adjacent sessions in the observation period.

InactivePeriod The time span (in days) from the last utterance to the end of the observation period.

InactivePeriod(t) **InactivePeriod** computed separately for each type t of the last response.

4.4 User profile features

Here, we describe the features of the user's profile information. Since it is not mandotory for users to register their profiles, we expect that those who have provided profile information are likely to be engaged with the system.

Nickname A binary feature representing whether or not the user has provided their nickname.

Birthday A binary feature representing whether or not the user has provided their birthday.

Age Six binary features representing the user's age. They respectively indicate whether the user is less than twenty years, in their 20's, 30's, 40's, or 50's, or is more than 60 years old. Note that these features are available only if the user has provided their birthday.

5 Experiments

In this section, we describe our experimental results and discuss them.

5.1 Experimental settings

We randomly divided the log data into training, development, and test sets with the ratio of 8:1:1. Note that we confirmed that the users in different data sets do not overlap with each other. We trained the model with the training set and optimized hyperparameters with the development set. The test set was used for a final blind test to evaluate the learnt model.

We used the LIBLINEAR tool (Fan et al., 2008) to train the SVM for the dropout prediction and

	Accuracy	F–measure
Baseline	56.8	0.482

Utterance frequency	70.2	0.578
Response frequency	54.8	0.489
Time interval	74.6	0.617
User profile	39.9	0.406

Table 6: Classification accuracies and F–measures in the dropout prediction task.

	Precision	Recall
Baseline	0.350	0.774
Proposed	**0.553**	0.714
Utterance frequency	0.458	0.785
Response frequency	0.346	**0.831**
Time interval	0.507	0.789
User profile	0.273	0.793

Table 7: Precisions and Recalls in the dropout prediction task.

the SVR for the engagement level prediction task. We optimized the C parameter on the development set. In the dropout prediction task, we used the `-w` option to weigh the C parameter of each class with the inverse ratio of the number of users in that class. We also used the `-B` option to introduce the bias term.

Next, we describe the evaluation metrics. We used accuracy and F_1–measure in the dropout prediction task. Mean squared error (MSE) and Spearman rank correlation coefficient were used in the engagement level prediction task. These evaluation metrics are commonly used in classification and regression tasks.

We compare the proposed models with baseline method. Because we have no previous work on both tasks, we defined baseline method of our own. The baseline method was trained in the same framework as the proposed methods except that they used only **Session** feature. We chose **Session** for baseline because frequency of use features such as **Session** were shown predictive to similar tasks (Kloft et al., 2014; Sadeque et al., 2015) to prospective user engagement.

5.2 Results

Table 6 illustrates the result of dropout prediction task. The first row compares the proposed method with the baseline. We can see that the proposed

	MSE	Spearman
Baseline	0.784	0.595
Proposed	**0.578**	**0.727**
Utterance frequency	0.632	0.693
Response frequency	0.798	0.584
Time interval	0.645	0.692
User profile	1.231	0.146

Table 8: MSE and Spearman's ρ in the engagement level prediction task.

model outperforms the baseline. This indicates the effectiveness of our feature set. The second row illustrates the performances of the proposed method when only one feature type is used. This result suggests that the utterance frequency and time interval features are especially useful, while the combination of all types of features performs the best. We conducted McNemar test (McNemar, 1947) to investigate the significance of these improvements, and confirmed that all improvements are statistically significant ($p < 0.01$).

Table 7 shows the precisions and the recalls of dropout prediction task. As shown in Table 7, the precision of the proposed method performs the best while the recall is worst. We consider that the performance of the precision is more important for our model because taking proactive actions against users who are likely to stop using the system is one of the assumed applications. Taking proactive actions (*e.g.*, push notifications) against users continually using the system might irritate them and de-

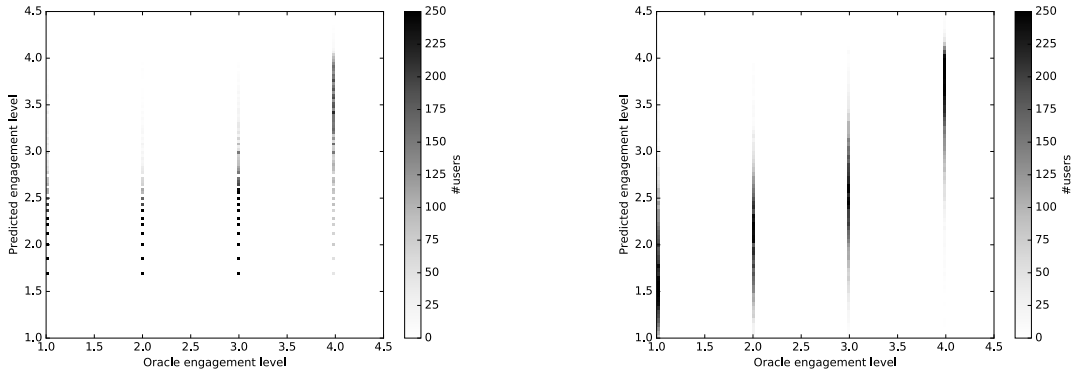

Figure 2: Correlation between the oracle engagement levels and the ones predicted by the baseline method (left) and by the proposed method (right).

crease their user engagement. Therefore, the rate of the users who actually intend to stop using the system in the users predicted as dropout affects the effectiveness of these proactive actions. The result that the precision of the proposed method is 0.553 and that of the baseline is 0.350 is, in other words, using the proposed model improves the effectiveness by 20% absolute in taking these actions.

Figure 1 shows the accuracies per the number of sessions in the observation period of the proposed method and the baseline. The proposed method consistently outperforms the baseline throughout the number of sessions in the observation period. In particular, the proposed method predicts well the dropout of users whose number of sessions is around five compared to the baseline. These results again indicate the effectiveness of the combination of our feature set.

Table 8 shows the result of engagement level prediction task. We again observe similar trends to the dropout prediction task. The proposed method outperforms the baseline. The utterance frequency and time interval features are the most effective, while the combination of all four feature types achieves the best performance in both evaluation metrics.

Figure 2 visualizes the correlation between the oracle engagement levels and the ones predicted by the baseline (left) and by the proposed method (right). We can intuitively reconfirm that the proposed method is able to predict the engagement levels reasonably well.

5.3 Investigation of feature weights

We investigate weights of the features learned by the SVR for figuring out what features contribute to the precise prediction of prospective user engagement.

Table 9 exemplifies features that received large weights for the four feature types. We observe that most features with large positive or negative weights are from the utterance frequency and time interval features. Those include **Session**, **Utterance**, and **InactivePeriod**. It is interesting to see that **UrgedUtterance**, which is based on an utterance type specific to mobile users, also receives a large positive weight.

Further detailed analysis revealed that the proposed model captures some linguistic properties that correlate with the prospective user engagement. For example, **UtteranceTopic36** and **UtteranceTopic23** recieve positive and negative weights, respectively. This follows our intuition since those clusters correspond to greeting and curse words (*c.f.* Table 5). We also observe **Response(WORD CHAIN)**, **Response(QUIZ)** (word association quiz), and **Response(TRIVIA)** (showing some trivia) receive positive weights. This means that playing games or showing some trivia attract users. It is interesting to see that this result is consistent with findings in (Kobayashi et al., 2015). It also follows our intuition that the weight of **ErrorMessage** feature is negative.

5.4 Discussion on length of observation period

Next, we investigate how the length of the observation period affects the prediction performance. We varied the length of the observation periods from one to eight weeks, and evaluated the results (Figure 3).

Figure 3 demonstrates that the model perfor-

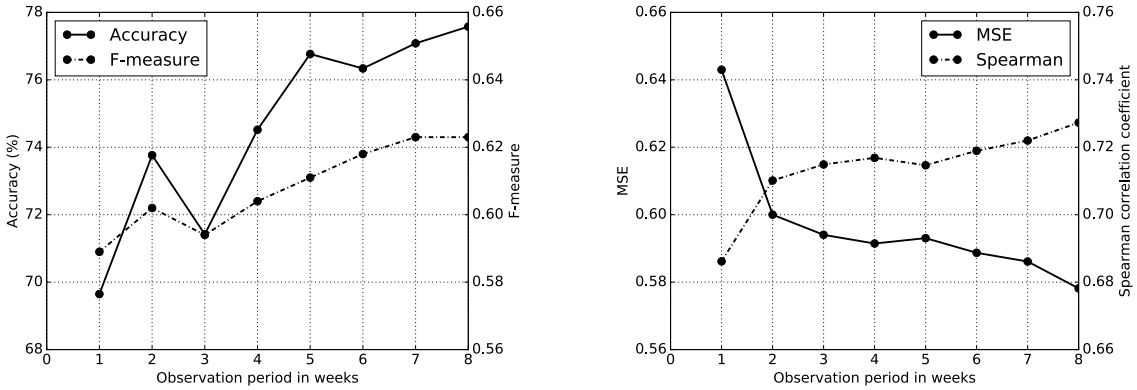

Figure 3: Results of dropout prediction (left) and engagement level prediction (right) across different observation periods (in weeks).

Weight	Feature
0.67	**Session**
0.59	**Utterance**
0.28	**Session7Weeks**
0.26	**UrgedUtterance**
0.02	**UtteranceTopic36**
-0.05	**UtteranceTopic23**
0.08	**Response(WORD CHAIN)**
0.08	**Response(QUIZ)**
0.04	**Response(TRIVIA)**
-0.03	**ErrorMessage**
-0.23	**InactivePeriod(ALARM)**
-0.46	**InactivePeriod**
0.05	**Birthday**
0.04	**Age60s**

Table 9: Feature weights learned by the SVR.

mance generally improves as the observation period becomes longer in both tasks. When we increase the length of the observation period from one week to eight weeks, the accuracy increases by 7.9% in the dropout prediction and Spearman's ρ increases by 4.1 point in the engagement level prediction. The most significant improvements are achieved when we increase the length from one week to two weeks in the three metrics except the F–measure. This suggests that it is generally effective to collect user dialogues of two weeks long, rather than as long as eight weeks or more. This approach would allow to make predictions promptly without waiting for user dialogues to be collected for a long time, while harming accuracy (or other evaluation metrics) as little as possible.

5.5 Application to other intelligent assistants

Here, we discuss how well our approach applies to intelligent assistants other than Voice Assist. The results of this study are considered to apply to other intelligent assistants so long as user logs like the ones in Table 2 are available. The concern is that some attributes in Table 2 may not be available in other systems. In the following, we investigate two attributes, response types and profiles, that are specific to Voice Assist.

We consider that response types like ours are available in user logs of many other intelligent assistants as well. Because our response types mostly correspond to commands issued when operating mobile devices, response types analogous to ours can be obtained by simply logging the commands. Alternatively, it would be possible to employ taggers like (Jiang et al., 2015) to automatically type system responses.

As for profiles, it is likely that similar information is also available in many other intelligent assistants because profile registration is a common function in many IT services including intelligent assistants. For example, Cortana offers greetings and other activities on special days registered by users.[6] Even if user profiles were not at all available, we consider that it would not seriously spoil the significance of this study, because our experiments revealed that user profiles are among the least predictive features.

6 Related Work

Many dialogue studies have explored the issue of detecting user engagement as well as related affects such as interest and uncertainty (Wang and Hirschberg, 2011; Forbes-Riley et al., 2012; Forbes-Riley and Litman, 2013; Oertel and Salvi, 2013). As discussed in Section 1, these studies typically use a single user utterance to predict whether the user is currently engaged in dialogues with systems. We introduced a new perspective on this line of research by exploring models of predicting prospective user engagement in a large-scale empirical study.

Kobayashi et al. (2015) investigated how games played with intelligent assistants affect prospective user engagement. Although their research interest was prospective user engagement like ours, they exclusively studied the effect of playing game, and left other factors unexplored. In addition, they did not develop any prediction models.

Recently, user satisfaction for intelligent assistants gain attention(Jiang et al., 2015; Kiseleva et al., 2016a; Kiseleva et al., 2016b). Jiang et al. (2015) proposed an automatic method of assessing user satisfaction with intelligent assistants. Kiseleva et al. extended the study of Jiang et al. for prediction (2016a) and detailed understanding (2016b) of user satisfaction with intelligent assistants. Although both satisfaction and engagement are affective states worth considering by intelligent assistants, their research goals were quite different from ours. In their studies, user satisfaction was measured as to whether intelligent assistants can accomplish predefined tasks (*e.g.*, checking the exchange rate between US dollars and Australian dollars). This virtually assesses task-level response accuracy, which is a different notion from user engagement.

Nevertheless, we consider that their studies are closely related to ours and indeed helpful for improving the proposed model. Since user satisfaction is considered to greatly affect prospective user engagement, it might be a good idea to use automatically evaluated satisfaction levels as additional features. The proposed model currently uses **ErrorMessage** feature as an alternative that can be implemented with ease.

Several studies have investigated the chances of predicting continuous participation in SNSs such as MOOC and health care forum (Rosé and Siemens, 2014; Kloft et al., 2014; Ramesh et al., 2014; Sadeque et al., 2015). Unlike those studies, this study exclusively investigates a specific type of dialogue system, namely intelligent assistants, and aims at uncovering usage and/or response patterns that strongly affect prospective user engagement. Consequently, many of the proposed features are specially designed to analyze intelligent assistant users rather than SNS participants.

Our work also relates to the evaluation of dialogue systems. Walker et al. (1997) presented the offline evaluation framework for spoken dialog system (PARADISE). They integrate various evaluation metrics such as dialogue success and dialogue costs into one performance measure function. Although our goal is to predict prospective user engagement and different from theirs, some measures (*e.g.*, the number of utterances) are useful to predict prospective user engagement with intelligent assistants.

7 Conclusion

This paper explored two tasks of predicting prospective user engagement with intelligent assistants: dropout prediction and engagement level prediction. The experiments successfully demonstrated that reasonable performance can be archived in both tasks. Also, we examined how the length of the observation period affects prediction performance, and investigated the trade-off between prediction accuracy and instancy. The future work includes using those prediction models in a real service to take targeted actions to users who are likely to stop using intelligent assistants.

Resolving References to Objects in Photographs using the Words-As-Classifiers Model

David Schlangen Sina Zarrieß Casey Kennington
Dialogue Systems Group // CITEC // Faculty of Linguistics and Literary Studies
Bielefeld University, Germany
first.last@uni-bielefeld.de

Abstract

A common use of language is to refer to visually present objects. Modelling it in computers requires modelling the link between language and perception. The "words as classifiers" model of grounded semantics views words as classifiers of perceptual contexts, and composes the meaning of a phrase through composition of the denotations of its component words. It was recently shown to perform well in a game-playing scenario with a small number of object types. We apply it to two large sets of real-world photographs that contain a much larger variety of object types and for which referring expressions are available. Using a pre-trained convolutional neural network to extract image region features, and augmenting these with positional information, we show that the model achieves performance competitive with the state of the art in a reference resolution task (*given expression, find bounding box of its referent*), while, as we argue, being conceptually simpler and more flexible.

1 Introduction

A common use of language is to refer to objects in the shared environment of speaker and addressee. Being able to simulate this is of particular importance for verbal human/robot interfaces (HRI), and the task has consequently received some attention in this field (Matuszek et al., 2012; Tellex et al., 2011; Krishnamurthy and Kollar, 2013).

Here, we study a somewhat simpler precursor task, namely that of resolution of reference to objects in static images (photographs), but use a larger set of object types than is usually done in HRI work ($>$ 300, see below). More formally, the task is to retrieve, given a referring expression e and an image I, the region bb^* of the image that is most likely to contain the referent of the expression. As candidate regions, we use both manually annotated regions as well as automatically computed ones.

As our starting point, we use the "words-as-classifiers" model recently proposed by Kennington and Schlangen (2015). It has before only been tested in a small domain and with specially designed features; here, we apply it to real-world photographs and use learned representations from a convolutional neural network (Szegedy et al., 2015). We learn models for between 400 and 1,200 words, depending on the training data set. As we show, the model performs competitive with the state of the art (Hu et al., 2016; Mao et al., 2016) on the same data sets.

Our background interest in situated interaction makes it important for us that the approach we use is 'dialogue ready'; and it is, in the sense that it supports incremental processing (giving results while the incoming utterance is going on) and incremental learning (being able to improve performance from interactive feedback). However, in this paper we focus purely on 'batch', non-interactive performance.[1]

2 Related Work

The idea of connecting words to what they denote in the real world via perceptual features goes back at least to Harnad (1990), who coined "The Symbol Grounding Problem": "*[H]ow can the semantic interpretation of a formal symbol system be made* intrinsic *to the system, rather than just parasitic on the meanings in our heads?*" The pro-

[1]The code for reproducing the results reported in this paper can be found at `https://github.com/dsg-bielefeld/image_wac`.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1213–1223,
Berlin, Germany, August 7-12, 2016.

posed solution was to link 'categorial representations' with "learned and innate feature detectors that pick out the invariant features of object and event categories from their sensory projections".

This suggestion has variously been taken up in computational work. An early example is Deb Roy's work from the early 2000s (Roy et al., 2002; Roy, 2002; Roy, 2005). In (Roy et al., 2002), computer vision techniques are used to detect object boundaries in a video feed, and to compute colour features (mean colour pixel value), positional features, and features encoding the relative spatial configuration of objects. These features are then associated in a learning process with certain words, resulting in an association of colour features with colour words, spatial features with prepositions, etc., and based on this, these words can be interpreted with reference to the scene currently presented to the video feed.

Of more recent work, that of Matuszek et al. (2012) is closely related to the approach we take. The task in this work is to compute (sets of) referents, given a (depth) image of a scene containing simple geometric shapes and a natural language expression. In keeping with the formal semantics tradition, a layer of logical form representation is assumed; it is not constructed via syntactic parsing rules, however, but by a learned mapping (*semantic parsing*). The non-logical constants of this representation then are interpreted by linking them to classifiers that work on perceptual features (representing shape and colour of objects). Interestingly, both mapping processes are trained jointly, and hence the links between classifiers and non-logical constants on the one hand, and non-logical constants and lexemes on the other are induced from data. In the work presented here, we take a simpler approach that forgoes the level of semantic representation and directly links lexemes and perceptions, but does not yet learn the composition.

Most closely related on the formal side is recent work by Larsson (2015), which offers a very direct implementation of the 'words as classifiers' idea (couched in terms of type theory with records (TTR; (Cooper and Ginzburg, 2015)) and not model-theoretic semantics). In this approach, some lexical entries are enriched with classifiers that can judge, given a representation of an object, how applicable the term is to it. The paper also describes how these classifiers could be trained (or adapted) in interaction. The model is only specified theoretically, however, with hand-crafted classifiers for a small set of words, and not tested with real data.

The second area to mention here is the recently very active one of image-to-text generation, which has been spurred on by the availability of large datasets and competitions structured around them. The task here typically is to generate a description (a caption) for a given image. A frequently taken approach is to use a convolutional neural network (CNN) to map the image to a dense vector (which we do as well, as we will describe below), and then condition a neural language model (typically, an LSTM) on this to produce an output string (Vinyals et al., 2015; Devlin et al., 2015). Fang et al. (2015) modify this approach somewhat, by using what they call "word detectors" first to specifically propose words for image regions, out of which the caption is then generated. This has some similarity to our word models as described below, but again is tailored more towards generation.

Socher et al. (2014) present a more compositional variant of this type of approach where sentence representations are composed along the dependency parse of the sentence. The representation of the root node is then mapped into a multimodal space in which distance between sentence and image representation can be used to guide image retrieval, which is the task in that paper. Our approach, in contrast, composes on the level of denotations and not that of representation.

Two very recent papers carry this type of approach over to the problem of resolving references to objects in images. Both (Hu et al., 2015) and (Mao et al., 2015) use CNNs to encode image information (and interestingly, both combine, in different ways, information from the candidate region with more global information about the image as a whole), on which they condition an LSTM to get a prediction score for fit of candidate region and referring expression. As we will discuss below, our approach has some similarities, but can be seen as being more compositional, as the expression score is more clearly composed out of individual word scores (with rule-driven composition, however). We will directly compare our results to those reported in these papers, as we were able to use the same datasets.

3 The "Words-As-Classifiers" Model

We now briefly review (and slightly reformulate) the model introduced by Kennington and Schlangen (2015). It has several components:

A Model of Word Meanings Let w be a word whose meaning is to be modelled, and let $\mathbf{x}$ be a representation of an object in terms of its visual features. The core ingredient then is a classifier then takes this representation and returns a score $f_w(\mathbf{x})$, indicating the "appropriateness" of the word for denoting the object.

Noting a (loose) correspondence to Montague's (1974) intensional semantics, where the intension of a word is a function from possible worlds to extensions (Gamut, 1991), the *intensional* meaning of w is then defined as the classifier itself, a function from a representation of an object to an "appropriateness score":[2]

$$[\![w]\!]_{obj} = \lambda \mathbf{x}.f_w(\mathbf{x}) \quad (1)$$

(Where $[\![.]\!]$ is a function returning the meaning of its argument, and $\mathbf{x}$ is a feature vecture as given by f_{obj}, the function that computes the representation for a given object.)

The *extension* of a word in a given (here, visual) discourse universe W can then be modelled as a probability distribution ranging over all candidate objects in the given domain, resulting from the application of the word intension to each object ($\mathbf{x}_i$ is the feature vector for object i, $normalize()$ vectorized normalisation, and I a random variable ranging over the k candidates):

$$\begin{aligned}&[\![w]\!]^W_{obj} = \\ &\quad normalize(([\![w]\!]_{obj}(\mathbf{x}_1), \ldots, [\![w]\!]_{obj}(\mathbf{x}_k))) = \\ &\quad normalize((f_w(\mathbf{x}_1), \ldots, f_w(\mathbf{x}_k))) = P(I|w) \end{aligned} \quad (2)$$

Composition Composition of word meanings into phrase meanings in this approach is governed by rules that are tied to syntactic constructions. In the following, we only use simple multiplicative composition for nominal constructions:

$$[\![[_{nom} w_1, \ldots, w_k]]\!]^W = [\![\text{NOM}]\!]^W [\![w_1, \ldots, w_k]\!]^W = \circ_{/N} ([\![w_1]\!]^W, \ldots, [\![w_k]\!]^W) \quad (3)$$

where $\circ_{/N}$ is defined as

$$\begin{aligned}&\circ_{/N} ([\![w_1]\!]^W, \ldots, [\![w_k]\!]^W) = P_\circ(I|w_1, \ldots, w_k) \\ &\quad \text{with } P_\circ(I = i|w_1, \ldots, w_k) = \\ &\quad \frac{1}{Z}(P(I = i|w_1) * \cdots * P(I = i|w_k)) \text{ for } i \in I \end{aligned} \quad (4)$$

(Z takes care that the result is normalized over all candidate objects.)

[2](Larsson, 2015) develops this intension/extension distinction in more detail for his formalisation.

Selection To arrive at the desired extension of a full referring expression—an individual object, in our case—, one additional element is needed, and this is contributed by the determiner. For uniquely referring expressions ("the red cross"), what is required is to pick the most likely candidate from the distribution:

$$[\![the]\!] = \lambda x. \arg\max_{Dom(x)} x \quad (5)$$

$$[\![[the]\ [_{nom} w_1, \ldots, w_k]]\!]^W = \arg\max_{i \in W} [\ [\![[_{nom} w_1, \ldots, w_k]]\!]^W\ ] \quad (6)$$

In other words, the prediction of an expression such as "the brown shirt guy on right" is computed by first getting the responses of the classifiers corresponding to the words, individually for each object. I.e., the classifier for "brown" is applied to objects $o_1, \ldots, o_n$. This yields a vector of responses (of dimensionality n, the number of candidate objects); similarly for all other words. These vectors are then multiplied, and the predicted object is the maximal component of the resulting vector. Figure 1 gives a schematic overview of the model as implemented here, including the feature extraction process.

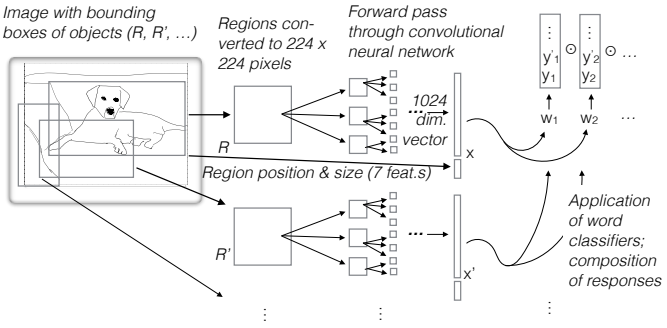

Figure 1: Overview of the model

4 Data: Images & Referring Expressions

SAIAPR TC-12 / ReferItGame The basis of this data set is the IAPR TC-12 image retrieval benchmark collection of "20,000 still natural images taken from locations around the world and comprising an assorted cross-section of still natural images" (Grubinger et al., 2006). A typical example of an image from the collection is shown in Figure 2 on the left.

This dataset was later augmented by Escalante et al. (2010) with segmentation masks identifying objects in the images (an average of 5 objects per image). Figure 2 (middle) gives an example of such a segmentation. These segmentations were

Figure 2: Image 27437 from IAPR TC-12 (left), with region masks from SAIAPR TC-12 (middle); "brown shirt guy on right" is a referring expression in REFERITGAME for the region singled out on the right

done manually and provide close maskings of the objects. This extended dataset is also known as "SAIAPR TC-12" (for "segmented and annotated IAPR TC-12").

The third component is provided by Kazemzadeh et al. (2014), who collected a large number of expressions referring to (pre-segmented) objects from these images, using a crowd-sourcing approach where two players were paired and a director needed to refer to a predetermined object to a matcher, who then selected it. (An example is given in Figure 2 (right).) This corpus contains 120k referring expressions, covering nearly all of the 99.5k regions from SAIAPR TC-12.[3] The average length of a referring expression from this corpus is 3.4 tokens. The 500k token realise 10,340 types, with 5785 hapax legomena. The most frequent tokens (other than articles and prepositions) are "left" and "right", with 22k occurrences. (In the following, we will refer to this corpus as REFERIT.)

This combination of segmented images and referring expressions has recently been used by Hu et al. (2015) for learning to resolve references, as we do here. The authors also tested their method on region proposals computed using the EdgeBox algorithm (Zitnick and Dollár, 2014). They kindly provided us with this region proposal data (100 best proposals per image), and we compare our results on these region proposals with theirs below. The authors split the dataset evenly into 10k images (and their corresponding referring expressions) for training and 10k for testing. As we needed more training data, we made a 90/10 split, ensuring that all our test images are from their test split.

MSCOCO / GoogleRefExp / ReferItGame

The second dataset is based on the "Microsoft Common Objects in Context" collection (Lin et al., 2014), which contains over 300k images with object segmentations (of objects from 80 pre-specified categories), object labels, and image captions. Figure 3 shows some examples of images containing objects of type "person".

This dataset was augmented by Mao et al. (2015) with what they call 'unambiguous object descriptions', using a subset of 27k images that contained between 2 and 4 instances of the same object type within the same image. The authors collected and validated 100k descriptions in a crowd-sourced approach as well, but unlike in the ReferItGame setup, describers and validators were not connected live in a game setting.[4] The average length of the descriptions is 8.3 token. The 790k token in the corpus realise 14k types, with 6950 hapax legomena. The most frequent tokens other than articles and prepositions are "man" (15k occurrences) and "white" (12k). (In the following, we will refer to this corpus as GREXP.)

The authors also computed automatic region proposals for these images, using the multibox method of Erhan et al. (2014) and classifying those using a model trained on MSCOCO categories, retaining on average only 8 per image. These region proposals are on average of a much higher quality than those we have available for the other dataset.

As mentioned in (Mao et al., 2015), Tamara Berg and colleagues have at the same time used their ReferItGame paradigm to collect referring expressions for MSCOCO images as well. Upon request, Berg and colleagues also kindly provided us with this data—140k referring expressions, for 20k images, average length 3.5 token, 500k token altogether, 10.3k types, 5785 hapax legomena; most frequent also "left" (33k occurrences)

[3]The IAPR TC-12 and SAIAPR TC-12 data is available from `http://imageclef.org`; REFERITGAME from `http://tamaraberg.com/referitgame`.

[4]The data is available from `https://github.com/mjhucla/Google_Refexp_toolbox`.

Figure 3: Examples from MSCOCO

and "right" (32k). (In the following, we will call this corpus REFCOCO.) In our experiments, we use the training/validation/test splits on the images suggested by Berg et al., as the splits provided by Mao et al. (2015) are on the level of objects and have some overlap in images.

It is interesting to note the differences in the expressions from REFCOCO and GREXP, the latter on average being almost 5 token longer. Figure 3 gives representative examples. We can speculate that the different task descriptions ("refer to this object" vs. "produce an unambiguous description") and the different settings (live to a partner vs. offline, only validated later) may have caused this. As we will see below, the GREXP descriptions did indeed cause more problems to our approach, which is meant for reference in interaction.

5 Training the Word/Object Classifiers

The basis of the approach we use are the classifiers that link words and images. These need to be trained from data; more specifically, from pairings of image regions and referring expressions, as provided by the corpora described in the previous section.

Representing Image Regions The first step is to represent the information from the image regions. We use a deep convolutional neural network, "GoogLeNet" (Szegedy et al., 2015), that was trained on data from the Large Scale Visual Recognition Challenge 2014 (ILSVRC2014) from the ImageNet corpus (Deng et al., 2009) to extract features.[5] It was optimised to recognise categories from that challenge, which are different from those occurring in either SAIAPR or COCO, but in any case we only use the final fully-connected layer before the classification layer, to give us a 1024 dimensional representation of the region. We augment this with 7 features that encode information about the region relative to the image: the (relative) coordinates of two corners, its (relative) area, distance to the center, and orientation of the image. The full representation hence is a vector of 1031 features. (See also Figure 1 above.)

Selecting candidate words How do we select the words for which we train perceptual classifiers? There is a technical consideration to be made here and a semantic one. The technical consideration is that we need sufficient training data for the classifiers, and so can only practically train classifiers for words that occur often enough in the training corpus. We set a threshold here of a minimum of 40 occurences in the training corpus, determined empirically on the validation set to provide a good tradeoff between vocabulary coverage and number of training instances.

The semantic consideration is that intuitively, the approach does not seem appropriate for all types of words; where it might make sense for attributes and category names to be modelled as image classifiers, it does less so for prepositions and other function words. Nevertheless, for now, we make the assumption that all words in a referring expression contribute information to the *visual* identification of its referent. We discuss the consequences of this decision below.

This assumption is violated in a different way in phrases that refer via a landmark, such as in "the thing next to the woman with the blue shirt". Here we cannot assume for example that the referent region provides a good instance of "blue" (since it is not the target object in the region that is described as blue), and so we exclude such phrases from the training set (by looking for a small set of expressions such as "left of", "behind", etc.; see appendix for a full list). This reduces the train-

[5] http://www.image-net.org/challenges/LSVRC/2014/.
We use the sklearn-theano (http://sklearn-theano.github.io/feature_extraction/index.html#feature-extraction) port of the Caffe replication and re-training (https://github.com/BVLC/caffe/tree/master/models/bvlc_googlenet) of this network structure.

ing portions of REFERIT, REFCOCO and GREXP to 86%, 95%, and 82% of their original size, respectively (counting referring expressions, not tokens).

Now that we have decided on the set of words for which to train classifiers, how do we assemble the training data?

Positive Instances Getting positive instances from the corpus is straightforward: We pair each word in a referring expression with the representation of the region it refers to. That is, if the word "left" occurs 20,000 times in expressions in the training corpus, we have 20,000 positive instances for training its classifier.

Negative Instances Acquiring negative instances is less straightforward. The corpus does not record inappropriate uses of a word, or 'negative referring expressions' (as in "this is not a red chair"). To create negative instances, we make a second assumption which again is not generally correct, namely that when a word was *never* in the corpus used to refer to an object, this object can serve as a negative example for that word/object classifier. In the experiments reported below, we randomly selected 5 image regions from the training corpus whose referring expressions (if there were any) did not contain the word in question.[6]

The classifiers Following this regime, we train binary logistic regression classifiers (with $\ell 1$ regularisation) on the visual object features representations, for all words that occurred at least 40 times in the respective training corpus.[7]

To summarise, we train separate binary classifiers for each word (not making any a-priori distinction between function words and others, or attribute labels and category labels), giving them the task to predict how likely it would be that the word they represent would be used to refer to the image region they are given. All classifiers are presented during training with data sets with the same balance of positive and negative examples (here, a fixed ratio of 1 positive to 5 negative). Hence, the classifiers themselves do not reflect any word frequency effects; our claim (to be validated in future work) is that any potential effects of this type are better modelled separately.

Table 1: Results; separately by corpus. See text for description of columns and rows.

6 Experiments

The task in our experiments is the following: Given an image I together with bounding boxes of regions $(bb_1, \ldots, bb_n)$ within it, and a referring expression e, predict which of these regions contains the referent of the expression.

By Corpus We start with training and testing models for all three corpora (REFERIT, REFCOCO, GREXP) separately. But first, we establish some baselines. The first is just randomly picking one of the candidate regions. The second is a 1-rule classifier that picks the largest region. The respective accuracies on the corpora are as follows: REFERIT 0.20/0.19; REFCOCO 0.16/0.23; GREXP 0.19/0.20.

Training on the training sets of REFERIT, REFCOCO and GREX with the regime described above (min. 40 occurrences) gives us classifiers for 429, 503, and 682 words, respectively. Table 1 shows the evaluation on the respective test parts: accuracy (*acc*), mean reciprocal rank (*mrr*) and for how much of the expression, on average, a word classifier is present (*arc*). '>0' shows how much of the testcorpus is left if expressions are filtered out for which not even a single word is the model (which we evaluate by default as false), and accuracy for that reduced set. The 'NR' rows give the same numbers for reduced test sets in which all relational expressions have been removed; '%tst' shows how much of a reduction that is relative to the full testset. The rows with the citations give the best reported results from the literature.[8]

As this shows, in most cases we come close, but do not quite reach these results. The distance is the biggest for GREXP with its much longer expressions. As discussed above, not only are the descriptions longer on average in this corpus, the

[6] This approach is inspired by the negative sampling technique of Mikolov et al. (2013) for training textual word embeddings.

[7] We used the implementation in the `scikit learn` package (Pedregosa et al., 2011).

[8] Using a different split than (Mao et al., 2015), as their train/test set overlaps on the level of images.

vocabulary size is also much higher. Many of the descriptions contain action descriptions ("the man smiling at the woman"), which do not seem to be as helpful to our model. Overall, the expressions in this corpus do appear to be more like 'mini-captions' describing the region rather than referring expressions that efficiently single it out among the set of distractors; our model tries to capture the latter.

Combining Corpora A nice effect of our setup is that we can freely mix the corpora for training, as image regions are represented in the same way regardless of source corpus, and we can combine occurrences of a word across corpora. We tested combining the testsets of REFERIT and REFCOCO (RI+RC in the Table below), REFCOCO and GREXP (RC+GR), and all three (REFERIT, REFCOCO, and GREXP; RI+RC+GR), yielding models for 793, 933, 1215 words, respectively (with the same "min. 40 occurrences" criterion). For all testsets, the results were at least stable compared to Table 1, for some they improved. For reasons of space, we only show the improvements here.

Table 2: Results, combined corpora

Computed Region Proposals Here, we cannot expect the system to retrieve exactly the ground truth bounding box, since we cannot expect the set of automatically computed regions to contain it. We follow Mao et al. (2015) in using *intersection over union* (IoU) as metric (the size of the intersective area between candidate and ground truth bounding box normalised by the size of the union) and taking an IoU ≥ 0.5 of the top candidate as a threshold for success (P@1). As a more relaxed metric, we also count for the SAIAPR proposals (of which there are 100 per image) as success when at least one among the top 10 candidates exceeds this IoU threshold (R@10). (For MSCOCO, there are only slightly above 5 proposals per image on average, so computing this more relaxed measure does not make sense.) The random baseline (RND) is computed by applying the P@1 criterion to a randomly picked region proposal. (That it is higher than 1/#regions for SAIAPR shows that the regions cluster around objects.)

	RP@1	RP@10	rnd
REFERIT	0.09	0.24	0.03
REFERIT; NR	**0.10**	0.26	0.03
(Hu et al., 2015)	0.18	0.45

REFCOCO; NR	**0.54**	–	0.17
(Mao et al., 2015)	0.52		
GREXP	0.36	–	0.16
GREXP; NR	**0.37**	–	0.17
(Mao et al., 2015)	0.45		

Table 3: Results on region proposals

With the higher quality proposals provided for the MSCOCO data, and the shorter, more prototypical referring expressions from REFCOCO, we narrowly beat the reported results. (Again, note that we use a different split that ensures separation on the level of images between training and test.) (Hu et al., 2015) performs relatively better on the region proposals (the gap is wider), on GREXP, we come relatively closer using these proposals. We can speculate that using automatically computed boxes of a lower selectivity (REFERIT) shifts the balance between needing to actually recognise the image and getting information from the shape and position of the box (our *positional* features; see Section 5).

Ablation Experiments To get an idea about what the classifiers actually pick up on, we trained variants given only the positional features (POS columns below in Table 4) and only object features (NOPOS columns). We also applied a variant of the model with only the top 20 classifiers (in terms of number of positive training examples; TOP20). We only show accuracy here, and repeat the relevant numbers from Table 1 for comparison (FULL).

	nopos	pos	full	top20
RI	0.53	0.60	0.65	0.46
RI; NR	0.56	0.62	0.68	0.48
RC	0.44	0.55	0.61	0.52
RC; NR	0.45	0.57	0.63	0.53

Table 4: Results with reduced models

This table shows an interesting pattern. To a large extent, the object image features and the positional features seem to carry redundant information, with the latter on their own performing better than the former on their own. The full model, however, still gains something from the combination

of the feature types. The top-20 classifiers (and consequently, top 20 most frequent words) alone reach decent performance (the numbers are shown for the full test set here; if reduced to only utterances where at least one word is known, the numbers rise, but the reduction of the testset is much more severe than for the full models with much larger vocabulary).

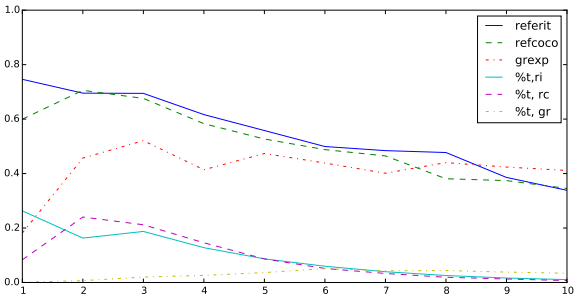

Figure 4: Accuracy by expression length (top 3 lines); percentage of expressions with this length (lower 3 lines).

Error Analysis Figure 4 shows the accuracy of the model split by length of the referring expression (top lines; lower lines show the proportion of expression of this length in the whole corpus). The pattern is similar for all corpora (but less pronounced for GREXP): shorter utterances fare better.

Manual inspection of the errors made by the system further corroborates the suspicion that composition as done here neglects too much of the internal structure of the expression. An example from REFERIT where we get a wrong prediction is "second person from left". The model clearly does not have a notion of counting, and here it wrongly selects the leftmost person. In a similar vein, we gave results above for a testset where spatial relations where removed, but other forms of relation (e.g., "child sitting on womans lap") that weren't modelled still remain in the corpus.

We see as an advantage of the model that we can inspect words individually. Given the performance of short utterances, we can conclude that the word/object classifiers themselves perform reasonably well. This seems to be somewhat independent of the number of training examples they received. Figure 5 shows, for REFERIT, # training instances (x-axis) vs. average accuracy on the validation set, for the whole vocabulary. As this shows, the classifiers tend to get better with more training instances, but there are good ones even with very little training material.

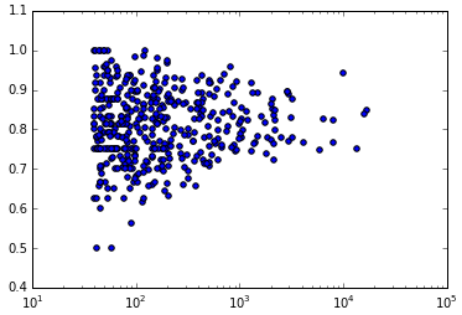

Figure 5: Average accuracy vs. # train instanc.

Mean average precision (i.e., area under the precision / recall curve) over all classifiers (exemplarily computed for the RI+RC set, 793 words) is 0.73 (std 0.15). Interestingly, the 155 classifiers in the top range (average precision over 0.85) are almost all for concrete nouns; the 128 worst performing ones (below 0.60) are mostly other parts of speech. (See appendix.) This is, to a degree, as expected: our assumption behind training classifiers for *all* ocurring words and not pre-filtering based on their part-of-speech or prior hypotheses about visual relevance was that words that can occur in all kinds of visual contexts will lead to classifiers whose contributions cancel out across all candidate objects in a scene.

However, the mean average precision of the classifiers for colour words is also relatively low at 0.6 (std 0.08), for positional words ("left", "right", "center", etc.) it is 0.54 (std 0.1). This might suggest that the features we take from the CNN might indeed be more appropriate for tasks close to what they were originally trained on, namely category and not attribute prediction. We will explore this in future work.

7 Conclusions

We have shown that the "words-as-classifiers" model scales up to a larger set of object types with a much larger variety in appearance (SAIAPR and MSCOCO); to a larger vocabulary and much less restricted expressions (REFERIT, REFCOCO, GREXP); and to use of automatically learned feature types (from a CNN). It achieves results that are comparable to those of more complex models.

We see as advantage that the model we use is "transparent" and modular. Its basis, the word/object classifiers, ties in more directly with

more standard approaches to semantic analysis and composition. Here, we have disregarded much of the internal structure of the expressions. But there is a clear path for bringing it back in, by defining other composition types for other construction types and different word models for other word types. Kennington and Schlangen (2015) do this for spatial relations in their simpler domain; for our domain, new and more richly annotated data such as VISUALgenome looks promising for learning a wide variety of relations.[9] The use of denotations / extensions might make possible transfer of methods from extensional semantics, e.g. for the addition of operators such as negation or generalised quantifiers. The design of the model, as mentioned in the introduction, makes it amenable for use in interactive systems that learn; we are currently exploring this avenue. Lastly, the word/object classifiers also show promise in the reverse task, generation of referring expressions (Zarrieß and Schlangen, 2016).

All this is future work. In its current state—besides, we believe, strongly motivating this future work—, we hope that the model can also serve as a strong baseline to other future approaches to reference resolution, as it is conceptually simple and easy to implement.

Acknowledgments

We thank Hu et al. (2016), Mao et al. (2016) and Tamara Berg for giving us access to their data. Thanks are also due to the anonymous reviewers for their very insightful comments. We acknowledge support by the Cluster of Excellence "Cognitive Interaction Technology" (CITEC; EXC 277) at Bielefeld University, which is funded by the German Research Foundation (DFG), and by the DUEL project, also funded by DFG (grant SCHL 845/5-1).

A Supplemental Material

Filtering relational expressions As described above, we filter out all referring expressions during training that contain either of the following tokens:

```
RELWORDS = ['below',
            'above',
            'between',
            'not',
            'behind',
            'under',
            'underneath',
            'front of',
            'right of',
            'left of',
            'ontop of',
            'next to',
            'middle of']
```

Average Precision See Section 6.
Classifiers with average precision over 0.85:

```
['giraffe', 'coffee', 'court', 'riding', 'penguin', 'balloon', 'ball',
'mug', 'turtle', 'tennis', 'beer', 'seal', 'cow', 'bird', 'horse',
'drink', 'koala', 'sheep', 'ceiling', 'parrot', 'bike', 'cactus',
'sun', 'smoke', 'llama', 'fruit', 'ruins', 'waterfall', 'nightstand',
'books', 'night', 'coke', 'skirt', 'leaf', 'wheel', 'label', 'pot',
'animals', 'cup', 'tablecloth', 'pillar', 'flag', 'field', 'monkey',
'bowl', 'curtain', 'plate', 'van', 'surfboard', 'bottle', 'fish',
'umbrella', 'bus', 'shirtless', 'train', 'bed', 'painting', 'lamp',

Abstract

Event extraction is a particularly challenging information extraction task, which intends to identify and classify event triggers and arguments from raw text. In recent works, when determining event types (trigger classification), most of the works are either pattern-only or feature-only. However, although patterns cannot cover all representations of an event, it is still a very important feature. In addition, when identifying and classifying arguments, previous works consider each candidate argument separately while ignoring the relationship between arguments. This paper proposes a **R**egularization-**B**ased **P**attern **B**alancing Method (RBPB). Inspired by the progress in representation learning, we use trigger embedding, sentence-level embedding and pattern features together as our features for trigger classification so that the effect of patterns and other useful features can be balanced. In addition, RBPB uses a regularization method to take advantage of the relationship between arguments. Experiments show that we achieve results better than current state-of-art equivalents.

1 Introduction

Event extraction has become a popular research topic in the area of information extraction. ACE 2005 defines event extraction task[1] as three sub-tasks: identifying the trigger of an event, identifying the arguments of the event, and distinguishing their corresponding roles. As an example in Figure 1, there is an "Attack" event triggered by "tear through" with three arguments. Each argument has one role.

In the trigger classification stage, some previous approaches (Grishman et al., 2005; Ji and Grishman, 2008; Liao and Grishman, 2010; Huang and Riloff, 2012) use patterns to decide the types of event triggers. However, pattern-based approaches suffer from low recall since real world events usually have a large variety of representations. Some other approaches (Hong et al., 2011; Li et al., 2013; Lu and Roth, 2012) identify and classify event triggers using a large set of features without using patterns. Although these features can be very helpful, patterns are still indispensable in many cases because they can identify a trigger with the correct event type with more than 96% accuracy according to our data analysis on ACE 2005 data sets.

In argument identification and classification, most approaches identify each candidate argument separately without considering the relation between arguments. We define two kinds of argument relations here: (1) Positive correlation: if one candidate argument belongs to one event, then the other is more likely to belong to the same event. For example, in Figure 1, the entity "a waiting shed" shares a common dependency head "tore" with "a powerful bomb", so when the latter entity is identified as an argument, the former is more likely to be identified. (2) Negative correlation: if one candidate argument belongs to one event, then the other is less likely to belong to the same event. For example, in Figure 1, "bus" is irrelevant to other arguments, so if other entities are identified as arguments "bus" is less likely to be identified. Note that although all the above relation examples have something to do with dependency analysis, the positive/negative relationship depends not only on dependency parsing, but many other aspects as well.

Berlin, Germany, August 7-12, 2016.

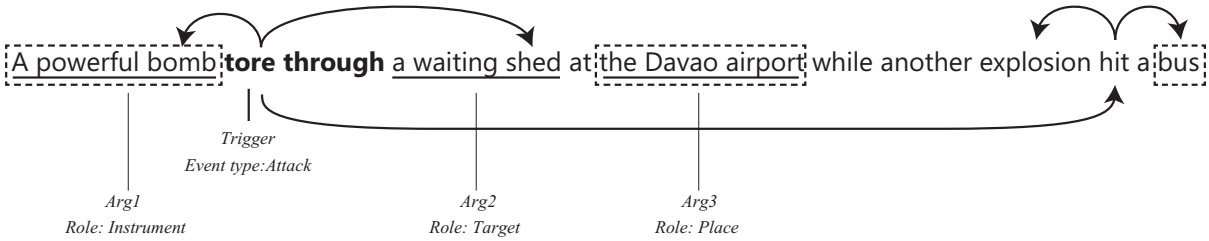

Figure 1: Event example: This is an event trigger by "tear through" with three arguments

In this paper, we propose using both patterns and elaborately designed features simultaneously to identify and classify event triggers. In addition, we propose using a regularization method to model the relationship between candidate arguments to improve the performance of argument identification. Our method is called Regularization-Based Pattern Balancing Method method.

The contributions of this paper are as follows:

- Inspired by the progress of representation learning, we use trigger embedding, sentence-level embedding, and pattern features together as the our features for balancing.
- We proposed a regularization-based method in order to make use of the relationship between candidate arguments. Our experiments on the ACE 2005 data set show that the regularization method does improve the performance of argument identification.

2 Related Work

There is a large body of previous work devoted to event extraction. Many traditional works focus on using pattern based methods for identifying event type (Kim and Moldovan, 1993; Riloff and others, 1993; Soderland et al., 1995; Huffman, 1996; Freitag, 1998b; Ciravegna and others, 2001; Califf and Mooney, 2003; Riloff, 1996; Riloff et al., 1999; Yangarber et al., 2000; Sudo et al., 2003; Stevenson and Greenwood, 2005; Grishman et al., 2005; Ji and Grishman, 2008; Liao and Grishman, 2010; Huang and Riloff, 2012). (Shinyama and Sekine, 2006; Sekine, 2006) are unsupervised methods of extracting patterns from open domain texts. Pattern is not always enough, although some methods (Huang and Riloff, 2012; Liu and Strzalkowski, 2012) use bootstrapping to get more patterns.

There are also feature-based classification methods (Freitag, 1998a; Chieu and Ng, 2002; Finn and Kushmerick, 2004; Li et al., 2005; Yu et al., 2005). Apart from the above methods, weakly supervised training (pattern-based and rule-based) of event extraction systems have also been explored (Riloff, 1996; Riloff et al., 1999; Yangarber et al., 2000; Sudo et al., 2003; Stevenson and Greenwood, 2005; Patwardhan and Riloff, 2007; Chambers and Jurafsky, 2011). In some of these systems, human work is needed to delete some nonsense patterns or rules. Other methods (Gu and Cercone, 2006; Patwardhan and Riloff, 2009) consider broader context when deciding on role fillers. Other systems take the whole discourse feature into consideration, such as (Maslennikov and Chua, 2007; Liao and Grishman, 2010; Hong et al., 2011; Huang and Riloff, 2011). Ji and Grishman (2008) even consider topic-related documents, proposing a cross-document method. (Liao and Grishman, 2010; Hong et al., 2011) use a series of global features (for example, the occurrence of one event type lead to the occurrence of another) to improve role assignment and event classification performance. Joint models (Li et al., 2013; Lu and Roth, 2012) are also considered an effective solution. (Li et al., 2013) make full use of the lexical and contextual features to get better results. The semi-CRF based method (Lu and Roth, 2012) trains separate models for each event type, which requires a lot of training data.

The dynamic multi-pooling convolutional neural network (DMCNN) (Chen et al., 2015) is currently the only widely used deep neural network based approach. DMCNN is mainly used to model contextual features. However, DMCNN still does not consider argument-argument interactions.

In summary, most of the above works are either pattern-only or features-only. Moreover, all of these methods consider arguments sepa-

rately while ignoring the relationship between arguments, which is also important for argument identification. Even the joint method (Li et al., 2013) does not model argument relations directly. We use trigger embedding, sentence-level embedding, and pattern features together as our features for trigger classification and design a regularization-based method to solve the two problems.

3 ACE Event Extraction Task

Automatic Content Extraction (ACE) is an event extraction task. It annotates 8 types and 33 subtypes of events. ACE defines the following terminologies:

- Entity: an object or a set of objects in one of the semantic categories of interest
- Entity mention: a reference to an entity, usually a noun phrase (NP)
- Event trigger: the main word which most clearly expresses an event occurrence
- Event arguments: the entity mentions that are involved in an event
- Argument roles: the relation of arguments to the event where they participate, with 35 total possible roles
- Event mention: a phrase or sentence within which an event is described, including trigger and arguments

Given an English document, an event extraction system should identify event triggers with their subtypes and arguments from each sentence. An example is shown in Figure 1. There is an "Attack" event triggered by "tear through" with three arguments. Each argument has a role type such as "Instrument", "Target", etc.

For evaluation, we follow previous works (Ji and Grishman, 2008; Liao and Grishman, 2010; Li et al., 2013) to use the following criteria to determine the correctness of the predicted event mentions.

- A trigger is considered to be correct if and only if its event type and offsets (position in the sentence) can match the reference trigger;
- An argument is correctly identified if and only if its event type and offsets can match any reference arguments;
- An argument is correctly identified and classified if and only if its event type, offsets, and role match any of the reference arguments.

4 Baseline: JET Extractor for Events

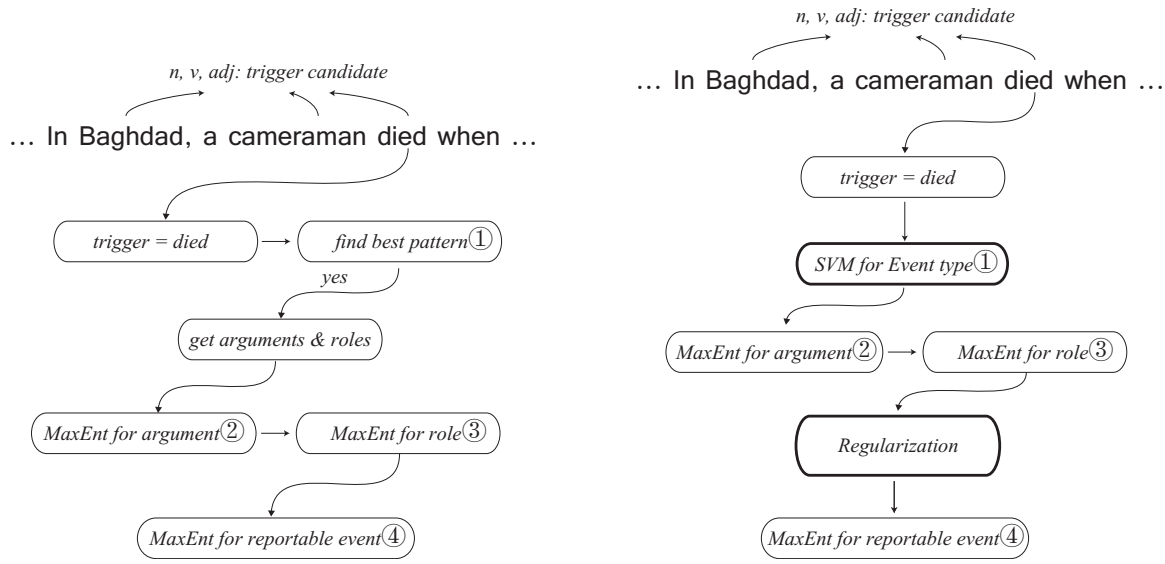
Many previous works take JET as their baseline system, including (Ji and Grishman, 2008), (Liao and Grishman, 2010), (Li et al., 2013). JET extracts events independently for each sentence. This system uses pattern matching to predict trigger and event types, then uses statistical modeling to identify and classify arguments. For each event mention in the training corpus of ACE, the patterns are constructed based on the sequences of constituent heads separating the trigger and arguments. After that, three Maximum Entropy classifiers are trained using lexical features.

- Argument Classifier: to distinguish arguments from non-arguments
- Role Classifier: to label arguments with an argument role
- Reportable-Event Classifier: to determine whether there is a reportable event mentioned (worth being taken as an event mention) according to the trigger, event type, and a set of arguments

Figure 2(a) shows the whole test procedure. In the test procedure, each sentence is scanned for nouns, verbs and adjectives as trigger candidates. When a trigger candidate is found, the system tries to match the context of the trigger against the set of patterns associated with that trigger. If this pattern matching process is successful, the best pattern will assign some of the entity mentions in the sentence as arguments of a potential event mention. Then JET uses the argument classifier to judge if the remaining entity mentions should also be identified. If yes, JET uses the role classifier to assign it a role. Finally, the reportable-event classifier is applied to decide whether this event mention should be reported.

5 Regularization-Based Pattern Balancing Method

Different with JET, as illustrated in Figure 2(b), our work introduces two major improvements: (1) balance the effect of patterns and other features (2)



(a) The flow chart of JET

(b) The flow chart of our approach

Figure 2: The left is the flow chart for JET. The right is the flow chart for our approach. The thick line block is our contribution

use a regularization-based method to make full use of the relation between candidate arguments.

The thick-edge blocks in Figure 2(b) represent our improvements. Since JET only uses patterns when predicting the event type, we use a SVM classifier to decide each candidate trigger's event type (classify the trigger). This classifier uses trigger embedding, sentence-level embedding and pattern features together for balancing. After the outputs of argument and role classifier are calculated, we make use of the argument relationship to regularize for a better result.

5.1 Balancing the Pattern effects

Deciding the event type is the same as classifying an event trigger. JET only uses patterns in this step: for a candidate trigger, we find that the best matched pattern and the corresponding event type are assigned to this trigger. We propose using feature-based methods while not ignoring the effect of patterns. Inspired by progress in representation learning, we use trigger embedding, sentence-level embedding and pattern embedding together as our features.

A pattern example is as follows:

(weapon) tore [through] (building) at (place) $\Rightarrow$ Attack{Roles...}

where each pair of round brackets represents an entity and the word inside is one of the 18 entity types defined by UIUC NER Tool[2]. The word in the square brackets can choose to exist or not. After the right arrow there is an event schema, which can tell us what kind of event this is and which roles each entity should take.

Each pattern has a corresponding event type. A candidate trigger may match more than one pattern so that it has an event type distribution. Assume that there are N_T event types in total, we denote the pattern feature vector (namely, the event type's probability distribution calculated by the trigger's pattern set) as $P_E \in \mathbb{R}^{N_T}$, which is calculated by Eq 1.

$$P_E(i) = \frac{\#(\text{matched patterns of event type } i)}{\#(\text{all matched patterns})} \quad (1)$$

Trigger embeddings are obtained using WORD2VEC[3] with the default "text8" training text data with length 200.

Since all of the NPs are potential roles in the event, they must contain the main information of the event. We extract all the NPs in the sentence and take the average word embedding of these NPs' head word as the sentence-level embedding. For example, in Figure 1, these NPs' head words are bomb, shed, and airport.

Pattern feature vectors, as distributions of event types over patterns, are also composed using

[2]http://cogcomp.cs.illinois.edu/page/software_view/NETagger
[3]http://code.google.com/p/word2vec/

continuous real values, which allows them to be viewed as a kind of pattern embedding and treated similarly to trigger and sentence embedding.

5.2 Capturing the Relationship Between Arguments

We find that there are two typical relations between candidate arguments: (1) positive correlation: if one candidate argument belongs to one event, then the other is more likely to belong to the same event; (2) negative correlation: if one candidate argument belongs to one event, then the other is less likely to belong to the same event.

We calculate a score for all the candidate arguments in a sentence to judge the quality of the argument identification and classification. For capturing the two kinds of relations, we intend to make that (1) the more positive relations the chosen arguments have, the higher the score is; (2) the more negative relations the chosen arguments have, the lower the score is.

For a trigger, if there are n candidate arguments, we set a $n \times n$ matrix C to represent the relationship between arguments. If $C_{i,j} = 1$, then argument i and argument j should belong to the same event. If $C_{i,j} = -1$, then argument i and argument j cannot belong to the same event. We will illustrate how to get matrix C in the next section.

We use a n-dim vector X to represent the identification result of arguments. Each entry of X is 0 or 1. 0 represents "noArg", 1 represents "arg". X can be assigned by maximizing $E(X)$ as defined by Eq 2.

$$\begin{aligned} X &= \underset{X}{\operatorname{argmax}}\, E(X) \\ E(X) &= \lambda_1 X^T C X + \lambda_2 P_{sum}^{arg} \\ &\quad + (1 - \lambda_1 - \lambda_2) P_{sum}^{role} \end{aligned} \tag{2}$$

Here, $X^T C X$ means adding up all the relationship values if the two arguments are identified. Hence, the more the identified arguments are related, the larger the value $X^T C X$ is. P_{sum}^{arg} is the sum of all chosen arguments' probabilities. The probability here is the output of the arguments' maximum entropy classifier. P_{sum}^{role} is the sum of all the classified roles' probabilities. The probability here is the output of the roles' maximum entropy classifier.

Eq 2 shows that while we should identify and classify the candidate arguments with a larger probability, the argument relationship evaluation should also be as large as possible. The arguments should also follow the following constraints. These constraints together with Eq 2 can make the argument identification and classification help each other for a better result.

- Each entity can only take one role
- Each role can belong to one or more entities
- The role assignment must follow the event schema of the corresponding type, which means that only the roles in the event schema can occur in the event mention

We use the Beam Search method to search for the optimal assignment X as is shown in Algorithm 1. The hyperparameters λ_1 and λ_2 can be chosen according to development set.

Input: Argument relationship matrix: C
the argument probabilities required by P_{sum}^{arg}
the role probabilities required by P_{sum}^{role}
Data: K: Beam size
n: Number of candidate arguments
Output: The best assignment X
Set beam $\mathcal{B} \leftarrow [\epsilon]$;
for $i \leftarrow 1 \cdots n$ **do**
  buf$\leftarrow \{z' \circ l | z' \in \mathcal{B}, l \in \{0, 1\}\}$;
  $\mathcal{B} \leftarrow [\epsilon]$;
  while $j \leftarrow 1 \cdots K$ **do**
    $x_{best} = \operatorname{argmax}_{x \in \text{buf}} E(x)$;
    $\mathcal{B} \leftarrow \mathcal{B} \cup \{x_{best}\}$;
    buf$\leftarrow$buf$-\{x_{best}\}$;
  end
end
Sort $\mathcal{B}$ descendingly according to $E(X)$;
return $\mathcal{B}[0]$;

Algorithm 1: Beam Search decoding algorithm for event extraction. $\circ$ means to concatenate an element to the end of a vector.

5.2.1 Training the Argument Relationship Structure

The argument relationship matrix C is very important in the regularization process. We train a maximum entropy classifier to predict the connection between two entities. We intend to classify the entity pairs into three classes: positive correlation, negative correlation, and unclear correlation. The entity pairs in the ground truth events (in training

data) are used for our training data. We choose the following features:

- TRIGGER: the trigger of the event. The whole model is a pipelined model, so when classifying the argument relationship, the trigger has been identified and classified. So the "trigger" is a feature of the argument relation.
- ENTITY DISTANCE: the distance between the two candidate arguments in the sentence, namely the number of intervening words
- Whether the two candidate arguments occur on the same side of the trigger
- PARENT DEPENDENCY DISTANCE: the distance between the two candidate arguments' parents in the dependency parse tree, namely, the path length.
- PARENT POS: if the two candidate arguments share the same parent, take the common parent's POS tag as a feature
- Whether the two candidate arguments occur on the same side of the common parent if the two candidate arguments share the same parent

For an entity pair, if both of the entities belong to the same event's arguments, we take it as positive example. For each positive example, we randomly exchange one of the entities with an irrelevant entity (an irrelevant entity is in the same sentence as the event, but it is not the event's argument) to get a negative example. In the testing procedure, we predict the relationship between entity i and entity j using the maximum entropy classifier.

When the output of the maximum entropy classifier is around 0.5, it is not easy to figure out whether it is the first relation or the second. We call this kind of information "uncertain information"(unclear correlation). For better performance, we **strengthen** the certain information and weaken the uncertain information. We set two thresholds, if the output of the maximum entropy classifier is larger than 0.8, we set $C_{i,j} = 1$ (positive correlation), if the output is lower than 0.2, we set $C_{i,j} = -1$ (negative correlation), otherwise, we set $C_{i,j} = 0$ (unclear correlation). The strengthen mapping is similar to the hard tanh in neural network. If we do not do this, according to the experiment, the performance cannot beat most of the baselines since the uncertain information has very bad noise.

6 Experiments

6.1 Data

We utilize ACE 2005 data sets as our testbed. As is consistent with previous work, we randomly select 10 newswire texts from ACE 2005 training corpora as our development set, and then conduct blind test on a separate set of 40 ACE 2005 newswire texts. The remaining 529 documents in ACE training corpus are used as the training data.

The training dataset of the argument relationship matrix contains 5826 cases (2904 positive and 2922 negative) which are randomly generated according to the ground truth in the 529 training documents.

6.2 Systems to Compare

We compare our system against the following systems:

- **JET** is the baseline of (Grishman et al., 2005), we report the paper values of this method;
- **Cross-Document** is the method proposed by Ji and Grishman (2008), which uses topic-related documents to help extract events in the current document;
- **Cross-Event** is the method proposed by Liao and Grishman (2010), which uses document-level information to improve the performance of ACE event extraction.
- **Cross-Entity** is the method proposed by Hong et al. (2011), which extracts events using cross-entity inference.
- **Joint** is the method proposed by Li et al. (2013), which extracts events based on structure prediction. It is the best-reported structure-based system.
- **DMCNN** is the method proposed by Chen et al. (2015), which uses a dynamic multi-pooling convolutional neural network to extract events. It is the only neural network based method.

The Cross-Document, Cross-Event and Cross-Entity are all extensions of JET. Among these

Method	Trigger Classification			Argument Identification			Argument Role		
	P	R	F_1	P	R	F_1	P	R	F_1
JET	67.6	53.5	59.7	46.5	37.2	41.3	41.0	32.8	36.5
Cross-Event	68.7	**68.9**	68.8	50.9	49.7	50.3	45.1	44.1	44.6
Cross-Entity	72.9	64.3	68.3	53.4	52.9	53.1	51.6	45.5	48.3
Joint	73.7	62.3	67.5	**69.8**	47.9	56.8	**64.7**	44.4	52.7
DMCNN	**75.6**	63.6	**69.1**	68.8	51.9	59.1	62.2	46.9	53.5
RBPB(JET)	62.3	59.9	61.1	50.4	45.8	48.0	41.9	36.5	39.0
+ ET	66.7	65.9	66.3	60.6	56.7	58.6	49.2	48.3	48.7
+ Regu	67.2	61.7	64.3	62.8	57.5	60.0	52.6	48.4	50.4
+ ET + Regu	70.3	67.5	68.9	63.2	**59.4**	**61.2**	54.1	**53.5**	**53.8**

Table 1: Overall performance with gold-standard entities, timex, and values, the candidate arguments are annotated in ACE 2005. "ET" means the pattern balancing event type classifier, "Regu" means the regularization method

methods, Cross-Event, Cross-Entity, and DMCNN make use of the gold-standard entities, timex, and values annotated in the corpus as the argument candidates. Cross-Document uses the JET system to extract candidate arguments. Li et al. (2013) report the performance with both gold-standard argument candidates and predicted argument candidates. Therefore, we compare our results with methods based on gold argument candidates in Table 1 and methods based on predicted argument candidates in Table 2.

We have done a series of ablation experiments:

- **RBPB(JET)**: Our own implementation of JET
- **RBPB(JET) + ET**: Add pattern balanced event type classifier to RBPB(JET)
- **RBPB(JET) + Regu**: Add regularization mechanism to RBPB(JET)
- **RBPB(JET) + ET + Regu**: Add both pattern balanced event type classifier and regularization mechanism to RBPB(JET)

6.2.1 The Selection of Hyper-parameters

We tune the coefficients λ_1 and λ_2 of Eq 2 on the development set, and finally we set $\lambda_1 = 0.10$ and $\lambda_2 = 0.45$. Figure 3 shows the variation of argument identification's F_1 measure and argument classification's F_1 measure when we fix one parameter and change another. Note that the third coefficient $1 - \lambda_1 - \lambda_2$ must be positive, which is the reason why the curve decreases sharply when λ_2 is fixed and $\lambda_1 > 0.65$. Therefore, Figure 3 illustrates that the robustness of our method is very good, which means if the hyperparameters λ_1, λ_2 are larger or smaller, it will not affect the result very much.

6.3 Experiment Results

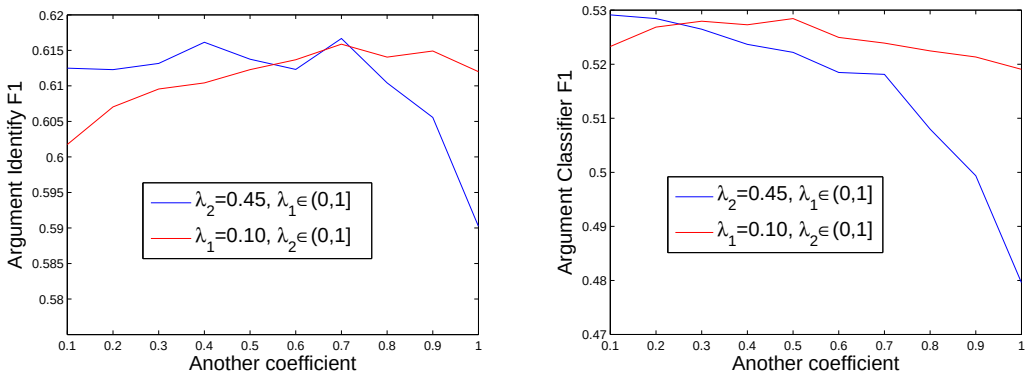
We conduct experiments to answer the following questions. (1) Can pattern balancing lead to a higher performance in trigger classification, argument identification, and classification while retaining the precision value? (2) Can the regularization step improve the performance of argument identification and classification?

Table 1 shows the overall performance on the blind test set. We compare our results with the JET baseline as well as the Cross-Event, Cross-Entity, and joint methods. When adding the event type classifier, in the line titled "+ ET", we see a significant increase in the three measures over the JET baseline in recall. Although our trigger's precision is lower than RBPB(JET), it gains 5.2% improvement on the trigger's F_1 measure, 10.6% improvement on argument identification's F_1 measure and 9.7% improvement on argument classification's F_1 measure. We also test the performance with argument candidates automatically extracted by JET in Table 2, our approach "+ ET" again significantly outperforms the JET baseline. Remarkably, our result is comparable with the Joint model although we only use lexical features.

The line titled "+ Regu" in Table 1 and Table 2 represents the performance when we only use the regularization method. In Table 1, Compared to the four baseline systems, the argument identifi-

Method	Trigger F_1	Arg id F_1	Arg id+cl F_1
JET	59.7	42.5	36.6
Cross-Document	67.3	46.2	42.6
Joint	65.6	-	41.8
RBPB(JET)	60.4	44.3	37.1
+ ET	66.0	47.8	39.7
+ Regu	64.8	54.6	42.0
+ ET + Regu	**67.8**	**55.4**	**43.8**

Table 2: Overall performance with predicted entities, timex, and values, the candidate arguments are extracted by JET. "ET" is the pattern balancing event type classifier, "Regu" is the regularization method



(a) Arg Identify (b) Arg Classify

Figure 3: The trend graph when fix one coefficient and change another

cation's F_1 measure of "+ Regu" is significantly higher. In Table 2, the "+ Regu" again gains a higher F_1 measure than the JET, Cross-Document, joint model baseline and "+ ET".

The complete approach is denoted as "RBPB" in Table 1 and Table 2. Remarkably, our approach performances comparable in trigger classification with the state-of art methods: Cross-Document, Cross-Event, Cross-Entity, Joint model, DMCNN and significantly higher than them in argument identification as well as classification although we did not use the cross-document, cross-event information or any global feature. Therefore, the relationship between argument candidates can indeed contribute to argument identification performance. The event type classifier also contributes a lot in trigger identification & classification. We do the Wilcoxon Signed Rank Test on trigger classification, argument identification and argument classification, all the three have $p < 0.01$.

A more detailed study of the pattern feature's effect is shown in Table 3. We can see that RBPB with both plain feature and pattern feature can gain much better performance than with two kinds of features alone.

Method (RBPB)	Trigger	Arg id	Arg id+cl
+ Plain feature	66.0	60.5	50.4
+ Pattern feature	65.8	60.1	49.2
+ Both	**68.9**	**61.2**	**53.8**

Table 3: The effect (F_1 value) of pattern feature

However, our approach is just a pipeline approach which suffers from error propagation and the argument performance may not affect the trigger too much. We can see from Table 1 that although we use gold argument candidates, the trigger performance is still lower than DMCNN. Another limitation is that our regularization method does not improve the argument classification too much since it only uses constraints to affect roles. Future work may be done to solve these two limitations.

6.4 Analysis of Argument Relationships

The accuracy of the argument relationship maxent classifier is 82.4%. Fig 4 shows an example of the argument relationship matrix, which works

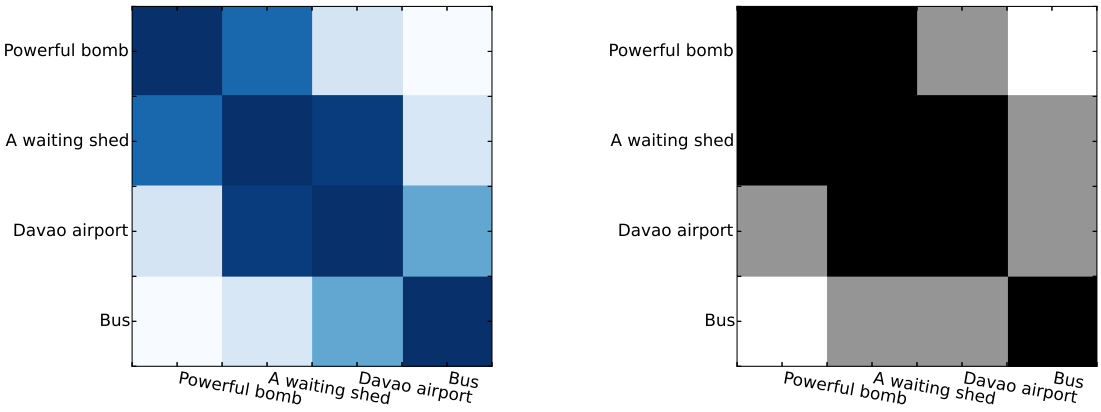


Figure 4: The Argument Relationship Matrix. Left is the origin matrix. Right is the strengthened matrix

for the sentence in Fig 1. In the left part of Fig 4, we can see the argument relationship we capture directly (the darker blue means stronger connection, lighter blue means weaker connection). After strengthening, on the right, the entities with strong connections are classified as positive correlations (the black squares), weak connections are classified as negative correlations (the white squares). Others (the grey squares) are unclear correlations. We can see that positive correlation is between "Powerful bomb" and "A waiting shed" as well as "A waiting shed" and "Davao airport". Therefore, these entities tend to be extracted at the same time. However, "Powerful bomb" and "Bus" has a negative correlation, so they tend not to be extracted at the same time. In practice, the argument probability of "Powerful bomb" and "A waiting shed" are much higher than the other two. Therefore, "Powerful bomb", "A waiting shed" and "Davao airport" are the final extraction results.

7 Conclusion

In this paper, we propose two improvements based on the event extraction baseline JET. We find that JET depends too much on event patterns for event type priori and JET considers each candidate argument separately. However, patterns cannot cover all events and the relationship between candidate arguments may help when identifying arguments. For a trigger, if no pattern can be matched, the event type cannot be assigned and the arguments cannot be correctly identified and classified. Therefore, we develop an event type classifier to assign the event type, using both pattern matching information and other features, which gives our system the capability to deal with failed match cases when using patterns alone.

On the other hand, we train a maximum entropy classifier to predict the relationship between candidate arguments. Then we propose a regularization method to make full use of the argument relationship. Our experiment results show that the regularization method is a significant improvement in argument identification over previous works.

In summary, by using the event type classifier and the regularization method, we have achieved a good performance in which the trigger classification is comparable to state-of-the-art methods, and the argument identification & classification performance is significantly better than state-of-the-art methods. However, we only use sentence-level features and our method is a pipelined approach. Also, the argument classification seems not to be affected too much by the regularization. Future work may be done to integrate our method into a joint approach, use some global feature, which may improve our performance. The code is available at `https://github.com/shalei120/RBPB/tree/master/RBET_release`

Abstract

This paper presents a novel model for Japanese predicate argument structure (PAS) analysis based on a neural network framework. Japanese PAS analysis is challenging due to the tangled characteristics of the Japanese language, such as case disappearance and argument omission. To unravel this problem, we learn selectional preferences from a large raw corpus, and incorporate them into a SOTA PAS analysis model, which considers the consistency of all PASs in a given sentence. We demonstrate that the proposed PAS analysis model significantly outperforms the base SOTA system.

1 Introduction

Research on predicate argument structure (PAS) analysis has been conducted actively these days. The improvement of PAS analysis would benefit many natural language processing (NLP) applications, such as information extraction, summarization, and machine translation.

The target of this work is Japanese PAS analysis. The Japanese language has the following characteristics:

- head final,
- free word order (among arguments), and
- postpositions function as (surface) case markers.

Japanese major surface cases are が (*ga*), を (*wo*), and に (*ni*), which correspond to Japanese postpositions (case markers). We call them nominative case, accusative case, and dative case, respectively. In this paper, we limit our target cases to these three cases. Note that though they are surface cases, they roughly correspond to Arg1, Arg2, and Arg3 of English semantic role labeling based on PropBank.

Japanese PAS analysis has been considered as one of the most difficult basic NLP tasks, due to the following two phenomena.

Case disappearance When a topic marker は (*wa*) is used or a noun is modified by a relative clause, their case markings disappear as in the following examples.[1]

(1) a. ジョンは パンを 食べた。 → ジョンが
John-TOP bread-ACC ate John-NOM
(John ate bread.)

b. パンは ジョンが 食べた。 → パンを
bread-TOP John-NOM ate bread-ACC
(John ate bread.)

(2) a. パンを 食べた ジョン を ... → ジョンが (食べた)
bread-ACC ate John-ACC John-NOM (ate)
(John, who ate bread, ...)

b. ジョンが 食べた パン が ...→ パンを (食べた)
John-NOM ate bread-NOM (ate) bread-ACC
(Bread, which John ate, ...)

In the example sentences (1a) and (1b), since a topic marker は is used, the NOM and ACC case markers disappear. In the example sentences (2a) and (2b), since a noun is modified by a relative clause, the NOM case of "ジョン" (John) for "食べた" (eat) and ACC case of "パン" (bread) for "食べた" disappear.

Argument omission Arguments are very often omitted in Japanese sentences. This phenomenon is totally different from English sentences, where the word order is fixed and pronouns are used con-

[1] In this paper, we use the following abbreviations: NOM (nominative), ACC (accusative), DAT (dative) and TOP (topic marker).

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1235–1244,
Berlin, Germany, August 7-12, 2016.

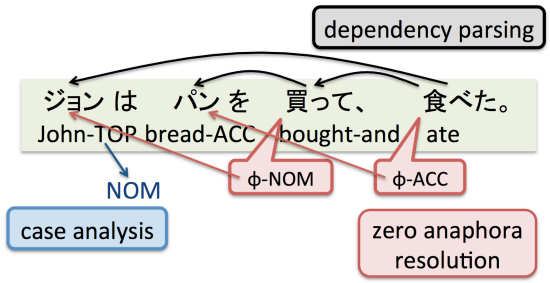

Figure 1: An example of PAS analysis. Input sentence: “ジョンはパンを買って、食べた。” (John bought bread, and ate it.)

sistently. For example, let us compare the following parallel Japanese and English sentences:

(3) a. ジョンは パンを 買って、 食べた。
John-TOP bread-ACC bought ate
b. John bought bread, and ate it.

The dependency parse of (3a) is shown in Figure 1. In general, the first phrase with a topic marker は is treated as modifying the final predicate according to the guidelines of Japanese dependency annotation. As a result, “買って” (bought) has no NOM argument (omitted), and “食べた” (ate) has no ACC argument. Note that “食べた” has an argument “ジョン” (John), but its case does not appear.

In the case of the parallel sentences (4) below, again we can witness the difficulty of Japanese PAS analysis.

(4) a. パンを 買った ジョンは 急いで 食べた。
bread-ACC bought John-TOP hurry ate
b. John who bought bread ate it in a hurry.

Although all the case arguments of the predicates “bought” and “ate” are explicit in (4b), the case of “ジョン” (John) for “買った” (bought) and that for “食べた” (ate) are hidden, and the ACC argument of “食べた” (ate) is omitted in (4a).

Many researchers have been tackling Japanese PAS analysis (Taira et al., 2008; Imamura et al., 2009; Hayashibe et al., 2011; Sasano and Kurohashi, 2011; Hangyo et al., 2013; Ouchi et al., 2015). However, because of the two aforementioned characteristics in Japanese sentences, the accuracy of Japanese PAS analysis for omitted (zero) arguments remains around 40%.

This paper proposes a novel Japanese PAS analysis model based on a neural network (NN) framework, which has been proved to be effective for several NLP tasks recently. To unravel the tangled situation in Japanese, we learn selectional preferences from a large raw corpus, and incorporate them into a SOTA PAS analysis model proposed by Ouchi et al. (2015), which considers the consistency of all PASs in a given sentence. This model is achieved by an NN-based two-stage model that acquires selectional preferences in an unsupervised manner in the first stage and predicts PASs in a supervised manner in the second stage as follows.

1. The most important clue for PAS analysis is selectional preferences, that is, argument prediction from a predicate phrase. For example, how likely the phrase “パンを買った” (bought bread) takes “ジョン” (John) as its NOM argument.

   Such information cannot be learned from a medium-sized PAS annotated corpus with size of the order of ten-thousand sentences; it is necessary to use a huge raw corpus by an unsupervised method. Ouchi et al. (2015) did not utilize such knowledge extracted from a raw corpus. Some work has utilized PMI between a predicate and an argument, or case frames obtained from a raw corpus. However, this is discrete word-based knowledge, not generalized semantic knowledge.

   As the first stage of the method, we learn a prediction score from a predicate phrase to an argument by an NN-based method. The resultant vector representations of predicates and arguments are used as initial vectors for the second stage of the method.

2. In the second stage, we calculate a score that a predicate in a given sentence takes an element in the sentence as an argument using NN framework. We use the prediction score in the first stage as one feature for the second stage NN. The system by Ouchi et al. (2015) used a manually designed feature template to take the interactions of the atomic features into consideration. In the case of an NN framework, no feature template is required, and a hidden layer in an NN can capture the interactions of the atomic features automatically and flexibly.

We demonstrate that the proposed PAS analysis model outperforms the SOTA system by Ouchi et al. (2015).

2 Related Work

Several methods for Japanese PAS analysis have been proposed. The methods can be divided into three types: (i) identifying one case argument independently per predicate (Taira et al., 2008; Imamura et al., 2009; Hayashibe et al., 2011), (ii) identifying all the three case arguments (NOM, ACC, and DAT) simultaneously per predicate (Sasano and Kurohashi, 2011; Hangyo et al., 2013), and (iii) identifying all case arguments of all predicates in a sentence (Ouchi et al., 2015). The third method can capture interactions between predicates and their arguments, and thus performs the best among the three types. This method is adopted as our base model (see Section 3 for details).

Most methods for PAS analysis handle both intra-sentential and inter-sentential zero anaphora. For identifying inter-sentential zero anaphora, an antecedent has to be searched in a broad search space, and the salience of discourse entities has to be captured. Therefore, the task of identifying inter-sentential zero anaphora is more difficult than that of intra-sentential zero anaphora. Thus, Ouchi et al. (2015) and Iida et al. (2015) focused on only intra-sentential zero anaphora. Following this trend, this paper focuses on intra-sentential zero anaphora.

Recently, NN-based approaches have achieved improvement for several NLP tasks. For example, in transition-based parsing, Chen and Manning (2014) proposed an NN-based approach, where the words, POS tags, and dependency labels are first represented by embeddings individually. Then, an NN-based classifier is built to make parsing decisions, where an input layer is a concatenation of embeddings of words, POS tags, and dependency labels. This model has been extended by several studies (Weiss et al., 2015; Dyer et al., 2015; Ballesteros et al., 2015). In semantic role labeling, Zhou and Xu (2015) propose an end-to-end approach using recurrent NN, where an original text is the input, and semantic role labeling is performed without any intermediate syntactic knowledge. Following these approaches, this paper proposes an NN-based PAS method.

3 Base Model

The model proposed by Ouchi et al. (2015) is adopted as our base model (Figure 2). We briefly introduce this base model before describing our proposed model.

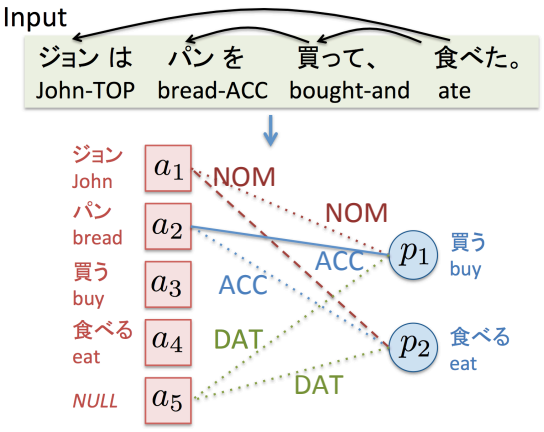

Figure 2: Our base model (Ouchi et al., 2015).

3.1 Predicate-Argument Graph

In this model, for an input sentence, a bipartite graph is constructed, consisting of the set of predicate and argument nodes. This is called Predicate-Argument Graph (PA Graph). A PA graph represents a possible interpretation of the input sentence, including case analysis result and zero anaphora resolution result.

A PA graph is a bipartite graph $\langle A, P, E \rangle$, where A is the node set consisting of candidate arguments, P is the node set consisting of predicates, and E is the set of edges. A PA graph is defined as follows:

$$\begin{aligned} A &= \{a_1, \ldots, a_n, a_{n+1} = \texttt{NULL}\} \\ P &= \{p_1, \ldots, p_m\} \\ E &= \{\langle a, p, c \rangle | deg(p, c) = 1, \\ &\quad \forall a \in A, \forall p \in P, \forall c \in C\} \end{aligned}$$

where n and m represent the number of predicates and arguments, and C denotes the case role set (NOM, ACC, and DAT). An edge $e \in E$ is represented by a tuple $\langle a, p, c \rangle$, indicating the edge with a case role c connecting a candidate argument node a and a predicate node p. $deg(p, c)$ is the number of the edges with a case role c outgoing from a predicate node p. An admissible PA graph satisfies the constraint $deg(p, c) = 1$, which means each predicate node p has only one edge with a case role c. A dummy node a_{n+1} is added, which is defined for the cases where a predicate requires no case argument (e.g. when the predicate node "ある" (exist) connects a NULL node with a case ACC, this means this predicate takes

no ACC argument) or the required argument does not appear in the sentence.

In the bipartite graph shown in Figure 2, the three kinds of edge lines have the meaning as follows:

solid line: the argument node and the predicate node has a dependency relation, and the argument node is followed by a case marking postposition. In this case, these nodes have a relation through its corresponding case marking postposition. Therefore, this edge is fixed.

dashed line: the argument node and the predicate node has a dependency relation, and the argument node is not followed by a case marking postposition. These nodes are likely to have a relation[2], but the case role is unknown. Identifying this case role corresponds to case analysis.

dotted line: the argument node and the predicate node do not have a dependency relation. Identifying this edge and its case role corresponds to zero anaphora resolution.

For an input sentence x, a scoring function $Score(x, y)$ is defined for a candidate graph y, and the PA graph that has the maximum score is searched.

$$\tilde{y} = \underset{y \in G(x)}{\operatorname{argmax}} Score(x, y) \tag{1}$$

where $G(x)$ is a set of admissible PA graphs for the input sentence x. $Score(x, y)$ is defined as follows[3]:

$$\sum_{e \in E(y)} score_l(x, e) + \sum_{e_i, e_j \in E_{pair}(y)} score_g(x, e_i, e_j). \tag{2}$$

$$\begin{aligned} score_l(x, e) &= \boldsymbol{\theta}_l \cdot \boldsymbol{\phi}_l(x, e) \\ score_g(x, e_i, e_j) &= \boldsymbol{\theta}_g \cdot \boldsymbol{\phi}_g(x, e_i, e_j) \end{aligned} \tag{3}$$

where $E(y)$ is the edge set on the candidate graph y, $E_{pair}(y)$ is a set of edge pairs in the edge set $E(y)$, $score_l(x, e)$ and $score_g(x, e_i, e_j)$ represent a local score for the edge e and a global score for the edge pair e_i and e_j, $\boldsymbol{\phi}_l(x, e)$ and $\boldsymbol{\phi}_g(x, e_i, e_j)$ represent local features and global features. While $\boldsymbol{\phi}_l(x, e)$ is defined for each edge e, $\boldsymbol{\phi}_g(x, e_i, e_j)$ is defined for each edge pair e_i, e_j $(i \neq j)$. $\boldsymbol{\theta}_l$ and $\boldsymbol{\theta}_g$ represent model parameters for local and global features. By using global scores, the interaction between multiple case assignments of multiple predicates can be considered.

[2]For example, in the sentence "今日は 暑い" (today-TOP hot), the predicate "暑い" does not take "今日", which represents time, as an argument. Therefore, these nodes do not always have a relation.

[3]Ouchi et al. (2015) introduce two models: Per-Case Joint Model and All-Cases Joint Model. Since All-Cases Joint Model performed better than Per-Case Joint Model, All-Cases Joint Model is adopted as our base model.

3.2 Inference and Training

Since global features make the inference of finding the maximum scoring PA graph more difficult, the randomized hill-climbing algorithm proposed in (Zhang et al., 2014) is adopted.

Figure 3 describes the pseudo code for hill-climbing algorithm. First, an initial PA graph $y^{(0)}$ is sampled from the set of admissible PA graph $G(x)$. Then, the union Y is constructed from the set of neighboring graphs $NeighborG(y^{(t)})$, which is a set of admissible graphs obtained by changing one edge in $y^{(t)}$, and the current graph $y^{(t)}$. The current graph $y^{(t)}$ is updated to a higher scoring graph $y^{(t+1)}$. This process continues until no more improvement is possible, and finally an optimal graph $\tilde{y}$ can be obtained.

Input: sentence x, parameter $\boldsymbol{\theta}$
Output: a locally optimal PA graph $\tilde{y}$
Sample a PA graph $y^{(0)}$ from $G(x)$
$t \leftarrow 0$
repeat
  $Y \leftarrow NeighborG(y^{(t)}) \bigcup y^{(t)}$
  $y^{(t+1)} \leftarrow \underset{y \in Y}{\operatorname{argmax}} Score(x, y; \boldsymbol{\theta})$
  $t \leftarrow t + 1$
until $y^{(t)} = y^{(t+1)}$
return $\tilde{y} \leftarrow y^{(t)}$

Figure 3: Hill climbing algorithm for obtaining optimal PA graph.

Given N training examples $D = \{(x, \hat{y})\}_k^N$, the model parameter $\boldsymbol{\theta}$ are estimated. $\boldsymbol{\theta}$ is the set of $\boldsymbol{\theta}_l$ and $\boldsymbol{\theta}_g$, and is estimated by averaged perceptron (Collins, 2002) with a max-margin framework (Taskar et al., 2005).

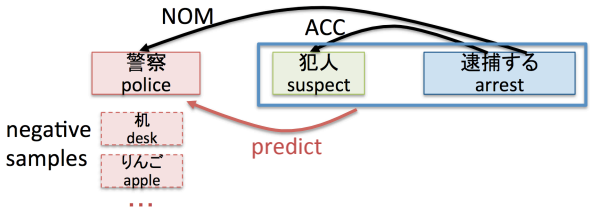

Figure 4: Argument prediction model. In the PAS "警察" (police) NOM "犯人" (suspect) ACC "逮捕" (arrest), "警察" with the NOM case is predicted given the predicate "逮捕" (arrest) and its ACC "犯人" (suspect).

4 Proposed Model

4.1 Argument Prediction Model

No external knowledge is utilized in the base model. One of the most important types of knowledge in PAS analysis is selectional preferences. Sasano and Kurohashi (2011) and Hangyo et al. (2013) extract knowledge of the selectional preferences in the form of case frames from a raw corpus, and the selectional preference score is used as a feature. In this work, *argument prediction model* is trained using a neural network from a raw corpus, in a similar way to Titov and Khoddam (2015) and Hashimoto et al. (2014).

PASs are first extracted from an automatically-parsed raw corpus, and in each PAS, the argument a_i is generated with the following probability $p(a_i|PAS_{-a_i})$:

$$p(a_i|PAS_{-a_i}) = \frac{\exp(\boldsymbol{v}_{a_i}^{\mathrm{T}} W_{a_i}^{\mathrm{T}}(W_{pred}\boldsymbol{v}_{pred} + \sum_{j\neq i} W_{a_j}\boldsymbol{v}_{a_j}))}{Z} \quad (4)$$

where PAS_{-a_i} represents a PAS excluding the target argument a_i, $\boldsymbol{v}_{pred}$, $\boldsymbol{v}_{a_i}$ and $\boldsymbol{v}_{a_j}$ represent embeddings of the predicate, argument a_i and argument a_j, and W_{pred}, W_{a_i}, and W_{a_j} represent transformation matrices for a predicate and an argument a_i and a_j. Z is the partition function.

Figure 4 illustrates the argument prediction model. The PAS "警察" (police) NOM "犯人" (suspect) ACC "逮捕" (arrest)" is extracted from a raw corpus, and the probability of NOM argument "警察" given the predicate "逮捕" and its ACC argument "犯人" is calculated.

All the parameters including predicate/argument embeddings and transformation matrices are trained, so that the likelihood given by Equation (4) is high. Since the denominator of Equation (4) is impractical to be calculated since the number of vocabulary is enormous, negative sampling (Mikolov et al., 2013) is adopted. In the example shown in Figure 4, as for a NOM argument, negative examples, such as "机" (desk) and "りんご" (apple), are drawn from the noise distribution, which is a unigram distribution raised to the 3/4th power.

In each PAS, all the arguments are predicted in turn. All the parameters are updated using stochastic gradient descent.

This model is first trained using the automatic parsing result on a raw corpus, and in performing PAS analysis described in Section 4.2, the score derived from this model is used as a feature.

4.2 Neural Network-Based Score Calculation

In the base model, the score for an edge (local score) or an edge pair (global score) is calculated using the dot product of a sparse high-dimensional feature vector with a model parameter, as shown in Equation (3). In our proposed model, these scores are calculated in a standard neural network with one hidden layer, as shown in Figure 5.

We first describe the calculation of the local score $score_l(x, e)$. A predicate p and an argument a are represented by embeddings (a d dimensional vector) $\boldsymbol{v}_p$ and $\boldsymbol{v}_a \in \mathbb{R}^d$, and $\boldsymbol{v}_{f_l} \in \mathbb{R}^{d_f}$ (d_f represents a dimensional of $\boldsymbol{v}_{f_l}$) represents a feature vector obtained by concatenating the case role between a and p, the argument prediction score obtained from the model described in Section 4.1, and the other atomic features. An input layer is a concatenation of these vectors, and then, a hidden layer $\boldsymbol{h}_l \in \mathbb{R}^{d_h}$ (d_h represents a dimension of the hidden layer) is calculated as follows:

$$\boldsymbol{h}_l = f(W_l^1[\boldsymbol{v}_p; \boldsymbol{v}_a; \boldsymbol{v}_{f_l}]) \quad (5)$$

where f is an element-wise activation function ($tanh$ is used in our experiments), and $W_l^1 \in \mathbb{R}^{d_h(2d+d_h)}$ is a weight matrix (for the local score) from the input layer to the hidden layer. The scalar score in an output layer is then calculated as follows:

$$score_l(x, e) = f(W_l^2 \boldsymbol{h}_l) \quad (6)$$

where $W_l^2 \in \mathbb{R}^{(2d+d_h)\cdot 1}$ is a weight matrix (for the local score) from the hidden layer to the output layer. By calculating the score in this way, all the

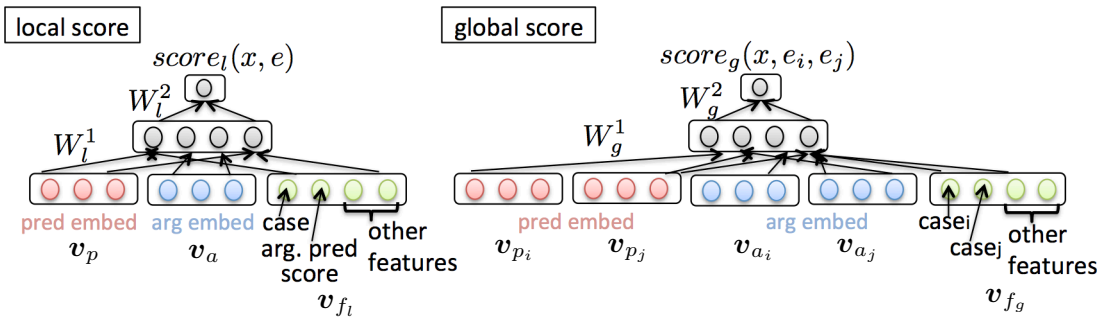

Figure 5: A score calculation in our proposed neural-network based model. The left part and right part represent a local and global score calculation.

combinations of features in the input layer can be considered.

Next we describe the calculation of the global score $score_g(x, e_i, e_j)$. In the base model, the two types of global features are utilized: one is for the two predicates having different arguments, and the other is for the two predicates sharing the same argument. The input layer is a concatenation of involving vectors of predicates/arguments and the other features $\boldsymbol{v}_{f_g}$. For example, when calculating the global score for the two predicates having different arguments, the input layer is a concatenation of the vectors of two predicates and two arguments and $\boldsymbol{v}_{f_g}$.

A hidden layer $\boldsymbol{h}_g$ is calculated as follows:

$$\boldsymbol{h}_g = f(W_g^1[\boldsymbol{v}_{p_i}; \boldsymbol{v}_{p_j}; \boldsymbol{v}_{a_i}; \boldsymbol{v}_{a_j}; \boldsymbol{v}_{f_g}]) \quad (7)$$

where W_g^1 is a weight matrix (for the global score) from the input layer to the hidden layer, $\boldsymbol{v}_{p_i}$ and $\boldsymbol{v}_{a_i}$ are the embeddings of the predicate/argument connected by e_i, and $\boldsymbol{v}_{p_j}$ and $\boldsymbol{v}_{a_j}$ are defined in the same way.

The scalar score in an output layer is then calculated as follows:

$$score_g(x, e_i, e_j) = f(W_g^2 \boldsymbol{h}_g) \quad (8)$$

where W_g^2 is a weight matrix (for the global score) from the hidden layer to the output layer.

4.3 Inference and Training

While inference is the same as the base model, training is slightly different.

In our proposed model, the model parameter $\boldsymbol{\theta}$ consists of the embeddings of predicates/arguments and weight matrices for the local/global score in the neural networks. Our objective is to minimize the following loss function:

case	# of dep arguments	# of zero arguments	total
NOM	1,402	1,431	2,833
ACC	278	113	391
DAT	92	287	379
ALL	1,772	1,831	3,603

Table 1: Test set statistics of the number of arguments.

$$J(\boldsymbol{\theta}) = \sum_k^N l_k(\boldsymbol{\theta}), \quad (9)$$

where

$$l_k(\boldsymbol{\theta}) = \max_{y_k \in G(x)} (Score(x_k, y_k; \boldsymbol{\theta}) - Score(x_k, \hat{y}_k; \boldsymbol{\theta}) + ||y_k - \hat{y}_k||_1), \quad (10)$$

and $||y_k - \hat{y}_k||_1$ denotes the Hamming distance between the gold PA graph $\hat{y}_k$ and a candidate PA graph y_k.

Stochastic gradient descent is used for parameter inference. Derivatives with respect to parameters are taken using backpropagation. Adam (Kingma and Ba, 2014) is adopted as the optimizer.

For initialization of the embeddings of a predicate/argument, the embeddings of the predicate/argument trained by the method described in Section 4.1 are utilized. The weight matrices are randomly initialized.

5 Experiment

5.1 Experimental Setting

The KWDLC (Kyoto University Web Document Leads Corpus) evaluation set (Hangyo et al., 2012) was used for our experiments, because it contains

a wide variety of Web documents, such as news articles and blogs. This evaluation set consists of the first three sentences of 5,000 Web documents. Morphology, named entities, dependencies, PASs, and coreferences were manually annotated.

This evaluation set was divided into 3,694 documents (11,558 sents.) for training, 512 documents (1,585 sents.) for development, and 700 documents (2,195 sents.) for testing. Table 1 shows the statistics of the number of arguments in the test set. While "dep argument" means that the argument and a predicate have a dependency relation, but a specified case marking postposition is hidden (corresponds to "dashed line" in Section 3.1), "zero argument" means that the argument and a predicate do not have a dependency relation (corresponds to "dotted line" in Section 3.1).

Since we want to focus on the accuracy of case analysis and zero anaphora resolution, gold morphological analysis, dependency analysis, and named entities were used.

The sentences having a predicate that takes multiple arguments in the same case role were excluded from training and test examples, since the base model cannot handle this phenomena (it assumes that each predicate has only one argument with one case role). For example, the following sentence,

(5) そんな 面白ネタ 満載な
such funny-material full
日々を 絵と共に
daily life-ACC picture-with
お届けします。,
report
(I report my daily life full of such funny materials along with pictures.)

where the predicate "お届けします" (report) takes both "日々" (daily life) and "絵" (picture) as ACC case arguments, was excluded from training and testing. About 200 sentences (corresponding to about 1.5% of the whole evaluation set) were excluded.

In this evaluation set, zero exophora, which is a phenomenon that a referent does not appear in a document, is annotated. Among five types of zero exophora, the two major types, "author" and "reader," are adopted, and the others are discarded. To consider "author" and "reader" as a referent, the two special nodes, AUTHOR and READER, are added as well as a NULL node in a PA graph of the base model. When the argument predication score is calculated for "author" or "reader," because its lemma does not appear in a document, for each noun in the following noun list of "author"/"reader" (Hangyo et al., 2013), the argument prediction score is calculated, and the maximum score is used as a feature.

- author: "私" (I), "我々" (we), "僕" (I), "弊社" (our company), · · ·
- reader: "あなた" (you), "客" (customer), "君" (you), "皆様"(you all), · · ·

In the argument prediction model training described in Section 4.1, a Japanese Web corpus consisting of 10M sentences was used. We preformed syntactic parsing with a publicly available Japanese parser, KNP[4]. The number of negative samples was 5, and the number of epochs was 10.

In the model training described in Section 4.3, the dimensions of both embeddings for predicates/arguments and hidden layer were set to 100. The number of epochs was set to 20, following the base model.

5.2 Result

We compared the following three methods:

- Baseline (Ouchi et al., 2015)
- Proposed model w/o arg. prediction score: in the PAS analysis model, the feature derived from the argument prediction model was not utilized. The embeddings of a predicate/argument were randomly initialized. This method corresponds to adopting the NN-based score calculation in the base model.
- Proposed model w/ arg. prediction score: the feature derived from the argument prediction model was utilized, and the embeddings of a predicate/argument were initialized with those obtained in the argument prediction model learning.

The performances of case analysis and zero anaphora resolution were evaluated by micro-averaged precision, recall, and F-measure. The precision, recall, and F-measure were averaged

[4]http://nlp.ist.i.kyoto-u.ac.jp/index.php?KNP

case	method	case analysis			zero anaphora		
		P	R	F	P	R	F
NOM	Baseline	0.880	0.868	0.874	**0.693**	0.377	0.488
	Proposed model w/o arg. prediction score	0.927	0.917	0.922	0.559	0.532	0.545
	Proposed model w arg. prediction score	**0.946**	**0.936**	**0.941**	0.568	**0.586**	**0.577**
ACC	Baseline	0.433	0.374	0.402	0.000	0.000	0.000
	Proposed model w/o arg. prediction score	0.805	0.553	0.656	0.151	0.060	0.085
	Proposed model w/ arg. prediction score	**0.890**	**0.658**	**0.756**	**0.297**	**0.124**	**0.173**
DAT	Baseline	0.224	**0.359**	0.276	0.531	0.059	0.107
	Proposed model w/o arg. prediction score	0.512	0.104	0.173	0.535	0.242	0.332
	Proposed model w/ arg. prediction score	**0.834**	0.185	**0.300**	**0.622**	**0.273**	**0.378**
ALL	Baseline	0.765	0.764	0.765	**0.686**	0.304	0.421
	Proposed model w/o arg. prediction score	0.908	0.818	0.860	0.544	0.458	0.497
	Proposed model w/ arg. prediction score	**0.937**	**0.853**	**0.893**	0.563	**0.509**	**0.534**

Table 2: Experimental results on the KWDLC corpus.

over 5 runs. Table 2 shows our experimental results. Our proposed method outperformed the baseline method by about 11 absolute points in F-measure. The comparison of "Proposed model w/o arg. prediction score" with the baseline showed that the neural network-based approach was effective, and the comparison of "Proposed model w/ arg. prediction score" with "Proposed model w/o arg. prediction score" showed that our arg. prediction model was also effective.

The following is improved by adding an argument prediction score.

(6) 久しぶりに　　パートですけど、
after a long time part-time job
働き始めて　新しい 一歩を
begin to work new　　step-ACC
踏み出しました。
step forward
(It's my first part-time job in a long time. I begin to work, and make a new step.)

While in the base model, the NOM arguments of the predicate "働き始める" (begin to work) and "踏み出す" (step forward) were wrongly classified as NULL, by adding an argument prediction score, they were correctly identified as "author."

The phenomenon "case disappearance" occurs in other languages such as Korean, and the phenomenon "argument omission" occurs in other languages such as Korean, Hindi, Chinese, and Spanish. We believe that our neural network approach to the argument prediction and the calculation of the local and global scores is also effective for such languages.

5.3 Error Analysis

Errors in our proposed model are listed below:

- Recall for ACC and DAT in both case analysis and zero anaphora resolution is low.

  One reason is that since the number of the ACC and DAT arguments is smaller than that of the NOM argument, the system tends to assign the ACC and DAT arguments with NULL. Another reason is that since this paper focuses on intra-sentential zero anaphora, the NULL arguments include arguments that appear in previous sentences as well as the case where a predicate takes no argument, which makes the training for NULL arguments difficult. We are planing to tackle with inter-sentential zero anaphora resolution.

- The distinction of "author" from NULL fails.

  (7) 肉を　　焼く だけが
  meat-ACC roast-only-NOM
  BBQ じゃない！
  BBQ-(COPULA)
  (Roasting meat isn't all in BBQ!)

  Although the NOM argument of the predicate "焼く" (roast) is "author," our proposed model wrongly classified it as NULL. Hangyo et al. (2013) identify mentions referring to an author or reader in a document, and utilize this result in the zero anaphora resolu-

tion. We plan to incorporate the author/reader identification into our model.

6 Conclusion

In this paper we presented a novel model for Japanese PAS analysis based on neural network framework. We learned selectional preferences from a large raw corpus, and incorporated them into a PAS analysis model, which considers the consistency of all PASs in a given sentence. In our experiments, we demonstrated that the proposed PAS analysis model significantly outperformed the base SOTA model.

In the future, we plan to extend our model to incorporate coreference resolution and inter-sentential zero anaphora resolution.

Abstract

We seek to address the lack of labeled data (and high cost of annotation) for textual entailment in some domains. To that end, we first create (for experimental purposes) an entailment dataset for the clinical domain, and a highly competitive supervised entailment system, ENT, that is effective (out of the box) on two domains. We then explore self-training and active learning strategies to address the lack of labeled data. With self-training, we successfully exploit unlabeled data to improve over ENT by 15% F-score on the newswire domain, and 13% F-score on clinical data. On the other hand, our active learning experiments demonstrate that we can match (and even beat) ENT using only 6.6% of the training data in the clinical domain, and only 5.8% of the training data in the newswire domain.

1 Introduction

Textual entailment is the task of automatically determining whether a natural language *hypothesis* can be inferred from a given piece of natural language *text*. The RTE challenges (Bentivogli et al., 2009; Bentivogli et al., 2011) have spurred considerable research in textual entailment over newswire data. This, along with the availability of large-scale datasets labeled with entailment information (Bowman et al., 2015), has resulted in a variety of approaches for textual *entailment recognition*.

A variation of this task, dubbed textual *entailment search*, has been the focus of RTE-5 and subsequent challenges, where the goal is to find all sentences in a corpus that entail a given hypothesis. The mindshare created by those challenges and the availability of the datasets has spurred many creative solutions to this problem. However, the evaluations have been restricted primarily to these datasets, which are in the newswire domain. Thus, much of the existing state-of-the-art research has focused on solutions that are effective in this domain.

It is easy to see though, that entailment search has potential applications in other domains too. For instance, in the clinical domain we imagine entailment search can be applied for clinical trial matching as one example. Inclusion criteria for a clinical trial (for e.g., *patient is a smoker*) become the hypotheses, and the patient's electronic health records are the text for entailment search. Clearly, an effective textual entailment search system could possibly one day fully automate clinical trial matching.

Developing an entailment system that works well in the clinical domain and, thus, automates this matching process, requires lots of labeled data, which is extremely scant in the clinical domain. Generating such a dataset is tedious and costly, primarily because it requires medical domain expertise. Moreover, there are always privacy concerns in releasing such a dataset to the community. Taking this into consideration, we investigate the problem of textual entailment in a low-resource setting.

We begin by creating a dataset in the clinical domain, and a supervised entailment system that

*This work was conducted during an internship at IBM

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1245–1255,
Berlin, Germany, August 7-12, 2016.

is competitive on multiple domains – newswire as well as clinical. We then present our work on self-training and active learning to address the lack of a large-scale labeled dataset. Our self-training system results in significant gains in performance on clinical (+13% F-score) and on newswire (+15% F-score) data. Further, we show that active learning with uncertainty sampling reduces the number of required annotations for the entailment search task by more than 90% in both domains.

2 Related work

Recognizing Textual Entailment (RTE) shared tasks (Dagan et al., 2013) conducted annually from 2006 up until 2011 have been the primary drivers of textual entailment research in recent years. Initially the task was defined as that of *entailment recognition*. RTE-5 (Bentivogli et al., 2009) then introduced the task of *entailment search* as a pilot. Subsequently, RTE-6 (Bentivogli et al., 2010) and RTE-7 (Bentivogli et al., 2011) featured entailment search as the primary task, but constrained the search space to only those candidate sentences that were first retrieved by Lucene, an open source search engine[1]. Based on the 80% recall from Lucene in RTE-5, the organizers of RTE-6 and RTE-7 deemed this filter to be an appropriate compromise between the size of the search space and the cost and complexity of the human annotation task.

Annotating data for these tasks has remained a challenge since they were defined in the RTE challenges. Successful approaches for entailment (Mirkin et al., 2009; Jia et al., 2010; Tsuchida and Ishikawa, 2011) have relied on annotated data to either train classifiers, or to develop rules for detecting entailing sentences. Operating under the assumption that more labeled data would improve system performance, some researchers have sought to augment their training data with automatically or semi-automatically obtained labeled pairs (Burger and Ferro, 2005; Hickl et al., 2006; Hickl and Bensley, 2007; Zanzotto and Pennacchiotti, 2010; Celikyilmaz et al., 2009).

Burger and Ferro (2005) automatically create an entailment recognition corpus using the news headline and the first paragraph of a news article as near-paraphrases. Their approach has an estimated accuracy of 70% on a held out set of 500 pairs. The primary limitation of the approach is that it only generates positive training examples. Hickl et al. (2006) improves upon this work by including negative examples selected using heuristic rules (e.g., sentences connected by *although*, *otherwise*, and *but*). On RTE-2 their method achieves accuracy improvements of upto 10%. However, Hickl and Bensley (2007) achieves only a 1% accuracy improvement on RTE-3 using the same method, suggesting that it is not always as beneficial.

Recent work by Bowman et al. (2015) describes a method for generating large scale annotated datasets, viz., the Stanford Natural Language Inference (SNLI) Corpus, for the problem of entailment recognition. They use Amazon Mechanical Turk to very inexpensively produce a large entailment annotated data set from image captions.

Zanzotto and Pennacchiotti (2010) create an entailment corpus using Wikipedia data. They hand-annotate original Wikipedia entries, and their associated revisions for entailment recognition. Using a previously published system for RTE (Zanzotto and Moschitti, 2006), they show that their expanded corpus does not result in improvement for RTE-1, RTE-2 or RTE-3.

Similarly, Celikyilmaz et al. (2009) address the lack of labeled data by semi-automatically creating an entailment corpus, which they use within their question answering system. They reuse text-hypothesis pairs from RTE challenges in addition to manually annotated pairs from a newswire corpus (with pairs for annotation obtained through a Lucene search over the corpus).

Note that all of the above research on expanding the labeled data for entailment has focused on *entailment recognition*. Our focus in this paper is on improving *entailment search* by exploiting unlabeled data with self-training and active learning.

3 Datasets

In this section, we describe the data sets from two domains, *newswire* and *clinical*, that we use in the development and evaluation of our work.

3.1 Newswire Domain

For the newswire domain, we use entailment search data from the PASCAL RTE-5, RTE-6 and RTE-7 challenges (Bentivogli et al., 2009; Bentivogli et al., 2010; Bentivogli et al., 2011). The dataset consists of a corpus of news documents, along with a set of hypotheses. The hypotheses come from a separate summarization task, where

[1] http://lucene.apache.org

Dataset	Size	Entailing
Newswire-train	20,104	810 (4.0%)
Newswire-dev	35,927	1,842 (5.1%)
Newswire-test	17,280	800 (4.6%)
Newswire-unlabeled	43,485	-
Clinical-train	7,026	293 (4.1%)
Clinical-dev	8,092	324 (4.0%)
Clinical-test	10,466	596 (5.6%)
Clinical-unlabeled	623,600	-

```

Figure 1: Excerpt from a sample clinical note

the summary sentences about a news story (given a topic) were manually created by human annotators. These summary sentences are used as hypotheses in the dataset. Entailment annotations are then provided for a subset of sentences from the document corpus, based on a Lucene filter for each hypothesis.

In this work, we use the RTE-5 development data to train our system (*Newswire-train*), RTE-5 test data for evaluation of our systems (*Newswire-test*), and we use the combined RTE-6 development and test data for our system development and parameter estimation (*Newswire-dev*). We use all of the development and test data from RTE-7, without the human annotation labels, as our unlabeled data (*Newswire-unlabeled*) for self-training and active learning experiments. A summary of the newswire data is shown in Table 1.

3.2 Clinical Domain

There are no public datasets available for textual entailment *search* in the clinical domain. In creating this dataset, we imagine a real-world clinical situation where hypotheses are facts about a patient that a physician seeing the patient might want to learn (e.g., *The patient underwent a surgical procedure within the last three months.*). The unstructured notes in the patients electronic medical record (EMR) is the text against which a system would determine the entailment status of the given hypotheses.

Observe that the aforementioned real-world clinical scenario is very closely related to a question answering problem, where instead of hypotheses a physician may pose natural language questions seeking information about the patient (e.g., *Has this patient undergone a surgical procedure within the past three months?*). Answers to such questions are words, phrases or passages from the patient's EMR. Since we have access to a patient-specific question answering dataset over EMRs[2] (henceforth, referred to as the QA dataset), we use it here as our starting point in constructing the clinical domain textual entailment dataset.

Given a question answering dataset, how might one go about creating a dataset on textual entailment? We follow a methodology similar to that of RTE-1 through RTE-5 for entailment set derived from question answering data. The text corpus in our entailment dataset is the set of de-identified patient records associated with the QA dataset. To generate hypotheses, human annotators converted questions into multiple assertive sentences, which is somewhat similar to what was done in the first five RTE challenges (RTE-1 through RTE-5). For a given question, the human annotators plugged in clinically-plausible answers to convert the question into a statement that may or may not be true about a given patient. Table 2 shows example hypotheses and their source questions. Note that this procedure for hypothesis generation diverges slightly from the RTE procedure, where answers from a question answering system were plugged into the questions to produce assertive sentences.

To generate entailment annotations, we paired a hypothesis with every sentence in a subset of clinical notes of the EHR, and asked human annotators to determine if the note sentence enabled them to conclude an entailment relationship with the hypothesis. For example, the text: *"The appearance is felt to be classic for early MS."* entails the hypothesis: *"She has multiple sclerosis"*. While in the RTE procedure, a Lucene search was used as a filter to limit the number of hypothesis-sentence pairs that are annotated, in our clinical dataset we

[2]a publication describing the question-answering dataset is currently under review at another venue

Question	Hypotheses
When was the patient diagnosed with dermatomyositis?	`The patient was diagnosed with dermatomyositis two years ago.`
Any creatinine elevation?	`Creatinine is elevated.`
	`Creatinine is normal.`
Why were xrays done on the forearm and hand?	`Xrays were done on the forearm and hand for suspected fracture.`

Table 2: Example question → hypotheses mappings

limit the number of annotations by pairing each hypothesis only with sentences from EMR notes containing an answer to the original question in the QA dataset.

The entailment annotations were generated by two medical students with the help of the annotations generated for QA. 11 medical students created our QA dataset of 5696 questions over 71 patient records, of which 1747 questions have corresponding answers. This was generated intermittently over a period of 11 months. Given the QA dataset, the time taken to generate entailment annotations includes conversion of questions to hypotheses, and annotating entailment. While conversion of questions to hypotheses took approx. 2 hours for 20 questions, generating about 3000 hypothesis and text pairs took approx. 16 hours.

At the end of this process, we had a total of 243 hypotheses annotated against sentences from 380 clinical notes, to generate 25,584 text-hypothesis pairs. We split this into train, development and test sets, summarized in Table 1. Although we have a fairly limited number of labeled text-hypothesis pairs, we do have a large number of patient health records (besides the ones in the annotated set). We generated unlabeled data in the clinical domain, by pairing the hypotheses from our training data with sentences from a set of randomly sampled subset of health records outside of the annotated data.

Datasets for the textual entailment search task are highly skewed towards the non-entailment class. Note that our clinical data, while smaller in size than the newswire data, maintains a similar class imbalance.

4 Supervised Entailment System

We begin by defining, in this section, our supervised entailment system (called ENT) that is used as the basis of our self-training and active learning experiments. Our system draws upon characteristics and features of systems that have previously been successful in the RTE challenges in the newswire domain. We further enhance this system with new features targeting the clinical domain. The purpose of this section is to demonstrate, through an experimental comparison with other entailment systems, that ENT is competitive on *both* domains, and is a reasonable supervised system to use in our investigations into self-training and active learning.

4.1 System Description

Top systems (Tsuchida and Ishikawa, 2011; Mirkin et al., 2009) in the RTE challenges have used various types of passage matching approaches in combination with machine learning for entailment. We follow along these lines, and design a classifier-based entailment system. For every text-hypothesis pair in the dataset we extract a feature vector representative of that pair. Then, using the training data, we train a classifier to make entailment decisions on unseen examples. In our system, we employ a logistic regression with ridge estimator (the Weka implementation (Hall et al., 2009)), powered by a variety of passage matching features described below.

Underlying many of our passage match features is a more fine-grained notion of "term match". *Term matchers* are a set of algorithms that attempt to match tokens (including multi-word tokens, such as *New York* or *heart attack*) across a pair of passages. One of the simplest examples of these is *exact string matcher*. A token in one text passage that matches exactly, character-for-character, with a token in another text passage would be considered a term match by this simple term matcher. However, these term matchers could be more sophisticated and match pairs of terms that are synonyms, or paraphrases, or

Exact	String match, ignore case
Multi-word	Overlapping terms in multi-word token
Head	String match head of multi-word token
Wikipedia	Wikipedia redirects and disamb. pages
Morphology	Derivational morphology, e.g. *archaeological* → *archaeology*
Date+Time	Match normalized dates and times
Verb resource	Match verbs using WordNet, Moby thesaurus, manual resources
UMLS	Medical concept match using UMLS
Translation	Affix-rule-based translation of medical terms to layman terms

Table 3: ENT term matchers

equivalent to one another according to other criteria. ENT employs a series of term matchers listed in Table 3. Each of these may also produce a confidence score for every match they find. Because we are working with clinical data, we added some medical domain term matchers as well – using UMLS (Bodenreider, 2004) and a rule-based "translator" of medical terms to layman terms[3].

Listed below are all of our features used in the ENT's classifier. Most passage match features aggregate the output of the term matchers along various linguistic dimensions – lexical, syntactic, semantic, and document/passage characteristics.

Lexical: This set includes a feature aggregating *exact string matches* across text-hypothesis, one aggregating *all term matchers*, a feature counting *skip-bigram matches* (using all matchers), a measure of *matched term coverage of text* (ratio of matched terms to unmatched terms). Additionally, we have some medical domain features, viz. *UMLS concept overlap*, and a measure of *UMLS-based similarity* (Shivade et al., 2015; Pedersen et al., 2007) using the UMLS::Similarity tool (McInnes et al., 2009).

Syntactic: Following the lead of several approaches textual entailment (Wang and Zhang, 2009; Mirkin et al., 2009; Kouylekov and Negri, 2010) we have a features measuring the *similarity of parse trees*. Our rule-based syntactic parser (McCord, 1989) produces dependency parses the text-hypothesis pair, whose nodes are aligned using all of the term matchers. The tree match feature is an aggregation of the aligned subgraphs in the tree (somewhat similar to a tree kernel (Moschitti, 2004)).

Semantic: We apply open domain as well as medical entity and relation detectors (Wang et al., 2011; Wang et al., 2012) to the texts, and post features measuring *overlap in detected entities* and *overlap in the detected relations* across the text-hypothesis pair. We also have a rule-based semantic frame detector for a "medical finding" frame (patient presenting with symptom or disease). We post a feature that aggregates matched *elements of detected frames*.

Passage Characteristics: Clinical notes typically have a structure and the content is often organized in sections (e.g. *History of Illness* followed by *Physical Examination* and ending with *Assessment and Plan*). We identified the section in which each note sentence was located and used them as features in the classifier. Clinical notes are also classified into many different categories (e.g., *discharge summary*, *radiology report*, etc.), which we generate features from. We also generate several features capturing the "readability" of the text segments – *parse failure*, *list detector*, *number of verbs*, *word capitalization*, *no punctuation* and *sentence size*. We also have *a measure of passage topic relevance* based on medical concepts in the pair of texts.

4.2 System Performance

To compare effectiveness of ENT on the entailment task, we chose two publicly available systems – EDITS and TIE – for comparison. Both these system are available under the Excitement Open Platform (EOP), an initiative (Magnini et al., 2014) to make tools for textual entailment freely available[4] to the NLP community. EDITS (Edit Distance Textual Entailment Suite) by Kouylekov and Negri (2010) is an open source textual entailment system that uses a set of rules and resources to perform "edit" operations on the text to convert it into the hypothesis. There are costs associated with the operations, and an overall cost is computed for the text-hypothesis pair, which determines the decision for that pair. This system has placed third (out of eight teams) in RTE-5, and seventh (out of thirteen teams) in RTE-7. The Textual Inference Engine (TIE) (Wang and Zhang, 2009) is a maximum entropy based entailment system relying on predicate argument structure matching. While this system did not partici-

[3]Rules for medical term translator were derived from http://www.globalrph.com/medterm.htm

System	Newswire			Clinical		
	Precision	Recall	F-score	Precision	Recall	F-score
Lucene	0.47	0.48	**0.47***	0.16	0.22	0.19
EDITS	0.22	0.57	0.32	0.23	0.21	0.20
TIE	0.66	0.21	0.31	0.43	0.01	0.02
ENT	0.77	0.26	0.39	0.42	0.15	**0.23***

Table 4: System performance on test data (* indicates statistical significance)

pate in the RTE challenges, it has been shown to be effective on the RTE datasets. In our experiments, we trained the EDITS system optimizing for F-score (the default optimization criterion is accuracy) and TIE with its default settings. We also used a Lucene baseline similar to the one used in RTE-5, RTE-6 and RTE-7 entailment challenges.

We trained the systems on the training set of each domain and tested on the test set. The Lucene baseline considers the first N sentences (where N is 5, 10, 15 or 20) top-ranked by the search engine to be entailing the hypothesis. The configuration with the top 10 sentences performed the best, and is reported in the results. Note that this baseline is a strong one, and none of the systems participating in RTE-5 could beat it.

Table 4 summarizes the system performance on newswire and clinical data. We observe that systems that did well on RTE datasets, were mediocre on the clinical dataset. We did not, however, put any effort into adaption of TIE and EDITS to the clinical data. So the mediocre performance on clinical is understandable. It is interesting to see though that ENT did well (comparatively) on both domains.

We note that our problem setting is most similar to the RTE-5 entailment search task. Of the 20 runs across eight teams that participated in RTE-5, the median F-Score was 0.30 and the best system (Mirkin et al., 2009) achieved an F-Score of 0.46. EDITS and TIE perform slightly above the median and ENT (with 0.39 F-score) would have ranked third in the challenge.

The performance of all systems on the clinical data is noticeably low as compared to the newswire data. An obvious difference in the two domains is the training data size (see Table 1). However, obtaining annotations for textual entailment search is expensive, particularly in the clinical domain. The remaining sections present our investigations into self-training and active learning, to overcome the lack of training data.

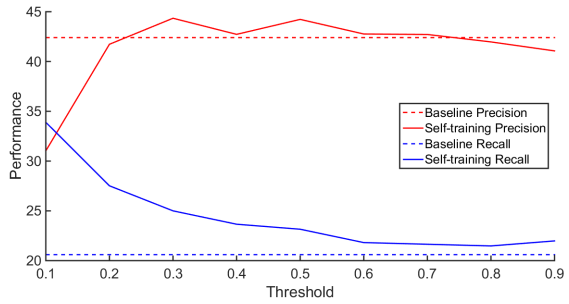
5 Self-Training

Our goal is to exploit unlabeled data, with the hope of augmenting the limited annotated data in a given domain. Self-training is a method that has been successfully used to address limited training data on many NLP tasks, such as parsing (McClosky et al., 2006), information extraction (Huang and Riloff, 2012; Patwardhan and Riloff, 2007), word sense disambiguation (Mihalcea, 2004), etc. Self-training iteratively increases the size of the training set, by automatically assigning labels to unlabeled examples, using a model trained in a previous iteration of the self-training regime.

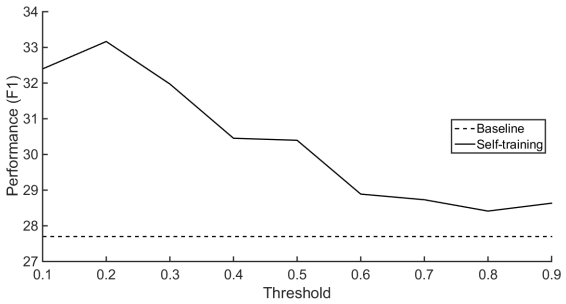
For our newswire and clinical datasets, using the set of unlabeled text-hypothesis pairs U, we ran the following training regime: A model was created using the training data L_n, and applied it to the unlabeled data U. From U, all such pairs that were classified by the model as entailing pairs with high confidence (above a threshold τ) were added to the labeled training data L_n to generate L_{n+1}. Non-entailing pairs were ignored. A new model is trained on data L_{n+1}, and the above process repeated iteratively, until a stopping criteria is reached (in our case, all pairs from U are exhausted).

The threshold τ determines the confidence of our model for a text-hypothesis pair being classified to the entailment class. This threshold was tuned by varying it incrementally from 0.1 to 0.9 in steps of 0.1. The best τ was determined on the development set, and chosen for the self-training system. Figure 2 shows the effect of τ on the development data.

As such, we see that the F-score of the self-trained model is always above that of the baseline ENT system. The F-score increases upto a peak of 0.33 at threshold τ of 0.2 before dropping at higher thresholds. Using this tuned threshold on test set, the comparitive performance on the test set is outlined in Table 5. We observe an F-score



(a) Precision and recall for clinical data



(b) F-Score for clinical data

(d) F-Score for newswire data

Figure 2: Self-training on development data

System	Newswire			Clinical		
	Precision	**Recall**	**F-score**	**Precision**	**Recall**	**F-score**
ENT	0.77	0.26	0.39	0.42	0.15	0.23
ENT + Self-Training	0.62	0.48	**0.54***	0.34	0.39	**0.36***

Table 5: Self-training results on test data (* indicates statistical significance)

of 0.36, which is significantly greater than that of the vanilla ENT system (0.23).

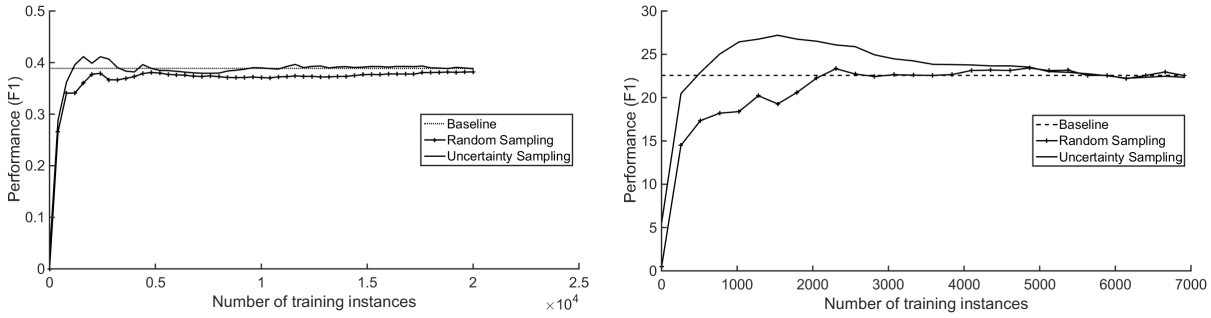
The effect of the threshold on performance correlates with the number of instances added to the training set. When the threshold is low, there are more instances being added (10,799 at threshold of 0.1) into the training set. Therefore, recall is likely to benefit, since the model is exposed to a larger variety of text-hypothesis pairs. However, the precision is low since noisy pairs are likely to be added. When the threshold is high, fewer instances are added (316 at threshold of 0.9). These are the ones that the model is most certain about, suggesting that these are likely to be less noisy. Therefore, the precision is comparatively high.

We also ran our self-training approach on the Newswire datasets. We observed similar variations in performance with newswire data as with the clinical data. At threshold of 0.9, fewer instances (49) are added to the training set from the unlabeled data, while a large number of instances (2,861) are added at a lower threshold τ of 0.1. The best performance (F-score of 0.52) was obtained at threshold of 0.3, on the development set.

This threshold also resulted in the best performance (0.54) on the test set. Similar to the clinical domain, precision increased but recall decreased as the threshold increased. Again, it is evident from Table 5 that gains obtained from self-training are due to recall. It should be noted that the self-trained system achieves an F-score of 0.54 – substantially better than the best performing system of Mirkin et al. (2009) (F-score, 0.46) in RTE-5.

6 Active Learning

Active learning is a popular training paradigm in machine learning (Settles, 2012) where a learning agent interacts with its environment in acquiring a training set, rather than passively receiving independent samples from an underlying distribution. This is especially pertinent in the clinical domain, where input from a medical professional should be sought only when really necessary, because of the high cost of such input. The purpose of exploring



(a) Newswire Data

(b) Clinical Data

Figure 3: Learning curves for uncertainty sampling and random sampling on test data

this paradigm is to achieve the best possible generalization performance at the lowest cost.

Active learning is an iterative process, and typically works as follows: a model M is trained using a minimal training dataset L. A query framework is used to identify an instance from an unlabeled set U that, if added to L, will result in maximum expected benefit. Gold standard annotations are obtained for this instance and added to the original training set L to generate a new training set L'. In the next iteration, a new model M' is trained using L' and used to identify the next most beneficial instance for the training set L'. This is repeated until a stopping criterion is met. This approach is often *simulated* using a training dataset L of reasonable size. The initial model M is created using a subset A of L. Further, instead of querying a large unlabeled set U, the remaining training data $(L - A)$ is treated as an unlabeled dataset and queried for the most beneficial addition.

We carried out active learning in this setting using a querying framework known as *uncertainty sampling* (Lewis and Gale, 1994). Here, the model M trained using A, queries the instances in $(L-A)$ for instance(s) it is least certain for a prediction label. For probabilistic classifiers the most uncertain instance is the one where posterior probability for a given class is nearest to 0.5. To estimate the effectiveness of this framework, it is always compared with a *random sampling* framework, where random instances from the training data are incrementally added to the model.

Starting with a model trained using a single randomly chosen instance, we carried out active learning using uncertainty sampling, adding one instance at a time. After the addition of each instance, the model was retrained and tested on a held out set. To minimize the effect of randomization associated with the first instance, we repeated the experiment ten times and averaged the performance scores across the ten runs.

Following previous work (Settles and Craven, 2008; Reichart et al., 2008) we evaluate active learning using learning curves on the test set. Figure 3 shows the learning curves for newswire and clinical data.

On clinical data, uncertainty sampling achieves a performance equal to the baseline ENT with only 470 instances. With random sampling, over 2,200 instances are required. The active learner matches the performance of the ENT with only 6.6% of training data. Newswire shows a similar trend, with both sampling strategies outperforming ENT, using less than half the training, and uncertainty sampling learning faster than random. While uncertainty sampling matches ENT F-score with only 1,169 instances, random sampling requires 2,305. Here, the active learner matches ENT performance using only 5.8% of the training data.

7 Effect of Class Distribution

After analyzing our experimental results, we considered that one possible explanation for the improvements over baseline ENT could plausibly be because of changes in the class distribution. From Table 1, we observe that the distribution of classes in both domains is highly skewed (only 4-5% positive instances). Self-training and active learning dramatically change the class distribution in training. To assess the effect of class distribution changes on performance, we ran additional experiments, described here.

We first investigated sub-sampling (Japkowicz, 2000) the training data to address class imbalance. This includes down-sampling the majority class or up-sampling the minority class until the classes are

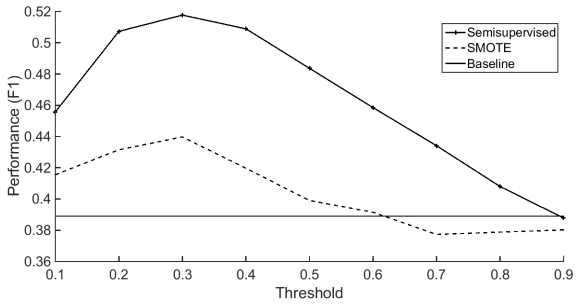


Figure 4: Comparison of SMOTE and self-training (on newswire development set)

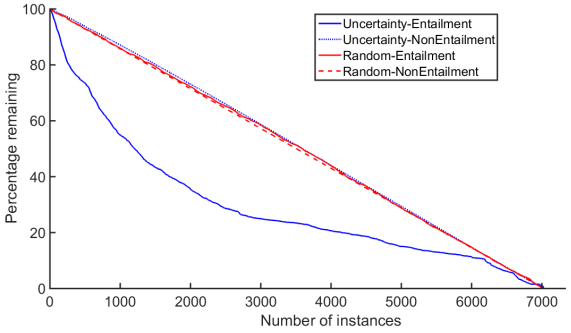

Figure 5: Comparison of sampling strategies for active learning (on newswire development set)

balanced. We found no significant gains over the vanilla ENT baseline with both strategies. Specifically, down-sampling resulted in gains of only 0.002 and 0.001 F-score and up-sampling resulted in a drop of 0.011 and 0.013 F-score on clinical-dev and newswire-dev, respectively.

Another approach to addressing class imbalance is to apply Synthetic Minority Oversampling Technique (SMOTE) (Chawla et al., 2002). SMOTE creates instances of the minority class by taking a minority class sample and introducing synthetic examples between its k nearest neighbors. Using SMOTE on newswire and clinical datasets resulted in improvements over baseline ENT in both domains. The improvements using self-training, however, are significantly higher than SMOTE. Figure 4 shows a comparison of SMOTE and self-training on newswire data, where equal number of instances are added to the training set by both techniques.

Finally, for active learning, we consider random sampling as a competing approach to uncertainty sampling. Figure 5 illustrates the percentage of positive and negative instances that get included in the training set for both sampling strategies, as active learning proceeds. The blue solid line shows that positive instances are *consumed* faster than the negative instances with uncertainty sampling. Thus, a higher percentage of positive instances (that approximately equals the number of negative instances getting added) get added and this helps maintain a balanced class distribution.

Once the positive instances are exhausted, more negative instances are added, resulting in some class imbalance that hurts performance (even though more training data is being added overall). In contrast, random sampling does not change the class balance, as it *consumes* a proportional number of positive and negative instances (resulting in more negative than positive instances). The plot indicates that when using uncertainty sampling 80% of the positive examples are added to the training set with less than 50% of the data. This also explains how the active learner matches the performance of the model using the entire labeled set, but with fewer training examples.

8 Conclusion

We explored the problem of textual entailment search in two domains – newswire and clinical – and focused a spotlight on the cost of obtaining labeled data in certain domains. In the process, we first created an entailment dataset for the clinical domain, and a highly competitive supervised entailment system, called ENT, which is effective (out of the box) on two domains. We then explored two strategies – self-training and active learning – to address the lack of labeled data, and observed some interesting results. Our self-training system substantially improved over ENT, achieving an F-score gain of 15% on newswire and 13% on clinical, using only additional unlabeled data. On the other hand, our active learning experiments demonstrated that we could match (and even beat) the baseline ENT system with only 6.6% of the training data in the clinical domain, and only 5.8% of the training data in the newswire domain.

Acknowledgments

We thank our in-house medical expert, Jennifer Liang, for guidance on the data annotation task, our medical annotators for annotating clinical data for us, and Murthy Devarakonda for valuable insights during the project. We also thank Eric Fosler-Lussier and Albert M. Lai for their help in conceptualizing this work.

Annotating and Predicting Non-Restrictive Noun Phrase Modifications

Gabriel Stanovsky **Ido Dagan**
Computer Science Department, Bar-Ilan University
gabriel.satanovsky@gmail.com
dagan@cs.biu.ac.il

Abstract

The distinction between restrictive and non-restrictive modification in noun phrases is a well studied subject in linguistics. Automatically identifying non-restrictive modifiers can provide NLP applications with shorter, more salient arguments, which were found beneficial by several recent works. While previous work showed that restrictiveness can be annotated with high agreement, no large scale corpus was created, hindering the development of suitable classification algorithms. In this work we devise a novel crowdsourcing annotation methodology, and an accompanying large scale corpus. Then, we present a robust automated system which identifies non-restrictive modifiers, notably improving over prior methods.

1 Introduction

Linguistic literature provides a large body of research distinguishing between two types of modifiers within noun phrases: (1) *Restrictive modifiers*, which constitute an integral part of the entity referenced by the NP, e.g., the underlined modifier in "*She wore the necklace that her mother gave her*", versus (2) Non-restrictive modifiers, which provide an additional or parenthetical information on an already definite entity, e.g., "*The speaker thanked president Obama who just came into the room*" (Huddleston et al., 2002; Fabb, 1990; Umbach, 2006).

The distinction between the two types is semantic in nature and relies heavily on the context of the NP. Evidently, many syntactic constructions can appear in both restrictive and non-restrictive uses. While the previous examples were of relative clauses, Figure 1 demonstrates this distinction in various other syntactic constructions.

Identifying and removing non-restrictive modifiers yields shorter NP arguments, which proved beneficial in many NLP tasks. In the context of abstractive summarization (Ganesan et al., 2010) or sentence compression (Knight and Marcu, 2002), non-restrictive modifiers can be removed to shorten sentences, while restrictive modification should be preserved.

Further, recent work in information extraction showed that shorter arguments can be beneficial for downstream tasks. Angeli et al. (2015) built an Open-IE system which focuses on shorter argument spans, and demonstrated its usefulness in a state-of-the-art Knowledge Base Population system. Stanovsky et al. (2015) compared the performance of several off-the-shelf analyzers in different semantic tasks. Most relevant to this work is the comparison between Open-IE and Semantic Role Labeling (Carreras and Màrquez, 2005). Specifically, they suggest that SRL's longer arguments introduce noise which hurts performance for downstream tasks.

Finally, in question answering, omitting non-restrictive modification can assist in providing more concise answers, or in matching between multiple answer occurrences.

Despite these benefits, there is currently no consistent large scale annotation of restrictiveness, which hinders the development of automatic tools for its classification. In prior art in this field, Dornescu et al. (2014) used trained annotators to mark restrictiveness in a large corpus. Although they reached good agreement levels in restrictiveness annotation, their corpus suffered from inconsistencies, since it conflated restrictiveness annotation with inconsistent modifier span annotation.

The contributions of this work are twofold. Primarily, we propose a novel crowdsroucing anno-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1256–1265,
Berlin, Germany, August 7-12, 2016.

tation methodology which decouples the binary (restrictive / non-restrictive) distinction from the modifier span annotation (Section 3). Following this methodology, in Section 4 we present a large scale annotated corpus, which will allow further research into the automatic identification of non-restrictive modification.

Additionally, we developed a strong automatic classifier, which learns from our new corpus (Section 5). This classifier uses new linguistically motivated features which are robust enough to perform well over automatically predicted parse trees.

The corpus and the automatic classifier are both made publicly available.[1]

While there is still much room for improvement, especially in some of the harder, more context-dependent, cases (most notably, prepositional and adjectival modifiers), our system provides an applicable means for identifying non-restrictive modification in a realistic NLP setting.

2 Background

In this section we cover relevant literature from several domains. In Section 2.1 we discuss the established linguistic distinction between restrictive and non-restrictive modification. Following, in Section 2.2 we discuss previous NLP work on annotating and identifying this distinction. Finally, in Section 2.3 we briefly describe the recent QA-SRL annotation paradigm (He et al., 2015), which we utilize in Section 3 as part of our annotation scheme.

2.1 Non-Restrictive Modification

Throughout the paper we follow Huddleston et al.'s (2002) well-known distinction between two types of NP modifiers: (1) *Restrictive modifiers*, for which the content of the modifier is an integral part of the meaning of the containing NP, and, in contrast, (2) *Non-restrictive modifiers*, that present a separate, parenthetical unit of information about the NP.

While some syntactic modifiers (such as determiners or genitives) are always restrictive, others are known to appear in both restrictive as well as non-restrictive uses, depending on semantics and context (Huddleston et al., 2002; Fabb, 1990; Umbach, 2006). Among these are relative clauses, adjectival, prepositional, non-finite, and verbal modifiers. See Figure 1 for examples of different syntactic constructions appearing in both restrictive as well as non-restrictive contexts.

(RC1) The necklace *that her mother gave her*$^{+}$ is in the safe.
(RC2) The governor disagreed with the U.S ambassador to China *who seemed nervous*$^{-}$.
(NF1) People *living near the site*$^{+}$ will have to be evacuated.
(NF2) sheriff Arthur Lester, *standing against the wall*$^{-}$, looked tired.
(PP1) The kid *from New York*$^{+}$ won the lottery.
(PP2) The assassination of Franz Ferdinand *from Austria*$^{-}$ started WWI.
(AD1) The *good*$^{+}$ boys won.
(AD2) The water level rose a *good*$^{-}$ 12 inches.

Figure 1: Restrictive (marked in red and a plus sign) and non-restrictive (marked in blue and a minus sign) examples in different syntactic constructions, see elaboration in Section 2. Examples index: RC - Relative clause, NF - Non-finite clauses (Huddleston et al. [p. 1265]), PP - Prepositional modifiers, AD - Adjectival modifiers (Huddleston et al. [p. 528]).

For example, for *relative clause*, Huddleston et al. [p. 1058] identifies both restrictive as well as non-restrictive uses (for which they use the terms *integrated* and *supplementary*, respectively). In the sentence marked (RC1), the highlighted relative clause is restrictive, distinguishing the necklace being referred to from other necklaces, while in sentence (RC2), the relative clause does not pick an entity from a larger set, but instead presents separate information about an already specified definite entity.

2.2 Non-Restrictive Modification in NLP

Syntactic and semantic annotations generally avoid the distinction between restrictive and non-restrictive modification (referred here as "restrictiveness" annotation).

The syntactic annotation of the Penn TreeBank (Marcus et al., 1993) and its common conversion to dependency trees (e.g., (de Marneffe and Manning, 2008)) do not differentiate the cases discussed above, providing the same syntactic structure for the semantically different instances. See Figure 2 for an example.

Furthermore, prominent semantic annotations,

[1] http://www.cs.biu.ac.il/~nlp/resources/downloads

such as PropBank (Palmer et al., 2005), AMR (Banarescu et al., 2013), CCG (Hockenmaier and Steedman, 2007), or FrameNet (Baker et al., 1998), also avoid this distinction. For example, PropBank does not differentiate between such modifiers, treating both types of modification as an integral part of an argument NP.

Two recent works have focused on automatically identifying non-restrictive modifications. Honnibal et al. (2010) added simple automated restrictiveness annotations to NP-modifiers in the CCGbank (Hockenmaier and Steedman, 2007). Following a writing style and grammar rule, a modifier was judged as non-restrictive if and only if it was preceded by a comma.[2] This annotation was not intrinsically evaluated, as it was carried as part of an extrinsic evaluation of a statistical parser.

Having similar goals to ours, Dornescu et al. (2014) sets the prior art at annotating and predicting non-restrictive modification. In the annotation phase, each of their trained annotators was asked to (1) Mark spans of words in the sentence as forming an NP modifier, and (2) Mark each span they annotated in (1) as either restrictive or non-restrictive, and specify its type from a predefined list (e.g., relative clause, adjectival modifier, etc.).

Their inter-annotator agreement on the first task (modifier span) was low, reaching pairwise F1 score of only 54.9%, possibly due to problems in the annotation procedure, as acknowledged by the authors. The second part of the annotation achieved better agreement levels, reaching kappa of 0.78 (substantial agreement) for type annotation and 0.51 (moderate agreement) for restrictiveness annotation.[3]

Following the creation of the annotated dataset, they developed rule based and machine learning classifiers. All of their classifiers performed only at about 47% F1, at least partly due to the inconsistencies in span annotation discussed above.

To conclude this survey, although an effort was made by Dorenscu et al. (2014), there is currently no available consistent corpus annotated with non-restrictive modifiers.

[2]Notice that this is indeed the case in some of the non-restrictive examples in Figure 1.

[3]Note that the agreement for the first task is reported in F1 while the second task is reported in Cohen's kappa.

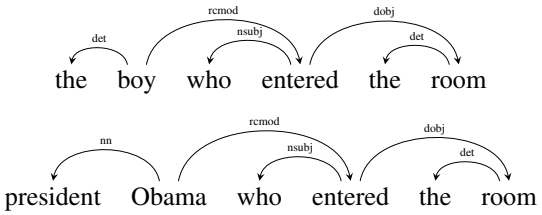

Figure 2: Restrictive (top) and non-restrictive (bottom) NP modifications receive the same representation in dependency trees. See Section 2.2.

2.3 QA-SRL

Traditional Semantic Role Labeling (SRL) (Carreras and Màrquez, 2005) is typically perceived as answering **argument role questions**, such as *who, what, to whom, when*, or *where*, regarding a target predicate. For instance, PropBank's ARG0 for the predicate **say** answers the question "*who* **said** *something?*".

QA-SRL (He et al., 2015) suggests that answering explicit role questions is an intuitive means to solicit predicate-argument structures from non-expert annotators. Annotators are presented with a sentence in which a target predicate[4] was marked, and are requested to annotate argument role questions, phrased using a restricted grammar, and corresponding answers.

For example, given the sentence "*President Obama who flew to Russia called the vice president*" and the target predicate **called**, an annotator can intuitively provide the following QA pairs: (1) *Who called?* **President Obama** and (2) *Whom did someone call?* **the vice president**.

In order to assess the validity of their annotation scheme, He et al. annotated a large sample of the PropBank corpus (1241 sentences) with QA-SRL, and showed high agreement with PropBank over this sample. In the following sections we make use of these explicit role questions for annotating non-restrictive modifiers.

3 Annotation Methodology

As mentioned in the Introduction, the first goal of this work is to assemble a large and consistent corpus, annotated with non-restrictive modifications. In this section, we present a crowdsourcing methodology which allows us to generate such corpus in a cost-effective manner (Section 3.2). As a preliminary step, we conducted a smaller scale

[4]Currently consisting of automatically annotated verbs.

expert annotation (Section 3.1), which will serve as a gold standard with which to test the crowsdsourced annotations.

3.1 Expert Annotation

Two researchers, with linguistics and NLP education, were presented with a sample of 219 modifiers of NPs in 100 sentences,[5] and were asked to annotate each modifier as either restrictive or non-restrictive, according to the linguistic definition presented in Section 2. Prior to annotating the expert dataset, the annotators discussed the process and resolved conflicts on a development set of 20 modifiers.

The annotators agreement was found to be high, reaching agreement on 93.5% of the instances, and κ of 84.2% . An analysis of the few disagreements found that the deviations between the annotators stem from semantic ambiguities, where two legitimate readings of the sentence led to disagreeing annotations. For example, in "*sympathetic fans have* **sent** *Ms. Shere copies of her recipes clipped from magazines over the years*", one annotator read the underlined modifier clause as restrictive, identifying particular recipes, while the second annotator read the modifier as non-restrictive, adding supplementary information on the sent recipes.

Finally, we compose the expert annotation dataset from the 207 modifiers agreed upon by both annotators. In the next section we use this dataset to evaluate the quality of our crowdsourced annotations.

3.2 Crowdsourcing Annotation Process

In our scheme, each annotation instance assigns a binary label (restrictive or non-restrictive) to a 4-tuple (s, v, p, m) – where m is a modifier of the noun phrase p, which is an argument of a verbal predicate v, in a sentence s. We incorporate v in our scheme in order to provide non-trained annotators with an argument role question (discussed in 2.3), as elaborated below.[6]

Consider, for example, the sentence s – "*the speaker* **thanked** *[President Obama who just entered the room]*". We want to annotate the restrictiveness value of the relative clause m (underlined), which modifies the matrix noun phrase p (bracketed), which is in turn an argument of a governing predicate v (in bold).

Our annotation procedure does not require the annotator to be familiar with the formal linguistic definition of restrictiveness. Instead, we use binary question-answering (true / false questions) as an intuitive formulation of non-restrictive modification. We present annotators with the argument role question pertaining to the argument NP, and ask whether this NP *without* the modifier gives the same answer to the argument role question as the original NP did.

In our example, an annotator is presented with the argument role question "*whom did someone thank?*" (which is answered by p), and is asked to decide whether the reduced NP, "*President Obama*", provides the same answer to the question as the full NP does. If the answer is positive (as in this case), we consider the modifier to be *non-restrictive*, otherwise we consider it to be *restrictive*.

As an example for the restrictive case, consider "*she* **wore** *[the necklace that her mother gave her]*", and the respective argument role-question "*what did someone wear?*". In this case, as opposed to the previous example, the reduced NP ("*the necklace*") does not refer to the same entity as the original NP, since we lose the specific identity of the necklace which was worn.

The intuition for this process arises from the linguistic definition for modifier restrictiveness. Namely, a restrictive modifier is defined as an integral part of the NP, and a non-restrictive modifier as providing supplementary or additional information about it. Therefore, in the restrictive case, omitting the modifier would necessarily change the meaning of the answer, while in the non-restrictive case, omitting it would not change the entity referenced by the full NP, and would therefore provide the same answer to the argument role question.

4 Corpus

In this section we describe the creation of a consistent human-annotated restrictiveness corpus, using the annotation process described in the previous section. We show this corpus to be of high quality by comparing it with the independent expert annotation. In Section 5 we use this corpus to train and test several automatic classifiers.

[5] These were taken at random from the development partition of the corpus described in Section 4.

[6] Our annotation currently covers the most common case of NPs which serve as arguments of verbal predicates.

Modifier Type	Identified By	#	Non-Restrictive	Agreement	
				κ	%
Adjectival	*pos* = JJ	684	41.36%	74.70	87.36
Prepositional	*pos* = IN / TMP / LOC	693	36.22%	61.65	85.10
Appositive	*rel* = APPO / PRN	342	73.68%	60.29	80.00
Non-Finite	*rel* = TO	279	68.82%	71.04	86.48
Verbal	*pos* = VB and not relative clause	150	69.33%	100	100
Relative clause	*pos* = VB and child *pos* = WP	43	79.07%	100	100
Total	**-**	**2191**	**51.12%**	**73.79**	**87.00**

Table 1: Corpus statistics by modifier types, which were identified by part of speech (*pos*) and dependency label (*rel*) (Section 4.1). The number of instances (#) and non-restrictiveness percentage refer to the full crowdsourced annotation. Agreement (Cohen's κ and percent of matching instances) is reported for the expert-annotated data (Section 4.2), between the expert and crowdsourced annotations.

4.1 Data Collection

We use the dataset which He et al. (2015) annotated with Question-Answer pairs (discussed in Section 2.3), and keep their train / dev / test split into 744 / 249 / 248 sentences, respectively. This conveniently allows us to link between argument NPs and their corresponding argument role question needed for our annotation process, as described in previous section.

This dataset is composed of 1241 sentences from the CoNLL 2009 English dataset (Hajič et al., 2009), which consists of newswire text annotated by the Penn TreeBank (Marcus et al., 1993), PropBank (Palmer et al., 2005), and NomBank (Meyers et al., 2004), and converted into dependency grammar by (Johansson and Nugues, 2008).

As mentioned in Section 3.2, each of our annotation instances is composed of a sentence s, a verbal predicate v, a noun phrase p, and a modifier m. We extract each such possible tuple from the set of sentences in the following automatic manner:

1. Identify a verb v in the gold dependency tree.
2. Follow its outgoing dependency arcs to a noun phrase argument p (a dependent of v with a nominal part of speech).
3. Find m, a modifying clause of p which might be non-restrictive, according to the rules described in Table 1, under the "Identified By" column. This filters out modifiers which are always restrictive, such as determiners or genitives, following (Huddleston et al., 2002), as discussed in Section 2. Notice that this automatic modifier detection decouples the span annotation from the restrictiveness annotation, which was a source for inconsistencies in Dornescu et al's annotation (Section 2.2).

This automatic process yields a dataset of 2191 modifiers of 1930 NPs in 1241 sentences. We note that our collection process ensures that the corpus correlates with the syntactic dependency annotation of the CoNLL 2009 shared task, and can therefore be seen as an augmentation of its modifier labels to include restrictiveness annotations.

In order to find the corresponding argument role question, we follow the process carried by He et al.; An argument NP is matched to an annotated Question-Answer pair if the NP head is within the annotated answer span. Following this matching process yields a match for 1840 of the NPs.

For the remaining 90 NPs we manually compose an argument role question by looking at the governing predicate and its argument NP. For example, given the sentence "*[The son of an immigrant stonemason of Slovenian descent] was* **raised** *in a small borough outside Ebensburg*", the predicate **raised** and the bracketed NP argument, we produce the argument role question "*Who was raised?*".

The corpus category distribution is depicted in Table 1, under column labeled "#". In later sections we report agreement and performance across these categories to produce finer grained analyses.

4.2 Crowdsourcing Annotation

We use Amazon Mechanical Turk[7] to annotate the 2191 modifiers for restrictiveness, according to the

[7] https://www.mturk.com

process defined in Section 3.2. Each modifier was given to 5 annotators, and the final tag was assigned by majority vote. We used the development set to refine the guidelines, task presentation, and the number of annotators.

Each annotator was paid 5c for the annotation of an NP, which in average provided 1.16 modifiers. This sets the average price for obtaining a single modifier annotation at $5 \cdot \frac{5}{1.16} = 21.5$c.

The agreement with the 217 NP modifiers annotated by the experts (Section 3.1) and percentage of positive (non-restrictive) examples per category can be found in Table 1, in the columns labeled "agreement". The labels are generally balanced, with 51.12% non-restrictive modifiers in the entire dataset (varying between 36.22% for prepositional modifiers and 79.07% for relative clauses).

Overall, the crowdsourced annotation reached good agreement levels with our expert annotation, achieving 73.79 κ score (substantial agreement). The lowest agreement levels were found on prepositional and appositive modifiers (61.65% and 60.29%).[8] Indeed, as discussed in Section 2, these are often subtle decisions which rely heavily on context. For example, the following instances were disagreed upon between our expert annotation and the crowdsourced annotation: In "*[Charles LaBella , the assistant U.S. attorney prosecuting the Marcos case], did n't* **return** *phone calls seeking comment*" (an appositive example), the experts annotated the underlined modifier as non-restrictive, while the crowdsource annotation marked it as restrictive. Inversely, in "*The amendment* **prompted** *[an ironic protest] from Mr. Thurmond*", the experts annotated the adjectival modifier as restrictive, while the crowdsource annotation tagged it as non-restrictive.

5 Predicting Non-Restrictive Modification

In this section we present an automatic system which: (1) Identifies NP modifiers in a dependency parser's output (as shown in Table 1, column "Identified By") and (2) Uses a CRF model to classify each modifier as either restrictive or non-restrictive, based on the features listed in Table 2, and elaborated below.[9]

5.1 Baselines

We begin by replicating the algorithms in the two prior works discussed in Section 2.2. This allows us to test their performance consistently against our new human annotated dataset.

Replicating (Honnibal et al., 2010) They annotated a modifier as restrictive if and only if it was preceded with a comma. We re-implement this baseline and classify all of the modifiers in the test set according to this simple property.

Replicating (Dornescu et al., 2014) Their best performing ML-based algorithm[10] uses the supervised CRFsuite classifier (Okazaki, 2007) over "standard features used in chunking, such as word form, lemma and part of speech tags". Replicating their baseline, we extract the list of features detailed in Table 2 (in the row labeled "chunking features").

5.2 Our Classifier

In addition to Dornescu et al.'s generic chunking framework, we also extract features which were identified in the linguistic literature as indicative for non-restrictive modifications. These features are then used in the CRFsuite classifier (the same CRF classifier used by Donescu et al.) to make the binary decision. The following paragraphs elaborate on the motivation for each of the features.

Enclosing commas We extend Honnibal's et al.'s classification method as a binary feature which marks whether the clause is both preceded and terminated with a comma. This follows from a well-known writing style and grammar rule which indicates that non-restrictive clausal modifiers should be enclosed with a comma.

Governing relative In the linguistic literature, it was posited that the word introducing a clausal modifier (termed *relative*) is an indication for the restrictiveness of the subordinate clause. For example, Huddleston. et al. (2002) [p. 1059] analyzes the word "that" as generally introducing a restrictive modifier, while a wh-pronoun is

[8] While linguistic literature generally regards appositives as non-restrictive, some of the appositions marked in the dependency conversion are in fact misclassified coordinations, which explains why some of them were marked as restrictive.

[9] We use our new crowdsourced corpus to train our model as well as the baseline model.

[10] They also implement a rule-based method, named DAPR, which, when combined with the described ML approach surpasses their ML algorithm by ∼1.5% increase in F1. We could not find a publicly available implementation of this method.

more likely to introduce non-restrictive modification. We therefore extract features of the word which governs the relative, such as the surface form, its lemma, POS tag, and more. The full list is shown under "Governing relative" in Table 2.

Named entities As illustrated throughout the paper, modifiers of named entities tend to be non-restrictive. We run the Stanford Named Entity Recognizer (NER) (Finkel et al., 2005) and introduce a feature indicating the type of named entity (PERSON, ORG or LOC), where applicable.

Lexical word embeddings We include the pre-trained word embeddings of the modifier's head word, calculated by (Mikolov et al., 2013). These distributional features help the classifier associate between similar words (for example, if "good" is non-restrictive in some contexts, it is likely that "fine" is also non-restrictive within similar contexts).

Modifier type We add the automatically identified modifier type as a feature, to associate certain features as indicative for certain types of modifiers (e.g., enclosing commas might be good indicators for relative clause, while word embeddings can be specifically helpful for adjectival modifiers).

System	Feature Type	Description
Honnibal et al.	Preceding comma	w[-1] == ,
This paper	Chunking features (Dornescu et al.)	feats[head-1] feats[head] feats[head+1]
	Enclosing commas	true iff the clause is preceded and terminated with commas
	Governing relative	feats[parent-1] feats[parent] feats[parent+1]
	Prepositions	feats[pobj-1] feats[pobj] feats[pobj+1]
	NER	PERSON, ORGANIZATION, LOCATION
	Lexical word embeddings	Mikolov et al's 300-dimensional continuous word embeddings
	Modifier type	one of the types described in Table 1

Table 2: Features used for classification in each of the systems as described in Section 5. *head* - head of the modifier in the dependency tree. *parent* - parent of *head* in the dependency tree. *pobj* - object of the preposition, in case of prepositional *head*. *feats[i]* refers to extracting the following features from the word i: POS tag, lemma, is title, is all lower case, is all upper case, is beginning / end of sentence.

6 Evaluation

We use the QA-SRL test section (containing 412 NP modifiers) to evaluate each of the systems described in Section 5 on gold and predicted trees, both provided in the CoNLL 2009 dataset (the predicted dependency relations were obtained using MaltParser (Nivre et al., 2007)). The gold setting allows us to test the performance of the systems without accumulating parser errors. In addition, it allows us to partition and analyze our dataset according to the gold modifier type. The predicted setting, on the other hand, allows us to evaluate our classifier in a real-world application scenario, given automatic parsing output.

6.1 Gold Trees

The results for each of the systems across our categories on the gold trees are shown in Table 3. Note that we regard non-restrictive modification as positive examples, and restrictive modification as negative examples. This is in line with the applicative goal of reducing argument span by removing non-restrictive modifiers, discussed in the Introduction. Switching the labels does not significantly change the numbers, since the corpus is relatively well balanced between the two labels (as can be seen in Table 1). Following are several observations based on an error analysis of these results.

Prepositional and adjectival modifiers are harder to predict All systems had more difficulties in classifying both of these categories. This reiterates the relatively lower agreement for these categories between the crowdsource and expert annotation, discussed in Section 4.2.

For clausal modifiers, preceding commas are good in precision but poor for recall As can be seen in Honnibal et al.'s columns, a preceding comma is a good indication for a non-restrictive clausal modifier (all categories excluding adjectival or verbal modifiers), but classifying solely by its existence misses many of the non-restrictive instances.

Modifier Type	#	Precision			Recall			F1		
		Honnibal	Dornescu	Our	Honnibal	Dornescu	Our	Honnibal	Dornescu	Our
Prepositional	135	.83	.67	.69	.1	.16	.41	.18	.26	.51
Adjectival	111	.33	.38	.59	.06	.06	.21	.11	.11	.31
Appositive	78	.77	.81	.82	.34	.93	.98	.47	.87	.89
Non-Finite	55	.77	.63	.64	.29	.97	.97	.42	.76	.77
Verbal	20	0	.75	.75	0	1	1	0	.86	.86
Relative clause	13	1	.85	.85	.27	1	1	.43	.92	.92
Total	412	.72	.72	**.73**	.19	.58	**.68**	.3	.64	**.72**

Table 3: Test set performance of the 3 different systems described in Sections 5 and 6 on gold trees from the CoNLL 2009 dataset, across the different categories defined in Section 4.

Features		**P**	**R**	**F1**
All		.73	.68	.72
Baseline	- comma	.72	.68	.70
	- chunking	.72	.66	.69
New	- governing relative	.74	.61	.67
	- prepositions	.73	.67	.70
	- word embeddings	.72	.69	.71
	- NER	.71	.68	.70
	- mod type	.74	.66	.70

Table 4: Feature ablation tests on gold trees. Each row specifies a different feature set – "All" specifies the entire feature set from Table 2, while each subsequent line removes one type of features.

(Dornescu et al., 2014) performs better on our dataset Their method achieves much better results on our dataset (compare 64% overall F1 on our dataset with their reported 45.29% F1 on their dataset). This speaks both for their method as a valid signal for restrictiveness annotation, as well as for the improved consistency of our dataset.

Our system improves recall Overall, our system significantly outperforms both baselines by more than 8% gain in F1 score. Specifically, the numbers show clearly that we improve recall in the frequent categories of prepositional and adjectival modifiers. Furthermore, the results of an ablation test on our features (shown in Table 4) show that chunking and governing relative features provide the highest individual impact.

6.2 Predicted Trees

To test our classifier in a realistic setting we evaluate its performance on predicted dependency trees. To obtain the candidate modifiers, we use the same extractor presented in previous sections, applied on the predicted trees in the test section of the CoNLL 2009 dataset. We then apply the models trained on the gold train set of the same corpus.

System	**P**	**R**	**F1**
Candidate Extraction	.91	.93	.92
Honnibal	.71	.18	.29
Dornescu	.68	.53	.59
Our	**.69**	**.63**	**.66**

Table 5: Restrictiveness results (bottom three lines) on predicted trees. The top line (Candidate Extraction) measures the percent of correct modifiers identified in the predicted trees (shared across all of the classifiers). See Section 6.2.

For evaluation, we use the gold labels and compute (1) precision – the percent of predicted non-restrictive modifiers which match a gold non-restrictive modifier, and (2) recall – the percent of gold non-restrictive modifiers which match a predicted non-restrictive modifier. Note that this metric is strict, conflating both parser errors with our classifier's errors. The results are shown in Table 5.

The first line in the table measures the performance of the modifier extractor module on the predicted trees. A predicted modifier is considered correct if it agrees with a gold modifier on both its syntactic head as well as its span. The modifier extractor module is shared across all classifiers, as discussed in Section 5, and its performance on the predicted trees imposes an upper bound on all the classifiers.

Both our and Dornescu's classifiers drop 5-6 points in F1, keeping the differences observed on the gold trees, while Honnibal et al.'s simple comma-based classifier is less sensitive to parser errors, dropping only one point in F1.

This small drop stems from our classifiers largely relying only on the modifier head and its span for feature computation, generally ignoring

parsing errors within the modifier subtree.

7 Conclusions and Future Work

We presented an end-to-end framework for restrictiveness annotation, including a novel QA-SRL based crowdsourcing methodology and a first consistent human-annotated corpus. Furthermore, we presented a linguistically motivated classifier, surpassing the previous baseline by 8% gain in F1.

Future work can use our annotated corpus to develop classifiers that deal better with prepositional and adjectival modifiers, which require deeper semantic analysis.

Acknowledgments

We would like to thank Michael Elhadad and Yoav Goldberg for fruitful discussions, and the anonymous reviewers for their helpful comments.

Abstract

This study proposes the bilingual segmented topic model (BiSTM), which hierarchically models documents by treating each document as a set of segments, e.g., sections. While previous bilingual topic models, such as bilingual latent Dirichlet allocation (BiLDA) (Mimno et al., 2009; Ni et al., 2009), consider only cross-lingual alignments between entire documents, the proposed model considers cross-lingual alignments between segments in addition to document-level alignments and assigns the same topic distribution to aligned segments. This study also presents a method for simultaneously inferring latent topics and segmentation boundaries, incorporating unsupervised topic segmentation (Du et al., 2013) into BiSTM. Experimental results show that the proposed model significantly outperforms BiLDA in terms of perplexity and demonstrates improved performance in translation pair extraction (up to +0.083 extraction accuracy).

1 Introduction

Probabilistic topic models, such as probabilistic latent semantic analysis (PLSA) (Hofmann, 1999) and latent Dirichlet allocation (LDA) (Blei et al., 2003), are generative models for documents that have been used as unsupervised frameworks to discover latent topics in document collections without prior knowledge. These topic models were originally applied to monolingual data; however, various recent studies have proposed the use of probabilistic topic models in multilingual settings[1], where latent topics are shared across multiple languages. These models have improved several multilingual tasks, such as translation pair extraction and cross-lingual text classification (see the survey paper by Vulić et al. (2015) for details).

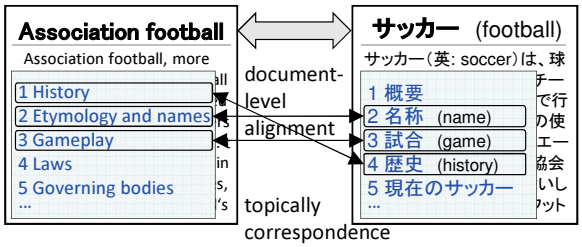

Figure 1: Wikipedia Article Example

Most multilingual topic models, including bilingual LDA (BiLDA) (Mimno et al., 2009; Ni et al., 2009), model a document-aligned comparable corpus, such as a collection of Wikipedia articles, where aligned documents are topically similar but are not direct translations[2]. In particular, these models assume that the documents in each tuple share the same topic distribution and that each cross-lingual topic has a language-specific word distribution.

Existing multilingual topic models consider only document-level alignments. However, most documents are hierarchically structured, i.e., a document comprises segments (e.g., sections and paragraphs) that can be aligned across languages. Figure 1 shows a Wikipedia article example, which contains a set of sections. Sections 1, 2, and 3 in the English article correspond topically to sections 4, 2, and 3 in the Japanese counterpart, re-

[1] In this work, we deal with a bilingual setting, but our approach can be extended straightforwardly to apply to more than two languages.

[2] In this study, we focus on models for a document-aligned comparable corpus. We describe other types of multilingual topic models and their limitations in Section 7.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1266–1276,
Berlin, Germany, August 7-12, 2016.

spectively. To date, such segment-level alignments have been ignored; however, we consider that such corresponding segments must share the same topic distribution.

Du et al. (2010) have shown that segment-level topics and their dependencies can improve modeling accuracy in a monolingual setting. Based on that research, we expect that segment-level topics can also be useful for modeling multilingual data.

This study proposes a bilingual segmented topic model (BiSTM) that extends BiLDA to capture segment-level alignments through a hierarchical structure. In particular, BiSTM considers each document as a set of segments and models a document as a document-segment-word structure. The topic distribution of each segment (per-segment topic distribution) is generated using a Pitman–Yor process (PYP) (Pitman and Yor, 1997), in which the base measure is the topic distribution of the related document (per-document topic distribution). In addition, BiSTM introduces a binary variable that indicates whether two segments in different languages are aligned. If two segments are aligned, their per-segment topic distributions are shared; if they are not aligned, they are independently generated.

BiSTM leverages existing segments from a given segmentation. However, a segmentation is not always given, and a given segmentation might not be optimal for statistical modeling. Therefore, this study also presents a model, BiSTM+TS, that incorporates unsupervised topic segmentation into BiSTM. BiSTM+TS integrates point-wise boundary sampling into BiSTM in a manner similar to that proposed by Du et al. (2013) and infers segmentation boundaries and latent topics jointly.

Experiments using an English–Japanese and English–French Wikipedia corpus show that the proposed models (BiSTM and BiSTM+TS) significantly outperform the standard bilingual topic model (BiLDA) in terms of perplexity, and that they improve performance in translation extraction (up to +0.083 top 1 accuracy). The experiments also reveal that BiSTM+TS is comparable to BiSTM, which uses manually provided segmentation, i.e., section boundaries in Wikipedia articles.

2 Bilingual LDA

This section describes the BiLDA model (Mimno et al., 2009; Ni et al., 2009), which we take as our baseline. BiLDA is a bilingual extension of basic monolingual LDA (Blei et al., 2003) for a document-aligned comparable corpus. While monolingual LDA assumes that each document has its own topic distribution, BiLDA assumes that aligned documents share the same topic distribution and discovers latent cross-lingual topics.

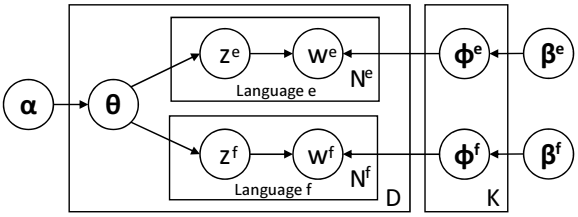

Figure 2: Graphical Model of BiLDA

Algorithm 1 Generative Process of BiLDA

1: **for** each topic $k \in \{1, ..., K\}$ **do**
2: **for** each language $l \in \{e, f\}$ **do**
3: choose $\boldsymbol{\phi}^{\boldsymbol{l}}_{\boldsymbol{k}} \sim$ Dirichlet($\boldsymbol{\beta}^{\boldsymbol{l}}$)
4: **end for**
5: **end for**
6: **for** each document pair d_i ($i \in \{1, ..., D\}$) **do**
7: choose $\boldsymbol{\theta}_{\boldsymbol{i}} \sim$ Dirichlet($\boldsymbol{\alpha}$)
8: **for** each language $l \in \{e, f\}$ **do**
9: **for** each word w^l_{im} ($m \in \{1, ..., N^l_i\}$) **do**
10: choose $z^l_{im} \sim$ Multinomial($\boldsymbol{\theta}_{\boldsymbol{i}}$)
11: choose $w^l_{im} \sim p(w^l_{im}|z^l_{im}, \boldsymbol{\phi}^{\boldsymbol{l}})$
12: **end for**
13: **end for**
14: **end for**

Algorithm 1 and Figure 2 show the generative process and graphical model, respectively, of BiLDA. BiLDA models a document-aligned comparable corpus, i.e., a set of D document pairs in two languages, e and f. Each document pair d_i ($i \in \{1, ..., D\}$) comprises aligned documents in the language e and f: d_i=(d^e_i, d^f_i). BiLDA assumes that each topic $k \in \{1, ..., K\}$ comprises the set of a discrete distribution over words for each language. Each language-specific per-topic word distribution $\boldsymbol{\phi}^{\boldsymbol{l}}_{\boldsymbol{k}}$ ($l \in \{e, f\}$) is drawn from a Dirichlet distribution with the prior $\boldsymbol{\beta}^{\boldsymbol{l}}$ (Steps 1-5). To generate a document pair d_i, the per-document topic distribution $\boldsymbol{\theta}_{\boldsymbol{i}}$ is first drawn from a Dirichlet distribution with the prior $\boldsymbol{\alpha}$ (Step 7). Thus, aligned documents d^e_i and d^f_i share the same topic distribution. Then, for each word at $m \in \{1, ..., N^l_i\}$ in document d^l_i in language l, a latent topic assignment z^l_{im} is drawn from a multinomial

14: choose $\boldsymbol{\nu_{ig}} \sim$ PYP($a, b, \boldsymbol{\theta_i}$)
15: **end for**
16: **for** each language $l \in \{e, f\}$ **do**
17: **for** each segment s_{ij}^l ($j \in \{1, ..., S_i^l\}$) **do**
18: get index of s_{ij}^l in $\boldsymbol{AS_i}$: g =get_idx($\boldsymbol{AS_i}$,s_{ij}^l)
19: **for** each word w_{ijm}^l ($m \in \{1, ..., N_{ij}^l\}$) **do**
20: choose $z_{ijm}^l \sim$ Multinomial($\boldsymbol{\nu_{ig}}$)
21: choose $w_{ijm}^l \sim p(w_{ijm}^l | z_{ijm}^l, \boldsymbol{\phi^l})$
22: **end for**
23: **end for**
24: **end for**
25: **end for**

distribution with the prior $\boldsymbol{\theta_i}$ (Step 10). Later, a word w_{im}^l is drawn from a probability distribution $p(w_{im}^l | z_{im}^l, \boldsymbol{\phi^l})$ given the topic z_{im}^l (Step 11).

3 Bilingual Segmented Topic Model

Here, we describe BiSTM, which extends BiLDA to capture segment-level alignments. Algorithm 2 and Figure 3 show the generative process and graphical model, respectively, of BiSTM. As can be seen in Figure 3, BiSTM introduces a segment-level layer between the document- and word-level layers in both languages. In other words, per-segment topic distributions for each language, $\boldsymbol{\nu^e}$ and $\boldsymbol{\nu^f}$, are introduced between per-document topic distributions $\boldsymbol{\theta}$ and topic assignments for words, $\boldsymbol{z^e}$ and $\boldsymbol{z^f}$. In addition, BiSTM incorporates binary variables $\boldsymbol{y}$ to represent segment-level alignments.

Each document d_i^l in a pair of aligned documents d_i is divided into S_i^l segments: $d_i^l = \bigcup_{j=1}^{S_i^l} s_{ij}^l$. BiSTM makes the same assumption for per-topic word distributions as BiLDA, i.e., $\boldsymbol{\phi_k^l}$ are language-specific and drawn from Dirichlet distributions (Steps 1-5).

In the generative process for a document pair d_i, the per-document topic distribution $\boldsymbol{\theta_i}$ is first drawn in the same way as in BiLDA (Step 7). Thus, in BiSTM, each document pair shares the same topic distribution.

Then, if segment-level alignments are not given, $\boldsymbol{y_i}$ are generated (Steps 8-11). We assume that each document pair d_i has a probability γ_i that indicates comparability between segments across languages. γ_i is drawn from a Beta distribution with the priors η_0 and η_1 (Step 9). Then, each of $\boldsymbol{y_i}$ is drawn from a Bernoulli distribution with the prior γ_i (Step 10). Here, $y_{ijj'}$ = 1 if and only if s_{ij}^e and $s_{ij'}^f$ are aligned; otherwise, $y_{ijj'}$ = 0. Note that if segment-level alignments are observed, then Steps 8-11 are skipped. Later, a set of aligned segment sets $\boldsymbol{AS_i}$ is generated based on $\boldsymbol{y_i}$ (Step 12). For example, given $d_i^e = \{s_{i1}^e, s_{i2}^e\}, d_i^f = \{s_{i1}^f, s_{i2}^f, s_{i3}^f\}$, y_{i11} and y_{i12} are 1, and the other y's are 0, $\boldsymbol{AS_i} = \{\boldsymbol{AS_{i1}} = \{s_{i1}^e, s_{i1}^f, s_{i2}^f\}, \boldsymbol{AS_{i2}} = \{s_{i2}^e\}, \boldsymbol{AS_{i3}} = \{s_{i3}^f\}\}$ is generated in Step 12. Then, for each aligned segment set $\boldsymbol{AS_{ig}}$ ($g \in \{1, ..., |\boldsymbol{AS_i}|\}$), the per-segment topic distribution $\boldsymbol{\nu_{ig}}$ is obtained from a Pitman–Yor process with the base measure $\boldsymbol{\theta_i}$, the concentration parameter a, and the discount parameter b (Step 14). Through Steps 12-15, aligned segments indicated by $\boldsymbol{y}$ share the same per-segment topic distribution. For instance, s_{i1}^e, s_{i1}^f, and s_{i2}^f have the same topic distribution $\boldsymbol{\nu_{i1}} \sim$ PYP(a, b, $\boldsymbol{\theta_i}$) in the above example.

Then, for each word at $m \in \{1, ..., N_{ij}^l\}$ in segment s_{ij}^l in document d_i^l in language l, a latent topic assignment z_{ijm}^l is drawn from a multinomial distribution with the prior $\boldsymbol{\nu_{ig}}$ (Step 20), where g denotes the index of the element set of $\boldsymbol{AS_i}$ that includes the segment s_{ij}^l, e.g., g for s_{i2}^f is 1. Subsequently, a word w_{ijm}^l is drawn based on the assigned topic z_{ijm}^l and the language-specific per-topic word distribution $\boldsymbol{\phi^l}$ in the same manner as in BiLDA (Step 21).

t_{igk}	Table count of topic k in the CRP for aligned segment set g in document pair i.
$\boldsymbol{t_{ig}}$	K-dimensional vector, where k-th value is t_{igk}.
$t_{ig\cdot}$	Total table count in aligned segment set g in document pair i, i.e., $\sum_k t_{igk}$.
n_{igk}	Total number of words with topic k in aligned segment set g in document pair i.
$n_{ig\cdot}$	Total number of words in aligned segment set g in document pair i, i.e., $\sum_k n_{igk}$.
M^l_{kw}	Total number of word w with topic k in language l.
$\boldsymbol{M^l_k}$	$\lvert\boldsymbol{W^l}\rvert$-dimensional vector, where w-th value is M^l_{kw}.

Table 1: Statistics used in our Inference

3.1 Inference for BiSTM

In inference, we find the set of latent variables $\boldsymbol{\theta}$, $\boldsymbol{\nu}$, $\boldsymbol{z}$, and $\boldsymbol{\phi}$ that maximizes their posterior probability given the model parameters $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$ and observations $\boldsymbol{w}$, $\boldsymbol{y}$, i.e., $p(\boldsymbol{\theta}, \boldsymbol{\nu}, \boldsymbol{z}, \boldsymbol{\phi} | \boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{w}, \boldsymbol{y})$. Here, a language-dependent variable without a superscript denotes both of the variable in language e and that in f, e.g., $\boldsymbol{z} = \{\boldsymbol{z^e}, \boldsymbol{z^f}\}$. Unfortunately, as in other probabilistic topic models, such as LDA and BiLDA, we cannot compute this posterior using an exact inference method. This section presents an approximation method for BiSTM based on blocked Gibbs sampling, inspired by Du et al. (2013).

In our inference, the hierarchy in BiSTM, i.e., the generation of $\boldsymbol{\nu}$ and $\boldsymbol{z}$, is explained by the Chinese restaurant process (CRP), through which the parameters $\boldsymbol{\theta}$, $\boldsymbol{\nu}$, and $\boldsymbol{\phi}$ are integrated out, and the statistics on table counts in the CRP, $\boldsymbol{t}$, are introduced. Table 1 lists all statistics used in our inference, where $\boldsymbol{W^l}$ denotes a vocabulary set in language l. Moreover, to accelerate convergence, we introduce an auxiliary binary variable δ^l_{ijm} for w^l_{ijm}, indicating whether w^l_{ijm} is the first customer on a table ($\delta^l_{ijm} = 1$) or not ($\delta^l_{ijm} = 0$), and t_{igk} is computed based on $\boldsymbol{\delta}$ in the same manner as in Chen et al. (2011): $t_{igk} = \sum_{s^l_{ij} \in \boldsymbol{AS_{ig}}} \sum_{m=1}^{N^l_{ij}} \delta^l_{ijm} I(z^l_{ijm} = k)$, where $I(x)$ is a function that returns 1 if the condition x is true and 0 otherwise.

Our inference groups z^l_{ijm} and δ^l_{ijm} (each group is called a "block") and jointly samples them. Moreover, if $\boldsymbol{y}$ is not observed, our inference alternates two different kinds of blocks, $(z^l_{ijm}, \delta^l_{ijm})$ and $y_{ijj'}$. In each sampling, individual variables are resampled, conditioned on all other variables. In the following, we describe each sampling stage.

Sampling $(\boldsymbol{z}, \boldsymbol{\delta})$:

The joint posterior distribution of $\boldsymbol{z}$, $\boldsymbol{w}$, and $\boldsymbol{\delta}$ is induced in a manner similar to that in Du et al. (2010; 2013): $p(\boldsymbol{z}, \boldsymbol{w}, \boldsymbol{\delta} | \boldsymbol{\alpha}, \boldsymbol{\beta}, a, b, \boldsymbol{y})$

$$= \prod_{i=1}^{D} \left(\frac{\mathrm{Beta}_K(\boldsymbol{\alpha} + \sum_{\boldsymbol{AS_i}} \boldsymbol{t_{ig}})}{\mathrm{Beta}_K(\boldsymbol{\alpha})} \prod_{\boldsymbol{AS_i}} \left(\frac{(b|a)_{t_{ig\cdot}}}{(b)_{n_{ig\cdot}}} \prod_{k=1}^{K} S\left(n_{igk}, t_{igk}, a\right) \binom{n_{igk}}{t_{igk}}^{-1} \right) \right)$$

$$\prod_{k=1}^{K} \left(\frac{\mathrm{Beta}_{W^e}(\boldsymbol{\beta^e} + \boldsymbol{M^e_k})}{\mathrm{Beta}_{W^e}(\boldsymbol{\beta^e})} \frac{\mathrm{Beta}_{W^f}(\boldsymbol{\beta^f} + \boldsymbol{M^f_k})}{\mathrm{Beta}_{W^f}(\boldsymbol{\beta^f})} \right),$$

where $\mathrm{Beta}_K(\cdot)$ and $\mathrm{Beta}_{W^l}(\cdot)$ are K- and $|\boldsymbol{W^l}|$-dimensional beta functions, respectively, $(b|a)_n$ is the Pochhammer symbol[3], and $(b)_n$ is given by $(b|1)_n$. $S(n, m, a)$ is a generalized Stirling number of the second kind (Hsu and Shiue, 1998), which is given by the linear recursion $S(n+1, m, a) = S(n, m-1, a) + (n - ma) S(n, m, a)$. To reduce computational cost, the Stirling numbers are preliminarily calculated in a logarithm format (Buntine and Hutter, 2012). Then, the cached values are used in our sampling.

The joint conditional distributions of z^l_{ijm} and δ^l_{ijm} are obtained from the above joint distribution using Bayes' rule: $p(z^l_{ijm} = k, \delta^l_{ijm} = 1 | \boldsymbol{z}^{-z^l_{ijm}}, \boldsymbol{w}, \boldsymbol{\delta}^{-\delta^l_{ijm}}, \boldsymbol{\alpha}, \boldsymbol{\beta}, a, b, \boldsymbol{y})$

$$= \frac{\beta^l_{w^l_{ijm}} + M^l_{kw^l_{ijm}}}{\sum_{w \in \boldsymbol{W^l}} (\beta^l_w + M^l_{kw})} \frac{\alpha_k + \sum_{\boldsymbol{AS_i}} t_{igk}}{\sum_{k=1}^{K} (\alpha_k + \sum_{\boldsymbol{AS_i}} t_{igk})} \frac{b + a t_{ig'\cdot}}{b + n_{ig'\cdot}} \frac{S(n_{ig'k} + 1, t_{ig'k} + 1, a)}{S(n_{ig'k}, t_{ig'k}, a)} \frac{t_{ig'k} + 1}{n_{ig'k} + 1},$$

$p(z^l_{ijm} = k, \delta^l_{ijm} = 0 | \boldsymbol{z}^{-z^l_{ijm}}, \boldsymbol{w}, \boldsymbol{\delta}^{-\delta^l_{ijm}}, \boldsymbol{\alpha}, \boldsymbol{\beta}, a, b, \boldsymbol{y})$

$$= \frac{\beta^l_{w^l_{ijm}} + M^l_{kw^l_{ijm}}}{\sum_{w \in \boldsymbol{W^l}} (\beta^l_w + M^l_{kw})} \frac{1}{b + n_{ig'\cdot}} \frac{S(n_{ig'k} + 1, t_{ig'k}, a)}{S(n_{ig'k}, t_{ig'k}, a)} \frac{n_{ig'k} + 1 - t_{ig'k}}{n_{ig'k} + 1},$$

where s^l_{ij} is included in $\boldsymbol{AS_{ig'}}$.

Sampling $\boldsymbol{y}$:

In our inference, each aligned segment set corresponds to a restaurant in the CRP. We regard the sampling of $y_{ijj'}$ as the choice of splitting or merging restaurant(s) in a manner similar to that

[3] $(b|a)_n = \prod_{t=0}^{n-1} (b + ta)$.

in the sampling of segmentation boundaries in Du et al. (2013). In particular, if $y_{ijj'} = 0$, then one aligned segment set $\boldsymbol{AS_m}$ is split into two aligned segment sets $\boldsymbol{AS_l}$ and $\boldsymbol{AS_r}$, where $\boldsymbol{AS_l}$, $\boldsymbol{AS_r}$, and $\boldsymbol{AS_m}$ include s^e_{ij}, $s^f_{ij'}$, and both, respectively. If $y_{ijj'} = 1$, then $\boldsymbol{AS_l}$ and $\boldsymbol{AS_r}$ are merged to $\boldsymbol{AS_m}$. For simplicity, our inference specifies $\boldsymbol{AS_l}$ and $\boldsymbol{AS_r}$ based on the current $\boldsymbol{y}$ as follows: if $AS_i(s^e_{ij}) = AS_i(s^f_{ij'})$, then $\boldsymbol{AS_l} = \{s^e_{ij}\} \cup AS^f_i(s^e_{ij}) \setminus \{s^f_{ij'}\}$ and $\boldsymbol{AS_r} = \{s^f_{ij'}\} \cup AS^e_i(s^f_{ij'}) \setminus \{s^e_{ij}\}$; otherwise, $\boldsymbol{AS_l} = AS_i(s^e_{ij})$ and $\boldsymbol{AS_r} = AS_i(s^f_{ij'})$. Here, $AS_i(j)$ is the element set of $\boldsymbol{AS_i}$ that includes the segment j, and $AS^l_i(j)$ is the set of segments in language l included in $AS_i(j)$. For example, in the example in Section 3, $AS_i(s^f_{i1}) = \boldsymbol{AS_{i1}} = \{s^e_{i1}, s^f_{i1}, s^f_{i2}\}$, $AS^e_i(s^f_{i1}) = \{s^e_{i1}\}$, and $AS^f_i(s^f_{i1}) = \{s^f_{i1}, s^f_{i2}\}$. In addition, if $y_{i11} = 0$, then $\boldsymbol{AS_m} = \{s^e_{i1}, s^f_{i1}, s^f_{i2}\}$ is split into $\boldsymbol{AS_l} = \{s^e_{i1}\} \cup AS^f_i(s^e_{i1}) \setminus \{s^f_{i1}\} = \{s^e_{i1}, s^f_{i2}\}$ and $\boldsymbol{AS_r} = \{s^f_{i1}\} \cup AS^e_i(s^f_{i1}) \setminus \{s^e_{i1}\} = \{s^f_{i1}\}$. If $y_{i23} = 1$, then $\boldsymbol{AS_l} = AS_i(s^e_{i2}) = \{s^e_{i2}\}$ and $\boldsymbol{AS_r} = AS_i(s^f_{i3}) = \{s^f_{i3}\}$ are merged to $\boldsymbol{AS_m} = \{s^e_{i2}, s^f_{i3}\}$.

The conditional distributions of $y_{ijj'}$ are as follows:

$$p(y_{ijj'} = 0|\boldsymbol{y}^{-y_{ijj'}}, \boldsymbol{z}, \boldsymbol{w}, \boldsymbol{\delta}, \boldsymbol{\alpha}, a, b, \eta_0, \eta_1)$$
$$\propto \frac{\eta_0 + c_{i0}}{\eta_0 + \eta_1 + c_{i0} + c_{i1}} \mathrm{Beta}_K\left(\boldsymbol{\alpha} + \sum_{\boldsymbol{AS_i}} \boldsymbol{t_{ig}}\right)$$
$$\prod_{g \in \{\boldsymbol{AS_l}, \boldsymbol{AS_r}\}} \frac{(b|a)_{t_{ig\cdot}}}{(b)_{n_{ig\cdot}}} \prod_{k=1}^{K} S(n_{igk}, t_{igk}, a),$$
$$p(y_{ijj'} = 1|\boldsymbol{y}^{-y_{ijj'}}, \boldsymbol{z}, \boldsymbol{w}, \boldsymbol{t} \setminus \mathbb{T}, \boldsymbol{\alpha}, a, b, \eta_0, \eta_1)$$
$$\propto \sum_{\mathbb{T}} \left(\frac{\eta_1 + c_{i1}}{\eta_0 + \eta_1 + c_{i0} + c_{i1}} \mathrm{Beta}_K\left(\boldsymbol{\alpha} + \sum_{\boldsymbol{AS_i}} \boldsymbol{t_{ig}}\right) \right.$$
$$\left. \frac{(b|a)_{t_{i,\boldsymbol{AS_m},\cdot}}}{(b)_{n_{i,\boldsymbol{AS_m},\cdot}}} \prod_{k=1}^{K} S(n_{i,\boldsymbol{AS_m},k}, t_{i,\boldsymbol{AS_m},k}, a) \right),$$

where $\mathbb{T}$ is the set of t_{igk} such that for either or both of $\boldsymbol{AS_l}$ and $\boldsymbol{AS_r}$, $t_{igk} = 1$. c_{i0} and c_{i1} are the total number of y_i's whose values are 0 and that of y_i's whose values are 1, respectively. Note that we change y_i's that relate to the selected action (merging or splitting), in addition to $y_{ijj'}$ to maintain consistency between $\boldsymbol{y}$ and the aligned segment sets.

Inference of $\boldsymbol{\theta}$, $\boldsymbol{\nu}$, $\boldsymbol{\phi}$:

Although our inference does not directly estimate $\boldsymbol{\theta}$, $\boldsymbol{\nu}$, and $\boldsymbol{\phi}$, these variables can be inferred from the following posterior expected values via sampling:

$$\hat{\theta}_{ik} = \mathbb{E}_{\boldsymbol{z_i}, \boldsymbol{t_i}|\boldsymbol{w_i}, \boldsymbol{\alpha}, \boldsymbol{\beta}, a, b, \boldsymbol{y}}\left[\frac{\alpha_k + \sum_{\boldsymbol{AS_i}} t_{igk}}{\sum_{k=1}^{K}(\alpha_k + \sum_{\boldsymbol{AS_i}} t_{igk})}\right],$$
$$\hat{\nu}_{igk} = \mathbb{E}_{\boldsymbol{z_i}, \boldsymbol{t_i}|\boldsymbol{w_i}, \boldsymbol{\alpha}, \boldsymbol{\beta}, a, b, \boldsymbol{y}}\left[\frac{n_{igk} - at_{igk}}{b + n_{ig\cdot}} + \theta_{ik}\frac{at_{ig\cdot} + b}{b + n_{ig\cdot}}\right],$$
$$\hat{\phi}^l_{kw} = \mathbb{E}_{\boldsymbol{z}, \boldsymbol{t}|\boldsymbol{w}, \boldsymbol{\alpha}, \boldsymbol{\beta}, a, b, \boldsymbol{y}}\left[\frac{\beta^l_w + M^l_{kw}}{\sum_{w' \in \boldsymbol{W}^l}(\beta^l_{w'} + M^l_{kw'})}\right].$$

Algorithm 3 Generative Process for Segments

2: choose $\pi^l_i \sim$ Beta(λ_0,λ_1)
3: **for** each passage u^l_{ih} ($h \in \{1, ..., U^l_i\}$) **do**
4: choose $\rho^l_{ih} \sim$ Bernoulli(π^l_i)
5: **end for**
6: $\boldsymbol{s^l_i}$ = concatenate($\boldsymbol{u^l_i}$, $\boldsymbol{\rho^l_i}$)
7: **end for**

4 Integration of Topic Segmentation into BiSTM (BiSTM+TS)

To infer segmentation boundaries simultaneously with cross-lingual topics, we integrate the unsupervised Bayesian topic segmentation method proposed by Du et al. (2013) into the proposed BiSTM (BiSTM+TS).

We assume that each segment is a sequence of topically-related passages. In particular, we consider a sentence as a passage. Our segmentation model defines a segment in document d^l_i by a boundary indicator variable ρ^l_{ih} for each passage u^l_{ih} ($h \in \{1, ..., U^l_i\}$); ρ^l_{ih} is 1 if there is a boundary after passage u^l_{ih} (otherwise 0). For example, $\boldsymbol{\rho^l_i} = (0, 1, 0, 0, 1)$ indicates that the document d^l_i comprises the two segments $\{u^l_{i1}, u^l_{i2}\}$ and $\{u^l_{i3}, u^l_{i4}, u^l_{i5}\}$.

Algorithm 3 shows the generative process for segments. The generative process of BiSTM+TS inserts Algorithm 3 between Steps 7 and 8 of Algorithm 2. Note that two documents $(d^e_i, d^f_i) \in d_i$ are segmented independently. BiSTM+TS assumes that each document d^l_i has its own topic shift probability π^l_i. For each document d^l_i, π^l_i is first drawn from a Beta distribution with the priors λ_0 and λ_1 (Step 2). Then, for each passage u^l_{ih} ($h \in \{1, ..., U^l_i\}$), ρ^l_{ih} is drawn from a Bernoulli distribution with the prior π^l_i (Step 4). Finally, segments $\boldsymbol{s^l_i}$ are generated by concatenating passages based on $\boldsymbol{\rho^l_i}$ (Step 6).

4.1 Inference for BiSTM+TS

Our inference for BiSTM+TS alternates three different kinds of blocks, sampling of $\boldsymbol{\rho}$ and samplings for BiSTM (($\boldsymbol{z}$, $\boldsymbol{\delta}$) and $\boldsymbol{y}$). The conditional distribution of $\boldsymbol{\rho}$ comprises the Gibbs probability for splitting one segment s_m into two segments s_r and s_l by placing the boundary after u^l_{ih} ($\rho^l_{ih} = 1$) and that for merging s_r and s_l to s_m by removing the boundary after u^l_{ih} ($\rho^l_{ih} = 0$).

These probabilities are estimated in the same manner as the conditional probabilities of $y_{ijj'}$, where $\boldsymbol{y}$ ($y_{ijj'} = 0, 1$), $\boldsymbol{AS_l}$, $\boldsymbol{AS_r}$, $\boldsymbol{AS_m}$, η_0, and η_1 are replaced with $\boldsymbol{\rho}$ ($\rho^l_{ih} = 1, 0$), s_l, s_r, s_m, λ_1, and λ_0, respectively, and the statistics t and n are summed for every segment rather than for every aligned segment set (see Equation (6) and (9) in Du et al. (2013)).

Our inference assumes that sampling $\boldsymbol{\rho}$ does not depend on aligned segments in the other language, i.e., $\boldsymbol{y}$[4]. After splitting or merging, we set the y's of s_m, s_l, and s_r as follows: if s_m is split into s_l and s_r, then $AS(s_l) = AS(s_m)$ and $AS(s_r) = AS(s_m)$; if s_l and s_r are merged to s_m, then $AS(s_m) = AS(s_l) \cup AS(s_r)$.

5 Experiment

We evaluated the proposed models in terms of perplexity and performance in translation pair extraction, which is a well-known application that uses a bilingual topic model. We used a document-aligned comparable corpus comprising 3,995 document pairs, each of which is a Japanese Wikipedia article in the Kyoto Wiki Corpus[5] and its corresponding English Wikipedia article[6]. Note that the English articles were collected from the English Wikipedia database dump (2 June 2015)[7] based on inter-language links, even though the original Kyoto Wiki corpus is a parallel corpus, in which each sentence in the Japanese articles is manually translated into English. Thus, our experimental data is not a parallel corpus. We extracted texts from the collected English articles using an open-source script[8]. All Japanese and English texts were segmented using MeCab[9] and TreeTagger[10] (Schmid, 1994), respectively. Then, function words were removed, and the remaining words were lemmatized to reduce data sparsity.

For translation extraction experiments, we automatically created a gold-standard translation set according to Liu et al. (2013). We first computed $p(w^e|w^f)$ and $p(w^f|w^e)$ by running IBM Model 4 on the original Kyoto Wiki corpus, which is a parallel corpus, using GIZA++ (Och and Ney, 2003), and then extracted word pairs $(\hat{w^e}, \hat{w^f})$ that satisfy both of the following conditions: $\hat{w^e} = \text{argmax}_{w^e} p(w^e|w^f = \hat{w^f})$ and $\hat{w^f} = \text{argmax}_{w^f} p(w^f|w^e = \hat{w^e})$. Finally, we eliminated word pairs that do not appear in the document pairs in the document-aligned comparable corpus. We used all 7,930 Japanese words in the resulting gold-standard set as the evaluation input.

5.1 Competing Methods

We compared the proposed models (BiSTM and BiSTM+TS) with a standard bilingual topic model (BiLDA). BiSTM considers each section in Wikipedia articles as a segment. Note that alignments between sections are not given in our experimental data. Thus, $\boldsymbol{y}$ is inferred in both BiSTM and BiSTM+TS.

As in the proposed models, BiLDA was trained using Gibbs sampling (Mimno et al., 2009; Ni et al., 2009; Vulić et al., 2015). In the training of each model, each variable was first initialized. Here, z^l_{ijm} is randomly initialized to an integer between 1 and K, and each of δ^l_{ijm}, $y_{ijj'}$, and ρ^l_{ih} is randomly initialized to 0 or 1. We then performed 10,000 Gibbs iterations. We used the symmetric prior $\alpha_k = 50/K$ and $\beta^l_w = 0.01$ over $\boldsymbol{\theta}$ and $\boldsymbol{\phi}^l$, respectively, in accordance with Vulić et al. (2011). The hyperparameters a, b, λ_0, and λ_1 were set to 0.2, 10, 0.1, and 0.1, respectively, in accordance with Du et al. (2010; 2013). Both η_0 and η_1 were set to 0.2 as a result of preliminary experiments. We used several values of K to measure the impact of topic size: we used $K = 100$ and $K = 400$ in accordance with Liu et al. (2013) in addition to the suggested value $K = 2,000$ in Vulić et al. (2011).

In the translation extraction experiments,

[4] We leave a bilingual extension of the topic segmentation, i.e., incorporation of $\boldsymbol{y}$, for future work.

[5] http://alaginrc.nict.go.jp/WikiCorpus/index_E.html

[6] We filtered out the Japanese articles that do not have corresponding English articles.

Model	K=100	K=400	K=2,000
BiLDA	693.6	530.7	479.9
BiSTM	520.1	429.3	394.6
BiSTM+TS	537.5	445.3	411.8

Table 2: Test Set Perplexity

we used two translation extraction methods, i.e., *Cue* (Vulić et al., 2011) and *Liu* (Liu et al., 2013). Both methods first infer cross-lingual topics for words using a bilingual topic model (BiLDA/BiSTM/BiSTM+TS) and then extract word pairs (w^e, w^f) with a high value of the probability $p(w^e|w^f)$ defined by the inferred topics. *Cue* calculates $p(w^e|w^f) = \sum_{k=1}^{K} p(w^e|k)p(k|w^f)$, where $p(k|w) \propto \frac{p(w|k)}{\sum_{k=1}^{K} p(w|k)}$ and $p(w|k) = \phi_{kw}$. Liu first converts a document-aligned comparable corpus into a topic-aligned parallel corpus according to the topics of words and computes $p(w^e|w^f, k)$ by running IBM Model 1 on the parallel corpus. Liu then calculates $p(w^e|w^f) = \sum_{k=1}^{K} p(w^e|w^f, k)p(k|w^f)$. Hereafter, a bilingual topic model used in an extraction method is shown in parentheses, e.g., *Cue*(BiLDA) denotes *Cue* with BiLDA.

5.2 Experimental Results

We evaluated the predictive performance of each model by computing the test set perplexity based on 5-fold cross validation. A lower perplexity indicates better generalization performance. Table 2 shows the perplexity of each model. As can be seen, BiSTM and BiSTM+TS are better than BiLDA in terms of perplexity.

We measured the performance of translation extraction with top N accuracy (ACC_N), the number of test words whose top N translation candidates contain a correct translation over the total number of test words (7,930). Table 3 summarizes ACC_1 and ACC_{10} for each model. As can be seen, *Cue*/*Liu*(BiSTM) and *Cue*/*Liu*(BiSTM+TS) significantly outperform *Cue*/*Liu*(BiLDA) ($p < 0.01$ in the sign test). This indicates that BiSTM and BiSTM+TS improve the performance of translation extraction for both the *Cue* and *Liu* methods by assigning more suitable topics.

Both experiments prove that capturing segment-level alignments is effective for modeling bilingual data. In addition, these experiments show that BiSTM+TS is comparable with BiSTM, indicating that the proposed model could yield a significant benefit even if the boundaries of segments are unknown.

ACC_1			
Method	K=100	K=400	K=2,000
Cue(BiLDA)	0.024	0.056	0.101
Cue(BiSTM)	0.055	0.112	0.184
Cue(BiSTM+TS)	0.052	0.107	0.176
Liu(BiLDA)	0.206	0.345	0.426
Liu(BiSTM)	0.287	0.414	0.479
Liu(BiSTM+TS)	0.283	0.406	0.467
ACC_{10}			
Method	K=100	K=400	K=2,000
Cue(BiLDA)	0.093	0.170	0.281
Cue(BiSTM)	0.218	0.286	0.410
Cue(BiSTM+TS)	0.196	0.274	0.398
Liu(BiLDA)	0.463	0.550	0.603
Liu(BiSTM)	0.531	0.625	0.671
Liu(BiSTM+TS)	0.536	0.612	0.667

Table 3: Performance of Translation Extraction

	Reference $y = 1$	Reference $y = 0$
Inference $y = 1$	195	174
Inference $y = 0$	43	1132

Table 4: Distribution of Segment-level Alignments

Tables 2 and 3 show that a larger topic size yields better performance for each model. Furthermore, *Liu* outperforms *Cue* regardless of the choice of bilingual topic models, which is consistent with previously reported results (Liu et al., 2013). The results of our experiments demonstrate that the proposed models have the same tendencies as BiLDA.

6 Discussion

6.1 Inferred Segment-level Alignments

We created a reference set to evaluate segment-level alignments $\boldsymbol{y}$ inferred by BiSTM (K=2,000). We randomly selected 100 document pairs from the comparable corpus and then manually identified cross-lingual alignments between sections. Table 4 shows the distribution of inferred $\boldsymbol{y}$ values and that of $\boldsymbol{y}$ values in the reference set. As can be seen, the accuracy of $\boldsymbol{y}$ is 0.859 (1,327/1,544).

The majority of false negatives (121/174) are sections that are not parallel but correspond partially. An example is the alignment between the

Model	Japanese article	English article
BiSTM	4.8	2.9
BiSTM+TS	10.6	4.1

Table 5: Average Number of Segments

Japanese section "history" and the English section "Bujutsu (old type of Budo)" in the "Budo (a Japanese martial art)" article pair, where a part of the English section "Bujutsu" is described in the Japanese section "history." Such errors might not necessarily have a negative effect, because partial alignments can be useful.

6.2 Inferred Segmentation Boundaries

This section compares segment boundaries inferred by BiSTM+TS (K=2,000) with section boundaries in the original articles, which have been referred to by BiSTM. The recall of BiSTM+TS for the original section boundaries is 0.727. This indicates that the unsupervised segmentation in BiSTM+TS finds drastic topical changes, i.e., section boundaries, with high recall.

Table 5 shows the average number of segments per article for each model. As can be seen, BiSTM+TS divides an article into segments smaller than the original sections. This seems to be reasonable, because some original sections include multiple topics. However, Tables 2 and 3 show that inferred boundaries do not work better than section boundaries. One reason for that is that some errors are caused by a sparseness problem, when BiSTM+TS separates an article into extremely fine-grained segments. In addition, Table 5 reveals that BiSTM+TS increases the gap between languages. Thus, segmentation with a comparable granularity between languages might be favorable for the proposed models.

6.3 Effectiveness for an English–French Wikipedia Corpus

We evaluated BiLDA, BiSTM, and BiSTM+TS in terms of perplexity and performance in translation extraction on an English–French Wikipedia corpus to verify the effectiveness of the proposed models for language pairs other than English–Japanese. The settings, e.g., parameters, for each model are the same as in Section 5. Note that we report only the performances of each model with $K = 2,000$, because all models achieved the best performances when $K = 2,000$.

Model	Test Set Perplexity	
BiLDA	439.1	
BiSTM	379.4	
BiSTM+TS	396.6	
Model	ACC_1	ACC_{10}
Cue(BiLDA)	0.219	0.556
Cue(BiSTM)	0.275	0.580
Cue(BiSTM+TS)	0.257	0.582
Liu(BiLDA)	0.715	0.838
Liu(BiSTM)	0.742	0.859
Liu(BiSTM+TS)	0.732	0.852

Table 6: Performance on an English–French Wikipedia Corpus ($K = 2,000$)

We collected French articles that correspond to the English articles used in the experiments in Section 5, from the French Wikipedia database dump (2 June 2015) based on inter-language links. As a result, our English–French corpus comprises 3,159 document pairs. The French articles were preprocessed in the same manner as the English articles: text extraction using the open-source script, segmentation using TreeTagger, removal of function words, and lemmatization.

We created a gold-standard translation set for translation extraction experiments using Google Translate service[11] in a manner similar to that in Gouws et al. (2015) and Coulmance et al. (2015), translating the French words in our corpus using Google Translate, and then eliminating word pairs that do not appear in the document pairs in our corpus. We used the top 1,000 most frequent French words in the resulting gold-standard set as the evaluation input.

Table 6 summarizes ACC_1, ACC_{10}, and perplexity. It shows that the proposed models are effective also for the English–French Wikipedia corpus. BiSTM and BiSTM+TS outperform BiLDA in terms of perplexity and performance of translation extraction, and BiSTM+TS works well even if the boundaries of segments are unknown.

7 Related Work

Multilingual topic models other than BiLDA (Section 2) have been proposed for document-aligned comparable corpora. Fukumasu et al. (2012) applied SwitchLDA (Newman et al., 2006) and Correspondence LDA (Blei and Jordan, 2003), which

[11] http://translate.google.com/

were originally intended to work with multimodal data, such as annotated image data, to modeling multilingual text data. They also proposed a symmetric version of Correspondence LDA. Platt et al. (2010) projected monolingual models based on PLSA or Principal Component Analysis into a shared multilingual space with the constraint that document pairs must map to similar locations. Hu et al. (2014) proposed a multilingual tree-based topic model that uses a hierarchical bilingual dictionary in addition to document alignments. Note that these models do not consider segment-level alignments.

There are several multilingual topic models tailored for data other than a document-aligned comparable corpus, including bilingual topic models for word alignment and machine translation on parallel sentence pairs (Zhao and Xing, 2006; Zhao and Xing, 2008). Some models have mined multilingual topics from unaligned text data by bridging the gap between different languages using a bilingual dictionary (Jagarlamudi and Daumé III, 2010; Zhang et al., 2010; Negi, 2011). Boyd-Graber and Blei (2009) used parallel sentences in combination with a bilingual dictionary. However, these models have the drawback that they require a parallel corpus or a bilingual dictionary in advance, which cannot be obtained for some language pairs or domains.

In a monolingual setting, some topic models that consider segment-level topics have been proposed. Du et al. (2010) considered a document as a set of segments and generated each per-segment topic distribution from the topic distribution of the related document through a Pitman–Yor process. Others have considered a document as a sequence of segments. Cheng et al. (2009) reflected the underlying sequences of segments' topics by positing a permutation distribution over a document. Wang et al. (2011) modeled topical sequences in documents with a latent first-order Markov chain, and Du et al. (2012) generated each per-segment topic distribution from the topic distribution of its document and that of its previous segment. Note that none of these models have been extended to a multilingual setting.

8 Conclusions

In this paper, we proposed BiSTM, which models a document hierarchically and deals with segment-level alignments. BiSTM assigns the same topic distribution to both aligned documents and aligned segments. We also presented an extended model, BiSTM+TS, that infers segmentation boundaries in addition to latent topics by incorporating unsupervised topic segmentation (Du et al., 2013). Our experimental results show that capturing segment-level alignments improves perplexity and translation extraction performance, and that BiSTM+TS yields a significant benefit even if the boundaries of segments are not given.

This paper presented an extension to BiLDA, but hierarchical structures can also be incorporated into other bilingual topic models (Section 7). As future work, we would like to verify the effectiveness of the proposed models for other datasets or other cross-lingual tasks, such as cross-lingual document classification (Ni et al., 2009; Platt et al., 2010; Ni et al., 2011; Smet et al., 2011) and cross-lingual information retrieval (Vulić et al., 2013).

Abstract

This paper connects a vector-based composition model to a formal semantics, the Dependency-based Compositional Semantics (DCS). We show theoretical evidence that the vector compositions in our model conform to the logic of DCS. Experimentally, we show that vector-based composition brings a strong ability to calculate similar phrases as similar vectors, achieving near state-of-the-art on a wide range of phrase similarity tasks and relation classification; meanwhile, DCS can guide building vectors for structured queries that can be directly executed. We evaluate this utility on sentence completion task and report a new state-of-the-art.

1 Introduction

A major goal of semantic processing is to map natural language utterances to representations that facilitate calculation of meanings, execution of commands, and/or inference of knowledge. Formal semantics supports such representations by defining words as some functional units and combining them via a specific logic. A simple and illustrative example is the Dependency-based Compositional Semantics (DCS) (Liang et al., 2013). DCS composes meanings from denotations of words (i.e. sets of things to which the words apply); say, the denotations of the concept `drug` and the event `ban` is shown in Figure 1b, where `drug` is a list of drug names and `ban` is a list of the subject-complement pairs in any *ban* event; then, a list of *banned drugs* can be constructed by first taking the COMP column of all records in `ban` (projection "π_{COMP}"), and then intersecting the results with `drug` (intersection "$\cap$"). This procedure defined how words can be combined to form a meaning. Better yet, the procedure can be concisely illustrated by the DCS tree of "*banned drugs*" (Figure 1a), which is similar to a dependency tree but possesses precise procedural and logical meaning (Section 2). DCS has been shown useful in question answering (Liang et al., 2013) and textual entailment recognition (Tian et al., 2014).

Orthogonal to the formal semantics of DCS, distributional vector representations are useful in capturing lexical semantics of words (Turney and Pantel, 2010; Levy et al., 2015), and progress is made in combining the word vectors to form meanings of phrases/sentences (Mitchell and Lapata, 2010; Baroni and Zamparelli, 2010; Grefenstette and Sadrzadeh, 2011; Socher et al., 2012; Paperno et al., 2014; Hashimoto et al., 2014). However, less effort is devoted to finding a link between vector-based compositions and the composition operations in any formal semantics. We believe that if a link can be found, then symbolic formulas in the formal semantics will be realized by vectors composed from word embeddings, such that similar things are realized by similar vectors; meanwhile, vectors will acquire formal meanings that can directly be used in execution or inference process. Still, to find a link is challenging because any vector compositions that realize such a link must conform to the logic of the formal semantics.

In this paper, we establish a link between DCS and certain vector compositions, achieving a *vector-based DCS* by replacing denotations of words with word vectors, and realizing the composition operations such as intersection and projection as addition and linear mapping, respectively. For example, to construct a vector for "*banned drugs*", one takes the word vector $\mathbf{v}_{ban}$ and multiply it by a matrix M_{COMP}, corresponding to the projection π_{COMP}; then, one adds the result to the word vector $\mathbf{v}_{drug}$ to realize the intersection operation (Figure 1c). We provide a method to train the

Berlin, Germany, August 7-12, 2016.

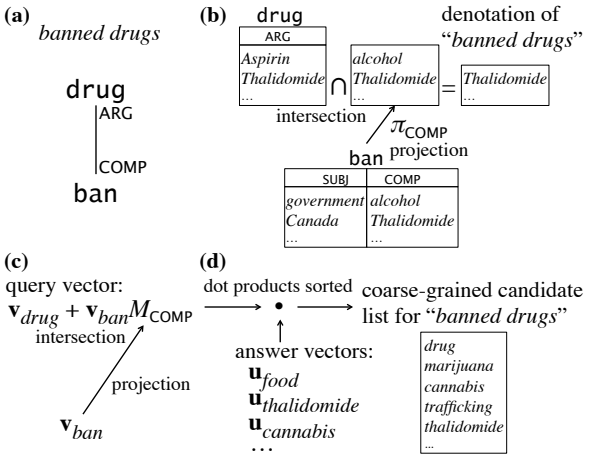

Figure 1: (a) The DCS tree of "*banned drugs*", which controls (b) the calculation of its denotation. In this paper, we learn word vectors and matrices such that (c) the same calculation is realized in distributional semantics. The constructed query vector can be used to (d) retrieve a list of coarse-grained candidate answers to that query.

word vectors and linear mappings (i.e. matrices) jointly from unlabeled corpora.

The rationale for our model is as follows. First, recent research has shown that additive composition of word vectors is an approximation to the situation where two words have overlapping context (Tian et al., 2015); therefore, it is suitable to implement an "and" or intersection operation (Section 3). We design our model such that the resulted distributional representations are expected to have additive compositionality. Second, when intersection is realized as addition, it is natural to implement projection as linear mapping, as suggested by the logical interactions between the two operations (Section 3). Experimentally, we show that vectors and matrices learned by our model exhibit favorable characteristics as compared with vectors trained by GloVe (Pennington et al., 2014) or those learned from syntactic dependencies (Section 5.1). Finally, additive composition brings our model a strong ability to calculate similar vectors for similar phrases, whereas syntactic-semantic roles (e.g. SUBJ, COMP) can be distinguished by different projection matrices (e.g. M_{SUBJ}, M_{COMP}). We achieve near state-of-the-art performance on a wide range of phrase similarity tasks (Section 5.2) and relation classification (Section 5.3).

Furthermore, we show that a vector as constructed above for "*banned drugs*" can be used as a *query vector* to retrieve a coarse-grained candidate list of banned drugs, by sorting its dot products with *answer vectors* that are also learned by our model (Figure 1d). This is due to the ability of our approach to provide a language model that can find likely words to fill in the blanks such as "__ *is a banned drug*" or "*the drug* __ *is banned by* ...". A highlight is the calculation being done as if a query is "executed" by the DCS tree of "*banned drugs*". We quantitatively evaluate this utility on sentence completion task (Zweig et al., 2012) and report a new state-of-the-art (Section 5.4).

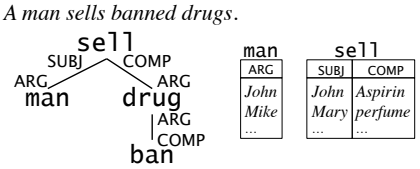

Figure 2: DCS tree for a sentence

2 DCS Trees

DCS composes meanings from denotations, or sets of things to which words apply. A "thing" (i.e. element of a denotation) is represented by a tuple of features of the form Field=*Value*, with a fixed inventory of fields. For example, a denotation `ban` might be a set of tuples $\texttt{ban} = \{(\mathsf{SUBJ}{=}\textit{Canada}, \mathsf{COMP}{=}\textit{Thalidomide}), \ldots\}$, in which each tuple records participants of a banning event (e.g. Canada banning Thalidomide).

Operations are applied to sets of things to generate new denotations, for modeling semantic composition. An example is the intersection of `pet` and `fish` giving the denotation of "*pet fish*". Another necessary operation is projection; by π_{N} we mean a function mapping a tuple to its value of the field N. For example, $\pi_{\mathsf{COMP}}(\texttt{ban})$ is the value set of the COMP fields in `ban`, which consists of banned objects (i.e. $\{\textit{Thalidomide}, \ldots\}$). In this paper, we assume a field ARG to be names of things representing themselves, hence for example $\pi_{\mathsf{ARG}}(\texttt{drug})$ is the set of names of drugs.

For a value set V, we also consider inverse image $\pi_{\mathsf{N}}^{-1}(V) := \{x \mid \pi_{\mathsf{N}}(x) \in V\}$. For example,

$$\texttt{D}_1 := \pi_{\mathsf{SUBJ}}^{-1}(\pi_{\mathsf{ARG}}(\texttt{man}))$$

consists of all tuples of the form $(\mathsf{SUBJ}{=}x, \ldots)$, where x is a man's name (i.e. $x \in \pi_{\mathsf{ARG}}(\texttt{man})$). Thus, $\texttt{sell} \cap \texttt{D}_1$ denotes men's selling events (i.e. $\{(\mathsf{SUBJ}{=}\textit{John}, \mathsf{COMP}{=}\textit{Aspirin}), \ldots\}$ as in Figure 2). Similarly, the denotation of "*banned*

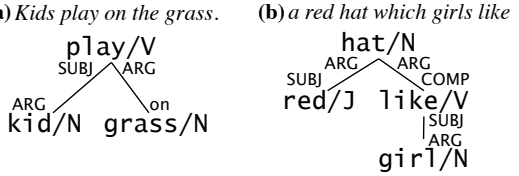

Figure 3: DCS trees in this work

drugs" as in Figure 1b is formally written as

$$\mathtt{D}_2 := \mathtt{drug} \cap \pi^{-1}_{\mathsf{ARG}}(\pi_{\mathsf{COMP}}(\mathtt{ban})),$$

Hence the following denotation

$$\mathtt{D}_3 := \mathtt{sell} \cap \mathtt{D}_1 \cap \pi^{-1}_{\mathsf{COMP}}(\pi_{\mathsf{ARG}}(\mathtt{D}_2))$$

consists of selling events such that the SUBJ is a man and the COMP is a banned drug.

The calculation above can proceed in a recursive manner controlled by DCS trees. The DCS tree for the sentence "*a man sells banned drugs*" is shown in Figure 2. Formally, a DCS tree is defined as a rooted tree in which nodes are denotations of content words and edges are labeled by fields at each ends. Assume a node $\mathtt{x}$ has children $\mathtt{y}_1, \ldots, \mathtt{y}_n$, and the edges $(\mathtt{x}, \mathtt{y}_1), \ldots, (\mathtt{x}, \mathtt{y}_n)$ are labeled by $(\mathsf{P}_1, \mathsf{L}_1), \ldots, (\mathsf{P}_n, \mathsf{L}_n)$, respectively. Then, the denotation $[\![\mathtt{x}]\!]$ of the subtree rooted at $\mathtt{x}$ is recursively calculated as

$$[\![\mathtt{x}]\!] := \mathtt{x} \cap \bigcap_{i=1}^{n} \pi^{-1}_{\mathsf{P}_i}(\pi_{\mathsf{L}_i}([\![\mathtt{y}_i]\!])). \qquad (1)$$

As a result, the denotation of the DCS tree in Figure 2 is the denotation $\mathtt{D}_3$ of "*a man sells banned drugs*" as calculated above. DCS can be further extended to handle phenomena such as quantifiers or superlatives (Liang et al., 2013; Tian et al., 2014). In this paper, we focus on the basic version, but note that it is already expressive enough to at least partially capture the meanings of a large portion of phrases and sentences.

DCS trees can be learned from question-answer pairs and a given database of denotations (Liang et al., 2013), or they can be extracted from dependency trees if no database is specified, by taking advantage of the observation that DCS trees are similar to dependency trees (Tian et al., 2014). We use the latter approach, obtaining DCS trees by rule-based conversion from universal dependency (UD) trees (McDonald et al., 2013). Therefore, nodes in a DCS tree are content words in a UD tree, which are in the form of lemma-POS pairs (Figure 3). The inventory of fields is designed to be ARG, SUBJ, COMP, and all prepositions. Prepositions are unlike content words which denote sets of things, but act as relations which we treat similarly as SUBJ and COMP. For example, a prepositional phrase attached to a verb (e.g. *play on the grass*) is treated as in Figure 3a. The presence of two field labels on each edge of a DCS tree makes it convenient for modeling semantics in several cases, such as a relative clause (Figure 3b).

3 Vector-based DCS

For any content word w, we use a query vector $\mathbf{v}_w$ to model its denotation, and an answer vector $\mathbf{u}_w$ to model a prototypical element in that denotation. Query vector $\mathbf{v}$ and answer vector $\mathbf{u}$ are learned such that $\exp(\mathbf{v} \cdot \mathbf{u})$ is proportional to the probability of $\mathbf{u}$ answering the query $\mathbf{v}$. The learning source is a collection of DCS trees, based on the idea that the DCS tree of a declarative sentence usually has non-empty denotation. For example, "*kids play*" means there exists some kid who plays. Consequently, some element in the play denotation belongs to $\pi^{-1}_{\mathsf{SUBJ}}(\pi_{\mathsf{ARG}}(\mathtt{kid}))$, and some element in the kid denotation belongs to $\pi^{-1}_{\mathsf{ARG}}(\pi_{\mathsf{SUBJ}}(\mathtt{play}))$. This is a signal to increase the dot product of $\mathbf{u}_{play}$ and the query vector of $\pi^{-1}_{\mathsf{SUBJ}}(\pi_{\mathsf{ARG}}(\mathtt{kid}))$, as well as the dot product of $\mathbf{u}_{kid}$ and the query vector of $\pi^{-1}_{\mathsf{ARG}}(\pi_{\mathsf{SUBJ}}(\mathtt{play}))$. When optimized on a large corpus, the "typical" elements of play and kid should be learned by $\mathbf{u}_{play}$ and $\mathbf{u}_{kid}$, respectively. In general, one has

Theorem 1 *Assume the denotation of a DCS tree is not empty. Given any path from node* $\mathtt{x}$ *to* $\mathtt{y}$*, assume edges along the path are labeled by* $(\mathsf{P}, \mathsf{L}), \ldots, (\mathsf{K}, \mathsf{N})$*. Then, an element in the denotation* $\mathtt{y}$ *belongs to* $\pi^{-1}_{\mathsf{N}}(\pi_{\mathsf{K}}(\ldots(\pi^{-1}_{\mathsf{L}}(\pi_{\mathsf{P}}(\mathtt{x}) \ldots).$

Therefore, for any two nodes in a DCS tree, the path from one to another forms a training example, which signals increasing the dot product of the corresponding query and answer vectors.

It is noteworthy that the above formalization happens to be closely related to the skip-gram model (Mikolov et al., 2013b). The skip-gram learns a target vector $\mathbf{v}_w$ and a context vector $\mathbf{u}_w$ for each word w. It assumes the probability of a word y co-occurring with a word x in a context window is proportional to $\exp(\mathbf{v}_x \cdot \mathbf{u}_y)$. Hence, if x and y co-occur within a context window, then one gets a signal to increase $\mathbf{v}_x \cdot \mathbf{u}_y$. If the context window is taken as the same DCS tree, then

the learning of skip-gram and vector-based DCS will be almost the same, except that the target vector $\mathbf{v}_x$ becomes the query vector $\mathbf{v}$, which is no longer assigned to the word x but the path from x to y in the DCS tree (e.g. the query vector for $\pi^{-1}_{\mathsf{SUBJ}}(\pi_{\mathsf{ARG}}(\mathtt{kid}))$ instead of $\mathbf{v}_{kid}$). Therefore, our model can also be regarded as extending skip-gram to take account of the changes of meanings caused by different syntactic-semantic roles.

Additive Composition Word vectors trained by skip-gram are known to be semantically additive, such as exhibited in word analogy tasks. An effect of adding up two skip-gram vectors is further analyzed in Tian et al. (2015). Namely, the target vector $\mathbf{v}_w$ can be regarded as encoding the distribution of context words surrounding w. If another word x is given, $\mathbf{v}_w$ can be decomposed into two parts, one encodes context words shared with x, and another encodes context words not shared. When $\mathbf{v}_w$ and $\mathbf{v}_x$ are added up, the non-shared part of each of them tend to cancel out, because non-shared parts have nearly independent distributions. As a result, the shared part gets reinforced. An error bound is derived to estimate how close $\frac{1}{2}(\mathbf{v}_w + \mathbf{v}_x)$ gets to the distribution of the shared part. We can see the same mechanism exists in vector-based DCS. In a DCS tree, two paths share a context word if they lead to a same node y; semantically, this means some element in the denotation $\mathtt{y}$ belongs to both denotations of the two paths (e.g. given the sentence "*kids play balls*", $\pi^{-1}_{\mathsf{SUBJ}}(\pi_{\mathsf{ARG}}(\mathtt{kid}))$ and $\pi^{-1}_{\mathsf{COMP}}(\pi_{\mathsf{ARG}}(\mathtt{ball}))$ both contain a playing event whose SUBJ is a kid and COMP is a ball). Therefore, addition of query vectors of two paths approximates their intersection because the shared context y gets reinforced.

Projection Generally, for any two denotations $\mathtt{X}_1, \mathtt{X}_2$ and any projection π_{N}, we have

$$\pi_{\mathsf{N}}(\mathtt{X}_1 \cap \mathtt{X}_2) \subseteq \pi_{\mathsf{N}}(\mathtt{X}_1) \cap \pi_{\mathsf{N}}(\mathtt{X}_2). \quad (2)$$

And the "$\subseteq$" can often become "$=$", for example when π_{N} is a one-to-one map or $\mathtt{X}_1 = \pi^{-1}_{\mathsf{N}}(V)$ for some value set V. Therefore, if intersection is realized by addition, it will be natural to realize projection by linear mapping because

$$(\mathbf{v}_1 + \mathbf{v}_2)M_{\mathsf{N}} = \mathbf{v}_1 M_{\mathsf{N}} + \mathbf{v}_2 M_{\mathsf{N}} \quad (3)$$

holds for any vectors $\mathbf{v}_1, \mathbf{v}_2$ and any matrix M_{N}, which is parallel to (2). If π_{N} is realized by a matrix M_{N}, then π^{-1}_{N} should correspond to the inverse matrix M^{-1}_{N}, because $\pi_{\mathsf{N}}(\pi^{-1}_{\mathsf{N}}(V)) = V$ for any value set V. So we have realized all composition operations in DCS.

Query vector of a DCS tree Now, we can define the query vector of a DCS tree as parallel to (1):

$$\mathbf{v}_{[\![\mathtt{x}]\!]} := \mathbf{v}_x + \frac{1}{n}\sum_{i=1}^{n} \mathbf{v}_{[\![\mathtt{y}_i]\!]} M_{\mathsf{L}_i} M^{-1}_{\mathsf{P}_i}. \quad (4)$$

4 Training

As described in Section 3, vector-based DCS assigns a query vector $\mathbf{v}_w$ and an answer vector $\mathbf{u}_w$ to each content word w. And for each field N, it assigns two matrices M_{N} and M^{-1}_{N}. For any path from node x to y sampled from a DCS tree, assume the edges along are labeled by $(\mathsf{P}, \mathsf{L}), \ldots, (\mathsf{K}, \mathsf{N})$. Then, the dot product $\mathbf{v}_x M_{\mathsf{P}} M^{-1}_{\mathsf{L}} \ldots M_{\mathsf{K}} M^{-1}_{\mathsf{N}} \cdot \mathbf{u}_y$ gets a signal to increase.

Formally, we adopt the noise-contrastive estimation (Gutmann and Hyvärinen, 2012) as used in the skip-gram model, and mix the paths sampled from DCS trees with artificially generated noise. Then, $\sigma(\mathbf{v}_x M_{\mathsf{P}} M^{-1}_{\mathsf{L}} \ldots M_{\mathsf{K}} M^{-1}_{\mathsf{N}} \cdot \mathbf{u}_y)$ models the probability of a training example coming from DCS trees, where $\sigma(\theta) = 1/\{1 + \exp(-\theta)\}$ is the sigmoid function. The vectors and matrices are trained by maximizing the log-likelihood of the mixed data. We use stochastic gradient descent (Bottou, 2012) for training. Some important settings are discussed below.

Noise For any $\mathbf{v}_x M_1 M_2^{-1} \ldots M_{2l-1} M_{2l}^{-1} \cdot \mathbf{u}_y$ obtained from a path of a DCS tree, we generate noise by randomly choosing an index $i \in [2, 2l]$, and then replacing M_j or M_j^{-1} ($\forall j \geq i$) and $\mathbf{u}_y$ by $M_{\mathsf{N}(j)}$ or $M^{-1}_{\mathsf{N}(j)}$ and $\mathbf{u}_z$, respectively, where $\mathsf{N}(j)$ and z are independently drawn from the marginal (i.e. unigram) distributions of fields and words.

Update For each data point, when i is the chosen index above for generating noise, we view indices $j < i$ as the "target" part, and $j >= i$ as the "context", which is completely replaced by the noise, as an analogous to the skip-gram model. Then, at each step we only update one vector and one matrix from each of the target, context, and noise part; more specifically, we only update $\mathbf{v}_x$, M_{i-1} or M^{-1}_{i-1}, M_i or M_i^{-1}, $M_{\mathsf{N}(i)}$ or $M^{-1}_{\mathsf{N}(i)}$, $\mathbf{u}_y$ and $\mathbf{u}_z$, at the step. This is much faster than always updating all matrices.

Initialization Matrices are initialized as $\frac{1}{2}(I + G)$, where I is the identity matrix; and G and all

vectors are initialized with i.i.d. Gaussians of variance $1/d$, where d is the vector dimension. We find that the diagonal component I is necessary to bring information from $\mathbf{v}_x$ to $\mathbf{u}_y$, whereas the randomness of G makes convergence faster. M_{N}^{-1} is initialized as the transpose of M_{N}.

Learning Rate We find that the initial learning rate for vectors can be set to 0.1. But for matrices, it should be less than 0.0005 otherwise the model diverges. For stable training, we rescale gradients when their norms exceed a threshold.

Regularizer During training, M_{N} and M_{N}^{-1} are treated as independent matrices. However, we use the regularizer $\gamma\|M_{\mathsf{N}}^{-1}M_{\mathsf{N}} - \frac{1}{d}\operatorname{tr}(M_{\mathsf{N}}^{-1}M_{\mathsf{N}})I\|^2$ to drive M_{N}^{-1} close to the inverse of M_{N}.[1] We also use $\kappa\|M_{\mathsf{N}}^{\perp}M_{\mathsf{N}} - \frac{1}{d}\operatorname{tr}(M_{\mathsf{N}}^{\perp}M_{\mathsf{N}})I\|^2$ to prevent M_{N} from having too different scales at different directions (i.e., to drive M_{N} close to orthogonal). We set $\gamma = 0.001$ and $\kappa = 0.0001$. Despite the rather weak regularizer, we find that M_{N}^{-1} can be learned to be exactly the inverse of M_{N}, and M_{N} can actually be an orthogonal matrix, showing some semantic regularity (Section 5.1).

5 Experiments

For training vector-based DCS, we use Wikipedia Extractor[2] to extract texts from the 2015-12-01 dump of English Wikipedia[3]. Then, we use Stanford Parser[4] (Klein and Manning, 2003) to parse all sentences and convert the UD trees into DCS trees by handwritten rules. We assign a weight to each path of the DCS trees as follows.

[1]Problem with the naive regularizer $\|M^{-1}M - I\|^2$ is that, when the scale of M goes larger, it will drive M^{-1} smaller, which may lead to degeneration. So we scale I according to the trace of $M^{-1}M$.

Table 2: Top 10 answers of high dot products

For any path P passing through k intermediate nodes of degrees $n_1, \ldots, n_k$, respectively, we set

$$\mathrm{Weight}(P) := \prod_{i=1}^{k} \frac{1}{n_i - 1}. \qquad (5)$$

Note that $n_i \geq 2$ because there is a path P passing through the node; and $\mathrm{Weight}(P) = 1$ if P consists of a single edge. The equation (5) is intended to degrade long paths which pass through several high-valency nodes. We use a random walk algorithm to sample paths such that the expected times a path is sampled equals its weight. As a result, the sampled path lengths range from 1 to 19, average 2.1, with an exponential tail. We convert all words which are sampled less than 1000 times to `*UNKNOWN*/POS`, and all prepositions occurring less than 10000 times to an *UNKNOWN* field. As a result, we obtain a vocabulary of 109k words and 211 field names.

Using the sampled paths, vectors and matrices are trained as in Section 4 (vecDCS). The vector dimension is set to $d = 250$. We compare with three baselines: (i) all matrices are fixed to identity ("no matrix"), in order to investigate the effects of meaning changes caused by syntactic-semantic roles and prepositions; (ii) the regularizer enforcing M_{N}^{-1} to be actually the inverse matrix of M_{N} is set to $\gamma = 0$ ("no inverse"), in order to investigate the effects of a semantically motivated constraint; and (iii) applying the same training scheme to UD trees directly, by modeling UD relations as matrices ("vecUD"). In this case, one edge is assigned one UD relation rel, so we implement the transfor-

mation from child to parent by M_{rel}, and from parent to child by M_{rel}^{-1}. The same hyper-parameters are used to train vecUD. By comparing vecDCS with vecUD we investigate if applying the semantics framework of DCS makes any difference. Additionally, we compare with the GloVe (6B, 300d) vector[5] (Pennington et al., 2014). Norms of all word vectors are normalized to 1 and Frobenius norms of all matrices are normalized to $\sqrt{d}$.

5.1 Qualitative Analysis

We observe several special properties of the vectors and matrices trained by our model.

Words are clustered by POS In terms of cosine similarity, word vectors trained by vecDCS and vecUD are clustered by POS tags, probably due to their interactions with matrices during training. This is in contrast to the vectors trained by GloVe or "no matrix" (Table 1).

Matrices show semantic regularity Matrices learned for ARG, SUBJ and COMP are exactly orthogonal, and some most frequent prepositions[6] are remarkably close. For these matrices, the corresponding M^{-1} also exactly converge to their inverse. It suggests regularities in the semantic space, especially because orthogonal matrices preserve cosine similarity – if M_{N} is orthogonal, two words x, y and their projections $\pi_{\mathsf{N}}(\mathtt{x})$, $\pi_{\mathsf{N}}(\mathtt{y})$ will have the same similarity measure, which is semantically reasonable. In contrast, matrices trained by vecUD are only orthogonal for three UD relations, namely conj, dep and appos.

Words transformed by matrices To illustrate the matrices trained by vecDCS, we start from the query vectors of two words, house and learn, applying different matrices to them, and show the 10 answer vectors of the highest dot products (Tabel 2). These are the lists of likely words which: take *house* as a subject, take *house* as a complement, fills into "__ *in house*", serve as a subject of *learn*, serve as a complement of *learn*, and fills into "*learn about* __", respectively. As the table shows, matrices in vecDCS are appropriately learned to map word vectors to their syntactic-semantic roles.

5.2 Phrase Similarity

To test if vecDCS has the composition ability to calculate similar things as similar vectors, we conduct evaluation on a wide range of phrase similarity tasks. In these tasks, a system calculates similarity scores for pairs of phrases, and the performance is evaluated as its correlation with human annotators, measured by Spearman's ρ.

Datasets Mitchell and Lapata (2010) create datasets[7] for pairs of three types of two-word phrases: adjective-nouns (AN) (e.g. "*black hair*" and "*dark eye*"), compound nouns (NN) (e.g. "*tax charge*" and "*interest rate*") and verb-objects (VO) (e.g. "*fight war*" and "*win battle*"). Each dataset consists of 108 pairs and each pair is annotated by 18 humans (i.e., 1,944 scores in total). Similarity scores are integers ranging from 1 to 7. Another dataset[8] is created by extending VO to Subject-Verb-Object (SVO), and then assessing similarities by crowd sourcing (Kartsaklis and Sadrzadeh, 2014). The dataset GS11 created by Grefenstette and Sadrzadeh (2011) (100 pairs, 25 annotators) is also of the form SVO, but in each pair only the verbs are different (e.g. "*man pro-*

vide/supply money"). The dataset GS12 described in Grefenstette (2013a) (194 pairs, 50 annotators) is of the form Adjective-Noun-Verb-Adjective-Noun (e.g. "*local family run/move small hotel*"), where only verbs are different in each pair.

Our method We calculate the cosine similarity of query vectors corresponding to phrases. For example, the query vector for "*fight war*" is calculated as $\mathbf{v}_{war} M_{\mathsf{ARG}} M_{\mathsf{COMP}}^{-1} + \mathbf{v}_{fight}$. For vecUD we use M_{nsubj} and M_{dobj} instead of M_{SUBJ} and M_{COMP}, respectively. For GloVe we use additive compositions.

Results As shown in Table 3, vecDCS is competitive on AN, NN, VO, SVO and GS12, consistently outperforming "no inverse", vecUD and GloVe, showing strong compositionality. The weakness of "no inverse" suggests that relaxing the constraint of inverse matrices may hurt compositionaly, though our preliminary examination on word similarities did not find any difference. The GS11 dataset appears to favor models that can learn from interactions between the subject and object arguments, such as the non-linear model Wadd_{nl} in Hashimoto et al. (2014) and the entanglement model in Kartsaklis and Sadrzadeh (2014). However, these models do not show particular advantages on other datasets. The recursive autoencoder (RAE) proposed in Socher et al. (2011) shares an aspect with vecDCS as to construct meanings from parse trees. It is tested by Blacoe and Lapata (2012) for compositionality, where vecDCS appears to be better. Nevertheless, we note that "no matrix" performs as good as vecDCS, suggesting that meaning changes caused by syntactic-semantic roles might not be major factors in these datasets, because the syntactic-semantic relations are all fixed in each dataset.

dos Santos et al. (2015)	84.1
Xu et al. (2015)	**85.6**

Table 5: F1 on relation classification

5.3 Relation Classification

In a relation classification task, the relation between two words in a sentence needs to be classified; we expect vecDCS to perform better than "no matrix" on this task because vecDCS can distinguish the different syntactic-semantic roles of the two slots the two words fit in. We confirm this conjecture in this section.

Dataset We use the dataset of SemEval-2010 Task 8 (Hendrickx et al., 2009), in which 9 directed relations (e.g. *Cause-Effect*) and 1 undirected relation *Other* are annotated, 8,000 instances for training and 2,717 for test. Performance is measured by the 9-class direction-aware Macro-F1 score excluding *Other* class.

Our method For any sentence with two words marked as e_1 and e_2, we construct the DCS tree of the sentence, and take the subtree T rooted at the common ancestor of e_1 and e_2. We construct four vectors from T, namely: the query vector for the subtree rooted at e_1 (resp. e_2), and the query vector of the DCS tree obtained from T by re-rooting it at e_1 (resp. e_2) (Figure 4). The four vectors are normalized and concatenated to form the only feature used to train a classifier. For vecUD, we use the corresponding vectors calculated from UD trees. For GloVe, we use the word vector of e_1 (resp. e_2), and the sum of vectors of all words within the span $[e_1, e_2)$ (resp. $(e_1, e_2]$) as

"banned drugs"	*"banned movies"*	*"banned books"*

the four vectors. Classifier is SVM[9] with RBF kernel, $C = 2$ and $\Gamma = 0.25$. The hyper-parameters are selected by 5-fold cross validation.

Results VecDCS outperforms baselines on relation classification (Table 5). It makes 16 errors in misclassifying the direction of a relation, as compared to 144 such errors made by "no matrix", 23 by "no inverse", 30 by vecUD, and 161 by GloVe. This suggests that models with syntactic-semantic transformations (i.e. vecDCS, "no inverse", and vecUD) are indeed good at distinguishing the different roles played by e_1 and e_2. VecDCS scores moderately lower than the state-of-the-art (Xu et al., 2015), however we note that these results are achieved by adding additional features and training task-specific neural networks (dos Santos et al., 2015; Xu et al., 2015). Our method only uses features constructed from unlabeled corpora. From this point of view, it is comparable to the MV-RNN model (without features) in Socher et al. (2012), and vecDCS actually does better. Table 4 shows an example of clustered training instances as assessed by cosine similarities between their features. It suggests that the features used in our method can actually cluster similar relations.

5.4 Sentence Completion

If vecDCS can compose query vectors of DCS trees, one should be able to "execute" the vectors to get a set of answers, as the original DCS trees can do. This is done by taking dot products with answer vectors and then ranking the answers. Examples are shown in Table 6. Since query vectors and answer vectors are trained from unlabeled corpora, we can only obtain a coarse-grained candidate list. However, it is noteworthy that despite a common word "*banned*" shared by the phrases, their answer lists are largely different, suggesting that composition actually can be done. Moreover, some words indeed answer the queries (e.g. *Thalidomide* for "banned drugs" and *Samizdat* for "*banned books*").

Quantitatively, we evaluate this utility of executing queries on the sentence completion task. In this task, a sentence is presented with a blank that need to be filled in. Five possible words are given as options for each blank, and a system needs to choose the correct one. The task can be viewed as a coarse-grained question answering or an evaluation for language models (Zweig et al., 2012). We use the MSR sentence completion dataset[10] which consists of 1,040 test questions and a corpus for training language models. We train vecDCS on this corpus and use it for evaluation.

Results As shown in Table 7, vecDCS scores better than the N-gram model and demonstrates promising performance. However, to our surprise, "no matrix" shows an even better result which is the new state-of-the-art. Here we might be facing the same problem as in the phrase similarity task (Section 5.2); namely, all choices in a question fill into the same blank and the same syntactic-semantic role, so the transforming matrices in vecDCS might not be able to distinguish different choices; on the other hand, vecDCS would suffer more from parsing and POS-tagging errors. Nonetheless, we believe the result by "no matrix" reveals a new horizon of sentence completion, and suggests that composing semantic vectors according to DCS trees could be a promising direction.

6 Discussion

We have demonstrated a way to link a vector composition model to a formal semantics, combining the strength of vector representations to calculate phrase similarities, and the strength of formal semantics to build up structured queries. In this section, we discuss several lines of previous research related to this work.

Logic and Distributional Semantics Logic is necessary for implementing the functional aspects of meaning and organizing knowledge in a structured and unambiguous way. In contrast, distributional semantics provides an elegant methodology for assessing semantic similarity and is well suited for learning from data. There have been repeated calls for combining the strength of these two approaches (Coecke et al., 2010; Baroni et al., 2014; Liang and Potts, 2015), and several systems (Lewis and Steedman, 2013; Beltagy et al., 2014; Tian et al., 2014) have contributed to this direction. In the remarkable work by Beltagy et al. (to appear), word and phrase similarities are explicitly transformed to weighted logical rules that are used in a probabilistic inference framework. However, this approach requires considerable amount of engineering, including the generation of rule candidates (e.g. by aligning sentence fragments), converting distributional similarities to weights, and efficiently handling the rules and inference. What if the distributional representations are equipped with a logical interface, such that the inference can be realized by simple vector calculations? We have shown it possible to realize semantic composition; we believe this may lead to significant simplification of the system design for combining logic and distributional semantics.

Compositional Distributional Models There has been active exploration on how to combine word vectors such that adequate phrase/sentence similarities can be assessed (Mitchell and Lapata, 2010, *inter alia*), and there is nothing new in using matrices to model changes of meanings. However, previous model designs mostly rely on linguistic intuitions (Paperno et al., 2014, *inter alia*), whereas our model has an exact logic interpretation. Furthermore, by using additive composition we enjoy a learning guarantee (Tian et al., 2015).

Vector-based Logic Models This work also shares the spirit with Grefenstette (2013b) and Rocktaeschel et al. (2014), in exploring vector calculations that realize logic operations. However, the previous works did not specify how to integrate contextual distributional information, which is necessary for calculating semantic similarity.

Formal Semantics Our model implements a fragment of logic capable of semantic composition, largely due to the simple framework of Dependency-based Compositional Semantics (Liang et al., 2013). It fits in a long tradition of logic-based semantics (Montague, 1970; Dowty et al., 1981; Kamp and Reyle, 1993), with extensive studies on extracting semantics from syntactic representations such as HPSG (Copestake et al., 2001; Copestake et al., 2005) and CCG (Baldridge and Kruijff, 2002; Bos et al., 2004; Steedman, 2012; Artzi et al., 2015; Mineshima et al., 2015).

Logic for Natural Language Inference The pursue of a logic more suitable for natural language inference is also not new. For example, MacCartney and Manning (2008) has implemented a model of natural logic (Lakoff, 1970). We would not reach the current formalization of logic of DCS without reading the work by Calvanese et al. (1998), which is an elegant formalization of database semantics in description logic.

Semantic Parsing DCS-related representations have been actively used in semantic parsing and we see potential in applying our model. For example, Berant and Liang (2014) convert λ-DCS queries to canonical utterances and assess paraphrases at the surface level; an alternative could be using vector-based DCS to bring distributional similarity directly into calculation of denotations. We also borrow ideas from previous work, for example our training scheme is similar to Guu et al. (2015) in using paths and composition of matrices, and our method is similar to Poon and Domingos (2009) in building structured knowledge from clustering syntactic parse of unlabeled data.

Further Applications Regarding the usability of distributional representations learned by our model, a strong point is that the representation takes into account syntactic/structural information of context. Unlike several previous models (Padó and Lapata, 2007; Levy and Goldberg, 2014; Pham et al., 2015), our approach learns matrices at the same time that can extract the information according to different syntactic-semantic roles. A related application is selectional preference (Baroni and Lenci, 2010; Lenci, 2011; Van de Cruys, 2014), wherein our model might has potential for smoothly handling composition.

Inner Attention based Recurrent Neural Networks for Answer Selection

Bingning Wang, Kang Liu, Jun Zhao
National Laboratory of Pattern Recognition, Institute of Automation
Chinese Academy of Sciences, Beijing, China
{bingning.wang, kliu, jzhao}@nlpr.ia.ac.cn

Abstract

Attention based recurrent neural networks have shown advantages in representing natural language sentences (Hermann et al., 2015; Rocktäschel et al., 2015; Tan et al., 2015). Based on recurrent neural networks (RNN), external attention information was added to hidden representations to get an attentive sentence representation. Despite the improvement over non-attentive models, the attention mechanism under RNN is not well studied. In this work, we analyze the deficiency of traditional attention based RNN models quantitatively and qualitatively. Then we present three new RNN models that add attention information before RNN hidden representation, which shows advantage in representing sentence and achieves new state-of-art results in answer selection task.

1 Introduction

Answer selection (AS) is a crucial subtask of the open domain question answering (QA) problem. Given a question, the goal is to choose the answer from a set of pre-selected sentences (Heilman and Smith, 2010; Yao et al., 2013). Traditional AS models are based on lexical features such as parsing tree edit distance. Neural networks based models are proposed to represent the meaning of a sentence in a vector space and then compare the question and answer candidates in this hidden space (Wang and Nyberg, 2015; Feng et al., 2015), which have shown great success in AS. However, these models represent the question and sentence separately, which may ignore the information subject to the question when representing the answer. For example, given a candidate answer:

Michael Jordan abruptly retired from Chicago Bulls before the beginning of the 1993-94 NBA season to pursue a career in baseball.

For a question: **When did Michael Jordan retired from NBA?** we should focus on *the beginning of the 1993-94* in the sentence; however, when we were asked: **Which sports does Michael Jordan participates after his retirement from NBA?** we should pay more attention to *pursue a career in baseball*.

Recent years, attention based models are proposed in light of this purpose and have shown great success in many NLP tasks such as machine translation (Bahdanau et al., 2014; Sutskever et al., 2014), question answering (Sukhbaatar et al., 2015) and recognizing textual entailments (Rocktäschel et al., 2015). When building the representation of a sentence, some attention information is added to the hidden state. For example, in attention based recurrent neural networks models (Bahdanau et al., 2014) each time-step hidden representation is weighted by attention. Inspired by the attention mechanism, some attention-based RNN answer selection models have been proposed (Tan et al., 2015) in which the attention when computing answer representation is from question representation.

However, in the RNN architecture, at each time step a word is added and the hidden state is updated recurrently, so those hidden states near the end of the sentence are expected to capture more information[1]. Consequently, after adding the attention information to the time sequence hidden representations, the near-the-end hidden variables will be more attended due to their comparatively abundant semantic accumulation, which may result in a biased attentive weight towards the later coming words in RNN.

In this work, we analyze this attention bias

[1] so in many previous RNN-based model use the last hidden variable as the whole sentence representation

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1288–1297,
Berlin, Germany, August 7-12, 2016.

problem qualitatively and quantitatively, and then propose three new models to solve this problem. Different from previous attention based RNN models in which attention information is added after RNN computation, we add the attention before computing the sentence representation. Concretely, the first one uses the question attention to adjust word representation (i.e. word embedding) in the answer directly, and then we use RNN to model the attentive word sequence. However, this model attends a sentence word by word which may ignore the relation between words. For example, if we were asked: *what is his favorite food?* one answer candidate is: *He likes hot dog best*. *hot* or *dog* may be not relate to the question by itself, but they are informative as a whole in the context. So we propose the second model in which every word representation in answer is impacted by not only question attention but also the context representation of the word (i.e. the last hidden state). In our last model, inspired by previous work on adding gate into inner activation of RNN to control the long and short term information flow, we embed the attention to the inner activation gate of RNN to influence the computation of RNN hidden representation. In addition, inspired by recent work called Occam's Gate in which the activation of input units are penalized to be as less as possible, we add regulation to the summation of the attention weights to impose sparsity.

Overall, in this work we make three contributions: (1) We analyze the attention bias problem in traditional attention based RNN models. (2) We propose three inner attention based RNN models and achieve new state-of-the-art results in answer selection. (3) We use Occam's Razor to regulate the attention weights which shows advantage in long sentence representation.

2 Related Work

Recent years, many deep learning framework has been developed to model the text in a vector space, and then use the embedded representations in this space for machine learning tasks. There are many neural networks architectures for this representation such as convolutional neural networks(Yin et al., 2015), recursive neural networks(Socher et al., 2013) and recurrent neural networks(Mikolov et al., 2011). In this work we propose **I**nner **A**ttention based **RNN** (**IARNN**) for answer selection, and there are two main works which we are related to.

2.1 Attention based Models

Many recent works show that attention techniques can improve the performance of machine learning models (Mnih et al., 2014; Zheng et al., 2015). In attention based models, one representation is built with attention (or supervision) from other representation. Weston et al (2014) propose a neural networks based model called Memory Networks which uses an external memory to store the knowledge and the memory are read and written on the fly with respect to the attention, and these attentive memory are combined for inference. Since then, many variants have been proposed to solve question answering problems (Sukhbaatar et al., 2015; Kumar et al., 2015). Hermann (2015) and many other researchers (Tan et al., 2015; Rocktäschel et al., 2015) try to introduce the attention mechanism into the LSTM-RNN architecture. RNN models the input sequence word-by-word and updates its hidden variable recurrently. Compared with CNN, RNN is more capable of exploiting long-distance sequential information. In attention based RNN models, after computing each time step hidden representation, attention information is added to weight each hidden representation, then the hidden states are combined with respect to that weight to obtain the sentence (or document) representation. Commonly there are two ways to get attention from source sentence, either by the whole sentence representation (which they call *attentive*) or word by word attention (called *impatient*).

2.2 Answer Selection

Answer selection is a sub-task of QA and many other tasks such as machine comprehension. Given a question and a set of candidate sentences, one should choose the best sentence from a candidate sentence set that can answer the question. Previous works usually stuck in employing feature engineering, linguistic tools, or external resources. For example, Yih et al. (2013) use semantic features from WordNet to enhance lexical features. Wang and Manning (2007) try to compare the question and answer sentence by their syntactical matching in parse trees. Heilman and Smith (Heilman and Smith, 2010) try to fulfill the matching using minimal edit sequences between their dependency parse trees. Severyn and Moschitti (2013) automate the extraction of discriminative tree-edit features over parsing trees.

While these methods show effectiveness, they might suffer from the availability of additional resources and errors of many NLP tools such as dependency parsing. Recently there are many works use deep learning architecture to represent the question and answer in a same hidden space, and then the task can be converted into a classification or learning-to-rank problem (Feng et al., 2015; Wang and Nyberg, 2015). With the development of attention mechanism, Tan et.al(2015) propose an attention-based RNN models which introduce question attention to answer representation.

3 Traditional Attention based RNN Models and Their Deficiency

The attention-based models introduce the attention information into the representation process. In answer selection, given a question $Q = \{q_1, q_2, q_3, ..., q_n\}$ where q_i is i-th word, n is the question length, we can compute its representation in RNN architecture as follows:

$$\begin{aligned} \mathbf{X} &= \mathbf{D}[q_1, q_2, ..., q_n] \\ \mathbf{h}_t &= \sigma(\mathbf{W}_{ih}\mathbf{x}_t + \mathbf{W}_{hh}\mathbf{h}_{t-1} + \mathbf{b}_h) \\ \mathbf{y}_t &= \sigma(\mathbf{W}_{ho}\mathbf{h}_t + \mathbf{b}_o) \end{aligned} \tag{1}$$

where $\mathbf{D}$ is an embedding matrix that projects word to its embedding space in R^d; $\mathbf{W}_{ih}$, $\mathbf{W}_{hh}$, $\mathbf{W}_{ho}$ are weight matrices and $\mathbf{b}_h$, $\mathbf{b}_o$ are bias vectors; σ is active function such as $tanh$. Usually we can ignore the output variables and use the hidden variables. After recurrent process, the last hidden variable $\mathbf{h}_n$ or all hidden states average $\frac{1}{n}\sum_{t=1}^{n}\mathbf{h}_t$ is adopted as the question representation $\mathbf{r}_q$.

When modeling the candidate answer sentence with length m:$S = \{s_1, s_2, s_3, ..., s_m\}$ in attention based RNN model,

instead of using the last hidden state or average hidden states, we use attentive hidden states that are weighted by $\mathbf{r}_q$:

$$\begin{aligned} \mathbf{H}_a &= [\mathbf{h}_a(1), \mathbf{h}_a(2), ..., \mathbf{h}_a(m)] \\ s_t &\propto f_{attention}(\mathbf{r}_q, \mathbf{h}_a(t)) \\ \tilde{\mathbf{h}}_a(t) &= \mathbf{h}_a(t)s_t \\ \mathbf{r}_a &= \sum_{t=1}^{m}\tilde{\mathbf{h}}_a(t) \end{aligned} \tag{2}$$

where $\mathbf{h}_a(t)$ is hidden state of the answer at time t. In many previous work (Hermann et al., 2015; Rocktäschel et al., 2015; Tan et al., 2015), the attention function $f_{attention}$ was computed as:

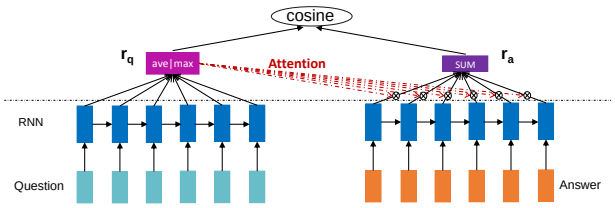

Figure 1: Traditional attention based RNN answer selection model. Dark blue rectangles represent hidden virable, $\otimes$ means gate opperation.

$$\begin{aligned} \mathbf{m}(t) &= tanh(\mathbf{W}_{hm}\mathbf{h}_a(t) + \mathbf{W}_{qm}\mathbf{r}_q) \\ f_{attention}(\mathbf{r}_q, \mathbf{h}_a(t)) &= exp(\mathbf{w}_{ms}^T\mathbf{m}(t)) \end{aligned} \tag{3}$$

$\mathbf{W}_{hm}$ and $\mathbf{W}_{qm}$ are attentive weight matrices and $\mathbf{w}_{ms}$ is attentive weight vector. So we can expect that the candidate answer sentence representation $\mathbf{r}_a$ may be represented in a question-guided way: when its hidden state $\mathbf{h}_a(t)$ is irrelevant to the question (determined by attention weight s_t), it will take less part in the final representation; but when this hidden state is relavent to the question, it will contribute more in representing $\mathbf{r}_a$. We call this type of attention based RNN model OARNN which stands for *Outer Attention based RNN* models because this kind of model adds attention information outside the RNN hidden representation computing process. An illustration of traditional attention-based RNN model is in Figure 1.

However, we know in the RNN architecture, the input words are processed in time sequence and the hidden states are updated recurrently, so the current hidden state $\mathbf{h}_t$ is supposed to contain all the information up to time t, when we add question attention information, aiming at finding the useful part of the sentence, these near-the-end hidden states are prone to be selected because they contains much more information about the whole sentence. In other word, if the question pays attention to the hidden states at time t , then it should also pay attention to those hidden states after t (i.e $\{\mathbf{h}_{t'}|t' > t\}$) as they contain the information at least as much as $\mathbf{h}_t$, but in answer selection for a specific candidate answer, the useful parts to answer the question may be located anywhere in a sentence, so the attention should also distribute uniformly around the sentence. Traditional attention-based RNN models under *attention after representation* mechanism may cause the attention to bias towards the later coming hidden states. We will analyze this attention bias problem quantita-

tively in the experiments.

4 Inner Attention based Recurrent Neural Networks

In order to solve the attention bias problem, we propose an intuition:

Attention before representation

Instead of adding attention information after encoding the answer by RNN, we add attention before computing the RNN hidden representations. Based on this intuition, we propose three inner attention based RNN models detailed below.

4.1 IARNN-WORD

As attention mechanism aims at finding useful part of a sentence, the first model applies the above intuition directly. Instead of using the original answer words to the RNN model, we weight the words representation according to question attention as follows:

$$\begin{aligned} \alpha_t &= \sigma(\mathbf{r}_q^T \mathbf{M}_{qi} \mathbf{x}_t) \\ \tilde{\mathbf{x}}_t &= \alpha_t * \mathbf{x}_t \end{aligned} \tag{4}$$

where $\mathbf{M}_{qi}$ is an attention matrix to transform a question representaion into the word embedding space. Then we use the dot value to determine the question attention strength, σ is sigmoid function to normalize the weight α_t between 0 and 1.

The above attention process can be understood as sentence distillation where the input words are distilled (or filtered) by question attention. Then, we can represent the whole sentence based on this distilled input using traditional RNN model. In this work, we use GRU instead of LSTM as building block for RNN because it has shown advantages in many tasks and has comparatively less parameter(Jozefowicz et al., 2015) which is formulated as follows:

$$\begin{aligned} \mathbf{z}_t &= \sigma(\mathbf{W}_{xz}\tilde{\mathbf{x}}_t + \mathbf{W}_{hz}\mathbf{h}_{t-1}) \\ \mathbf{f}_t &= \sigma(\mathbf{W}_{xf}\tilde{\mathbf{x}}_t + \mathbf{W}_{hf}\mathbf{h}_{t-1}) \\ \tilde{\mathbf{h}}_t &= tanh(\mathbf{W}_{xh}\tilde{\mathbf{x}}_t + \mathbf{W}_{hh}(\mathbf{f}_t \odot \mathbf{h}_{t-1})) \\ \mathbf{h}_t &= (1 - \mathbf{z}_t) \odot \mathbf{h}_{t-1} + \mathbf{z}_t \odot \tilde{\mathbf{h}}_t \end{aligned} \tag{5}$$

where $\mathbf{W}_{xz}, \mathbf{W}_{hz}, \mathbf{W}_{xf}, \mathbf{W}_{hh}, \mathbf{W}_{xh}$ are weight matrices and $\odot$ stands for element-wise multiplication. Finally, we get candidate answer representation by average pooling all the hidden state $\mathbf{h}_t$. we call this model IARNN-WORD as the attention is paid to the original input words. This model is shown in Figure 2.

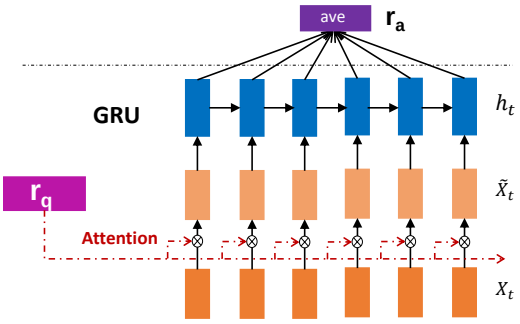

Figure 2: IARNN-WORD architecture. $\mathbf{r}_q$ is question representation.

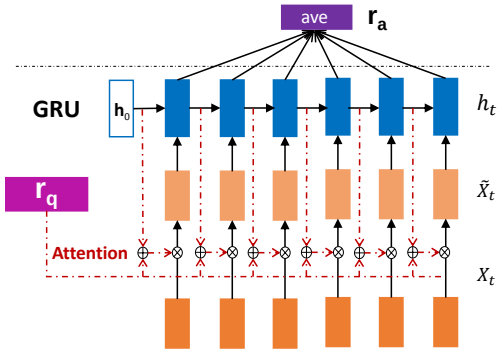

Figure 3: IARNN-CONTEXT architecture for building candidate answer sentence representation. $\mathbf{h}_0$ is added for completeness.

4.2 IARNN-CONTEXT

IABRNN-WORD attend input word embedding directly. However, the answer sentence may consist of consecutive words that are related to the question, and a word may be irrelevant to question by itself but relevant in the context of answer sentence.

So the above word by word attention mechanism may not capture the relationship between multiple words. In order to import contextual information into attention process, we modify the attention weights in Equation 4 with additional context information:

$$\begin{aligned} \mathbf{w}_C(t) &= \mathbf{M}_{hc}\mathbf{h}_{t-1} + \mathbf{M}_{qc}\mathbf{r}_q \\ \alpha_C^t &= \sigma(\mathbf{w}_C^T(t)\mathbf{x}_t) \\ \tilde{\mathbf{x}}_t &= \alpha_C^t * \mathbf{x}_t \end{aligned} \tag{6}$$

where we use $\mathbf{h}_{t-1}$ as context, $\mathbf{M}_{hc}$ and $\mathbf{M}_{qc}$ are attention weight matrices, $\mathbf{w}_C(t)$ is the attention representation which consists of both question and word context information. This additional context attention endows our model to capture relevant part in longer text span. We show this model in Figure 3.

4.3 IARNN-GATE

Inspired by the previous work of LSTM (Hochreiter and Schmidhuber, 1997) on solving the gradient exploding problem in RNN and recent work on building distributed word representation with topic information(Ghosh et al., 2016), instead of adding attention information to the original input, we can apply attention deeper to the GRU inner activation (i.e $\mathbf{z}_t$ and $\mathbf{f}_t$). Because these inner activation units control the flow of the information within the hidden stage and enables information to pass long distance in a sentence, we add attention information to these active gates to influence the hidden representation as follows:

$$\begin{aligned}
\mathbf{z}_t &= \sigma(\mathbf{W}_{xz}\mathbf{x}_t + \mathbf{W}_{hz}\mathbf{h}_{t-1} + \mathbf{M}_{qz}\mathbf{r}_q) \\
\mathbf{f}_t &= \sigma(\mathbf{W}_{xf}\mathbf{x}_t + \mathbf{W}_{hf}\mathbf{h}_{t-1} + \mathbf{M}_{qf}\mathbf{r}_q) \\
\tilde{\mathbf{h}}_t &= tanh(\mathbf{W}_{xh}\mathbf{x}_t + \mathbf{W}_{hh}(\mathbf{f}_t \odot \mathbf{h}_{t-1})) \\
\mathbf{h}_t &= (1 - \mathbf{z}_t) \odot \mathbf{h}_{t-1} + \mathbf{z}_t \odot \tilde{\mathbf{h}}_t
\end{aligned} \tag{7}$$

where $\mathbf{M}_{qz}$ and $\mathbf{M}_{hz}$ are attention weight matrices. In this way, the update and forget units in GRU can focus on not only long and short term memory but also the attention information from the question. The architecture is shown in Figure 4.

4.4 IARNN-OCCAM

In answer selection, the answer sentence may only contain small number of words that are related to the question. In IARNN-WORD and IARNN-CONTEXT, we calculate each word attention weight without considering total weights. Similar with Raiman(2015) who adds regulation to the input gate, we punish the summation of the attention weights to enforce sparsity. This is an application of Occam's Razor: *Among the whole words set, we choose those with fewest number that can represent the sentence*. However, assigning a pre-defined hyper-parameter for this regulation[2] is not an ideal way because it punishes all question attention weights with same strength. For different questions there may be different number of snippets in candidate answer that are required. For example, when the question type is *When* or *Who*, answer sentence may only contains a little relavant words so we should impose more sparsity on the summation of the attention. But when the question type is *Why* or *How*, there may be much more words on the sentence that are relevant to the question so we should set the regulation value small accordingly. In this work, this attention regulation is added as follows: for the specific question Q_i and its representation $\mathbf{r}_q^i$, we use a vector $\mathbf{w}_{qp}$ to project it into scalar value n_p^i, and then we add it into the original objective J_i as follows:

$$\begin{aligned}
n_p^i &= \max\{\mathbf{w}_{qp}^T \mathbf{r}_q^i, \lambda_q\} \\
J_i^* &= J_i + n_p^i \sum_{t=1}^{mc} \alpha_t^i
\end{aligned} \tag{8}$$

where α_t^i is attention weights in Equation 4 and Equation 6. λ_q is a small positive hyper-parameter. It needs to mention that we do not regulate IARNN-GATE because the attention has been embedded to gate activation.

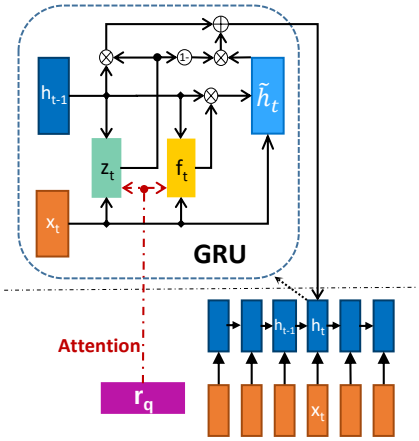

Figure 4: IABRNN-GATE architecture. We show one time step GRU inner state process within the blue dotted line.

5 Experiments

5.1 Quantify Traditional Attention based Model Bias Problem

In order to quantify the outer attention based RNN model's attention bias problem in Section 3, we build an outer attention based model similar with Tan (2015). First of all, for the question we build its representation by averaging its hidden states in LSTM, then we build the candidate answer sentence representation in an attentive way introduced in Section 3. Next we use the cosine similarity to compare question and answer representation similarity. Finally, we adopt max-margin hinge loss as objective:

$$\begin{aligned}
L = max\{0, M - cosine(\mathbf{r}_q, \mathbf{r}_{a_+}) \\
+ cosine(\mathbf{r}_q, \mathbf{r}_{a_-})\}
\end{aligned} \tag{9}$$

[2]For example, in many machine learning problem the original objective sometimes followed with a L_1 or L_2 regulation with hyper-parameter $\lambda 1$ or $\lambda 2$ to control the tradeoff between the original objective J and the sparsity criterion:$J^* = J + (\lambda 1 | \lambda 2) \sum(L_1 | L_2 norm)$

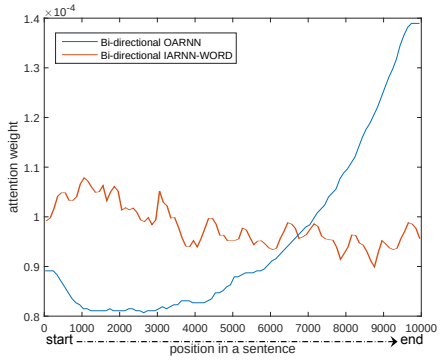

Figure 5: One directional OARNN attention distribution, the horizontal axis is position of word in a sentence that has been normalized from 1 to 10000.

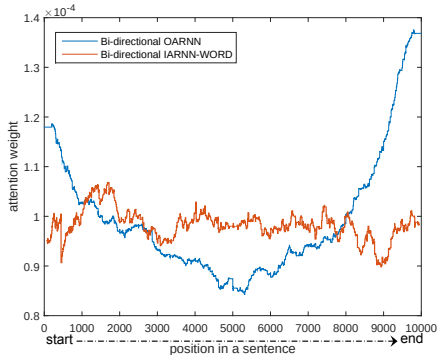

Figure 6: Bi-directional OARNN attention distribution, the horizontal axis is the postion of the word in a sentence that has been normalized from 1 to 10000.

where a_+ is ground truth answer candidate and a_- stands for negative one, the scalar M is a predefined margin. When training result saturates after 50 epoches, we get the attention weight distribution (i.e. s_q in Equation 2). The experiment is conducted on two answer selection datasets: WikiQA (Yang et al., 2015) and TrecQA (Wang et al., 2007). The normalized attention weights is reported in Figure 5.

However, the above model use only forward LSTM to build hidden state representation, the attention bias problem may attribute to the biased answer distribution: the useful part of the answer to the question sometimes may located at the end of the sentence. So we try OARNN in bidirectional architecture, where the forward LSTM and backward LSTM are concatenated for hidden representation, The bidirectional attention based LSTM attention distribution is shown in Figure 6.

Analysis: As is shown in Figure 5 and 6, for one-directional OARNN, as we move from beginning to the end in a sentence, the question attention gains continuously; when we use bidirectional OARNN, the hidden representations near two ends of a sentence get more attention. This is consistent with our assumption that for a hidden representation in RNN, the closer to the end of a sentence, the more attention it should drawn from question. But the relevant part may be located anywhere in a answer. As a result, when the sample size is large enough[3], the attention weight should be unformly distributed. The traditional *attention after representation* style RNN may suffer from the biased attention problem. Our IARNN models are free from this problem and distribute nearly uniform (orange line) in a sentence.

5.2 IARNN evaluation

Common Setup: We use the off-the-shelf 100-dimension word embeddings from word2vec[4], and initiate all weights and attention matrices by fixing their largest singular values to 1 (Pascanu et al., 2013). IARNN-OCCAM base regulation hyper-parameter λ_q is set to 0.05, we add L_2 penalty with a coefficient of 10^{-5} . Dropout (Srivastava et al., 2014) is further applied to every parameters with probability 30%. We use Adadelta(Zeiler, 2012) with $\rho = 0.90$ to update parameters.

We choose three datasets for evaluation: InsuranceQA, WikiQA and TREC-QA. These datasets contain questions from different domains. Table 1 presents some statistics about these datasets. We adopt a max-margin hinge loss as training objective. The results are reported in terms of MAP and MRR in WikiQA and TREC-QA and accuracy in InsuranceQA.

We use bidirectional GRU for all models. We share the GRU parameter between question and answer which has shown significant improvement on performance and convergency rate (Tan et al., 2015; Feng et al., 2015).

There are two common baseline systems for above three datasets:

- **GRU**: A non-attentive GRU-RNN that models the question and answer separately.
- **OARNN**: Outer attention-based RNN models (OARNN) with GRU which is detailed in Section 5.1.

WikiQA (Yang et al., 2015) is a recently released open-domain question answering

IARNN-Gate	0.7258	0.7394

Table 2: Performances on WikiQA

dataset in which all answers are collected from Wikipedia. In addition to the original (question,positive,negative) triplets, we randomly select a bunch of negative answer candidates from answer sentence pool and finally we get a relatively abundant 50,298 triplets. We use cosine similarity to compare the question and candidate answer sentence. The hidden variable's length is set to 165 and batch size is set to 1. We use *sigmoid* as GRU inner active function, we keep word embedding fixed during training. Margin M was set to 0.15 which is tuned in the development set. We adopt three additional baseline systems applied to WikiQA: (1) A bigram CNN models with average pooling(Yang et al., 2015). (2) An attention-based CNN model which uses an interactive attention matrix for both question and answer(Yin et al., 2015) [5] (3) An attention based CNN models which builds the attention matrix after sentence representation(Santos et al., 2016). The result is shown in Table 2.

InsuranceQA (Feng et al., 2015) is a domain specific answer selection dataset in which all questions is related to insurance. Its vocabulary size is comparatively small (22,353), we set the batch size to 16 and the hidden variable size to 145, hinge loss margin M is adjusted to 0.12 by evaluation behavior. Word embeddings are also learned during training. We adopt the Geometric mean of Euclidean and Sigmoid Dot (GESD) proposed in (Feng et al., 2015) to measure the similarity between two representations:

$$GESD(x,y) = \frac{1}{1+||x-y||} \times \frac{1}{1+exp(-\gamma(xy^T+c))} \quad (10)$$

which shows advantage over cosine similarity in experiments.

We report accuracy instead of MAP/MRR because one question only has one right answers in InsuranceQA. The result is shown in Table 3.

Table 4: Result of different systems in Trec-QA.(Wang and Ittycheriah, 2015) propose a question similarity model to extract features from word alignment between two questions which is suitable to FAQ based QA. It needs to mention that the system marked with † are learned on TREC-QA original full training data.

TREC-QA was created by Wang et al.(2007) based on Text REtrieval Conference (TREC) QA track (8-13) data. The size of hidden variable was set to 80, M was set to 0.1. This dataset is comparatively small so we set word embedding vector

[5] In their experiment some extra linguistic features was also added for better performance.

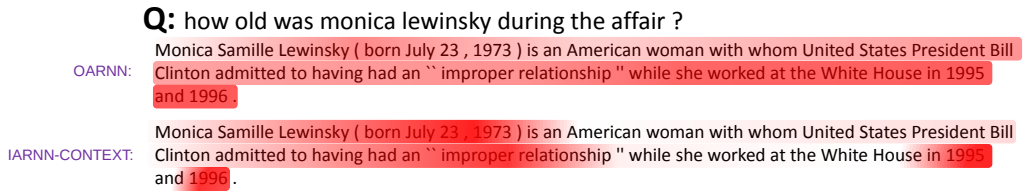

Figure 7: An example demonstrates the advantage of IARNN in capturing the informed part of a sentence compared with OARNN.

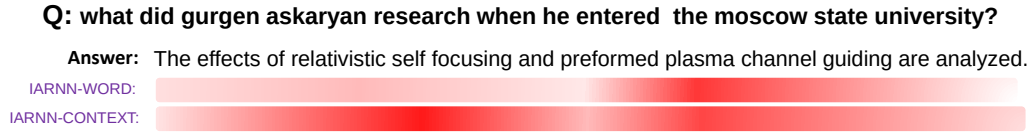

Figure 8: An example illustrates the IARNN-CONTEXT could attend the consecutive words in a sentence.

size to 50 and update it during training. It needs to mention that we do not use the original TREC-QA training data but the smaller one which has been edited by human. The result is shown in Table 4.

6 Result and Analysis

We can see from the result tables that the attention based RNN models achieve better results than the non-attention RNN models (GRU). OARNN and IARNN beat the non-attentive GRU in every datasets by a large margin, which proves the importance of attention mechanism in representing answer sentence in AS. For the non-attentive models, the fixed width of the hidden vectors is a bottleneck for interactive information flow, so the informative part of the question could only propagate through the similarity score which is blurred for the answer representation to be properly learned. But in attention based models, the question attention information is introduced to influence the answer sentence representation explicitly, in this way we can improve sentence representation for the specific target (or topic (Ghosh et al., 2016)).

The inner attention RNN models outperform outer attention model in three datasets, this is corresponds to our intuition that the bias attention problem in OARNN may cause a biasd sentence representation. An example of the attention heatmap is shown in Figure7. To answer the question, we should focus on *"born July 23 , 1973"* which is located at the beginning of the sentence. But in OARNN, the attention is biases towards the last few last words in the answer. In IARNN-CONTEXT, the attention is paid to the relevant part and thus results in a more relevant representation.

The attention with context information could also improves the result, we can see that IARNN-CONTEXT and IARNN-GATE outperform IARNN-WORD in three experiments. IARNN-WORD may ignore the importance of some words because it attends answer word by word, for example in Figure8, the specific word *self* or *focusing* may not be related to the question by itself, but their combination and the previous word *relativistic* is very informative for answering the question. In IARNN-CONTEXT we add attention information dynamically in RNN process, thus it could capture the relationship between word and its context.

In general, we can see from table3-5 that the IARNN-GATE outperforms IARNN-CONTEXT and IARNN-WORD. In IARNN-WORD and IARNN-CONTEXT, the attention is added to impact each word representation, but the recurrent process of updating RNN hidden state representations are not influenced. IARNN-GATE embeds the attention into RNN inner activation, the *attentive activation gate* are more capable of controlling the attention information in RNN. This enlights an important future work: we could add attention information as an individual activation gate, and use this additional gate to control attention information flow in RNN. The regulation of the attention weights (Occam's attention) could also improve the representation. We also conduct an experiment on WikiQA (training process) to measure the Occam's attention regulation on different type of questions. We use rules to classify question into 6 types

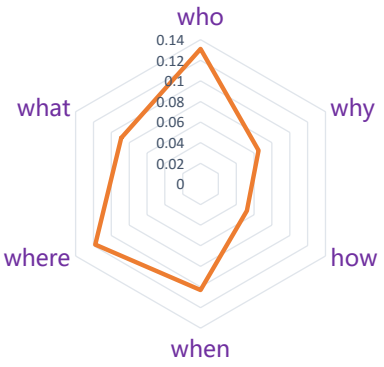

Figure 9: The Occam's attention regulation on different types of question.

(i.e. who,why,how,when,where,what), and each of them has the same number of samples to avoid data imbalance. We report the Occam'm regulation (n_p^i in Equation.8) in Figure 9. As we can see from the radar graph, *who* and *where* are regulized severely compared with other types of question, this is correspond to their comparetively less information in the answer candidate to answer the question. This emphasize that different types question should impose different amount of regulation on its candidate answers. The experiment result on three AS datasets shows that the improvement of Occam's attention is significant in WikiQA and insuranceQA. Because most of the sentence are relatively long in these two datasets, and the longer the sentence, the more noise it may contain, so we should punish the summation of the attention weights to remove some irrelevant parts. Our question-specific Occam's attention punishes the summation of attention and thus achieves a better result for both IARNN-WORD and IARNN-CONTEXT.

7 Conclusion and Future Work

In this work we present some variants of traditional attention-based RNN models with GRU. The key idea is *attention before representation*. We analyze the deficiency of traditional outer attention-based RNN models qualitatively and quantitatively. We propose three models where attention is embedded into representation process. Occam's Razor is further implemented to this attention for better representation. Our results on answer selection demonstrate that the inner attention outperforms the outer attention in RNN. Our models can be further extended to other NLP tasks such as recognizing textual entailments where attention mechanism is important for sentence representation. In the future we plan to apply our *inner-attention* intuition to other neural networks such as CNN or multi-layer perceptron.

Abstract

Relation classification is a crucial ingredient in numerous information extraction systems seeking to mine structured facts from text. We propose a novel convolutional neural network architecture for this task, relying on two levels of attention in order to better discern patterns in heterogeneous contexts. This architecture enables end-to-end learning from task-specific labeled data, forgoing the need for external knowledge such as explicit dependency structures. Experiments show that our model outperforms previous state-of-the-art methods, including those relying on much richer forms of prior knowledge.

1 Introduction

Relation classification is the task of identifying the semantic relation holding between two nominal entities in text. It is a crucial component in natural language processing systems that need to mine explicit facts from text, e.g. for various information extraction applications as well as for question answering and knowledge base completion (Tandon et al., 2011; Chen et al., 2015). For instance, given the example input

"Fizzy [drinks] and meat cause heart disease and [diabetes]."

with annotated target entity mentions e_1 = "drinks" and e_2 = "diabetes", the goal would be to automatically recognize that this sentence expresses a cause-effect relationship between e_1 and e_2, for which we use the notation Cause-Effect(e_1,e_2). Accurate relation classification facilitates precise sentence interpretations, discourse processing, and higher-level NLP tasks (Hendrickx et al., 2010). Thus, relation classification has attracted considerable attention from researchers over the course of the past decades (Zhang, 2004; Qian et al., 2009; Rink and Harabagiu, 2010).

In the example given above, the verb corresponds quite closely to the desired target relation. However, in the wild, we encounter a multitude of different ways of expressing the same kind of relationship. This challenging variability can be lexical, syntactic, or even pragmatic in nature. An effective solution needs to be able to account for useful semantic and syntactic features not only for the meanings of the target entities at the lexical level, but also for their immediate context and for the overall sentence structure.

Thus, it is not surprising that numerous feature- and kernel-based approaches have been proposed, many of which rely on a full-fledged NLP stack, including POS tagging, morphological analysis, dependency parsing, and occasionally semantic analysis, as well as on knowledge resources to capture lexical and semantic features (Kambhatla, 2004; Zhou et al., 2005; Suchanek et al., 2006; Qian et al., 2008; Mooney and Bunescu, 2005; Bunescu and Mooney, 2005). In recent years, we have seen a move towards deep architectures that are capable of learning relevant representations and features without extensive manual feature engineering or use of external resources. A number of convolutional neural network (CNN), recurrent neural network (RNN), and other neural architectures have been proposed for relation classification (Zeng et al., 2014; dos Santos et al., 2015; Xu et al., 2015b). Still, these models often fail to identify critical cues, and many of them still require an external dependency parser.

We propose a novel CNN architecture that addresses some of the shortcomings of previous approaches. Our key contributions are as follows:

1. Our CNN architecture relies on a novel multi-

[*] Equal contribution.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1298–1307,
Berlin, Germany, August 7-12, 2016.

level attention mechanism to capture both entity-specific attention (primary attention at the input level, with respect to the target entities) and relation-specific pooling attention (secondary attention with respect to the target relations). This allows it to detect more subtle cues despite the heterogeneous structure of the input sentences, enabling it to automatically learn which parts are relevant for a given classification.

2. We introduce a novel pair-wise margin-based objective function that proves superior to standard loss functions.
3. We obtain the new state-of-the-art results for relation classification with an F1 score of 88.0% on the SemEval 2010 Task 8 dataset, outperforming methods relying on significantly richer prior knowledge.

2 Related Work

Apart from a few unsupervised clustering methods (Hasegawa et al., 2004; Chen et al., 2005), the majority of work on relation classification has been supervised, typically cast as a standard multi-class or multi-label classification task. Traditional feature-based methods rely on a set of features computed from the output of an explicit linguistic preprocessing step (Kambhatla, 2004; Zhou et al., 2005; Boschee et al., 2005; Suchanek et al., 2006; Chan and Roth, 2010; Nguyen and Grishman, 2014), while kernel-based methods make use of convolution tree kernels (Qian et al., 2008), subsequence kernels (Mooney and Bunescu, 2005), or dependency tree kernels (Bunescu and Mooney, 2005). These methods thus all depend either on carefully handcrafted features, often chosen on a trial-and-error basis, or on elaborately designed kernels, which in turn are often derived from other pre-trained NLP tools or lexical and semantic resources. Although such approaches can benefit from the external NLP tools to discover the discrete structure of a sentence, syntactic parsing is error-prone and relying on its success may also impede performance (Bach and Badaskar, 2007). Further downsides include their limited lexical generalization abilities for unseen words and their lack of robustness when applied to new domains, genres, or languages.

In recent years, deep neural networks have shown promising results. The Recursive Matrix-Vector Model (MV-RNN) by Socher et al. (2012) sought to capture the compositional aspects of the sentence semantics by exploiting syntactic trees. Zeng et al. (2014) proposed a deep convolutional neural network with softmax classification, extracting lexical and sentence level features. However, these approaches still depend on additional features from lexical resources and NLP toolkits. Yu et al. (2014) proposed the Factor-based Compositional Embedding Model, which uses syntactic dependency trees together with sentence-level embeddings. In addition to dos Santos et al. (2015), who proposed the Ranking CNN (CR-CNN) model with a class embedding matrix, Miwa and Bansal (2016) similarly observed that LSTM-based RNNs are outperformed by models using CNNs, due to limited linguistic structure captured in the network architecture. Some more elaborate variants have been proposed to address this, including bidirectional LSTMs (Zhang et al., 2015), deep recurrent neural networks (Xu et al., 2016), and bidirectional tree-structured LSTM-RNNs (Miwa and Bansal, 2016). Several recent works also reintroduce a dependency tree-based design, e.g., RNNs operating on syntactic trees (Hashimoto et al., 2013), shortest dependency path-based CNNs (Xu et al., 2015a), and the SDP-LSTM model (Xu et al., 2015b). Finally, Nguyen and Grishman (2015) train both CNNs and RNNs and variously aggregate their outputs using voting, stacking, or log-linear modeling (Nguyen and Grishman, 2015). Although these recent models achieve solid results, ideally, we would want a simple yet effective architecture that does not require dependency parsing or training multiple models. Our experiments in Section 4 demonstrate that we can indeed achieve this, while also obtaining substantial improvements in terms of the obtained F1 scores.

3 The Proposed Model

Given a sentence S with a labeled pair of entity mentions e_1 and e_2 (as in our example from Section 1), relation classification is the task of identifying the semantic relation holding between e_1 and e_2 among a set of candidate relation types (Hendrickx et al., 2010). Since the only input is a raw sentence with two marked mentions, it is non-trivial to obtain all the lexical, semantic and syntactic cues necessary to make an accurate prediction.

To this end, we propose a novel multi-level attention-based convolution neural network model. A schematic overview of our architecture is given

Notation	Definition	Notation	Definition
$\mathbf{w}_i^{\mathrm{M}}$	Final word emb.	$\mathbf{z}_i$	Context emb.
W_f	Conv. weight	B_f	Conv. bias
$\mathbf{w}^{\mathrm{O}}$	Network output	W^{L}	Relation emb.
A^j	Input att.	A^{p}	Pooling att.
G	Correlation matrix		

Table 1: Overview of main notation.

in Figure 1. The input sentence is first encoded using word vector representations, exploiting the context and a positional encoding to better capture the word order. A primary attention mechanism, based on diagonal matrices is used to capture the relevance of words with respect to the target entities. To the resulting output matrix, one then applies a convolution operation in order to capture contextual information such as relevant n-grams, followed by max-pooling. A secondary attention pooling layer is used to determine the most useful convolved features for relation classification from the output based on an attention pooling matrix. The remainder of this section will provide further details about this architecture. Table 1 provides an overview of the notation we will use for this. The final output is given by a new objective function, described below.

3.1 Classification Objective

We begin with top-down design considerations for the relation classification architecture. For a given sentence S, our network will ultimately output some $\mathbf{w}^{\mathrm{O}}$. For every output relation $y \in \mathcal{Y}$, we assume there is a corresponding output embedding W_y^{L}, which will automatically be learnt by the network (dos Santos et al., 2015).

We propose a novel distance function $\delta_\theta(S)$ that measures the proximity of the predicted network output $\mathbf{w}^{\mathrm{O}}$ to a candidate relation y as follows.

$$\delta_\theta(S, y) = \left\| \frac{\mathbf{w}^{\mathrm{O}}}{|\mathbf{w}^{\mathrm{O}}|} - W_y^{\mathrm{L}} \right\| \quad (1)$$

using the L_2 norm (note that W_y^{L} are already normalized). Based on this distance function, we design a margin-based pairwise loss function $\mathcal{L}$ as

$$\begin{aligned}\mathcal{L} &= \left[\delta_\theta(S, y) + (1 - \delta_\theta(S, \hat{y}^-))\right] + \beta\|\theta\|^2 \\ &= \left[1 + \left\| \frac{\mathbf{w}^{\mathrm{O}}}{|\mathbf{w}^{\mathrm{O}}|} - W_y^{L} \right\| - \left\| \frac{\mathbf{w}^{\mathrm{O}}}{|\mathbf{w}^{\mathrm{O}}|} - W_{\hat{y}^-}^{\mathrm{L}} \right\|\right] \\ &\quad + \beta\|\theta\|^2, \end{aligned} \quad (2)$$

where 1 is the margin, β is a parameter, $\delta_\theta(S, y)$ is the distance between the predicted label embedding W^{L} and the ground truth label y and $\delta_\theta(S, \hat{y}^-)$ refers to the distance between $\mathbf{w}^{\mathrm{O}}$ and a selected incorrect relation label $\hat{y}^-$. The latter is chosen as the one with the highest score among all incorrect classes (Weston et al., 2011; dos Santos et al., 2015), i.e.

$$\hat{y}^- = \underset{y' \in \mathcal{Y}, y' \neq y}{\operatorname{argmax}} \ \delta(S, y'). \quad (3)$$

This margin-based objective has the advantage of a strong interpretability and effectiveness compared with empirical loss functions such as the ranking loss function in the CR-CNN approach by dos Santos et al. (2015). Based on a distance function motived by word analogies (Mikolov et al., 2013b), we minimize the gap between predicted outputs and ground-truth labels, while maximizing the distance with the selected incorrect class. By minimizing this pairwise loss function iteratively (see Section 3.5), $\delta_\theta(S, y)$ are encouraged to decrease, while $\delta_\theta(S, \hat{y}^-)$ increase.

3.2 Input Representation

Given a sentence $S = (w_1, w_2, ..., w_n)$ with marked entity mentions e_1(=w_p) and e_2(=w_t), $(p, t \in [1, n],\ p \neq t)$, we first transform every word into a real-valued vector to provide lexical-semantic features. Given a word embedding matrix W_V of dimensionality $d_{\mathrm{w}} \times |V|$, where V is the input vocabulary and d_{w} is the word vector dimensionality (a hyper-parameter), we map every w_i to a column vector $\mathbf{w}_i^{\mathrm{d}} \in \mathbb{R}^{d_{\mathrm{w}}}$.

To additionally capture information about the relationship to the target entities, we incorporate word position embeddings (WPE) to reflect the relative distances between the i-th word to the two marked entity mentions (Zeng et al., 2014; dos Santos et al., 2015). For the given sentence in Fig. 1, the relative distances of word "and" to entity e_1 "drinks" and e_2 "diabetes" are -1 and 6, respectively. Every relative distance is mapped to a randomly initialized position vector in $\mathbb{R}^{d_{\mathrm{p}}}$, where d_{p} is a hyper-parameter. For a given word i, we obtain two position vectors $\mathbf{w}_{i,1}^{\mathrm{p}}$ and $\mathbf{w}_{i,2}^{\mathrm{p}}$, with regard to entities e_1 and e_2, respectively. The overall word embedding for the i-th word is $\mathbf{w}_i^{\mathrm{M}} = [(\mathbf{w}_i^{\mathrm{d}})^\intercal, (\mathbf{w}_{i,1}^{\mathrm{p}})^\intercal, (\mathbf{w}_{i,2}^{\mathrm{p}})^\intercal]^\intercal$.

Using a sliding window of size k centered around the i-th word, we encode k successive

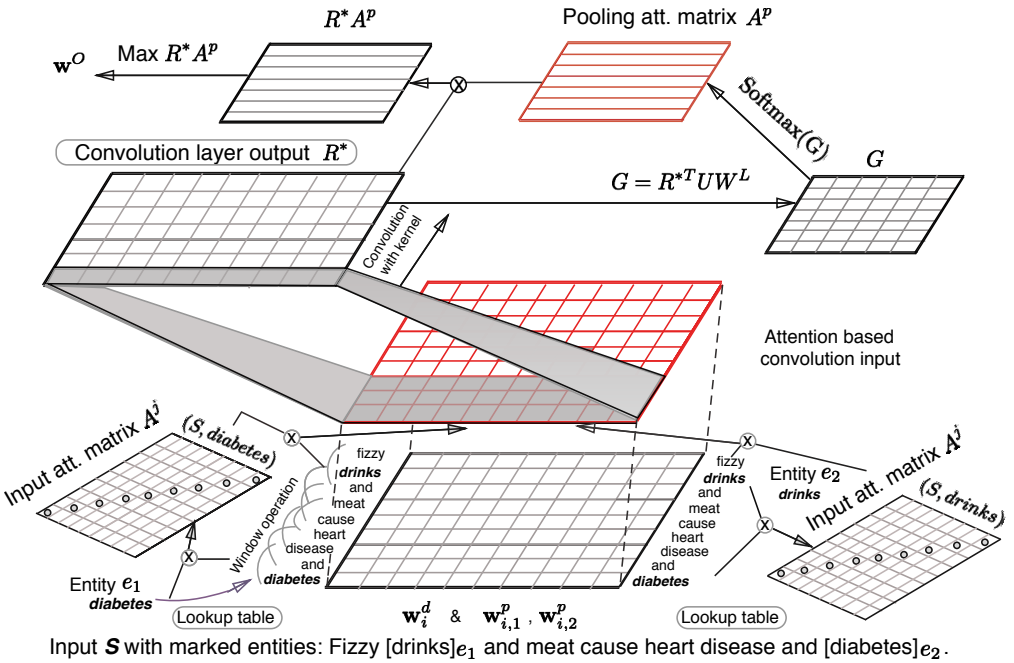

Figure 1: Schematic overview of our Multi-Level Attention Convolutional Neural Networks

words into a vector $\mathbf{z}_i \in \mathbb{R}^{(d_\mathrm{w}+2d_\mathrm{p})k}$ to incorporate contextual information as

$$\mathbf{z}_i = [(\mathbf{w}^{\mathrm{M}}_{i-(k-1)/2})^\intercal, ..., (\mathbf{w}^{\mathrm{M}}_{i+(k-1)/2})^\intercal]^\intercal \quad (4)$$

An extra padding token is repeated multiple times for well-definedness at the beginning and end of the input.

3.3 Input Attention Mechanism

While position-based encodings are useful, we conjecture that they do not suffice to fully capture the relationships of specific words with the target entities and the influence that they may bear on the target relations of interest. We design our model so as to automatically identify the parts of the input sentence that are relevant for relation classification.

Attention mechanisms have successfully been applied to sequence-to-sequence learning tasks such as machine translation (Bahdanau et al., 2015; Meng et al., 2015) and abstractive sentence summarization (Rush et al., 2015), as well as to tasks such as modeling sentence pairs (Yin et al., 2015) and question answering (Santos et al., 2016). To date, these mechanisms have generally been used to allow for an alignment of the input and output sequence, e.g. the source and target sentence in machine translation, or for an alignment between two input sentences as in sentence similarity scoring and question answering.

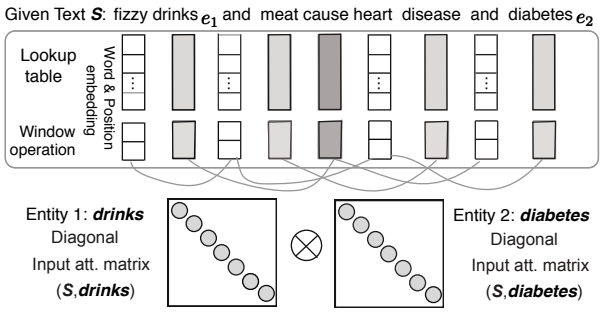

Figure 2: Input and Primary Attention

In our work, we apply the idea of modeling attention to a rather different kind of scenario involving heterogeneous objects, namely a sentence and two entities. With this, we seek to give our model the capability to determine which parts of the sentence are most influential with respect to the two entities of interest. Consider that in a long sentence with multiple clauses, perhaps only a single verb or noun might stand in a relevant relationship with a given target entity.

As depicted in Fig. 2, the input representation layer is used in conjunction with diagonal attention matrices and convolutional input composition.

Contextual Relevance Matrices. Consider the example in Fig. 1, where the non-entity word "cause" is of particular significance in determining the relation. Fortunately, we can exploit the fact

that there is a salient connection between the words "cause" and "diabetes" also in terms of corpus cooccurrences. We introduce two diagonal attention matrices A^j with values $A^j_{i,i} = f(e_j, w_i)$ to characterize the strength of contextual correlations and connections between entity mention e_j and word w_i. The scoring function f is computed as the inner product between the respective embeddings of word w_i and entity e_j, and is parametrized into the network and updated during the training process. Given the A^j matrices, we define

$$\alpha^j_i = \frac{\exp(A^j_{i,i})}{\sum_{i'=1}^{n} \exp(A^j_{i',i'})}, \tag{5}$$

to quantify the relative degree of relevance of the i-th word with respect to the j-th entity ($j \in \{1, 2\}$).

Input Attention Composition. Next, we take the two relevance factors α^1_i and α^2_i and model their joint impact for recognizing the relation via simple averaging as

$$\mathbf{r}_i = \mathbf{z}_i \, \frac{\alpha^1_i + \alpha^2_i}{2}. \tag{6}$$

Apart from this default choice, we also evaluate two additional variants. The first (Variant-1) concatenates the word vectors as

$$\mathbf{r}_i = [(\mathbf{z}_i \, \alpha^1_i)^\intercal, (\mathbf{z}_i \, \alpha^2_i)^\intercal]^\intercal, \tag{7}$$

to obtain an information-enriched input attention component for this specific word, which contains the relation relevance to both entity 1 and entity 2.

The second variant (Variant-2) interprets relations as mappings between two entities, and combines the two entity-specific weights as

$$\mathbf{r}_i = \mathbf{z}_i \, \frac{\alpha^1_i - \alpha^2_i}{2}, \tag{8}$$

to capture the relation between them.

Based on these $\mathbf{r}_i$, the final output of the input attention component is the matrix $R = [\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_n]$, where n is the sentence length.

3.4 Convolutional Max-Pooling with Secondary Attention

After this operation, we apply convolutional max-pooling with another secondary attention model to extract more abstract higher-level features from the previous layer's output matrix R.

Convolution Layer. A convolutional layer may, for instance, learn to recognize short phrases such as trigrams. Given our newly generated input attention-based representation R, we accordingly apply a filter of size d^{c} as a weight matrix W_{f} of size $d^{\mathrm{c}} \times k(d^{\mathrm{w}} + 2d^{\mathrm{p}})$. Then we add a linear bias B_{f}, followed by a non-linear hyperbolic tangent transformation to represent features as follows:

$$R^* = \tanh(W_{\mathrm{f}} R + B_{\mathrm{f}}). \tag{9}$$

Attention-Based Pooling. Instead of regular pooling, we rely on an attention-based pooling strategy to determine the importance of individual windows in R^*, as encoded by the convolutional kernel. Some of these windows could represent meaningful n-grams in the input. The goal here is to select those parts of R^* that are relevant with respect to our objective from Section 3.1, which essentially calls for a relation encoding process, while neglecting sentence parts that are irrelevant for this process.

We proceed by first creating a correlation modeling matrix G that captures pertinent connections between the convolved context windows from the sentence and the relation class embedding W^{L} introduced earlier in Section 3.1:

$$G = R^{*\intercal} \, U \, W^{\mathrm{L}}, \tag{10}$$

where U is a weighting matrix learnt by the network.

Then we adopt a softmax function to deal with this correlation modeling matrix G to obtain an attention pooling matrix A^{p} as

$$A^{\mathrm{p}}_{i,j} = \frac{\exp(G_{i,j})}{\sum_{i'=1}^{n} \exp(G_{i',j})}, \tag{11}$$

where $G_{i,j}$ is the (i,j)-th entry of G and $A^{\mathrm{p}}_{i,j}$ is the (i,j)-th entry of A^{p}.

Finally, we multiply this attention pooling matrix with the convolved output R^* to highlight important individual phrase-level components, and apply a max operation to select the most salient one (Yin et al., 2015; Santos et al., 2016) for a given dimension of the output. More precisely, we obtain the output representation $\mathbf{w}^{\mathrm{O}}$ as follows in Eq. (12):

$$\mathbf{w}^{\mathrm{O}}_i = \max_j \, (R^* A^{\mathrm{p}})_{i,j}, \tag{12}$$

where $\mathbf{w}^{\mathrm{O}}_i$ is the i-th entry of $\mathbf{w}^{\mathrm{O}}$ and $(R^* A^{\mathrm{p}})_{i,j}$ is the (i,j)-th entry of $R^* A^{\mathrm{p}}$.

3.5 Training Procedure

We rely on stochastic gradient descent (SGD) to update the parameters with respect to the loss function in Eq. (2) as follows:

$$\theta' = \theta + \lambda \frac{d(\sum_{i=1}^{|\mathcal{S}|} [\delta_\theta(S_i, y) + (1 - \delta_\theta(S_i, \hat{y}_i^-))])}{d\theta} + \lambda_1 \frac{d(\beta||\theta||^2)}{d\theta} \quad (13)$$

where λ and λ_1 are learning rates, and incorporating the β parameter from Eq. (2).

4 Experiments

4.1 Experimental Setup

Dataset and Metric. We conduct our experiments on the commonly used SemEval-2010 Task 8 dataset (Hendrickx et al., 2010), which contains 10,717 sentences for nine types of annotated relations, together with an additional "Other" type. The nine types are: Cause-Effect, Component-Whole, Content-Container, Entity-Destination, Entity-Origin, Instrument-Agency, Member-Collection, Message-Topic, and Product-Producer, while the relation type "Other" indicates that the relation expressed in the sentence is not among the nine types. However, for each of the aforementioned relation types, the two entities can also appear in inverse order, which implies that the sentence needs to be regarded as expressing a different relation, namely the respective inverse one. For example, Cause-Effect(e_1,e_2) and Cause-Effect(e_2,e_1) can be considered two distinct relations, so the total number $|\mathcal{Y}|$ of relation types is 19. The SemEval-2010 Task 8 dataset consists of a training set of 8,000 examples, and a test set with the remaining examples. We evaluate the models using the official scorer in terms of the Macro-F1 score over the nine relation pairs (excluding Other).

Settings. We use the word2vec skip-gram model (Mikolov et al., 2013a) to learn initial word representations on Wikipedia. Other matrices are initialized with random values following a Gaussian distribution. We apply a cross-validation procedure on the training data to select suitable hyperparameters. The choices generated by this process are given in Table 2.

Parameter	Parameter Name	Value
d^{p}	Word Pos. Emb. Size	25
d^{c}	Conv. Size	1000
k	Word Window Size	3
λ	Learning rate	0.03
λ_1	Learning rate	0.0001

Table 2: Hyperparameters.

4.2 Experimental Results

Table 3 provides a detailed comparison of our Multi-Level Attention CNN model with previous approaches. We observe that our novel attention-based architecture achieves new state-of-the-art results on this relation classification dataset. Att-Input-CNN relies only on the primal attention at the input level, performing standard max-pooling after the convolution layer to generate the network output $\mathbf{w}^{\mathrm{O}}$, in which the new objective function is utilized. With Att-Input-CNN, we achieve an F1-score of 87.5%, thus already outperforming not only the original winner of the SemEval task, an SVM-based approach (82.2%), but also the well-known CR-CNN model (84.1%) with a relative improvement of 4.04%, and the newly released DRNNs (85.8%) with a relative improvement of 2.0%, although the latter approach depends on the Stanford parser to obtain dependency parse information. Our full dual attention model Att-Pooling-CNN achieves an even more favorable F1-score of 88%.

Table 4 provides the experimental results for the two variants of the model given by Eqs. (7) and (8) in Section 3.3. Our main model outperforms the other variants on this dataset, although the variants may still prove useful when applied to other tasks. To better quantify the contribution of the different components of our model, we also conduct an ablation study evaluating several simplified models. The first simplification is to use our model without the input attention mechanism but with the pooling attention layer. The second removes both attention mechanisms. The third removes both forms of attention and additionally uses a regular objective function based on the inner product $s = r \cdot w$ for a sentence representation r and relation class embedding w. We observe that all three of our components lead to noticeable improvements over these baselines.

4.3 Detailed Analysis

Primary Attention. To inspect the inner workings of our model, we considered the primary attention matrices of our multi-level attention model

for the following randomly selected sentence from the test set:

> The disgusting scene was retaliation against her brother Philip who rents the [room]$_{e_1}$ inside this apartment [house]$_{e_2}$ on Lombard street.

Fig. 3 plots the word-level attention values for the input attention layer to act as an example, using the calculated attention values for every individual word in the sentence. We find the word "inside" was assigned the highest attention value, while words such as "room" and "house" also are deemed important. This appears sensible in light of the ground-truth labeling as a Component-Whole(e_1,e_2) relationship. Additionally, we observe that words such as "this", which are rather irrelevant with respect to the target relationship, indeed have significantly lower attention scores.

Most Significant Features for Relations. Table 5 lists the top-ranked trigrams for each relation class y in terms of their contribution to the score for determining the relation classification. Recall the definition of $\delta_\theta(x, y)$ in Eq. (1). In the network, we trace back the trigram that contributed most to the correct classification in terms of $\delta_\theta(S_i, y)$ for each sentence S_i. We then rank all such trigrams in the sentences in the test set according to their total contribution and list the top-ranked trigrams.[*] In Table 5, we see that these are indeed very informative for deducing the relation. For example, the top trigram for Cause-Effect(e_2,e_1) is "are caused by", which strongly implies that the first entity is an effect caused by the latter. Similarly, the top trigram for Entity-Origin(e_1,e_2) is "from the e_2", which suggests that e_2 could be an original location, at which entity e_1 may have been located.

Table 4: Comparison between the main model and variants as well as simplified models.

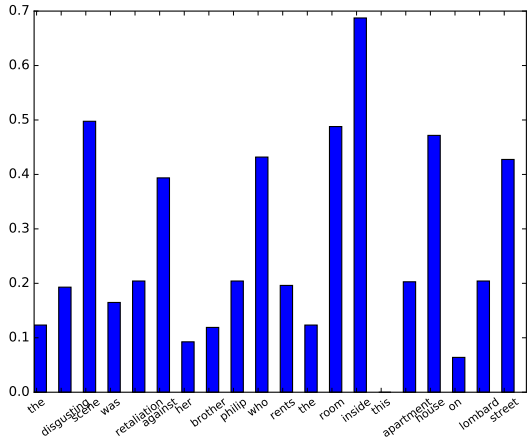

Figure 3: Input Attention Visualization. The value of the y-coordinate is computed as $100 * (A_i^t - \min_{i \in \{1,\ldots,n\}} A_i^t)$, where A_i^t stands for the overall attention weight assigned to the word i.

Error Analysis. Further, we examined some of the misclassifications produced by our model. The following is a typical example of a wrongly classified sentence:

[*]For Entity-Destination(e_2,e_1), there was only one occurrence in the test set.

Relation	(e_1, e_2)	(e_2, e_1)
Cause-Effect	e_1 caused a, caused a e_2, e_1 resulted in, the cause of, had caused the, poverty cause e_2	e_2 caused by, e_2 from e_1, is caused by, are caused by, was caused by, been caused by
Component-Whole	e_1 of the, of a e_2, of the e_2, in the e_2, part of the	with its e_2, e_1 consists of, e_1 has a, e_1 comprises e_2
Content-Container	in a e_2, was hidden in, inside a e_2, was contained in	e_1 with e_2, filled with e_2, e_1 contained a, full of e_2,
Entity-Destination	e_1 into the, e_1 into a, was put inside, in a e_2	had thrown into
Entity-Origin	from this e_2, is derived from, from the e_2, away from the	e_1 e_2 is, the e_1 e_2, for e_1 e_2, the source of
Instrument-Agency	for the e_2, is used by, by a e_2, with the e_2, a e_1 e_2	e_1 use e_2, with a e_2, by using e_2
Member-Collection	of the e_2, in the e_2, a member of, from the e_2	a e_1 of, e_1 of various, e_1 of e_2, the e_1 of
Message-Topic	on the e_2, e_1 asserts the, e_1 points out, e_1 is the	the e_1 of, described in the, the topic for, in the e_2
Product-Producer	e_1 made by, made by e_2, from the e_2, by the e_2	has constructed a, came up with, has drawn up, e_1 who created

Table 5: Most representative trigrams for different relations.

> A [film]$_{e_1}$ revolves around a [cadaver]$_{e_2}$ who seems to bring misfortune on those who come in contact with it.

This sentence is wrongly classified as belonging to the "Other" category, while the ground-truth label is Message-Topic(e_1,e_2). The phrase "revolves around" does not appear in the training data, and moreover is used metaphorically, rather than in its original sense of turning around, making it difficult for the model to recognize the semantic connection.

Another common issue stems from sentences of the form "... e_1 e_2 ...", such as the following ones:

> The size of a [tree]$_{e_1}$ [crown]$_{e_2}$ is strongly ...
> Organic [sesame]$_{e_1}$ [oil]$_{e_2}$ has an ...
> Before heading down the [phone]$_{e_1}$ [operator]$_{e_2}$ career ...

These belong to three different relation classes, Component-Whole(e_2,e_1), Entity-Origin(e_2,e_1), and Instrument-Agency(e_1,e_2), respectively, which are only implicit in the text, and the context is not particularly helpful. More informative word embeddings could conceivably help in such cases.

Convergence. Finally, we examine the convergence behavior of our two main methods. We plot the performance of each iteration in the Att-Input-CNN and Att-Pooling-CNN models in Fig. 4. It can be seen that Att-Input-CNN quite smoothly converges to its final F1 score, while for the Att-Pooling-CNN model, which includes an additional attention layer, the joint effect of these two attention layer induces stronger back-propagation effects. On the one hand, this leads to a seesaw phenomenon in the result curve, but on the other hand it enables us to obtain better-suited models with slightly higher F1 scores.

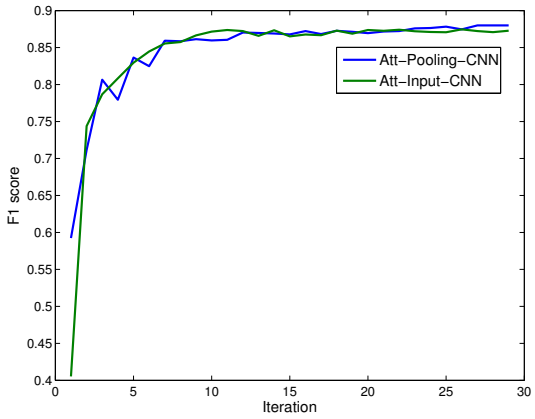

Figure 4: Training Progress of Att-Input-CNN and Att-Pooling-CNN across iterations.

5 Conclusion

We have presented a CNN architecture with a novel objective and a new form of attention mechanism that is applied at two different levels. Our results show that this simple but effective model is able to outperform previous work relying on substantially richer prior knowledge in the form of structured models and NLP resources. We expect this sort of architecture to be of interest also beyond the specific task of relation classification, which we intend to explore in future work.

Abstract

Knowledge bases (KBs) are often greatly incomplete, necessitating a demand for KB completion. The path ranking algorithm (PRA) is one of the most promising approaches to this task. Previous work on PRA usually follows a single-task learning paradigm, building a prediction model for each relation independently with its own training data. It ignores meaningful associations among certain relations, and might not get enough training data for less frequent relations. This paper proposes a novel multi-task learning framework for PRA, referred to as coupled PRA (CPRA). It first devises an agglomerative clustering strategy to automatically discover relations that are highly correlated to each other, and then employs a multi-task learning strategy to effectively couple the prediction of such relations. As such, CPRA takes into account relation association and enables implicit data sharing among them. We empirically evaluate CPRA on benchmark data created from Freebase. Experimental results show that CPRA can effectively identify coherent clusters in which relations are highly correlated. By further coupling such relations, CPRA significantly outperforms PRA, in terms of both predictive accuracy and model interpretability.

1 Introduction

Knowledge bases (KBs) like Freebase (Bollacker et al., 2008), DBpedia (Lehmann et al., 2014), and NELL (Carlson et al., 2010) are extremely useful resources for many NLP tasks (Cucerzan, 2007; Schuhmacher and Ponzetto, 2014). They provide large collections of facts about entities and their relations, typically stored as (*head entity*, *relation*, *tail entity*) triples, *e.g.*, (`Paris`, `capitalOf`, `France`). Although such KBs can be impressively large, they are still quite incomplete and missing crucial facts, which may reduce their usefulness in downstream tasks (West et al., 2014; Choi et al., 2015). KB completion, *i.e.*, automatically inferring missing facts by examining existing ones, has thus attracted increasing attention. Approaches to this task roughly fall into three categories: (i) path ranking algorithms (PRA) (Lao et al., 2011); (ii) embedding techniques (Bordes et al., 2013; Guo et al., 2015); and (iii) graphical models such as Markov logic networks (MLN) (Richardson and Domingos, 2006). This paper focuses on PRA, which is easily interpretable (as opposed to embedding techniques) and requires no external logic rules (as opposed to MLN).

The key idea of PRA is to explicitly use paths connecting two entities to predict potential relations between them. In PRA, a KB is encoded as a graph which consists of a set of heterogeneous edges. Each edge is labeled with a relation type that exists between two entities. Given a specific relation, random walks are first employed to find paths between two entities that have the given relation. Here a path is a sequence of relations linking two entities, *e.g.*, $h \xrightarrow{\texttt{bornIn}} e \xrightarrow{\texttt{capitalOf}} t$. These paths are then used as features in a binary classifier to predict if new instances (*i.e.*, entity pairs) have the given relation.

While KBs are naturally composed of multiple relations, PRA models these relations separately during the inference phase, by learning an individual classifier for each relation. We argue, however, that it will be beneficial for PRA to model certain relations in a collective way, particularly when the relations are closely related to each other. For example, given two relations `bornIn` and `livedIn`,

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1308–1318,
Berlin, Germany, August 7-12, 2016.

there must be a lot of paths (features) that are predictive for both relations, *e.g.*, $h \xrightarrow{\texttt{nationality}} e \xrightarrow{\texttt{hasCapital}} t$. These features make the corresponding relation classification tasks highly related. Numerous studies have shown that learning multiple related tasks simultaneously (a.k.a. multi-task learning) usually leads to better predictive performance, profiting from the relevant information available in different tasks (Carlson et al., 2010; Chapelle et al., 2010).

This paper proposes a novel multi-task learning framework that couples the path ranking of multiple relations, referred to as coupled PRA (CPRA). The new model needs to answer two critical questions: (i) *which relations should be coupled*, and (ii) *in what manner they should be coupled*.

As to the first question, it is obvious that not all relations are suitable to be learned together. For instance, modeling `bornIn` together with `hasWife` might not bring any real benefits, since there are few common paths between these two relations. CPRA introduces a common-path based similarity measure, and accordingly devises an agglomerative clustering strategy to group relations. Only relations that are grouped into the same cluster will be coupled afterwards.

As to the second question, CPRA follows the common practice of multi-task learning (Evgeniou and Pontil, 2004), and couples relations by using classifiers with partially shared parameters. Given a cluster of relations, CPRA builds the classifiers upon (i) relation-specific parameters to address the specifics of individual relations, and (ii) shared parameters to model the commonalities among different relations. These two types of parameters are balanced by a coupling coefficient, and learned jointly for all relations. In this way CPRA couples the classification tasks of multiple relations, and enables implicit data sharing and regularization.

The major contributions of this paper are as follows. (i) We design a novel framework for multi-task learning with PRA, *i.e.*, CPRA. To the best of our knowledge, this is the first study on multi-task PRA. (ii) We empirically verify the effectiveness of CPRA on a real-world, large-scale KB. Specifically, we evaluate CPRA on benchmark data created from Freebase. Experimental results show that CPRA can effectively identify coherent clusters in which relations are highly correlated. By further coupling such relations, CPRA substantially outperforms PRA, in terms of not only predictive accuracy but also model interpretability. (iii) We compare CPRA and PRA to the embedding-based TransE model (Bordes et al., 2013), and demonstrate their superiority over TransE. As far as we know, this is the first work that formally compares PRA-style approaches to embedding-based ones, on publicly available Freebase data.

In the remainder of this paper, we first review related work in Section 2, and formally introduce PRA in Section 3. We then detail the proposed CPRA framework in Section 4. Experiments and results are reported in Section 5, followed by the conclusion and future work in Section 6.

2 Related Work

We first review three lines of related work: (i) KB completion, (ii) PRA and its extensions, and (iii) multi-task learning, and then discuss the connection between CPRA and previous approaches.

KB completion. This task is to automatically infer missing facts from existing ones. Prior work roughly falls into three categories: (i) path ranking algorithms (PRA) which use paths that connect two entities to predict potential relations between them (Lao et al., 2011; Lao and Cohen, 2010); (ii) embedding-based models which embed entities and relations into a latent vector space and make inferences in that space (Nickel et al., 2011; Bordes et al., 2013); (iii) probabilistic graphical models such as the Markov logic network (MLN) and its variants (Pujara et al., 2013; Jiang et al., 2012). This paper focuses on PRA, since it is easily interpretable (as opposed to embedding-based models) and requires no external logic rules (as opposed to MLN and its variants).

PRA and its extensions. PRA is a random walk inference technique designed for predicting new relation instances in KBs, first proposed by Lao and Cohen (2010). Recently various extensions have been explored, ranging from incorporating a text corpus as additional evidence during inference (Gardner et al., 2013; Gardner et al., 2014), to introducing better schemes to generate more predictive paths (Gardner and Mitchell, 2015; Shi and Weninger, 2015), or using PRA in a broader context such as Google's Knowledge Vault (Dong et al., 2014). All these approaches are based on some single-task version of PRA, while our work explores multi-task learning for it.

Multi-task learning. Numerous studies have shown that learning multiple related tasks simulta-

neously can provide significant benefits relative to learning them independently (Caruana, 1997). A key ingredient of multi-task learning is to model the notion of task relatedness, through either parameter sharing (Evgeniou and Pontil, 2004; Ando and Zhang, 2005) or feature sharing (Argyriou et al., 2007; He et al., 2014). In recent years, there has been increasing work showing the benefits of multi-task learning in NLP-related tasks, such as relation extraction (Jiang, 2009; Carlson et al., 2010) and machine translation (Sennrich et al., 2013; Cui et al., 2013; Dong et al., 2015). This paper investigates the possibility of multi-task learning with PRA, in a parameter sharing manner.

Connection with previous methods. Actually, modeling multiple relations collectively is a common practice in embedding-based approaches. In such a method, embeddings are learned jointly for all relations, over a set of shared latent features (entity embeddings), and hence can capture meaningful associations among different relations. As shown by (Toutanova and Chen, 2015), observed features such as PRA paths usually perform better than latent features for KB completion. In this context, CPRA is designed in a way that gets the multi-relational benefit of embedding techniques while keeping PRA-style path features. Nickel et al. (2014) and Neelakantan et al. (2015) have tried similar ideas. However, their work focuses on improving embedding techniques with observed features, while our approach aims at improving PRA with multi-task learning.

3 Path Ranking Algorithm

PRA was first proposed by Lao and Cohen (2010), and later slightly modified in various ways (Gardner et al., 2014; Gardner and Mitchell, 2015). The key idea of PRA is to explicitly use paths that connect two entities as features to predict potential relations between them. Here a path is a sequence of relations $\langle r_1, r_2, \cdots, r_\ell \rangle$ that link two entities. For example, $\langle \texttt{bornIn}, \texttt{capitalOf} \rangle$ is a path linking `SophieMarceau` to `France`, through an intermediate node `Paris`. Such paths are then used as features to predict the presence of specific relations, *e.g.*, `nationality`. A typical PRA model consists of three steps: feature extraction, feature computation, and relation-specific classification.

Feature extraction. The first step is to generate and select path features that are potentially useful for predicting new relation instances. To this end, PRA first encodes a KB as a multi-relation graph. Given a pair of entities (h, t), PRA then finds the paths by performing random walks over the graph, recording those starting from h and ending at t with bounded lengths. More exhaustive strategies like breadth-first (Gardner and Mitchell, 2015) or depth-first (Shi and Weninger, 2015) search could also be used to enumerate the paths. After that a set of paths are selected as features, according to some precision-recall measure (Lao et al., 2011), or simply frequency (Gardner et al., 2014).

Feature computation. Once path features are selected, the next step is to compute their values. Given an entity pair (h, t) and a path π, PRA computes the feature value as a random walk probability $p(t|h, \pi)$, *i.e.*, the probability of arriving at t given a random walk starting from h and following exactly all relations in π. Computing these random walk probabilities could be at great expense. Gardner and Mitchell (2015) recently showed that such probabilities offer no discernible benefits. So they just used a binary value to indicate the presence or absence of each path. Similarly, Shi and Weninger (2015) used the frequency of a path as its feature value. Besides paths, other features such as path bigrams and vector space similarities could also be incorporated (Gardner et al., 2014).

Relation-specific classification. The last step of PRA is to train an individual classifier for each relation, so as to judge whether two entities should be linked by that relation. Given a relation and a set of training instances (*i.e.*, pairs of entities that are linked by the relation or not, with features selected and computed as above), one can use any kind of classifier to train a model. Most previous work simply chooses logistic regression.

4 Coupled Path Ranking Algorithm

As we can see, PRA (as well as its variants) follows a single-task learning paradigm, which builds a classifier for each relation independently with its own training data. We argue that such a single-task strategy might not be optimal for KB completion: (i) by learning the classifiers independently, it fails to discover and leverage meaningful associations among different relations; (ii) it might not perform well on less frequent relations for which only a few training instances are available. This section presents coupled PRA (CPRA), a novel multi-task learning framework that couples the path ranking of multiple relations. Through a multi-task strat-

egy, CPRA takes into account relation association and enables implicit data sharing among them.

4.1 Problem Formulation

Suppose we are given a KB containing a collection of triples $\mathcal{O} = \{(h, r, t)\}$. Each triple is composed of two entities $h, t \in \mathcal{E}$ and their relation $r \in \mathcal{R}$, where $\mathcal{E}$ is the entity set and $\mathcal{R}$ the relation set. The KB is then encoded as a graph $\mathcal{G}$, with entities represented as nodes, and triple (h, r, t) a directed edge from node h to node t. We formally define KB completion as a binary classification problem. That is, given a particular relation r, for any entity pair (h, t) such that $(h, r, t) \notin \mathcal{O}$, we would like to judge whether h and t should be linked by r, by exploiting the graph structure of $\mathcal{G}$. Let $\overline{\mathcal{R}} \subseteq \mathcal{R}$ denote a set of relations to be predicted.

Each relation $r \in \overline{\mathcal{R}}$ is associated with a set of training instances. Here a training instance is an entity pair (h, t), with a positive label if $(h, r, t) \in \mathcal{O}$ or a negative label otherwise.[1] For each of the entity pairs, path features could be extracted and computed using techniques described in Section 3. We denote by $\mathbf{\Pi}_r$ the set of path features extracted for relation r, and define its training set as $\mathcal{T}_r = \{(\mathbf{x}_{ir}, y_{ir})\}$. Here $\mathbf{x}_{ir}$ is the feature vector for an entity pair, with each dimension corresponding to a path $\pi \in \mathbf{\Pi}_r$, and $y_{ir} = \pm 1$ is the label. Note that our primary goal is to verify the possibility of multi-task learning with PRA. It is beyond the scope of this paper to further explore better feature extraction or computation.

Given the relations and their training instances, CPRA performs KB completion using a multi-task learning strategy. It consists of two components: relation clustering and relation coupling. The former automatically discovers highly correlated relations, and the latter further couples the learning of these relations, described in detail as follows.

4.2 Relation Clustering

It is obvious that not all relations are suitable to be coupled. We propose an agglomerative clustering algorithm to automatically discover relations that are highly correlated and should be learned together. Our intuition is that relations sharing more common paths (features) are probably more similar in classification, and hence should be coupled.

Specifically, we start with $|\overline{\mathcal{R}}|$ clusters and each cluster contains a single relation $r \in \overline{\mathcal{R}}$. Here $|\cdot|$ is the cardinality of a set. Then we iteratively merge the most similar clusters, say $\mathcal{C}_m$ and $\mathcal{C}_n$, into a new cluster $\mathcal{C}$. The similarity between two clusters is defined as:

$$\text{Sim}(\mathcal{C}_i, \mathcal{C}_j) = \frac{|\mathbf{\Pi}_{\mathcal{C}_i} \cap \mathbf{\Pi}_{\mathcal{C}_j}|}{\min(|\mathbf{\Pi}_{\mathcal{C}_i}|, |\mathbf{\Pi}_{\mathcal{C}_j}|)}, \qquad (1)$$

where $\mathbf{\Pi}_{\mathcal{C}_i}$ is the feature set associated with cluster $\mathcal{C}_i$ (if $\mathcal{C}_i$ contains a single relation, $\mathbf{\Pi}_{\mathcal{C}_i}$ the feature set associated with that relation). It essentially measures the overlap between two feature sets. The larger the overlap is, the higher the similarity will be. Once two clusters are merged, we update the feature set associated with the new cluster: $\mathbf{\Pi}_{\mathcal{C}} = \mathbf{\Pi}_{\mathcal{C}_m} \cup \mathbf{\Pi}_{\mathcal{C}_n}$. The algorithm stops when the highest cluster similarity is below some predefined threshold δ. This paper empirically sets $\delta = 0.5$. As such, relations sharing a substantial number of common paths are grouped into the same cluster.

4.3 Relation Coupling

After clustering, the next step of CPRA is to couple the path ranking of different relations within each cluster, *i.e.*, to learn the classification tasks for these relations simultaneously. We employ a multi-task classification algorithm similar to (Evgeniou and Pontil, 2004), and learn the classifiers jointly in a parameter sharing manner.

Consider a cluster containing K relations $\mathcal{C} = \{r_1, r_2, \cdots, r_K\}$. Recall that during the clustering phase a shared feature set has been generated for that cluster, *i.e.*, $\mathbf{\Pi}_{\mathcal{C}} = \mathbf{\Pi}_{r_1} \cup \cdots \cup \mathbf{\Pi}_{r_K}$. We first reform the training instances for the K relations using this shared feature set, so that all training data is represented in the same space.[2] We denote by $\mathcal{T}_k = \{(\mathbf{x}_{ik}, y_{ik})\}_{i=1}^{N_k}$ the reformed training data associated with the k-th relation. Then our goal is to jointly learn K classifiers $f_1, f_2, \cdots, f_K$ such that $f_k(\mathbf{x}_{ik}) \approx y_{ik}$.

We first assume that the classifier for each relation has a linear form $f_k(\mathbf{x}) = \mathbf{w}_k \cdot \mathbf{x} + b_k$, where $\mathbf{w}_k \in \mathbb{R}^d$ is the weight vector and b_k the bias. To model associations among different relations, we further assume that all $\mathbf{w}_k$ and b_k can be written, for every $k \in \{1, \cdots, K\}$, as:

$$\mathbf{w}_k = \mathbf{w}_0 + \mathbf{v}_k \ \text{ and } \ b_k = b_0. \qquad (2)$$

Here the shared $\mathbf{w}_0$ is used to model the commonalities among different relations, and the relation-specific $\mathbf{v}_k$ to address the specifics of individual

[1] We will introduce the details of generating negative training instances in Section 5.1.

[2] Note that $\mathbf{\Pi}_{r_k} \subseteq \mathbf{\Pi}_{\mathcal{C}}$. We just assign zero values to features that are contained in $\mathbf{\Pi}_{\mathcal{C}}$ but not in $\mathbf{\Pi}_{r_k}$.

relations. If the relations are closely related ($\mathbf{v}_k \approx \mathbf{0}$), they will have similar weights ($\mathbf{w}_t \approx \mathbf{w}_0$) on the common paths. We use the same bias b_0 for all the relations.[3]

We estimate $\mathbf{v}_k$, $\mathbf{w}_0$, and b_0 simultaneously in a joint optimization problem, defined as follows.

Problem 1 *CPRA amounts to solving the general optimization problem:*

$$\min_{\{\mathbf{v}_k\},\mathbf{w}_0,b_0} \sum_{k=1}^{K}\sum_{i=1}^{N_k} \ell\left(\mathbf{x}_{ik}, y_{ik}\right) + \frac{\lambda_1}{K}\sum_{k=1}^{K}\left\|\mathbf{v}_k\right\|_2^2 + \lambda_2\left\|\mathbf{w}_0\right\|_2^2,$$

where $\ell\left(\mathbf{x}_{ik}, y_{ik}\right)$ is the loss on a training instance. It can be instantiated into a logistic regression (LR) or support vector machine (SVM) version, by respectively defining the loss $\ell\left(\mathbf{x}_{ik}, y_{ik}\right)$ as:

$$\ell\left(\mathbf{x}_{ik}, y_{ik}\right) = \log\left(1+\exp\left(-y_{ik}f_k(\mathbf{x}_{ik})\right)\right),$$
$$\ell\left(\mathbf{x}_{ik}, y_{ik}\right) = \left[1-y_{ik}f_k(\mathbf{x}_{ik})\right]_+,$$

where $f_k(\mathbf{x}_{ik}) = (\mathbf{w}_0+\mathbf{v}_k)\cdot\mathbf{x}_{ik}+b_0$. We call them CPRA-LR and CPRA-SVM respectively.

In this problem, λ_1 and λ_2 are regularization parameters. By adjusting their values, we control the degree of parameter sharing among different relations. The larger the ratio $\frac{\lambda_1}{\lambda_2}$ is, the more we believe that all $\mathbf{w}_t$ should conform to the common model $\mathbf{w}_0$, and the smaller the relation-specific weight $\mathbf{v}_t$ will be.

The multi-task learning problem can be directly linked to a standard single-task learning one, built on all training data from different relations.

Proposition 1 *Suppose the training data associated with the k-th relation, for every $k=1,\cdots,K$, is transformed into:*

$$\widetilde{\mathbf{x}}_{ik} = [\frac{\mathbf{x}_{ik}}{\sqrt{\rho K}}, \underbrace{\mathbf{0},\cdots,\mathbf{0}}_{k-1}, \mathbf{x}_{ik}, \underbrace{\mathbf{0},\cdots,\mathbf{0}}_{K-k}],$$

where $\mathbf{0}\in\mathbb{R}^d$ is a vector whose coordinates are all zero, and $\rho=\frac{\lambda_2}{\lambda_1}$ a coupling coefficient. Consider a linear classifier for the transformed data $\widetilde{f}(\widetilde{\mathbf{x}}) = \widetilde{\mathbf{w}}\cdot\widetilde{\mathbf{x}}+\widetilde{b}$, with $\widetilde{\mathbf{w}}$ and $\widetilde{b}$ constructed as:

$$\widetilde{\mathbf{w}} = [\sqrt{\rho K}\mathbf{w}_0, \mathbf{v}_1, \cdots, \mathbf{v}_K] \;\; \textit{and} \;\; \widetilde{b} = b_0.$$

Then the objective function of Problem 1 is equivalent to:

$$\mathcal{L} = \sum_{k=1}^{K}\sum_{i=1}^{N_k} \widetilde{\ell}\left(\widetilde{\mathbf{x}}_{ik}, y_{ik}\right) + \widetilde{\lambda}\left\|\widetilde{\mathbf{w}}\right\|_2^2,$$

where $\widetilde{\ell}=\log(1+\exp(-y_{ik}\widetilde{f}(\widetilde{\mathbf{x}}_{ik})))$ is a logistic loss for CPRA-LR, and $\widetilde{\ell}=[1-y_{ik}\widetilde{f}(\widetilde{\mathbf{x}}_{ik})]_+$ a hinge loss for CPRA-SVM; and $\widetilde{\lambda}=\frac{\lambda_1}{K}$.

That means, after transforming data from different relations into a unified representation, Problem 1 is equivalent to a standard single-task learning problem, built on the transformed data from all the relations. So it can easily be solved by existing tools such as LR or SVM.

5 Experiments

In this section we present empirical evaluation of CPRA in the KB completion task.

5.1 Experimental Setups

We create our data on the basis of FB15K (Bordes et al., 2011)[4], a relatively dense subgraph of Freebase containing 1,345 relations and the corresponding triples.

KB graph construction. We notice that in most cases FB15K encodes a relation and its reverse relation at the same time. That is, once a new fact is observed, FB15K creates two triples for it, *e.g.*, (`x`, `film/edited-by`, `y`) and (`y`, `editor/film`, `x`). Reverse relations provide no additional knowledge. They may even hurt the performance of PRA-style methods. Actually, to enhance graph connectivity, PRA-style methods usually automatically add an inverse version for each relation in a KB (Lao and Cohen, 2010; Lao et al., 2011). That is, for each observed triple (h,r,t), another triple (t,r^{-1},h) is constructed and added to the KB. Consider the prediction of a relation, say `film/edited-by`. In the training phase, we could probably find that every two entities connected by this relation are also connected by the path `editor/film`$^{-1}$, and hence assign an extremely high weight to it.[5] However, in the testing phase, for any entity pair (`x`, `y`) such that (`y`, `editor/film`, `x`) has not been encoded, we might not even find that path and hence could always make a negative prediction.[6]

For this reason, we remove reverse relations in FB15K. Specifically, we regard r_2 to be a reverse relation of r_1 if the triple (t,r_2,h) holds whenever (h,r_1,t) is observed, and we randomly discard

[3] It implicitly assumes that all the relations have the same proportion of positive instances. This assumption actually holds since given any relation we can always generate the same number of negative instances for each positive one. We set this number to 4 in our experiments.

[4] https://everest.hds.utc.fr/doku.php?id=en:smemlj12

[5] For every observed triple (`x`, `film/edited-by`, `y`), FB15K also encodes (`y`, `editor/film`, `x`), for which (`x`, `editor/film`$^{-1}$, `y`) is further constructed.

[6] Note that such test cases are generally more meaningful: if we already know (`y`, `editor/film`, `x`), predicting (`x`, `film/edited-by`, `y`) could be trivial.

one of the two relations.[7] As such, we keep 774 out of 1,345 relations in FB15K, covering 14,951 entities and 327,783 triples. Then we build a graph based on this data and use it as input to CPRA (and our baseline methods).

Labeled instance generation. We select 171 relations to test our methods. To do so, we pick 10 popular domains, including award, education, film, government, location, music, olympics, organization, people, and tv. Relations in these domains with at least 50 triples observed for them are selected. For each of the 171 relations, we split the associated triples into roughly 80% training, 10% validation, and 10% testing. Since the triple number varies significantly among the relations, we allow at most 200 validation/testing triples for each relation, so as to make the test cases as balanced as possible. Note that validation and testing triples are not used for constructing the graph.

We generate positive instances for each relation directly from these triples. Given a relation r and a triple (h, r, t) observed for it (training, validation, or testing), we take the pair of entities (h, t) as a positive instance for that relation. Then we follow (Shi and Weninger, 2015; Krompaß et al., 2015) to generate negative instances. Given each positive instance (h, t) we generate four negative ones, two by randomly corrupting the head h, and the other two the tail t. To make the negative instances as difficult as possible, we corrupt a position using only entities that have appeared in that position. That means, given the relation `capitalOf` and the positive instance (`Paris`, `France`), we could generate a negative instance (`Paris`, `UK`) but never (`Paris`, `NBA`), since `NBA` never appears as a tail entity of the relation. We further ensure that the negative instances do not overlap with the positive ones.

Feature extraction and computation. Given the labeled instances, we extract path features for them using the code provided by Shi and Weninger (2015)[8]. It is a depth-first search strategy that enumerates all paths between two entities. We set the maximum path length to be $\ell = 3$. There are about 8.2% of the labeled instances for which no path could be extracted. We remove such cases, giving on average about 5,250 training, 323 validation, and 331 testing instances per relation. Then we remove paths that appear only once in each relation, getting 5,515 features on average per relation. We simply compute the value of each feature as its frequency in an instance. Table 1 lists the statistics of the data used in our experiments.

# Relations	774
# Entities	14,951
# Triples	327,783
# Relations tested	171
# Avg. training instances/relation	5,250
# Avg. validation instances/relation	323
# Avg. testing instances/relation	331
# Avg. features/relation	5,515

Table 1: Statistics of the data.

Evaluation metrics. As evaluation metrics, we use mean average precision (MAP) and mean reciprocal rank (MRR), following recent work evaluating KB completion performance (West et al., 2014; Gardner and Mitchell, 2015). Both metrics evaluate some ranking process: if a method ranks the positive instances before the negative ones for each relation, it will get a high MAP or MRR.

Baseline methods. We compare CPRA to traditional single-task PRA. CPRA first groups the 171 relations into clusters, and then learns classifiers jointly for relations within the same cluster. We implement two versions of it: CPRA-LR and CPRA-SVM. As we have shown in Proposition 1, both of them could be solved by standard classification tools. PRA learns an individual classifier for each of the relations, using LR or SVM classification techniques, denoted by PRA-LR or PRA-SVM. We use LIBLINEAR (Fan et al., 2008)[9] to solve the LR and SVM classification problems. For all these methods, we tune the cost c in the range of $\{2^{-5}, 2^{-4}, \cdots, 2^4, 2^5\}$. And we set the coupling coefficient $\rho = \frac{\lambda_2}{\lambda_1}$ in CPRA in the range of $\{0.1, 0.2, 0.5, 1, 2, 5, 10\}$.

We further compare CPRA to TransE, a widely adopted embedding-based method (Bordes et al., 2013). TransE learns vector representations for entities and relations (*i.e.*, embeddings), and uses the learned embeddings to determine the plausibility of missing facts. Such plausibility can then be used to rank the labeled instances. We implement TransE using the code provided by Bordes et al. (2013)[10]. To learn embeddings, we take as input the triples used to construct the graph (from which CPRA and PRA extract their paths). We tune the embedding dimension in $\{20, 50, 100\}$, the margin in $\{0.1, 0.2, 0.5, 1, 2, 5\}$, and the learning rate

[7] We still add an inverse version for the relation kept during path extraction.

in $\{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}, 1\}$. For details please refer to (Bordes et al., 2013). For each of these methods, we select the optimal configuration that leads to the highest MAP on the validation set and report its performance on the test set.

5.2 Relation Clustering Results

We first test the effectiveness of our agglomerative strategy (Section 4.2) in relation clustering. With the stopping criterion $\delta = 0.5$, 96 out of the 171 relations are grouped into clusters which contain at least two relations. Each of these 96 relations will later be learned jointly with some other relations. The other 75 relations cannot be merged, and will still be learned individually. Table 2 shows the six largest clusters discovered by our algorithm. Relations in each cluster are arranged in the order they were merged. The results indicate that our algorithm can effectively identify coherent clusters in which relations are highly correlated to each other. For example, the top left cluster describes relations between a film and its crew members, and the middle left between an organization and a location.

During clustering we might obtain clusters that contain too many relations and hence too many training instances for our CPRA model to learn efficiently. We split such clusters into sub-clusters, either according to the domain (*e.g.*, the film cluster and tv cluster) or randomly (*e.g.*, the two location clusters on the top right).

5.3 KB Completion Results

We further test the effectiveness of our multi-task learning strategy (Section 4.3) in KB completion. Table 3 gives the results on the 96 relations that are actually involved in multi-tasking learning (*i.e.*, grouped into clusters with size larger than one).[11] The 96 relations are grouped into 29 clusters, and relations within the same cluster are learned jointly. Table 3 reports (i) MAP and MRR within each cluster and (ii) overall MAP and MRR on the 96 relations. Numbers marked in bold type indicate that CPRA-LR/SVM outperforms PRA-LR/SVM, within a cluster (with its ID listed in the first column) or on all the 96 relations (ALL). We judge statistical significance of the overall improvements achieved by CPRA-LR/SVM over PRA-LR/SVM and TransE, using a paired t-test. The average precision (or reciprocal rank) on each relation is used as paired data. The symbol "$**$" indicates a significance level of $p < 0.0001$, and "$*$" a significance level of $p < 0.05$.

From the results, we can see that (i) CPRA outperforms PRA (using either LR or SVM) and TransE on the 96 relations (ALL) in both metrics. All the improvements are statistically significant, with a significance level of $p < 0.0001$ for MAP and a significance level of $p < 0.05$ for MRR. (ii) CPRA-LR/SVM outperforms PRA-LR/SVM in 22/24 out of the 29 clusters in terms of MAP. Most of the improvements are quite substantial. (iii) Improving PRA-LR and PRA-SVM in terms of MRR could be hard, since they already get the best performance (MRR = 1) in 19 out of the 29 clusters. But even so, CPRA-LR/SVM still improves 7/8 out of the remaining 10 clusters. (iv) The PRA-style methods perform substantially better than the embedding-based TransE model in most of the 29 clusters and on all the 96 relations. This observation demonstrates the superiority of observed features (*i.e.*, PRA paths) over latent features.

Table 4 further shows the top 5 most discriminative paths (*i.e.*, features with the highest weights) discovered by PRA-SVM (left) and CPRA-SVM (right) for each relation in the 6th cluster.[12] The average precision on each relation is also provid-

[11] The other 75 relations are still learned individually. So CPRA and PRA perform the same on these relations. The MAP values on these 75 relations are 0.6360, 0.6558, 0.6543 for TransE, PRA-LR, and PRA-SVM respectively, and the MRR values are 0.9049, 0.9033, and 0.9013 respectively.

[12] This is one of the largest clusters on which CPRA-SVM improves PRA-SVM substantially.

Table 3: KB completion results on the 96 relations that have been grouped into clusters with size larger than one (with the stopping criterion $\delta = 0.5$), and hence involved in multi-tasking learning.

ed. We can observe that (i) CPRA generally discovers more predictive paths than PRA. Almost all the top paths discovered by CPRA are easily interpretable and provide sensible reasons for the final prediction, while some of the top paths discovered by PRA are hard to interpret and less predictive. Take `org/place-founded` as an example. All the 5 CPRA paths are useful to predict the place where an organization was founded, *e.g.*, the 3rd one tells that "the organization headquarter in a city which is located in that place". However, the PRA path "common/class $\rightarrow$ common/class^{-1} $\rightarrow$ film/debut-venue" is hard to interpret and less predictive. (ii) For the 1st/4th/6th relation on which PRA gets a low average precision, CPRA learns almost completely different top paths and gets a substantially higher average precision. While for the other relations (2nd/3rd/5th) on which PRA already performs well enough, CPRA learns similar top paths and gets a comparable average precision. We have conducted the same analyses with CPRA-LR and PRA-LR, and observed similar phenomena. All these observations demonstrate the superiority of CPRA, in terms of not only predictive accuracy but also model interpretability.

6 Conclusion

In this paper we have studied the path ranking algorithm (PRA) from the viewpoint of multi-task learning. We have designed a novel multi-task learning framework for PRA, called coupled PRA (CPRA). The key idea of CPRA is to (i) automatically discover relations highly correlated to each other through agglomerative clustering, and (ii) effectively couple the prediction of such relations through multi-task learning. By coupling different relations, CPRA takes into account relation associations and enables implicit data sharing among them. We have tested CPRA on benchmark data created from Freebase. Experimental results show that CPRA can effectively identify coherent clusters in which relations are highly correlated. By further coupling such relations, CPRA significantly outperforms PRA, in terms of both predictive

accuracy and model interpretability.

This is the first work that investigates the possibility of multi-task learning with PRA, and we just provide a very simple solution. There are still many interesting topics to study. For instance, the agglomerative clustering strategy can only identify highly correlated relations, *i.e.*, those sharing a lot of common paths. Relations that are only loosely correlated, *e.g.*, those sharing no common paths but a lot of sub-paths, will not be identified. We would like to design new mechanisms to discover loosely correlated relations, and investigate whether coupling such relations still provides benefits. Another example is that the current method is a two-step approach, performing relation clustering first and then relation coupling. It will be interesting to study whether one can merge the clustering step and the coupling step so as to have a richer inter-task dependent structure. We will investigate such topics in our future work.

Abstract

In this work, we propose a novel method to incorporate corpus-level discourse information into language modelling. We call this larger-context language model. We introduce a late fusion approach to a recurrent language model based on long short-term memory units (LSTM), which helps the LSTM unit keep intra-sentence dependencies and inter-sentence dependencies separate from each other. Through the evaluation on four corpora (IMDB, BBC, Penn TreeBank, and Fil9), we demonstrate that the proposed model improves perplexity significantly. In the experiments, we evaluate the proposed approach while varying the number of context sentences and observe that the proposed late fusion is superior to the usual way of incorporating additional inputs to the LSTM. By analyzing the trained larger-context language model, we discover that content words, including nouns, adjectives and verbs, benefit most from an increasing number of context sentences. This analysis suggests that larger-context language model improves the unconditional language model by capturing the theme of a document better and more easily.

1 Introduction

The goal of language modelling is to estimate the probability distribution of various linguistic units, e.g., words, sentences (Rosenfeld, 2000). Among the earliest techniques were count-based n-gram language models which intend to assign the probability distribution of a given word observed after a fixed number of previous words. Later Bengio et al. (2003) proposed feed-forward neural language model, which achieved substantial improvements in perplexity over count-based language models. Bengio et al. showed that this neural language model could simultaneously learn the conditional probability of the latest word in a sequence as well as a vector representation for each word in a predefined vocabulary.

Recently recurrent neural networks have become one of the most widely used models in language modelling (Mikolov et al., 2010). Long short-term memory unit (LSTM, Hochreiter and Schmidhuber, 1997) is one of the most common recurrent activation function. Architecturally, the memory state and output state are explicitly separated by activation gates such that the vanishing gradient and exploding gradient problems described in Bengio et al. (1994) is avoided. Motivated by such gated model, a number of variants of RNNs (e.g. Cho et al. (GRU, 2014b), Chung et al. (GF-RNN, 2015)) have been designed to easily capture long-term dependencies.

When modelling a corpus, these language models assume the mutual independence among sentences, and the task is often reduced to assigning a probability to a single sentence. In this work, we propose a method to incorporate corpus-level discourse dependency into neural language model. We call this larger-context language model. It models the influence of context by defining a conditional probability in the form of $P(w_n|w_{1:n-1}, S)$, where $w_1, ..., w_n$ are words from the same sentence, and S represents the context which consists a number of previous sentences of arbitrary length.

We evaluated our model on four different corpora (IMDB, BBC, Penn TreeBank, and Fil9). Our experiments demonstrate that the proposed larger-context language model improve perplex-

*Recently, (Ji et al., 2015) independently proposed a similar approach.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1319–1329,
Berlin, Germany, August 7-12, 2016.

ity for sentences, significantly reducing per-word perplexity compared to the language models without context information. Further, through Part-Of-Speech tag analysis, we discovered that content words, including nouns, adjectives and verbs, benefit the most from increasing number of context sentences. Such discovery led us to the conclusion that larger-context language model improves the unconditional language model by capturing the theme of a document.

To achieve such improvement, we proposed a late fusion approach, which is a modification to the LSTM such that it better incorporates the discourse context from preceding sentences. In the experiments, we evaluated the proposed approach against early fusion approach with various numbers of context sentences, and demonstrated the late fusion is superior to the early fusion approach.

Our model explores another aspect of context-dependent recurrent language model. It is novel in that it also provides an insightful way to feed information into LSTM unit, which could benefit all encoder-decoder based applications.

2 Statistical Language Modelling with Recurrent Neural Network

Given a document $D = (S_1, S_2, \ldots, S_L)$ which consists of L sentences, statistical language modelling aims at computing its probability $P(D)$. It is often assumed that each sentence in the whole document is mutually independent from each other:

$$P(D) \approx \prod_{l=1}^{L} P(S_l). \tag{1}$$

We call this probability (before approximation) a *corpus-level probability*. Under this assumption of mutual independence among sentences, the task of language modelling is often reduced to assigning a probability to a single sentence $P(S_l)$.

A sentence $S_l = (w_1, w_2, \ldots, w_{T_l})$ is a variable-length sequence of words or tokens. By assuming that a word at any location in a sentence is largely predictable by preceding words, we can rewrite the sentence probability into

$$P(S) = \prod_{t=1}^{T_l} p(w_t | w_{<t}), \tag{2}$$

where $w_{<t}$ denotes all the preceding words. We call this a *sentence-level probability*.

This rewritten probability expression can be either directly modelled by a recurrent neural network (Mikolov et al., 2010) or further approximated as a product of n-gram conditional probabilities such that

$$P(S) \approx \prod_{t=1}^{T_l} p(w_t | w_{t-(n-1)}^{t-1}), \tag{3}$$

where $w_{t-(n-1)}^{t-1} = (w_{t-(n-1)}, \ldots, w_{t-1})$. The latter is called *$n$-gram language modelling*.

A recurrent language model is composed of two functions–transition and output functions. The transition function reads one word w_t and updates its hidden state such that

$$\mathbf{h}_t = \phi\left(w_t, \mathbf{h}_{t-1}\right), \tag{4}$$

where $\mathbf{h}_0$ is an all-zero vector. ϕ is a recurrent activation function. For more details on widely-used recurrent activation units, we refer the reader to (Jozefowicz et al., 2015; Greff et al., 2015).

At each timestep, the output function computes the probability over all possible *next* words in the vocabulary V. This is done by

$$p(w_{t+1} = w' | w_1^t) \propto \exp\left(g_{w'}(\mathbf{h}_t)\right). \tag{5}$$

g is commonly an affine transformation:

$$g(\mathbf{h}_t) = \mathbf{W}_o \mathbf{h}_t + \mathbf{b}_o,$$

where $\mathbf{W}_o \in \mathbb{R}^{|V| \times d}$ and $\mathbf{b}_o \in \mathbb{R}^{|V|}$.

The whole model is trained by maximizing the log-likelihood of a training corpus often using stochastic gradient descent with backpropagation through time (see, e.g., Rumelhart et al., 1988).

This conventional approach to statistical language modelling often treats every sentence in a document to be independent from each other This is often due to the fact that downstream tasks, such as speech recognition and machine translation, are done sentence-wise. In this paper, we ask how strong an assumption this is, how much impact this assumption has on the final language model quality and how much gain language modelling can get by making this assumption less strong.

Long Short-Term Memory Here let us briefly describe a long short-term memory unit which is widely used as a recurrent activation function ϕ (see Eq. (4)) for language modelling (see, e.g., Graves, 2013).

A layer of long short-term memory (LSTM) unit consists of three gates and a single memory cell. They are computed by

$$\begin{aligned}\mathbf{i}_t =& \sigma\left(\mathbf{W}_i\mathbf{x}_t + \mathbf{U}_i\mathbf{h}_{t-1} + \mathbf{b}_i\right)\\ \mathbf{o}_t =& \sigma\left(\mathbf{W}_o\mathbf{x}_t + \mathbf{U}_o\mathbf{h}_{t-1} + \mathbf{b}_o\right)\\ \mathbf{f}_t =& \sigma\left(\mathbf{W}_f\mathbf{x}_t + \mathbf{U}_f\mathbf{h}_{t-1} + \mathbf{b}_f\right),\end{aligned}$$

where σ is a sigmoid function. $\mathbf{x}_t$ is the input at time t. The memory cell is computed by

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tanh\left(\mathbf{W}_c\mathbf{x} + \mathbf{U}_c\mathbf{h}_{t-1} + \mathbf{b}_c\right),$$

where $\odot$ is an element-wise multiplication. This adaptive leaky integration of the memory cell allows the LSTM to easily capture long-term dependencies in the input sequence.

The output, or the activation of this LSTM layer, is then computed by $\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t)$.

3 Larger-Context Language Modelling

In this paper, we aim not at improving the sentence-level probability estimation $P(S)$ (see Eq. (2)) but at improving the corpus-level probability $P(D)$ from Eq. (1) directly. One thing we noticed at the beginning of this work is that it is not necessary for us to make the assumption of mutual independence of sentences in a corpus. Rather, similarly to how we model a sentence probability, we can loosen this assumption by

$$P(D) \approx \prod_{l=1}^{L} P(S_l|S_{l-n}^{l-1}), \quad (6)$$

where $S_{l-n}^{l-1} = (S_{l-n}, S_{l-n+1}, \ldots, S_{l-1})$. n decides on how many preceding sentences each conditional sentence probability conditions on, similarly to what happens with a usual n-gram language modelling.

From the statistical modelling's perspective, estimating the corpus-level language probability in Eq. (6) is equivalent to build a statistical model that approximates

$$P(S_l|S_{l-n}^{l-1}) = \prod_{t=1}^{T_l} p(w_t|w_{<t}, S_{l-n}^{l-1}), \quad (7)$$

similarly to Eq. (2). One major difference from the existing approaches to statistical language modelling is that now each conditional probability of a next word is conditioned not only on the preceding words in the same sentence, but also on the $n-1$ preceding *sentences*.

A conventional, count-based n-gram language model is not well-suited due to the issue of data sparsity. In other words, the number of rows in the table storing n-gram statistics will explode as the number of possible sentence combinations grows exponentially with respect to both the vocabulary size, each sentence's length and the number of context sentences.

Either neural or recurrent language modelling however does not suffer from this issue of data sparsity. This makes these models ideal for modelling the *larger-context sentence probability* in Eq. (7). More specifically, we are interested in adapting the recurrent language model for this.

In doing so, we answer two questions in the following subsections. First, there is a question of how we should represent the context sentences S_{l-n}^{l-1}. We consider two possibilities in this work. Second, there is a large freedom in how we build a recurrent activation function to be conditioned on the context sentences. We also consider two alternatives in this case.

3.1 Context Representation

A sequence of preceding sentences can be represented in many different ways. Here, let us describe two alternatives we test in the experiments.

The first representation is to simply bag all the words in the preceding sentences into a single vector $\mathbf{s} \in [0, 1]^{|V|}$. Any element of $\mathbf{s}$ corresponding to the word that exists in one of the preceding sentences will be assigned the frequency of that word, and otherwise 0. This vector is multiplied from left by a matrix $\mathbf{P}$ which is tuned together with all the other parameters: $\mathbf{p} = \mathbf{P}\mathbf{s}$. We call this representation $\mathbf{p}$ a *bag-of-words (BoW) context*.

Second, we try to represent the preceding context sentences as a sequence of bag-of-words. Each bag-of-word $\mathbf{s}_j$ is the bag-of-word representation of the j-th context sentence, and they are put into a sequence $(\mathbf{s}_{l-n}, \ldots, \mathbf{s}_{l-1})$. Unlike the first BoW context, this allows us to incorporate the order of the preceding context sentences.

This sequence of BoW vectors are read by a recurrent neural network which is separately from the one used for modelling a sentence (see Eq. (4).) We use LSTM units as recurrent activations, and for each context sentence in the sequence, we get $\mathbf{z}_t = \phi\left(\mathbf{x}_t, \mathbf{z}_{t-1}\right)$, for $t = l-n, \ldots, l-1$. We set the last hidden state $\mathbf{z}_{l-1}$ of this *context recurrent neural network* as the con-

text vector $\mathbf{p}$.

Attention-based Context Representation The sequence of BoW vectors can be used in a bit different way from the above. Instead of a unidirectional recurrent neural network, we first use a bidirectional recurrent neural network to read the sequence. The forward recurrent neural network reads the sequence as usual in a forward direction, and the reverse recurrent neural network in the opposite direction. The hidden states from these two networks are then concatenated for each context sentence in order to form a sequence of annotation vectors $(\mathbf{z}_{l-n}, \ldots, \mathbf{z}_{l-1})$.

Unlike the other approaches, in this case, the context vector $\mathbf{p}$ differs for each word w_t in the current sentence, and we denote it by $\mathbf{p}_t$. The context vector $\mathbf{p}_t$ for the t-th word is computed as the weighted sum of the annotation vectors:

$$\mathbf{p}_t = \sum_{l'=l-n}^{l-1} \alpha_{t,l'} \mathbf{z}_{l'},$$

where the attention weight $\alpha_{t,l'}$ is computed by

$$\alpha_{t,l'} = \frac{\exp \text{score}\left(\mathbf{z}_{l'}, \mathbf{h}_t\right)}{\sum_{k=l-n}^{l-1} \exp \text{score}\left(\mathbf{z}_k, \mathbf{h}_t\right)}.$$

$\mathbf{h}_t$ is the hidden state of the recurrent language model of the current sentence from Eq. (5). The scoring function $\text{score}(\mathbf{z}_{l'}, \mathbf{h}_t)$ returns a relevance score of the l'-th context sentence w.r.t. $\mathbf{h}_t$.

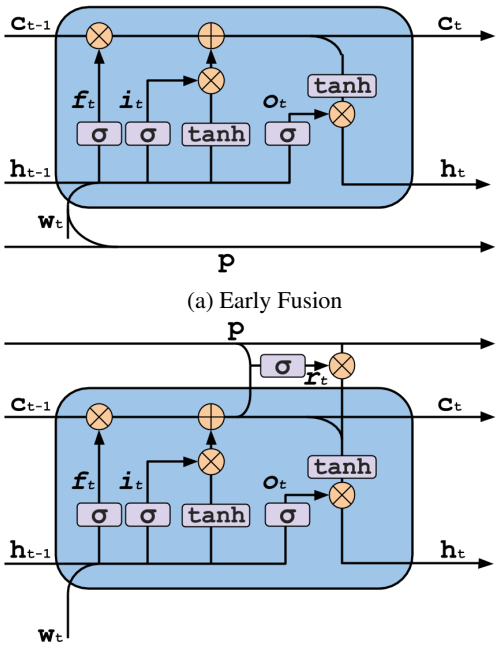
3.2 Conditional LSTM

Early Fusion Once the context vector $\mathbf{p}$ is computed from the n preceding sentences, we need to feed this into the sentence-level recurrent language model. One most straightforward way is to simply consider it as an input at every time step such that

$$\mathbf{x} = \mathbf{E}^\top \mathbf{w}_t + \mathbf{W}_p \mathbf{p},$$

where $\mathbf{E}$ is the word embedding matrix that transforms the one-hot vector of the t-th word into a continuous word vector. We call this approach an *early fusion* of the context.

Late Fusion In addition to this approach, we propose here a modification to the LSTM such that it better incorporates the context from the preceding sentences (summarized by $\mathbf{p}_t$.) The basic idea is to keep dependencies within the sentence being modelled (*intra-sentence dependencies*) and those between the preceding sentences and the current sent (*inter-sentence dependencies*) separately from each other.



(a) Early Fusion

(b) Late Fusion

Figure 1: Proposed fusion methods

We let the memory cell $\mathbf{c}_t$ of the LSTM to model intra-sentence dependencies. This simply means that there is no change to the existing formulation of the LSTM.

The inter-sentence dependencies are reflected on the interaction between the memory cell $\mathbf{c}_t$, which models intra-sentence dependencies, and the context vector $\mathbf{p}$, which summarizes the n preceding sentences. We model this by first computing the amount of influence of the preceding context sentences as

$$\mathbf{r}_t = \sigma\left(\mathbf{W}_r \left(\mathbf{W}_p \mathbf{p}\right) + \mathbf{W}_r \mathbf{c}_t + \mathbf{b}_r\right).$$

This vector $\mathbf{r}_t$ controls the strength of each of the elements in the context vector $\mathbf{p}$. This amount of influence from the n preceding sentences is decided based on the currently captured intra-sentence dependency structures and the preceding sentences.

This controlled context vector $\mathbf{r}_t \odot (\mathbf{W}_p \mathbf{p})$ is used to compute the output of the LSTM layer:

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh\left(\mathbf{c}_t + \mathbf{r}_t \odot \left(\mathbf{W}_p \mathbf{p}\right)\right).$$

This is illustrated in Fig. 1 (b).

We call this approach a *late fusion*, as the effect of the preceding context is fused together with

the intra-sentence dependency structure in the later stage of the recurrent activation.

Late fusion is a simple, but effective way to mitigate the issue of vanishing gradient in corpus-level language modelling. By letting the context representation flow without having to pass through saturating nonlinear activation functions, it provides a linear path through which the gradient for the context flows easily.

4 Related Work

Context-dependent Language Model This possibility of extending a neural or recurrent language modeling to incorporate larger context was explored earlier. Especially, (Mikolov and Zweig, 2012) proposed an approach, called context-dependent recurrent neural network language model, very similar to the proposed approach here. The basic idea of their approach is to use a topic distribution, represented as a vector of probabilities, of previous n *words* when computing the hidden state of the recurrent neural network each time.

There are three major differences in the proposed approach from the work by Mikolov and Zweig (2012). First, the goal in this work is to explicitly model *preceding sentences* to better approximate the corpus-level probability (see Eq. (6)) rather than to get a better context of the current sentence. Second, Mikolov and Zweig (2012) use an external method, such as latent Dirichlet allocation (Blei et al., 2003) or latent semantics analysis (Dumais, 2004) to extract a feature vector, whereas we learn the whole model, including the context vector extraction, end-to-end. Third, we propose a late fusion approach which is well suited for the LSTM units which have recently been widely adopted many works involving language models (see, e.g., Sundermeyer et al., 2015). This late fusion is later shown to be superior to the early fusion approach.

Dialogue Modelling with Recurrent Neural Networks A more similar model to the proposed larger-context recurrent language model is a hierarchical recurrent encoder decoder (HRED) proposed recently by Serban et al. (2015). The HRED consists of three recurrent neural networks to model a dialogue between two people from the perspective of one of them, to which we refer as a speaker. If we consider the last utterance of the speaker, the HRED is a larger-context recurrent language model with early fusion.

Aside the fact that the ultimate goals differ (in their case, dialogue modelling and in our case, document modelling), there are two technical differences. First, they only test with the early fusion approach. We show later in the experiments that the proposed late fusion gives a better language modelling quality than the early fusion. Second, we use a sequence of bag-of-words to represent the preceding sentences, while the HRED a sequence of sequences of words. This allows the HRED to potentially better model the order of the words in each preceding sentence, but it increases computational complexity (one more recurrent neural network) and decreases statistical efficient (more parameters with the same amount of data.)

Skip-Thought Vectors Perhaps the most similar work is the skip-thought vector by Kiros et al. (2015). In their work, a recurrent neural network is trained to read a current sentence, as a sequence of words, and extract a so-called skip-thought vector of the sentence. There are two other recurrent neural networks which respectively model preceding and following sentences. If we only consider the prediction of the following sentence, then this model becomes a larger-context recurrent language model which considers a single preceding sentence as a context.

As with the other previous works we have discussed so far, the major difference is in the ultimate goal of the model. Kiros et al. (2015) fully focused on using their model to extract a good, generic sentence vector, while in this paper we are focused on obtaining a good language model. There are less major technical differences. First, the skip-thought vector model conditions only on the immediate preceding sentence, while we extend this to multiple preceding sentences. Second, similarly to the previous works by Mikolov and Zweig (2012), the skip-thought vector model only implements early fusion.

Neural Machine Translation Neural machine translation is another related approach (Forcada and Ñeco, 1997; Kalchbrenner and Blunsom, 2013; Cho et al., 2014b; Sutskever et al., 2014; Bahdanau et al., 2014). In neural machine translation, often two recurrent neural networks are used. The first recurrent neural network, called an encoder, reads a source sentence, represented as a sequence of words in a source language, to form a context vector, or a set of context vectors. The

other recurrent neural network, called a decoder, then, models the target translation *conditioned on* this source context.

This is similar to the proposed larger-context recurrent language model, if we consider the source sentence as a preceding sentence in a corpus. The major difference is in the ultimate application, machine translation vs. language modelling, and technically, the differences between neural machine translation and the proposed larger-context language model are similar to those between the HRED and the larger-context language model.

Context-Dependent Question-Answering Models Context-dependent question-answering is a task in which a model is asked to answer a question based on the facts from a natural language paragraph. The question and answer are often formulated as filling in a missing word in a query sentence (Hermann et al., 2015; Hill et al., 2015). This task is closely related to the larger-context language model we proposed in this paper in the sense that its goal is to build a model to learn

$$p(q_k|q_{<k}, q_{>k}, D), \tag{8}$$

where q_k is the missing k-th word in a query Q, and $q_{<k}$ and $q_{>k}$ are the context words from the query. D is the paragraph containing facts about this query. It is explicitly constructed so that the query q does not appear in the paragraph D.

It is easy to see the similarity between Eq. (8) and one of the conditional probabilities in the r.h.s. of Eq. (7). By replacing the context sentences S_{l-n}^{l-1} in Eq. (7) with D in Eq. (8) and conditioning w_t on both the preceding and following words, we get a context-dependent question-answering model. In other words, the proposed larger-context language model can be used for context-dependent question-answering, however, with computational overhead. The overhead comes from the fact that for every possible answer the conditional probability completed query sentence must be evaluated.

5 Experimental Settings

5.1 Models

There are six possible combinations of the proposed methods. First, there are two ways of representing the context sentences; (1) bag-of-words (BoW) and (2) a sequence of bag-of-words (SeqBoW), from Sec. 3.1. There are two separate ways to incorporate the SeqBoW; (1) with attention mechanism (ATT) and (2) without it. Then, there are two ways of feeding the context vector into the main recurrent language model (RLM); (1) early fusion (EF) and (2) late fusion (LF), from Sec. 3.2. We will denote them by

1. RLM-BoW-EF-n
2. RLM-SeqBoW-EF-n
3. RLM-SeqBoW-ATT-EF-n
4. RLM-BoW-LF-n
5. RLM-SeqBoW-LF-n
6. RLM-SeqBoW-ATT-LF-n

n denotes the number of preceding sentences to have as a set of context sentences. We test four different values of n; 1, 2, 4 and 8.

As a baseline, we also train a recurrent language model without any context information. We refer to this model by RLM. Furthermore, we also report the result with the conventional, count-based n-gram language model with the modified Kneser-Ney smoothing with KenLM (Heafield et al., 2013).

Each recurrent language model uses 1000 LSTM units and is trained with Adadelta (Zeiler, 2012) to maximize the log-likelihood; $\mathcal{L}(\boldsymbol{\theta}) = \frac{1}{K}\sum_{k=1}^{K} \log p(S_k|S_{k-n}^{k-1})$. We early-stop training based on the validation log-likelihood and report the perplexity on the test set using the best model according to the validation log-likelihood.

We use only those sentences of length up to 50 words when training a recurrent language model for the computational reason. For KenLM, we used all available sentences in a training corpus.

5.2 Datasets

We evaluate the proposed larger-context language model on three different corpora. For detailed statistics, see Table 1.

IMDB Movie Reviews A set of movie reviews is an ideal dataset to evaluate many different settings of the proposed larger-context language models, because each review is highly likely of a single theme (the movie under review.) A set of words or the style of writing will be well determined based on the preceding sentences.

We use the IMDB Movie Review Corpus (IMDB) prepared by Maas et al. (2011).[1] This corpus has 75k training reviews and 25k test reviews.

[1] http://ai.stanford.edu/~amaas/data/sentiment/

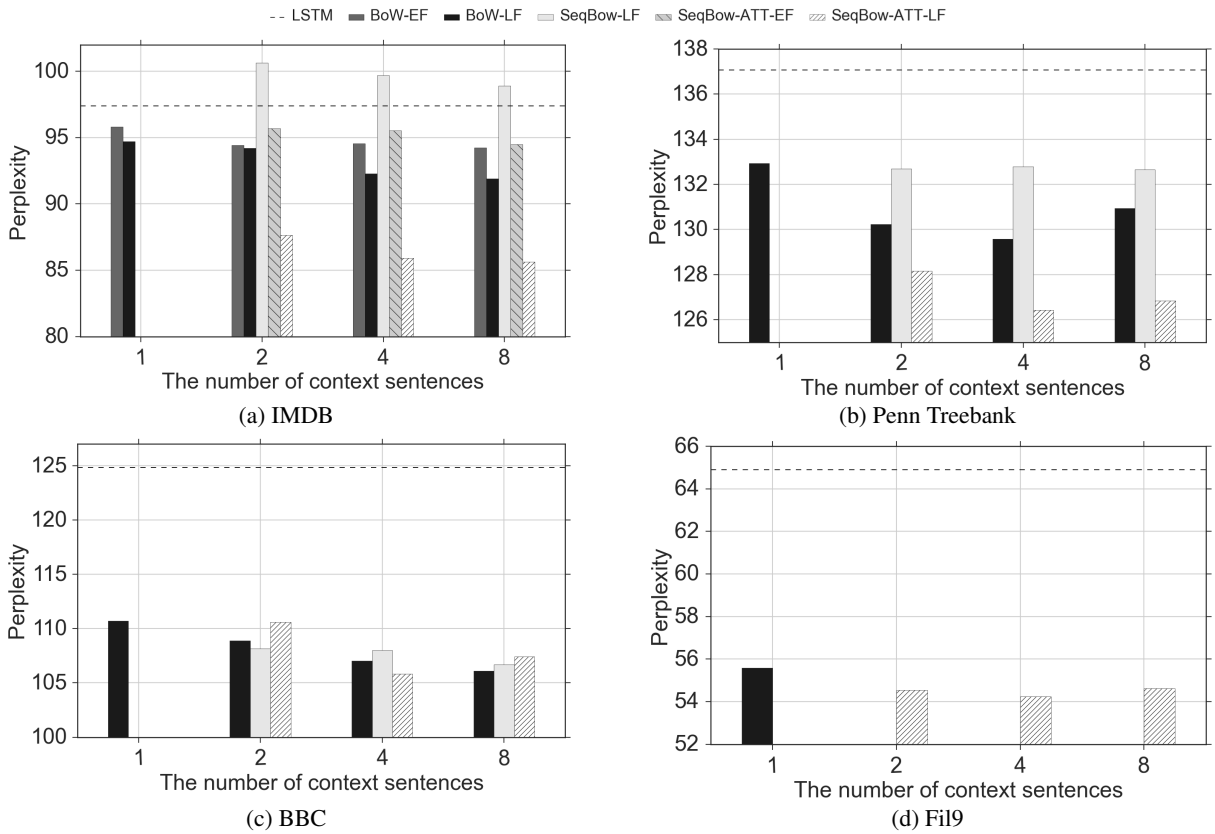


Figure 2: Corpus-level perplexity on (a) IMDB, (b) Penn Treebank, (c) BBC and (d) Fil9. The count-based 5-gram language models with Kneser-Ney smoothing respectively resulted in the perplexities of 110.20, 148, 127.32 and 65.21, and are not shown here.

We use the 30k most frequent words in the training corpus for recurrent language models.

BBC Similarly to movie reviews, each new article tends to convey a single theme. We use the BBC corpus prepared by Greene and Cunningham (2006).[2] Unlike the IMDB corpus, this corpus contains news articles which are almost always written in a formal style. By evaluating the proposed approaches on both the IMDB and BBC corpora, we can tell whether the benefits from larger context exist in both informal and formal languages. We use the 10k most frequent words in the training corpus for recurrent language models.

Both with the IMDB and BBC corpora, we did not do any preprocessing other than tokenization.[3]

Penn Treebank We evaluate a normal recurrent language model, count-based n-gram language model as well as the proposed RLM-BoW-EF-n and RLM-BoW-LF-n with varying $n = 1, 2, 4, 8$ on the Penn Treebank Corpus. We preprocess the corpus according to (Mikolov et al., 2011) and use a vocabulary of 10k words from the training corpus.

Fil9 Fil9 is a cleaned Wikipedia corpus, consisting of approximately 140M tokens, and is provided on Matthew Mahoney's website.[4] We tokenized the corpus and used the 44k most frequent words in the training corpus for recurrent language models.

6 Results and Analysis

Corpus-level Perplexity We evaluated the models, including all the proposed approaches (RLM-{BoW,SeqBoW}-{ATT,∅}-{EF,LF}-n), on the IMDB corpus. In Fig. 2 (a), we see three major trends. First, RLM-BoW, either with the early fusion or late fusion, outperforms both the count-based n-gram and recurrent language model (LSTM) regardless of the number of context sentences. Second, the improvement grows as the number n of context sentences increases, and this is most visible with the novel *late fusion*. Lastly,

we see that the RLM-SeqBoW does not work well regardless of the fusion type (RLM-SeqBow-EF not shown), while the attention-based model (RLM-SeqBow-ATT) outperforms all the others.

After observing that the late fusion clearly outperforms the early fusion, we evaluated only RLM-{BoW,SeqBoW}-{ATT}-LF-n's on the other two corpora.

On the other two corpora, PTB and BBC, we observed a similar trend of RLM-SeqBoW-ATT-LF-n and RLM-BoW-LF-n outperforming the two conventional language models, and that this trend strengthened as the number n of the context sentences grew. We also observed again that the RLM-SeqBoW-ATT-LF outperforms RLM-SeqBoW-LF and RLM-BoW in almost all the cases.

Observing the benefit of RLM-SeqBoW-ATT-LF, we evaluated only such model on Fil9 to validate its performance on large corpus. Similar to the results on all three previous corpora, we continue to observe the advantage of RLM-SeqBoW-ATT-LF-n on Fil9 corpus.

From these experiments, the benefit of allowing larger context to a recurrent language model is clear, however, with the right choice of the context representation (see Sec. 3.1) and the right mechanism for feeding the context information to the recurrent language model (see Sec. 3.2.) In these experiments, the sequence of bag-of-words representation with attention mechanism, together with the late fusion was found to be the best choice in all four corpora.

One possible explanation on the failure of the SeqBoW representation with a context recurrent neural network is that it is simply difficult for the context recurrent neural network to compress multiple sentences into a single vector. This difficulty in training a recurrent neural network to compress a long sequence into a single vector has been observed earlier, for instance, in neural machine translation (Cho et al., 2014a). Attention mechanism, which was found to avoid this problem in machine translation (Bahdanau et al., 2014), is found to solve this problem in our task as well.

Perplexity per Part-of-Speech Tag Next, we attempted at discovering why the larger-context recurrent language model outperforms the unconditional one. In order to do so, we computed the *perplexity per part-of-speech (POS) tag*.

We used the Stanford log-linear part-of-speech tagger (Stanford POS Tagger, Toutanova et al., 2003) to tag each word of each sentence in the corpora.[5] We then computed the perplexity of each word and averaged them for each tag type separately. Among the 36 POS tags used by the Stanford POS Tagger, we looked at the perplexities of the ten most frequent tags (NN, IN, DT, JJ, RB, NNS, VBZ, VB, PRP, CC), of which we combined NN and NNS into a new tag Noun and VB and VBZ into a new tag Verb.

We show the results using the RLM-BoW-LF and RLM-SeqBoW-ATT-LF on three corpora– IMDB, BBC and Penn Treebank– in Fig. 3. We observe that the predictability, measured by the perplexity (negatively correlated), grows most for nouns (Noun) and adjectives (JJ) as the number of context sentences increases. They are followed by verbs (Verb). In other words, nouns, adjec-

Table 1: Statistics of IMDB, BBC, Penn TreeBank and Fil9.

tives and verbs are the ones which become more predictable by a language model given more context. We however noticed the relative degradation of quality in coordinating conjunctions (CC), determiners (DT) and personal pronouns (PRP).

It is worthwhile to note that nouns, adjectives and verbs are open-class, content, words, and conjunctions, determiners and pronouns are closed-class, function, words (see, e.g., Miller, 1999). The functions words often play grammatical roles, while the content words convey the content of a sentence or discourse, as the name indicates. From this, we may carefully conclude that the larger-context language model improves upon the conventional, unconditional language model by capturing the theme of a document, which is reflected by the improved perplexity on "content-heavy" open-class words (Chung and Pennebaker, 2007). In our experiments, this came however at the expense of slight degradation in the perplexity of function words, as the model's capacity stayed same (though, it is not necessary.)

This observation is in line with a recent finding by Hill et al. (2015). They also observed significant gain in predicting open-class, or content, words when a question-answering model, including humans, was allowed larger context.

7 Conclusion

In this paper, we proposed a method to improve language model on corpus-level by incorporating larger context. Using this model results in the improvement in perplexity on the IMDB, BBC, Penn Treebank and Fil9 corpora, validating the advantage of providing larger context to a recurrent language model.

From our experiments, we found that the sequence of bag-of-words with attention is better than bag-of-words for representing the context sentences (see Sec. 3.1), and the late fusion is better than the early fusion for feeding the context vector into the main recurrent language model (see Sec. 3.2). Our part-of-speech analysis revealed that content words, including nouns, adjectives and verbs, benefit most from an increasing number of context sentences. This analysis suggests that larger-context language model improves perplexity because it captures the theme of a document better and more easily.

To explore the potential of such a model, there are several aspects in which more research needs to be done. First, the four datasets we used in this paper are relatively small in the context of language modelling, therefore the proposed larger-context language model should be evaluated on larger corpora. Second, more analysis, beyond the one based on part-of-speech tags, should be conducted in order to better understand the advantage of such larger-context models. Lastly, it is important to evaluate the impact of the proposed larger-context models in downstream tasks such as machine translation and speech recognition.

Abstract

Website privacy policies are often ignored by Internet users, because these documents tend to be long and difficult to understand. However, the significance of privacy policies greatly exceeds the attention paid to them: these documents are binding legal agreements between website operators and their users, and their opaqueness is a challenge not only to Internet users but also to policy regulators. One proposed alternative to the status quo is to automate or semi-automate the extraction of salient details from privacy policy text, using a combination of crowdsourcing, natural language processing, and machine learning. However, there has been a relative dearth of datasets appropriate for identifying data practices in privacy policies. To remedy this problem, we introduce a corpus of 115 privacy policies (267K words) with manual annotations for 23K fine-grained data practices. We describe the process of using skilled annotators and a purpose-built annotation tool to produce the data. We provide findings based on a census of the annotations and show results toward automating the annotation procedure. Finally, we describe challenges and opportunities for the research community to use this corpus to advance research in both privacy and language technologies.

1 Introduction

Privacy policies written in natural language are a nearly pervasive feature of websites and mobile applications. The "notice and choice" legal regimes of many countries require that website operators post a notice of how they gather and process users' information. In theory, users then choose whether to accept those practices or to abstain from using the website or service. In practice, however, the average Internet user struggles to understand the contents of privacy policies (McDonald and Cranor, 2008) and generally does not read them (Federal Trade Commission, 2012; President's Concil of Advisors on Science and Technology, 2014). This disconnect between Internet users and the data practices that affect them has led to the assessment that the notice and choice model is ineffective in the status quo (Reidenberg et al., 2015b; Cate, 2010).

Thus, an opening exists for language technologies to help "bridge the gap" between privacy policies in their current form and representations that serve the needs of Internet users. Such a bridge would also serve unmet needs of policy regulators, who do not have the means to assess privacy policies in large numbers. Legal text is a familiar domain for natural language processing, and the legal community has demonstrated some reciprocal interest (Mahler, 2015). However, the scale of the problem and its significance—i.e., to virtually any Internet user, as well as to website operators and policy regulators—distinguishes it and provides immense motivation (Sadeh et al., 2013).

To this end, we introduce a corpus of 115 website privacy policies annotated with detailed information about the data practices that they describe.[1] This information consists of 23K data practices, 128K practice attributes, and 103K annotated text spans, all produced by skilled anno-

[1]The dataset is available for download at www.usableprivacy.org/data.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1330–1340,
Berlin, Germany, August 7-12, 2016.

tators. To the best of our knowledge, this is the first large-scale effort to annotate privacy policies at such a fine level of detail. It exceeds prior efforts to annotate sentence-level fragments of policy text (Breaux and Schaub, 2014), answer simple overarching questions about privacy policy contents (Wilson et al., 2016; Zimmeck and Bellovin, 2014), or analyze the readability of privacy policies (Massey et al., 2013). We further present analysis that demonstrates the richness of the corpus and the feasibility of partly automating the annotation of privacy policies.

The remainder of this paper is structured as follows. We discuss related work and contextualize the corpus we have created in Section 2. In Section 3 we describe the creation of the corpus, including the collection of a diverse set of policies and the creation of a privacy policy annotation tool. Section 4 presents analysis that illustrates the diversity and complexity of the corpus, and Section 5 shows results on the prediction of policy structure. Finally, in Section 6 we describe some promising avenues for future work.

2 Related Work

Prior attempts on analyzing privacy policies focused largely on manually assessing their usability (Jensen and Potts, 2004) or compliance with self-regulatory requirements (Hoke et al., 2015). Breaux et al. proposed a description logic to analyze and reason about data sharing properties in privacy policies (2013), but rely on a small set of manually annotated privacy policies to instantiate their language. Automated assessments have largely focused on readability scores (Massey et al., 2013; Meiselwitz, 2013; Ermakova et al., 2015). Cranor et al. leveraged the standardized format of privacy notices in the U.S. financial industry to automatically analyze privacy polices of financial institutions (2013). However, in spite of notable efforts such as P3P (Wenning et al., 2006), the majority of privacy policies are unstructured and do not follow standardized formats.

Costante et al. (2012) proposed a supervised learning approach to determine which data practice categories are covered in a privacy policy. Rule-based extraction techniques have been proposed to extract some of a website's data collection practices from its privacy policy (Costante et al., 2013) or to answer certain binary questions about a privacy policy (Zimmeck and Bellovin, 2014). Other approaches leverage topic modeling (Chundi and Subramaniam, 2014; Stamey and Rossi, 2009) or sequence alignment techniques (Liu et al., 2014; Ramanath et al., 2014) to analyze privacy policies or identify similar policy sections and paragraphs. However, the complexity and vagueness of privacy policies makes it difficult to automatically extract complex data practices from privacy policies without substantial gold standard data.

Crowdsourcing has been proposed as a potential approach to obtain annotations for privacy policies (Sadeh et al., 2013; Breaux and Schaub, 2014; Wilson et al., 2016). However, crowdworkers are not trained in understanding and interpreting legal documents, which may result in interpretation discrepancies compared to experts (Reidenberg et al., 2015a). Our policy annotation tool shares some common features with GATE (Bontcheva et al., 2013), although the interface for our tool is simpler to fit the specific requirements of the task.

Few prior efforts, aside from those we cite above, have applied natural language processing to privacy policies or other legal documents purported for the general public to regularly read. More generally, legal text has a history of attention from natural language processing (Bach et al., 2013; Galgani et al., 2012; Francesconi et al., 2010) and from artificial intelligence (Sartor and Rotolo, 2013; Bench-Capon et al., 2012). Classifying legal text into categories has received some interest (Šavelka and Ashley, 2015; Mickevicius et al., 2015), as well as making the contents of legal texts more accessible (Boella et al., 2015; Curtotti and McCreath, 2013).

Compared to prior efforts, our data set is notable for its combination of size, input from experts (for the label scheme) and skilled annotators (for the annotation procedure), and fine-grained detail.

3 Corpus Creation and Structure

In this section we describe our procedure for selecting a diverse set of privacy policies, our annotation scheme, how we obtained annotations, and the structure of the corpus.

3.1 Privacy Policy Selection

Privacy policies vary in length, complexity, legal sophistication, and coverage of services. For instance, privacy policies of large companies may cover multiple services, websites, apps, and even physical stores; such policies are often crafted by legal teams and frequently updated. Privacy poli-

cies of smaller or less popular companies may have narrower focus or vary in employed language, and they may be updated less frequently.

To reflect this diversity, we used a two-step process for policy selection: (1) relevance-based website pre-selection and (2) sector-based sub-sampling. First, we monitored Google Trends (Google, 2015) for one month (May 2015) to collect the top five search queries for each trend. Then, for each query we retrieved the first five websites listed on each of the first 10 pages of results. This process produced a diverse sample of 1,799 unique websites.

Second, we sub-sampled from this website dataset according to DMOZ.org's top-level website sectors.[2] More specifically, we organized the dataset into 15 sectors (e.g., Arts, Shopping, Business, News). We excluded the "World" sector and limited the "Regional" sector to the "U.S." subsector in order to ensure that all privacy policies in our corpus are subject to the same legal and regulatory requirements. We ranked the websites in each sector according to their frequency in the retrieved search results. Then we selected eight websites from each sector by randomly chosing two websites from each rank quartile.

For each selected website, we manually verified that it had an English-language privacy policy and that it pertained to a US company (based on contact information and WHOIS entry) before downloading its privacy policy. Excluded websites were replaced with random re-draws from the same sector rank quartile. Some privacy policies covered more than one of the selected websites (e.g., the Disney privacy policy covered disney.go.com and espn.go.com), resulting in a final dataset of 115 privacy policies across 15 sectors.

3.2 Annotation Scheme and Process

We developed a policy annotation scheme to capture the data practices specified by privacy policies. To ensure the scheme reflected actual policy contents, development occurred as an iterative refinement process, in which a small group of domain experts (privacy experts, public policy experts, and legal scholars) identified different data practice categories and their descriptive attributes from multiple privacy policies. The annotation scheme was then applied to additional policies and refined over multiple iterations during discussions among the experts.

The final annotation scheme consists of ten data practice categories:

1. *First Party Collection/Use*: how and why a service provider collects user information.
2. *Third Party Sharing/Collection*: how user information may be shared with or collected by third parties.
3. *User Choice/Control*: choices and control options available to users.
4. *User Access, Edit, & Deletion*: if and how users may access, edit, or delete their information.
5. *Data Retention*: how long user information is stored.
6. *Data Security*: how user information is protected.
7. *Policy Change*: if and how users will be informed about changes to the privacy policy.
8. *Do Not Track*: if and how Do Not Track signals[3] for online tracking and advertising are honored.
9. *International & Specific Audiences*: practices that pertain only to a specific group of users (e.g., children, Europeans, or California residents).
10. *Other*: additional sub-labels for introductory or general text, contact information, and practices not covered by the other categories.

An individual *data practice* belongs to one of the ten categories above, and it is articulated by a category-specific set of *attributes*. For example, a User Choice/Control data practice is associated with four mandatory attributes (*Choice Type*, *Choice Scope*, *Personal Information Type*, *Purpose*) and one optional attribute (*User Type*). The annotation scheme defines a set of potential values for each attribute. To ground the data practice in the policy text, each attribute also may be associated with a *text span* in the privacy policy.

The set of mandatory and optional attributes reflects the potential level of specificity with which a data practice of a given category may be described. Optional attributes are less common, while mandatory attributes are necessary to represent a data practice. However, privacy policies are often vague or ambiguous on many of these attributes. Therefore, a valid value for each attribute is *Unspecified*, allowing annotators to express an absence of information.

[2]The DMOZ.org website sectors are notable for their use by Alexa.com.

Annotated Attributes	128,347
Annotated Text Spans	102,576
Annotators Per Document	3
Annotators Total	10

Table 1: Totalized statistics on the corpus.

We developed a web-based annotation tool, shown in Figure 1, for skilled annotators to apply our annotation scheme to the selected privacy policies.[4] In preparation, privacy policies were divided into paragraph-length *segments* for annotators to read in the tool, one at a time in sequence. For each segment, an annotator may label zero or more data practices from each category. To create a data practice, an annotator first selects a practice category and then specifies values and text spans for each of its attributes. Annotators can see a list of data practices they have created for a segment and selectively duplicate and edit them to annotate practices that differ only slightly, though we omit these features from the figure for brevity.

4 Composition of the OPP-115 Corpus

The annotation process produced a nuanced and diverse dataset, which we describe in detail below. We name the dataset the *OPP-115 Corpus* (Online Privacy Policies, set of 115) for convenience.

4.1 Policy Contents

Table 1 shows some descriptive statistics for the corpus as a whole. Each privacy policy was read by three skilled annotators, who worked independently, and a total of ten annotators participated in the process. All annotators were law students and were compensated for their work at rates appropriate for student employees at their respective universities. They required a mean of 72 minutes per policy, though this number is slightly inflated by outliers when they stepped away from in-progress sessions for extended periods of time. The annotators produced a total of 23K data practices, although this number contains some redundancies between annotators' efforts.[5] In aggregate, these data practices are associated with 128K values for attributes and 103K selected spans of policy text. Note that the annotation tool required the selection of a text span for mandatory attributes, but did not require a text-based justification for optional attributes or attributes marked as "Unspecified".

The corpus allows us to investigate the composition of typical privacy policies in terms of data practices. Privacy policies are known for their length and complexity, but those notions do not necessarily entail a density of pertinent information. Table 2 shows the pre-consolidation quantities of practices that we collected in each of the ten annotation categories, along with the mean and median counts of practices per privacy policy. Intuitively, First Party Collection/Use and Third Party Sharing/Collection dominated the rankings by frequency: the collection, usage, and sharing of user data are the primary concerns that compel the production of privacy policies. Data practices in the Other category, while frequent, were mostly statements that were ostensibly not about user data; 57% were introductory, contact, or generic information. Means were above medians for all categories, reflecting rightward skews for all the distributions.

Table 2 also contains statistics on segment-level category coverage and annotator agreement. Here, *coverage* is meant in an *ipso facto* sense: a practice category covers a policy segment if two of three annotators each identified at least one practice from that category in the segment text. Differences in the category rankings by frequency and by coverage reveal that practices in some categories are less tightly clustered than others. In particular, Data Retention is the second rarest practice category but ranks fourth by segment coverage. Since Kappa is applied here to an artificial task (annotators were not asked to label entire segments) the common conventions for its interpretation (Carletta, 1996; Viera and Garrett, 2005) are not directly applicable. However, Do Not Track and International and Specific Audiences remain standout categories with the greatest segment-level agreement. We hypothesize that these two categories have the most easily recognizable cues for annotation. Do Not Track practices, for example, are associated with the eponymous phrase.

Finally, the pre-consolidation mean and median

[4] Our experts for the annotation scheme development and our skilled annotators were mutually exclusive groups.

[5] We describe a method to *consolidate* annotations (i.e., to eliminate redundancies between annotators' data) in Section 4.2. Here, we analyze policy contents pre-consolidation to avoid propagating the effects of nontrivial assumptions necessary for consolidation.

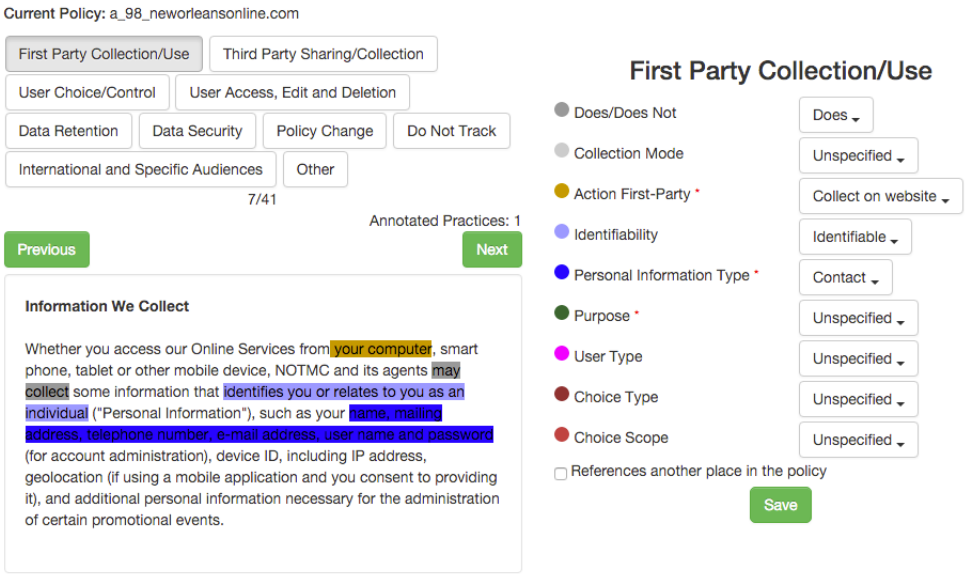

Figure 1: Web-based tool for our skilled annotators of privacy policies.

Category	Freq.	Mean	Median	Coverage	Fleiss' Kappa
First Party Collection/Use	8,956	78	74	.27	.76
Third Party Sharing/Collection	5,230	45	39	.21	.76
Other	3,551	31	25	.24	.49
User Choice/Control	1,791	16	13	.08	.61
Data Security	1,009	9	7	.05	.67
International and Specific Audiences	941	8	6	.07	.87
User Access, Edit and Deletion	747	6	5	.03	.74
Policy Change	550	5	4	.03	.73
Data Retention	370	3	2	.20	.55
Do Not Track	90	1	0	.01	.91

Table 2: By-category descriptive statistics for the data practices in the corpus. These statistics are calculated prior to consolidating multiple annotators' work. Means and medians are calculated across the population of policies in the corpus. Coverage and Kappa are calculated in terms of by-segment contents.

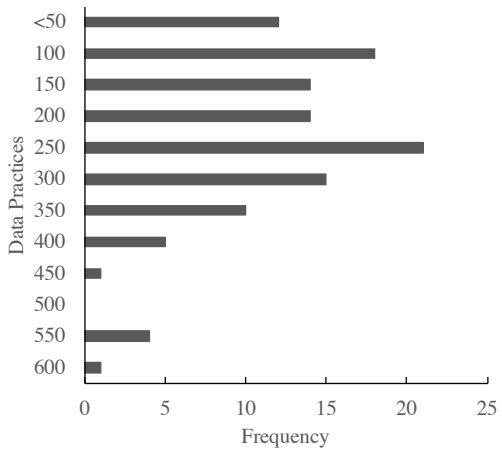

Figure 2: Distribution of data practices per policy.

quantities of data practices per policy were 202 and 200, respectively. These do not correspond to columnar totals that may be calculated from Table 2 because the categories were not equally distributed among the privacy policies. Figure 2 shows the distribution of quantities of data practices per policy. The distribution exhibits a skew toward larger numbers of data practices per policy. Importantly, differences in the number of data practices should not be interpreted as varying levels of data protection or privacy. A privacy policy that contains many data practices may exhibit substantial redundancy among them, and a privacy policy with relatively few data practices could merely be concise. In either case, the data practices may be responsive to users concerns or at odds with them.

4.2 Consolidating Annotators' Work

In this section we discuss the problem of *consolidation*, or merging data practices from multiple annotators if those practices refer to the same underlying practice expressed by the text. The ambiguity and vagueness of privacy policies (Reidenberg et al., 2016) and the sophistication of the annotation scheme are natural limitations on annotator agreement. With that in mind, we present a consolidation procedure to collapse redundant annotations with the proviso that practices labeled by only one or two skilled annotators also have substantial value and merit retention.

First, we institute some basic requirements about locality and topicality to determine which data practices are eligible for consolidation. Given a segment, if annotators $A_1, ..., A_n$ (for $n = 2$ or $n = 3$ in our dataset) respectively produce sets of data practices $P_1, ..., P_n$, then a selection of data practices $p_1 \in P_1, ..., p_n \in P_n$ is eligible to be consolidated into a single data practice only if all of them belong to the same category. Additionally, three implicit assumptions in this requirement are that (1) at least two annotators contribute practices to a consolidation set, (2) all the practices are located in the same policy segment, and (3) each practice must belong to a unique annotator.

For each segment we create an exhaustive list of eligible combinations of data practices to consolidate, score and rank each combination using a method detailed below, prune the list with a score threshold, and finally perform consolidations in order of ranking until no further consolidations are possible. Consolidation sets containing three annotators' practices are considered prior to sets containing practices from only two annotators. The data practices in a chosen consolidation set are removed and replaced by a single "master" data practice. To do this, it is necessary to merge sets of values and sets of text spans respectively associated with each attribute. Sets of values are merged using a majority vote if possible and set to Unspecified if otherwise; the latter case occurs in approximately a third of all mergers. Sets of text spans are merged with a strong bias toward recall, by creating a new text span that begins and ends with respectively the first and last indexes in the set.

Our scoring method is based on the summative overlap between the sets of text spans associated with attributes of data practices, with normalization to account for longer spans. Since the text spans connect data practices to the policy text, we use their overlaps as evidence that two annotators' data practices refer to the same underlying practice in the text. Thus, a score for two data practices that are associated with roughly the same policy text is relatively high, and a score for two data practices that are associated with different text is low.

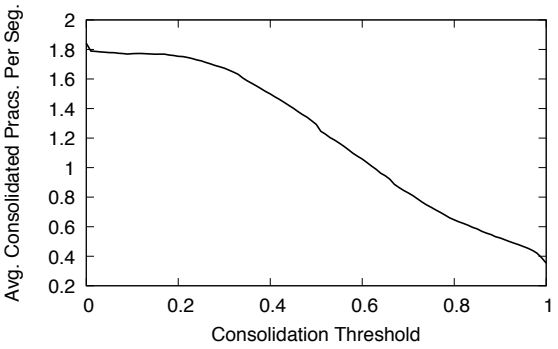

Figure 3: Consolidation threshold value versus the average number of data practices per segment produced by consolidation.

Figure 3 shows the effect of the consolidation threshold on the average number of practices produced by consolidation per policy segment (i.e., excluding those original data practices that were retained because they were not subject to consolidation). Past a threshold value of approximately 0.2, the number of practices steadily decreases. Notably the average number of practices produced by consolidation is substantially less than the average practices per annotator per segment (2.04) at any point on the curve, indicating a relative lack of agreement between annotators in terms of text span selections. As part of the corpus, we release consolidated datasets at threshold values of 0.5, 0.75, and 1.

4.3 Data Exploration Website

The data practice annotations are difficult for human readers to interpret without visual connections to the policy text. To help researchers, policy regulators, and the general public understand the structure and utility of the data set, we created a data exploration website[6] that visually integrates the data practice annotations with the texts of privacy policies. Site interactivity allows users to search for websites in the dataset or browse by DMOZ sectors.

The website also allows users to compare privacy policies by categorical structure, data prac-

[6] explore.usableprivacy.org

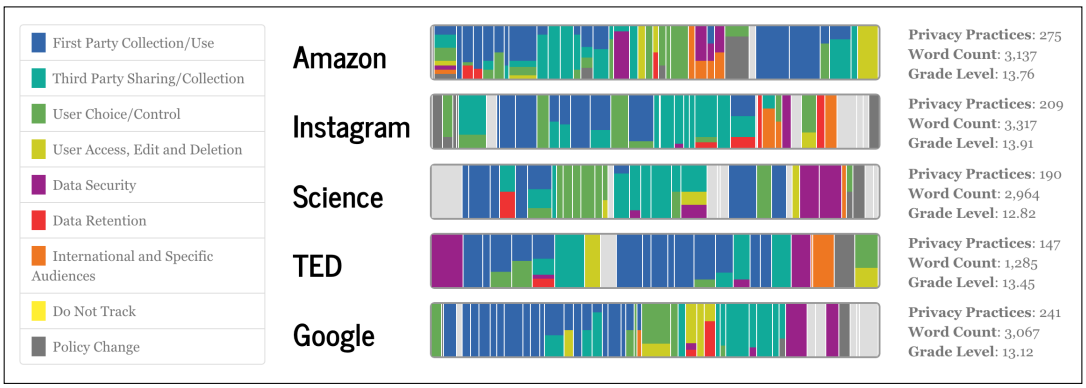

Figure 4: Comparing five policies on the data exploration website.

tice quantities, and reading level.[7] Figure 4 shows a sample comparison between five websites. Each policy's segments are depicted in order from left to right. Segments are colored according to the practice categories that annotators labeled within them. Qualitative patterns are discernible; for example, several of these policies have large blocks of First Party Collection/Use toward the beginning or large blocks of Third Party Sharing/Collection further inward. We discuss exploiting such recurring structures in the next section.

5 Prediction of Policy Structure

The current human annotation procedure is impractical for covering the entire Internet or accounting for changes in privacy policies. This raises the question of whether the process can be partly automated. In this section we describe our experiments to automatically assign category labels to policy segments, which would enable the simplification of the annotation task.

5.1 Experiments

Our dataset consisted of 3,792 segments from 115 privacy policies. We represented the text of each segment as a dense vector using Paragraph2Vec (Le and Mikolov, 2014) and the GENSIM toolkit (Řehůřek and Sojka, 2010). This approach exploited semantic similarities between words in the vocabulary of privacy policies, acknowledging that the vocabulary in this domain is specialized but not completely standardized. We assigned each policy segment a binary vector of category-specific labels, with each element in the vector corresponding to the presence or absence of a data practice category in the segment. We considered a vector with twelve elements, with nine of them coming from existing practice categories (all except Other). The remaining three came from elevating three attributes of Other to category status: *Introductory/Generic*, *Practice Not Covered*, and *Privacy Contact Information*. We created gold standard data for this problem using a simplified consolidation approach: if two or more annotators agreed that a category is present in a segment, then we labeled that segment with the category.

To predict the category labels of privacy policy segments, we tried three approaches. Two were logistic regression and SVM models, for which we treated this as a multi-class classification problem. Since 2^{12} unique category vectors exist, we trimmed the label space to only those that occur in the training set. The third was a sequence labeling approach inspired by prior work to apply hidden Markov models (HMMs) to privacy policy text (Ramanath et al., 2014). Our work differs from this prior work by using labels from an annotation scheme constructed by privacy experts rather than topics developed from an unsupervised method. Additionally, in our formulation, each hidden state corresponds to one of the unique binary vectors that represent classes of category combinations in the training data. The HMM's transition probabilities capture the tendency of privacy policy authors to organize topics (i.e., practice categories in our annotation scheme) in similar sequences. Since each segment is represented by a unique real-valued vector from Paragraph2Vec, it was not possible to directly obtain an emission probability distribution from the training data. Therefore, we ran the K-Means++ algorithm using the scikit-learn toolkit (Pedregosa et al., 2011) on the segment vector representations and assigned each segment to a cluster. The emission probability distribution then captured the tendencies of a given class and generated the segment

[7] `explore.usableprivacy.org/compare`

that is represented as a cluster. These two distributions are estimated empirically from the training data, and we used Viterbi decoding to obtain the best labeling sequence during the prediction.

5.2 Results

We split the set of 115 policies into subsets of 75 for training and 40 for testing. The number of clusters in the HMM approach[8] is set to 100 and the results are shown in Table 3 as means across 10 runs. The standard deviations for these performance figures are generally between 0.01 and 0.05; the one exception is Do Not Track (the least frequent category) with a standard deviation of 0.2. As the table shows, although the HMM does not reach the same performance as SVM, it performs similarly to logistic regression and meets or exceeds its F1-score for five categories.

We interpret the strength of the SVM as indicating the strong potential to partly automate the policy labeling procedure, especially for two categories: First Party Collection/Use (a standout performance and the category for which the most labeled data exists) and Do Not Track (a perfect performance, likely due to the limited vocabulary used to describe practices in this category). Additionally, while the HMM did not perform as well overall, we note that its micro-average F1 was a slight improvement over logistic regression. With relatively little data to train this HMM, we expect that the accumulation of more labeled instances can improve its performance substantially.

6 Future Directions

The OPP-115 Corpus enables research in several directions of interest to natural language processing and usable privacy. We sketch some opportunites for future work below.

A central challenge for this research is the scalability of policy annotation. Although it was necessary to annotate the first 115 policies manually, to ensure the annotations were responsive to the annotation scheme, a less labor-intensive approach will be required for large-scale Web coverage. The OPP-115 Corpus is a valuable dataset for this move toward automated methods. Additionally, a strong potential exists for a combination of automated annotation of coarse information and human annotation of finer details. For example, automated category labeling of policy segments is feasible, as demonstrated in Section 5. Asking a human to label practices in a single category would be a reduction in effort, especially if they are shown text that is relevant to the category. Crowdsourcing also becomes a possibility when the complexity of the task is reduced.

An ambitious goal will be to eliminate human annotators altogether. Our preliminary analysis has shown that the policy vocabularies associated with certain annotations are very distinctive (e.g., the Do Not Track category or financial information as a data type, for example), lending themselves to automatic identification. By producing confidence ratings alongside data practice predictions, an automated system could mitigate its shortcomings.

Separately, data practices must be presented to Internet users in a way that is responsive to their concerns. Text summarization is a possibility, using the annotations as a guide for important details to retain. Internet users have already demonstrated limited patience with text-based privacy policies, which adds a nuance to this challenge and suggests the need for a combination of text and pictorial representations (or chiefly pictorial representations) to communicate data practices (Schaub et al., 2015).

Additional questions of interest include:

- *How can the data practice annotations for a policy be combined into a cohesive interpretation?* The relationships between data practices are not straightforward. Vagueness, contradictions, and unclear scope are all problems for constructing a knowledge base of them.
- *How can the balance between human and automated methods for annotation be optimized?* The model for the ideal combination is subject to parameters such as the availability of resources and the necessary level of confidence for annotations.
- *How can sectoral norms and outliers be identified automatically?* A bank website that collects users' health information, for example, deserves scrutiny. It seems appropriate to address this question with clustering techniques, using features from the data practices and from the policy text.

[8] We tuned the parameters of the HMM approach and SVM after performing a five-fold cross validation on the training data.

Table 3: Precision/Recall/F1 for the three models. The three starred categories resulted from the decomposition of the original Other category, which is excluded here. Categories are ordered in this table in descending order by frequency in the dataset.

7 Conclusion

We have described the motivation, creation, and analysis of a unique corpus of 115 privacy policies and 23K fine-grained data practice annotations, and we have demonstrated the feasibility of partly automating the annotation process. The annotations reveal the structure and complexity of these documents, which Internet users are expected to understand and accept. This corpus should serve as a resource for language technologies research to help Internet users understand the privacy practices of businesses and other entities that they interact with online.

Abstract

We propose an approach for semantic parsing that uses a recurrent neural network to map a natural language question into a logical form representation of a KB query. Building on recent work by (Wang et al., 2015), the interpretable logical forms, which are structured objects obeying certain constraints, are enumerated by an underlying grammar and are paired with their canonical realizations. In order to use sequence prediction, we need to sequentialize these logical forms. We compare three sequentializations: a direct linearization of the logical form, a linearization of the associated canonical realization, and a sequence consisting of derivation steps relative to the underlying grammar. We also show how grammatical constraints on the derivation sequence can easily be integrated inside the RNN-based sequential predictor. Our experiments show important improvements over previous results for the same dataset, and also demonstrate the advantage of incorporating the grammatical constraints.

1 Introduction

Learning to map natural language utterances (NL) to logical forms (LF), a process known as semantic parsing, has received a lot of attention recently, in particular in the context of building Question-Answering systems (Kwiatkowski et al., 2013; Berant et al., 2013; Berant and Liang, 2014). In this paper, we focus on such a task where the NL question may be semantically complex, leading to a logical form query with a fair amount of compositionality, in a spirit close to (Pasupat and Liang, 2015).

Given the recently shown effectiveness of RNNs (Recurrent Neural Networks), in particular Long Short Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997), for performing sequence prediction in NLP applications such as machine translation (Sutskever et al., 2014) and natural language generation (Wen et al., 2015), we try to exploit similar techniques for our task. However we observe that, contrary to those applications which try to predict intrinsically *sequential* objects (texts), our task involves producing a *structured* object, namely a logical form that is tree-like by nature and also has to respect certain *a priori* constraints in order to be interpretable against the knowledge base.

In our case, building on the work "Building a Semantic Parser Overnight" (Wang et al., 2015), which we will refer to as SPO, the LFs are generated by a grammar which is known *a priori*, and it is this grammar that makes explicit the structural constraints that have to be satisfied by the LFs. The SPO grammar, along with generating logical forms, generates so-called "canonical forms" (CF), which are direct textual realizations of the LF that, although they are not "natural" English, transparently convey the meaning of the LF (see Fig. 1 for an example).

Based on this grammar, we explore three different ways of representing the LF structure through a sequence of items. The first one (LF Prediction, or LFP), and simplest, consists in just linearizing the LF tree into a sequence of individual tokens; the second one (CFP) represents the LF through its associated CF, which is itself a sequence of words; and finally the third one (DSP) represents the LF through a derivation sequence (DS), namely the sequence of grammar rules that were chosen to produce this LF.

We then predict the LF via LSTM-based models that take as input the NL question and map it into

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1341–1350,
Berlin, Germany, August 7-12, 2016.

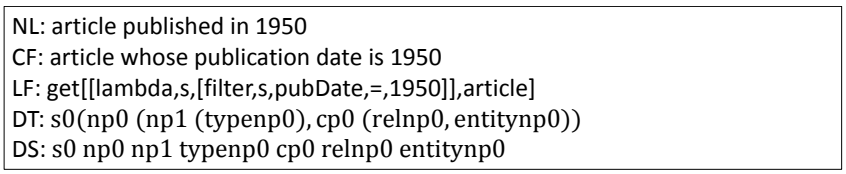

Figure 1: Example of natural language utterance (NL) from the SPO dataset and associated representations considered in this work. CF: canonical form, LF: logical form, DT: derivation tree, DS: derivation sequence.

one of the three sequentializations. In the three cases, the LSTM predictor cannot on its own ensure the grammaticality of the predicted sequence, so that some sequences do not lead to well-formed LFs. However, in the DSP case (in contrast to LFP and CFP), it is easy to integrate inside the LSTM predictor local constraints which guarantee that only grammatical sequences will be produced.

In summary, the contribution of our paper is twofold. Firstly, we propose to use sequence prediction for semantic parsing. Our experimental results show some significant improvements over previous systems. Secondly, we propose to predict derivation sequences taking into account grammatical constraints and we show that the model performs better than sequence prediction models not exploiting this knowledge. These results are obtained without employing any reranking or linguistic features such as POS tags, edit distance, paraphrase features, etc., which makes the proposed methodology even more promising.

2 Background on SPO

The SPO paper (Wang et al., 2015) proposes an approach for quickly developing semantic parsers for new knowledge bases and domains when no training data initially exists. In this approach, a small underlying grammar is used to generate canonical forms and pair them with logical forms. Crowdsourcing is then used to paraphrase each of these canonical forms into several natural utterances. The crowdsourcing thus creates a dataset (SPO dataset in the sequel) consisting of (NL, CF, LF) tuples where NL is a natural language question with CF and LF the canonical and the logical form associated with this question.

SPO learns a semantic parser on this dataset by firstly learning a log-linear similarity model based on a number of features (word matches, ppdb matches, matches between semantic types and POSs, etc.) between NL and the corresponding (CF, LF) pair. At decoding time, SPO parses a natural utterance NL by searching among the derivations of the grammar for one for which the projected (CF, LF) is most similar to the NL based on this log-linear model. The search is based on a so-called "floating parser" (Pasupat and Liang, 2015), a modification of a standard chart-parser, which is able to guide the search based on the similarity features.

In contrast, our approach does not search among the derivations for the one that maximizes a match with the NL, but instead directly tries to predict a decision sequence that can be mapped to the LF.

The SPO system together with its dataset were released to the public[1] and our work exploits this release.

3 Approach

3.1 Grammars and Derivations

```
s0:  s(S) → np(S).
np0: np(get[CP,NP]) → np(NP), cp(CP).
np1: np(NP) → typenp(NP).
cp0: cp([lambda,s,[filter,s,RELNP,=,ENTNP]]) →
       [whose], relnp(RELNP), [is], entitynp(ENTNP).
...
typenp0:   typenp(article) → [article].
relnp0:    relnp(pubDate) → [publication, date]
entitynp0: entitynp(1950) → [1950].
...
```

Figure 2: Some general rules (top) and domain-specific rules (bottom) in DCG format.

The core grammatical resource released by SPO is a generic grammar connecting logical forms with canonical form realizations. They also provide seven domain-specific lexica that can be used in combination with the generic grammar to obtain domain-specific grammars which generate (LF, CF) pairs in each domain, in such a way that LF can then be used to query the corresponding knowledge base. While SPO also released a set of

Figure 4: Projection of the derivation tree nodes into (i) a canonical form and (ii) a logical form.

Java-based parsers and generators for these grammars, for our own purposes we found it convenient to translate the grammars into the formalism of Definite Clause Grammars (Pereira and Warren, 1980), a classical unification-based extension of CFGs, which — through a standard Prolog interpreter such as SWIPL[2] — provide direct support for jointly generating textual realizations and logical forms and also for parsing text into logical forms; we found this translation process to be rather straightforward and we were able to cover all of the SPO grammars.

Figure 2 lists a few DCG rules, general rules first, then lexical rules, for the SPO "publications" domain. Nonterminals are indicated in bold, terminals in italics. We provide each rule with a unique identifier (e.g. s0, np0, ...), which is obtained by concatenating the name of its head nonterminal with a position number relative to the rules that may expand this nonterminal; we can then consider that the nonterminal (e.g. **np**) is the "type" of all its expanding rules (e.g. np0, np1, ...).

According to standard DCG notation, uppercase items `S, NP, CP, RELNP, ENTNP` denote unification variables that become instantiated during processing. In our case unificaion variables range over logical forms and each nonterminal has a single argument denoting a partially instantiated associated logical form. For instance, in the cp0 rule, **`relnp`** is associated with the logical form `RELNP`, **`entitynp`** with the logical form `ENTNP`, and the LHS nonterminal **cp** is then associated with the logical form `[lambda, s, [filter, s, RELNP, =, ENTNP]]`.[3]

In Figure 3, we display a *derivation tree* DT (or simply *derivation*) relative to this grammar, where each node is labelled with a rule identifier. This tree projects on the one hand onto the canonical form *article whose publication date is 1950*, on the other hand onto the logical form `get[[lambda,s,[filter,s,pubDate,=,1950]],article]`.

Figure 4 shows how these projections are obtained by bottom-up composition. For instance, the textual projection of node cp0 is obtained from the textual representations of nodes relnp0 and entitynp0, according to the RHS of the rule cp0, while its logical form projection is obtained by instantiation of the variables `RELNP` and `ENTNP` respectively to the LFs associated with relnp0 and entitynp0.

Relative to these projections, one may note a fundamental difference between derivation trees DT and their projections CF and LF: while the well-formedness of DT can simply be assessed locally by checking that each node expansion is valid according to the grammar, there is in principle no such easy, local, checking possible for the canonical or the logical form; in fact, in order to check the validity of a proposed CF (resp. LF), one needs to *search* for *some* DT that projects onto this CF (resp LF). The first process, of course, is known as "parsing", the second process as "generation". While parsing has polynomial complexity for grammars with a context-free backbone such as the ones considered here, deciding whether a logical form is well-formed or not could in principle be undecidable for certain forms of LF composition.[4]

[2]http://www.swi-prolog.org/

[3]This logical form is written here in DCG list notation; in the more "Lispian" format used by SPO, it would be written `(lambda s (filter s RELNP = ENTNP))`.

[4]The term 'projection' is borrowed from the notion of *bimorphism* in formal language theory (Shieber, 2014) and refers in particular to the fact that the overall logical form is constructed by bottom-up composition of logical forms asso-

To be able to leverage sequence prediction models, we can associate with each derivation tree DT its leftmost *derivation sequence* DS, which corresponds to a preorder traversal of the tree. For the tree of Figure 3, this sequence is [s0, np0, np1, typenp0, cp0, relnp0, entitynp0]. When the grammar is known (in fact, as soon as the CFG core of the grammar is known), two properties of the DS hold (we omit the easy algorithms underlying these properties; they involve using a prefix of the DS for constructing a partial derivation tree in a top-down fashion):

1. knowing the DS uniquely identifies the derivation tree.

2. knowing a prefix of the DS (for instance [s0, np0, np1, typenp0]) completely determines the *type* of the next item (here, this type is **cp**).

The first property implies that if we are able to predict DS, we are also able to predict DT, and therefore also LF and CF. The second property implies that the sequential prediction of DS is strongly constrained by *a priori* knowledge of the underlying grammar: instead of having to select the next item among all the possible rules in the grammar, we only have to select among those rules that are headed by a specific nonterminal. Under a simple condition on the grammar (namely that there are no "unproductive" rules, rules that can never produce an output[5]), following such constrained selection for the next rule guarantees that the derivation sequence will always lead to a valid derivation tree.

At this point, a theoretical observation should be made: *there is no finite-state mechanism on the sequence of rule-names that can control whether the next rule-name is valid or not*.[6] The relevance of that observation for us is that the RNNs that we use are basically finite-state devices (with a huge number of states, but still finite-state), and therefore we do not expect them in principle to be able to always produce valid derivation sequences *unless* they can exploit the underlying grammar for constraining the next choice.

ciated with lower nodes in the derivation tree. In our DCG grammars, this composition actually involves more complex operations (such as "beta-reduction") than the simple copyings illustrated in the small excerpt of Fig. 2.

[5]The general grammar ensures a good coverage of possible logical and canonical forms. However, when this general grammar is used in particular domains, some rules are not relevant any more (i.e. become "unproductive"), but these can be easily eliminated at compile time.

[6]This is easy to see by considering a CFG generating the non finite-state language $a^n b^n$.

3.2 Sequence prediction models

In all these models, we start from a natural utterance NL and we predict a sequence of target items, according to a common sequence prediction architecture that will be described in section 3.3.

3.2.1 Predicting logical form (LFP model)

The most direct approach is to directly predict a linearization of the logical form from NL, the input question. While an LF such as that of Figure 1 is really a structured object respecting certain implicit constraints (balanced parentheses, consistency of the variables bound by lambda expressions, and more generally, conformity with the underlying grammar), the linearization treats it simply as a sequence of tokens: `get [ [ lambda s [ filter s pubDate = 1950 ] ] article ]`. At training time, the LFP model only sees such sequences, and at test time, the next token in the target sequence is then predicted without taking into account any structural constraints. The training regime is the standard one attempting to minimize the cross-entropy of the model relative to the logical forms in the training set.

3.2.2 Predicting derivation sequence (DSP-X models)

Rather than predicting LF directly, we can choose to predict a derivation sequence DS, that is, a sequence of rule-names, and then project it onto LF. We consider three variants of this model.

DSP This basic derivation sequence prediction model is trained on pairs (NL, DS) with the standard training regime. At test time, it is possible for this model to predict ill-formed sequences, which do not correspond to grammatical derivation trees, and therefore do not project onto any logical form.

DSP-C This is a Constrained variant of DSP where we use the underlying grammar to constrain the next rule-name. We train this model exactly as the previous one, but at test time, when sampling the next rule-name inside the RNN, we reject any rule that is not a possible continuation.

DSP-CL This last model is also constrained, but uses a different training regime, with Constrained Loss. In the standard learning regime (used for the

Target sequence	DS	CF	LF
Length	10.5	11.8	47.0
Vocabulary Size	106.0	55.8	59.9

Table 1: Characteristics of different target sequences.

two previous models), the incremental loss when predicting the next item y_t of the sequence is computed as $-\log p(y_t)$, where $p(y_t)$ is the probability of y_t according to the RNN model, normalized (through the computation of a softmax) over *all* the potential values of y_t (namely, here, all the rules in the grammar). By contrast, in the CL learning regime, the incremental loss is computed as $-\log p'(y_t)$, where $p'(y_t)$ is normalized *only over the values of* y_t *that are possible continuations* once the grammar-induced constraints are taken into account, ignoring whatever weights the RNN predictor may (wrongly) believe should be put on impossible continuations. In other words, the DSP-CL model incorporates the prior knowledge about well-formed derivation sequences that we have thanks to the grammar. It computes the actual cross-entropy loss according to the underlying generative process of the model that is used once the constraints are taken into account.

3.2.3 Predicting canonical form (CFP model)

The last possibility we explore is to predict the sequence of words in the canonical form CF, and then use our grammar to parse this CF into its corresponding LF, which we then execute against the knowledge base.[7]

Table 1 provides length and vocabulary-size statistics for the LFP, DSP and CFP tasks.

We see that, typically, for the different domains, DS is a shorter sequence than LF or CF, but its vocabulary size (i.e. number of rules) is larger than that of LF or CF. However DS is unique in allowing us to easily validate grammatical constraints. We also note that the CF is less lengthy than the LF, which uses a number of non "word-like" symbols such as parentheses, lambda variables, and the like.

[7] Although the general intention of SPO is to unambiguously reflect the logical form through the canonical form (which is the basis on which Turkers provide their paraphrases), we do encounter some cases where, although the CF is well-formed and therefore parsable by the grammar, several parses are actually possible, some of which do not correspond to queries for which the KB can return an answer. In these cases, we return the first parse whose logical form does return an answer. Such situations could be eliminated by refining the SPO grammar to a moderate extent, but we did not pursue this.

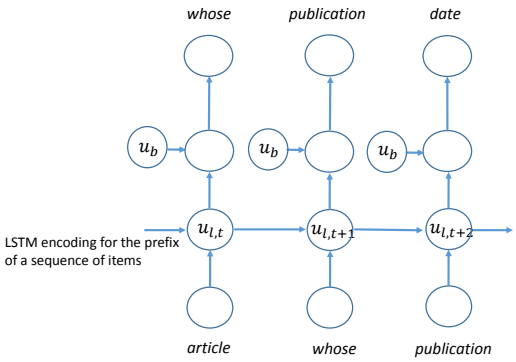

Figure 5: Our neural network model which is shared between all the systems. An MLP encodes the sentence in unigrams and bigrams and produces u_b. An LSTM encodes the prefix of the predicted sequence generating $u_{l,t}$ for each step t. The two representations are then fed into a final MLP to predict the next choice of the target sequence.

3.3 Sequence prediction architecture

3.3.1 Neural network model

The goal of our neural network is to estimate the conditional probability $p(y_1, \ldots, y_{T'}|x_1, \ldots, x_T)$ where $(x_1, \ldots, x_T)$ is a natural language question and $(y_1, \ldots, y_{T'})$ is a target sequence (linearized LF, CF or derivation sequence). In all three cases, we use the same neural network model, which we explain in this subsection.

Suppose that the content of the NL is captured in a real-valued vector u_b, while the prefix of the target sequence up to time t is captured in another real-valued vector $u_{l,t}$. Now, the probability of the target sequence given the input question can be estimated as:

$$p(y_1, \ldots y_{T'}|x_1, \ldots, x_T) = \prod_{t=1}^{T'} p(y_t|u_b, y_1, \ldots y_{t-1})$$
$$= \prod_{t=1}^{T'} p(y_t|u_b, u_{l,t-1})$$

In all our systems, the u_b capturing the content of the NL is calculated from the concatenation of a vector u_1 reading the sentence based on unigrams and another vector u_2 reading the sentence based on bigrams. Mathematically, $u_1 = \tanh(W_1 v_1)$ where v_1 is the 1-hot unigram encoding of the NL

and $u_2 = \tanh(W_2 v_2)$ where v_2 is its 1-hot bigram encoding. Then $u_b = \tanh(Wu)$, where u is the concatenation of u_1 and u_2. W_1, W_2 and W are among the parameters to be learnt. For regularization purposes, a dropout procedure (Srivastava et al., 2014) is applied to u_1 and u_2.

The prefix of the target sequence up to time t is modelled with the vector $u_{l,t}$ generated by the latest hidden state of an LSTM (Hochreiter and Schmidhuber, 1997); LSTM is appropriate here in order to capture the long distance dependencies inside the target sequence. The vector $u_{l,t}$ is then concatenated with u_b (forming u_{bl} in the equation below) before passing through a two-layer MLP (Multi-Layer Perceptron) for the final prediction:

$$p(y_{t+1}|u_{l,t}, u_b) = \text{softmax}(W_2' \tanh(W_1' u_{bl}))$$

Using deep structures such as this MLP for RNN prediction has been shown to be beneficial in previous work (Pascanu et al., 2013).

The overall network architecture is summarized in Figure 5. We train the whole network to minimize the cross entropy between the predicted sequence of items and the reference sequence.

This network architecture can easily support other representations for the input sentence than unigrams and bigrams, as long as they are real-valued vectors of fixed length. We can just concatenate them with u_1 and u_2 and generate u_b as previously. In fact, in initial experiments, we did concatenate an additional representation which reads the sentence through an LSTM, but the performance was not improved.

3.3.2 Decoding the target sequence

We implemented a uniform-cost search algorithm (Russell and Norvig, 2003) to decode the best decision sequence as the sequence with the highest probability. The algorithm finishes in a reasonable time for two reasons: 1) as indicated by Table 1, the vocabulary size of each domain is relatively small, and 2) we found that our model predicts relatively peaked distributions. Of course, it would also be easy to use a beam-search procedure, for situations where these conditions would not hold.

4 Experiments

4.1 Setup

We conduct our experiments on the SPO dataset. To test the overall performance of a semantic parser, the SPO dataset contains seven domains focusing on different linguistic phenomena such as multi-arity relations, sublexical compositionality etc. The utterances in each domain are annotated both with logical forms (LFs) and canonical forms (CFs). The number of such utterances vary from 800 to 4000 depending on the domain. The size of training data is indeed small but as the target vocabulary is always in the domain, thus very small as well, it is actually possible to learn a reasonable semantic parser.

In the SPO dataset, the natural utterances were split randomly into 80%-20% for training and test, and we use the same sets. We perform an additional 80%-20% random split on the SPO training data and keep the 20% as development set to choose certain hyperparameters of our model. Once the hyperparameters are chosen, we retrain on the whole training data before testing.

For LFP experiments, we directly tokenize the LF, as explained earlier, and for CFP experiments we directly use the CF. For DSP experiments (DSP, DSP-C, DSP-CL) where our training data consist of (NL, DS) pairs, the derivation sequences are obtained by parsing each canonical form using the DCG grammar of section 3.

We compare our different systems to SPO. While we only use unigram and bigram features on the NL, SPO uses a number of features of different kinds: linguistic features on NL such as POS tags, lexical features computing the similarity between words in NL and words in CF, semantic features on types and denotations, and also features based on PPDB (Ganitkevitch et al., 2013).

At test time, like SPO, we evaluate our system on the proportion of questions for which the system is able to find the correct answer in the knowledge base.

4.2 Implementation details

We choose the embedding vectors u_1 for unigrams and u_2 for bigrams to have 50 dimensions. The vector u_b representing the sentence content has 200 dimensions. The word embedding layer has 100 dimensions, which is also the case of the hidden layer of the LSTM $u_{l,t}$. Thus u_{bl} which is the concatenation of u_b and $u_{l,t}$ has 300 dimensions and we fix the next layer to u_{bl} to have 100 dimensions. The model is implemented in Keras[8] on top of Theano (Bergstra et al., 2010). For all the exper-

[8] https://github.com/fchollet/keras

iments, we train our models using rmsprop (Tieleman and Hinton., 2012) as the backpropagation algorithm[9]. We use our development set to select the number of training epochs, the dropout factor over unigrams representation and the dropout factor over bigrams representation, by employing a grid search over these hyperparameters: epochs in $\{20, 40, 60\}$, unigrams dropout in $\{0.05, 0.1\}$ and bigrams dropout in $\{0.1, 0.2, 0.3\}$.

4.3 Experimental results

4.3.1 Results on test data

Table 2 shows the test results of SPO and of our different systems over the seven domains.

It can be seen that all of our sequence-based systems are performing better than SPO by a large margin on these tests. When averaging over the seven domains, our 'worst' system DSP scores at 64.7% compared to SPO at 57.1%.

We note that these positive results hold despite the fact that DSP has the handicap that it may generate ungrammatical sequences relative to the underlying grammar, which do not lead to interpretable LFs. The LFP and CFP models, with higher performance than DSP, also may generate ungrammatical sequences.

The best results overall are obtained by the DSP-C system, which does take into account the grammatical constraints. This model performs not only considerably better than its DSP baseline (72.7% over 64.7%), but also better than the models LFP and CFP. Somewhat contrary to our expectations, the DSP-CL model, which exploits constraints not only during decoding, but also during training, performs somewhat worse than the DSP-C, which only exploits them during decoding.

We note that, for all the sequence based models, we strictly base our results on the performance of the *first* sequence predicted by the model. It would probably be possible to improve them further by reranking n-best sequence lists using a set of features similar to those used by SPO.

4.4 Analysis of results

4.4.1 Grammatical errors

We just observed that CFP and LFP perform well on test data although the sequences generated are not guaranteed to be grammatical. We analysed the percentage of grammatical errors made by these models and also by DSP for three domains, which we report in Table 3.[10]

	Basketball	Publication	Housing
LFP	6.6	3.7	1.6
CFP	1.8	1.9	2.2
DSP	9.5	11.8	5.8
DSP-C(L)	0.0	0.0	0.0

Table 3: Grammatical error rate of different systems on test.

The table shows that LFP and especially CFP make few grammatical errors while DSP makes them more frequently. For DSP-C and DSP-CL, the error rate is always 0 since by construction, the derivations must be well-formed. Note that as DSP is not constrained by prior knowledge about the grammar, the grammatical error rate can be high – even higher than CFP or LFP because DSP typically has to choose among more symbols, see Table 1.

4.4.2 Difference between DSP-C and DSP-CL

We observed that the DSP-CL model performs somewhat worse than DSP-C in our experiments. While we were a bit surprised by that behavior, given that the DSP-CL has strong theoretical motivations, let us note that the two models are quite different. To stress the difference, suppose that, for a certain prediction step, only two rules are considered as possible by the grammar, among the many rules of the grammar. Suppose that the LSTM gives probabilities 0.004 and 0.006 respectively to these two rules, the rest of the mass being on the ungrammatical rules. While the DSP-C model associates respective losses of $-\log 0.004, -\log 0.006$ with the two rules, the DSP-CL model normalizes the probabilites first, resulting in smaller losses $-\log 0.4, -\log 0.6$.

As we choose the best complete sequence during decoding, it means that DSP-C will be more likely to prefer to follow a different path in such a case, in order not to incur a loss of at least $-\log 0.006$. Intuitively, this means that DSP-C will prefer paths where the LSTM *on its own*

[9] All the hyperparameters of rmsprop as well as options for initializing the neural network are left at their default values in Keras.

[10] Our DCG permits to compute this error rate directly for canonical forms and derivation sequences. For logical forms, we made an estimation by executing them against the knowledge base and eliminating the cases where the errors are not due to the ungrammaticality of the logical form.

	Basketball	Social	Publication	Blocks	Calendar	Housing	Restaurants	Avg
SPO	46.3	48.2	59.0	41.9	74.4	54.0	75.9	57.1
LFP	73.1	70.2	72.0	55.4	71.4	61.9	76.5	68.6
CFP	80.3	79.5	70.2	54.1	73.2	**63.5**	71.1	70.3
DSP	71.6	67.5	64.0	53.9	64.3	55.0	76.8	64.7

DSP-CL	**80.6**	77.6	70.2	53.1	**75.0**	59.3	74.4	70.0

Table 2: Test results over different domains on SPO dataset. The numbers reported correspond to the proportion of cases in which the predicted LF is interpretable against the KB *and* returns the correct answer. LFP = Logical Form Prediction, CFP = Canonical Form Prediction, DSP = Derivation Sequence Prediction, DSP-C = Derivation Sequence constrained using grammatical knowledge, DSP-CL = Derivation Sequence using a loss function constrained by grammatical knowledge.

gives small probability to ungrammatical choices, a property not shared by DSP-CL. However, a more complete understanding of the difference will need more investigation.

5 Related Work and Discussion

In recent work on developing semantic parsers for open-domain and domain-specific question answering, various methods have been proposed to handle the mismatch between natural language questions and knowledge base representations including, graph matching, paraphrasing and embeddings techniques.

Reddy et al. (2014) exploits a weak supervision signal to learn a mapping between the logical form associated by a CCG based semantic parser with the input question and the appropriate logical form in Freebase (Bollacker et al., 2008).

Paraphrase-based approaches (Fader et al., 2013; Berant and Liang, 2014) generate variants of the input question using a simple hand-written grammar and then rank these using a paraphrase model. That is, in their setting, the logical form assigned to the input question is that of the generated sentence which is most similar to the input question.

Finally, Bordes et al. (2014b; 2014a) learn a similarity function between a natural language question and the knowledge base formula encoding its answer.

We depart from these approaches in that we learn a direct mapping between natural language questions and their corresponding logical form or equivalently, their corresponding derivation and canonical form. This simple, very direct approach to semantic parsing eschews the need for complex feature engineering and large external resources required by such paraphrase-based approaches as (Fader et al., 2013; Berant and Liang, 2014). It is conceptually simpler than the two steps, graph matching approach proposed by Reddy et al. (2014). And it can capture much more complex semantic representations than Bordes et al. (2014b; 2014a)'s embeddings based method.[11]

At a more abstract level, our approach differs from previous work in that it exploits the fact that logical forms are structured objects whose shape is determined by an underlying grammar. Using the power of RNN as sequence predictors, we learn to predict, from more or less explicit representations of this underlying grammar, equivalent but different representations of a sentence content namely, its canonical form, its logical form and its derivation sequence.

We observe that the best results are obtained by using the derivation sequence, when also exploiting the underlying grammatical constraints. However the results obtained by predicting directly the linearization of the logical form or canonical form are not far behind; we show that often, the predicted linearizations actually satisfy the underlying grammar. This observation can be related to the results obtained by Vinyals et al. (2014), who use an RNN-based model to map a sentence to the linearization of its parse tree,[12] and find that in most cases, the predicted sequence produces well-balanced parentheses. It would be interest-

[11] In (Bordes et al., 2014b; Bordes et al., 2014a), the logical forms denoting the question answers involve only few RDF triples consisting of a subject, a property and an object i.e., a binary relation and its arguments.

[12] Note a crucial difference with our approach. While in their case the underlying ("syntactic") grammar is only partially and implicitly represented by a set of parse annotations, in our case the explicit ("semantic") grammar is known *a priori* and can be exploited as such.

ing to see if our observation would be maintained for more complex LFs than the ones we tested on, where it might be more difficult for the RNN to predict not only the parentheses, but also the dependencies between several lambda variables inside the overall structure of the LF.

6 Conclusion and Future Work

We propose a sequence-based approach for the task of semantic parsing. We encode the target logical form, a structured object, through three types of sequences: direct linearization of the logical form, canonical form, derivation sequence in an underlying grammar. In all cases, we obtain competitive results with previously reported experiments. The most effective model is one using derivation sequences and taking into account the grammatical constraints.

In order to encode the underlying derivation tree, we chose to use a leftmost derivation sequence. But there are other possible choices that might make the encoding even more easily learnable by the LSTM, and we would like to explore those in future work.

In order to improve performance, other promising directions would involve adding re-reranking techniques and extending our neural networks with attention models in the spirit of (Bahdanau et al., 2015).

wenpeng@cis.lmu.de

Abstract

Word embeddings – distributed representations of words – in deep learning are beneficial for many tasks in NLP. However, different embedding sets vary greatly in quality and characteristics of the captured information. Instead of relying on a more advanced algorithm for embedding learning, this paper proposes an ensemble approach of combining different public embedding sets with the aim of learning *metaembeddings*. Experiments on word similarity and analogy tasks and on part-of-speech tagging show better performance of metaembeddings compared to individual embedding sets. One advantage of metaembeddings is the increased vocabulary coverage. We release our metaembeddings publicly at http://cistern.cis.lmu.de/meta-emb.

1 Introduction

Recently, deep neural network (NN) models have achieved remarkable results in NLP (Collobert and Weston, 2008; Sutskever et al., 2014; Yin and Schütze, 2015). One reason for these results are *word embeddings*, compact distributed word representations learned in an unsupervised manner from large corpora (Bengio et al., 2003; Mnih and Hinton, 2009; Mikolov et al., 2013a; Pennington et al., 2014).

Some prior work has studied differences in performance of different embedding sets. For example, Chen et al. (2013) show that the embedding sets HLBL (Mnih and Hinton, 2009), SENNA (Collobert and Weston, 2008), Turian (Turian et al., 2010) and Huang (Huang et al., 2012) have great variance in quality and characteristics of the semantics captured. Hill et al. (2014; 2015a) show that embeddings learned by NN machine translation models can outperform three representative monolingual embedding sets: word2vec (Mikolov et al., 2013b), GloVe (Pennington et al., 2014) and CW (Collobert and Weston, 2008). Bansal et al. (2014) find that Brown clustering, SENNA, CW, Huang and word2vec yield significant gains for dependency parsing. Moreover, using these representations together achieved the best results, suggesting their complementarity. These prior studies motivate us to explore an ensemble approach. Each embedding set is trained by a different NN on a different corpus, hence can be treated as a distinct description of words. We want to leverage this *diversity* to learn better-performing word embeddings. Our expectation is that the ensemble contains more information than each component embedding set.

The ensemble approach has two benefits. First, *enhancement* of the representations: metaembeddings perform better than the individual embedding sets. Second, *coverage*: metaembeddings cover more words than the individual embedding sets. The first three ensemble methods we introduce are CONC, SVD and 1TON and they directly only have the benefit of enhancement. They learn metaembeddings on the overlapping vocabulary of the embedding sets. CONC concatenates the vectors of a word from the different embedding sets. SVD performs dimension reduction on this concatenation. 1TON assumes that a metaembedding for the word exists, e.g., it can be a randomly initialized vector in the beginning, and uses this metaembedding to predict representations of the word in the individual embedding sets by projections – the resulting fine-tuned metaembedding is expected to contain knowledge from all individual embedding sets.

To also address the objective of increased coverage of the vocabulary, we introduce 1TON$^+$,

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1351–1360,
Berlin, Germany, August 7-12, 2016.

a modification of 1TON that learns metaembeddings for all words in the *vocabulary union* in one step. Let an out-of-vocabulary (OOV) word w of embedding set ES be a word that is not covered by ES (i.e., ES does not contain an embedding for w).[1] 1TON$^+$ first randomly initializes the embeddings for OOVs and the metaembeddings, then uses a prediction setup similar to 1TON to update metaembeddings *as well as OOV embeddings*. Thus, 1TON$^+$ simultaneously achieves two goals: learning metaembeddings and extending the vocabulary (for both metaembeddings and individual embedding sets).

An alternative method that increases coverage is MUTUALLEARNING. MUTUALLEARNING learns the embedding for a word that is an OOV in embedding set from its embeddings in other embedding sets. We will use MUTUALLEARNING to increase coverage for CONC, SVD and 1TON, so that these three methods (when used together with MUTUALLEARNING) have the advantages of both performance enhancement and increased coverage.

In summary, metaembeddings have two benefits compared to individual embedding sets: *enhancement* of performance and improved *coverage* of the vocabulary. Below, we demonstrate this experimentally for three tasks: word similarity, word analogy and POS tagging.

If we simply view metaembeddings as a way of coming up with better embeddings, then the alternative is to develop a single embedding learning algorithm that produces better embeddings. Some improvements proposed before have the disadvantage of increasing the training time of embedding learning substantially; e.g., the NNLM presented in (Bengio et al., 2003) is an order of magnitude less efficient than an algorithm like word2vec and, more generally, replacing a linear objective function with a nonlinear objective function increases training time. Similarly, fine-tuning the hyperparameters of the embedding learning algorithm is complex and time consuming. In terms of coverage, one might argue that we can retrain an existing algorithm like word2vec on a bigger corpus. However, that needs much longer training time than our simple ensemble approaches which achieve coverage as well as enhancement with less effort. In many cases, it is not possible to retrain using a different algorithm because the corpus is not publicly available. But even if these obstacles could be overcome, *it is unlikely that there ever will be a single "best" embedding learning algorithm*. So the current situation of multiple embedding sets with different properties being available is likely to persist for the forseeable future. Metaembedding learning is a simple and efficient way of taking advantage of this diversity. As we will show below they combine several complementary embedding sets and the resulting metaembeddings are stronger than each individual set.

[1] We do not consider words in this paper that are not covered by any of the individual embedding sets. OOV refers to a word that is covered by a proper subset of ESs.

2 Related Work

Related work has focused on improving performance on specific tasks by using several embedding sets simultaneously. To our knowledge, there is no work that aims to learn generally useful metaembeddings from individual embedding sets.

Tsuboi (2014) incorporates word2vec and GloVe embeddings into a POS tagging system and finds that using these two embedding sets together is better than using them individually. Similarly, Turian et al. (2010) find that using Brown clusters, CW embeddings and HLBL embeddings for Name Entity Recognition and chunking tasks together gives better performance than using these representations individually.

Luo et al. (2014) adapt CBOW (Mikolov et al., 2013a) to train word embeddings on different datasets – a Wikipedia corpus, search clickthrough data and user query data – for web search ranking and for word similarity. They show that using these embeddings together gives stronger results than using them individually.

Both (Yin and Schütze, 2015) and (Zhang et al., 2016) try to incorporate multiple embedding sets into channels of convolutional neural network system for sentence classification tasks. The better performance also hints the complementarity of component embedding sets, however, such kind of incorporation brings large numbers of training parameters.

In sum, these papers show that using multiple embedding sets is beneficial. However, they either use embedding sets trained on the same corpus (Turian et al., 2010) or enhance embedding sets by more training data, not by innovative learning algorithms (Luo et al., 2014), or make the system architectures more complicated (Yin and

	Vocab Size	Dim	Training Data
HLBL (Mnih and Hinton, 2009)	246,122	100	Reuters English newswire August 1996-August 1997

Table 1: Embedding Sets (Dim: dimensionality of word embeddings).

Schütze, 2015; Zhang et al., 2016). In our work, we can leverage any publicly available embedding set learned by any learning algorithm. Our metaembeddings (i) do not require access to resources such as large computing infrastructures or proprietary corpora; (ii) are derived by fast and simple ensemble learning from existing embedding sets; and (iii) have much lower dimensionality than a simple concatentation, greatly reducing the number of parameters in any system that uses them.

An alternative to learning metaembeddings from embeddings is the MVLSA method that learns powerful embeddings directly from multiple data sources (Rastogi et al., 2015). Rastogi et al. (2015) combine a large number of data sources and also run two experiments on the embedding sets Glove and word2vec. In contrast, our focus is on metaembeddings, i.e., embeddings that are exclusively based on embeddings. The advantages of metaembeddings are that they outperform individual embeddings in our experiments, that few computational resources are needed, that no access to the original data is required and that embeddings learned by new powerful (including nonlinear) embedding learning algorithms in the future can be immediately taken advantage of without any changes being necessary to our basic framework. In future work, we hope to compare MVLSA and metaembeddings in effectiveness (Is using the original corpus better than using embeddings in some cases?) and efficiency (Is using SGD or SVD more efficient and in what circumstances?).

3 Experimental Embedding Sets

In this work, we use five released embedding sets. (i) **HLBL.** Hierarchical log-bilinear (Mnih and Hinton, 2009) embeddings released by Turian et al. (2010);[2] 246,122 word embeddings, 100 dimensions; training corpus: RCV1 corpus (Reuters English newswire, August 1996 – August 1997). (ii) **Huang.**[3] Huang et al. (2012) incorporate global context to deal with challenges raised by words with multiple meanings; 100,232 word embeddings, 50 dimensions; training corpus: April 2010 snapshot of Wikipedia. (iii) **GloVe**[4] (Pennington et al., 2014). 1,193,514 word embeddings, 300 dimensions; training corpus: 42 billion tokens of web data, from Common Crawl. (iv) **CW** (Collobert and Weston, 2008). Released by Turian et al. (2010);[5] 268,810 word embeddings, 200 dimensions; training corpus: same as HLBL. (v) **word2vec** (Mikolov et al., 2013b) CBOW;[6] 929,022 word embeddings (we discard phrase embeddings), 300 dimensions; training corpus: Google News (about 100 billion words). Table 1 gives a summary of the five embedding sets.

The intersection of the five vocabularies has size 35,965, the union has size 2,788,636.

4 Ensemble Methods

This section introduces the four ensemble methods: CONC, SVD, 1TON and 1TON$^+$.

4.1 CONC: Concatenation

In CONC, the metaembedding of w is the concatenation of five embeddings, one each from the five embedding sets. For GloVe, we perform L2 normalization for each dimension across the vocabulary as recommended by the GloVe authors. Then each embedding of each embedding set is L2-normalized. This ensures that each embedding set contributes equally (a value between -1 and 1) when we compute similarity via dot product.

We would like to make use of prior knowledge and give more weight to well performing embedding sets. In this work, we give GloVe and word2vec weight $i > 1$ and weight 1 to the other three embedding sets. We use MC30 (Miller and Charles, 1991) as dev set, since all embedding sets fully cover it. We set $i = 8$, the value in Figure 1

[2] metaoptimize.com/projects/wordreprs

[3] ai.stanford.edu/~ehhuang

[4] nlp.stanford.edu/projects/glove

[5] metaoptimize.com/projects/wordreprs

[6] code.google.com/p/Word2Vec

where performance reaches a plateau. After L2 normalization, GloVe and word2vec embeddings are multiplied by i and remaining embedding sets are left unchanged.

The dimensionality of CONC metaembeddings is $k = 100+50+300+200+300 = 950$. We also tried equal weighting, but the results were much worse, hence we skip reporting it. It nevertheless gives us insight that simple concatenation, without studying the difference among embedding sets, is unlikely to achieve enhancement. The main disadvantage of simple concatenation is that word embeddings are commonly used to initialize words in DNN systems; thus, the high-dimensionality of concatenated embeddings causes a great increase in training parameters.

4.2 SVD: Singular Value Decomposition

We do SVD on above weighted concatenation vectors of dimension $k = 950$.

Given a set of CONC representations for n words, each of dimensionality k, we compute an SVD decomposition $C = USV^T$ of the corresponding $n \times k$ matrix C. We then use U_d, the first d dimensions of U, as the SVD metaembeddings of the n words. We apply L2-normalization to embeddings; similarities of SVD vectors are computed as dot products.

d denotes the dimensionality of metaembeddings in SVD, 1TON and 1TON$^+$. We use $d = 200$ throughout and investigate the impact of d below.

4.3 1TON

Figure 2 depicts the simple neural network we employ to learn metaembeddings in 1TON. White rectangles denote known embeddings. The target to learn is the metaembedding (shown as shaded rectangle). Metaembeddings are initialized randomly.

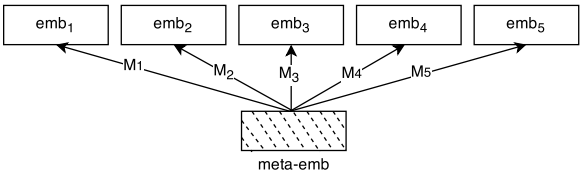

Figure 2: 1toN

Let c be the number of embedding sets under consideration, $V_1, V_2, \ldots, V_i, \ldots, V_c$ their vocabularies and $V^{\cap} = \cap_{i=1}^{c} V_i$ the intersection, *used as training set*. Let V_* denote the metaembedding space. We define a projection f_{*i} from space V_* to space V_i ($i = 1, 2, \ldots, c$) as follows:

$$\hat{\mathbf{w}}_i = \mathbf{M}_{*i}\mathbf{w}_* \quad (1)$$

where $\mathbf{M}_{*i} \in \mathbb{R}^{d_i \times d}$, $\mathbf{w}_* \in \mathbb{R}^d$ is the metaembedding of word w in space V_* and $\hat{\mathbf{w}}_i \in \mathbb{R}^{d_i}$ is the projected (or learned) representation of word w in space V_i. The training objective is as follows:

$$E = \sum_{i=1}^{c} k_i \cdot \Big(\sum_{\mathbf{w} \in V^{\cap}} |\hat{\mathbf{w}}_i - \mathbf{w}_i|^2 + l_2 \cdot |\mathbf{M}_{*i}|^2 \Big) \quad (2)$$

In Equation 2, k_i is the weight scalar of the i^{th} embedding set, determined in Section 4.1, i.e, $k_i = 8$ for GloVe and word2vec embedding sets, otherwise $k_i = 1$; l_2 is the weight of L2 normalization.

The principle of 1TON is that we treat each individual embedding as a projection of the metaembedding, similar to principal component analysis. An embedding is a description of the word based on the corpus and the model that were used to create it. The metaembedding tries to recover a more comprehensive description of the word when it is trained to predict the individual descriptions.

1TON can also be understood as a sentence modeling process, similar to DBOW (Le and Mikolov, 2014). The embedding of each word in a sentence s is a partial description of s. DBOW combines all partial descriptions to form a comprehensive description of s. DBOW initializes the sentence representation randomly, then uses this representation to predict the representations of individual words. The sentence representation of s corresponds to the metaembedding in 1TON; and the representations of the words in s correspond to the five embeddings for a word in 1TON.

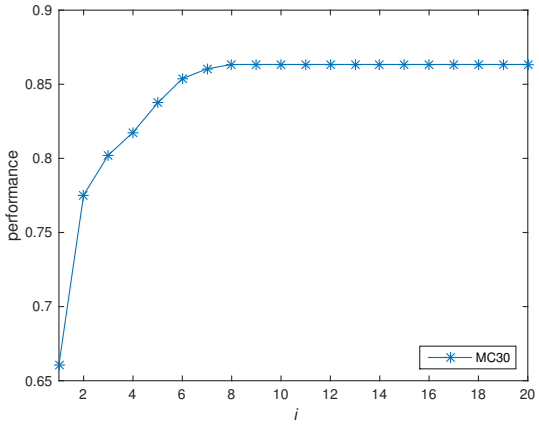

Figure 1: Performance vs. Weight scalar i

4.4 1TON$^+$

Recall that an OOV (with respect to embedding set ES) is defined as a word unknown in ES. 1TON$^+$ is an extension of 1TON that learns embeddings for OOVs; thus, it does not have the limitation that it can only be run on overlapping vocabulary.

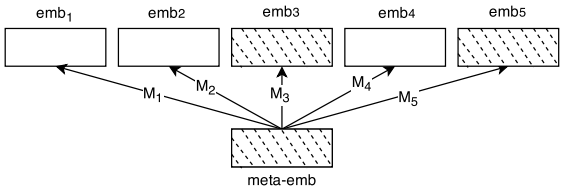

Figure 3: 1toN$^+$

Figure 3 depicts 1TON$^+$. In contrast to Figure 2, we assume that the current word is an OOV in embedding sets 3 and 5. Hence, in the new learning task, embeddings 1, 2, 4 are known, and embeddings 3 and 5 and the metaembedding are targets to learn.

We initialize all OOV representations and metaembeddings randomly and use the same mapping formula as for 1TON to connect a metaembedding with the individual embeddings. Both metaembedding and initialized OOV embeddings are updated during training.

Each embedding set contains information about only a part of the overall vocabulary. However, it can predict what the remaining part should look like by comparing words it knows with the information other embedding sets provide about these words. Thus, 1TON$^+$ learns a model of the dependencies between the individual embedding sets and can use these dependencies to infer what the embedding of an OOV should look like.

CONC, SVD and 1TON compute metaembeddings only for the intersection vocabulary. 1TON$^+$ computes metaembeddings for the union of all individual vocabularies, thus greatly increasing the coverage of individual embedding sets.

5 MUTUALLEARNING

MUTUALLEARNING is a method that extends CONC, SVD and 1TON such that they have increased coverage of the vocabulary. With MUTUALLEARNING, all four ensemble methods – CONC, SVD, 1TON and 1TON$^+$ – have the benefits of both performance enhancement and increased coverage and we can use criteria like performance, compactness and efficiency of training to select the best ensemble method for a particular application.

	bs	lr	l_2
1TON	200	0.005	5×10^{-4}
MUTUALLEARNING (ml)	200	0.01	5×10^{-8}
1TON$^+$	2000	0.005	5×10^{-4}

Table 2: Hyperparameters. bs: batch size; lr: learning rate; l_2: L2 weight.

MUTUALLEARNING is applied to learn OOV embeddings for all c embedding sets; however, for ease of exposition, let us assume we want to compute embeddings for OOVs for embedding set j only, based on known embeddings in the other $c-1$ embedding sets, with indexes $i \in \{1 \dots j-1, j+1 \dots c\}$. We do this by learning $c-1$ mappings f_{ij}, each a projection from embedding set E_i to embedding set E_j.

Similar to Section 4.3, we train mapping f_{ij} on the intersection $V_i \cap V_j$ of the vocabularies covered by the two embedding sets. Formally, $\hat{\mathbf{w}}_j = f_{ij}(\mathbf{w}_i) = \mathbf{M}_{ij}\mathbf{w}_i$ where $\mathbf{M}_{ij} \in \mathbb{R}^{d_j \times d_i}$, $\mathbf{w}_i \in \mathbb{R}^{d_i}$ denotes the representation of word w in space V_i and $\hat{\mathbf{w}}_j$ is the projected metaembedding of word w in space V_j. Training loss has the same form as Equation 2 except that there is no "$\sum_{i=1}^{c} k_i$" term. A total of $c-1$ projections f_{ij} are trained to learn OOV embeddings for embedding set j.

Let w be a word unknown in the vocabulary V_j of embedding set j, but known in $V_1, V_2, \dots, V_k$. To compute an embedding for w in V_j, we first compute the k projections $f_{1j}(\mathbf{w}_1)$, $f_{2j}(\mathbf{w}_2)$, ..., $f_{kj}(\mathbf{w}_k)$ from the source spaces $V_1, V_2, \dots, V_k$ to the target space V_j. Then, the element-wise average of $f_{1j}(\mathbf{w}_1)$, $f_{2j}(\mathbf{w}_2)$, ..., $f_{kj}(\mathbf{w}_k)$ is treated as the representation of w in V_j. Our motivation is that – assuming there is a true representation of w in V_j and assuming the projections were learned well – we would expect all the projected vectors to be close to the true representation. Also, each source space contributes potentially complementary information. Hence averaging them is a balance of knowledge from all source spaces.

6 Experiments

We train NNs by back-propagation with AdaGrad (Duchi et al., 2011) and mini-batches. Table 2 gives hyperparameters.

We report results on three tasks: word similarity, word analogy and POS tagging.

		Model	SL999	WS353	MC30	MEN	RW	sem.	syn.	tot.

Table 3: Results on five word similarity tasks (Spearman correlation metric) and analogical reasoning (accuracy). The number of OOVs is given in parentheses for each result. "ind-full/ind-overlap": individual embedding sets with respective full/overlapping vocabulary; "ensemble": ensemble results using all five embedding sets; "discard": one of the five embedding sets is removed. If a result is better than all methods in "ind-overlap", then it is bolded. Significant improvement over the best baseline in "ind-overlap" is underlined (online toolkit from `http://vassarstats.net/index.html` for Spearman correlation metric, test of equal proportions for accuracy, $p < .05$).

Table 4: Comparison of effectiveness of four methods for learning OOV embeddings. RND: random initialization. AVG: average of embeddings of known words. ml: MUTUALLEARNING. RW(21) means there are still 21 OOVs for the vocabulary union.

6.1 Word Similarity and Analogy Tasks

We evaluate on SimLex-999 (Hill et al., 2015b), WordSim353 (Finkelstein et al., 2001), MEN (Bruni et al., 2014) and RW (Luong et al., 2013). For completeness, we also show results for MC30, the validation set.

The word analogy task proposed in (Mikolov et al., 2013b) consists of questions like, "a is to b as c is to _ ?". The dataset contains 19,544 such questions, divided into a semantic subset of size 8869 and a syntactic subset of size 10,675. Accuracy is reported.

We also collect the state-of-the-art report for each task. SimLex-999: (Wieting et al., 2015), WS353: (Halawi et al., 2012). Not all state-of-the-art results are included in Table 3. One reason is that a fair comparison is only possible on the shared vocabulary, so methods without released embeddings cannot be included. In addition, some prior systems can possibly generate better performance, but those literature reported lower results than ours because different hyperparameter setup, such as smaller dimensionality of word embeddings or different evaluation metric. In any case, our main contribution is to present ensemble frameworks which show that a combination of complementary embedding sets produces better-performing metaembeddings.

Table 3 reports **results on similarity and analogy**. Numbers in parentheses are the sizes of words in the datasets that are uncovered by intersection vocabulary. We do not consider them for fair comparison. Block "ind-full" (1-5) lists the performance of individual embedding sets on the *full vocabulary*. Results on lines 6-34 are for the intersection vocabulary of the five embedding sets: "ind-overlap" contains the performance of individual embedding sets, "ensemble" the performance of our four ensemble methods and "discard" the performance when one component set is removed.

The four ensemble approaches are very promising (31-34). For CONC, discarding HLBL, Huang or CW does not hurt performance: CONC (31), CONC(-HLBL) (11), CONC(-Huang) (12) and CONC(-CW) (14) beat each individual embedding set (6-10) in all tasks. GloVe contributes most in SimLex-999, WS353, MC30 and MEN; word2vec contributes most in RW and word analogy tasks.

SVD (32) reduces the dimensionality of CONC from 950 to 200, but still gains performance in SimLex-999 and MEN. GloVe contributes most in SVD (larger losses on line 18 vs. lines 16-17, 19-20). Other embeddings contribute inconsistently.

1TON performs well only on word analogy, but it gains great improvement when discarding CW embeddings (24). 1TON$^+$ performs better than 1TON: it has stronger results when considering all embedding sets, and can still outperform individual embedding sets while discarding HLBL (26), Huang (27) or CW (29).

These results demonstrate that ensemble methods using multiple embedding sets produce stronger embeddings. However, *it does not mean the more embedding sets the better. Whether an embedding set helps, depends on the complementarity of the sets and on the task.*

CONC, the simplest ensemble, has robust performance. However, size-950 embeddings as input means a lot of parameters to tune for DNNs. The other three methods (SVD, 1TON, 1TON$^+$) have the advantage of smaller dimensionality. SVD reduces CONC's dimensionality dramatically and still is competitive, especially on word similarity. 1TON is competitive on analogy, but weak on word similarity. 1TON$^+$ performs consistently strongly on word similarity and analogy.

Table 3 uses the metaembeddings of intersection vocabulary, hence it shows directly the *quality enhancement* by our ensemble approaches; this enhancement is not due to bigger coverage.

System comparison of learning OOV embeddings. In Table 4, we extend the vocabularies of each individual embedding set ("ind" block) and our ensemble approaches ("ensemble" block) to the vocabulary union, reporting results on RW and analogy – these tasks contain the most OOVs. As both word2vec and GloVe have full coverage on analogy, we do not rereport them in this table. This subtask is specific to "coverage" property. Apparently, our mutual learning and 1TON$^+$ can cover the union vocabulary, which is bigger than each individual embedding sets. But the more important issue is that we should keep or even improve the embedding quality, compared with their original embeddings in certain component sets.

For each embedding set, we can compute the representation of an OOV (i) as a randomly initialized vector (RND); (ii) as the average of embeddings of all known words (AVG); (iii) by MUTUALLEARNING (ml) and (iv) by 1TON$^+$. 1TON$^+$ learns OOV embeddings for individual embedding sets and metaembeddings simultaneously, and it

Table 5: POS tagging results on six target domains. "baselines" lists representative systems for this task, including FLORS. "+indiv / +meta": FLORS with individual embedding set / metaembeddings. Bold means higher than "baselines" and "+indiv".

would not make sense to replace these OOV embeddings computed by 1TON$^+$ with embeddings computed by "RND/AVG/ml". Hence, we do not report "RND/AVG/ml" results for 1TON$^+$.

Table 4 shows four interesting aspects. (i) MUTUALLEARNING helps much if an embedding set has lots of OOVs in certain task; e.g., MUTUALLEARNING is much better than AVG and RND on RW, and outperforms RND considerably for CONC, SVD and 1TON on analogy. However, it cannot make big difference for HLBL/CW on analogy, probably because these two embedding sets have much fewer OOVs, in which case AVG and RND work well enough. (ii) AVG produces bad results for CONC, SVD and 1TON on analogy, especially in the syntactic subtask. We notice that those systems have large numbers of OOVs in word analogy task. If for analogy "a is to b as c is to d", all four of a, b, c, d are OOVs, then they are represented with the same average vector. Hence, similarity between $b - a + c$ and each OOV is 1.0. In this case, it is almost impossible to predict the correct answer d. Unfortunately, methods CONC, SVD and 1TON have many OOVs, resulting in the low numbers in Table 4. (iii) MUTUALLEARNING learns very effective embeddings for OOVs. *CONC-ml,* 1TON*-ml and SVD-ml all get better results than word2vec and GloVe on analogy (e.g., for semantic analogy: 88.1, 87.3, 88.2 vs. 81.4 for GloVe).* Considering further their bigger vocabulary, these ensemble methods are very strong representation learning algorithms. (iv) The performance of 1TON$^+$ for learning embeddings for OOVs is competitive with MUTUALLEARNING. For HLBL/Huang/CW, 1TON$^+$ performs slightly better than MUTUALLEARNING in all four met-

rics. Comparing 1TON-ml with 1TON$^+$, 1TON$^+$ is better than "ml" on RW and semantic task, while performing worse on syntactic task.

Figure 4 shows the **influence of dimensionality** d for SVD, 1TON and 1TON$^+$. Peak performance for different data sets and methods is reached for $d \in [100, 500]$. There are no big differences in the averages across data sets and methods for high enough d, roughly in the interval $[150, 500]$. In summary, as long as d is chosen to be large enough (e.g., ≥ 150), performance is robust.

6.2 Domain Adaptation for POS Tagging

In this section, we test the quality of those individual embedding embedding sets and our metaembeddings in a Part-of-Speech (POS) tagging task. For POS tagging, we add word embeddings into FLORS[7] (Schnabel and Schütze, 2014) which is the state-of-the-art POS tagger for unsupervised domain adaptation.

FLORS tagger. It treats POS tagging as a window-based (as opposed to sequence classification), multilabel classification problem using LIBLINEAR,[8] a linear SVM. A word's representation consists of four feature vectors: one each for its suffix, its shape and its left and right distributional neighbors. Suffix and shape features are standard features used in the literature; our use of them in FLORS is exactly as described in (Schnabel and Schütze, 2014).

Let $f(w)$ be the concatenation of the two distributional and suffix and shape vectors of word w. Then FLORS represents token v_i as follows:
$f(v_{i-2}) \oplus f(v_{i-1}) \oplus f(v_i) \oplus f(v_{i+1}) \oplus f(v_{i+2})$
where $\oplus$ is vector concatenation. Thus, token v_i is tagged based on a 5-word window.

FLORS is trained on sections 2-21 of Wall Street Journal (WSJ) and evaluate on the development sets of six different target domains: five SANCL (Petrov and McDonald, 2012) domains – newsgroups, weblogs, reviews, answers, emails – and sections 22-23 of WSJ for in-domain testing.

Original FLORS mainly depends on distributional features. We insert word's embedding as the *fifth* feature vector. All embedding sets (except for 1TON$^+$) are extended to the union vocabulary by MUTUALLEARNING. We test if this additional feature can help this task.

Table 5 gives results for some representative systems ("baselines"), FLORS with individual embedding sets ("+indiv") and FLORS with metaembeddings ("+meta"). Following conclusions can be drawn. (i) Not all individual embedding sets are beneficial in this task; e.g., HLBL embeddings make FLORS perform worse in 11 out of 12 cases. (ii) However, in most cases, embeddings improve system performance, which is consistent with prior work on using embeddings for this type of task (Xiao and Guo, 2013; Yang and Eisenstein, 2014; Tsuboi, 2014). (iii) Metaembeddings generally help more than the individual embedding sets, except for SVD (which only performs better in 3 out of 12 cases).

7 Conclusion

This work presented four ensemble methods for learning metaembeddings from multiple embedding sets: CONC, SVD, 1TON and 1TON$^+$. Experiments on word similarity and analogy and POS tagging show the high quality of the metaembeddings; e.g., they outperform GloVe and word2vec on analogy. The ensemble methods have the added advantage of increasing vocabulary coverage. We make our metaembeddings available at `http://cistern.cis.lmu.de/meta-emb`.

Abstract

In this paper, we investigate the possibility to automatically generate sports news from live text commentary scripts. As a preliminary study, we treat this task as a special kind of document summarization based on sentence extraction. We formulate the task in a supervised learning to rank framework, utilizing both traditional sentence features for generic document summarization and novelly designed task-specific features. To tackle the problem of local redundancy, we also propose a probabilistic sentence selection algorithm. Experiments on our collected data from football live commentary scripts and corresponding sports news demonstrate the feasibility of this task. Evaluation results show that our methods are indeed appropriate for this task, outperforming several baseline methods in different aspects.

1 Introduction

There are a huge number of sports games played each day. It is demanding and challenging to write corresponding news reports instantly after various games. Meanwhile, live text commentary services are available on the web and becoming increasingly popular for sports fans who do not have access to live video streams due to copyright reasons. Some people may also prefer live texts on portable devices. The emergence of live texts has produced huge amount of text commentary data. To the best of our knowledge, there exists few studies about utilizing this rich data source.

Manually written sports news for match report usually share the same information and vocabulary as live texts for the corresponding sports game. Sports news and commentary texts can be treated as two different sources of descriptions for the same sports events. It is tempting to investigate whether we can utilize the huge amount of live texts to automatically construct sports news, typically in a form of match report. Building such a system will largely relax the burden of sports news editors, making them free from repetitive tedious efforts for writing while producing sports news more efficiently.

In this work, we study the possibility to construct sports news in the form of match reports from given live text commentary scripts. As a concrete example we collect live text data and corresponding news reports for football (called soccer more often in the United States) games and conduct our study thereby. However, our methods and discussions made in this paper can be trivially adapted to other types of sports games as well.

As a preliminary study, we treat this task as a special kind of document summarization: extracting sentences from live texts to form a match report as generated news. However, generating sports news from live texts is still challenging due to some unique properties of live text commentary scripts. For almost every minute of the game there are usually several sentences describing various kinds of events. Texts are ordered and organized by the timeline, without apparent highlights for many important events [1]. Descriptions are usually in short sentences, which is not helpful for sentence scoring and selection in general. The commentators may tend to use similar, repeated words describing the same type of key events, which may bring additional challenges to traditional summarization methods that are designed to avoid literal repetitions in nature. As a result, naively treating the task as an ordinary document summarization

[1] Some live texts services may use different textual format for scoring events, which is not enough for our more general purposes.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1361–1371,
Berlin, Germany, August 7-12, 2016.

problem can hardly lead to the construction of reasonable sports news reports.

To overcome these difficulties, we explore some specific features of live text commentary scripts and formulate a system based on supervised learning to rank models for this task. In order to tackle the local redundancy issue, we also propose a probabilistic sentence selection strategy.

We summarize our contributions as follows:

- We originally study the task of sports news construction from live text commentary and we build datasets for supervised learning and evaluation for this task.
- We formulate the task in a learning to rank framework, utilizing both traditional features for document summarization and novel task-specific features during supervised learning.
- We propose a probabilistic sentence selection algorithm to address the issue of local redundancy in description.
- We conduct a series of experiments on a real dataset and the evaluation results verify the performance of our system. Results suggest that constructing sports news from live texts is feasible and our proposed methods can outperform a few strong baselines.

2 Problem Statement

2.1 Task Description

In this work, we treat the task of constructing sports news from live text commentary as a special kind of document summarization: extracting sentences from live text scripts to form a match report.

Formally, given a piece of live text commentary containing a collection of candidate sentences $S = \{s_1, s_2, \ldots, s_n\}$ describing a particular sports game G, we need to extract sentences to form a summary of G which are suitable to be formed as sports news. The total length should not exceed a pre-specified length budget B.

The overall framework of generic document summarization can still be retained for this preliminary study. We first rank all candidate sentences according to a sentence scoring scheme and then select a few sentences according to certain criteria to form the final generated news.

2.2 Data Collection

To the best of our knowledge, there does not exist off-the-shelf datasets for evaluating sports news construction. Therefore we have to build a new dataset for this study. We will focus on live text scripts for football (soccer) games as a concrete instance, since football live texts are the easiest to collect. Note that the methods and discussions described in this paper can trivially generalize to other types of sports games.

Meanwhile, live text commentary services are extremely popular in China, where sports fans in many cases do not have access to live video streams due to copyright reasons. The most influential football live services are Sina Sports Live [2] and 163 Football Live [3]. For evaluation purposes we need to simultaneously collect both live texts and news texts describing the same sports games. Due to the convenience and availability of parallel data collection, we build our dataset from Chinese websites. For most football games, there exist both live text scripts recorded after the games and human-written news reports on both Sina Sports and 163 Football. We crawl live text commentary scripts for 150 football matches on Sina Sports Live. Figure 1 displays an example of the format of the live texts, containing the main commentary text along with information of the current timeline and scoreline.

Text Commentary	Timeline	Scoreline
莱万多夫斯基右路传球给到穆勒 (Lewandowski passes the ball to the right and finds Müller)	上半场 42' (first half 42')	2-0
穆勒停球后直接射门 (Müller stops the ball and gets a direct shot)	上半场 43' (first half 43')	2-0
切赫这边反应很快将球托出横梁 (Fast reaction from Cech to tip the ball over the bar)	上半场 43' (first half 43')	2-0

Figure 1: Illustration of the live text format

For every match, two different corresponding sports news reports are collected from Sina Sports Live and 163 Football Matches Live, respectively. These news reports are manually written by professional editors and therefore suitable to be treated as gold-standard news for our task. The average number of sentences in the live texts for one match is around 242, containing around 4,590 Chinese characters for that match. The gold-standard news reports contain 1,185 Chinese characters on average, forming around 32 sentences.

For both the gold-standard news and live text commentary scripts, we split them into sentences

[2] http://match.sports.sina.com.cn/
[3] http://goal.sports.163.com/

and then use a Chinese word segmentation tool [4] to segment the sentences into word sequences. For each sentence, we compute its TFIDF vector for calculating literal cosine similarity when used.

3 Constructing Sports News via Sentence Extraction

We build a system to automatically construct match reports from live text commentary. Since we have described the new challenges for this task, we may design a number of relevant features to address them. In this work, we cast the problem into supervised sentence extraction. Supervised approaches, especially those based on learning to rank (LTR), can better utilize the power of various task-dependent features (Shen and Li, 2011; Wang et al., 2013). For a given specific sports game, we extract features from all candidate sentences in the corresponding live texts and score the sentences using a learning to rank (LTR) model learned from the training data (Section 3.1). Then we select a few of them according to the ranking scores to form the constructed news (Section 3.3).

3.1 Training Data Format

Supervised sentence scoring models based on LTR require input training data in the format of (x_i, y_i) for each candidate sentence s_i, where x_i is the feature vector and y_i is the preference score. The feature vector x is described in Section 3.2. The score y will be defined to reflect the importance, or the tendency to be included in the final news report, of the candidate sentence. In this work we first calculate a group of ROUGE-2 F-scores (cf. Section 4.4.1) of the candidate sentence, treating each sentence in the gold-standard news as reference. The score y of the candidate sentence is then set to be the maximum among those ROUGE-2 F-scores. Later we will see that this scores can indeed serve as good learning targets.

3.2 Features

In this work, we extract both common features which have been widely used for generic document summarization (Shen and Li, 2011; Wang et al., 2013) and novel task-specific features aiming at proper sports news generation from live broadcast script. The features are described as follows.

3.2.1 Basic Features

Position: The position of each candidate sentence. Suppose there are n sentences in a document. For the i-th sentence, its position feature is computed as $1 - \frac{i-1}{n}$.

Length: The number of words contained in the sentence after stopwords removal.

Number of stopwords: The Number of stopwords contained in each sentence. Sentences with many stopwords should be treated as less important candidates.

Sum of word weights: The sum of TF-IDF weights for each word in a sentence.

Similarity to the Neighboring Sentences: We calculate the average cosine similarity of a candidate sentence to its previous N and the next N neighboring sentences. We set N as 1 and 2 here to get two different features.

3.2.2 Task-specific Features

The task we study has some unique properties compared with generic document summarization. For instance, in live text commentary for sports games such as football matches, the scripts not only contain descriptive texts but also the scoreline and timeline information. Such information can be utilized to judge the quality of candidate sentences as well. We extract a rich set of new features, which can be grouped into four types:

Explicit highlight markers: Explicit highlight marker words in a sentence are usually good indicators for its importance. Sentences with more marker words are more probable to be extracted and contained in news or reports for the games. For example, words such as "破门 (scores)" and "红牌 (red card)" in a sentence may indicate that the sentence is describing important events and will be more likely to be extracted. We collect a short list of 25 explicit highlight marker words [5]. For each marker word we create a binary feature to denote the presence or absence of that markers in each candidate sentence. We also use the number of markers as one feature, with the intuition that containing more marker words typically suggests more important sentences.

Scoreline features: An audience of sports games typically pays more attention on scoreline changes, especially those deadlock-breaking scores that break the game from ties. We use three

[4] We use the ICTCLAS toolkit for word segmentation in this work: http://ictclas.nlpir.org/

[5] We include the full list of marker words in the supplementary materials due to the space limit.

binary features to describe the scoreline information of each candidate sentence:

- An indicator feature on whether there was a change of scoreline when the narrator or commentator was producing that sentence.
- An indicator feature on whether the distance between the candidate sentence and the previous closest sentence with a change of scoreline is less than or equal to 5.
- An indicator feature showing whether the game was a draw or not at that time.

To better describe these features we give an example in Figure 2, where S1-S3 corresponds to the above three binary features, respectively.

Text Commentary	Timeline	Scoreline	S1	S2	S3
Both sides take advantages of counter attacks.	32'	1-1	0	0	0
1-2!!	33'	1-2	1	1	1
Alexis!!	33'	1-2	0	1	1
Özil finds the teammate byline followed by a low cross to far post, Alexis sends the ball into the net!	34'	1-2	0	1	1
Leicester players are unhappy.	34'	1-2	0	1	1

Figure 2: An example of scoreline features

Timeline features: The timestamp on each sentence can reflect the progress of a sports game. We divide a match into five different stages as "未赛 (not started)", "上半场(first half)", "中场休息(half-time)", "下半场(second half)" and "完赛(full-time)". Then we use five binary features to represent whether the sentence was describing a specific stage. We also use the specific time-stamp (in integral minutes) of the candidate sentence in the match as an additional feature. Suppose there are n minutes of the match (typically 90 minutes for football), for sentences on the time-stamp of the i-th minute , this feature is computed as $\frac{i}{n}$.

Player popularity: Sports fans usually focus more on the performance of the star players or inform players during the games. We design two features to utilize player information described in a candidate sentence: the number of players contained in the sentence and the sum of their popularity measurements. In this work the popularity of a player is measured using search engines for news: we use the name of a certain player as input query to Baidu News [6], and use the number of recent news retrieved to measure this player's popularity.

[6]http://news.baidu.com/

3.3 Sentence Selection

Once we have the trained LTR model, we can immediately construct news reports by selecting sentences with the highest scores. Unfortunately this simple strategy will suffer from redundancy in commentary, since the LTR scores are predicted independently for each sentence and assigning high scores for repeated commentary texts describing the same key event. Therefore, special care is needed in sentence selection. In principle, any In this work we propose a probabilistic approach based on determinantal point processes (Kulesza and Taskar, 2012, DPPs). This approach can naturally integrate the predicted scores from the LTR model while trying to avoid certain redundancy by producing more diverse extractions [7]. We first review some background knowledge on the model. More details can be found in the comprehensive survey (Kulesza and Taskar, 2012) covering this topic.

3.3.1 Determinantal Point Processes

Determinantal point processes (DPPs) are distributions over subsets that jointly prefer quality of each item and diversity of the whole subset. Formally, a DPP is a probability measure defined on all possible subsets of a group of items $\mathcal{Y} = \{1, 2, \ldots, N\}$. For every $Y \subseteq \mathcal{Y}$ we have:

$$\mathcal{P}(Y) = \frac{\det(L_Y)}{\det(L + I)}$$

where L is a positive semidefinite matrix typically called an *L-ensemble*. $L_Y \equiv [L_{ij}]_{i,j \in Y}$ denotes the restriction of L to the entries indexed by elements of Y, and $\det(L_\emptyset) = 1$. The term $\det(L + I)$ is the normalization constant which has a succinct closed-form and easy to compute. We can define the entries of L as follows:

$$L_{ij} = q_i \phi_i^\top \phi_j q_j = q_i \cdot \mathrm{sim}(i, j) \cdot q_j \qquad (1)$$

where we can think of $q_i \in \mathbb{R}^+$ as the *quality* of an item i and $\phi_i \in \mathbb{R}^n$ with $\|\phi_i\|_2 = 1$ denotes a normalised feature vector such that $\mathrm{sim}(i, j) \in [-1, 1]$ measures *similarity* between item i and item j. This simple definition gives rise to a distribution that places most of its mass on sets that are both high quality and diverse. This is intuitive in a

[7]Many other approaches can also be used to achieve similar effect, such as submodular maximization (Lin and Bilmes, 2010). We leave the comparison with these alternatives for future work study.

geometric sense since determinants are closely related to volumes; in particular, $\det(L_Y)$ is proportional to the volume spanned by the vectors $q_i\phi_i$ for $i \in Y$. Thus, item sets with both high-quality and diverse items will have the highest probability (Figure 3).

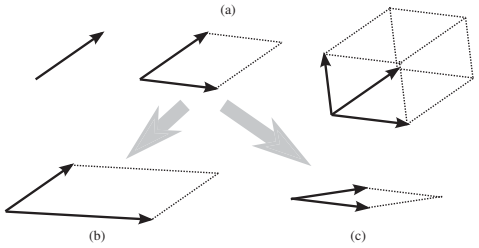

Figure 3: (a) The DPP probability of a set Y depends on the volume spanned by vectors $q_i\phi_i$ for $i \in Y$ (b) As length increases, so does volume. (c) As similarity increases, volume decreases.

3.3.2 Sentence Selection

In this work we formulate the sentence selection problem as maximum a posteriori (MAP) inference for DPPs, i.e. finding $\text{argmax}_Y \log\det(L_Y)$. It is known that MAP inference for DPPs is NP-hard (Gillenwater et al., 2012). Therefore we adopt the greedy approximate inference procedure used by Kulesza and Taskar (2011) which is fast and performs reasonably well in practice.

The remaining question is how to define the L-ensemble matrix L, or equivalently how to define itemwise quality q_i and pairwise similarity $\text{sim}(i, j)$, where each item corresponds to a candidate sentence. Since we have predicted scores for all candidates with the LTR model, we simply set q_i to be the ranking score for sentence i.

The definition of $\text{sim}(i, j)$ is more subtle since it directly address specific types of redundancy. The most straightforward definition is to use literal cosine similarity. This is used for traditional summarization problems (Kulesza and Taskar, 2011). However, the problem for constructing sports news from live broadcast script is rather different. A live broadcast script may use literally similar sentences to describe similar types of events happened at different time stamps. Simply removing sentences that are similar in content may become harmful to the preservation of important events [8].

One typical redundancy that we found in this study is local description redundancy. In live texts, an important event (such as goals) may be stressed multiple times consecutively by the commentator. Therefore in this study we use local literal similarity as a first attempt. Formally, the pairwise similarity is defined as:

$$\text{sim}(i,j) = \begin{cases} 0, \text{if } \max\{|i_p - j_p|, |i_t - j_t|\} > 1, \\ \cos(i,j), \text{ otherwise,} \end{cases}$$

where the subscripts i_p and i_t denotes position and timestamp for sentence i, respectively. In other words we treat sentences written consecutively within one minute as local descriptions and only calculate literal cosine similarity for them.

4 Experimental Setup

4.1 Data Preparation

As described earlier in Section 2.2, we evaluate the performance of different systems on our collected dataset. To utilize the dataset more sufficiently and draw more reliable conclusions, we perform cross-validation during evaluation. Specifically, we randomly divide the dataset into three parts with equal sizes, i.e. each has 50 pairs of live texts and gold-standard news. Each time we set one of them as the test set and use the remaining two parts for training and validation. We will mainly report the averaged results from all three folds. For unsupervised baselines the results are calculated similarly via averaging the performance on the test set.

4.2 Learning to Rank

For predicting ranking scores we use the Random Forest (RF) (Breiman, 2001) ensemble ranker of LambdaMart (Wu et al., 2010), implemented in RankLib [9]. We set the number of iterations to 300 and the sampling rate to 0.3. Using different values did not show real differences.

4.3 Compared Baseline Methods

Our system is compared with several baselines, typically traditional summarization approaches:

HeadTail: Using head and tail sentences only. Commentators usually describe some basic information of the two sides at the beginning and summarize the scoring events in the end of commentary. This baseline resembles the baseline of leading sentences for traditional summarization.

[8] Using cosine similarity for all similarity-dependent methods performs poorly in our experiments. Therefore we will not discuss cosine similarity in more details later.

[9] http://sourceforge.net/p/lemur/wiki/RankLib/; In preliminary experiments, we contrasted RF with support vector regression predictor as well as other pairwise and listwise LTR models. We found that RF consistently outperformed others.

Centroid: In centroid-based summarization (Radev et al., 2000), a pseudo-sentence of the document called centroid is calculated. The centroid consists of words with TFIDF scores above a predefined threshold. The score of each sentence is defined by summing the scores based on different features including cosine similarity of sentences with the centroid, position weight and cosine similarity with the first sentence.

LexRank: LexRank (Erkan and Radev, 2004) computes sentence importance based on the concept of eigenvector centrality in a graph representation of sentences. In this model, a connectivity matrix based on intra-sentence cosine similarity is used as the adjacency matrix of the graph representation of sentences.

ILP: Integer linear programming (ILP) approaches (Gillick et al., 2008) cast document summarization as combinatorial optimization. An ILP model selects sentences by maximizing the sum of frequency-induced weights of bigram concepts [10] contained in the summary.

Highlight: This method is designed to show the effect of using merely the explicit highlight markers described in Section 3.2.2. The importance of a sentence is represented by the number of highlight markers it includes.

For fair comparisons the length of each constructed news report is limited to be no more than 1,000 Chinese characters, roughly the same with the average length of the gold-standard news. Note that we do not use the traditional MMR redundancy removal algorithm based on literal similarity (Carbonell and Goldstein, 1998) since we find only ignorable differences between using MMR or not for all systems.

4.4 Evaluation Methods and Metrics

4.4.1 Automatic Evaluation

Similar to the evaluation for traditional summarization tasks, we use the ROUGE metrics (Lin and Hovy, 2003) to automatically evaluate the quality of produced summaries given the gold-standard reference news. The ROUGE metrics measure summary quality by counting the precision, recall and F-score of overlapping units, such as n-grams and skip grams, between a candidate summary and the reference summaries.

We use the ROUGE-1.5.5 toolkit to perform the evaluation. In this paper we report the F-scores of the following metrics in the experimental results: ROUGE-1 (unigram-based), ROUGE-2 (bigram-based) and ROUGE-SU4 (based on skip bigrams with a maximum skip distance of 4).

4.4.2 Pyramid Evaluation

We also conduct manual pyramid evaluation in this study. Specifically, we use the modified pyramid scores as described in (Passonneau et al., 2005) to manually evaluate the summaries generated by different methods. We randomly sample 20 games from the data set and manually annotate facts on the gold-standard news. The annotated facts are mostly describing specific events happened during the game, e.g. "伊万被黄牌警告" (Ivanovic is shown the yellow card) and "内马尔开出角球" (Neymar takes the corner). Each fact is treated as a Summarization Content Unit, (SCU) (Nenkova and Passonneau, 2004). The number of occurrences for each SCU in the gold-standard news is regarded as the weight of this SCU.

5 Results and Analysis

5.1 Comparison with Baseline Methods

The average performance on all three folds of different methods are displayed in Table 1.

Method	R-1	R-2	R-SU4
HeadTail	0.30147	0.07779	0.10336
Centroid	0.32508	0.08113	0.11245
LexRank	0.31284	0.06159	0.09376
ILP	0.32552	0.07285	0.10378
Highlight	0.34687	0.08748	0.11924
RF	0.38559	0.11887	0.14907
RF+DPP	0.39391	0.11986	0.15097

Table 1: Comparison results of different methods

As we can see from the results, our learning to rank approach based on RF achieves significantly (< 0.01 significance level for pairwise-t testing) better results compared with traditional unsupervised summarization approaches [11]. The ILP model, which is believed to be suitable for multi-document summarization, did not perform well in our settings. Head and tail sentences are informative but merely using them lacks specific descriptions for procedural events, therefore not

[10] We also tried words rather than bigrams but found slightly worse performance.

[11] We also conducted experiments on using our proposed features to calculate LexRank, but did not observe real difference compared with normal LexRank. This suggest that the performance gain comes from supervised learning to rank approach, not merely from the features.

providing competitive results either.

The comparison between RF and RF+DPP shows the effectiveness of our sentence selection strategy. However, the increase is still limited [12]. This may become reasonable later when we discuss more about the errors from our systems.

Merely using highlight markers to construct news also provides competitive results, but inferior to supervised models. This suggests that the highlight marker features are relatively strong indicators for good sentences while merely using these features may not be sufficient.

Table 2 shows the average pyramid scores for the systems in comparison. The "Gold-standard" row denotes manually written news report and is listed for reference. We can see our learning to rank systems based on RF constructs news with the highest pyramid scores.

Method	Pyramid scores
HeadTail	0.13657
Centroid	0.30663
LexRank	0.28756
ILP	0.20867
Highlight	0.41121
RF	0.53766
RF+DPP	0.62500
Gold-standard	0.88329

Table 2: Average Pyramid scores

Overall, the experimental results indicate that our system can generate much better news than the baselines in both automatic and manual evaluations. We include examples of our constructed news reports in the supplementary materials.

5.2 Feature Validation

Different groups of features may play different roles in the LTR models. In order to validate the impact of both the traditional features and the novel task-specific features, we conduct experiments with different combinations by removing each group of features respectively. Table 3 shows the results, with "w/o" denotes experiments without the corresponding group of features.

Method	R-1	R-2	R-SU4
RF	0.38559	0.11887	0.14907
RF-w/o novel	0.37297	0.10964	0.14021
RF-w/o trad.	0.36314	0.09910	0.13102

Table 3: Results of feature validation

[12] Significance level < 0.05 for pairwise-t testing only for ROUGE-1.

We can observe that both the traditional features and the novel features contribute useful information for learning to rank models. Due to the nature of the sentence extraction approach, features designed for traditional document summarization are still playing an indispensable role for our task, although they might be important in this work for different reasons. For example, position features are indicative for traditional summarization since sentences appearing in the very beginning or the end are more probable as summarizing sentences. For sports commentary, positions are closely related to timeline in a more coarse fashion. Certain types of key events, for example player substitutions and even scores, may tend to happen in certain period in a game rather than uniformly spread out in every minute.

5.3 Room for Improvements

5.3.1 Upper Bounds

To get a rough estimate of what is actually achievable in terms of the final ROUGE scores, we looked at different "upper bounds" under various scenarios (Table 4). We first evaluate one *reference* news with the other reference news served as the gold-standard result. The results are given in the row labeled *reference* of Table 4. This provides a reasonable estimate of human performance.

Second, in sentence extraction we restrict the constructed news to sentences from the original commentary texts themselves. We use the greedy algorithm to *extract* sentences that maximize ROUGE-2F scores. The resulting performance is given in the row *extract* of Table 4. We observe numerically superior scores compared with *reference*. This is not strange since we are intentionally optimizing ROUGE scores. And also this suggests that the sentence extraction approach for sports news construction is rather reasonable, in terms of information overlap.

Method	R-1	R-2	R-SU4
reference	0.44725	0.15265	0.18064
extract	0.43270	0.16872	0.18622
target	0.40987	0.15901	0.17941
target+DPP	0.41536	0.15994	0.18232
RF+DPP	0.39391	0.11986	0.15097

Table 4: Upper bounds on ROUGE scores

Third, we use the partial ROUGE-2 values, i.e. the targets used to train LTR models (cf. Section 3.1) for greedy selection and DPP selection, with results listed in the row *target* and *tar-*

Time	Live Text Commentary Script
55	内马尔 为 巴 萨 制造 了 一个 位置 不错 的 定位球 Neymar wins a free kick in a good position.
56	内马尔 ~~~ Neymar!!!!!!!
56	内马尔 的 定位球 直接 打入 了 球门 左上 角 的 死角 ！ ！ ！ 门将 无能为力 The free kick from Neymar goes directly into the top left corner! The keeper can do nothing.
56	球 在 飞 向 球门 的 过程 中 下坠 速度 非常 快 The ball drops quickly and flies to the goal.

Figure 4: Case I: short and noisy sentences

Time	Live Text Commentary Script
FT	切尔西中场快发任意球，科斯塔打进全场唯一入球！！！ From a quick free kick from Chelsea, Costa scored the only goal of the game!!!
FT	整场比赛切尔西占据了主动，可面对诺维奇的铁桶阵，办法不多 Chelsea dominated the game but found it difficult against Norwich's defense.
FT	下半场利用对方的一次疏忽，阿扎尔中场被放倒，威廉快发任意球，科斯塔完成致命一击 From an error from the opponent, Hazard was fouled. Willian launches a quick free kick and assists Costa for the lethal strike.

Figure 5: Case II: summarizing sentences

get+DPP of Table 4. This validates that using partial ROUGE-2 as the training target for LTR models is somewhat reasonable for this study.

5.3.2 Error Analysis

In this preliminary study, we use LTR models and probabilistic sentence selection procedure. While reasonable performance has been achieved, there exist certain types of errors as we found in the constructed news results.

Error I: First, sentences in live commentary are mostly short, and sometimes noisy. Sometimes an important event has been described using a number of consecutive short sentences. Our LTR models failed to generate high scores for such sentences and therefore will cause some lack of information. Figure 4 illustrates an example of this type of error in the constructed news report. All the sentences are describing a key scoring event. However, none of them were selected to construct the news because our LTR model assigns low scores for these short sentences. Meanwhile the second sentence can be treated as noisy.

Error II: Second, commentators are likely to summarize important events during the game, not at the point when the event happens. Our sentence selection algorithm can only address local redundancy, while this issue is more global. Figure 5 illustrates an example of this case in the constructed news report. The only goal of the match is described during full-time (FT). Our method redundantly included this in the final constructed news even it had already selected that event.

These two issues are highly non-trivial and have not been well addressed in the method we explored in this paper. We leave them for further study in the future.

5.3.3 Readability Assessment

In this work we only consider sentence extraction. Unlike traditional summarization tasks, sports commentary texts are describing a different specific action in almost every sentence. Descriptive coherence becomes a more difficult challenge in this scenario. We conduct manual evaluation on systems in comparison along with manually written news reports (gold-standard). Three volunteers who are fluent in Chinese were asked to perform manual ratings on three factors: coherence (Coh.), non-redundancy (NR) and overall readability (Read.). The ratings are in the format of 1-5 numerical scores (not necessarily integral), with higher scores denote better quality. The results are shown in Table 5.

Method	Coh.	NR	Read.
HeadTail	3.47	3.07	3.56
Centroid	2.87	3.72	2.66
LexRank	2.90	3.23	2.43
ILP	2.87	3.23	2.50
Highlight	3.36	3.72	3.06
RF	3.23	3.64	3.13
RF+DPP	3.23	3.87	3.06
Gold-Standard	4.67	4.23	4.77

Table 5: Manual readability ratings

The differences between systems in terms of readability factors are not as large as information coverage suggested by ROUGE metrics and pyramid scores. Meanwhile, while we can observe that our approaches outperforms the unsupervised extractive summarization approaches in coherence and readability for certain level, the results also clearly suggest that there still exists large room for improvements in terms of the readability factors.

6 Discussions

The general challenges for the particular task of sports news generation are mostly addressed in those designed features in the learning to rank framework. We utilize the timeline and scoreline information, while also keep traditional features such as sentence length. Experimental results show that our framework indeed outperforms strong traditional summarization baselines, while still having much room for improvement.

We might also notice that there may exist some issues if merely using automatic metrics to evaluate the overall quality of the generated news reports. The ROUGE metrics are mainly based on

ngram overlaps. For sports texts most of the proportions are dominated by proper names, certain types of actions or key events, etc. Compared with traditional summarization tasks, it might be easier to achieve high ROUGE scores with an emphasize on selecting important entities. In our experiments, methods with higher ROUGE scores can indeed achieve better coverage of important units such as events, as shown in pyramid scores in Table 2. However, we can also observe from Table 5 that automatic metrics currently cannot reflect readability factors very well. Generally speaking, while big difference in ROUGE may suggest big difference in overall quality, smaller ROUGE differences may not be that indicative enough. Therefore, it is interesting to find alternative automatic metrics in order to better reflect the general quality for this task.

7 Related Work

To the best of our knowledge, generation of sports news from live text commentary is not a well-studied task in related fields. One related study focused on generating textual summaries for sports events from status updates in Twitter (Nichols et al., 2012). There also exists earlier work on generation of sports highlight frames from sports videos, focusing on a very different type of data (Tjondronegoro et al., 2004). Bouayad-Agha et al. (2011) and Bouayad-Agha et al. (2012) constructed an ontology-based knowledge base for the generation of football summaries, using predefined extraction templates.

Our task is closely related to document summarization, which has been studied quite intensively. Various approaches exist to challenge the document summarization task, including centroid-based methods, link analysis and graph-based algorithms (Erkan and Radev, 2004; Wan et al., 2007), combinatorial optimization techniques such as integer linear programming (Gillick et al., 2008) and submodular optimization (Lin and Bilmes, 2010). Supervised models including learning to rank models (Metzler and Kanungo, 2008; Shen and Li, 2011; Wang et al., 2013) and regression (Ouyang et al., 2007; Galanis and Malakasiotis, 2008; Hong and Nenkova, 2014) have also been adapted in the scenario of document summarization.

Since sports live texts contain timeline information, summarization paradigms that utilize timeline and temporal information (Yan et al., 2011; Ng et al., 2014; Li et al., 2015) are also conceptually related. Supervised approaches related to this work have also been applied for timeline summarization, including linear regression for important scores (Tran et al., 2013a) and learning to rank models (Tran et al., 2013b). In this preliminary work we only use the timestamps in the definition of similarity for sentence selection. More crafted usages will be explored in the future.

8 Conclusion and Future Work

In this paper we study a challenging task to automatically construct sports news from live text commentary. Using football live texts as an instance, we collect training data jointly from live text commentary services and sports news portals. We develop a system based on learning to rank models, with several novel task-specific features. To generate the final news summary and tackle the local redundancy problem, we also propose a probabilistic sentence selection method. Experimental results demostrate that this task is feasible and our proposed methods are appropriate.

As a preliminary work, we only perform sentence extraction in this work. Since sports news and live commentary are in different genres, some post-editing rewritings will make the system generating more natural descriptions for sports news. We would like to extend our system to produce sports news beyond pure sentence extraction.

Another important direction is to focus on the construction of datasets in larger scale. One feasible approach is to use a speech recognition system on live videos or broadcasts of sports games to collect huge amount of transcripts as our raw data source. Although more data can be easily collected in this case, the noisiness of audio transcripts may bring some additional challenges, therefore worthwhile for further study.

Abstract

One of the major challenges for statistical machine translation (SMT) is to choose the appropriate translation rules based on the sentence context. This paper proposes a continuous space rule selection (CSRS) model for syntax-based SMT to perform this context-dependent rule selection. In contrast to existing maximum entropy based rule selection (MERS) models, which use discrete representations of words as features, the CSRS model is learned by a feed-forward neural network and uses real-valued vector representations of words, allowing for better generalization. In addition, we propose a method to train the rule selection models only on minimal rules, which are more frequent and have richer training data compared to non-minimal rules. We tested our model on different translation tasks and the CSRS model outperformed a baseline without rule selection and the previous MERS model by up to 2.2 and 1.1 points of BLEU score respectively.

1 Introduction

In syntax-based statistical machine translation (SMT), especially tree-to-string (Liu et al., 2006; Graehl and Knight, 2004) and forest-to-string (Mi et al., 2008) SMT, a source tree or forest is used as input and translated by a series of tree-based translation rules into a target sentence. A tree-based translation rule can perform reordering and translation jointly by projecting a source subtree into a target string, which can contain both terminals and nonterminals.

One of the difficulties in applying this model is the ambiguity existing in translation rules: a source subtree can have different target translations extracted from the parallel corpus as shown in Figure 1. Selecting correct rules during decoding is a major challenge for SMT in general, and syntax-based models are no exception.

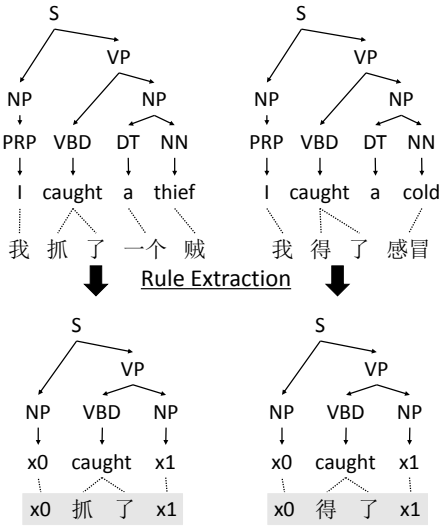

Figure 1: An ambiguous source subtree with different translations (English-to-Chinese).

There have been several methods proposed to resolve this ambiguity. The most simple method, used in the first models of tree-to-string translation (Liu et al., 2006), estimated the probability of a translation rule by relative frequencies. For example, in Figure 1, the rule that occurs more times in the training data will have a higher score. Later, Liu et al. (2008) proposed a maximum entropy based rule selection (MERS, Section 2) model for syntax-based SMT, which used contextual information for rule selection, such as words surrounding a rule and words covered by nonterminals in a rule. For example, to choose the correct rule from the two rules in Figure 1 for decoding a particular input sentence, if the source phrase covered by "x1" is "a thief" and this child phrase

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1372–1381,
Berlin, Germany, August 7-12, 2016.

has been seen in the training data, then the MERS model can use this information to determine that the first rule should be applied. However, if the source phrase covered by "x1" is a slightly different phrase, such as "a gunman", it will be hard for the MERS model to select the correct rule, because it treats "thief" and "gunman" as two different and unrelated words.

In this paper, we propose a continuous space rule selection (CSRS, Section 3) model, which is learned by a feed-forward neural network and replaces the discrete representations of words used in the MERS model with real-valued vector representations of words for better generalization. For example, the CSRS model can use the similarity of word representations for "gunman" and "thief" to infer that "a gunman" is more similar with "a thief" than "a cold".

In addition, we propose a new method, applicable to both the MERS and CSRS models, to train rule selection models only on minimal rules. These minimal rules are more frequent and have richer training data compared to non-minimal rules, making it possible to further relieve the data sparsity problem.

In experiments (Section 4), we validate the proposed CSRS model and the minimal rule training method on English-to-German, English-to-French, English-to-Chinese and English-to-Japanese translation tasks.

2 Tree-to-String SMT and MERS

2.1 Tree-to-String SMT

In tree-to-string SMT (Liu et al., 2006), a parse tree for the source sentence F is transformed into a target sentence E using translation rules R. Each tree-based translation rule $r \in R$ translates a source subtree $\tilde{t}$ into a target string $\tilde{e}$, which can contain both terminals and nonterminals. During decoding, the translation system examines different derivations for each source sentence and outputs the one with the highest probability,

$$\hat{E} = \arg\max_{E,R} \Pr(E, R|F). \quad (1)$$

For a translation E of a source sentence F with derivation R, the translation probability is calculated as follows,

$$\Pr(E, R|F) \approx \frac{\exp\left(\sum_{k=1}^{K} \lambda_k h_k(E, R, F)\right)}{\sum_{E',R'} \exp\left(\sum_{k=1}^{K} \lambda_k h_k(E', R', F)\right)}. \quad (2)$$

Here, h_k are features used in the translation system and λ_k are feature weights. Features used in Liu et al. (2006)'s model contain a language model and simple features based on relative frequencies, which do not consider context information.

One of the most important features used in this model is based on the log conditional probability of the target string given the input source subtree $\log \Pr(\tilde{e}|\tilde{t})$. This allows the model to determine which target strings are more likely to be used in translation. However, as the correct translation of the rules may depend on context that is not directly included in the rule, this simple context-independent estimate is inherently inaccurate.

2.2 Maximum Entropy Based Rule Selection

To perform context-dependent rule selection, Liu et al. (2008) proposed the MERS model for syntax-based SMT. They built a maximum entropy classifier for each ambiguous source subtree $\tilde{t}$, which introduced contextual information C and estimated the conditional probability using a log-linear model as shown below,

$$\Pr(\tilde{e}|\tilde{t}, C) = \frac{\exp\left(\sum_{k=1}^{K} \lambda_k h_k(\tilde{e}, C)\right)}{\sum_{\tilde{e}'} \exp\left(\sum_{k=1}^{K} \lambda_k h_k(\tilde{e}', C)\right)}. \quad (3)$$

The target strings $\tilde{e}$ are treated as different classes for the classifier.

Supposing that,

- r covers source span $[f_\varphi, f_\vartheta]$ and target span $[e_\gamma, e_\sigma]$,
- $\tilde{t}$ contains K nonterminals $\{X_k | 0 \le k \le K-1\}$,
- X_k covers source span $[f_{\varphi_k}, f_{\vartheta_k}]$ and target span $[e_{\gamma_k}, e_{\sigma_k}]$,

the MERS model used 5 kinds of source-side features as follows,

1. Lexical features: words around a rule (e.g. $f_{\varphi-1}$) and words covered by nonterminals in a rule (e.g. f_{φ_0}).

2. Part-of-speech features: part-of-speech (POS) of context words that are used as lexical features.

3. Span features: span lengths of source phrases covered by nonterminals in r.

4. Parent features: the parent node of $\tilde{t}$ in the parse tree of the source sentence.

5. Sibling features: the siblings of the root of $\tilde{t}$.

Note that the MERS model does not use features of the source subtree $\tilde{t}$, because the source subtree $\tilde{t}$ is fixed for each classifier.

The MERS model was integrated into the translation system as two additional features in Equation 2. Supposing that the derivation R contains M rules $r_1, ..., r_M$ with ambiguous source subtrees, then these two MERS features are as follows,

$$\begin{aligned} h_1(E,R,F) &= \sum_{m=1}^{M} \log \Pr\left(\tilde{e}_m|\tilde{t}_m, C_m\right) \\ h_2(E,R,F) &= M, \end{aligned} \tag{4}$$

where $\tilde{t}_m$ and $\tilde{e}_m$ are the source subtree and the target string contained in r_m, and C_m is the context of r_m. h_1 is the MERS probability feature, and, h_2 is a penalty feature counting the number of predictions made by the MERS model.

3 Our CSRS Approach

3.1 Modeling

The proposed CSRS model differs from the MERS model in three ways.

1. Instead of learning a single classifier for each source subtree $\tilde{t}$, it learns a single classifier for all rules.

2. Instead of hand-crafted features, it uses a feed-forward neural network to induce features from context words.

3. Instead of one-hot representations, it uses distributed representations to exploit similarities between words.

First, with regard to training, our CSRS model follows Zhang et al. (2015) in approximating the posterior probability by a binary classifier as follows,

$$\Pr\left(\tilde{e}|\tilde{t}, C\right) \approx \Pr\left(v = 1|\tilde{e}, \tilde{t}, C\right), \tag{5}$$

where $v \in \{0, 1\}$ is an indicator of whether $\tilde{t}$ is translated into $\tilde{e}$. This is in contrast to the MERS model, which treated the rule selection problem as a multi-class classification task. If instead we attempted to estimate output probabilities for all different $\tilde{e}$, the cost of estimating the normalization coefficient would be prohibitive, as the number of unique output-side word strings $\tilde{e}$ is large. There are a number of remedies to this, including noise contrastive estimation (Vaswani et al., 2013), but the binary approximation method has been reported to have better performance (Zhang et al., 2015).

To learn this model, we use a feed-forward neural network with structure similar to neural network language models (Vaswani et al., 2013). The input of the neural rule selection model is a vector representation for $\tilde{t}$, another vector representation for $\tilde{e}$, and a set of ξ vector representations for both source-side and target-side context words of r:

$$C(r) = w_1, ..., w_\xi \tag{6}$$

In our model, $C(r)$ is calculated differently depending on the number of nonterminals included in the rule. Specifically, Equation 7 defines $C_{out}(r, n)$ to be context words (n-grams) around r and $C_{in}(r, n, X_k)$ to be boundary words (n-grams) covered by nonterminal X_k in r.[1]

$$\begin{aligned} &C_{out}(r, n) \\ &= f_{\varphi-n}^{\varphi-1}, f_{\theta+1}^{\theta+n}, e_{\gamma-n}^{\gamma-1}, e_{\sigma+1}^{\sigma+n} \\ &C_{in}(r, n, X_k) \\ &= f_{\varphi_k}^{\varphi_k+n-1}, f_{\theta_k-(n-1)}^{\theta_k}, e_{\gamma_k}^{\gamma_k+n-1}, e_{\sigma_k-(n-1)}^{\sigma_k} \end{aligned} \tag{7}$$

The context words used for a translation rule r with K nonterminals are shown as below.

K	$C(r)$
$= 0$	$C_{out}(r, 6)$
$= 1$	$C_{out}(r, 4), C_{in}(r, 2, X_0)$
> 1	$C_{out}(r, 2), C_{in}(r, 2, X_0), C_{in}(r, 2, X_1)$

We can see that rules with different numbers of nonterminals K use different context words.[2]

[1] Note that when extracting C_{out}, we use "$\langle s \rangle$" and "$\langle /s \rangle$" for context words that exceed the length of the sentence; When extracting C_{in}, we use "$\langle non \rangle$" for context words that exceed the length of the nonterminal. Words that occur less than twice in the training data are replaced by "$\langle unk \rangle$".

[2] In most cases, restrictions on extracted rules will ensure that rules will only contain two nonterminals. However, when using minimal rules as described in the next section, more than two nonterminals are possible, and in these cases, only contextual information covered by the first two nonterminals is used in the input. These cases are sufficiently rare, however, that we chose to consider only the first two.

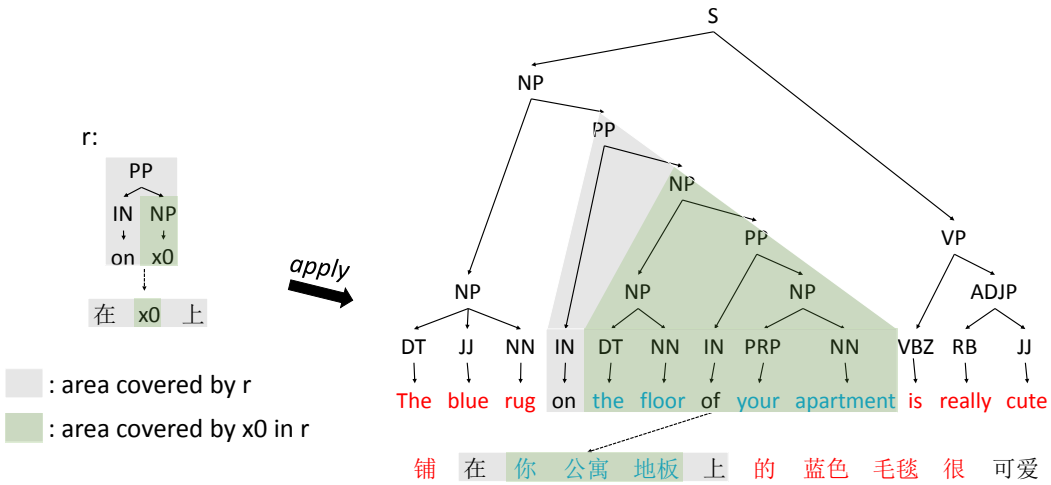

Figure 2: Context word examples. The red words are contained in $C_{out}(r, 4)$ and the blue words are contained in $C_{in}(r, 2, X_0)$.

For example, if r does not contain nonterminals, then C_{in} is not used. Besides, we use more context words surrounding the rule ($C_{out}(r, 6)$) for rules with $K = 0$ than rules that contain nonterminals ($C_{out}(r, 4)$ for $K = 1$ and $C_{out}(r, 2)$ for $K > 1$). This is based on the intuition that rules with $K = 0$ can only use the context words surrounding the rule as information for rule selection, hence this information is more important than for other rules. Figure 2 gives an example of context words when applying the rule r to the example sentence.

Note that we use target-side context because source-side context is not enough for selecting correct rules. Since it is not uncommon for one source sentence to have different correct translations, a translation rule used in one correct derivation may be incorrect for other derivations. In these cases, target-side context is useful for selecting appropriate translation rules. [3]

The vector representations for $\tilde{t}$, $\tilde{e}$ and C are obtained by using a projection matrix to project each one-hot input into a real-valued embedding vector. This projection is another key advantage over the MERS model. Because the CSRS model learns one unified model for all rules and can share all training data to learn better vector representations of words and rules, and the similarities between vectors can be used to generalize in cases such as the "thief/gunman" example in the introduction.

[3]It is also possible to consider target-side context in a framework like the MERS model, but we show in experiments that a linear model using the same features as the CSRS model did not improve accuracy.

After calculating the projections, two hidden layers are used to combine all inputs. Finally, the neural network has two outputs $\Pr(v = 1|\tilde{e}, \tilde{t}, C)$ and $\Pr(v = 0|\tilde{e}, \tilde{t}, C)$.

To train the CSRS model, we need both positive and negative training examples. Positive examples, $\langle \tilde{e}, \tilde{t}, C, 1 \rangle$, can be extracted directly from the parallel corpus. For each positive example, we generate one negative example, $\langle \tilde{e}', \tilde{t}, C, 0 \rangle$. Here, $\tilde{e}'$ is randomly generated according to the translation distribution (Zhang et al., 2015),

$$\Pr(\tilde{e}|\tilde{t}) = \frac{Count(\tilde{e}, \tilde{t})}{\sum_{\tilde{e}'} Count(\tilde{e}', \tilde{t})}, \quad (8)$$

where, $Count(\tilde{e}, \tilde{t})$ is how many times $\tilde{t}$ is translated into $\tilde{e}$ in the parallel corpus.

During translating, following the MERS model, the CSRS model only calculates probabilities for rules with ambiguous source subtrees. These predictions are converted into two CSRS features for the translation system similar to the two MERS features in Equation 4: one is the product of probabilities calculated by the CSRS model and the other one is a penalty feature that stands for how many rules with ambiguous source subtrees are contained in one translation.

3.2 Usage of Minimal Rules

Despite the fact that the CSRS model can share information among instances using distributed word representations, it still poses an extremely sparse learning problem. Specifically, the numbers of unique subtrees $\tilde{t}$ and strings $\tilde{e}$ are extremely large,

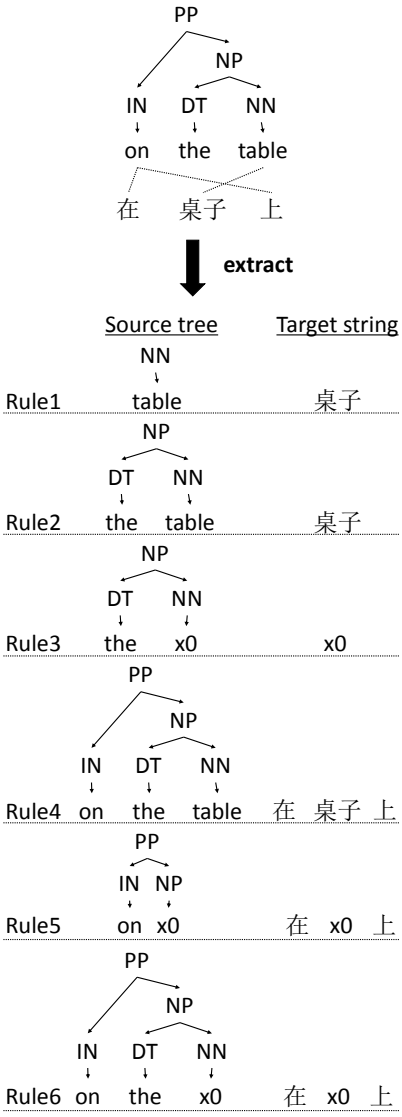

Figure 3: Rules.

and many may only appear a few times in the corpus. To reduce these problems of sparsity, we propose another improvement to the model, specifically through the use of minimal rules.

Minimal rules (Galley et al., 2004) are translation rules that cannot be split into two smaller rules. For example, in Figure 3, Rule2 is not a minimal rule, since Rule2 can be split into Rule1 and Rule3. In the same way, Rule4 and Rule6 are not minimal while Rule1, Rule3 and Rule5 are minimal.

Minimal rules are more frequent than non-minimal rules and have richer training data. Hence, we can expect that a rule selection model trained on minimal rules will suffer less from data sparsity problems. Besides, without non-minimal rules, the rule selection model will need less memory and can be trained faster.

To take advantage of this fact, we train another version of the CSRS model (CSRS-MINI) over only minimal rules. The probability of a non-minimal rule is then calculated using the product of the probability of minimal rules contained therein.

Note that for both the standard CSRS and CSRS-MINI models, we use the same baseline translation system which can use non-minimal translation rules. The CSRS-MINI model will break translation rules used in translations down into minimal rules and multiply all probabilities to calculate the necessary features.

4 Experiments

4.1 Setting

We evaluated the proposed approach for English-to-German (ED), English-to-French (EF), English-to-Chinese (EC) and English-to-Japanese (EJ) translation tasks. For the ED and EF tasks, the translation systems are trained on Europarl v7 parallel corpus and tested on the WMT 2015 translation task.[4] The test sets for the WMT 2014 translation task were used as development sets in our experiments. For the EC and EJ tasks, we used datasets provided for the patent machine translation task at NTCIR-9 (Goto et al., 2011).[5] The detailed statistics for training, development and test sets are given in Table 1. The word segmentation was done by BaseSeg (Zhao et al., 2006) for Chinese and Mecab[6] for Japanese.

For each translation task, we used Travatar (Neubig, 2013) to train a forest-to-string translation system. GIZA++ (Och and Ney, 2003) was used for word alignment. A 5-gram language model was trained on the target side of the training corpus using the IRST-LM Toolkit[7] with modified Kneser-Ney smoothing. Rule extraction was

[4]The WMT tasks provided other training corpora. We used only the Europarl corpus, because training a large-scale system on the whole data set requires large amounts of time and computational resources.

[5]Note that NTCIR-9 only contained a Chinese-to-English translation task. Because we want to test the proposed approach with a similarly accurate parsing model across our tasks, we used English as the source language in our experiments. In NTCIR-9, the development and test sets were both provided for the CE task while only the test set was provided for the EJ task. Therefore, we used the sentences from the NTCIR-8 EJ and JE test sets as the development set in our experiments.

Table 1: Data sets.

performed using the GHKM algorithm (Galley et al., 2006) and the maximum numbers of nonterminals and terminals contained in one rule were set to 2 and 10 respectively. Note that when extracting minimal rules, we release this limit. The decoding algorithm is the bottom-up forest-to-string decoding algorithm of Mi et al. (2008). For English parsing, we used Egret[8], which is able to output packed forests for decoding.

We trained the CSRS models (CSRS and CSRS-MINI) on translation rules extracted from the training set. Translation rules extracted from the development set were used as validation data for model training to avoid over-fitting. For different training epochs, we resample negative examples for each positive example to make use of different negative examples. The embedding dimension was set to be 50 and the number of hidden nodes was 100. The initial learning rate was set to be 0.1. The learning rate was halved each time the validation likelihood decreased. The number of epoches was set to be 20. A model was saved after each epoch and the model with highest validation likelihood was used in the translation system.

We implemented Liu et al. (2008)'s MERS model to compare with our approach. The training instances for their model were extracted from the training set. Following their work, the iteration number was set to be 100 and the Gaussian prior was set to be 1. We also compared the original MERS model and the MERS model trained only on minimal rules (MERS-MINI) to test the benefit of using minimal rules for model training.

CSRS-MINI vs. MERS-MINI	$>>$	$-$	$>>$	$-$
MERS-MINI vs. MERS	$-$	$>>$	$>>$	$>>$
CSRS-MINI vs. CSRS	$>$	$-$	$>>$	$>>$

Table 3: Significance test results. The symbol $>>$ ($>$) represents a significant difference at the $p < 0.01$ ($p < 0.05$) level and the symbol - represents no significant difference at the $p < 0.05$ level.

The MERS and CSRS models were both used to calculate features used to rerank unique 1,000-best outputs of the baseline system. Tuning is performed to maximize BLEU score using minimum error rate training (Och, 2003).

4.2 Results

Table 2 shows the translation results and Table 3 shows significance test results using bootstrap resampling (Koehn, 2004): "Base" stands for the baseline system without any; "MERS", "CSRS", "MERS-MINI" and "CSRS-MINI" means the outputs of the baseline system were reranked using features from the MERS, CSRS, MERS-MINI and CSRS-MINI models respectively. Generally, the CSRS model outperformed the MERS model and the CSRS-MINI model outperformed the MERS-MINI model on different translation tasks. In addition, using minimal rules for model training benefitted both the MERS and CSRS models.

Table 4 shows translation examples in the EC task to demonstrate the reason why our approach improved accuracy. Among all translations, $T_{CSRS-MINI}$ is basically the same as the reference with only a few paraphrases that do not alter the meaning of the sentence. In con-

Source	typical dynamic response rate of an optical gap sensor as described above is approximately 2 khz , or 0.5 milliseconds .
Reference	上述(described above) 光学(optical) 间隙(gap) 传感器(sensor) 的 典型(typical) 动态(dynamic) 响应(response) 率(rate) 约(approximately) 为(is) 2KHz 或(or) 为 0.5 毫秒(milliseconds) 。
T_{Base}	典 型(typical) 的 动 态(dynamic) 响 应(response) 速 率(rate) 间隙(gap) 传感器(sensor) 的 光学(optical) 如上(above) 描述(described) 的 是(is) 约(approximately) 2 千赫(khz) 兹 ， 或(or) 0.5 毫秒(milliseconds) 。
T_{MERS}	典型(typical) 的 动态(dynamic) 响应(response) 率(rate) 光学(optical) 传感器(sensor) ， 如(as) 以上(above) 所 述(described) 间隙(gap) 的 约(approximately) 2 千赫(khz) ， 或(or) 0.5 毫秒(milliseconds) 。
T_{CSRS}	光学(optical) 传感器(sensor) ， 如(as) 以上(above) 所 述(described) 间隙(gap) 的 典型(typical) 的 动态(dynamic) 响应(response) 速率(rate) 为(is) 约(approximately) 2 千赫(khz) 兹 ， 或(or) 0.5 毫秒(milliseconds) 。
$T_{MERS-MINI}$	典 型(typical) 的 动 态(dynamic) 响 应(response) 率(rate) 间隙(gap) 传感器(sensor) 的 光学(optical) 如 上(above) 描 述(described) 的 是(is) 约(approximately) 2 千 赫(khz) 兹 ， 或(or) 0.5 毫秒(milliseconds) 。
$T_{CSRS-MINI}$	如 上(above) 描 述(described) 的 光学(optical) 间隙(gap) 传感器(sensor) 典 型(typical) 的 动 态(dynamic) 响应(response) 速率(rate) 为(is) 约(approximately) 2 千赫(khz) 兹 ， 或(or) 0.5 毫秒(milliseconds) 。

Table 4: Translation examples.

R_1: T_{MERS}&T_{CSRS}	PP (IN (“of”) NP (NP (DT (“an”) NP’ (JJ (“optical”) x0:NN)) x1:NP’)) → “光学(optical)” x1 x0 “的”
R_2: $T_{MERS-MINI}$	PP (IN (“of”) NP (NP (DT (“an”) NP’ (JJ (“optical”) x0:NP’)) x1:SBAR)) → x0 “的” “光学(optical)” x1 “的”
R_3 : $T_{CSRS-MINI}$	NP’ (JJ (“optical”) x0:NP’) → “光学(optical)” x0

Table 5: Rules used to translate the source word “optical” in different translations. Shadows (R_3) stand for ambiguous rules.

trast, T_{Base}, T_{MERS}, T_{CSRS} and $T_{MERS-MINI}$ all contain apparent mistakes. For example, the source phrase “optical gap sensor” (covered by gray shadows in Table 4) is wrongly translated in T_{Base}, T_{MERS}, T_{CSRS} and $T_{MERS-MINI}$ due to incorrect reorderings.

Table 5 shows rules used to translate the source word “optical” in different translations: R_1 is used in T_{MERS} and T_{CSRS}; R_2 is used in $T_{MERS-MINI}$; R_3 is used in $T_{CSRS-MINI}$. Although the source word “optical” is translated to the correct translation “光学(optical)” in all translations, R_1, R_2 and R_3 cause different reorderings for the source phrase “optical gap sensor”. R_3 reorders this source phrase correctly while R_1 and R_2 cause wrong reorderings for this source phrase.

We can see that R_1 is umambiguous, so the MERS and CSRS models will give probability 1 to R_1, which could make the MERS and CSRS models prefer T_{MERS} and T_{CSRS}. This is a typical translation error caused by sparse rules since the source subtree in R_1 does not have other translations in the training corpus.

To compare the MERS-MINI and CSRS-MINI models, Table 6 shows minimal rules (R_{2a}, R_{2b}, R_{3a} and R_{3b}) contained in R_2 and R_3. Table 7 shows probabilities of these minimal rules calculated by the MERS-MINI and CSRS-MINI models respectively. We can see that the CSRS-MINI model gave higher scores for the correct translation rules R_{3a} and R_{3b} than the MERS-MINI model, while the MERS-MINI model gave a higher score to the incorrect rule R_{2b} than the CSRS-MINI model.

Note that R_{2b} and R_{3b} are the same rule, but the target-side context in $T_{MERS-MINI}$ and $T_{CSRS-MINI}$ is different. The CSRS-MINI model will give R_{2b} and R_{3b} different scores because the CSRS-MINI model used target-side context. However, the MERS-MINI model only used source-side features and gave R_{2b} and R_{3b} the same score. The fact that the CSRS-MINI model

R_{2a}	PP (IN (“of”) NP (NP (DT (“an”) NP’ (x0:JJ x1:NP’)) x2:SBAR)) → x1 “的” x0 x2 “的”
R_{2b}	JJ (“optical”) → “光学(optical)”
R_{3a}	NP’ (x0:JJ x1:NP’) → x0 x1
R_{3b}	JJ (“optical”) → “光学(optical)”

Table 6: Minimal rules contained in R_2 and R_3. Shadows (R_{2b}, R_{3a} and R_{3b}) stand for ambiguous rules.

	MERS-MINI	CSRS-MINI
R_{2a}	1	1
R_{2b}	0.5441	0.09632
R_{3a}	0.9943	0.9987
R_{3b}	0.5441	0.7317

Table 7: Scores of minimal rules.

gave a higher score for R_{3b} than R_{2b} means that the CSRS-MINI model predicted the target string in R_{2b} and R_{3b} is a good translation in the context of $T_{CSRS-MINI}$ but not so good in the context of $T_{MERS-MINI}$. As we can see, the target phrase “如上(above) 描述(described) 的(of) 光学(optical) 间隙(gap) 传感器(sensor)” around “光学(optical)” in $T_{CSRS-MINI}$ is a reasonable Chinese phrase while the target phrase “间隙(gap) 传感器(sensor) 的(of) 光学(optical) 如上(above) 描述(described) 的(of)” around “光学(optical)” in $T_{MERS-MINI}$ does not make sense. Namely, the CSRS model trained with target-side context can perform rule selection considering target sentence fluency, which is the reason why target-side context can help in the rule selection task.

4.3 Analysis

To analyze the influence of different features, we trained the MERS model using source-side and target-side n-gram lexical features similar to the CSRS model. When using this feature set, the performance of the MERS model dropped significantly. This indicates that the syntactic, POS and span features used in the original MERS model are important for their model, since these features can generalize better. Purely lexical features are less effective due to sparsity problems when training one maximum entropy based classifier for each ambiguous source subtree and training data for each classifier is quite limited. In contrast, the CSRS model is trained in a continuous space and does not split training data, which relieves the sparsity problem of lexical features. As a result, the CSRS model achieved better performance using only lexical features compared to the MERS model. We also tried to use pre-trained word embedding features for the MERS model, but it did not improve the performance of the MERS model, which indicates that the log-linear model is not able to benefit from distributed representations as well as the neural network model.

We also tried reranking with both the CSRS and MERS models added as features, but it did not achieve further improvement compared to only using the CSRS model. This indicates that although these two models use different type of features, the information contained in these features are similar. For example, the POS features used in the MERS model and the distributed representations used in the CSRS model are both used for better generalization.

In addition, using both the CSRS and CSRS-MINI models did not improve over using only the CSRS-MINI model in our experiments. There are two main differences between the CSRS and CSRS-MINI models. First, minimal rules are more frequent and have more training data than non-minimal rules, which is why the CSRS-MINI model is more robust than the CSRS model. Second, non-minimal rules contain more information than minimal rules. For example, in Figure 3, Rule4 contains more information than Rule1, which could be an advantage for rule selection. However, the information contained in Rule4 will be considered as context features for Rule1. Therefore, this is no longer an advantage for the CSRS model as long as we use rich enough context features, which could be the reason why using both the CSRS and CSRS-MINI models cannot further improve the translation quality compared to using only the CSRS-MINI model.

5 Related Work

The rule selection problem for syntax-based SMT has received much attention. He et al. (2008) proposed a lexicalized rule selection model to perform context-sensitive rule selection for hierarchical phrase-base translation. Cui et al. (2010) introduced a joint rule selection model for hierarchical phrase-based translation, which also approximated the rule selection problem by a binary classification problem like our approach. However, these two models adopted linear classifiers similar to those used in the MERS model (Liu et al., 2008), which suffers more from the data sparsity

problem compared to the CSRS model.

There are also existing works that exploited neural networks to learn translation probabilities for translation rules used in the phrase-based translation model. Namely, these methods estimated translation probabilities for phrase pairs extracted from the parallel corpus. Schwenk (2012) proposed a continuous space translation model, which calculated the translation probability for each word in the target phrase and then multiplied the probabilities together as the translation probability of the phrase pair. Gao et al. (2014) and Zhang et al. (2014) proposed methods to learn continuous space phrase representations and use the similarity between the source and target phrases as translation probabilities for phrase pairs. All these three methods can only be used for the phrase-based translation model, not for syntax-based translation models.

There are also works that used minimal rules for modeling. Vaswani et al. (2011) proposed a rule Markov model using minimal rules for both training and decoding to achieve a slimmer model, a faster decoder and comparable performance with using non-minimal rules. Durrani et al. (2013) proposed a method to model with minimal translation units and decode with phrases for phrase-based SMT to improve translation performances. Both of these two methods do not use distributed representations as used in our model for better generalization.

In addition, neural machine translation (NMT) has shown promising results recently (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015a; Jean et al., 2015; Luong et al., 2015b). NMT uses a recurrent neural network to encode the whole source sentence and then produce the target words one by one. These models can be trained on parallel corpora and do not need word alignments to be learned in advance. There are also neural translation models that are trained on word-aligned parallel corpus (Devlin et al., 2014; Meng et al., 2015; Zhang et al., 2015; Setiawan et al., 2015), which use the alignment information to decide which parts of the source sentence are more important for predicting one particular target word. All these models are trained on plain source and target sentences without considering any syntactic information while our neural model learns rule selection for tree-based translation rules and makes use of the tree structure of natural language for better translation. There is also a new syntactic NMT model (Eriguchi et al., 2016), which extends the original sequence-to-sequence NMT model with the source-side phrase structure. Although this model takes source-side syntax into consideration, it still produces target words one by one as a sequence. In contrast, the tree-based translation rules used in our model can take advantage of the hierarchical structures of both source and target languages.

6 Conclusion

In this paper, we propose a CSRS model for syntax-based SMT, which is learned by a feed-forward neural network on a continuous space. Compared with the previous MERS model that used discrete representations of words as features, the CSRS model uses real-valued vector representations of words and can exploit similarity information between words for better generalization. In addition, we propose to use only minimal rules for rule selection to further relieve the data sparsity problem, since minimal rules are more frequent and have richer training data. In our experiments, the CSRS model outperformed the previous MERS model and the usage of minimal rules benefitted both CSRS and MERS models on different translation tasks.

For future work, we will explore more sophisticated features for the CSRS model, such as syntactic dependency relationships and head words, since only simple lexical features are used in the current incarnation.

Abstract

This paper presents neural probabilistic parsing models which explore up to third-order graph-based parsing with maximum likelihood training criteria. Two neural network extensions are exploited for performance improvement. Firstly, a convolutional layer that absorbs the influences of all words in a sentence is used so that sentence-level information can be effectively captured. Secondly, a linear layer is added to integrate different order neural models and trained with perceptron method. The proposed parsers are evaluated on English and Chinese Penn Treebanks and obtain competitive accuracies.

1 Introduction

Neural network methods have shown great promise in the field of parsing and other related natural language processing tasks, exploiting more complex features with distributed representation and non-linear neural network (Wang et al., 2013; Wang et al., 2014; Cai and Zhao, 2016; Wang et al., 2016). In transition-based dependency parsing, neural models that can represent the partial or whole parsing histories have been explored (Weiss et al., 2015; Dyer et al., 2015). While for graph-based parsing, on which we focus in this work, Pei et al. (2015) also show the effectiveness of neural methods.

The graph-based parser generally consists of two components: one is the parsing algorithm for inference or searching the most likely parse tree, the other is the parameter estimation approach for the machine learning models. For the former, classical dynamic programming algorithms are usually adopted, while for the latter, there are various solutions. Like some previous neural methods (Socher et al., 2010; Socher et al., 2013), to tackle the structure prediction problems, Pei et al. (2015) utilize a max-margin training criterion, which does not include probabilistic explanations. Re-visiting the traditional probabilistic criteria in log-linear models, this work utilizes maximum likelihood for neural network training. Durrett and Klein (2015) adopt this method for constituency parsing, which scores the anchored rules with neural models and formalizes the probabilities with tree-structured random fields. Motivated by this work, we utilize the probabilistic treatment for dependency parsing: scoring the edges or high-order sub-trees with a neural model and calculating the gradients according to probabilistic criteria. Although scores are computed by a neural network, the existing dynamic programming algorithms for gradient calculation remain the same as those in log-linear models.

Graph-based methods search globally through the whole space for trees and get the highest-scored one, however, the scores for the sub-trees are usually locally decided, considering only surrounding words within a limited-sized window. Convolutional neural network (CNN) provides a natural way to model a whole sentence. By introducing a distance-aware convolutional layer, sentence-level representation can be exploited for parsing. We will especially verify the effectiveness of such representation incorporated with window-based representation.

Graph-based parsing has a natural extension

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1382–1392,
Berlin, Germany, August 7-12, 2016.

through raising its order and higher-order parsers usually perform better. In previous work on high-order graph-parsing, the scores of high-order sub-trees usually include the lower-order parts in their high-order factorizations. In traditional linear models, combining scores can be implemented by including low-order features. However, for neural models, this is not that straightforward because of nonlinearity. A straightforward strategy is simply adding up all the scores, which in fact works well; another way is stacking a linear layer on the top of the representation from various already-trained neural parsing models of different orders.

This paper presents neural probabilistic models for graph-based projective dependency parsing, and explores up to third-order models. Here are the three highlights of the proposed methods:

- Probabilistic criteria for neural network training. (Section 2.2)
- Sentence-level representation learned from a convolutional layer. (Section 3.2)
- Ensemble models with a stacked linear output layer. (Section 3.3)

Our main contribution is exploring sub-tree scoring models which combine local features with a window-based neural network and global features from a distance-aware convolutional neural network. A free distribution of our implementation is publicly available[1].

The remainder of the paper is organized as follows: Section 2 explains the probabilistic model for graph-based parsing, Section 3 describes our neural network models, Section 4 presents our experiments and Section 5 discusses related work, we summarize this paper in Section 6.

2 Probabilistic Graph-based Dependency Parsing

2.1 Graph-based Dependency Parsing

Dependency parsing aims to predict a dependency tree, in which all the edges connect head-modifier pairs. In graph-based methods, a dependency tree is factored into sub-trees, from single edge to multiple edges with different patterns; we will call these specified sub-trees *factors* in this paper. According to the sub-tree size of the factors, we can define the order of the graph model. Three different ordered factorizations considered in this work and their sub-tree patterns are shown in Figure 1.

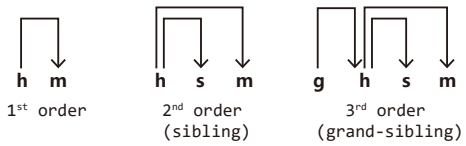

Figure 1: The decompositions of factors.

The score for a dependency tree (T) is defined as the sum of the scores of all its factors (p):

$$Score(T) = \sum_{p \in T} Score(p)$$

In this way, the dependency parsing task is to find a max-scoring tree. For projective dependency parsing considered in this work, this searching problem is conquered by dynamic programming algorithms with the key assumption that the factors are scored independently. Previous work (Eisner, 1996; McDonald et al., 2005; McDonald and Pereira, 2006; Koo and Collins, 2010; Ma and Zhao, 2012) explores ingenious algorithms for decoding ranging from first-order to higher-orders. Our proposed parsers also take these algorithms as backbones and use them for inference.

2.2 Probabilistic Model

With the graph factorization and inference, the remaining problems are how to obtain the scores and how to train the scoring model. For the scoring models, traditional linear methods utilize manually specified features and linear scoring models, while we adopt neural network models, which may exploit better feature representations.

For the training methods, in recent neural graph-based parsers, non-probabilistic margin-based methods are usually used. However, following the maximum likelihood criteria in traditional log-linear models, we can treat it in a probabilistic way. In fact, the probabilistic treatment still utilizes the scores of sub-tree factors in graph models. As in log-linear models like Conditional Random Field (CRF) (Lafferty et al., 2001), the exponentials of scores are taken before re-normalizing, and the probability distribution over trees condi-

[1] https://github.com/zzsfornlp/nnpgdparser

tioned on a sentence X is defined as follows:

$$Pr(T|X,\theta) = \frac{1}{Z(X)}\exp(Score(T|\theta))$$
$$Z(X) = \sum_{T'}\exp(Score(T'|\theta))$$

where θ represents the parameters and $Z(X)$ is the re-normalization partition function. The intuition is that the higher the score is, the more potential or mass it will get, leading to higher probability.

The training criteria will be log-likelihood in the classical setting of maximum likelihood estimation, and we define the loss for a parse tree as negative log-likelihood:

$$\begin{aligned} L(\theta) &= -\log Pr(T_g|X,\theta) \\ &= -Score(T_g|\theta) + \log(Z(X)) \end{aligned}$$

where T_g stands for the golden parse tree. Now we need to calculate the gradients of θ according to gradient-based optimization. Focusing on the second term, we have (some conditions are left out for simplicity):

$$\begin{aligned} \frac{\partial \log(Z(X))}{\partial\theta} &= \sum_{T'} Pr(T') \sum_{p\in T'} \frac{\partial Score(p)}{\partial\theta} \\ &= \sum_{p} \frac{\partial Score(p)}{\partial\theta} \sum_{T'\in T(p)} Pr(T') \end{aligned}$$

Here, $T(p)$ is the set of trees that contain the factor p, and the inner summation is defined as the marginal probability $m(p)$:

$$m(p) = \sum_{T'\in T(p)} Pr(T')$$

which can be viewed as the mass of all the trees containing the specified factor p. The calculation of $m(p)$ (Paskin, 2001; Ma and Zhao, 2015) is solved by a variant of inside-outside algorithm, which is of the same complexity compared with the corresponding inference algorithms. Finally, the gradients can be represented as:

$$\frac{\partial L(\theta)}{\partial\theta} = \sum_{p} \frac{\partial Score(p)}{\partial\theta}\Big(-\big[p\in T_g\big] + m(p)\Big)$$

where $[p \in T_g]$ is a binary value which indicates whether p is in tree T_g.

Traditional models usually utilize linear functions for the *Score* function, which might need carefully feature engineering such as (Zhao et al., 2009a; Zhao et al., 2009b; Zhao et al., 2009c; Zhao, 2009; Zhao et al., 2013), while we adopt neural models with the probabilistic training criteria unchanged.

2.3 Training Criteria

We take a further look between the maximum-likelihood criteria and the max-margin criteria. For the max-margin method, the loss is the difference between the scores of the golden tree and a predicted tree, and its sub-gradient can be written in a similar form:

$$\frac{\partial L_m(\theta)}{\partial\theta} = \sum_{p} \frac{\partial Score(p)}{\partial\theta}\Big(-\big[p\in T_g\big] + \big[p\in T_b\big]\Big)$$

Here, the predicted tree T_b is the best-scored tree with a structured margin loss in the score.

Comparing the derivatives, we can see that the one of probabilistic criteria can be viewed as a soft version of the max-margin criteria, and all the possible factors are considered when calculating gradients for the probabilistic way, while only wrongly predicted factors have non-zero sub-gradients for max-margin training. This observation is not new and Gimpel and Smith (2010) provide a good review of several training criteria. It might be interesting to explore the impacts of different training criteria on the parsing performance, and we will leave it for future research.

2.4 Labeled Parsing

In a dependency tree, each edge can be given a label indicating the type of the dependency relation, this labeling procedure can be integrated directly into the parsing task, instead of a second pass after obtaining the structure.

For the probabilistic model, integrating labeled parsing only needs some extensions for the inference procedure and marginal probability calculations. For the simplicity, we only consider a single label for each factor (even for high-order ones) which corresponds to Model 1 in (Ma and Hovy, 2015): the label of the edge between head and modifier word, which will only multiply $O(l)$ to the complexity. We find this direct approach not only achieves labeled parsing in one pass, but also improves unlabeled attachment accuracies (see Section 4.3), which may benefit from the joint learning with the labels.

3 Neural Model

The task for the neural models is computing the labeled scores of the factors. The inputs are the words in a factor with contexts, and the outputs are the scores for this factor to be valid in the dependency tree. We propose neural models to in-

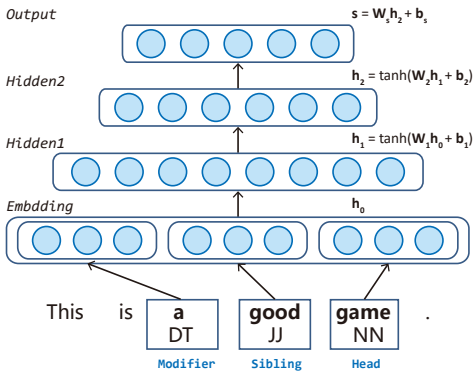

Figure 2: The architecture for the basic model (second order parsing).

tegrate features from both local word-neighboring windows and the entire sentence, and furthermore explore ensemble models with different orders.

3.1 Basic Local Model

Architecture The basic model uses a window-based approach, which includes only surrounding words for the contexts. Figure 2 illustrates a second-order sibling model and models of other orders adopt similar structures. It is simply a standard feed-forward neural network with two hidden layers ($\mathbf{h}_1$ and $\mathbf{h}_2$) above the embedding layer ($\mathbf{h}_0$), the hidden layers all adopt $tanh$ activation function, and the output layer (noted as $\mathbf{s}$) directly represents the scores for different labels.

Feature Sets All the features representing the input factor are atomic and projected to embeddings, then the embedding layer is formed by concatenating them. There are three categories of features: word forms, POS (part-of-speech) tags and distances. For each node in the factor, word forms and POS tags of the surrounding words in a specified window are also considered. Special tokens for start or end of sentences, root node and unknown words are added for both word forms and POS tags. Distances can be negative or positive to represent the relative positions between the factor nodes in surface string. Take the situation for the second-order model as an example, there are three nodes in a factor: h for head, m for modifier and s for sibling. When considering three-word windows, there will be three word forms and three tags for each node and its surrounding context. m and s both have one distance feature while h does not have one as its parent does not exist in the factor.

Training As stated in Section 2.2, we use the maximum likelihood criteria. Moreover, we add two L2-regularizations: one is for all the weights θ' (biases and embeddings not included) to avoid over-fitting and another is for preventing the final output scores from growing too large. The former is common practice for neural network, while the latter is to set soft limits for the norms of the scores. Although the second term is not usually adopted, it directly puts soft constraints on the scores and improves the accuracies (about 0.1% for UAS/LAS overall) according to our primary experiments. So the final loss function will be:

$$L'(\theta) = \sum_p \Big(Score(p) \cdot \big(- \big[p \in T_g \big] + m(p) \big) + \lambda_s \cdot Score(p)^2 \Big) + \lambda_m \cdot \|\theta'\|^2$$

where λ_m and λ_s respectively represent regularization parameters for model and scores. The training process utilizes a mini-batched stochastic gradient descent method with momentum.

Comparisons Our basic model resembles the one of Pei et al. (2015), but with some major differences: probabilistic training criteria are adopted, the structures of the proposed networks are different and direction information is encoded in distance features. Moreover, they simply average embeddings in specified regions for phrase-embedding, while we will include sentence-embedding in convolutional model as follows.

3.2 Convolutional Model

To encode sentence-level information and obtain sentence embeddings, a convolutional layer of the whole sentence followed by a max-pooling layer is adopted. However, we intend to score a factor in a sentence and the position of the nodes should also be encoded. The scheme is to use the distance embedding for the whole convolution window as the position feature.

We will take the second-order model as an example to introduce the related operations. Figure 3 shows the convolution operation for a convolution window, the input atomic features are the word forms and POS tags for each word inside the window, and the distances of only the center word (assuming an odd-sized window) to specified nodes in the factor are adopted as position features. In the example, "*game-good-a*" is to be scored as a second-order sibling factor, and for a

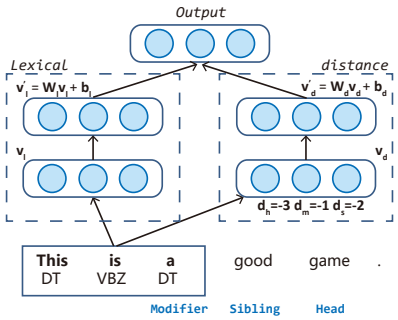

Figure 3: The operations for one convolution window (second order parsing).

convolution window of "*This is a*", word forms and corresponding POS tags are projected to embeddings and concatenated as the lexical vector $\mathbf{v}_l$, the distances of the center word "*is*" to all the three nodes in the factor are also projected to embeddings and concatenated as the distance vector $\mathbf{v}_d$, then these two vectors go through difference linear transformations into the same dimension and are combined together through element-wise addition or multiplication.

In general, assuming after the projection layer, embeddings of the word forms and POS tags of the sentence are represented as $[\mathbf{w}_0, \mathbf{w}_1, ..., \mathbf{w}_{n-1}]$ and $[\mathbf{p}_0, \mathbf{p}_1, ..., \mathbf{p}_{n-1}]$. Those embeddings in the basic model may be reused here by sharing the embedding look-up table. The second-order sibling factor to be scored has nodes with indexes of m (modifier), h (head) and s (sibling). The distance embeddings are denoted by $\mathbf{d}$, which can be either negative or positive. These distance embeddings are different from the ones in the basic model, because here we measure the distances between the convolution window (its center word) and factor nodes, while the distances between nodes inside the factors are measured in the basic model.

For a specified window $[i : j]$, always assuming an odd number sized window, and the center token is indexed to $c = \frac{i+j}{2}$, the $\mathbf{v}_l$ and $\mathbf{v}_d$ are obtained through simple concatenation:

$$\mathbf{v}_l = [\mathbf{w}_i, \mathbf{p}_i, \mathbf{w}_{i+1}, \mathbf{p}_{i+1}, ..., \mathbf{w}_j, \mathbf{p}_j]$$
$$\mathbf{v}_d = [\mathbf{d}_{c-h}, \mathbf{d}_{c-m}, \mathbf{d}_{c-s}]$$

then $\mathbf{v}_l$ and $\mathbf{v}_d$ go through difference linear transformations into same dimension space: $\mathbf{v'}_l, \mathbf{v'}_d \in \mathbb{R}^n$, where n is also the dimension of the output vector $\mathbf{v}_o$ for the window. The linear operations can be expressed as:

$$\mathbf{v'}_l = \mathbf{W}_l \cdot \mathbf{v}_l + \mathbf{b}_l$$
$$\mathbf{v'}_d = \mathbf{W}_d \cdot \mathbf{v}_d + \mathbf{b}_d$$

The final vector $\mathbf{v}_o$ is obtained by element-wise operations of $\mathbf{v'}_l$ and $\mathbf{v'}_d$. We consider two strategies: (1) add: simple element-wise addition, (2) mul: element-wise multiplication with $\mathbf{v'}_d$ activated by $tanh$. They can be formalized as:

$$\mathbf{v}_{o\text{-}add} = \mathbf{v'}_l \oplus \mathbf{v'}_d$$
$$\mathbf{v}_{o\text{-}mul} = \mathbf{v'}_l \odot tanh(\mathbf{v'}_d)$$

All the windows whose center-located word is valid (exists) in the sentence are considered and we will get a sequence of convolution outputs whose number is the same as the sentence length. The convolution outputs (all $\mathbf{v}_o$) are collapsed into one global vector $\mathbf{v}_g$ using a standard max-pooling operation. Finally, for utilizing the sentence-level representation in the basic model, we can either replace the original first hidden layer $\mathbf{h}_1$ with $\mathbf{v}_g$ or concatenate $\mathbf{v}_g$ to $\mathbf{h}_1$ for combining local and global features.

3.3 Ensemble Models

For higher-order dependency parsing, it is a standard practice to include the impact of lower-order parts in the scoring of higher-order factors, which actually is an ensemble method of different order models for scoring.

A simple adding scheme is often used. For nonlinear neural models, we use an explicit adding method. For example, in third-order parsing, the final score for the factor (g, h, m, s) will be:

$$\mathbf{s}_{add}(g, h, m, s) = \mathbf{s}_{o3}(g, h, m, s) + \mathbf{s}_{o2}(h, m, s) + \mathbf{s}_{o1}(h, m)$$

Here, g, h, m and s represent the grandparent, head, modifier and sibling nodes in the grand-sibling third-order factor; $\mathbf{s}_{o1}$, $\mathbf{s}_{o2}$ and $\mathbf{s}_{o3}$ stand for the corresponding lower-order scores from first, second and third order models, respectively.

We notice that ensemble or stacking methods for dependency parsing have explored in previous work (Nivre and McDonald, 2008; Torres Martins et al., 2008). Recently, Weiss et al. (2015) stack a linear layer for the final scoring in a single model, and we extend this method to combine multiple models by stacking a linear layer on their output and hidden layers. The simple adding scheme can

be viewed as adopting a final layer with specially fixed weights.

For each model to be combined, we concatenate the output layer and all hidden layers (except embedding layer $\mathbf{h}_0$):

$$\mathbf{v}_{all} = [\mathbf{s}, \mathbf{h}_1, \mathbf{h}_2]$$

All $\mathbf{v}_{all}$ from different models are again concatenated to form the input for the final linear layer and the final scores are obtained through a linear transformation (no bias adding):

$$\mathbf{v}_{combine} = [\mathbf{v}_{all\text{-}o1}, \mathbf{v}_{all\text{-}o2}, \mathbf{v}_{all\text{-}o3}]$$
$$\mathbf{s}_{combine} = \mathbf{W}_{combine} \cdot \mathbf{v}_{combine}$$

We no longer update weights for the underlying neural models, and the learning of the final layer is equally training a linear model, for which structured average perceptron (Collins, 2002; Collins and Roark, 2004) is adopted for simplicity.

This ensemble scheme can be extended in several ways which might be explored in future work: (1) feed-forward network can be stacked rather than a single linear layer, (2) traditional sparse features can also be concatenated to $\mathbf{v}_{combine}$ to combine manually specified representations with distributed neural representations as in (Zhang and Zhang, 2015).

4 Experiments

The proposed parsers are evaluated on English Penn Treebank (PTB) and Chinese Penn Treebank (CTB). Unlabeled attachment scores (UAS), labeled attachment scores (LAS) and unlabeled complete matches (CM) are the metrics. Punctuations[2] are ignored as in previous work (Koo and Collins, 2010; Zhang and Clark, 2008).

For English, we follow the splitting convention for *PTB3*: sections 2-21 for training, 22 for developing and 23 for test. We prepare three datasets of PTB, using different conversion tools: (1) Penn2Malt[3] and the head rules of Yamada and Matsumoto (2003), noted as *PTB-Y&M*; (2) dependency converter in Stanford parser v3.3.0 with Stanford Basic Dependencies (De Marneffe et al., 2006), noted as *PTB-SD*; (3) LTH Constituent-to-Dependency Conversion Tool[4] (Johansson and Nugues, 2007), noted as *PTB-LTH*. We use Stanford POS tagger (Toutanova et al., 2003) to get predicted POS tags for development and test sets, and the accuracies for their tags are 97.2% and 97.4%, respectively.

For Chinese, we adopt the splitting convention for *CTB5* described in (Zhang and Clark, 2008). The dependencies (noted as *CTB*), are converted with the Penn2Malt converter. Gold segmentation and POS tags are used as in previous work.

4.1 Settings

Settings of our models will be described in this sub-section, including pre-processing and initializations, hyper-parameters, and training details.

We ignore the words that occur less than 3 times in the training treebank and use a special token to replace them. For English parsing, we initialize word embeddings with word vectors trained on Wikipedia using *word2vec* (Mikolov et al., 2013); all other weights and biases are initialized randomly with uniform distribution.

For the structures of neural models, all the embeddings (word, POS and distances) have dimensions of 50. For basic local models, $\mathbf{h}_1$ and $\mathbf{h}_2$ are set to 200 and 100, and the local window size is set to 7. For convolutional models, a three-word-sized window for convolution is specified, and convolution output dimension (number of filters) is 100. When concatenating the convolution vector (after pooling) to $\mathbf{h}_1$, it will make the first hidden layer's dimension 300.

For the training of neural network, we set the initial learning rate to 0.1 and the momentum to 0.6. After each iteration, the parser is tested on the development set and if the accuracy decreases, the learning rate will be halved. The learning rate will also be halved if no decreases of the accuracy for three epochs. We train the neural models for 12 epochs and select the one that performs best on the development set. The regularization parameters λ_m and λ_s are set to 0.0001 and 0.001. For the perceptron training of the ensemble model, only one epoch is enough based on the results of the development set.

The runtime of the model is influenced by the hyper-parameter setting. According to our experiments, using dual-core on 3.0 GHz i7 CPU, the training costs 6 to 15 hours for different-order models and the testing is comparably efficient as recent neural graph-parsers. The calculation of the

[2]Tokens whose gold POS tags are one of {“ ” : , .} for PTB or *PU* for CTB.

convolution model approximately takes up 40% of all computations. The convolution operation indeed costs more, but the lexical parts $\mathbf{v}'_l$ of the convolution do not concern the factors and are computed only once for one sentence, which makes it less computationally expensive.

4.2 Pruning

For high-order parsing, the computation cost rises in proportion to the length of the sentence, and it will be too expensive to calculate scores for all the factors. Fortunately, many edges are quite unlikely to be valid and can be pruned away using low-order models. We follow the method of Koo and Collins (2010) and directly use the first-order probabilistic neural parser for pruning. We compute the marginal probability $m(h, m)$ for each edge and prune away the edges whose marginal probability is below $\epsilon \times \max_{h'} m(h', m)$. ϵ means the pruning threshold that is set to 0.0001 for second-order. For third-order parsing, considering the computational cost, we set it to 0.001.

4.3 Model Analysis

This section presents experiments to verify the effectiveness of the proposed methods and only the *PTB-SD* development set will be used in these experiments, which fall into three groups concerning basic models, convolutional models and ensemble ones, as shown in Table 1.

The first group focuses on the basic local models of first order. The first two, *Unlabeled* and *Labeled*, do not use pre-training vectors for initialization, while the third, *Labeled+pre-training*, utilizes them. The *Unlabeled* does not utilize the labels in training set and its model only gives one dependency score (we do not train a second stage labeling model, so the LAS of the unlabeled one is not available) and the *Labeled* directly predicts the scores for all labels. We can see that labeled parsing not only demonstrates the convenience of outputting dependency relations and labels for once, but also obtains better parsing performances. Also, we observe that pre-trained word vectors bring slight improvements. Pre-trained initialization and labeled parsing will be adopted for the next two groups and the rest experiments.

Next, we explore the effectiveness of the CNN enhancement. In the four entries of this group, *concatenate* or *replace* means whether to concatenate the sentence-level vector $\mathbf{v}_g$ to the first hidden layer $\mathbf{h}_1$ or just replace it (just throw away the representation from basic models), *add* or *mul* means to use which way for attaching distance information. Surprisingly, simple adding method surpasses the more complex multiplication-with-activation method, which might indicate that the direct activation operation may not be suitable for encoding distance information. With no surprises, the concatenating method works better because it combines both the local window-based and global sentence-level information. We also explore the influences of the convolution operations on dependencies of different lengths, as shown in Figure 4, the convolutional methods help the decisions of long-range dependencies generally. For the high-order parsing in the rest of this paper, we will all adopt the *concatenate-add* setting.

In the third group, we can see that high-order parsing brings significant performance improvement. For high-order parsing, three ensemble schemes are examined: no combination, adding

and stacking another linear perceptron layer (with the suffixes of *-nope*, *-adding* and *-perceptron* respectively). The results show that model ensemble improves the accuracies quite a few. For third-order parsing, the no-combination method performs quite poorly compared to the others, which may be caused by the relative strict setting of the pruning threshold. Nevertheless, with model ensemble, the third-order models perform better than the second-order ones. Though the perceptron strategy does not work well for third-order parsing in this dataset, it is still more general than the simple adding method, since the latter can be seen as a special parameter setting of the former.

4.4 Results

We show the results of two of the best proposed parsers: third-order adding (*o3-adding*) and third-order perceptron (*o3-perceptron*) methods, and compare with the reported results of some previous work in Table 2. We compare with three categories of models: other *Graph*-based *NN* (neural network) models, traditional *Graph*-based *Linear* models and *Transition*-based *NN* models. For PTB, there have been several different dependency converters which lead to different sets of dependencies and we choose three of the most popular ones for more comprehensive comparisons. Since not all work report results on all of these dependencies, some of the entries might be not available.

From the comparison, we see that the proposed parser has output competitive performance for different dependency conversion conventions and treebanks. Compared with traditional graph-based linear models, neural models may benefit from better feature representations and more general non-linear transformations.

The results and comparisons in Table 2 demonstrate the proposed models can obtain comparable accuracies, which show the effectiveness of combining local and global features through window-based and convolutional neural networks.

5 Related Work

CNN has been explored in recent work of relation classification (Zeng et al., 2014; Chen et al., 2015), which resembles the task of deciding dependency relations in parsing. However, relation classification usually involves labeling for given arguments and seldom needs to consider the global structure. Parsing is more complex for it needs to predict structures and the use of CNN should be incorporated with the searching algorithms.

Neural network methods have been proved effective for graph-based parsing. Lei et al. (2014) explore a tensor scoring method, however, it needs to combine scores from linear models and we are not able to compare with it because of different datasets (they take datasets from CoNLL shared task). Zhang and Zhao (2015) also explore a probabilistic treatment, but its model may give mass to illegal trees or non-trees. Fonseca and Aluísio (2015) utilize CNN for scoring edges, though only explore first-order parsing. Its model is based on head selection for each modifier and might be difficult to be extended to high-order parsing. Recently, several neural re-ranking models, like Inside-Outside Recursive Neural Network

(Le and Zuidema, 2014) and Recursive CNN (Zhu et al., 2015), are utilized for capturing features with more contexts. However, re-ranking models depend on the underlying base parsers, which might already miss the correct trees. Generally, the re-ranking techniques play a role of additional enhancement for basic parsing models, and therefore they are not included in our comparisons.

The conditional log-likelihood probabilistic criterion utilized in this work is actually a (conditioned) Markov Random Field for tree structures, and it has been applied to parsing since long time ago. Johnson et al. (1999) utilize the Markov Random Fields for stochastic grammars and gradient based methods are adopted for parameter estimations, and Geman and Johnson (2002) extend this with dynamic programming algorithms for inference and marginal-probability calculation. Collins (2000) uses the same probabilistic treatment for re-ranking and the denominator only includes the candidate trees which can be seen as an approximation for the whole space of trees. Finkel et al. (2008) utilize it for feature-based parsing. The probabilistic training criterion for linear graph-based dependency models have been also explored in (Li et al., 2014; Ma and Zhao, 2015). However, these previous methods usually exploit log-linear models utilizing sparse features for input representations and linear models for score calculations, which are replaced by more sophisticated distributed representations and neural models, as shown in this work.

6 Conclusions

This work presents neural probabilistic graph-based models for dependency parsing, together with a convolutional part which could capture the sentence-level information. With distributed vectors for representations and complex non-linear neural network for calculations, the model can effectively capture more complex features when deciding the scores for sub-tree factors and experiments on standard treebanks show that the proposed techniques improve parsing accuracies.

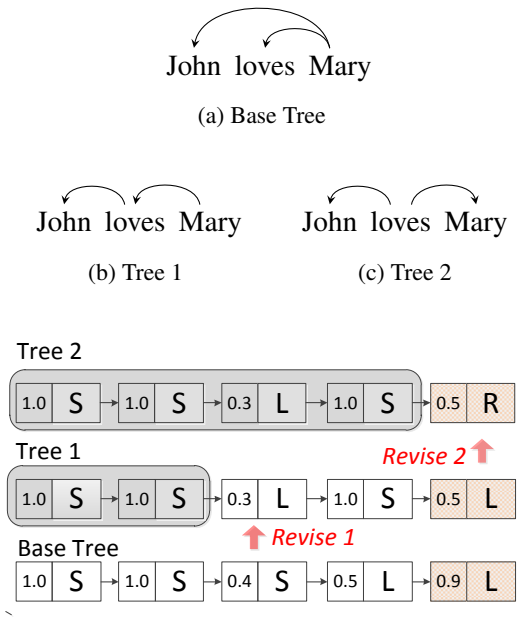
Abstract

We propose a novel reranking method to extend a deterministic neural dependency parser. Different to conventional k-best reranking, the proposed model integrates search and learning by utilizing a dynamic action revising process, using the reranking model to guide modification for the base outputs and to rerank the candidates. The dynamic reranking model achieves an absolute 1.78% accuracy improvement over the deterministic baseline parser on PTB, which is the highest improvement by neural rerankers in the literature.

1 Introduction

Neural network models have recently been exploited for dependency parsing. Chen and Manning (2014) built a seminal model by replacing the SVM classifier at the transition-based MaltParser (Nivre et al., 2007) with a feed-forward neural network, achieving significantly higher accuracies and faster speed. As a local and greedy neural baseline, it does not outperform the best discrete-feature parsers, but nevertheless demonstrates strong potentials for neural network models in transition-based dependency parsing.

Subsequent work aimed to improve the model of Chen and Manning (2014) in two main directions. First, global optimization learning and beam search inference have been exploited to reduce error propagation (Weiss et al., 2015; Zhou et al., 2015). Second, recurrent neural network models have been used to extend the range of neural features beyond a local window (Dyer et al., 2015; Ballesteros et al., 2015). These methods give accuracies that are competitive to the best results in the literature.



(d) 2-step action revising process for sentence "John loves Mary". Numbers before actions are the probabilities for that action.

Figure 1: Example action revising process. S, L, R stand for the SHIFT, LEFT, RIGHT actions, respectively (Section 2).

Another direction to extend a baseline parser is reranking (Collins and Koo, 2000; Charniak and Johnson, 2005; Huang, 2008). Recently, neural network models have been used to constituent (Socher et al., 2013; Le et al., 2013) and dependency (Le and Zuidema, 2014; Zhu et al., 2015) parsing reranking. Compared with rerankers that rely on discrete manual features, neural network rerankers can potentially capture more global information over whole parse trees.

Traditional rerankers are based on chart parsers, which can yield exact k-best lists and forests. For reranking, this is infeasible for the transition-based neural parser and neural reranker, which

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1393–1402,
Berlin, Germany, August 7-12, 2016.

have rather weak feature locality. In addition, k-best lists from the baseline parser are not necessarily the best candidates for a reranker. Our preliminary results show that reranking candidates can be constructed by modifying unconfident actions in the baseline parser output, and letting the baseline parser re-decode the sentence from the modified action. In particular, revising two incorrect actions of the baseline parser yields oracle with 97.79% UAS, which increases to 99.74% by revising five actions. Accordingly, we design a novel search-based dynamic reranking algorithm by revising baseline parser outputs.

For example, the sentence: "*John loves Mary*", the baseline parser generates a *base tree* (Figure 1a) using 5 shift-reduce actions (Figure 1d) of Section 2. The gold parse tree can be obtained by a 2-step action revising process:

$$\text{Base Tree} \xrightarrow{\text{Revise 1}} \text{Tree 1} \xrightarrow{\text{Revise 2}} \text{Tree 2}$$

As shown in Figure 1d, we first revise the least confident action S of the *base tree*, running the baseline parser again from the revised action to obtain *tree 1*. This corrects the *John* $\curvearrowleft$ *loves* dependency arc. Then we obtain the gold parsing tree (*tree 2*) by further revising the least confident action in *tree 1* on the second action sequence.

Rather than relying on the baseline model scores alone for deciding the action to revise (*static search*), we build a neural network model to guide which actions to revise, as well as to rerank the output trees (*dynamic search*). The resulting model integrates search and learning, yielding the minimum amount of candidates for the best accuracies. Given the extensively fast speed of the baseline parser, the reranker can be executed with high efficiency.

Our dynamic search reranker has two main advantages over the static one: the first is *training diversity*, the dynamic reranker searches over more different structurally diverse candidate trees, which allows the reranker to distinguish candidates more easily; the second is *reranking oracle*, with the guidance of the reranking model, the dynamic reranker has a better reranking oracle compared to the static reranker.

On WSJ, our dynamic reranker achieved 94.08% and 93.61% UAS on the development and test sets, respectively, at a speed of 16.1 sentences per second. It yields a 0.44% accuracy improvement (+1.78%) from the same number of candidates, compared to a static reranker (+1.34%), obtaining the largest accuracy improvement among related neural rerankers.

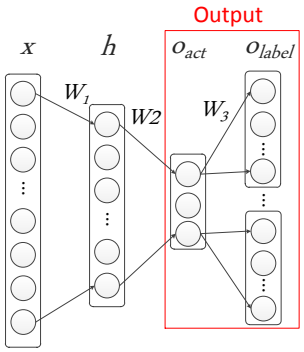


Figure 2: Hierarchical neural parsing model.

2 Baseline Dependency Parser

Transition-based dependency parsers scan an input sentence from left to right, performing a sequence of transition actions to predict its parse tree (Nivre, 2008). We employ the *arc-standard* system (Nivre et al., 2007), which maintains partially-constructed outputs using a *stack*, and orders the incoming words in the sentence in a *queue*. Parsing starts with an empty stack and a queue consisting of the whole input sentence. At each step, a *transition action* is taken to consume the input and construct the output.

Formally, a *parsing state* is denoted as $\langle j, S, L \rangle$, where S is a stack of subtrees $[\dots s_2, s_1, s_0]$, j is the head of the queue (i.e. $[\ q_0 = w_j, q_1 = w_{j+1} \cdots]$), and L is a set of dependency arcs that has been built. At each step, the parser chooses one of the following actions:

- SHIFT (S): move the front word w_j from the queue onto the stacks.
- LEFT-l (L): add an arc with label l between the top two trees on the stack ($s_1 \leftarrow s_0$), and remove s_1 from the stack.
- RIGHT-l (R): add an arc with label l between the top two trees on the stack ($s_1 \rightarrow s_0$), and remove s_0 from the stack.

Given the sentence "*John loves Mary*", the gold standard action sequence is S, S, L, S, R.

2.1 Model

Chen and Manning (2014) proposed a deterministic neural dependency parser, which rely on dense embeddings to predict the optimal actions at each step. We propose a variation of Chen and Manning

(2014), which splits the output layer into two hierarchical layers: the action layer and dependency label layer. The hierarchical parser determines a action in two steps, first deciding the *action type*, and then the *dependency label* (Figure 2).

At each step of deterministic parsing, the neural model extracts n atomic features from the parsing state. We adopt the feature templates of Chen and Manning (2014). Every atomic feature is represented by a feature embedding $e_i \in \mathbb{R}^d$, An *input layer* is used to concatenate the n feature embeddings into a vector $x = [e_1; e_2 \dots e_n]$, where $x \in \mathbb{R}^{d \cdot n}$. Then x is mapped to a d_h-dimensional *hidden layer* h by a mapping matrix $W_1 \in \mathbb{R}^{d_h \times d \cdot n}$ and a cube activation function for feature combination:

$$h = (W_1 x + b_1)^3 \tag{1}$$

Our method is different from Chen and Manning (2014) in the output layer. Given the hidden layer h, the action type output layer o_{act} and the label output layer $o_{label}(a_i)$ of the action type a_i are computed as

$$o_{act} = W_2 h \tag{2}$$

$$o_{label}(a_i) = W_3^i h \ , \tag{3}$$

Where $W_2 \in \mathbb{R}^{d_a \times d_h}$ is the mapping matrix from the hidden layer to the action layer, and d_a is the number of action types. $W_3^i \in \mathbb{R}^{d_{label} \times d_h}$ is the mapping matrix from the hidden layer to the corresponding label layer, d_{label} is the number of dependency labels.

The probability of a labeled action $y_{i,j}$ given its history $Acts$ and input x is computed as:

$$\begin{aligned} & p(y_{i,j} \mid x, Acts) \\ = \ & p(a_i \mid x, Acts) \times p(l_j \mid x, Acts, a_i) \end{aligned} \tag{4}$$

where

$$p(a_i \mid x, Acts) = \frac{e^{o^i_{act}}}{\sum_{k=1}^{d_a} e^{o^k_{act}}} \tag{5}$$

$$p(l_j \mid x, Acts, a_i) = \frac{e^{o^j_{label}(a_i)}}{\sum_{k=1}^{d_{label}} e^{o^k_{label}(a_i)}} \ , \tag{6}$$

Here a_i is the i_{th} action in the action layer, and l_j is the j_{th} label in the label layer for a_i.

In training, we use the cross-entropy loss to maximum the probability of training data A:

$$L(\theta) = -\sum_{y_{i,j} \in A} \log p(y_{i,j} \mid x, Acts) \tag{7}$$

Experiments show that our hierarchical neural parser is both faster and slightly accurate than the original neural parser.

3 Reranking Scorer

We adopt the recursive convolutional neural network (RCNN) of Zhu et al. (2015) for scoring full trees. Given a dependency subtree rooted at h, c_i ($0 < i \leq L$) is the i_{th} child of h. The dependency arc (h, c_i) is represented by:

$$z_i = tanh(W^{(h,c_i)} p_i) \ , \tag{8}$$

where

$$p_i = w_h \oplus x_{c_i} \oplus d^{(h,c_i)} \tag{9}$$

Here $p_i \in \mathbb{R}^n$ is the concatenation of head word embedding w_h, child phrase representation x_{c_i} and the distance embeddings $d^{(h,c_i)}$. $W^{(h,c_i)} \in \mathbb{R}^{m \times n}$ is a linear composition matrix, which depends on the POS tags of h and c_i. The subtree phrase representation x^h are computed using a max-pooling function on rows, over the matrix of arc representations Z^h.

$$Z^h = [z_1, z_2, \dots, z_L] \tag{10}$$

$$x^h_j = \max_i Z^h_{j,i}, 0 < j < m \tag{11}$$

The subtree with the head h is scored by:

$$score(h) = \sum_{i=1}^{L} v^{h,c_i} z_i \tag{12}$$

Here, v^{h,c_i} is the score vector, which is a vector of parameters that need to be trained. The score of the whole dependency tree y is computed as:

$$s_t(x, y, \Theta) = \sum_{w \in y} score(w), \tag{13}$$

where w is the node in tree y and Θ denotes the set of parameters in the network.

4 Search-based Dynamic Reranking for Dependency Parsing

Using the hierarchical parser of Section 2 as the baseline parser, we propose a search-based dynamic reranking model, which integrates search and learning by searching the reranking candidates dynamically, instead of limiting the scope to a fixed k-best list. The efficiency of the reranking model is guaranteed by 3 properties of the baseline parser, namely *revising efficiency*, *probability diversity* and *search efficiency*.

Revising Depth	UAS	LAS
0	92.28	91.15
1	95.76	94.42
2	97.79	96.63
3	98.77	97.55
4	99.39	98.15
5	99.74	98.47

Table 1: Oracle of the baseline parser after revising actions. Revising depth is the maximum number of revised actions for one sentence.

Action Type		Num	Average Probability
Gold	Shift	39194	99.38%
	Right	19477	98.90%
	Left	19556	99.61%
Incorrect	Shift	968	84.96%
	Right	746	85.88%
	Left	338	85.03%

Table 2: Average action probabilities.

4.1 Properties of the Baseline Parser

To demonstrate the above three properties, we give some preliminary results for the baseline. To parse the 1,695 sentences in Section 22 of WSJ, our baseline parser needs to perform 78,227 shift-reduce actions. During the process, if we correct every encountered incorrectly determined action and let the baseline parser re-decode the sentence from the point, we need to revise 2,052 actions, averaging 1.2 actions per sentence. In other words, the baseline parser can parse the 1,695 sentences correctly with 2,052 action being revised.

Note that the revise operation is required to change the action type (i.e. S, L). After revising the action type, the optimal dependency label will be chosen for parsing by the hierarchical baseline parser. We only modify the action type in the revising process. Thus the modified trees are always structurally different instead of only with different dependency labels compared to the original one, which guarantees structured diversity.

Revising Efficiency It can be seen from Table 1 that revising one incorrect action results in 3.5% accuracy improvement. We obtain a 99.74% UAS after a maximum 5 depth revising. Although we only revise the action type, the LAS goes up with the UAS. The property of *revising efficiency* suggests that high quality tree candidates can be found with a small number of changes.

Probability Diversity Actions with lower probabilities are more likely to be incorrect. We compute the average probabilities of gold and incorrect actions in parsing the section 22 of WSJ (Table 2), finding that most gold actions have very high probabilities. The average probabilities of the gold actions is much higher than that of the incorrectly predicted ones, indicating that revising actions with lower probabilities can lead to better trees.

Search Efficiency The fast speed of the baseline parser allows the reranker to search a large number of tree candidates efficiently. With the graph stack trick (Goldberg et al., 2013), the reranker only needs to perform partial parsing to obtain new trees. This enables a fast reranker in theory.

4.2 Search Strategy

Given an output sequence of actions by the baseline parser, we revise the action with the lowest *probability margin*, and start a new branch by taking a new action at this point. The probability margin of an action a is computed as: $p(a_{max}) - p(a)$, where a_{max} is the action taken by the baseline, which has the highest model probability. a is taken instead of a_{max} for this branch, and the baseline parser is executed deterministically until parsing finishes, thus yielding a new dependency tree. We require that the action type must change in the revision and the most probable dependency label among all for the revised action type will be used.

Multiple strategies can be used to search for the revised reranking process. For example, one intuitive strategy is best-first, which modifies the action with the lowest probability margin among all sequences of actions constructed so far. Starting from the original output of the baseline parser, modifying the action with the lowest probability margin results in a new tree. According to the best-first strategy, the action with the lowest probability margin in the two outputs will be revised next to yield the third output. The search repeats until k candidates are obtained, which are used as candidates for reranking.

The best-first strategy, however, does not consider the quality of the output, which is like a greedy process. A better candidate (with higher F1 score) is more likely to take us to the gold tree. With the best-first strategy, we revise one tree at each time. If the selected tree is not the optimal one, the revised tree will be less likely the gold one. Revising a worse output is less likely to generate the gold parse tree compared with revising a relatively better output. Our preliminary experi-

ments confirms this intuition. As a result, we take a beam search strategy, which uses a beam to hold b outputs to modify.

For each tree in beam search, most f actions with the lowest probability margin are modified, leading to $b \times f$ new trees. Here, b is the beam size, f is the revising factor. From these trees, the b best are put to the beam for the next step. Search starts with the beam containing only the original base parse, and repeats for l steps, where l is called the revising depth. The best tree will be selected from all the trees constructed. The search process for example in Figure 1 is illustrated in Figure 3, in which $b = 1$, $f = 3$ and $l = 2$.

At each iteration, the b best candidates can be decided by the baseline parser score alone, which is the product of the probability of each action. We call this the *static search* reranking. As mentioned in the introduction, the baseline model score might not be the optimal criteria to select candidates for reranking, since they may not reflect the best oracle or diversity. We introduce a *dynamic search* strategy instead, using the reranking model to calculate heuristic scores for guiding the search.

4.3 Search-Based Dynamic Reranking

Doppa et al. (2013) propose that structured-prediction by learning guide search should maintain two different scoring functions, a heuristic function for guiding search and a cost function for obtaining the best output. Following Doppa et al. (2013), we use the RCNN in Section 3 to yield two different scores, namely a heuristic score $s_t(x, y, \Theta_h)$ to guide the search of revising, and a cost score $s_t(x, y, \Theta_c)$ to select the best tree output.

Denote $b(i)$ as the beam at i-th step of search, k-best candidates in the beam of $i + 1$ step is:

$$b(i+1) = \arg\underset{c \in c(i)}{K}(s_t(x, c, \Theta_h) + s_b(x, c)), \quad (14)$$

where $c(i)$ denotes the set of newly constructed trees by revising trees in $b(i)$, $s_b(x, c)$ is the baseline model score and $\arg K$ leaves the k best candidate trees to the next beam. Finally, the output tree y_i of reranking is selected from all searched trees C in the revising process

$$y_i = \arg\max_{c \in C}(s_t(x, c, \Theta_c) + s_b(x, c)) \quad (15)$$

Interpolated Reranker In testing, we also adopt the popular mixture reranking strategy (Hayashi et al., 2013; Le and Mikolov, 2014), which obtains better reranking performance by a linear combination of the reranking score and the baseline model score.

$$y_i = \arg\max_{y \in \tau(x_i)} (\beta(s_t(x_i, y, \Theta_c) + s_t(x, y, \Theta_h)) + (1 - \beta)s_b(x_i, y)) \quad (16)$$

Here y_i is the final output tree for a sentence x_i; $\tau(x_i)$ returns all the trees candidates of the dynamic reranking; $\beta \in [0, 1]$ is a hyper-parameter.

    D_c.ADD (x, y, *bestCScoreT*);
  UPDATE(D_h, Θ_h);
  UPDATE(D_c, Θ_c);

4.4 Training

As k-best neural rerankers (Socher et al., 2013; Zhu et al., 2015), we use the max-margin criterion to train our model in a stage-wise manner (Doppa et al., 2013). Given training data D_c = $(x_i, y_i, \hat{y}_i)_{i=1}^N$, where x_i is the sentence, $\hat{y}_i$ is the output tree with highest cost score and y_i is the corresponding gold tree, the final training objective is to minimize the loss function $J(\Theta_c)$, plus a

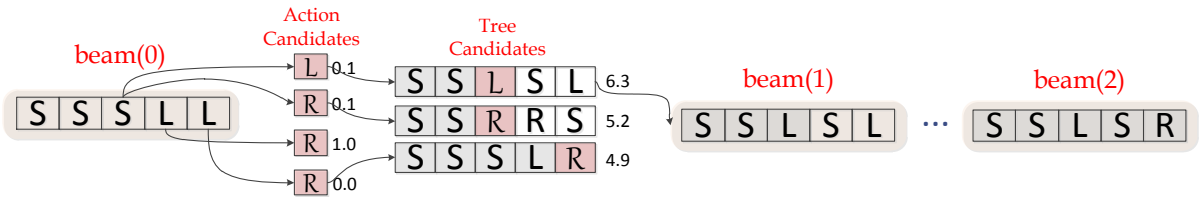

Figure 3: The beam search revising process of the example in Figure 1 with $b = 1$, $f = 3$ and $l = 2$

l_2-regularization:

$$J(\Theta_c) = \frac{1}{|D_c|} \sum_{(x_i, y_i, \hat{y}_i) \in D_c} r_i(\Theta_c) + \frac{\lambda}{2}||\Theta_c|| \quad (17)$$

$$r_i(\Theta_c) = \max(0, s_t(x_i, \hat{y}_i, \Theta_c) + \Delta(y_i, \hat{y}_i) - s_t(x_i, y_i, \Theta_c)) \quad (18)$$

Here, Θ_c is the model, $s_t(x_i, y_i, \Theta_c)$ is the cost reranking score for y_i.

$$\Delta(y_i, \hat{y}_i) = \sum_{d \in \hat{y}_i} \kappa \mathbf{1}\{d \notin y_i\} \quad (19)$$

$\Delta(y_i, \hat{y}_i)$ is the structured margin loss between y_i and $\hat{y}_i$, measured by counting the number of incorrect dependency arcs in the tree (Goodman, 1998; Zhu et al., 2015).

Given training data $D_h = (x_i, y'_i, \hat{y}'_i)_{i=1}^N$ for the heuristic score model, the training objective is to minimize the loss between the tree with the best UAS y'_i and the tree with the best heuristic reranking score $\hat{y}'_i$.

$$J(\Theta_h) = \frac{1}{|D_h|} \sum_{(x_i, y'_i, \hat{y}'_i) \in D_h} r_i(\Theta_h) + \frac{\lambda}{2}||\Theta_h|| \quad (20)$$

$$r_i(\Theta_h) = \max(0, s_t(x_i, \hat{y}'_i, \Theta_h)) - s_t(x_i, y'_i, \Theta_h) \quad (21)$$

The detailed training algorithm is given by Algorithm 1. AdaGrad (Duchi et al., 2011) updating with subgradient (Ratliff et al., 2007) and mini-batch is adopted for optimization.

5 Experiments

5.1 Set-up

Our experiments are performed using the English Penn Treebank (PTB; Marcus et al., (1993)). We follow the standard splits of PTB3, using sections 2-21 for training, section 22 for development and section 23 for final testing. Following prior work on reranking, we use Penn2Malt[1] to convert constituent trees to dependency trees. Ten-fold POS jackknifing is used in the training of the baseline parser. We use the POS-tagger of Collins (2002) to assign POS automatically. Because our reranking model is a dynamic reranking model, which generates training instances during search, we train 10 baseline parsing models on the 10-fold jackknifing data, and load the baseline parser model dynamically for reranking training .

We follow Chen and Manning (2014), using the set of pre-trained word embeddings with a dictionary size of 13,000[2] from Collobert et al. (2011). The word embeddings were trained on the entire English Wikipedia, which contains about 631 million words.

5.2 Hyper-parameters

There are two different networks in our system, namely a hierarchical feed-forward neural network for the baseline parsing and a recursive convolution network for dynamic reranking. The hyper-parameters of the hierarchical parser are set as described by Chen and Manning (2014), with the embedding size $d = 50$, the hidden layer size $d_h = 300$, the regularization parameter $\lambda = 10^{-8}$, the initial learning rate of Adagrad $\alpha = 0.01$ and the batch size $b = 100{,}000$. We set the hyper-parameters of the RCNN as follows: word embedding size $d^w_{rnn} = 25$, distance embedding size $d^d_{rnn} = 25$, initial learning rate of Adagrad $\alpha_{rnn} = 0.1$, regularization parameter $\lambda_{rnn} = 10^{-4}$, margin loss discount $\kappa = 0.1$ and revising factor $f = 8$.

5.3 The Hierarchical Neural Parser

Shown in Table 3, the proposed hierarchical base parser is 1.3 times faster, and obtains a slight accuracy improvement (Table 3) upon the parser of Chen and Manning (2014). The reason for the

Parser	dev		test		Speed
	UAS	LAS	UAS	LAS	
hiero	92.28	91.15	91.83	90.76	884.7
original	92.00	90.89	91.67	90.62	682.3

Table 3: Performance comparison between the hierarchical and original neural parsers. Speed: sentences per second.

Beam Size	1	2	4	8
UAS	93.38	93.45	93.81	93.51
Oracle	96.95	97.29	97.80	97.81
K	22.57	37.16	65.8	118.7

Table 4: Accuracies of the revising reranker with different beam sizes on the development set.

speed gain is that smaller output layer leads to less computation of mapping from the hidden layer to the output layer in neural networks (Morin and Bengio, 2005; Mnih and Hinton, 2009).

5.4 Development Tests

For the beam search dynamic reranking model, the selection of beam size b and revising depth l affect the accuracy and efficiency of the reranker. We tune the values on the development set.

Beam Size A proper beam size balances efficiency and accuracy in the search process. The reranking accuracies with different beam sizes are listed in Table 4. Here, the oracle is the best UAS among searched trees during reranking. K is the number of searched candidate trees in testing. The UAS and parsing oracle both go up with increasing the beam size. Reranking with beam size = 4 gives the best development performance. We set the final beam size as 4 in the next experiments.

Revising Depth As shown in Table 5, with revising depth increasing from 1 to 3, the reranker obtains better parsing oracle. The depth of 3 gives the best UAS 93.81% on the development set. The parsing oracle stops improving with deeper revised search. This may because in the fourth search step, the high quality trees begin to fall out the beam, resulting in worse output candidates, which make the revising step yield less oracle gains. We set the search depth as 3 in the next experiments.

Integrating Search and Learning Shown in Table 6, the dynamic and static rerankers both achieve significant accuracy improvements over the baseline parser. The dynamic reranker gives much better improvement, although the oracle of dynamic reranker is only 0.2% higher than the static one. This demostrates the benefit of diversity. The candidates are always the same for static search, but the dynamic reranker searches more diverse tree candidates in different iterations of training.

Revising Depth	1	2	3	4
UAS	93.22	93.50	93.81	93.53
Oracle	96.31	97.57	97.80	97.81
K	8.87	38.45	65.8	90.28

Table 5: Accuracies of the revised reranker with different revising depths on development set.

Search Type	UAS	+UAS	Oracle
Dynamic	93.81	+1.53	97.80
Static	93.29	+1.01	97.61

Table 6: Comparing dynamic and the static search.

To further explore the impact of training diversity to dynamic reranking, we also compare the dynamic search reranker of training and testing with different revising depth. In Table 7, *origin* is the results by training and testing with the same depth d. Results of *ts* is obtained by training with d = 3, and testing with a smaller d. For example, a reranker with training d = 3 and testing d = 2 achieves better performance than with training d = 2 and testing d = 2. The testing oracle of the former reranker is lower than the later, yet the former learns more from the training instance, obtaining better parsing accuracies. This again indicates that training diversity is very important besides the oracle accuracy.

Interpolated Reranker Finally, we mix the baseline model score and the reranking score by following Hayashi et al. (2013) and Zhu et al. (2015), and the mixture parameter β is optimized by searching with the step size of 0.005. With the mixture reranking trick, the dynamic reranker obtains an accuracy of 94.08% (Table 8), with an improvement of 0.28% on the development set.

5.5 Final Results

Comparison with Dependency Rerankers In Table 9, we compare the search-based dynamic rerankers with a list of dependency rerankers. The reranking models of Hayashi et al. (2013) and Hayashi et al. (2011) are forest reranking models. Le and Zuidema (2014) and Zhu et al. (2015) are neural k-best reranking models. Our dynamic

Depth		1	2	3
ordinary	UAS	93.22	93.50	93.81
	oracle	96.31	97.57	97.80
ts	UAS	93.59	93.79	93.81
	oracle	96.29	93.42	97.80

Table 7: Accuracies of the revised reranker with different revising depths on the development set.

Type	static	dynamic
w/o mixture	93.29	93.81
w/ mixture	93.53	94.08

Table 8: Effects of interpolated reranking.

reranking model achieves the highest accuracy improvement over the baseline parser on both the development and test sets. We obtain the best performance on the development set. Zhu et al. (2015) achieved higher accuracy on the test set, but they adopted a better baseline parser than ours, which could not be used in our dynamic reranker because it is not fast enough and will make our reranker slow in practice.

Comparing with Neural Dependency Parsers We also compare parsing accuracies and speeds with a number of neural network dependency parsers. Dyer et al. (2015) proposed a dependency parser with stack LSTM; Zhou et al. (2015) applied the beam search for structured dependency parsing. Both achieved significant accuracy improvements over the deterministic neural parser of Chen and Manning (2014). Our dynamic search reranker obtains a 93.61% UAS on the test set, which is higher than most of the neural parsers except Weiss et al. (2015), who employ a structured prediction model upon the neural greedy baseline, achieving very high parsing accuracy.

5.6 Results on Stanford dependencies

We also evaluate the proposed static and dynamic rerankers on Staford dependency treebank. The main results are consistent with CoNLL dependency treebank with the dynamic reranker achieving a 0.41% accuracy improvement upon the static reranker on test data. But the parsing accuracy on Stanford dependency is not the state-of-the-art. We speculate that there may be two reasons. First, the baseline parsing accuracy on Stanford dependencies is lower than CoNLL. Second, all the hyper-parameters are tuned on the CoNLL data.

6 Related Work

Neural Networks Reranking A line of work has been proposed to explore reranking using neural networks. Socher et al. (2013) first proposed a neural reranker using a recursive neural network for constituent parsing. Le and Zuidema (2014) extended the neural reranker to dependency parsing using a inside-outside recursive neural network (IORNN), which can process trees both bottom-up and top-down. Zhu et al. (2015) proposed a RCNN method, which solved the problem of modeling k-ary parsing tree in dependency parsing. The neural rerankers are capable of capturing global syntax features across the tree. In contrast, the most non-local neural parser with LSTM (Dyer et al., 2015) cannot exploit global features. Different to previous neural rerankers, our work in this paper contributes on integrating search and learning for reranking, instead of proposing a new neural model.

Forest Reranking Forest reranking (Huang, 2008; Hayashi et al., 2013) offers a different way to extend the coverage of reranking candidates, with computing the reranking score in the trees forests by decomposing non-local features with cube-pruning (Huang and Chiang, 2005). In contrast, the neural reranking score encodes the whole dependency tree, which cannot be decomposed for forest reranking efficiently and accurately.

HC-Search Doppa et al. (2013) proposed a structured prediction model with HC-Search strategy and imitation learning, which is closely related to our work in spirit. They used the complete space search (Doppa et al., 2012) for sequence labeling tasks, and the whole search process halts after a specific time bound. Different from them, we propose a dynamic parsing reranking model based on the action revising process, which is a multi-step process by revising the least confident

actions from the base output and the search stops in a given revising depth. The dynamic reranking model concentrates on extending the training diversity and testing oracle for parsing reranking, which is built on the transition-based parsing framework.

7 Conclusion

In this paper, we proposed a search-based dynamic reranking model using a hierarchical neural base parser and a recursive convolutional neural score model. The dynamic model is the first reranker integrating search and learning for dependency parsing. It achieves significant accuracy improvement (+1.78%) upon the baseline deterministic parser. With the dynamic search process, our reranker obtains a 0.44% accuracy improvement upon the static reranker. The code of this paper can be downloaded from `http://github.com/zhouh/dynamic-reranker`.

Cross-Lingual Sentiment Classification with Bilingual Document Representation Learning

Xinjie Zhou, **Xianjun Wan** and **Jianguo Xiao**
Institute of Computer Science and Technology, Peking University
The MOE Key Laboratory of Computational Linguistics, Peking University
{zhouxinjie,wanxiaojun,xiaojianguo}@pku.edu.cn

Abstract

Cross-lingual sentiment classification aims to adapt the sentiment resource in a resource-rich language to a resource-poor language. In this study, we propose a representation learning approach which simultaneously learns vector representations for the texts in both the source and the target languages. Different from previous research which only gets bilingual word embedding, our Bilingual Document Representation Learning model BiDRL directly learns document representations. Both semantic and sentiment correlations are utilized to map the bilingual texts into the same embedding space. The experiments are based on the multilingual multi-domain Amazon review dataset. We use English as the source language and use Japanese, German and French as the target languages. The experimental results show that BiDRL outperforms the state-of-the-art methods for all the target languages.

1 Introduction

Sentiment analysis for online user-generated contents has become a hot research topic during the last decades. Among all the sentiment analysis tasks, polarity classification is the most widely studied topic. It has been proved to be invaluable in many applications, such as opinion polling (Tang et al., 2012), customer feedback tracking (Gamon, 2004), election prediction (Tumasjan et al., 2010), stock market prediction (Bollen et al., 2011) and so on.

Most of the current sentiment classification systems are built on supervised machine learning algorithms which require manually labelled data. However, sentiment resources are usually unbalanced in different languages. Cross-lingual sentiment classification aims to leverage the resources in a resource-rich language (such as English) to classify the sentiment polarity of texts in a resource-poor language (such as Japanese). The biggest challenge for cross-lingual sentiment classification is the vocabulary gap between the source language and the target language. This problem is addressed with different strategies in different approaches. Wan (2009) use machine translation tools to translate the training data directly into the target language. Meng et al. (2012) and Lu et al. (2011) exploit parallel unlabeled data to bridge the language barrier. Prettenhofer and Stein (2010) use correspondence learning algorithm to learn a map between the source language and the target language. Recently, representation learning methods has been proposed to solve the cross-lingual classification problem (Xiao and Guo, 2013; Zhou et al., 2015). These methods aim to learn common feature representations for different languages. However, most of the current researches only focus on bilingual word embedding. In addition, these models only use the semantic correlations between aligned words or sentences in different languages while the sentiment correlations are ignored.

In this study, we propose a cross-lingual representation learning model BiDRL which simultaneously learns both the word and document representations in both languages. We propose a joint learning algorithm which exploits both monolingual and bilingual constraints. The monolingual constraints help to model words and documents in each individual language while the bilingual constraints help to build a consistent embedding space across languages.

For each individual language, we extend the paragraph vector model (Le and Mikolov, 2014)

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1403–1412,
Berlin, Germany, August 7-12, 2016.

to obtain word and document embeddings. The traditional paragraph vector model is fully unsupervised without using the valuable sentiment labels. We extend it into a semi-supervised manner by forcing the positive and negative documents to fall into different sides of a classification hyperplane. Learning task-specific embedding has been proved to be effective in previous research. To address the cross-language problem, different strategies are proposed to obtain a consistent embedding space across different languages. Both sentiment and semantic relatedness are exploited while previous studies only use the semantic connection between parallel sentences or documents.

The performance of BiDRL is evaluated on a multilingual multi-domain Amazon review dataset (Prettenhofer and Stein, 2010). By selecting English as the source language, a total of nine tasks are evaluated with different combinations of three different target languages and three different domains. The proposed method achieves the state-of-the-art performance on all the tasks.

The main contributions of this study are summarized as follows:

1) We propose a novel representation learning method BiDRL which directly learns bilingual document representations for cross-lingual sentiment classification. Different from previous studies which only obtain word embeddings, our model can learn vector representations for both words and documents in bilingual texts.

2) Our model leverages both the semantic and sentiment correlations between bilingual documents. Not only the parallel documents but also the documents with the same sentiment are required to get similar representations.

3) Our model achieves the state-of-the-art performances on nine benchmark cross-lingual sentiment classification tasks and it consistently outperforms the existing methods by a large margin.

2 Related Work

Sentiment analysis is the field of studying and analyzing people's opinions, sentiments, evaluations, appraisals, attitudes, and emotions (Liu, 2012). Most of the previous sentiment analysis researches focus on customer reviews and classifying the sentiment polarity is the most widely studied task (Pang et al., 2002).

Cross-lingual sentiment classification is a popular topic in the sentiment analysis community which aims to solve the sentiment classification task from a cross-language view. It is of great importance for the area since it can exploit the existing labeled information in a source language to build a sentiment classification system in any other target language. It saves us from manually labeling data for all the languages in the world which is expensive and time-consuming. Cross-lingual sentiment classification has been extensively studied in the very recent years. Mihalcea et al. (2007) translate English subjectivity words and phrases into the target language to build a lexicon-based classifier. Banea et al. (2010) also use the machine translation service to obtain parallel corpus. It investigates several questions based on the parallel corpus including both the monolingual sentiment classification and cross-lingual sentiment classification. Wan (2009) translates both the training data (English to Chinese) and the test data (Chinese to English) to train different models in both the source and target languages. The co-training algorithm (Blum and Mitchell, 1998) is used to combine the bilingual models together and improve the performance. In addition to the translation-based methods, several studies utilize parallel corpus or existing resources to bridge the language barrier. Balamurali (2012) use WordNet senses as features for supervised sentiment classification. They use the linked WordNets of two languages to bridge the language gap. Lu et al. (2011) consider the multilingual scenario where small amount of labeled data is available in the target language. They attempted to jointly classify the sentiment for both source language and target language. Meng et al. (2012) propose a generative cross-lingual mixture model to leverage unlabeled bilingual parallel data. Prettenhofer and Stein (2010) use the structural correspondence learning algorithm to learn a map between the source language and the target language. Xiao and Guo (2014) treat the bilingual feature learning problem as a matrix completion task.

This work is also related to bilingual representation learning. Zou et al. (2013) propose to use word alignment as the constraints in bilingual word embedding. Each word in one language should be similar to the aligned words in another language. Gouws et al. (2015) propose a similar algorithm but only use sentence-level alignment. It tries to minimize a sampled L2-loss between the bag-of-words sentence vectors of the parallel cor-

pus. Xiao and Guo (2013) learn different representations for words in different languages. Part of the word vector is shared among different languages and the rest is language-dependent. Klementiev et al. (2012) treat the task as a multi-task learning problem where each task corresponds to a single word, and task relatedness is derived from co-occurrence statistics in bilingual parallel data. Hermann and Blunsom (2015) propose the bilingual CVM model which directly minimizes the representation of a pair of parallel documents. The document representation is calculated with a composition function based on words. Chandar A P et al. (2014) and Zhou et al. (2015) use the autoencoder to model the connections between bilingual sentences. It aims to minimize the reconstruction error between the bag-of-words representations of two parallel sentences. Luong et al. (2015) propose the bilingual skip-gram model which leverages the word alignment between parallel sentences. Pham et al. (2015) extend the paragraph vector model to force bilingual sentences to share the same sentence vector.

This study differs with the existing works in the following three aspects, 1) we exploit both the semantic and sentiment correlations of the bilingual texts. Existing bilingual embedding algorithms only use the semantic connection between parallel sentences or documents. 2) Our algorithm learns both the word and document representations. Most of the previous studies simply compute the average of the word vectors in a document. 3) Sentiment labels are used in our embedding algorithm by introducing a classification hyperplane. It not only helps to achieve better embedding performance in each individual language but also helps to bridge the language barrier.

3 Framework

Firstly we introduce several notations used in BiDRL. Let S and S_u denote the documents from the training dataset and the documents from the unlabeled dataset in the source language respectively. For each document $d \in S$, it has a sentiment label $y \in \{1, -1\}$. We denote the sentiment label set of all the documents in S as Y. Let T and T_u denote the documents from the test dataset and the documents from the unlabeled dataset in the target language. The documents in the training and test datasets in the source and target languages are translated into the other language using the online machine translation service - Google Translate[1]. We denote them as T_s (the translation of S) and S_t (the translation of T). We wish to learn a D-dimensional vector representation for all the documents in the dataset.

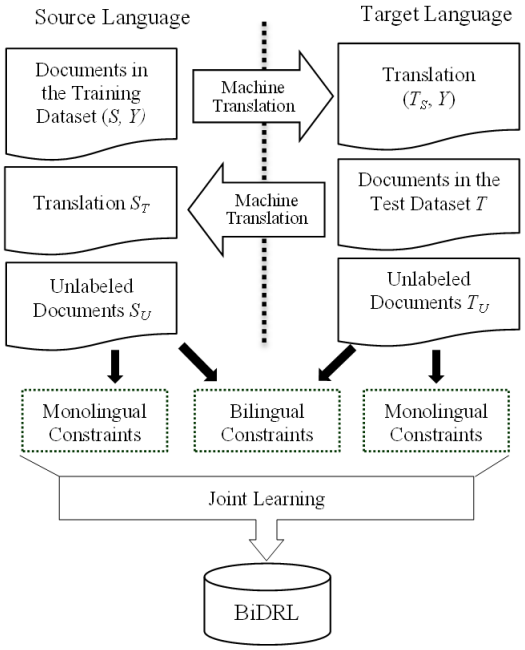

Figure 1: Framework of BiDRL

The general framework of BiDRL is shown in Figure 1. After we obtain the data in the source and target languages, we propose both the monolingual and bilingual constraints to learn the model. The monolingual constraints help to model words and documents in each individual language. The bilingual constraints help to build a consistent embedding space across different languages. The joint learning framework is semi-supervised which uses the sentiment labels Y of the training documents.

3.1 Monolingual Constraints

In this subsection, we describe the representation learning algorithm for the source and target languages. We start from the paragraph vector model (Le and Mikolov, 2014) which has been proved to be one of the state-of-the-art methods for document modeling. In the paragraph vector framework, both documents and words are mapped to unique vectors. Each document is treated as a unique token which is the context of all the words in the document. Therefore, each word in the doc-

[1] http://translate.google.com/

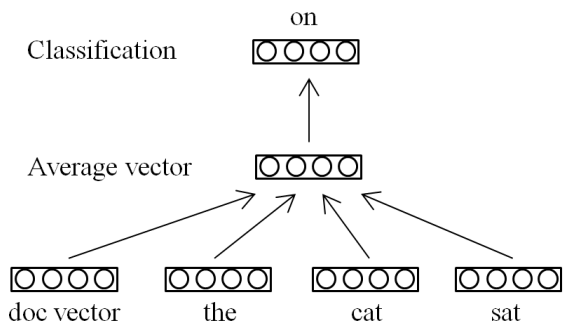

Figure 2: Paragraph vector

ument can be predicted by the context tokens and the document as shown in Figure 2. The idea leads to the following function,

$$\arg\max \sum_{d \in D} \sum_{(w,C) \in d} \log p(w \mid C, d) \quad (1)$$

where D is the document set, w and C are the word and its context in a document d. The only difference between paragraph vector algorithm and the well-known `word2vec` algorithm (Mikolov et al., 2013) is the additional document vector.

The conditional probability of predicting a word from its context is modeled via softmax which is very expensive to compute. It is usually approximately solved via negative sampling. A log-bilinear model is used instead to predict whether two words are in the same context. For a word and context pair (w, C) in a document d, the objective function becomes,

$$\begin{aligned} L_1 = &- \log \sigma(v_w^T \cdot \frac{1}{k+1} \cdot (v_d + \sum_{c \in C} v_c)) - \\ &\sum_{i=1}^{n} E_{w' \in p_n(w)} (\log \sigma(-v_w'^T \cdot \frac{1}{k+1} \cdot (v_d + \sum_{c \in C} v_c))) \end{aligned} \quad (2)$$

where $\sigma(\cdot)$ is the sigmoid function, c is a context word in C, k is the window size, v_w and v_c are the vectors for words and context words, v_d is the vector for the document d, w' is the negative sample from the noise distribution $P_n(w)$. Mikolov et al. (2013) set $P_n(w)$ as the $\frac{3}{4}$ power of the unigram distribution which outperforms the unigram and the uniform distribution significantly.

The paragraph vector model captures the semantic relations between words and documents. In addition, we hope that the vector representation of a document can directly reflect its sentiment. The document vectors associated with different sentiments should fall into different positions in the embedding space. We introduce a logistic regression classifier into the embedding algorithm. For each labeled document d with the label y, we use it to classify the sentiment based on the cross entropy loss function,

$$\begin{aligned} L_2 = &-y \log \sigma((x^T v_d + b) \\ &- (1 - y) \log \sigma(-x^T v_d - b)) \end{aligned} \quad (3)$$

where x is the weight vector for the features and b is the bias, v_d is the document vector.

Combining the above two loss functions, we obtain the monolingual embedding algorithm. For the source language, we get the word and document representations via

$$\arg\min L_s = \sum_{d \in S \cup S_u} \sum_{(w,C) \in d} L_1 + \sum_{d \in S} L_2 \quad (4)$$

The embedding for the target language is obtained similarly,

$$\arg\min L_t = \sum_{d \in T \cup T_u} \sum_{(w,C) \in d} L_1 + \sum_{d \in T_s} L_2 \quad (5)$$

where the labeled dataset T_s is translated from the source language.

3.2 Bilingual Constraints

The key problem of bilingual representation learning is to obtain a consistent embedding space across the source and the target languages. We propose three strategies for BiDRL to bridge the language gap.

The first strategy is to share the classification hyperplane in Equation 3. The logistics regression parameter x and b are the same in the source and the target languages. By sharing the same classification parameter, bilingual documents with the same sentiment will fall into similar areas in the embedding space. Therefore, introducing the logistic regression classifier in our embedding algorithm not only helps to obtain task-specific embedding but also helps to narrow the language barrier.

The second strategy is to minimize the difference between a pair of parallel documents, i.e., the

original documents and the translated documents. Such word or document based regularizer is widely used in previous works (Gouws et al., 2015; Zou et al., 2013). We simply measure the differences of two documents via the Euclidean Distance. The parallel documents refer to the documents in S and T and their corresponding translations (S_t and T_s). It leads to the following loss function,

$$L_3 = \sum_{(d_s,d_t)\in(S,T_s)} \|v_{d_s} - v_{d_t}\|^2 + \sum_{(d_s,d_t)\in(S_t,T)} \|v_{d_s} - v_{d_t}\|^2 \quad (6)$$

where (d_s, d_t) is a pair of parallel documents and v_* is their vector representations.

Our third strategy aims to generate similar representations for texts with the same sentiment. The traditional paragraph vector model focuses on modeling the semantic relationship between words and documents while our method aims to preserve the sentiment relationship as well. For each document $d \in S$ in the source language, we find K least similar documents with the same sentiment. The document similarity is measured by cosine similarity using TF-IDF features. We hope that these K documents should have similar representation with document d despite of their textual difference. We denote the K documents as Q_s and their parallel documents in the target language as Q_t. It leads to the following loss function,

$$L_4 = \sum_{d\in S}\Big(\sum_{d_s\in Q_s} \|v_{d_s} - v_d\|^2 + \sum_{d_t\in Q_t} \|v_{d_t} - v_d\|^2\Big) \quad (7)$$

where v_* denotes the vector representation of a document.

Combining the monolingual embedding algorithm and the cross-lingual correlations, we have the overall objective function as follows,

$$\arg\min L = L_s + L_t + L_3 + L_4 \quad (8)$$

which can be solved using stochastic gradient descent (SGD).

After learning BiDRL, we represent each document in the training and test dataset by the concatenation of its vector representation in both the source and the target languages. In particular, for each training document $d \in S$, we represent it as $[v_d\ v_{d'}]$ where d' is its corresponding translation and v_* is the learned document representation in BiDRL. Similarly, for each test document $d \in T$, we represent it as $[v_{d'}\ v_d]$. Afterwards, a logistic regression classifier is trained using the concatenated feature vectors of S. The polarity of the reviews in T can be predicted by applying the classifier on the concatenated feature vectors of T.

4 Experiments

4.1 Dataset

We use the multilingual multi-domain Amazon review dataset[2] created by (Prettenhofer and Stein, 2010). It contains three different domains book, DVD and music. Each domain has reviews in four different languages English, German, French and Japanese. In our experiments, we use English as the source language and the rest three as target languages. Therefore, we have a total of nine tasks with different combinations of three domains and three target languages. For each task, the training and test datasets have 1000 positive reviews and 1000 negative reviews. There are also several thousand of unlabeled reviews but the quantity of them varies significantly for different tasks. Following (Prettenhofer and Stein, 2010), when there are more than 50000 unlabeled reviews we randomly selected 50000 of them, otherwise we use all the unlabeled reviews. The detailed statistics of the dataset are shown in Table 1.

We translated the 2000 training reviews and 2000 test reviews into the other languages using Google Translate. Prettenhofer and Stein (2010) has already provided the translation of the test data. We only need to translate the English training data into the three target languages. All the review texts are tokenized and converted into lowercase. We use Mecab[3] to segment the Japanese reviews.

4.2 Implementation

In the bilingual representation learning algorithm, we set the vector size as 200 and the context windows as 10. The learning rate is set to 0.025 fol-

lowing `word2vec` and it declines with the training procedure. K is empirically chosen as 10. The algorithm runs 10 iterations on the dataset.

4.3 Baseline

We introduce several state-of-the-art methods used for comparison in our experiment as follows.

MT-BOW: It learns a classifier in the source language using bag-of-words features and the test data is translated into the source language via a Google Translate. We directly use the experimental results reported in (Prettenhofer and Stein, 2010).

MT-PV: We translate the training data into the target language and also translate the test data into the source language. In both the source and target languages, we use the paragraph vector model to learn the vector representation of the documents. Therefore, each document can be represented by the concatenation of the vector in two languages. A logistic regression classifier is trained using the concatenated feature vectors similarly to BiDRL. MT-PV can be regarded as a simplified version of BiDRL without the L_2, L_3 and L_4 regularizers.

CL-SCL: It is the cross-lingual structural correspondence learning algorithm proposed by (Prettenhofer and Stein, 2010). It learns a map between the bag-of-words representations in the source and the target languages. It also leverages Google Translate to obtain the word translation oracle.

BSE: It is the bilingual embedding method of (Tang et al., 2012). It aims to learn two different mapping matrices for the source and target languages. The two matrices map the bag-of-words representations in the source and the target languages into the same feature space. Tang et al. (2012) only report their results on 6 of the 9 tasks.

CR-RL: It is the bilingual word representation learning method of (Xiao and Guo, 2013). It learns different representations for words in different languages. Part of the word vector is shared among different languages and the rest is language-dependent. The document representation is calculated by taking average over all words in the document.

Bi-PV: Pham et al. (2015) extended the paragraph vector model into bilingual setting by sharing the document representation of a pair of parallel documents. Their method requires large amounts of parallel data and does not need the machine translation service during test phase. In our setting, there are not enough parallel data to train the model and it will lead to an unfair comparison without using the machine translated text. We implement a variant of their method which learns the

vector representation for the training and test data using both the original and the translated texts. Each pair of parallel documents shares the same document representation.

We also implement the method of (Zhou et al., 2015) which is originally designed for the English-Chinese cross-lingual sentiment classification task. We find that it is not very adaptable in our case because the negation pattern and sentiment words are hard to choose for our target languages. The results of our replication do not achieve comparable results with the rest methods and are not listed here to avoid misleading the readers.

4.4 Results and Analysis

Table 2 shows the experimental results for all the baselines and our method. For all the nine tasks, our bilingual document representation learning method achieves the state-of-the-art performance. The two most simple approaches MT-BOW implemented by (Prettenhofer and Stein, 2010) and MT-PV implemented by us are both strong baselines. They achieve comparable results with the more complex baselines on many tasks. MT-PV performs better than MT-BOW on most tasks which proves that the representation learning method is more useful than the traditional bag-of-words features.

The three word-based representation learning methods CL-SCL, BSE and CR-RL achieve similar results with the simple model MT-BOW and only outperform it on some tasks. However, the document representation learning methods MT-PV, Bi-PV and BiDRL performs much better. It shows that capturing the compositionality of words is important for sentiment classification. The isolated word representations are not enough to model the whole document. The Bi-PV model outperforms MT-PV on most tasks and shows that the authors idea of learning a single representation for a pair of parallel documents is more useful than learning them separately.

For all the baselines and our method, the performance of the English-Japanese tasks is lower than that of the English-German and English-French tasks. It is reasonable because the English language is much closer to German and French than Japanese. The machine translation tool also performs better when translating between the Western languages.

Our BiDRL model outperforms all the existing methods on all the tasks. The accuracy is over 80% on all the six tasks for the two European target languages. The mean accuracy of the nine tasks shows a significant gap between BiRDL and the existing models. It achieves an improvement about 3% compared to the previous state-of-the-art methods.

4.5 Parameter Sensitivity Study

In this subsection, we investigate the influence of the vector size of our representation learning algorithm. We conduct the experiments by changing the vector size from 50 to 400. For each parameter setting, we run the algorithm for ten times and get the mean accuracy.

The results of MT-PV and BiDRL on all the nine tasks are shown in Figure 3. For almost all the tasks, we can observe that our model BiDRL steadily outperforms the strong baseline MT-PV. It proves the efficacy of our bilingual embedding constraints.

For most of the nine tasks including DE-DVD, DE-MUSIC, FR-DVD, FR-MUSIC and JP-MUSIC, the performance of BiDRL increases with the growth of the vector size at the beginning and remains stable afterwards. For the rest tasks, our model responds less sensitively to the change of the vector size and the prediction accuracy keeps steady. However, the results of MT-PV show no regular patterns with the change of the vector size which makes it hard to choose a satisfying parameter value.

The parameter K is empirically chosen as 10 because we find that its value has little influence to our model when it is chosen between 10 and 50. Selecting a small K will help to accelerate the training procedure.

4.6 Analysis of the Sentiment Information

The traditional paragraph vector model only models the semantic relatedness between texts via the word co-occurrence statistics. In this study, we propose to learn the bilingual representation utilizing the sentiment information. Firstly, we introduce a classification hyperplane to separate the embedding of texts with different polarities, i.e the loss function L_2. Secondly, we consider the texts with the same sentiment but has largely different textual expressions. They are forced the have similar representations, i.e. L_4. Table 3 shows the

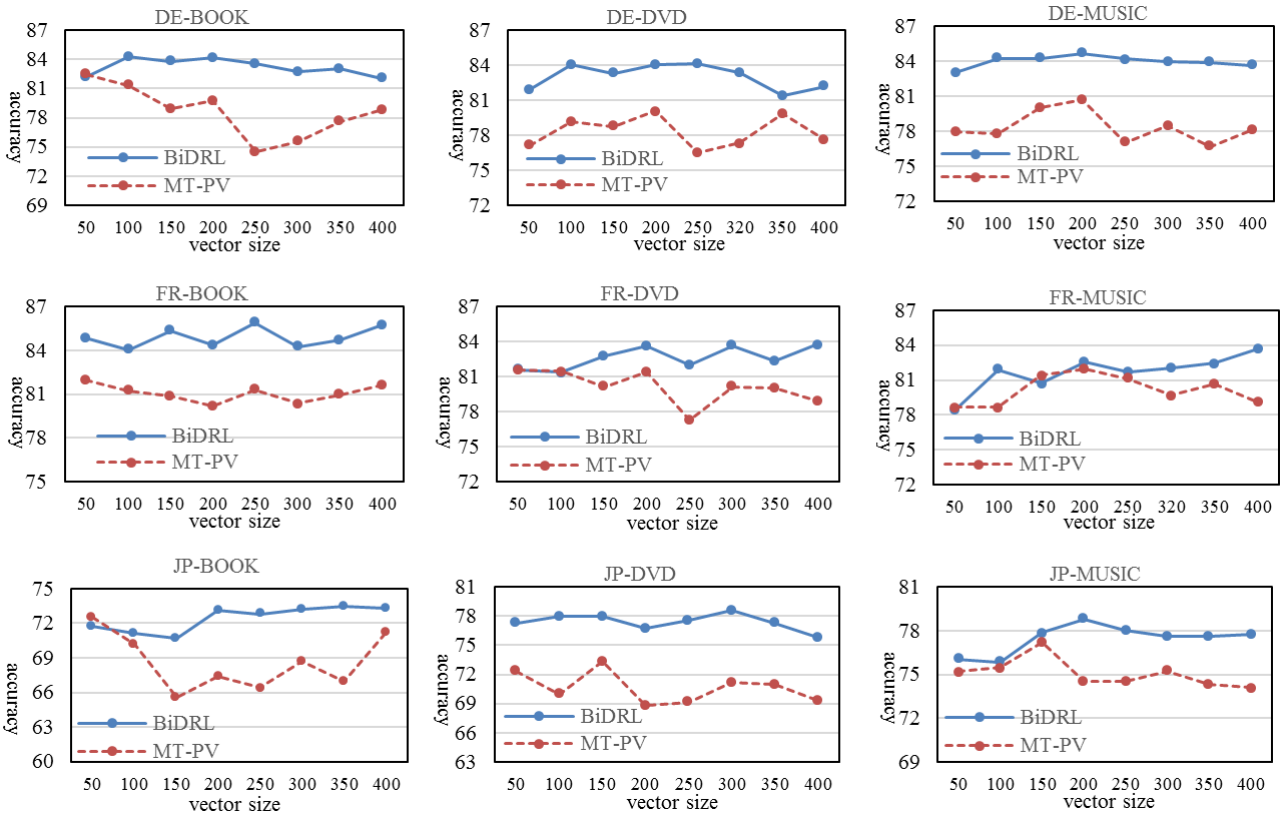

Figure 3: Influence of vector size for the nine cross-lingual sentiment classification tasks

results of our model without using these sentiment information.

Model	MT-PV	BiDRL-L_2	BiDRL-L_4	BiDRL
Accuracy	77.23	79.51	80.43	81.34

Table 3: Influence of the sentiment information. We only show the mean accuracy of the nine tasks due to space limit.

MT-PV can be regarded as BiDRL without all the sentiment information. It achieves lower results than the other three methods. We can also observe that removing L_2 or L_4 both decreases the accuracy. It proves that the sentiment information helps BiDRL to achieve better results.

5 Conclusion and Future Work

In this study, we propose a bilingual document representation learning method for cross-lingual sentiment classification. Different from previous studies which only get bilingual word embeddings, we directly learn the vector representation for documents in different languages. We propose three strategies to achieve a consistent embedding space for the source and target languages. Both sentiment and semantic correlations are exploited in our algorithm while previous works only use the semantic relatedness between parallel documents. Our model is evaluated on a benchmarking dataset which contains three different target languages and three different domains. Several state-of-the-art methods including several bilingual representation learning models are used for comparison. Our algorithm outperforms all the baseline methods on all the nine tasks in the experiment.

Our future work will focus on extending the bilingual document representation model into the multilingual scenario. We will try to learn a single embedding space for a source language and multiple target languages simultaneously. In addition, we will also explore the possibility of using more complex neural network models such as convolutional neural network and recurrent neural network to build bilingual document representation system.

Abstract

Most of the sequence tagging tasks in natural language processing require to recognize segments with certain syntactic role or semantic meaning in a sentence. They are usually tackled with Conditional Random Fields (CRFs), which do indirect word-level modeling over word-level features and thus cannot make full use of segment-level information. Semi-Markov Conditional Random Fields (Semi-CRFs) model segments directly but extracting segment-level features for Semi-CRFs is still a very challenging problem. This paper presents Gated Recursive Semi-CRFs (grSemi-CRFs), which model segments directly and automatically learn segment-level features through a gated recursive convolutional neural network. Our experiments on text chunking and named entity recognition (NER) demonstrate that grSemi-CRFs generally outperform other neural models.

1 Introduction

Most of the sequence tagging tasks in natural language processing (NLP) are segment-level tasks, such as text chunking and named entity recognition (NER), which require to recognize segments (i.e., a set of continuous words) with certain syntactic role or semantic meaning in a sentence. These tasks are usually tackled with Conditional Random Fields (CRFs) (Lafferty et al., 2001), which do word-level modeling as putting each word a tag, by using some predefined tagging schemes, e.g., the "IOB" scheme (Ramshaw and Marcus, 1995). Such tagging schemes are lossy transformations of original segment tags: They do indicate the boundary of adjacent segments but lose the length information of segments to some extent. Besides, CRFs can only employ word-level features, which are either hand-crafted or extracted with deep neural networks, such as window-based neural networks (Collobert et al., 2011) and bidirectional Long Short-Term Memory networks (BI-LSTMs) (Huang et al., 2015). Therefore, CRFs cannot make full use of segment-level information, such as inner properties of segments, which cannot be fully encoded in word-level features.

Semi-Markov Conditional Random Fields (Semi-CRFs) (Sarawagi and Cohen, 2004) are proposed to model segments directly and thus readily utilize segment-level features that encode useful segment information. Existing work has shown that Semi-CRFs outperform CRFs on segment-level tagging tasks such as sequence segmentation (Andrew, 2006), NER (Sarawagi and Cohen, 2004; Okanohara et al., 2006), web data extraction (Zhu et al., 2007) and opinion extraction (Yang and Cardie, 2012). However, Semi-CRFs need many more features compared to CRFs as they need to model segments with different lengths. As manually designing the features is tedious and often incomplete, *how to automatically extract good features* becomes a very important problem for Semi-CRFs. A naive solution that builds multiple feature extractors, each of which extracts features for segments with a specific length, is apparently time-consuming. Moreover, some of these separate extractors may underfit as the segments with specific length may be very rare in the training data. By far, Semi-CRFs are lacking of an automatic segment-level feature extractor.

In this paper, we fill the research void by

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1413–1423,
Berlin, Germany, August 7-12, 2016.

proposing Gated Recursive Semi-Markov Conditional Random Fields (grSemi-CRFs), which can automatically learn features for segment-level sequence tagging tasks. Unlike previous approaches which usually use a neural-based feature extractor with a CRF layer, a grSemi-CRF consists of a gated recursive convolutional neural network (grConv) (Cho et al., 2014) with a Semi-CRF layer. The grConv is a variant of recursive neural networks. It builds a pyramid-like structure to extract segment-level features in a hierarchical way. This feature hierarchy well matches the intuition that long segments are combinations of their short sub-segments. This idea was first explored in Cho et al. (2014) to build an encoder in neural machine translation and then extended to solve other problems, such as sentence-level classification (Zhao et al., 2015) and Chinese word segmentation (Chen et al., 2015).

The advantages of grSemi-CRFs are two folds. First, thanks to the pyramid architecture of grConvs, grSemi-CRFs can extract all the segment-level features using one single feature extractor, and there is no underfitting problem as all parameters of the feature extractor are shared globally. Besides, unlike recurrent neural network (RNN) models, the training and inference of grSemi-CRFs are very fast as there is no time dependency and all the computations can be done in parallel. Second, thanks to the semi-Markov structure of Semi-CRFs, grSemi-CRFs can model segments in sentences directly without the need to introduce extra tagging schemes, which solves the problem that segment length information cannot be fully encoded in tags. Besides, grSemi-CRFs can also utilize segment-level features which can flexibly encode segment-level information such as inner properties of segments, compared to word-level features as used in CRFs. By combining grConvs with Semi-CRFs, we propose a new way to automatically extract segment-level features for Semi-CRFs.

Our major contributions can be summarized as:

(1) We propose grSemi-CRFs, which solve both the automatic feature extraction problem for Semi-CRFs and the indirect word-level modeling problem in CRFs. As a result, grSemi-CRFs can do segment-level modeling directly and make full use of segment-level features;

(2) We evaluate grSemi-CRFs on two segment-level sequence tagging tasks, text chunking and NER. Experimental results show the effectiveness of our model.

2 Preliminary

In sequence tagging tasks, given a word sequence, the goal is to assign each word (e.g., in POS Tagging) or each segment (e.g., in text chunking and NER) a tag. By leveraging a tagging scheme like "IOB", all the tasks can be regarded as word-level tagging. More formally, let $\mathcal{X}$ denote the set of words and $\mathcal{Y}$ denote the set of tags. A word sentence with length T can be denoted by $\mathbf{x} = (x_1, ..., x_T)$ and its corresponding tags can be denoted as $\mathbf{y} = (y_1, ..., y_T)$. A CRF (Lafferty et al., 2001) defines a conditional distribution

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\left(\sum_{t=1}^{T} F(y_t, \mathbf{x}) + A(y_{t-1}, y_t)\right), \quad (1)$$

where $F(y_t, \mathbf{x})$ is the tag score (or potential) for tag y_t at position t, $A(y_{t-1}, y_t)$ is the transition score between y_{t-1} and y_t to measure the tag dependencies of adjacent words and $Z(\mathbf{x}) = \sum_{\mathbf{y}'} \exp\left(\sum_{t=1}^{T} F(y'_t, \mathbf{x}) + A(y_{t-1}, y'_t)\right)$ is the normalization factor. For the common log-linear models, $F(y_t, \mathbf{x})$ can be computed by

$$F(y_t, \mathbf{x}) = \mathbf{v}_{y_t}^{\mathrm{T}} \mathbf{f}(y_t, \mathbf{x}) + b_{y_t}, \quad (2)$$

where $\mathrm{V} = (\mathbf{v}_1, ..., \mathbf{v}_{|\mathcal{Y}|})^{\mathrm{T}} \in \mathbb{R}^{|\mathcal{Y}| \times D}$, $\mathbf{b}_{\mathrm{V}} = (b_1, ..., b_{|\mathcal{Y}|})^{\mathrm{T}} \in \mathbb{R}^{|\mathcal{Y}|}$, $f(y_t, \mathbf{x}) \in \mathbb{R}^D$ are the word-level features for y_t over the sentence $\mathbf{x}$ and D is the number of features. $f(y_t, \mathbf{x})$ can be manually designed or automatically extracted using neural networks, such as window-based neural networks (Collobert et al., 2011).

If we consider segment-level tagging directly[1], we get a segmentation of the previous tag sentence. With a little abuse of notation, we denote a segmentation by $\mathbf{s} = (s_1, ..., s_{|\mathbf{s}|})$ in which the jth segment $s_j = \langle h_j, d_j, y_j \rangle$ consists of a start position h_j, a length $d_j < L$ where L is a predefined upperbound and a tag y_j. Conceptually, s_j means a tag y_j is given to words $(x_{h_j}, ..., x_{h_j + d_j - 1})$. A Semi-CRF (Sarawagi and Cohen, 2004) defines a conditional distribution

$$p(\mathbf{s}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\left(\sum_{j=1}^{|\mathbf{s}|} F(s_j, \mathbf{x}) + A(y_{j-1}, y_j)\right), \quad (3)$$

[1] Word-level tagging can be regarded as segment-level tagging over length-1 segments.

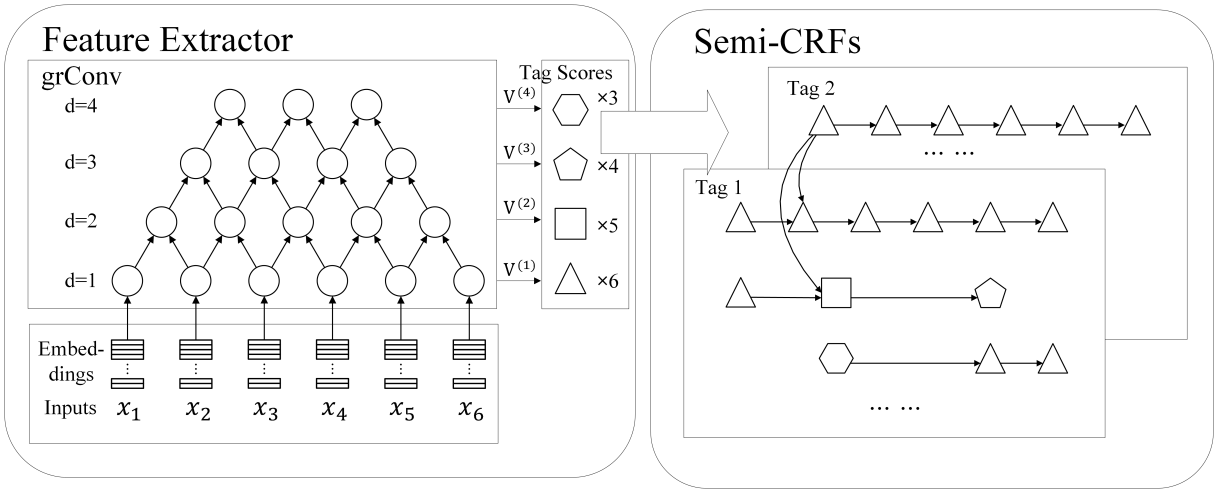

Figure 1: An overview of grSemi-CRFs. For simplicity, we set the segment length upperbound $L = 4$, and the sentence length $T = 6$. The left side is the feature extractor, in which each node denotes a vector of segment-level features (e.g., $\mathbf{z}_k^{(d)}$ for the kth node in the dth layer). Embeddings of word-level input features are used as length-1 segment-level features, and the length-d feature is extracted from two adjacent length-$(d-1)$ features. The right side is the Semi-CRF. Tag score vectors are computed as linear transformations of segment-level features and the number of them equals the number of nodes in the same layer. For clarity, we use triangle, square, pentagon and hexagon to denote the tag score vectors for length-$1, 2, 3, 4$ segments and directed links to denote the tag transformations of adjacent segments.

where $F(s_j, \mathbf{x})$ is the potential or tag score for segment s_j, $A(y_{j-1}, y_j)$ is the transition score to measure tag dependencies of adjacent segments and $Z(\mathbf{x}) = \sum_{\mathbf{s}'} \exp\left(\sum_{j=1}^{|\mathbf{s}'|} F(s'_j, \mathbf{x}) + A_{y'_{j-1}, y'_j}\right)$ is the normalization factor. For the common log-linear models, $F(s_j, \mathbf{x})$ can be computed by

$$F(s_j, \mathbf{x}) = \mathbf{v}_{y_j}^{\mathrm{T}} \mathbf{f}(s_j, \mathbf{x}) + b_{y_j}, \tag{4}$$

where $\mathrm{V} = (\mathbf{v}_1, ..., \mathbf{v}_{|\mathcal{Y}|})^{\mathrm{T}} \in \mathbb{R}^{|\mathcal{Y}| \times D}$, $\mathbf{b}_{\mathrm{V}} = (b_1, ..., b_{|\mathcal{Y}|})^{\mathrm{T}} \in \mathbb{R}^{|\mathcal{Y}|}$ and $f(s_j, \mathbf{x}) \in \mathbb{R}^D$ are the segment-level features for s_j over the sentence $\mathbf{x}$.

As Eq. (1) and Eq. (3) show, CRFs can be regarded as a special case of Semi-CRFs when $L = 1$. CRFs need features for only length-1 segments (i.e., words), while Semi-CRFs need features for length-ℓ segments ($1 \leq \ell \leq L$). Therefore, to model the same sentence, Semi-CRFs generally need many more features than CRFs, especially when L is large. Besides, unlike word-level features used in CRFs, the sources of segment-level features are often quite limited. In existing work, the sources of $f(s_j, \mathbf{x})$ can be roughly divided into two parts: (1) Concatenations of word-level features (Sarawagi and Cohen, 2004; Okanohara et al., 2006); and (2) Hand-crafted segment-level features, including task-insensitive features, like the length of segments, and task-specific features, like the verb phrase patterns in opinion extraction (Yang and Cardie, 2012). As manually designing features is time-consuming and often hard to capture rich statistics underlying the data, how to automatically extract features for Semi-CRFs remains a challenge.

3 Gated Recursive Semi-Markov CRFs

In this section, we present Gated Recursive Semi-CRFs (grSemi-CRFs), which inherit the advantages of Semi-CRFs in segment-level modeling, and also solve the feature extraction problem of Semi-CRFs by introducing a gated recursive convolutional neural network (grConv) as the feature extractor. Instead of building multiple feature extractors at different scales of segment lengths, grSemi-CRFs can extract features with any length by using a single grConv, and learn the parameters effectively via sharing statistics.

3.1 Architecture

The architecture of grSemi-CRFs is illustrated in Figure 1. A grSemi-CRF can be divided into two parts, a feature extractor (i.e., grConv) and a Semi-CRF. Below, we explain each part in turn.

As is shown, the feature extractor is a pyramid-like directed acyclic graph (DAG), in which nodes

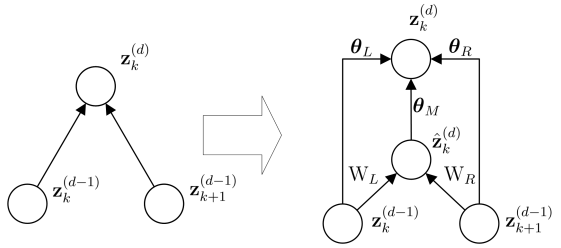

Figure 2: The the building block of the feature extractor (i.e., grConv), in which parameters are shared among the pyramid structure. We omit the dependency of $\boldsymbol{\theta}_L, \boldsymbol{\theta}_R, \boldsymbol{\theta}_M$ on $\mathrm{G}_L, \mathrm{G}_R$.

are stacked layer by layer and information is propagated from adjacent nodes in the same layer to their co-descendants in the higher layer through directed links. Recall that L denotes the upper-bound of segment length (i.e., the height of the grConv), we regard the bottom level as the 1st level and the top level as the Lth level. Then, for a length-T sentence, the dth level will have $T-d+1$ nodes, which correspond to features for $T-d+1$ length-d segments. The kth node in the dth layer corresponds to the segment-level latent features $\mathbf{z}_k^{(d)} \in \mathbb{R}^D$, which denote the meaning of the segment, e.g., the syntactic role (i.e., for text chunking) or semantic meaning (i.e., for NER).

Like CRFs, grSemi-CRFs allow word-level categorical inputs (i.e., $\mathbf{x}_k$) which are transformed into continuous vectors (i.e., embeddings) according to look-up tables and then used as length-1 segment-level features (i.e., $\mathbf{z}_k^{(1)}$). To be clear, we call these inputs as input features and those extracted segment-level features (i.e., $\mathbf{z}_k^{(d)}$) as segment-level latent features. Besides, grSemi-CRFs also allow segment-level input features (e.g., gazetteers) directly as shown in Eq. (12). We will discuss more details in section 4.3.

The building block of the feature extractor is shown in Figure 2, where an intermediate node $\hat{\mathbf{z}}_{(d)} \in \mathbb{R}^D$ is introduced to represent the interactions of two length-$(d-1)$ segments. To capture such complex interactions, $\hat{\mathbf{z}}_k^{(d)}$ is computed through a non-linear transformation, i.e.,

$$\hat{\mathbf{z}}_k^{(d)} = g(\boldsymbol{\alpha}_k^{(d)}) = g(\mathrm{W}_L \mathbf{z}_k^{(d-1)} + \mathrm{W}_R \mathbf{z}_{k+1}^{(d-1)} + \mathbf{b}_{\mathrm{W}}), \quad (5)$$

where $\mathrm{W}_L, \mathrm{W}_R \in \mathbb{R}^{D \times D}$ and $\mathbf{b}_{\mathrm{W}} \in \mathbb{R}^D$ are shared globally, and $g(\cdot)$ is a non-linear activation function[2].

[2]We use a modified version of the sigmoid function, i.e., $g(x) = 4\left(\frac{1}{1+e^{-x}} - \frac{1}{2}\right)$.

Then, the length-d segment-level latent features $\mathbf{z}_k^{(d)}$ can be computed as

$$\mathbf{z}_k^{(d)} = \theta_L \mathbf{z}_k^{(d-1)} + \theta_R \mathbf{z}_{k+1}^{(d-1)} + \theta_M \hat{\mathbf{z}}_k^{(d)}, \quad (6)$$

where θ_L, θ_M and $\theta_R \in \mathbb{R}$ are the gating coefficients which satisfy the condition $\theta_L, \theta_R, \theta_M \geq 0$ and $\theta_L + \theta_R + \theta_M = 1$. Here, we make a little modification of grConvs by making the gating coefficients as vectors instead of scalars, i.e.,

$$\mathbf{z}_k^{(d)} = \boldsymbol{\theta}_L \circ \mathbf{z}_k^{(d-1)} + \boldsymbol{\theta}_R \circ \mathbf{z}_{k+1}^{(d-1)} + \boldsymbol{\theta}_M \circ \hat{\mathbf{z}}_k^{(d)}, \quad (7)$$

where $\circ$ denotes the element-wise product and $\boldsymbol{\theta}_L$, $\boldsymbol{\theta}_R$ and $\boldsymbol{\theta}_M \in \mathbb{R}^D$ are vectorial gating coefficients[3] which satisfy the condition that $\theta_{L,i}, \theta_{R,i}, \theta_{M,i} \geq 0$ and $\theta_{L,i} + \theta_{R,i} + \theta_{M,i} = 1$ for $1 \leq i \leq D$. There are two reasons for this modification: (1) Theoretically, the element-wise combination makes a detailed modeling as each feature in $\mathbf{z}_k^{(d)}$ may have its own combining; and (2) Experimentally, this setting makes our grSemi-CRF[4] more flexible, which increases its generalizability and leads to better performance in experiments as shown in Table 4.

We can regard Eq. (7) as a soft gate function to control the propagation flows. Besides, all the parameters (i.e., $\mathrm{W}_L, \mathrm{W}_R, \mathbf{b}_{\mathrm{W}}, \mathrm{G}_L, \mathrm{G}_R, \mathbf{b}_{\mathrm{G}}$) are shared globally and recursively applied to the input sentence in a bottom-up manner. All of these account for the name *gated recursive convolutional neural networks* (grConvs).

Eq. (5) and Eq. (7) build the information propagation criteria in a grConv. The basic assumption behind Eq. (5) and Eq. (7) is that the meaning of one segment can be represented as a linear combination of three parts: (1) the meaning of its prefix segment, (2) the meaning of its suffix segment and (3) the joint meaning of both (i.e., the complex interaction). This process matches our intuition about the hierarchical structure in the composition of a sentence. For example, the meaning of *the United States* depends on the suffix segment *United States*, whose meaning is not only from its prefix *United* or suffix *States*, but the interaction of both.

The vectorial gating coefficients $\boldsymbol{\theta}_L$, $\boldsymbol{\theta}_R$ and $\boldsymbol{\theta}_M$

[3]We omit the dependency of $\boldsymbol{\theta}_L, \boldsymbol{\theta}_R$ and $\boldsymbol{\theta}_M$ on d and k for notation simplicity.

[4]Unless otherwise stated, we regard "grSemi-CRF" as grSemi-CRF with vectorial gating coefficients in default.

are computed adaptively, i.e.,

$$\begin{pmatrix}\boldsymbol{\theta}_L\\ \boldsymbol{\theta}_R\\ \boldsymbol{\theta}_M\end{pmatrix} = \begin{pmatrix}1/\mathbf{Z}\\ 1/\mathbf{Z}\\ 1/\mathbf{Z}\end{pmatrix} \circ \exp\left(\mathrm{G}_L\mathbf{z}_k^{(d-1)} + \mathrm{G}_R\mathbf{z}_{k+1}^{(d-1)} + \mathbf{b}_\mathrm{G}\right), \tag{8}$$

where $\mathrm{G}_L, \mathrm{G}_R \in \mathbb{R}^{3D\times D}$ and $\mathbf{b}_\mathrm{G} \in \mathbb{R}^{3D}$ are shared globally. $\mathbf{Z} \in \mathbb{R}^d$ is normalization coefficients and the ith element of $\mathbf{Z}$ is computed via

$$Z_i = \sum_{j=1}^{3}\left[\exp\left(\mathrm{G}_L\mathbf{z}_k^{(d-1)} + \mathrm{G}_R\mathbf{z}_{k+1}^{(d-1)} + \mathbf{b}_\mathrm{G}\right)\right]_{D\times(j-1)+i}. \tag{9}$$

After the forward propagation of the feature extractor is over, the tag scores (i.e., the potential functions for Semi-CRFs) are computed through a linear transformation. For segment $s_j = \langle h_j, d_j, y_j\rangle$, its latent feature is $f(s_j, \mathbf{x}) = \mathbf{z}_{h_j}^{(d_j)}$ and corresponding potential/tag score is

$$F(\mathbf{s}_j;\mathbf{x}) = f(\langle h_j, d_j, y_j\rangle;\mathbf{x}) = \left[\mathrm{V}_0^{(d_j)}\mathbf{z}_{h_j}^{(d_j)} + \mathbf{b}_\mathrm{V}^{(d_j)}\right]_{y_j}, \tag{10}$$

where $\mathrm{V}_0^{(d_j)} \in \mathbb{R}^{|\mathcal{Y}|\times D}$ and $\mathbf{b}^{(d_j)} \in \mathbb{R}^{|\mathcal{Y}|}$ are parameters for length-d_j segments. To encode contextual information, we can assume that the tag of a segment depends not only on itself but also its neighbouring segments with the same length, i.e.,

$$F(\mathbf{s}_j;\mathbf{x}) = \left[\sum_{i=-H}^{H}\mathrm{V}_i^{(d_j)}\mathbf{z}_{h_j+i}^{(d_j)} + \mathbf{b}_\mathrm{V}^{(d_j)}\right]_{y_j}, \tag{11}$$

where $\mathrm{V}_{-H}^{(d_j)}, ..., \mathrm{V}_0^{(d_j)}, ..., \mathrm{V}_H^{(d_j)} \in \mathbb{R}^{|\mathcal{Y}|\times D}$ and H is the window width for neighbouring segments. Apart from the automatically extracted segment-level latent features $\mathbf{z}_k^{(d)}$, grSemi-CRFs also allow segment-level input features (e.g., gazetteers), i.e.,

$$F(\mathbf{s}_j;\mathbf{x}) = \left[\sum_{i=-H}^{H}\mathrm{V}_i^{(d_j)}\mathbf{z}_{h_j+i}^{(d_j)} + \mathbf{b}_\mathrm{V}^{(d_j)} + \mathrm{U}^{(d_j)}\mathbf{c}_{h_j}^{(d_j)}\right]_{y_j}, \tag{12}$$

where $\mathrm{U}^{(d_j)} \in \mathbb{R}^{|\mathcal{Y}|\times D'}$ and $\mathbf{c}_{h_j}^{(d_j)} \in \mathbb{R}^{D'}$ is a vector of segment-level input features.

Then, we can use Eq. (3) for inference by using a Semi-CRF version of Viterbi algorithms (Sarawagi and Cohen, 2004).

3.2 Learning of Parameters

To learn grSemi-CRFs, we maximize the log likelihood $\mathcal{L} = \log p(\mathbf{s}|\mathbf{x})$ over all the parameters. Here, for notation simplity, we consider the simpliest case, i.e., using Eq. (10) to compute tag scores. More details can be found in the supplementary note.

Gradients of Semi-CRF-based parameters (i.e., A and V_0) and tag scores $F(s_j, \mathbf{x})$ can be computed based on the marginal probability of neighbouring segments via a Semi-CRF version of forward-backward algorithms (Sarawagi and Cohen, 2004). As for the grConv-based parameters, we can compute their gradients by back propagation. For example, gradients for W_L and G_L are[5]

$$\frac{\partial\mathcal{L}}{\partial\mathrm{W}_L} = \sum_{d=1}^{L}\sum_{k=1}^{T-d+1}\frac{\partial\mathcal{L}}{\partial\mathbf{z}_k^{(d)}}\frac{\partial\mathbf{z}_k^{(d)}}{\partial\mathrm{W}_L}, \frac{\partial\mathcal{L}}{\partial\mathrm{G}_L} = \sum_{d=1}^{L}\sum_{k=1}^{T-d+1}\frac{\partial\mathcal{L}}{\partial\mathbf{z}_k^{(d)}}\frac{\partial\mathbf{z}_k^{(d)}}{\partial\mathrm{G}_L}, \tag{13}$$

where $\frac{\partial\mathbf{z}_k^{(d)}}{\partial\mathrm{W}_L}$ and $\frac{\partial\mathbf{z}_k^{(d)}}{\partial\mathrm{G}_L}$ can be derived from Eq. (5), Eq. (7) and Eq. (8). For $\frac{\partial\mathcal{L}}{\partial\mathbf{z}_k^{(d)}}$, thanks to the recursive structure, it can be computed as

$$\begin{aligned}\frac{\partial\mathcal{L}}{\partial\mathbf{z}_k^{(d)}} =& \frac{\partial\mathbf{z}_k^{(d+1)}}{\partial\mathbf{z}_k^{(d)}}\frac{\partial\mathcal{L}}{\partial\mathbf{z}_k^{(d+1)}} + \frac{\partial\mathbf{z}_{k-1}^{(d+1)}}{\partial\mathbf{z}_k^{(d)}}\frac{\partial\mathcal{L}}{\partial\mathbf{z}_{k-1}^{(d+1)}}\\ &+ \mathrm{V}_0^{(d)\mathrm{T}}\frac{\partial\mathcal{L}}{\partial F(\mathbf{s}_k^{(d)},\mathbf{x})},\end{aligned} \tag{14}$$

where $\mathbf{s}_k^{(d)} = \langle k, d, \mathcal{Y}\rangle$ is a length-$|\mathcal{Y}|$ vector which denotes segments with all possible tags for $\mathbf{z}_k^{(d)}$, $\frac{\partial\mathcal{L}}{\partial F(\mathbf{s}_k^{(d)},\mathbf{x})}$ is the gradient for $F(\mathbf{s}_k^{(d)},\mathbf{x})$ and

$$\frac{\partial\mathbf{z}_k^{(d+1)}}{\partial\mathbf{z}_k^{(d)}} = \mathrm{diag}(\boldsymbol{\theta}_L) + \mathrm{diag}(\boldsymbol{\theta}_M \circ g'(\boldsymbol{\alpha}_k^{(d+1)}))\mathrm{W}_L, \tag{15}$$

where $\mathrm{diag}(\boldsymbol{\theta}_L)$ denotes the diagonal matrix spanned by vector $\boldsymbol{\theta}_L$, and $\frac{\partial\mathbf{z}_{k-1}^{(d+1)}}{\partial\mathbf{z}_k^{(d)}}$ has a similar form. As Eq. (14) shows, for each node in the feature extractor of grSemi-CRFs, its gradient consists of two parts: (1) the gradients back propagated from high layer nodes (i.e., longer segments); and (2) the supervising signals from Semi-CRFs. In other words, the supervision in the objective function is added to each node in grSemi-CRFs. This is a nice property compared to other neural-based feature extractors used in CRFs, in which only the nodes of several layers on the top receive supervision. Besides, the term $\mathrm{diag}(\boldsymbol{\theta}_L)$ in Eq. (15) prevents $\frac{\partial\mathbf{z}_k^{(d+1)}}{\partial\mathbf{z}_k^{(d)}}$ from being too small when $g'(\boldsymbol{\alpha}_k^{(d)})$ and W_L are small, which acts as the linear unit recurrent connection in the memory block of LSTM (Hochreiter and Schmidhuber, 1997; Zhao et al., 2015). All of these help in avoiding gradient vanishing problems in training grSemi-CRFs.

[5]Gradients for $\mathrm{W}_R, \mathbf{b}_\mathrm{W}, \mathrm{G}_R, \mathbf{b}_\mathrm{G}$ can be computed in similar ways.

4 Experiments

We evaluate grSemi-CRFs on two segment-level sequence tagging NLP tasks: text chunking and named entity recognition (NER).

4.1 Datasets

For text chunking, we use the CONLL 2000 text chunking shared dataset[6] (Tjong Kim Sang and Buchholz, 2000), in which the objective is to divide the whole sentence into different segments according to their syntactic roles, such as noun *phrases* ("NP"), *verb phrases* ("VP") and *adjective phrases* ("ADJP"). We call it a "segment-rich" tasks as the number of phrases are much higher than that of non-phrases which is tagged with *others* ("O"). We evaluate performance over all the chunks instead of only noun pharse (NP) chunks.

For NER, we use the CONLL 2003 named entity recognition shared dataset[7] (Tjong Kim Sang and De Meulder, 2003), in which segments are tagged with one of four entity types: *person* ("PER"), *location* ("LOC"), *organization* ("ORG") and *miscellaneous*("MISC"), or *others* ("O") which is used to denote non-entities. We call it a "segment-sparse" task as entities are rare while non-entities are common.

4.2 Input Features

For each word, we use multiple input features, including the word itself, its length-3 prefix and length-4 suffix, its capitalization pattern, its POS tag, the length-4,8,12,20 prefixs of its Brown clusters (Brown et al., 1992) and gazetteers[8]. All of them are used as word-level input features except gazetteers, which are used as segment-level features directly. All the embeddings for word-level inputs are randomly initialized except word embeddings, which can be initialized randomly or by pretraining over unlabeled data, which is external information compared to the dataset. Besides word embeddings, Brown clusters and gazetteers are also based on external information, as summarized below:

- **Word embeddings**. We use Senna embeddings[9] (Collobert et al., 2011), which are 50-dimensional and have been commonly used in sequence tagging tasks (Collobert et al., 2011; Turian et al., 2010; Huang et al., 2015);
- **Brown clusters**. We train two types of Brown clusters using the implementation from Liang (2005): (1) We follow the setups of Ratinov and Roth (2009), Turian et al. (2010) and Collobert et al. (2011) to generate 1000 Brown clusters on Reuters RCV1 dataset (Lewis et al., 2004); (2) We generate 1000 Brown clusters on New York Times (NYT) corpus (Sandhaus, 2008);
- **Gazetteers**. We build our gazetteers based on the gazetteers used in Senna (Collobert et al., 2011) and Wikipedia entries, mainly the locations and organizations. We also denoise our gazetteers by removing overlapped entities and using BBN Pronoun Coreference and Entity Type Corpus (Weischedel and Brunstein, 2005) as filters[10].

4.3 Implementation Details

To learn grSemi-CRFs, we employ Adagrad (Duchi et al., 2011), an adaptive stochastic gradient descent method which has been proved successful in similar tasks (Chen et al., 2015; Zhao et al., 2015). To avoid overfitting, we use the dropout strategy (Srivastava et al., 2014) and apply it on the first layer (i.e., $\mathbf{z}_k^{(0)}$). We also use the strategy of ensemble classifiers, which is proved an effective way to improve generalization performance (Collobert et al., 2011). All results are obtained by decoding over an average Semi-CRF after 10 training runs with randomly initialized parameters.

For the CONLL 2003 dataset, we use the F_1 scores on the development set to help choose the best-performed model in each run. For the CONLL 2000 dataset, as there is no development set provided, we use cross validation as Turian et al. (2010) to choose hyperparameters. After that, we retrain model according to the hyperparameters and choose the final model in each run.

Our hyperparameter settings for these two tasks are shown in Table 1. The segment length is set according to the maximum segment length in training set. We set the minibatch size to 10, which means that we process 10 sentences in a batch. The window width defines the parameter H in Eq. (12) when producing tag score vectors.

[10] We apply gazetteers on BBN corpus, collect lists of false positive entities and clean our gazetteers according to these lists.

Hyperparameters	CONLL 2000	CONLL 2003
Segment length	15	10
Dropout	0.3	0.3
Learning rate	0.3	0.3
Epochs	15	20
Minibatches	10	10
Window width	2	2

Table 1: Hyperparameter settings for our model.

4.4 Results and Analysis

Table 2 shows the results of our grSemi-CRFs and other models[11]. We divide other models into two categories, i.e., neural models and non-neural models, according to whether neural networks are used as automatic feature extractors. For neural models, Senna (Collobert et al., 2011) consists of a window-based neural network for feature extraction and a CRF for word-level modeling while BI-LSTM-CRF (Huang et al., 2015) uses a bidirectional Long Short-Term Memory network for feature extraction and a CRF for word-level modeling.

For non-neural models, JESS-CM (Suzuki and Isozaki, 2008) is a semi-supervised model which combines Hidden Markov Models (HMMs) with CRFs and uses 1 billion unlabelled words in training. Lin and Wu (2009) cluster 20 million phrases over corpus with around 700 billion tokens, and use the resulting clusters as features in CRFs. Passos et al. (2014) propose a novel word embedding method which incorporates gazetteers as supervising signals in pretraining and builds a log-linear CRF over them. Ratinov and Roth (2009) use CRFs based on many non-local features and 30 gazetteers extracted from Wikipedia and other websites with more than 1.5 million entities.

As Table 2 shows, grSemi-CRFs outperform other neural models, in both text chunking and named entity recognition (NER) tasks. BI-LSTM-CRFs use many more input features than ours, which accounts for the phenomenon that the performance of our grSemi-CRFs is rather mediocre (i.e., 93.92% versus 94.13% and 84.66% versus 84.26%) without external information. However, once using Senna embeddings, our grSemi-CRFs perform much better than BI-LSTM-CRFs.

For non-neural models, one similarity of them is that they use a lot of hand-crafted features, and many of them are even task-specific. Unlike them, grSemi-CRFs use much fewer input features and most of them are task-insensitive[13]. However, grSemi-CRFs achieve almost the same performance, sometimes even better. For text chunking, grSemi-CRF outperforms all reported supervised models, except JESS-CM (Suzuki and Isozaki, 2008), a semi-supervised model using giga-word scale unlabeled data in training[14]. However, the performance of our grSemi-CRF (95.01%) is very close to that of JESS-CM (95.15%). For NER, the performance of grSemi-CRFs are also very closed to state-of-the-art results (90.87% versus 90.90%).

[11]Because of the space limit, we only compare our model with other models which follow similar settings and achieve high performance.

Input Features	CONLL 2000	CONLL 2003
None	93.92	84.66
Brown(NYT)	94.18	86.57
Brown(RCV1)	94.05	**88.22**
Emb	**94.73**	88.12
Gaz	–	87.94
Emb + Brown(NYT)	**95.01**	88.86
Emb + Brown(RCV1)	94.87	89.44
Emb + Gaz	–	**89.88**
Brown(NYT) + Gaz	–	88.69
Brown(RCV1) + Gaz	–	89.82
All(NYT)	–	90.00
All(RCV1)	–	**90.87**

Table 3: Results of grSemi-CRF with external information, measured in F_1 score. None = no external information, Emb = Senna embeddings, Brown = Brown clusters, Gaz = gazetteers and All = Emb + Brown + Gaz. NYT and RCV1 in the parenthesis denote the corpus used to generate Brown clusters. "–" means no results. Notice that gazetteers are only applied to NER.

4.4.1 Impact of External Information

As Table 3 shows, external information improve the performance of grSemi-CRFs for both tasks. Compared to text chunking, we can find out that external information plays an extremely important role in NER, which coincides with the general idea that NER is a knowledge-intensive task (Ratinov and Roth, 2009). Another interesting thing is that, Brown clusters generated from NYT corpus performs better on the CONLL 2000 task while those generated from Reuters RCV1 dataset performs better on the CONLL 2003 task. The reason is

[13]E.g.: for NER, JESS-CM uses 79 different features; Lin and Wu (2009) use 48 baseline and phrase cluster features; while we only use 11. Besides, grSemi-CRFs use almost the same features for chunking and NER (except gazetteers).

[14]Being semi-supervised, JESS-CM can learn from interactions between labelled and unlabelled data during training but the training is slow compared to supervised models.

	Models	CONLL 2000	CONLL 2003
Ours	grSemi-CRF (Random embeddings)	93.92	84.66
	grSemi-CRF (Senna embeddings)	**95.01**	**89.44** (**90.87**)
Neural Models	Senna (Random embeddings)	90.33	81.47
	Senna (Senna embeddings)	94.32	88.67 (89.59)
	BI-LSTM-CRF (Random)	94.13	84.26
	BI-LSTM-CRF (Senna embeddings)	94.46	88.83 (90.10)
Non-Neural Models	JESS-CM (Suzuki and Isozaki, 2008), 15M	94.67	89.36
	JESS-CM (Suzuki and Isozaki, 2008), 1B	**95.15**	89.92
	Ratinov and Roth (2009)[12]	–	90.57
	Lin and Wu (2009)	–	**90.90**
	Passos et al. (2014)	–	**90.90**

Table 2: Experimental results over the CONLL-2000 and CONLL-2003 shared datasets, measured in F_1 score. Numbers in parentheses are the F_1 score when using gazetteers. JESS-CM (Suzuki and Isozaki, 2008) is a semi-supervised model, in which 15M or 1B denotes the number of unlabeled words it uses for training.

Gating Coefficients	CONLL 2000	CONLL 2003
Scalars	94.47	89.27(90.54)
Vectors	**95.01**	**89.44**(**90.87**)

Table 4: F_1 scores of grSemi-CRF with scalar or vectorial gating coefficients. Numbers in parentheses are the F_1 score when using gazetteers.

that the CONLL 2000 dataset is the subset of Wall Street Journal (WSJ) part of the Penn Treebank II Corpus (Marcus et al., 1993) while the CONLL 2003 dataset is a subset of Reuters RCV1 dataset. Maybe the writing styles between NYT and WSJ are more similar than those between RCV1 and WSJ.

4.4.2 Impact of Vectorial Gating Coefficients

As Table 4 shows, a grSemi-CRF using vectorial gating coefficients (i.e., Eq. (7)) performs better than that using scalar gating coefficients (i.e., Eq. (6)), which provides evidences for the theoretical intuition that vectorial gating coefficients can make a detailed modeling of the combinations of segment-level latent features and thus performs better than scalar gating coefficients.

4.4.3 Visualization of Learnt Segment-Level Features

To demonstrate the quality of learnt segment-level features, we use an indirect way as widely adopted in previous work, e.g., Collobert et al. (2011). More specifically, we show 10 nearest neighbours for some selected queried segments according to Euclidean metric of corresponding features[15]. To fully demonstrate the power of grSemi-CRF in learning segment-level features, we use the Emb+Brown(RCV1) model in Table 3, which uses no gazetteers. We train the model on the CONLL 2003 training set and find nearest neighbours in the CONLL 2003 test set. We make no restrictions on segments, i.e., all possible segments with different lengths in the CONLL 2003 test set are candidates.

As Table 5 shown, most of the nearest segments are meaningful and semantically related. For example, the nearest segments for "Filippo Inzaghi" are not only tagged with *person*, but also names of famous football players as "Filippo Inzaghi".

There also exist some imperfect results. E.g., for "Central African Republic", nearest segments, which contain the same queried segment, are semantically related but not syntactically similar. The major reason may be that the CONLL 2003 dataset is a small corpus (if compared to the vast unlabelled data used to train Senna embeddings), which restricts the range for candidate segments and the quality of learnt segment-level features. Another reason is that labels in the CONLL 2003 dataset mainly encodes semantic information (e.g., named entities) instead of syntactic information (e.g., chunks).

Besides, as we make no restriction on the formulation of candidate segments, sometimes only a part of the whole phrase will be retrieved, e.g., "FC Hansa", which is the prefix of "FC Hansa Rostock". Exploring better way of utilizing unla-

[15]Using the cosine similarity generates similar results. However, as Collobert et al. (2011) use Euclidean metric, we follow their settings.

Queried Segments	Filippo Inzaghi	AC Milan	Central African Republic	Asian Cup
Nearest Neighbour Results	Pierluigi Casiraghi	FC Hansa	From Central African Republic	Scottish Cup
	Fabrizio Ravanelli	SC Freiburg	Southeast Asian Nations	European Cup
	Bogdan Stelea	FC Cologne	In Central African Republic	African Cup
	Francesco Totti	Aston Villa	The Central African Republic	World Cup
	Predrag Mijatovic	Red Cross	South African Breweries	UEFA Cup
	Fausto Pizzi	Yasuto Honda	Of Southeast Asian Nations	Europoean Cup
	Pierre Laigle	NAC Breda	New South Wales	Asian Games
	Pavel Nedved	La Plagne	Central African Republic .	Europa Cup
	Anghel Iordanescu	Sporting Gijon	Papua New Guinea	National League
	Zeljko Petrovic	NEC Nijmegen	Central Africa	F.A. Cup

Table 5: Visualization of segment-level features learnt on the CONLL 2003 dataset. For each column the queried segment is followed by its 10 nearest neighbors (measured by the cosine similarity of their feature vectors). Corresponding tags for these four queried segments are (from left to right): *person*, *organization*, *location* and *miscellaneous*.

belled data to improve learning segment-level features is part of the future work.

5 Discussions and Related Work

Cho et al. (2014) first propose grConvs to learn fix-length representations of the whole source sentence in neural machine translation. Zhao et al. (2015) use grConvs to learn hierarchical representations (i.e., multiple fix-length representations) of the whole sentence for sentence-level classification problem. Both of them focus on sentence-level classification problems while grSemi-CRFs are solving segment-level classification (sequence tagging) problems, which is fine-grained. Chen et al. (2015) propose Gated Recursive Neural Networks (GRNNs), a variant of grConvs, to solve Chinese word segmentation problem. GRNNs still do word-level modeling by using CRFs while grSemi-CRFs do segment-level modeling directly by using semi-CRFs and makes full use of the recursive structure of grConvs.

We believe that, the recursive neural network (e.g., grConv) is a natural feature extractor for Semi-CRFs, as it extracts features for every possible segments by one propagation over one trained model, which is fast-computing and efficient. In this sense, grSemi-CRFs provide a promising direction to explore.

6 Conclusions

In this paper, we propose Gated Recursive Semi-Markov Conditional Random Fields (grSemi-CRFs) for segment-level sequence tagging tasks. Unlike word-level models such as CRFs, grSemi-CRFs model segments directly without the need of using extra tagging schemes and also readily utilize segment-level features, both hand-crafted and automatically extracted by a grConv. Experimental evaluations demonstrate the effectiveness of grSemi-CRFs on both text chunking and NER tasks.

In future work, we are interested in exploring better ways of utilizing vast unlabelled data to improve grSemi-CRFs, e.g., to learn phrase embeddings from unlabelled data or designing a semi-supervised version of grSemi-CRFs.

Abstract

The automatic detection of causal relationships in text is important for natural language understanding. This task has proven to be difficult, however, due to the need for world knowledge and inference. We focus on a sub-task of this problem where an open class set of linguistic markers can provide clues towards understanding causality. Unlike the explicit markers, a closed class, these markers vary significantly in their linguistic forms. We leverage parallel Wikipedia corpora to identify new markers that are variations on known causal phrases, creating a training set via distant supervision. We also train a causal classifier using features from the open class markers and semantic features providing contextual information. The results show that our features provide an 11.05 point absolute increase over the baseline on the task of identifying causality in text.

1 Introduction

The automatic detection of causal relationships in text is an important but difficult problem. The identification of causality is useful for the understanding and description of events. Causal inference may also aid upstream applications such as question answering and text summarization. Knowledge of causal relationships can improve performance in question answering for "why" questions. Summarization of event descriptions can be improved by selecting causally motivated sentences. However, causality is frequently expressed implicitly, which requires world knowledge and inference. Even when causality is explicit, there is a wide variety in how it is expressed.

Causality is one type of relation in the Penn Discourse Tree Bank (PDTB) (Prasad et al, 2008). In general, discourse relations indicate how two text spans are logically connected. In PDTB theory, these discourse relations can be marked explicitly or conveyed implicitly. In the PDTB, there are 102 known explicit discourse markers such as "and", "but", "after", "in contrast", or "in addition". Of these, 28 explicitly mark causal relations (e.g., "because", "as a result", "consequently").

In addition to explicit markers, PDTB researchers recognize the existence of an open class of markers, which they call *AltLex*. There is a tremendous amount of variation in how AltLexes are expressed and so the set of AltLexes is arguably infinite in size. In the PDTB, non-causal AltLexes include "That compares with" and "In any event." Causal AltLexes include "This may help explain why" and "This activity produced."

Discourse relations with explicit discourse markers can be identified with high precision (Pitler and Nenkova, 2009) but they are also relatively rare. Implicit relations are much more common but very difficult to identify. AltLexes fall in the middle; their linguistic variety makes them difficult to identify but their presence improves the identification of causality.

One issue with causality identification is the lack of data. Unsupervised identification on open domain data yields low precision (Do et al, 2011) and while supervised methods on the PDTB have improved (Ji and Eisenstein, 2015), creating enough labeled data is difficult. Here, we present a distant supervision method for causality identification that uses parallel data to identify new causal connectives given a seed set. We train a classifier on this data and self-train to obtain new data. Our novel approach uses AltLexes that were automatically identified using semi-supervised learning over a parallel corpus. Since we do not know

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 1424–1433,
Berlin, Germany, August 7-12, 2016.

a priori what these phrases are, we used a monolingual parallel corpus to identify new phrases that are aligned with known causal connectives. As large corpora of this type are rare, we used Simple and English Wikipedia to create one.

Section 2 discusses prior research in causality and discourse. Section 4 describes how we created a new corpus from Wikipedia for causality and extracted a subset of relations with AltLexes. In section 5, we recount the semantic and marker features and how they were incorporated into a classifier for causality. We show that these features improve causal inference by an 11.05 point increase in F-measure over a naive baseline in 6. Finally, we discuss the results and future work in 7.

2 Related Work

Recent work on causality involved a combination of supervised discourse classification with unsupervised metrics such as PMI (Do et al, 2011). They used a minimally supervised approach using integer linear programming to infer causality. Other work focused on specific causal constructions events paired by verb/verb and verb/noun (Riaz and Girju, 2013) (Riaz and Girju, 2014). Their work considered semantic properties of nouns and verbs as well as text-only features.

There has also been significant research into discourse semantics over the past few years. One theory of discourse structure is represented in the PDTB (Prasad et al, 2008). The PDTB represents discourse relationships as connectives between two arguments. Early work with the PDTB (Pitler and Nenkova, 2009) showed that discourse classes with explicit discourse connectives can be identified with high accuracy using a combination of the connective and syntactic features. Further work (Pitler et al, 2009) resulted in the identification of implicit discourse relations using word pair features; this approach extended earlier work using word pairs to identify rhetorical relations (Marcu, 2001) (Blair-Goldensohn et al, 2007). These word pairs were created from text by taking the cross product of words from the Gigaword corpus for explicit causal and contrast relations. Others built on this work by aggregating word pairs for every explicit discourse connective (Biran and McKeown, 2013). They then used the cosine similarity between a prospective relation and these word pairs as a feature. Recently, the first end-to-end discourse parser was completed (Lin et al, 2012). This parser jointly infers both argument spans and relations. The current state-of-the-art discourse relation classifier is a constituent parse recursive neural network with coreference (Ji and Eisenstein, 2015).

Our work is similar to previous work to identify discourse connectives using unsupervised methods (Laali, 2014). In their research, they used the EuroParl parallel corpus to find discourse connectives in French using known English connectives and filtering connectives using patterns. Unlike this effort, we created our own parallel corpus and we determined new English connectives.

Compared to previous work on causality, we focus specifically on causality and the AltLex. The work by Do and Riaz used minimally supervised (Do et al, 2011) or unsupervised (Riaz and Girju, 2013) approaches and a slightly different definition of causality, similar to co-ocurrence. The work of Riaz and Girju (2013) is most similar to our own. We also examine causality as expressed by the author of the text. However, they focus on intra-sentence constructions between noun or verb phrases directly whereas we attempt to examine how the AltLex connectives express causality in context. Lastly, Riaz and Girju used FrameNet and WordNet to identify training instances for causal verb-verb and verb-noun pairs (Riaz and Girju, 2014) whereas we use them as features for an annotated training set. Overall our contributions are a new dataset created using a distant supervision approach and new features for causality identification. One major advantage is that our method requires very little prior knowledge about the data and requires only a small seed set of known connectives.

3 Linguistic Background

One disadvantage of the PDTB is that the marked AltLexes are limited only to discourse relations across sentences. We know that there are additional phrases that indicate causality within sentences but these phrases are neither found in the set of Explicit connectives nor AltLexes. Thus we expand our definition of AltLex to include these markers when they occur within a sentence. Although some phrases or words could be identified by consulting a thesaurus or the Penn Paraphrase Database (Ganitkevitch et al, 2013), we still need the context of the phrase to identify causality.

We hypothesize that there is significant linguis-

tic variety in causal AltLexes. In the set of known explicit connectives there are adjectives ("subsequent"), adverbs ("consequently"), and prepositions and prepositional phrases ("as a result"). We consider that these parts of speech and syntactic classes can be found in AltLexes as well. In addition, verbs and nouns often indicate causality but are not considered explicit connectives.

Some obvious cases of AltLexes are the verbal forms of connectives such as "cause" and "result". In addition to these verbs, there exist other verbs that can occur in causal contexts but are ambiguous. Consider that "make" and "force" can replace "cause" in this context:

> The explosion **made** people evacuate the building.
>
> The explosion **forced** people to evacuate the building.
>
> The explosion **caused** people to evacuate the building.

However, the words can not be substituted in the following sentence:

> The baker **made** a cake.
>
> *The baker **caused** a cake.
>
> *The baker **forced** a cake.

Furthermore, verbs such as "given" may replace additional causal markers:

> It's not surprising he is tired **since** he did not get any sleep.
>
> It's not surprising he is tired **given that** he did not get any sleep.

There are also some phrases with the same structure as partial prepositional phrases like "as a result" or "as a result of", where the pattern is preposition and noun phrase followed by an optional preposition. Some examples of these phrases include "on the basis of," "with the goal of," and "with the idea of."

We may also see phrases that are only causal when ending in a preposition such as "thanks to" or "owing to." "Lead" may only be causal as a part of "lead to" and the same for "develop" versus "develop from." In addition, prepositions can affect the direction of the causality. Comparing "resulting in" versus "resulting from", the preposition determines that the latter is of the "reason" class and the former is of the "result" class.

Ultimately, we want to be able to detect these phrases automatically and determine whether they are a large/small and open/closed class of markers.

4 Data

In order to discover new causal connectives, we can leverage existing information about known causal connectives. It should be the case that if a phrase is a causal AltLex, it will occur in some context as a replacement for at least one known explicit connective. Thus, given a large dataset, we would expect to find some pairs of sentences where the words are very similar except for the connective. This approach requires a parallel corpus to identify new AltLexes. As large English paraphrase corpora are rare, we draw from previous work identifying paraphrase pairs in Wikipedia (Hwang et al, 2015).

The dataset we used was created from the English and Simple Wikipedias from September 11, 2015. We used the software WikiExtractor to convert the XML into plain text. All articles with the same title were paired and any extra articles were ignored. Each article was lemmatized, parsed (both constituent and dependency), and named-entity tagged using the Stanford CoreNLP suite (Manning et al, 2014). We wish to identify paraphrase pairs where one element is in English Wikipedia and one is in Simple Wikipedia. Furthermore, we do not limit these elements to be single sentences because an AltLex can occur within a sentence or across sentences.

Previous work (Hwang et al, 2015) created a score for similarity (WikNet) between English Wikipedia and Simple Wikipedia. Many similarity scores are of the following form comparing sentences W and W':

$$s(W, W') = \frac{1}{Z} \sum_{w \in W} \max_{w' \in W'} \sigma(w, w') idf(w) \quad (1)$$

where $\sigma(w, w')$ is a score[1] between 2 words and Z is a normalizer ensuring the score is between 0 and 1. For their work, they created a score where $\sigma(w, w') = \sigma_{wk}(w, w') + \sigma_{wk}(h, h')\sigma_r(r, r')$. σ_{wk} is a distance function derived from Wiktionary by creating a graph based on words appearing in a definition. h and h' are the governors of w and w' in a dependency parse and r and r' are the relation. Similar sentences should have similar structure and the governors of two words in different sentences should also be similar. σ_r is 0.5 if h and h' have the same relation and 0 otherwise.

For this work, we also include partial matches, as we only need the connective and the immediate

[1]The score is not a metric, as it is not symmetric.

Combined	0.6263

Table 1: Paraphrase Results

surrounding context on both sides. If one sentence contains an additional clause, it does not affect whether it contains a connective. Thus, one disadvantage to this score is that when determining whether a sentence is a partial match to a longer sentence or a shorter sentence, the longer sentence will often be higher as there is no penalty for unmatched words between the two elements. We experimented with penalizing content words that do not match any element in the other sentence. The modified score, where W and W' are nouns, verbs, adjectives, or adverbs, is then:

$$s(W, W') = \frac{1}{Z} \sum_{w \in W} \max_{w' \in W'} \sigma(w, w') idf(w) - \lambda(|W' - W| + |W - W'|) \quad (2)$$

We also compared results with a model trained using doc2vec (Le and Mikolov, 2014) on each sentence and sentence pair and identifying paraphrases with their cosine similarity.

As these methods are unsupervised, only a small amount of annotated data is needed to tune the similarity thresholds. Two graduate computer science students annotated a total of 45 Simple/English article pairs. There are 3,891 total sentences in the English articles and 794 total sentences in the Simple Wikipedia articles. Inter-annotator agreement (IAA) was 0.9626, computed on five of the article pairs using Cohen's Kappa. We tune the threshold for each possible score: for doc2vec the cosine similarity and for WikNet the scoring function. We also tune the lambda penalty for WikNet. F1 scores were calculated via grid search over these parameters and the best settings are a combined score using doc2vec and penalized WikNet with $\lambda = 0.75$ where a pair is considered to be a paraphrase if either threshold is greater than 0.69 or 0.65 respectively.

Using the combined score we obtain 187,590 paraphrase pairs. After combining and deduping this dataset with the publicly available dataset released by (Hwang et al, 2015), we obtain 265,627 pairs, about 6 times as large as the PDTB.

In order to use this dataset for training a model to distinguish between causal and non-causal instances, we use the paired data to identify pairs where an explicit connective appears in at least one element of the pair. The explicit connective can appear in a Simple Wikipedia sentence or an English Wikipedia sentence. We then use patterns to find new phrases that align with these connectives in the matching sentence.

Table 2: PDTB Discourse Classes

To identify a set of seed words that unambiguously identify causal and non-causal phrases we examine the PDTB. As seen in Table 2, causal relations fall under the Contingency class and Cause type. We consider connectives from the PDTB that either only or never appear as that type. The connective "because" is the only connective to be almost always a "reason" connective, whereas there are 11 unambiguous connectives for "result", including "accordingly", "as a consequence", "as a result", and "thus". There were many markers that were unambiguously not causal (e.g. "but", "though", "still", "in addition").

In order to label paraphrase data, we use constraints to identify possible AltLexes.[2] We used Moses (Koehn et al, 2007) to train an alignment model on the created paraphrase dataset. Then for every paraphrase pair we identify any connectives that match with any potential AltLexes. Based on our linguistic analysis, we require these phrases to contain at least one content word, which we identify based on part of speech. We also draw on previous work (Pitler and Nenkova, 2009) that used the left and right sibling of a phrase. Therefore, we use the following rules to label new AltLexes:

1. Must be less than 7 words.
2. Must contain at least one content word:
   (a) A non-proper noun
   (b) A non-modal and non-auxiliary verb
   (c) An adjective or adverb
3. Left sibling of the connective must be a noun phrase, verb phrase, or sentence.
4. Right sibling of the connective must be a noun phrase, verb phrase, or sentence.

[2]We do not attempt to label arguments at this point.

5. May not contain a modal or auxilary verb.

Because connectives identify causality between events or agents, we require that each potential connective link 2 events/agents. We define an event or agent as a noun, verb, or an entire sentence. This means that we require the left sibling of the first word in a phrase and the right sibling of the last word in a phrase to be an event, where a sibling is the node at the same level in the constituent parse. We also require the left and right sibling rule for the explicit connectives, but we allow additional non-content words (for example, we would mark "because of" as a connective rather than "because." We then mark the AltLex as causal or not causal.

Given that the paraphrases and word alignments are noisy, we use the syntactic rules to decrease the amount of noise in the data by more precisely determining phrase boundaries. These rules are the same features used by Pitler and Nenkova (2009) for the early work on the PDTB on explicit connectives. These features were successful on the Wall Street Journal and they are applicable for other corpora as well. Also, they are highly indicative of discourse/non-discourse usage so we believe that we are improving on noisy alignments without losing valuable data. In the future, however, we would certainly like to move away from encoding these constraints using a rule-based method and use a machine learning approach to automatically induce rules.

This method yields 72,135 non-causal and 9,190 causal training examples. Although these examples are noisy, the dataset is larger than the PDTB and was derived automatically. There are 35,136 argument pairs in the PDTB marked with one of the 3 relations that implies a discourse connective (Implicit, Explicit, and AltLex), and of these 6,289 are causal. Of the 6,289 causal pairs, 2,099 are explicit and 273 contain an AltLex.

5 Methods

Given training data labeled by this distant supervision technique, we can now treat this problem as a supervised learning problem and create a classifier to identify causality.

We consider two classes of features: features derived from the parallel corpus data and lexical semantic features. The parallel corpus features are created based on where AltLexes are used as paraphrases for causal indicators and in what context. The lexical semantic features use FrameNet, WordNet, and VerbNet to derive features from all the text in the sentence pair. These lexical resources exploit different perspectives on the data in complementary ways.

The parallel corpus features encourage the classifier to select examples with AltLexes that are likely to be causal whereas the lexical semantic features allow the classifier to consider context for disambiguation. In addition to the dataset, the parallel corpus and lexical semantic features are the main contributions of this effort.

5.1 Parallel Corpus Features

We create a subclass of features from the parallel corpus: a KL-divergence score to encourage the identification of phrases that replace causal connectives. Consider the following datapoints and assume that they are aligned in the parallel corpus:

I was late **because of** traffic.

I was late **due to** traffic.

We want both of these examples to have a high score for causality because they are interchangeable causal phrases. Similarly, we want non-causal phrases that are often aligned to have a high score for non-causality.

We define several distributions in order to determine whether an AltLex is likely to replace a known causal or non-causal connective. We consider all aligned phrases, not just ones containing a causal or non-causal connective to attempt to reduce noisy matches. The idea is that non-connective paraphrases will occur often and in other contexts.

The following conditional Bernoulli distributions are calculated for every aligned phrase in the dataset, where w is the phrase, s is the sentence it occurs in, c is "causal" and nc is "not causal":

$$p_1 = p(w_1 \in s_1 | rel(s_1) \in \{c\}, w_1 \notin s_2) \quad (3)$$

$$p_2 = p(w_1 \in s_1 | rel(s_1) \in \{nc\}, w_1 \notin s_2) \quad (4)$$

We compare these two distributions to other distributions with the same word and in a different context (where o represents "other"):

$$q_1 = p(w_1 \in s_1 | rel(s_1) \in \{nc, o\}, w_1 \notin s_2) \quad (5)$$

$$q_2 = p(w_1 \in s_1 | rel(s_1) \in \{c, o\}, w_1 \notin s_2) \quad (6)$$

We then calculate $D_{KL}(p_1||q_1)$ and $D_{KL}(p_2||q_2)$. In order to use KL-divergence as a feature, we multiply the score by $(-1)^{p<q}$ and add a feature for **causal** and one for **non-causal**.

5.2 Lexical Semantic Features

As events are composed of predicates and arguments and these are usually formed by nouns and verbs, we consider using lexical semantic resources that have defined hierarchies for nouns and verbs. We thus use the lexical resources FrameNet, WordNet, and VerbNet as complementary resources from which to derive features. We hypothesize that these semantic features provide context not present in the text; from these we are able to infer causal and anti-causal properties.

FrameNet is a resource for frame semantics, defining how objects and relations interact, and provides an annotated corpus of English sentences. WordNet provides a hierarchy of word senses and we show that the top-level class of verbs is useful for indicating causality. VerbNet provides a more fine-grained approach to verb categorization that complements the views provided by FrameNet and WordNet.

In **FrameNet**, a semantic frame is a conceptual construction describing events or relations and their participants (Ruppenhofer et al, 2010). Frame semantics abstracts away from specific utterances and ordering of words in order to represent events at a higher level. There are over 1,200 semantic frames in FrameNet and some of these can be used as evidence or counter-evidence for causality (Riaz and Girju, 2013). In Riaz's work, they identified 18 frames as causal (e.g. "Purpose", "Internal cause", "Reason", "Trigger").

We use these same frames to create a lexical score based on the FrameNet 1.5 corpus. This corpus contains 170,000 sentences manually annotated with frames. We used a part-of-speech tagged version of the FrameNet corpus and for each word and tag, we count how often it occurs in the span of one of the given frames. We only considered nouns, verbs, adjectives, and adverbs. We then calculate $p_w(c|t)$ and c_{wct}, the probability that a word w is causal given its tag t and its count, respectively. The lexical score of a word i is calculated by using the assigned part-of-speech tag and is given by $CS_i = p_{w_i}(c|t_i) \log c_{w_i c t_i}$. The total score of a sequence of words is then $\sum_{i=0}^{n} CS_i$.

We also took this further and determined what frames are likely to be *anti-causal*. We started with a small set of seed words derived directly from 11 discourse classes (types and subtypes from Table 2), such as "Compare", "Contrast", "Explain", "Concede", and "List". We expanded this list using WordNet synonyms for the seed words. We then extracted every frame associated with their stems in the stemmed FrameNet corpus. These derived frames were manually examined to develop a list of 48 anti-causal frames, including "Statement", "Occasion", "Relative time", "Evidence", and "Explaining the facts".

We create an anti-causal score using the FrameNet corpus just as we did for the causal score. The total anti-causal score of a sequence of words is $\sum_{i=0}^{n} ACS_i$ where $ACS_i = p_{w_i}(a|t_i) \log c_{w_i a t_i}$ for anti-causal probabilities and counts. We split each example into three parts: the text before the AltLex, the AltLex, and the text after. Each section is given a causal score and an anti-causal score. Overall, there are six features derived using FrameNet: causal score and anti-causal score for each part of the example.

In **WordNet**, words are grouped into "synsets," which represent all synonyms of a particular word sense. Each word sense in the WordNet hierarchy has a top-level category based on part of speech (Miller, 1995). Every word sense tagged as noun, verb, adjective, or adverb is categorized. Some examples of categories are "change", "stative", or "communication". We only include the top level because of the polysemous nature of WordNet synsets. We theorize that words having to do with change or state should be causal indicators and words for communication or emotion may be anti-causal indicators.

Similar to the FrameNet features, we split the example into three sections. However, we also consider the dependency parse of the data. We believe that causal relations are between events and agents which are represented by nouns and verbs. Events can also be represented by predicates and their arguments, which is captured by the dependency parse. As the root of a dependency parse is often a verb and sometimes a noun or adjective, we consider the category of the root of a dependency parse and its arguments.

We include a categorical feature indicating the top-level category of the root of each of the three sections, including the AltLex. For both sides of the AltLex, we include the top-level category of all arguments as well. If a noun has no category, we mark it using its named-entity tag. If there is still no tag, we mark the category as "none."

VerbNet VerbNet is a resource devoted to storing information for verbs (Kipper et al, 2000).

In contrast to WordNet, VerbNet provides a more fine-grained description of events while focusing less on polysemy. Some examples of VerbNet classes are "force", "indicate", and "wish". In VerbNet, there are 273 verb classes, and we include their presence as a categorical feature. Similar to WordNet, we use VerbNet categories for three sections of the sentence: the text pre-AltLex, the AltLex, and the text post-AltLex. Unlike WordNet, we only mark the verbs in the AltLex, root, or arguments.

Interaction Finally, we consider interactions between the WordNet and VerbNet features. As previous work (Marcu, 2001) (Biran and McKeown, 2013) used word pairs successfully, we hypothesize that pairs of higher-level categories will improve classification without being penalized as heavily by the sparsity of dealing with individual words. Thus we include interaction features between every categorical feature for the pre-AltLex text and every feature for the post-AltLex text.

In all, we include the following features (L refers to the AltLex, B refers to the text *before* the AltLex and A refers to the text *after* the AltLex):

1. FrameNet causal score for L, B, and A.
2. FrameNet anti-causal score for L, B, and A.
3. WordNet top-level of L.
4. WordNet top-level of the root of B and A.
5. WordNet top-level for arguments of B and A.
6. VerbNet category for verb at the root of L.
7. VerbNet top-level category for any verb in the root of B and A.
8. VerbNet top-level category for any verbs in the arguments of B and A.
9. Categorical interaction features between the features from B and the features from A.

6 Results

We evaluated our methods on two manually annotated test sets. We used one of these test sets for development only. For this set, one graduate computer science student and two students from the English department annotated a set of Wikipedia articles by marking any phrases they considered to indicate a causal relationship and marking the phrase as "reason" or "result." Wikipedia articles from the following categories were chosen as we believe they are more likely to contain causal relationships: science, medicine, disasters, history, television, and film. For each article in this category, both the English and Simple Wikipedia articles were annotated. A total of 12 article pairs were annotated. IAA was computed to be 0.31 on two article pairs using Kripendorff's alpha.

IAA was very low and we also noticed that annotators seemed to miss sentences containing causal connectives. It is easy for an annotator to overlook a causal relation when reading through a large quantity of text. Thus, we created a new task that required labeling a connective as causal or not when provided with the sentence containing the connective. For testing, we used CrowdFlower to annotate the output of the system using this method. We created a balanced test set by annotating 600 examples, where the system labeled 300 as causal and 300 as non-causal. Contributors were limited to the highest level of quality and from English-speaking countries. We required 7 annotators for each data point. The IAA was computed on the qualification task that all annotators were required to complete. There were 15 questions on this task and 410 annotators. On this simplified task, the IAA improved to 0.69.

We also considered evaluating the results on the PDTB but encountered several issues. As the PDTB only has a limited set of explicit intra-sentence connectives marked, this would not show the full strength of our method. Many causal connectives that we discovered are not annotated in the PDTB. Alternatively, we considered evaluating on the AltLexes in the PDTB but these examples are only limited to inter-sentence cases, whereas the vast majority of our automatically annotated training data was for the intra-sentence case. Thus we concluded that any evaluation on the PDTB would require additional annotation. Our goal in this work was to identify new ways in which causality is expressed, unlike the PDTB where annotators were given a list of connectives and asked to determine discourse relations.

We tested our hypothesis by training a binary[3] classifier on our data using the full set of features we just described. We used a linear Support Vector Machine (SVM) classifier (Vapnik, 1998) trained using stochastic gradient descent (SGD) through the sci-kit learn package. (Pedregosa et al, 2011)[4] We used elasticnet to encourage sparsity and tuned the regularization constant α through grid search.

We use two baselines. The first baseline is the

[3]We combine "reason" and "result" into one "causal" class and plan to work on distinguishing between non-causal, reason, and result in the future.

[4]We also considered a logistic regression classifier.

	Accuracy	True Precision	True Recall	True F-measure
Most Common Class	63.50	60.32	82.96	69.85
$CONN$	62.21	78.47	35.64	49.02
LS	67.68	61.98	58.51	60.19
KLD	58.03	**91.17**	19.55	32.20

$LS \cup LS_{inter}$	72.99	78.54	64.66	70.93
$KLD \cup LS \cup LS_{inter}$	70.09	76.95	58.99	66.78
$LS \cup KLD \cup CONN$	71.86	70.28	**77.60**	**73.76**
$Bootstrapping_1$	79.26	**77.97**	82.64	80.24
$Bootstrapping_2$	**79.58**	77.29	**84.85**	**80.90**

Table 3: Experimental Results

most common class of each AltLex according to its class in the initial training set. For example, "caused by" is almost always a causal AltLex. A second baseline uses the AltLex itself as a categorical feature and is shown as $CONN$ in Table 3. For comparison, this is the same baseline used in (Pitler and Nenkova, 2009) on the explicit discourse relations in the PDTB. We compare these two baselines to ablated versions of our system. We evaluate on the KLD (KLD) and semantic (LS and LS_{inter}) features described in sections 5 and 5.1. LS consists of features 1-8, all the FrameNet, VerbNet, and WordNet features. LS_{inter} includes only the interaction between categorical features from WordNet and VerbNet.

We calculate accuracy and true precision, recall, and F-measure for the causal class. As seen in Table 3, the best system ($LS \cup KLD \cup CONN$) outperforms the baselines.[5] The lexical semantic features by themselves (LS) are similar to those used by (Riaz and Girju, 2014) although on a different task and with the WordNet and VerbNet features included. Note that the addition of the Altlex words and KL divergence ($LS \cup KLD \cup CONN$) yields an absolute increase in f-measure of 13.57 points over lexical semantic features alone.

6.1 Bootstrapping

Our method for labeling AltLexes lends itself naturally to a bootstrapping approach. As we are using explicit connectives to identify new AltLexes, we can also use these new AltLexes to identify additional ones. We then consider any paraphrase pairs where at least one of the phrases contains one of our newly discovered AltLexes. We also use our classifier to automatically label these new data points and remove any phrases where the classifier did not agree on both elements in the pair. The set of features used were the $KLD \cup LS \cup LS_{inter}$ features as these performed best on the development set. We use early stopping on the development data to identify the point when adding additional data is not worthwhile. The bootstrapping method converges quickly. After 2 iterations we see a decrease in the F-measure of the development data.

The increase in performance on the test data is significant. In Table 3, $Bootstrapping_n$ refers to results after n rounds of bootstrapping. Bootstrapping yields improvement over the supervised method with an absolute gain of 7.14 points.

6.2 Discussion

Of note is that the systems without connectives (combinations of LS, LS_{inter}, and KLD) perform well on the development set without using any lexical features. Using this system enables the discovery of new AltLexes during bootstrapping, as we cannot rely on having a closed class of connectives but need a way of classifying connectives not seen in the initial training set.

Also important is that the Altlex by itself ($CONN$) performs poorly. In comparison, in the task of identifying discourse relations in the PDTB these features yield an 75.33 F-score and 85.85% accuracy in distinguishing between discourse and non-discourse usage (Pitler and Nenkova, 2009) and an accuracy of 93.67% when distinguishing between discourse classes. Although this is a different data set, this shows that identifying causality when there is an open class of connectives is much more difficult. We believe the connective by itself performs poorly because of the wide

[5]These results are statistically significant by a binomial test with $p < 7 * 10^{-6}$.

	True Precision	True Recall	True F-measure
$FrameNet$	67.88	53.14	59.61
$WordNet$	76.92	9.52	16.94
$VerbNet$	38.70	3.80	6.92

Table 4: Semantic Feature Ablation

linguistic variation in these alternative lexicalizations. Many connectives appear only once or not at all in the training set, so the additional features are required to improve performance.

In addition, the "most common class" baseline is a strong baseline. The strength of this performance provides some indication of the quality of the training data, as the majority of the time the connective is very indicative of its class in the held-out test data. However, the the overall accuracy is still much lower than if we use informative features.

The KLD and LS feature sets appear to be complementary. The KLD feature sets have higher precision on a smaller section of the data, whereas the LS system has higher recall overall. These lexical semantic features likely have higher recall because these resources are designed to represent *classes* of words rather than individual words. Some connectives occur very rarely, so it is necessary to generalize the key aspects of the connectives and class-based resources provide this capability.

In order to determine the contribution of each lexical resource, we perform additional feature ablation for each of FrameNet, WordNet, and VerbNet. As seen in Table 4, the lexical semantic resources each contribute uniquely to the classifier. The FrameNet features provide most of the performance of the classifier. The WordNet and VerbNet features, though not strong individually, supply complementary information and improve the overall performance of the LS system (see Table 3) compared to just using FrameNet alone.

Finally, the model ($LS \cup KLD \cup CONN$) correctly identifies some causal relations that neither baseline identifies, such as:

> Language is reduced to simple phrases or even single words, eventually **leading to** complete loss of speech.
>
> Kulap quickly accelerated north, **prompting** the PAGASA to issue their final advisory on the system.

These examples do not contain standard causal connectives and occur infrequently in the data, so the lexical semantic features help to identify them.

After two rounds of bootstrapping, the system is able to recover additional examples that were not found previously, such as:

> When he finally changed back, Buffy stabbed him **in order to** once again save the world.

This connective occurs rarely or not at all in the initial training data and is only recovered because of the improvements in the model.

7 Conclusion

We have shown a method for identifying and classifying phrases that indicate causality. Our method for automatically building a training set for causality is a new contribution. We have shown statistically significant improvement over the naive baseline using semantic and parallel corpus features. The text in the AltLex alone is not sufficient to accurately identify causality. We show that our features are informative by themselves and perform well even on rarely occurring examples.

Ultimately, the focus of this work is to improve detection of causal relations. Thus, we did not evaluate some intermediate steps, such as the quality of the automatically annotated corpus. Our use of distant supervision demonstrates that we can use a large amount of possibly noisy data to develop an accurate classifer. To evaluate on the intermediate step would have required an additional annotation process. In the future, we may improve this step using a machine learning approach.

Although we have focused exclusively on Wikipedia, these methods could be adapted to other domains and languages. Causality is not easily expressed in English using a fixed set of phrases, so we would expect these methods to apply to formal and informal text ranging from news and journals to social media. Linguistic expressions of causality in other languages is another avenue for future research, and it would be interesting to note if other languages have the same variety of expression.

Abstract

Modeling relation paths has offered significant gains in embedding models for knowledge base (KB) completion. However, enumerating paths between two entities is very expensive, and existing approaches typically resort to approximation with a sampled subset. This problem is particularly acute when text is jointly modeled with KB relations and used to provide direct evidence for facts mentioned in it. In this paper, we propose the first exact dynamic programming algorithm which enables efficient incorporation of all relation paths of bounded length, while modeling both relation types and intermediate nodes in the compositional path representations. We conduct a theoretical analysis of the efficiency gain from the approach. Experiments on two datasets show that it addresses representational limitations in prior approaches and improves accuracy in KB completion.

1 Introduction

Intelligent applications benefit from structured knowledge about the entities and relations in their domains. For example, large-scale knowledge bases (KB), such as Freebase (Bollacker et al., 2008) or DBPedia (Auer et al., 2007), have proven to be important resources for supporting open-domain question answering (Berant et al., 2013; Sun et al., 2015; Yih et al., 2015). In biomedicine, KBs such as the Pathway Interaction Database (NCI-PID) (Schaefer et al., 2009) are crucial for understanding complex diseases such as cancer and for advancing precision medicine. While these knowledge bases are often carefully curated, they are far from complete. In non-static domains, new facts become true or are discovered at a fast pace, making the manual expansion of knowledge bases impractical. Extracting relations from a text corpus (Mintz et al., 2009; Surdeanu et al., 2012; Poon et al., 2015) or inferring facts from the relationships among known entities (Lao and Cohen, 2010) are thus important approaches for populating existing knowledge bases.
