Improved Representation Learning for Question Answer Matching

Ming Tan, Cicero dos Santos, Bing Xiang & Bowen Zhou

Abstract

Passage-level question answer matching is a challenging task since it requires effective representations that capture the complex semantic relations between questions and answers. In this work, we propose a series of deep learning models to address passage answer selection. To match passage answers to questions accommodating their complex semantic relations, unlike most previous work that utilizes a single deep learning structure, we develop hybrid models that process the text using both convolutional and recurrent neural networks, combining the merits on extracting linguistic information from both structures. Additionally, we also develop a simple but effective attention mechanism for the purpose of constructing better answer representations according to the input question, which is imperative for better modeling long answer sequences. The results on two public benchmark datasets, InsuranceQA and TREC-QA, show that our proposed models outperform a variety of strong baselines.

1 Introduction

Passage-level answer selection is one of the essential components in typical question answering (QA) systems. It can be defined as follows: Given a question and a pool of candidate passages, select the passages that contain the correct answer. The performance of the passage selection task is not only crucial to non-factoid QA systems, where a question is expected to be answered with a sequence of descriptive text (e.g. the question in Table 1), but also very important to factoid QA systems, where the answer passage selection step is also known as passage scoring. In factoid QA, if the sentences selected by the passage scorer module do not contain the answer, it will definitely lead to an incorrect response from the QA system.

Question: Does Medicare cover my spouse?
Ground-truth answer: If your spouse has worked and paid Medicare taxes for the entire required 40 quarters, or is eligible for Medicare by virtue of being disabled or some other reason, your spouse can receive his/her own medicare benefits. If your spouse has not met those qualifications, if you have met them, and if your spouse is age 65, he/she can receive Medicare based on your eligibility.
Another candidate answer: If you were married to a Medicare eligible spouse for at least 10 years, you may qualify for Medicare. If you are widowed, and have not remarried, and you were married to your spouse at least 9 months before your spouse's death, you may be eligible for Medicare benefits under a spouse provision.

Table 1: An example of a question with the ground-truth answer and a negative answer extracted from the InsuranceQA dataset.

One central challenge of this task lies in the complex and versatile semantic relations observed between questions and passage answers. For example, while the task of supporting passage selection for factoid QA may be largely cast as a textual entailment problem, what makes an answer better than another in the real world for non-factoid QA often depends on many factors.

Specifically, different from many other pair-matching NLP tasks, the linguistic similarities between questions and answers may or may not be indicative for our task. This is because, depending on what the question is looking for, a good answer may come in different forms: sometimes a correct

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 464–473,
Berlin, Germany, August 7-12, 2016.

answer completes the question precisely with the missing information, and in other scenarios, good answers need to elaborate part of the question to rationalize it, and so on. For instance, the question in Table 1 only contains five words, while the best answer uses 60 words for elaboration. On the other hand, the best answers from a pool can also be noisy and include extraneous information irrelevant to the question. Additionally, while a good answer must relate to the question, they often do not share common lexical units. For instance, in the example question, "cover" is not directly mentioned in the answer. This issue may confuse simple word-matching systems.

These challenges consequently make handcrafting features much less desirable compared to deep learning based methods. Furthermore, they also require our systems to learn how to distinguish useful pieces from irrelevant ones, and further, to focus more on the former.

Finally, the system should be capable of capturing the nuances between the best answer and an acceptable one. For example, the second answer in Table 1 is suitable for a questioner, whose spouse is Medicare eligible, asking about his/her own coverage, while the example question is more likely asked by a person, who is Medicare eligible, asking about his/her spouse' coverage. Clearly, the first answer is more appropriate for the question, although the second one implicitly answers it. A good system should reflect this preference.

While this task is usually approached as a pairwise-ranking problem, the best strategy to capture the association between the questions and answers is still an open problem. Established approaches normally suffer from two weaknesses at this point. First, prior work, such as (Feng et al., 2015; Wang and Nyberg, 2015), resort to either convolutional neural network (CNN) or recurrent neural network (RNN) respectively. However, each structure describes only one semantic perspective of the text. CNN emphasizes the local interaction within n-gram, while RNN is designed to capture long range information and forget unimportant local information. How to combine the merits from both has not been sufficiently explored. Secondly, previous approaches are usually based on independently generated question and answer embeddings; the quality of such representations, however, usually degrades as the answer sequences grow longer.

In this work, we propose a series of deep learning models in order to address such weaknesses. We start with the basic discriminative framework for answer selection. We first propose two independent models, Convolutional-pooling LSTM and Convolution-based LSTM, which are designed to benefit from both of the two popular deep learning structures to distinguish better between useful and irrelevant pieces presented in questions and answers. Next, by breaking the independence assumption of the question and answer embedding, we introduce an effective attention mechanism to generate answer representations according to the question, such that the embeddings do not overlook informative parts of the answers. We report experimental results for two answer selection datasets: (1) InsuranceQA (Feng et al., 2015) [1], a recently released large-scale non-factoid QA dataset from the insurance domain, and (2) TREC-QA [2], which was created by Wang et al. (2007) based on Text REtrieval Conference (TREC) QA track data.

The contribution of this paper is hence threefold: 1) We propose hybrid neural networks, which learn better representations for both questions and answers by combining merits of both RNN and CNN. 2) We prove the effectiveness of attention on the answer selection task, which has not been sufficiently explored in prior work. 3) We achieve the state-of-the-art results on both TREC-QA and InsuranceQA datasets.

The rest of the paper is organized as follows: Section 2 describes the related work for answer selection; Section 3 provides the details of the proposed models; Experimental settings and results are discussed in Section 4 and 5; Finally, we draw conclusions in Section 6.

2 Related work

Previous work on answer selection normally used feature engineering, linguistic tools, or external resources. For example, semantic features were constructed based on WordNet in (Yih et al., 2013). This model pairs semantically related words based on word semantic relations. In (Wang and Manning, 2010; Wang et al., 2007), the answer selection problem was transformed to a syntacti-

[2] The data is obtained from (Yao et al., 2013) http://cs.jhu.edu/~xuchen/packages/jacana-qa-naacl2013-data-results.tar.bz2

cal matching between the question/answer parse trees. Some work tried to fulfill the matching using minimal edit sequences between dependency parse trees (Heilman and Smith, 2010; Yao et al., 2013). Discriminative tree-edit feature extraction and engineering over parsing trees were automated in (Severyn and Moschitti, 2013). Such methods might suffer from the availability of additional resources, the effort of feature engineering and the systematic complexity introduced by the linguistic tools, such as parse trees and dependency trees.

Some recent work has used deep learning methods for the passage-level answer selection task. The approaches normally pursue the solution on the following directions. First, a joint feature vector is constructed based on both the question and the answer, and then the task can be converted into a classification or ranking problem (Wang and Nyberg, 2015; Hu et al., 2014). Second, recently proposed models for text generation can intrinsically be used for answer selection and generation (Bahdanau et al., 2015; Vinyals and Le, 2015). Finally, the question and answer representations can be learned and then matched by certain similarity metrics (Feng et al., 2015; Yu et al., 2014; dos Santos et al., 2015; Qiu and Huang, 2015). Fundamentally, our proposed models belong to the last category.

Meanwhile, attention-based systems have shown very promising results on a variety of NLP tasks, such as machine translation (Bahdanau et al., 2015; Sutskever et al., 2014), machine reading comprehension (Hermann et al., 2015), text summarization (Rush et al., 2015) and text entailment (Rocktäschel et al., 2016). Such models learn to focus their attention to specific parts of their input and most of them are based on a one-way attention, in which the attention is basically performed merely over one type of input based on another (e.g. over target languages based on the source languages for machine translation, or over documents according to queries for reading comprehension). Most recently, several two-way attention mechanisms are proposed, where the information from the two input items can influence the computation of each others representations. Rocktäschel et al. (2016) develop a two-way attention mechanism including another one-way attention over the premise conditioned on the hypothesis, in addition to the one over hypothesis conditioned on premise. dos Santos et al. (2016) and Yin et al. (2015) generate interactive attention weights on both inputs by assignment matrices. Yin et al. (2015) use a simple Euclidean distance to compute the interdependence between the two input texts, while dos Santos et al. (2016) resort to attentive parameter matrices.

3 Approaches

In this section, we first present our basic discriminative framework for answer selection based on long short-term memory (LSTM), which we call QA-LSTM. Next, we detail the proposed hybrid and attentive neural networks that are built on top of the QA-LSTM framework.

3.1 LSTM for Answer Selection

Our LSTM implementation is similar to the one in (Graves et al., 2013) with minor modifications. Given an input sequence $\mathbf{X} = \{\mathbf{x}(1), \mathbf{x}(2), \cdots, \mathbf{x}(n)\}$, where $\mathbf{x}(t)$ is an E-dimension word vector in this paper, the hidden vector $\mathbf{h}(t)$ (with size H) at the time step t is updated as follows.

$$i_t = \sigma(\mathbf{W}_i\mathbf{x}(t) + \mathbf{U}_i\mathbf{h}(t-1) + \mathbf{b}_i) \quad (1)$$
$$f_t = \sigma(\mathbf{W}_f\mathbf{x}(t) + \mathbf{U}_f\mathbf{h}(t-1) + \mathbf{b}_f) \quad (2)$$
$$o_t = \sigma(\mathbf{W}_o\mathbf{x}(t) + \mathbf{U}_o\mathbf{h}(t-1) + \mathbf{b}_o) \quad (3)$$
$$\tilde{C}_t = \tanh(\mathbf{W}_c\mathbf{x}(t) + \mathbf{U}_c\mathbf{h}(t-1) + \mathbf{b}_c) \quad (4)$$
$$C_t = i_t * \tilde{C}_t + f_t * C_{t-1} \quad (5)$$
$$\mathbf{h}_t = o_t * \tanh(C_t) \quad (6)$$

There are three gates (input i, forget f and output o), and a cell memory vector C_t. σ is the $sigmoid$ function. $\mathbf{W} \in R^{H\times E}$, $\mathbf{U} \in R^{H\times H}$ and $\mathbf{b} \in R^{H\times 1}$ are the network parameters.

Single-direction LSTMs suffer from the weakness of not making use of the contextual information from the future tokens. Bidirectional LSTMs (biLSTMs) use both the previous and future context by processing the sequence in two directions, and generate two sequences of output vectors. The output for each token is the concatenation of the two vectors from both directions, i.e. $h_t = \overrightarrow{h_t} \parallel \overleftarrow{h_t}$.

QA-LSTM: Our basic answer selection framework is shown in Figure 1. Given an input pair (q,a), where q is a question and a is a candidate answer, first we retrieve the word embeddings (WEs) of both q and a. Then, we separately apply a biLSTM over the two sequences of WEs. Next,

we generate a fixed-sized distributed vector representations using one of the following three approaches: (1) the concatenation of the last vectors on both directions of the biLSTM; (2) average pooling over all the output vectors of the biLSTM; (3) max pooling over all the output vectors. Finally, we use cosine similarity $sim(q, a)$ to score the input (q, a) pair. It is important to note that the same biLSTM is applied to both q and a.

Similar to (Feng et al., 2015; Weston et al., 2014; Hu et al., 2014), we define the training objective as a hinge loss.

$$\mathcal{L} = \max\{0, M - sim(q, a_+) + sim(q, a_-)\} \quad (7)$$

where a_+ is a ground truth answer, a_- is an incorrect answer randomly chosen from the entire answer space, and M is a margin. We treat any question with more than one ground truth as multiple training examples. During training, for each question we randomly sample K negative answers, but only use the one with the highest $\mathcal{L}$ to update the model. Finally, dropout operation is performed on the representations before cosine similarity matching.

The same scoring function, loss function and negative sampling procedure is also used in the NN architectures presented in what follows.

3.2 Convolutional LSTMs

The pooling strategies used in QA-LSTM suffer from the incapability of filtering important local information, especially when dealing with long answer sequences.

Also, it is well known that LSTM models successfully keep the useful information from long-range dependency. But the strength has a trade-off effect of ignoring the local n-gram coherence. This can be partially alleviated with bidirectional architectures.

Meanwhile, the convolutional structures have been widely used in the question answering tasks, such as (Yu et al., 2014; Feng et al., 2015; Hu et al., 2014). Classical convolutional layers usually emphasize the local lexical connections of the n-gram. However, the local pieces are associated with each other only at the pooling step. No long-range dependencies are taken into account during the formulation of convolution vectors.

Fundamentally, recurrent and convolutional neural networks have their own pros and cons, due to their different topologies. How to keep both merits motivates our studies of the following two hybrid models.

3.2.1 Convolutional-pooling LSTMs

In Figure 2 we detail the convolutional-pooling LSTM architecture. In this NN architecture, we replace the simple pooling layers (average/max-pooling) by a convolutional layer, which allows to capture richer local information by applying a convolution over sequences of LSTM output vectors. The number of output vectors k (context window size) considered by the convolution is a hyper-parameter of the model.

The convolution structure adopted in this work is as follows: $Z \in \mathcal{R}^{k|h| \times L}$ is a matrix where the m-th column is the concatenation of k hidden vectors generated from biLSTM centralized in the m-th word of the sequence, L is the length of the sequence after wide convolution (Kalchbrenner et al., 2014). The output of the convolution with c filters is,

$$C = \tanh(\mathbf{W}_{cp} Z) \quad (8)$$

where W_{cp} are network parameters, and $C \in \mathcal{R}^{c \times L}$. The j-th element of the representation vectors ($\mathbf{o}_q$ and $\mathbf{o}_a$) is computed as follows,

$$[o_j] = \max_{1<l<L} [C_{j,l}] \quad (9)$$

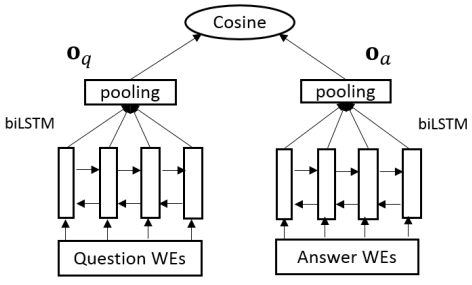

Figure 1: Basic Model: QA-LSTM

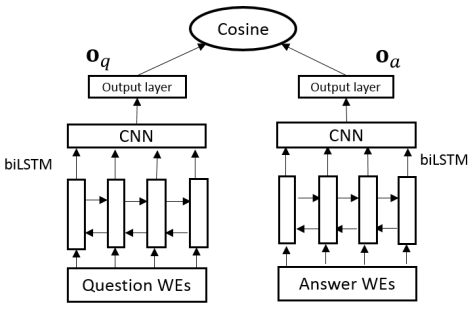

Figure 2: Convolutional-pooling LSTM

3.2.2 Convolution-based LSTMs

In Figure 3, we detail our second hybrid NN architecture. The aim of this approach is to capture the local n-gram interaction at the lower level using a convolution. At the higher level, we build bidirectional LSTMs, which extract the long range dependency based on convoluted n-gram. Combining convolutional and recurrent structures have been investigated in prior work other than question answering (Donahue et al., 2015; Zuo et al., 2015; Sainath et al., 2015).

As shown in Figure 3, the model first retrieves word vectors for each token in the sequence. Next, we compose the matrix $D \in \mathcal{R}^{kE \times L}$, where each column l in D consists of the concatenation of k word vectors of size E centered at the l-th word. The matrix $\mathbf{X} \in \mathcal{R}^{c \times L}$, which is the output of the convolution with c filters is computed as follows:

$$\mathbf{X} = \tanh(\mathbf{W}_{cb} D) \quad (10)$$

The matrix $\mathbf{X}$ is the input to the biLSTM structure in Eqs. 1-6. After the biLSTM step, we use max-pooling over the biLSTM output vectors to obtain the representations of both q and a.

3.3 Attentive LSTMs

In the previous subsections, the two most popular deep learning architectures are integrated to generate semantic representations for questions and answers from both the long-range sequential and local n-gram perspectives.

QA-LSTM and the two proposed hybrid models are basically siamese networks (Chopra et al., 2005). These structures overlook another potential issue. The answers might be extremely long and contain lots of words that are not related to the question at hand. No matter what advanced neural networks are exploited at the answer side, the resulting representation might still be distracted by non-useful information. A typical example is the second candidate answer in Table 1. If the construction of the answer representation is not aware of the input question, the representation might be strongly influenced by n-grams such as "are widowed" and "your spouse's death", which are informative if we only look at the candidate answer, but are not so important for the input question. We address this problem by developing a simple attention model for the answer vector generation, in order to alleviate this weakness by dynamically aligning the more informative parts of answers to the questions.

Inspired by the work in (Hermann et al., 2015), we develop a very simple but efficient word-level attention on the basic model. In Figure 4, we detail our Attentive LSTM architecture. Prior to the average or mean pooling, each biLSTM output vector is multiplied by a softmax weight, which is determined by the question representation from biLSTM. Specifically, given the output vector of biLSTM on the answer side at time step t, $\mathbf{h}_a(t)$, and the question representation, $\mathbf{o}_q$, the updated vector $\widetilde{\mathbf{h}}_a(t)$ for each answer token are formulated below.

$$\mathbf{m}_{a,q}(t) = \mathbf{W}_{am}\mathbf{h}_a(t) + \mathbf{W}_{qm}\mathbf{o}_q \quad (11)$$

$$s_{a,q}(t) \propto \exp(\mathbf{w}_{ms}^T \tanh(\mathbf{m}_{a,q}(t))) \quad (12)$$

$$\widetilde{\mathbf{h}}_a(t) = \mathbf{h}_a(t) s_{a,q}(t) \quad (13)$$

where $\mathbf{W}_{am}$, $\mathbf{W}_{qm}$ and $\mathbf{w}_{ms}$ are attention parameters. Conceptually, the attention mechanism gives more weight to certain words of the candidate answer, where the weights are computed by taking into consideration information from the question. The expectation is that words in the candidate answer that are more important with regard to the input question should receive larger weights.

The attention mechanism in this paper is conceptually analogous to the one used in one-layer

memory network (Sukhbaatar et al., 2015). The fundamental difference is that the transformed question vector and answer unit vectors are combined in an inner-product pattern in order to generate attentive weights in memory network, whereas this work adopts a summation operation (Eq. 11).

4 InsuranceQA Experiments

The first dataset we use to evaluate the proposed approaches is the InsuranceQA, which has been recently proposed by Feng et al. (2015). We use the first version of this dataset. This dataset contains question and answer pairs from the insurance domain and is already divided into a training set, a validation set, and two test sets. We do not see any obvious categorical differentiation between two tests' questions. We list the numbers of questions and answers of the dataset in Table 2. We refer the reader to (Feng et al., 2015), for more details regarding the InsuranceQA data. In this dataset, a question may have multiple correct answers, and normally the questions are much shorter than answers. The average length of questions in tokens is 7, while the average length of answers is 94. Such difference posts additional challenges for the answer selection task. This corpus contains 24981 unique answers in total. For the development and test sets, the InsuranceQA also includes an answer pool of 500 candidate answers for each question. These answer pools were constructed by including the correct answer(s) and randomly selected candidates from the complete set of unique answers. The top-1 accuracy of the answer selection is reported.

4.1 Setup

The proposed models are implemented with Theano (Bastien et al., 2012) and all experiments are conducted in a GPU cluster. We use the accuracy on validation set to select the best epoch and best hyper-parameter settings for testing.

The word embeddings are pre-trained, using word2vec (Mikolov et al., 2013) [3]. The training data for the word embeddings is a Wikipedia corpus of 164 million tokens combined with the questions and answers in the InsuranceQA training set. The word vector size is set to 100. Word embeddings are also part of the parameters and are optimized during the training. Stochastic Gradient Descent (SGD) is the optimization strategy. The learning rate λ is 1.1. We get the best performances when the negative answer count $K = 50$. We also tried different margins in the hing loss function, and finally fixed the margin as M=0.2. We train our models in mini-batches (with batch size as 20), and the maximum length L of questions and answers is 200. Any tokens out of this range are discarded. In order to get more obvious comparison between the proposed models and the basic framework, with respect to the ground-truth answer length in Fig. 5, we also provide the results of $K = 1$. In this case, we set $M = 0.1$, $\lambda = 0.1$ and mini-batches as 100 to get the best performance on the validation set. Also, the dimension of LSTM output vectors is 141x2 for bidirectional LSTM in QA-LSTM, Attentive LSTM and Convolutional-pooling LSTM, such that biLSTM has a comparable number of parameters with a single-direction LSTM with 200 dimensions. For Convolution-based LSTM, since LSTM structure is built on the top of CNN, we fixed the CNN output as 282 dimensions and tune the biLSTM hidden vector size in the experiments.

Because the sequences within a mini-batch have different lengths, we use a mask matrix to indicate the real length of each sequence.

4.2 Baselines

For comparison, we report the performances of four baselines in the top group in Table 3: two state-of-the-art non-DL approaches and two variations of a strong DL approach based on CNN.

Bag-of-word: The idf-weighted sum of word vectors is used as a feature vector. The candidates are ranked by the cosine similarity to the question.

Metzler-Bendersky IR model: A state-of-the-art weighted dependency model (Bendersky et al., 2010; Bendersky et al., 2011), which employs a weighted combination of term-based and term proximity-based features to score each candidate.

Architecture-II in (Feng et al., 2015): A CNN model is employed to learn distributed representations of questions and answers. Cosine similarity is used to rank answers.

[3] https://code.google.com/p/word2vec/

	Model	Validation	Test1	Test2
	Bag-of-word	31.9	32.1	32.2
	Metzler-Bendersky IR model	52.7	55.1	50.8
	CNN (Feng et al., 2015)	61.8	62.8	59.2
	CNN with GESD (Feng et al., 2015)	**65.4**	**65.3**	**61.0**

Architecture-II with Geometricmean of Euclidean and Sigmoid Dot product (GESD): Cosine similarity is replaced by GESD, which got the best performance in (Feng et al., 2015).

4.3 Results and discussions

In this section, we provide detailed analysis on the experimental results. Table 3 summarizes the results of our models on InsuranceQA. From Row (A) to (D), we list QA-LSTM without either CNN structure or attention. They vary on the pooling method used. We can see that by concatenating the last vectors from both directions, (A) performs the worst. We see that using max-pooling (C) is much better than average pooling (B). The potential reason may be that the max-pooling extracts more local values for each dimension. Compared to (C), (D) is better, showing the need of multiple negative answers in training.

Row (E) to (I) show the results of Convolutional-pooling LSTMs and Convolution-based LSTMs with different filter sizes c, biLSTM hidden sizes $|h|$ and negative answer pool size K. Increasing the negative answer pool size, we are allowed to use less filter counts (F vs E). Larger filter counts help on the test accuracies (G vs F) for Convolutional-pooling LSTMs. We have the same observation with larger biLSTM hidden vector size for Convolution-based LSTMs. Both convolutional models outperform the plain QA-LSTM (D) by about 1.0% on test1, and 0.7% on test2.

Rows (L-N) correspond to QA-LSTM with the attention model, with either max-pooling or average pooling. We observe that max-pooling is better than avg-pooling, which is consistent with QA-LSTMs. In comparison to Model (D), Model (N) shows over 2% improvement on both validation and Test1 sets. And (N) gets improvements over the best baseline in Table 3 by 3.5%, 3.7% and 3.8% on the validation, Test1 and Test2 sets, respectively. Compared to Architecture II in (Feng et al., 2015), which involved a large number of CNN filters, (N) model also has fewer parameters.

We also test the proposed attention mechanism on convolutional networks. (J) replaces the LSTM in QA-LSTM with a convolutional layer. We set the filter size $c = 400$ and window size $k = 3$ according to the validation accuracy. (K) performs the similar attention on the convolutional output of the answers. Similar to biLSTM, the attention on the convolutional layer gives over 2% accuracy improvement on both test sets, which proves the attention's efficiency on both CNN and RNN structures.

Finally, we investigate the proposed models on how they perform with respect to long answers. To better illustrate the performance difference, we

Models	MAP	MRR
(Yao et al., 2013)	0.631	0.748
(Severyn and Moschitti, 2013)	0.678	0.736

B. QA-LSTM (max-pooling)	0.733	0.819
C. Conv-pooling LSTM	0.742	0.819
D. Conv-based LSTM	0.737	0.827
E. Attentive LSTM	**0.753**	**0.830**

Table 4: The test set results on TREC-QA

compare the models with $K = 1$ (i.e. the models C, E, L). We divide the questions of Test1 and Test2 sets into eleven buckets, according to the average length of their ground truth answers. As shown in Figure 5, QA-LSTM gets better or similar performance compared to the proposed models on buckets with shorter answers ($L \leq 50$, $50 < L \leq 55$, $55 < L \leq 60$). As the answer lengths increase, the gap between QA-LSTM and other models becomes more obvious. It suggests the effectiveness of Convolutional-pooling LSTM and Attentive LSTM for long-answer questions.

In (Feng et al., 2015), GESD outperforms cosine similarity in their models. However, the proposed models with GESD as similarity scores do not provide any improvement on the accuracy.

5 TREC-QA Experiments

In this section we detail our experimental setup and results using the TREC-QA dataset.

5.1 Data, metrics and baselines

We test the models on TREC-QA dataset, created based on Text REtrieval Conference (TREC) QA track (8-13) data. More detail of the generation steps for this data can be found in (Wang et al., 2007). We follow the exact approach of train/dev/test questions selection in (Wang and Nyberg, 2015), in which all questions with only positive or negative answers are removed. Finally, we have 1162 training, 65 development and 68 test questions. Similar to previous work, we use Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR) as evaluation metrics, which are evaluated using the official scripts.

In the top part of Table 4, we list the performance of recent prior work on this dataset. We implemented the Architecture II in (Feng et al., 2015) from scratch. The CNN structure in (Severyn and Moschitti, 2015) combined with additional human-designed features achieved the best MAP and MRR.

5.2 Setup

We keep the configurations same as those in InsuranceQA in section 4.1, except the following differences: 1) Following Wang and Nyberg (2015), we use 300-dimensional vectors that were trained and provided by word2vec (Mikolov et al., 2013) using a part of the Google News dataset [4]. 2) Since the word vectors of TREC-QA have a greater dimension than InsuranceQA, we accordingly have larger biLSTM hidden vectors and CNN filters, in order not to lose information from word vectors. Here we set both of them as 600. 3) We use the models from the epoch with the best MAP on the validation set. 4) We also observe that because of the smaller data size, we need a decayed learning rate λ in order to stablize the models' training. Specifically, we set the initial $\lambda_0 = 1.1$, and decrease it for each epoch $T > 1$ as $\lambda_T = \lambda_0/T$. 5) We fix the negative answer size $K = 50$ during training.

5.3 Results

The bottom part of Table 4 shows the performance of the proposed models. For the comparison purpose, we replace biLSTM with a convolution in Model (A), and also use max-pooling to get question and answer embeddings, and call this model QA-CNN. QA-LSTM (B) improves MAP and MRR in more than 1% when compared to QA-CNN (A). Compared to (B), convolutional-pooling (C) performs better on MAP by 0.9%, and convolution-based models on MAP by 0.4% and MRR by 0.8%. Attentive LSTM is the best proposed model, and outperforms the best baseline (Severyn and Moschitti, 2015) by 0.7% on MAP and 2.2% on MRR. Note that the best result in (Severyn and Moschitti, 2015) was obtained by combining CNN-based features with additional human-defined features. In contrast, our attentive LSTM model achieves higher performance without using any human-defined features.

6 Conclusion

In this paper, we address the following problem for the answer passage selection: how can we construct the embeddings for questions and candidate

[4] https://code.google.com/archive/p/word2vec/

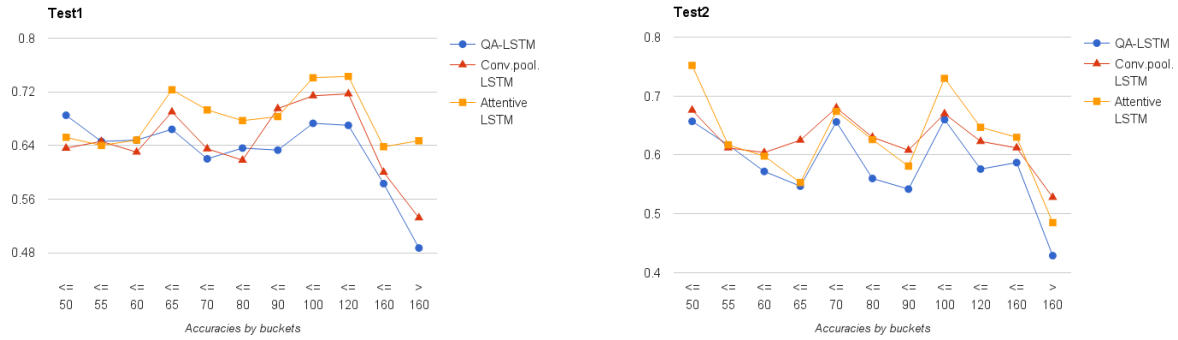

Figure 5: The accuracy of Test1 and Test2 of InsuranceQA sets for three models, i.e. maxpooling QA-LSTM (C), Convolutional-pooling LSTM (E) and Attentive LSTM (L) in Table 3, on different levels of ground truth answer lengths on each test set. The figures show the accuracy of each bucket.

answers, in order to better distinguish the correct answers from other candidates? We propose three independent models in two directions. First, we develop two hybrid models which combine the strength of both recurrent and convolutional neural networks. Second, we introduce a simple one-way attention mechanism, in order to generate answer embeddings influenced by the question context. Such attention fixes the issue of independent generation of the question and answer embeddings in previous work. All proposed models are departed from a basic architecture, built on bidirectional LSTMs. We conduct experiments on InsuranceQA and TREC-QA datasets, and the experimental results demonstrate that the proposed models outperform a variety of strong baselines. Potential future work include: 1) Evaluating the proposed approaches for different tasks, such as community QA and textual entailment; 2) Including the sentential attention mechanism; 3) Integrating the hybrid and the attentive mechanisms into a single framework.

Abstract

Question answering requires access to a knowledge base to check facts and reason about information. Knowledge in the form of natural language text is easy to acquire, but difficult for automated reasoning. Highly-structured knowledge bases can facilitate reasoning, but are difficult to acquire. In this paper we explore tables as a semi-structured formalism that provides a balanced compromise to this trade-off. We first use the structure of tables to guide the construction of a dataset of over 9000 multiple-choice questions with rich alignment annotations, easily and efficiently via crowd-sourcing. We then use this annotated data to train a semi-structured feature-driven model for question answering that uses tables as a knowledge base. In benchmark evaluations, we significantly outperform both a strong unstructured retrieval baseline and a highly-structured Markov Logic Network model.

1 Introduction

Question answering (QA) has emerged as a practical research problem for pushing the boundaries of artificial intelligence (AI). Dedicated projects and open challenges to the research community include examples such as Facebook AI Research's challenge problems for AI-complete QA (Weston et al., 2015) and the Allen Institute for AI's (AI2) Aristo project (Clark, 2015) along with its recently completed Kaggle competition[1]. The reason for this emergence is the diversity of core language and reasoning problems that a complex, integrated task like QA exposes: information extraction (Srihari and Li, 1999), semantic modelling (Shen and Lapata, 2007; Narayanan and Harabagiu, 2004), logic and reasoning (Moldovan et al., 2003), and inference (Lin and Pantel, 2001).

Complex tasks such as QA require some form of knowledge base to store facts about the world and reason over them. By knowledge base, we mean any form of knowledge: structured (e.g., tables, ontologies, rules) or unstructured (e.g., natural language text). For QA, knowledge has been harvested and used in a number of different modes and formalisms: large-scale extracted and curated knowledge bases (Fader et al., 2014), structured models such as Markov Logic Networks (Khot et al., 2015), and simple text corpora in information retrieval approaches (Tellex et al., 2003).

There is, however, a fundamental trade-off in the structure and regularity of a formalism and its ability to be curated, modelled or reasoned with easily. For example, simple text corpora contain no structure, and are therefore hard to reason with in a principled manner. Nevertheless, they are easily and abundantly available. In contrast, Markov Logic Networks come with a wealth of theoretical knowledge connected with their usage in principled inference. However, they are difficult to induce automatically from text or to build manually.

In this paper we explore tables as semi-structured knowledge for multiple-choice question (MCQ) answering. Specifically, we focus on tables that represent general knowledge facts, with cells that contain free-form text (Secton 3 details the nature and semantics of these tables). The structural properties of tables, along with their free-form text content represents a semi-structured balanced compromise in the trade-off between degree of structure and ubiquity. We present two main contributions, with tables and their structural properties playing a crucial role in both. First,

[1] https://www.kaggle.com/c/the-allen-ai-science-challenge

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 474–483,
Berlin, Germany, August 7-12, 2016.

we crowd-source a collection of over 9000 MCQs with alignment annotations to table elements, using tables as guidelines in efficient data harvesting. Second, we develop a feature-driven model that uses these MCQs to perform QA, while fact-checking and reasoning over tables.

Others have used tables in the context of QA. Question bank creation for tables has been investigated (Pasupat and Liang, 2015), but without structural guidelines or the alignment information that we propose. Similarly, tables have been used in QA reasoning (Yin et al., 2015b; Neelakantan et al., 2015; Sun et al., 2016) but have not explicitly attempted to encode all the semantics of table structure (see Section 3.1). To the best of our knowledge, no previous work uses tables for both creation and reasoning in a connected framework.

We evaluate our model on MCQ answering for three benchmark datasets. Our results consistently and significantly outperform a strong retrieval baseline as well as a Markov Logic network model (Khot et al., 2015). We thus show the benefits of semi-structured data and models over unstructured or highly-structured counterparts. We also validate our curated MCQ dataset and its annotations as an effective tool for training QA models. Finally, we find that our model learns generalizations that permit inference when exact answers may not even be contained in the knowledge base.

2 Related Work

Our work with tables, semi-structured knowledge bases and QA relates to several parallel lines of research. In terms of dataset creation via crowdsourcing, Aydin et al. (2014) harvest MCQs via a gamified app, although their work does not involve tables. Pasupat and Liang (2015) use tables from Wikipedia to construct a set of QA pairs. However their annotation setup does not impose structural constraints from tables, and does not collect fine-grained alignment to table elements.

On the inference side Pasupat and Liang (2015) also reason over tables to answer questions. Unlike our approach, they do not require alignments to table cells. However, they assume knowledge of the table that contains the answer, a priori – which we do not. Yin et al. (2015b) and Neelakantan et al. (2015) also use tables in the context of QA, but deal with synthetically generated query data. Sun et al. (2016) perform cell search over web tables via relational chains, but are more generally interested in web queries. Clark et al. (2016) combine different levels of knowledge for QA, including an integer-linear program for searching over table cells. None of these other efforts leverage tables for generation of data.

Our research more generally pertains to natural language interfaces for databases. Answering questions in this context refers to executing queries over relational databases (Cafarella et al., 2008; Pimplikar and Sarawagi, 2012). Yin et al. (2015a) consider databases where information is stored in n-tuples, which are essentially tables. Also, investigation of the relational structure of tables is connected with research on database schema analysis and induction (Venetis et al., 2011; Syed et al., 2010). Finally, unstructured text and structured formats links to work on open information extraction (Etzioni et al., 2008) and knowledge base population (Ji and Grishman, 2011).

3 Tables as Semi-structured Knowledge Representation

Tables can be found on the web containing a wide range of heterogenous data. To focus and facilitate our work on QA we select a collection of tables that were specifically designed for the task. Specifically we use AI2's Aristo Tablestore[2]. However, it should be noted that the contributions of this paper are not tied to specific tables, as we provide a general methodology that could equally be applied to a different set of tables. The structural properties of this class of tables is further described in Section 3.1.

The Aristo Tablestore consists of 65 hand-crafted tables organized by topic. Some of the topics are bounded, containing only a fixed number of facts, such as the possible phase changes of matter (see Table 1). Other topics are unbounded, containing a very large or even infinite number of facts, such as the kind of energy used in performing an action (the corresponding tables can only contain a sample subset of these facts). A total of 3851 facts (one fact per row) are present in the manually constructed tables. An individual table has between 2 and 5 content columns.

The target domain for these tables is two 4th grade science exam datasets. The majority of the tables were constructed to contain topics and facts

[2] http://allenai.org/content/data/AristoTablestore-Nov2015Snapshot.zip

Phase Change		Initial State		Final State		Form of Energy Transfer
Melting	causes a	solid	to change into a	liquid	by	adding heat
Vaporization	causes a	liquid	to change into a	gas	by	adding heat
Condensation	causes a	gas	to change into a	liquid	by	removing heat
Sublimation	causes a	solid	to change into a	gas	by	adding heat

Table 1: Part of a table concerning phase changes in matter. Rows are facts. Columns without header text provide filler text, so that each row forms a sentence. In columns with header text, the header describes the type of entry in the column; the header is a hypernym of the text in the body below.

from the publicly available Regents dataset[3]. The rest were targeted at an unreleased dataset called Monarch. In both cases only the training partition of each dataset was used to formulate and handcraft tables. However, for unbounded topics, additional facts were added to each table, using science education text books and websites.

3.1 Table Semantics and Relations

Part of a table from the Aristo Tablestore is given as an example in Table 1. The format is semi-structured: the rows of the table (with the exception of the header) are a list of sentences, but with well-defined recurring filler patterns. Together with the header, these patterns divide the rows into meaningful columns. This semi-structured data format is flexible. Since facts are presented as sentences, the tables can act as a text corpus for information retrieval. At the same time the structure can be used – as we do – to focus on specific nuggets of information. The flexibility of these tables allows us to compare our table-based system to an information retrieval baseline.

Such tables have some interesting structural semantics, which we will leverage throughout the paper. A row in a table corresponds to a *fact*[4]. The cells in a row correspond to concepts, entities, or processes that participate in this fact. A content column[5] corresponds to a group of concepts, entities, or processes that are the same *type*. The header cell of the column is an abstract description of the *type*. We may view the head as a hypernym and the cells in the column below as co-hyponyms of the head. The header row defines a generalization of which the rows in the table are specific instances.

This structure is directly relevant to multiple-choice QA. Facts (rows) form the basis for creating or answering questions, while instances of a type (columns) act as the choices of an MCQ. We use these observations both for crowd-sourcing MCQ creation as well as for designing features to answer MCQs with tables.

4 Crowd-sourcing Multiple-choice Questions from Tables

We use Amazon's Mechanical Turk (MTurk) service to generate MCQs by imposing constraints derived from the structure of the tables. These constraints help annotators create questions with scaffolding information, and lead to consistent quality in the generated output. An additional benefit of this format is the alignment information, linking cells in the tables to the MCQs generated by the Turkers. The alignment information is generated as a by-product of making the MCQs.

We present Turkers with a table such as the one in Figure 1. Given this table, we choose a target cell to be the correct answer for a new MCQ; for example, the red cell in Figure 1. First, Turkers create a question by using information from the rest of the row containing the target (i.e., the blue cells in Figure 1), such that the target is its correct answer. Then they select the cells in the row that they used to construct the question. Following this, they construct four succinct choices for the question, one of which is the correct answer and the other three are distractors. Distractors are formed from other cells in the column containing the target (i.e. yellow cells in Figure 1). If there are insufficient unique cells in the column Turkers create their own. Annotators can rephrase and shuffle the contents of cells as required.

In addition to an MCQ, we obtain alignment information with no extra effort from annotators. We know which table, row, and column contains the answer, and thus we know which header cells might be relevant to the question. We also know the cells of a row that were used to construct a question.

[3] `http://allenai.org/content/data/Regents.zip`

[4] Also predicates, or more generally frames with typed arguments.

[5] Different from filler columns, which only contain a recurring pattern, and no information in their header cells.

PHASE CHANGE		INITIAL PHASE		FINAL PHASE		HEAT TRANSFER
Melting	causes a	solid	to change into a	liquid	by	adding heat
Vaporization	causes a	liquid	to change into a	gas	by	adding heat
Sublimation	causes a	solid	to change into a	gas	by	adding heat
Freezing	causes a	liquid	to change into a	solid	by	removing heat
Deposition	causes a	gas	to change into a	solid	by	removing heat
Condensation	causes a	gas	to change into a	liquid	by	removing heat

Figure 1: Example table from MTurk annotation task illustrating constraints. We ask Turkers to construct questions from blue cells, such that the red cell is the correct answer, and yellow cells form distractors.

Task	Avg. Time (s)	$/hour	% Reject
Rewrite	345	2.61	48
Paraphrase	662	1.36	49
Add choice	291	2.47	24
Write new	187	**5.78**	38
TabMCQ	**72**	5.00	**2**

Table 2: Comparison of different ways of generating MCQs with MTurk.

What is the orbital event with the longest day and the shortest night?
A) **Summer solstice**
B) Winter solstice
C) Spring equinox
D) Fall equinox
Steel is a/an _____ of electricity
A) Separator
B) Isolator
C) Insulator
D) Conductor

Table 3: Examples of MCQs generated by MTurk. Correct answer choices are in bold.

4.1 The TabMCQ Dataset

We created a HIT (the MTurk acronym for Human Intelligence Task) for every non-filler cell (see Section 3) from each one of the 65 manually constructed tables of the Aristo Tablestore. We paid annotators 10 cents per MCQ, and asked for 1 annotation per HIT for most tables. For an initial set of four tables which we used in a pilot study, we asked for three annotations per HIT[6]. We required Turkers to have a HIT approval rating of 95% or higher, with a minimum of at least 500 HITs approved. We restricted the demographics of our workers to the US.

Table 2 compares our method with other studies conducted at AI2 to generate MCQs. These methods attempt to generate new MCQs from existing ones, or write them from scratch, but do not involve tables in any way. Our annotation procedure leads to faster data creation, with consistent output quality that resulted in the lowest percentage of rejected HITs. Manual inspection of the generated output also revealed that questions are of consistently good quality. They are good enough for training machine learning models and many are good enough as evaluation data for QA. A sample of generated MCQs is presented in Table 3.

We implemented some simple checks to evaluate the data before approving HITs. These included things like checking whether an MCQ has at least three choices and whether choices are repeated. We had to further prune our data to discard some MCQs due to corrupted data or badly constructed MCQs. A total of 159 MCQs were lost through the cleanup. In the end our complete data consists of 9092 MCQs, which is – to the best of our knowledge – orders of magnitude larger than any existing collection of science exam style MCQs available for research. These MCQs also come with alignment information to tables, rows, columns and cells. The dataset, bundled together with the Aristo Tablestore, can be freely downloaded[7].

5 Solving MCQs with Table Cell Search

Consider the MCQ "What is the process by which water is changed from a liquid to a gas?" with choices "melting, sublimation, vaporization, condensation", and the table given in Figure 1. Finding the correct answer amounts to finding a cell in the table that is most relevant to a candidate QA pair. In other words, a relevant cell should confirm the assertion made by a particular QA pair.

By applying the reasoning used to create MCQs

[6]The goal was to obtain diversity in the MCQs created for a target cell. The results were not sufficiently conclusive to warrant a threefold increase in the cost of creation.

[7]http://ai2-website.s3.amazonaws.com/data/TabMCQ_v_1.0.zip

(see Section 4) in the inverse direction, finding these relevant cells becomes the task of finding an intersection between rows and columns of interest. Consider the table in Figure 1: assuming we have some way of aligning a question to a row (blue cells) and choices to a column (yellow cells), then the relevant cell is at the intersection of the two (the red cell). This alignment is precisely what we get as a by-product of the annotation task we setup in Section 4 to harvest MCQs.

We can thus featurize connections between MCQs and elements of tables and use the alignment data to train a model over the features. This is outlined in the next section, describing our Feature Rich Table Embedding Solver (FRETS).

5.1 Model and Training Objective

Let $\mathcal{Q} = \{q_1, ..., q_N\}$ denote a set of MCQs, and $\mathcal{A}_n = \{a_n^1, ..., a_n^k\}$ be the set of candidate answer choices for a given question q_n. Let the set of tables be defined as $\mathcal{T} = \{T_1, ..., T_M\}$. Given a table T_m, let t_m^{ij} be the cell in that table corresponding to the ith row and jth column.

We define a log-linear model that scores every cell t_m^{ij} of every table in our collection according to a set of discrete weighted features, for a given QA pair. We have the following:

$$\log p(t_m^{ij} | q_n, a_n^k; \mathcal{A}_n, \mathcal{T}) = \sum_d \lambda_d f_d(q_n, a_n^k, t_m^{ij}; \mathcal{A}_n, \mathcal{T}) - \log Z \quad (1)$$

Here λ_d are weights and $f_d(q_n, a_n^k, t_m^{ij}; \mathcal{A}_n, \mathcal{T})$ are features. These features should ideally leverage both structure and content of tables to assign high scores to relevant cells, while assigning low scores to irrelevant cells. Z is the partition function, defined as follows:

$$Z = \sum_{m,i,j} \exp\left(\sum_d \lambda_d f_d(q_n, a_n^k, t_m^{ij}; \mathcal{A}_n, \mathcal{T})\right) \quad (2)$$

Z normalizes the scores associated with every cell over all the cells in all the tables to yield a probability distribution. During inference the partition term $\log Z$ can be ignored, making scoring cells of every table for a given QA pair efficient.

These scores translate to a solution for an MCQ. Every QA pair produces a hypothetical fact, and as noted in Section 3.1, the row of a table is in essence a fact. Relevant cells (if they exist) should confirm the hypothetical fact asserted by a given QA pair. During inference, we assign the score of the highest scoring row (or the most likely fact) to a hypothetical QA pair. Then the correct solution to the MCQ is simply the answer choice associated with the QA pair that was assigned the highest score. Mathematically, this is expressed as follows:

$$a_n^* = \arg\max_{a_n^k} \max_{m,i} \sum_j \sum_d \lambda_d f_d(q_n, a_n^k, t_m^{ij}; \mathcal{A}_n, \mathcal{T}) \quad (3)$$

5.1.1 Training

Since FRETS is a log-linear model, training involves optimizing a set of weights λ_d. As training data, we use alignment information between MCQs and table elements (see Section 4.1). The predictor value that we try to maximize with our model is an alignment score that is closest to the true alignments in the training data. True alignments to table cells for a given QA pair are essentially indicator values but we convert them to numerical scores as follows[8]. For a correct QA hypothesis we assign a score of 1.0 to cells whose row and column and both aligned to the MCQ (i.e. cells that exactly answer the question), 0.5 to cells whose row but not column is aligned in some way to the question (i.e. cells that were used to construct the question), and 0.0 otherwise. For an incorrect QA hypothesis we assign a score of 0.1 to random cells from tables that contain no alignments to the QA (so all except one), with a probability of 1%, while all other cells are scored 0.0. The intuition behind this scoring scheme is to guide the model to pick relevant cells for correct answers, while encouraging it to pick faulty evidence with low scores for incorrect answers.

Given these scores assigned to all cells of all tables for all QA pairs in the training set, suitably normalized to a probability distribution over tables for a given QA pair, we can then proceed to train our model. We use cross-entropy, which minimizes the following loss:

[8] On training data, we experimented with a few different scoring heuristics and found that these ones worked well.

Level	Feature	Description	Intuition	S-Var	Cmpct
Table	Table score	Ratio of words in **t** to **q+a**	Topical consistency	◊	
	†TF-IDF table score	Same but TF-IDF weights	Topical consistency	◊	●
Row	Row-question score	Ratio of words in **r** to **q**	Question align	◊	●
	Row-question w/o focus score	Ratio of words in **r** to **q-($\mathbf{a_f}$+$\mathbf{q_f}$)**	Question align	◊	
	Header-question score	Ratio of words in **h** to **q**	Prototype align	◊	
Column	Column overlap	Ratio of elements in **c** and **A**	Choices align	◊	●
	Header answer-type match	Ratio of words in $\mathbf{c_h}$ to $\mathbf{a_f}$	Choices hypernym align	◊	●
	Header question-type match	Ratio of words in $\mathbf{c_h}$ to $\mathbf{q_f}$	Question hypernym align	◊	
Cell	†Cell salience	Salience of **s** to **q+a**	QA hypothesis assert	◊	●
	†Cell answer-type entailment	Entailment score between **s** and $\mathbf{a_f}$	Hypernym-hyponym align		●
	Cell answer-type similarity	Avg. vector sim between **s** and $\mathbf{a_f}$	Hypernym-hyponym sim.		

Table 4: Summary of features. For a question (**q**) and answer (**a**) we compute scores for elements of tables: whole tables (**t**), rows (**r**), header rows (**h**), columns (**c**), column headers ($\mathbf{c_h}$) and cells (**s**). Answer-focus ($\mathbf{a_f}$) and question-focus ($\mathbf{q_f}$) terms added where appropriate. Features marked ◊ denote soft-matching variants, marked with while those marked with a † are described in further detail in Section 5.2. Finally, ● features denote those that received high weights during training with all features, and were subsequently selected to form a compact FRETS model.

$$L(\vec{\lambda}) = \sum_{\substack{q_n \\ a_n^k \in \mathcal{A}_n}} \sum_{m,i,j} p(t_m^{*ij} | q_n, a_n^k; \mathcal{T}) \cdot \log p(t_m^{ij} | q_n, a_n^k; \mathcal{A}_n, \mathcal{T}) \quad (4)$$

Here $p(t_m^{*ij} | q_n, a_n^k; \mathcal{T})$ is the normalized probability of the true alignment scores.

While this is an indirect way to train our model to pick the best answer, in our pilot experiments it worked better than direct maximum likelihood or ranking with hinge loss, achieving a training accuracy of almost 85%. Our experimental results on the test suite, presented in the next section, also support the empirical effectiveness of this approach.

5.2 Features

The features we use are summarized in Table 4. These features compute statistics between question-answer pairs and different structural components of tables. While the features are weighted and summed for each cell individually, they can capture more global properties such as scores associated with tables, rows or columns in which the specific cell is contained. Features are divided into four broad categories based on the level of granularity at which they operate. In what follows we give some details of Table 4 that require further elaboration.

5.2.1 Soft matching

Many of the features that we implement are based on string overlap between bags of words. However, since the tables are defined statically in terms of a fixed vocabulary (which may not necessarily match words contained in an MCQ), these overlap features will often fail. We therefore soften the constraint imposed by hard word overlap by a more forgiving soft variant. More specifically we introduce a word-embedding based soft matching overlap variant for every feature in the table marked with ◊. The soft variant targets high recall while the hard variant aims at providing high precision. We thus effectively have almost twice the number of features listed.

Mathematically, let a hard overlap feature define a score $|S_1 \cap S_2| \ / \ |S_1|$ between two bags of words S_1 and S_2. We can define the denominator S_1 here, without loss of generality. Then, a corresponding word-embedding soft overlap feature is given by this formula:

$$\frac{1}{|S_1|} \sum_{w_i \in S_1} \max_{w_j \in S_2} sim(\vec{w_i}, \vec{w_j}) \quad (5)$$

Intuitively, rather than matching a word to its exact string match in another set, we instead match it to its most similar word, discounted by the score of that similarity.

5.2.2 Question parsing

We parse questions to find the desired answer-type and, in rarer cases, question-type words. For example, in the question "What form of energy is required to convert water from a liquid to a gas?", the type of the answer we are expecting is a "form of energy". Generally, this answer-type corresponds to a hypernym of the answer choices, and can help find relevant information in the table, specifically related to columns.

By carefully studying the kinds of question patterns in our data, we implemented a rule-based parser that finds answer-types from queries. This parser uses a set of hand-coded regular expressions over phrasal chunks. The parser is designed to have high accuracy, so that we only produce an output for answer-types in high confidence situations. In addition to producing answer-types, in some rarer cases we also detect hypernyms for parts of the questions. We call this set of words question-type words. Together, the question-type and answer-type words are denoted as focus words in the question.

5.2.3 TF-IDF weighting

TF-IDF scores for weighting terms are precomputed for all words in all the tables. We do this by treating every table as a unique document. At run-time we discount scores by table length as well as length of the QA pair under consideration to avoid disproportionately assigning high scores to large tables or long MCQs.

5.2.4 Salience

The salience of a string for a particular QA pair is an estimate of how relevant it is to the hypothesis formed from that QA pair. It is computed by taking words in the question, pairing them with words in an answer choice and then computing PMI statistics between these pairs from a large corpus. A high salience score indicates words that are particularly relevant for a given QA pair hypothesis.

5.2.5 Entailment

To calculate the entailment score between two strings, we use several features, such as overlap, paraphrase probability, lexical entailment likelihood, and ontological relatedness, computed with n-grams of varying lengths.

5.2.6 Normalization

All the features in Table 4 produce numerical scores, but the range of these scores vary to some extent. To make our final model more robust, we normalize all feature scores to have a range between 0.0 and 1.0. We do this by finding the maximum and minimum values for any given feature on a training set. Subsequently, instead of using the raw feature value of a feature f_d, we instead replace it with $(f_d - \min f_d) \,/\, (\max f_d - \min f_d)$.

6 Experimental Results

We train FRETS (Section 5) on the TabMCQ dataset (Section 4) using adaptive gradient descent with an L2 penalty of 1.0 and a mini-batch size of 500 training instances. We train two variants: one consisting of all the features from Table 4, the other – a compact model – consisting of the most important features (above a threshold) from the first model by feature-weight. These features are noted by ● in the final column of Table 4.

We run experiments on three 4th grade science exam MCQ datasets: the publicly available Regents dataset, the larger but unreleased dataset called Monarch, and a third even larger public dataset of Elementary School Science Questions (ESSQ)[9]. For the first two datasets we use the test splits only, since the training sets were directly studied to construct the Aristo Tablestore, which was in turn used to generate our TabMCQ training data. On ESSQ we use all the questions since they are independent of the tables. The Regents test set consists of 129 MCQs, the Monarch test set of 250 MCQs, and ESSQ of 855 MCQs.

Since we are investigating semi-structured models, we compare against two baselines. The first is an unstructured information retrieval method, which uses the Lucene search engine. To apply Lucene to the tables, we ignore their structure and simply use rows as plain-text sentences. The score for top retrieved hits are used to rank the different choices of MCQs. The second baseline is the highly-structured Markov-logic Network (MLN) model from Khot et al. (2015) as reported in Clark et al. (2016), who use the model as a baseline[10]. Note that Clark et al. (2016) achieve a score of 71.3 on Regents Test, which is higher than FRETS' scores (see Table 5), but their results are not comparable to ours because they use an ensemble of algorithms. In contrast, we use a single algorithm with a much smaller collection of knowledge. FRETS rivals the best individual algorithm from their work.

We primarily use the tables from the Aristo Tablestore as knowledge base data in three different settings: with only tables constructed for Regents (40 tables), with only supplementary tables constructed for Monarch (25 tables), and with all ta-

[9] http://aristo-public-data.s3.amazonaws.com/AI2-Elementary-NDMC-Feb2016.zip

[10] We do not re-implement the MLN, and therefore only cite results from previous work on part of our test suite.

Model	Data	Regents Test	Monarch Test	ESSQ
Lucene	Regents Tables	37.5	32.6	36.9
	Monarch Tables	28.4	27.3	27.7
	Regents+Monarch Tables	34.8	35.3	37.3
	Waterloo Corpus	55.4	51.8	54.4
MLN (Khot et al., 2015)	-	47.5	-	-
FRETS (Compact)	Regents Tables	**60.7**	47.2	51.0
	Monarch Tables	56.0	45.6	48.4
	Regents+Monarch Tables	59.9	47.6	50.7
FRETS	Regents Tables	59.1	**52.8**	54.4
	Monarch Tables	52.9	49.8	49.5
	Regents+Monarch Tables	59.1	52.4	**54.9**

Table 5: Evaluation results on three benchmark datasets using different sets of tables as knowledge bases. Best results on a dataset are highlighted in bold.

bles together (all 65 tables; see Section 3). For the Lucene baseline we also experiment with several orders of magnitude more data by indexing over the 5×10^{10} words Waterloo corpus compiled by Charles Clarke at the University of Waterloo. Data is not a variable for MLN, since we directly cite results from Clark et al. (2016).

The word vectors we used in soft matching feature variants (i.e., $\Diamond$ features from Table 4) for all our experiments were trained on 300 million words of Newswire English from the monolingual section of the WMT-2011 shared task data. These vectors were improved post-training by retrofitting (Faruqui et al., 2014) them to PPDB (Ganitkevitch et al., 2013).

The results of these experiments is presented in Table 5. All numbers are reported in percentage accuracy. We perform statistical significance testing on these results using Fisher's exact test with a p-value of 0.05 and report them in our discussions.

First, FRETS – in both full and compact form – consistently outperforms the baselines, often by large margins. For Lucene, the improvements over all but the Waterloo corpus baseline are statistically significant. Thus FRETS is able to capitalize on data more effectively and rival an unstructured model with access to orders of magnitude more data. For MLN, the improvements are statistically significant in the case of *Regents* and *Regents+Monarch* tables. FRETS is thus performing better than a highly structured model while making use of a much simpler data formalism.

Our models are able to effectively generalize. With Monarch tables, the Lucene baseline is little better than random (25%). But with the same knowledge base data, FRETS is competitive and sometimes scores higher than the best Lucene or MLN models (although this difference is statistically insignificant). These results indicate that our models are able to effectively capture both content and structure, reasoning approximately (and effectively) when the knowledge base may not even contain the relevant information to answer a question. The Monarch tables themselves seem to add little value, since results for Regents tables by themselves are just as good or better than Regents+Monarch tables. This is not a problem with FRETS, since the same phenomenon is witnessed with the Lucene baseline. It is noteworthy, however, that our models do not suffer from the addition of more tables, showing that our search procedure over table cells is robust.

Model	REG	MON	ESSQ
FRETS	59.1	**52.4**	**54.9**
w/o tab features	59.1	47.6	52.8
w/o row features	49.0	40.4	44.3
w/o col features	59.9	47.2	53.1
w/o cell features	25.7	25.0	24.9
w/o $\Diamond$ features	**62.2**	47.5	53.3

Table 6: Ablation study on FRETS, removing groups of features based on level of granularity. $\Diamond$ refers to the soft matching features from Table 4. Best results on a dataset are highlighted in bold.

Finally, dropping some features in the compact model doesn't always hurt performance, in comparison with the full model. This indicates that potentially higher scores are possible by a principled and detailed feature selection process. In these experiments the difference between the two FRETS models on equivalent data is statistically insignificant.

6.1 Ablation Study

To evaluate the contribution of different features we perform an ablation study, by individually removing groups of features from the full FRETS

model, and re-training. Evaluation of these partial models is given in Table 6. In this experiment we use all tables as knowledge base data.

Judging by relative score differential, cell features are by far the most important group, followed by row features. In both cases the drops in score are statistically significant. Intuitively, these results make sense, since row features are crucial in alignment to questions, while cell features capture the most fine-grained properties. It is less clear which among the other three feature groups is dominant, since the differences are not statistically significant. It is possible that cell features replicate information of other feature groups. For example, the cell answer-type entailment feature indirectly captures the same information as the header answer-type match feature (a column feature). Similarly, salience captures weighted statistics that are roughly equivalent to the coarse-grained table features. Interestingly, the success of these fine-grained features would explain our improvements over the Lucene baseline in Table 5, which is incapable of such fine-grained search.

7 Conclusions

We have presented tables as knowledge bases for question answering. We explored a connected framework in which tables are first used to guide the creation of MCQ data with alignment information to table elements, then jointly with this data are used in a feature-driven model to answer unseen MCQs. A central research question of this paper was the trade-off between the degree of structure in a knowledge base and its ability to be harvested or reasoned with. On three benchmark evaluation sets our consistently and significantly better scores over an unstructured and a highly-structured baseline strongly suggest that tables can be considered a balanced compromise in this trade-off. We also showed that our model is able to generalize from content to structure, thus reasoning about questions whose answer may not even be contained in the knowledge base.

We are releasing our dataset of more than 9000 MCQs and their alignment information, to the research community. We believe it offers interesting challenges that go beyond the scope of this paper – such as question parsing, or textual entailment – and are exciting avenues for future research.

Acknowledgement

We'd like to thank AI2 for funding this research and the creation of our MCQ dataset. The first and third authors of this paper were also supported in part by the following grants: NSF grant IIS-1143703, NSF award IIS-1147810, DARPA grant FA87501220342. Thanks also go to the anonymous reviewers, whose valuable comments helped to improve the quality of the paper.

Neural Summarization by Extracting Sentences and Words

Abstract

Traditional approaches to extractive summarization rely heavily on human-engineered features. In this work we propose a data-driven approach based on neural networks and continuous sentence features. We develop a general framework for single-document summarization composed of a hierarchical document encoder and an attention-based extractor. This architecture allows us to develop different classes of summarization models which can extract sentences or words. We train our models on large scale corpora containing hundreds of thousands of document-summary pairs[1]. Experimental results on two summarization datasets demonstrate that our models obtain results comparable to the state of the art without any access to linguistic annotation.

1 Introduction

The need to access and digest large amounts of textual data has provided strong impetus to develop automatic summarization systems aiming to create shorter versions of one or more documents, whilst preserving their information content. Much effort in automatic summarization has been devoted to sentence extraction, where a summary is created by identifying and subsequently concatenating the most salient text units in a document.

Most extractive methods to date identify sentences based on human-engineered features. These include surface features such as sentence position and length (Radev et al., 2004), the words in the title, the presence of proper nouns, content features such as word frequency (Nenkova et al., 2006), and event features such as action nouns (Filatova and Hatzivassiloglou, 2004). Sentences are typically assigned a score indicating the strength of presence of these features. Several methods have been used in order to select the summary sentences ranging from binary classifiers (Kupiec et al., 1995), to hidden Markov models (Conroy and O'Leary, 2001), graph-based algorithms (Erkan and Radev, 2004; Mihalcea, 2005), and integer linear programming (Woodsend and Lapata, 2010).

In this work we propose a data-driven approach to summarization based on neural networks and continuous sentence features. There has been a surge of interest recently in repurposing sequence transduction neural network architectures for NLP tasks such as machine translation (Sutskever et al., 2014), question answering (Hermann et al., 2015), and sentence compression (Rush et al., 2015). Central to these approaches is an encoder-decoder architecture modeled by recurrent neural networks. The encoder reads the source sequence into a list of continuous-space representations from which the decoder generates the target sequence. An attention mechanism (Bahdanau et al., 2015) is often used to locate the region of focus during decoding.

We develop a general framework for single-document summarization which can be used to extract sentences or words. Our model includes a neural network-based hierarchical document reader or encoder and an attention-based content extractor. The role of the reader is to derive the meaning representation of a document based on its sentences and their constituent words. Our models adopt a variant of neural attention to extract sentences or words. Contrary to previous work where attention is an *intermediate* step used to blend hidden units of an encoder to a vector propagating additional information to the decoder, our model applies attention *directly* to select sentences or words of the input document as the output summary. Similar neural attention architectures have been previously used for geometry reasoning (Vinyals et al., 2015), under the name *Pointer Networks*.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 484–494,
Berlin, Germany, August 7-12, 2016.

One stumbling block to applying neural network models to extractive summarization is the lack of training data, i.e., documents with sentences (and words) labeled as summary-worthy. Inspired by previous work on summarization (Woodsend and Lapata, 2010; Svore et al., 2007) and reading comprehension (Hermann et al., 2015) we retrieve hundreds of thousands of news articles and corresponding highlights from the DailyMail website. Highlights usually appear as bullet points giving a brief overview of the information contained in the article (see Figure 1 for an example). Using a number of transformation and scoring algorithms, we are able to match highlights to document content and construct two large scale training datasets, one for sentence extraction and the other for word extraction. Previous approaches have used small scale training data in the range of a few hundred examples.

Our work touches on several strands of research within summarization and neural sequence modeling. The idea of creating a summary by extracting words from the source document was pioneered in Banko et al. (2000) who view summarization as a problem analogous to statistical machine translation and generate headlines using statistical models for selecting and ordering the summary words. Our word-based model is similar in spirit, however, it operates over continuous representations, produces multi-sentence output, and jointly selects summary words and organizes them into sentences. A few recent studies (Kobayashi et al., 2015; Yogatama et al., 2015) perform sentence extraction based on pre-trained sentence embeddings following an unsupervised optimization paradigm. Our work also uses continuous representations to express the meaning of sentences and documents, but importantly employs neural networks more directly to perform the actual summarization task.

Rush et al. (2015) propose a neural attention model for abstractive sentence compression which is trained on pairs of headlines and first sentences in an article. In contrast, our model summarizes documents rather than individual sentences, producing multi-sentential discourse. A major architectural difference is that our decoder selects output symbols from the document of interest rather than the entire vocabulary. This effectively helps us sidestep the difficulty of searching for the next output symbol under *a large vocabulary*, with *low-frequency words* and *named entities* whose representations can be challenging to learn. Gu et al. (2016) and Gulcehre et al. (2016) propose a similar "copy" mechanism in sentence compression and other tasks; their model can accommodate both generation and extraction by selecting which sub-sequences in the input sequence to copy in the output.

We evaluate our models both automatically (in terms of ROUGE) and by humans on two datasets: the benchmark DUC 2002 document summarization corpus and our own DailyMail news highlights corpus. Experimental results show that our summarizers achieve performance comparable to state-of-the-art systems employing hand-engineered features and sophisticated linguistic constraints.

2 Problem Formulation

In this section we formally define the summarization tasks considered in this paper. Given a document D consisting of a sequence of sentences $\{s_1, \cdots, s_m\}$ and a word set $\{w_1, \cdots, w_n\}$, we are interested in obtaining summaries at two levels of granularity, namely sentences and words.

Sentence extraction aims to create a summary from D by selecting a subset of j sentences (where $j < m$). We do this by scoring each sentence within D and predicting a label $y_L \in \{0, 1\}$ indicating whether the sentence should be included in the summary. As we apply supervised training, the objective is to maximize the likelihood of all sentence labels $\mathbf{y}_L = (y_L^1, \cdots, y_L^m)$ given the input document D and model parameters θ:

$$\log p(\mathbf{y}_L|D;\theta) = \sum_{i=1}^{m} \log p(y_L^i|D;\theta) \qquad (1)$$

Although extractive methods yield naturally grammatical summaries and require relatively little linguistic analysis, the selected sentences make for long summaries containing much redundant information. For this reason, we also develop a model based on **word extraction** which seeks to find a subset of words[2] in D and their optimal ordering so as to form a summary $\mathbf{y}_s = (w'_1, \cdots, w'_k), w'_i \in D$. Compared to sentence extraction which is a sequence labeling problem, this task occupies the middle ground between full abstractive summarization which can exhibit a wide range of rewrite operations and extractive

[2]The vocabulary can also be extended to include a small set of commonly-used (high-frequency) words.

AFL star blames vomiting cat for speeding

Adelaide Crows defender Daniel Talia has kept his driving license, telling a court he was speeding 36km over the limit because he was distracted by his sick cat.

The 22-year-old AFL star, who drove 96km/h in a 60km/h road works zone on the South Eastern expressway in February, said he didn't see the reduced speed sign because he was so distracted by his cat vomiting violently in the back seat of his car.

In the Adelaide magistrates court on Wednesday, Magistrate Bob Harrap fined Talia $824 for exceeding the speed limit by more than 30km/h.

He lost four demerit points, instead of seven, because of his significant training commitments.

- *Adelaide Crows defender Daniel Talia admits to speeding but says he didn't see road signs because his cat was vomiting in his car.*
- *22-year-old Talia was fined $824 and four demerit points, instead of seven, because of his 'significant' training commitments.*

Figure 1: DailyMail news article with highlights. Underlined sentences bear label 1, and 0 otherwise.

summarization which exhibits none. We formulate word extraction as a language generation task with an output vocabulary restricted to the original document. In our supervised setting, the training goal is to maximize the likelihood of the generated sentences, which can be further decomposed by enforcing conditional dependencies among their constituent words:

$$\log p(\mathbf{y}_s|D;\theta)=\sum_{i=1}^{k}\log p(w'_i|D,w'_1,\cdots,w'_{i-1};\theta) \quad (2)$$

In the following section, we discuss the data elicitation methods which allow us to train neural networks based on the above defined objectives.

3 Training Data for Summarization

Data-driven neural summarization models require a large training corpus of documents with labels indicating which sentences (or words) should be in the summary. Until now such corpora have been limited to hundreds of examples (e.g., the DUC 2002 single document summarization corpus) and thus used mostly for testing (Woodsend and Lapata, 2010). To overcome the paucity of annotated data for training, we adopt a methodology similar to Hermann et al. (2015) and create two large-scale datasets, one for sentence extraction and another one for word extraction.

In a nutshell, we retrieved[3] hundreds of thousands of news articles and their corresponding highlights from DailyMail (see Figure 1 for an example). The highlights (created by news editors) are genuinely abstractive summaries and therefore not readily suited to supervised training. To create the training data for **sentence extraction**, we reverse approximated the gold standard label of each document sentence given the summary based on their semantic correspondence (Woodsend and Lapata, 2010). Specifically, we designed a rule-based system that determines whether a document sentence matches a highlight and should be labeled with 1 (must be in the summary), and 0 otherwise. The rules take into account the position of the sentence in the document, the unigram and bigram overlap between document sentences and highlights, the number of entities appearing in the highlight and in the document sentence. We adjusted the weights of the rules on 9,000 documents with manual sentence labels created by Woodsend and Lapata (2010). The method obtained an accuracy of 85% when evaluated on a held-out set of 216 documents coming from the same dataset and was subsequently used to label 200K documents. Approximately 30% of the sentences in each document were deemed summary-worthy.

For the creation of the **word extraction** dataset, we examine the lexical overlap between the highlights and the news article. In cases where all highlight words (after stemming) come from the original document, the document-highlight pair constitutes a valid training example and is added to the word extraction dataset. For out-of-vocabulary (OOV) words, we try to find a semantically equivalent replacement present in the news article. Specifically, we check if a neighbor, represented

[3]The script for constructing our datasets is modified from the one released in Hermann et al. (2015).

by pre-trained[4] embeddings, is in the original document and therefore constitutes a valid substitution. If we cannot find any substitutes, we discard the document-highlight pair. Following this procedure, we obtained a word extraction dataset containing 170K articles, again from the DailyMail.

4 Neural Summarization Model

The key components of our summarization model include a neural network-based hierarchical document reader and an attention-based hierarchical content extractor. The hierarchical nature of our model reflects the intuition that documents are generated compositionally from words, sentences, paragraphs, or even larger units. We therefore employ a representation framework which reflects the same architecture, with global information being discovered and local information being preserved. Such a representation yields minimum information loss and is flexible allowing us to apply neural attention for selecting salient sentences and words within a larger context. In the following, we first describe the document reader, and then present the details of our sentence and word extractors.

4.1 Document Reader

The role of the reader is to derive the meaning representation of the document from its constituent sentences, each of which is treated as a sequence of words. We first obtain representation vectors at the sentence level using a single-layer convolutional neural network (CNN) with a max-over-time pooling operation (Kalchbrenner and Blunsom, 2013; Zhang and Lapata, 2014; Kim et al., 2016). Next, we build representations for documents using a standard recurrent neural network (RNN) that recursively composes sentences. The CNN operates at the word level, leading to the acquisition of sentence-level representations that are then used as inputs to the RNN that acquires document-level representations, in a hierarchical fashion. We describe these two sub-components of the text reader below.

Convolutional Sentence Encoder We opted for a convolutional neural network model for representing sentences for two reasons. Firstly, single-layer CNNs can be trained effectively (without any long-term dependencies in the model) and secondly, they have been successfully used for sentence-level classification tasks such as sentiment analysis (Kim, 2014). Let d denote the dimension of word embeddings, and s a document sentence consisting of a sequence of n words $(w_1, \cdots, w_n)$ which can be represented by a dense column matrix $\mathbf{W} \in \mathbb{R}^{n \times d}$. We apply a temporal narrow convolution between $\mathbf{W}$ and a kernel $\mathbf{K} \in \mathbb{R}^{c \times d}$ of width c as follows:

$$\mathbf{f}^i_j = \tanh(\mathbf{W}_{j:j+c-1} \otimes \mathbf{K} + b) \tag{3}$$

where $\otimes$ equates to the Hadamard Product followed by a sum over all elements. $\mathbf{f}^i_j$ denotes the j-th element of the i-th feature map $\mathbf{f}^i$ and b is the bias. We perform max pooling over time to obtain a *single* feature (the ith feature) representing the sentence under the kernel $\mathbf{K}$ with width c:

$$\mathbf{s}_{i,\mathbf{K}} = \max_j \mathbf{f}^i_j \tag{4}$$

In practice, we use multiple feature maps to compute a list of features that match the dimensionality of a sentence under each kernel width. In addition, we apply multiple kernels with different widths to obtain a set of different sentence vectors. Finally, we sum these sentence vectors to obtain the final sentence representation. The CNN model is schematically illustrated in Figure 2 (bottom). In the example, the sentence embeddings have six dimensions, so six feature maps are used under each kernel width. The blue feature maps have width two and the red feature maps have width three. The sentence embeddings obtained under each kernel width are summed to get the final sentence representation (denoted by green).

Recurrent Document Encoder At the document level, a recurrent neural network composes a sequence of sentence vectors into a document vector. Note that this is a somewhat simplistic attempt at capturing document organization at the level of sentence to sentence transitions. One might view the hidden states of the recurrent neural network as a list of partial representations with each focusing mostly on the corresponding input sentence given the previous context. These representations altogether constitute the document representation, which captures local and global sentential information with minimum compression.

The RNN we used has a Long Short-Term Memory (LSTM) activation unit for ameliorating the vanishing gradient problem when training long sequences (Hochreiter and Schmidhuber,

[4]We used the Python Gensim library and the 300-dimensional *GoogleNews* vectors.

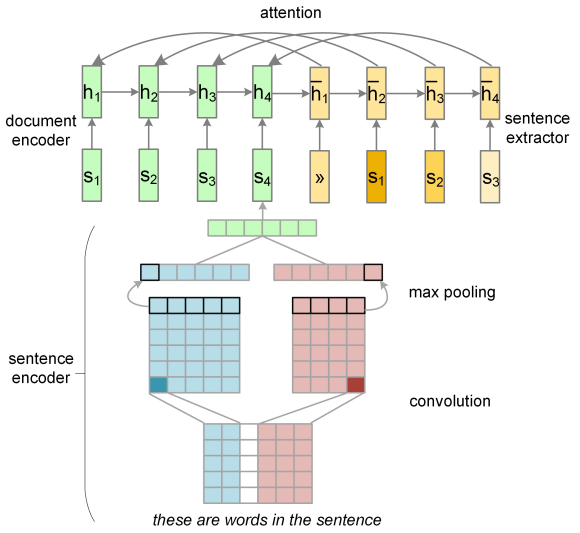

Figure 2: A recurrent convolutional document reader with a neural sentence extractor.

1997). Given a document $d = (s_1, \cdots, s_m)$, the hidden state at time step t, denoted by $\mathbf{h_t}$, is updated as:

$$\begin{bmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{o}_t \\ \hat{\mathbf{c}}_t \end{bmatrix} = \begin{bmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{bmatrix} \mathbf{W} \cdot \begin{bmatrix} \mathbf{h}_{t-1} \\ \mathbf{s}_t \end{bmatrix} \quad (5)$$

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \hat{\mathbf{c}}_t \quad (6)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t) \quad (7)$$

where $\mathbf{W}$ is a learnable weight matrix. Next, we discuss a special attention mechanism for extracting sentences and words given the recurrent document encoder just described, starting from the sentence extractor.

4.2 Sentence Extractor

In the standard neural sequence-to-sequence modeling paradigm (Bahdanau et al., 2015), an attention mechanism is used as an intermediate step to decide which input region to focus on in order to generate the next output. In contrast, our sentence extractor applies attention to directly extract salient sentences after reading them.

The extractor is another recurrent neural network that labels sentences sequentially, taking into account not only whether they are individually relevant but also mutually redundant. The complete architecture for the document encoder and the sentence extractor is shown in Figure 2. As can be seen, the next labeling decision is made

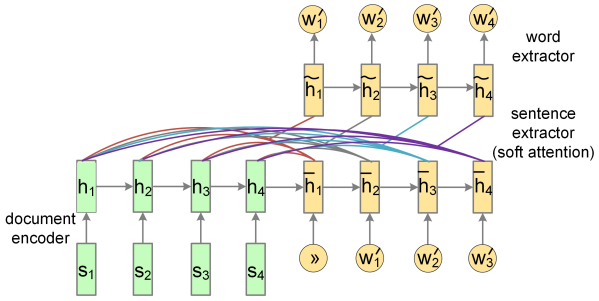

Figure 3: Neural attention mechanism for word extraction.

with both the encoded document and the previously labeled sentences in mind. Given encoder hidden states $(h_1, \cdots, h_m)$ and extractor hidden states $(\bar{h}_1, \cdots, \bar{h}_m)$ at time step t, the decoder attends the t-th sentence by relating its current decoding state to the corresponding encoding state:

$$\bar{\mathbf{h}}_t = \text{LSTM}(p_{t-1}\mathbf{s}_{t-1}, \bar{\mathbf{h}}_{t-1}) \quad (8)$$

$$p(y_L(t) = 1|D) = \sigma(\text{MLP}(\bar{\mathbf{h}}_t : \mathbf{h}_t)) \quad (9)$$

where MLP is a multi-layer neural network with as input the concatenation of $\bar{\mathbf{h}}_t$ and $\mathbf{h}_t$. p_{t-1} represents the degree to which the extractor believes the previous sentence should be extracted and memorized (p_{t-1}=1 if the system is certain; 0 otherwise).

In practice, there is a discrepancy between training and testing such a model. During training we know the true label p_{t-1} of the previous sentence, whereas at test time p_{t-1} is unknown and has to be predicted by the model. The discrepancy can lead to quickly accumulating prediction errors, especially when mistakes are made early in the sequence labeling process. To mitigate this, we adopt a curriculum learning strategy (Bengio et al., 2015): at the beginning of training when p_{t-1} cannot be predicted accurately, we set it to the true label of the previous sentence; as training goes on, we gradually shift its value to the predicted label $p(y_L(t-1) = 1|d)$.

4.3 Word Extractor

Compared to sentence extraction which is a purely sequence labeling task, word extraction is closer to a generation task where relevant content must be selected and then rendered fluently and grammatically. A small extension to the structure of the sequential labeling model makes it suitable for generation: instead of predicting a label for the next sentence at each time step, the model directly outputs the next word in the summary. The

model uses a *hierarchical* attention architecture: at time step t, the decoder softly[5] attends each document sentence and subsequently attends each word in the document and computes the probability of the next word to be included in the summary $p(w'_t = w_i|d, w'_1, \cdots, w'_{t-1})$ with a softmax classifier:

$$\bar{\mathbf{h}}_t = \text{LSTM}(\mathbf{w}'_{t-1}, \bar{\mathbf{h}}_{t-1})^6 \quad (10)$$

$$a^t_j = \mathbf{z}^{\text{T}} \tanh(\mathbf{W}_e \bar{\mathbf{h}}_t + \mathbf{W}_r \mathbf{h}_j), h_j \in D \quad (11)$$

$$b^t_j = \text{softmax}(a^t_j) \quad (12)$$

$$\tilde{\mathbf{h}}_t = \sum_{j=1}^{m} b^t_j \mathbf{h}_j \quad (13)$$

$$u^t_i = \mathbf{v}^{\text{T}} \tanh(\mathbf{W}_{e'} \tilde{\mathbf{h}}_t + \mathbf{W}_{r'} \mathbf{w}_i), w_i \in D \quad (14)$$

$$p(w'_t = w_i|D, w'_1, \cdots, w'_{t-1}) = \text{softmax}(u^t_i) \quad (15)$$

In the above equations, $\mathbf{w}_i$ corresponds to the vector of the i-th word in the input document, whereas $\mathbf{z}$, $\mathbf{W}_e$, $\mathbf{W}_r$, $\mathbf{v}$, $\mathbf{W}_{e'}$, and $\mathbf{W}_{r'}$ are model weights. The model architecture is shown in Figure 3.

The word extractor can be viewed as a conditional language model with a vocabulary constraint. In practice, it is not powerful enough to enforce grammaticality due to the lexical diversity and sparsity of the document highlights. A possible enhancement would be to pair the extractor with a neural language model, which can be pretrained on a large amount of unlabeled documents and then jointly tuned with the extractor during decoding (Gulcehre et al., 2015). A simpler alternative which we adopt is to use n-gram features collected from the document to rerank candidate summaries obtained via beam decoding. We incorporate the features in a log-linear reranker whose feature weights are optimized with minimum error rate training (Och, 2003).

5 Experimental Setup

In this section we present our experimental setup for assessing the performance of our summarization models. We discuss the datasets used for training and evaluation, give implementation details, briefly introduce comparison models, and explain how system output was evaluated.

Datasets We trained our sentence- and word-based summarization models on the two datasets created from DailyMail news. Each dataset was split into approximately 90% for training, 5% for validation, and 5% for testing. We evaluated the models on the DUC-2002 single document summarization task. In total, there are 567 documents belonging to 59 different clusters of various news topics. Each document is associated with two versions of 100-word[7] manual summaries produced by human annotators. We also evaluated our models on 500 articles from the DailyMail test set (with the human authored highlights as goldstandard). We sampled article-highlight pairs so that the highlights include a minimum of 3 sentences. The average byte count for each document is 278.

Implementation Details We trained our models with Adam (Kingma and Ba, 2014) with initial learning rate 0.001. The two momentum parameters were set to 0.99 and 0.999 respectively. We performed mini-batch training with a batch size of 20 documents. All input documents were padded to the same length with an additional mask variable storing the real length for each document. The size of word, sentence, and document embeddings were set to 150, 300, and 750, respectively. For the convolutional sentence model, we followed Kim et al. (2016)[8] and used a list of kernel sizes $\{1, 2, 3, 4, 5, 6, 7\}$. For the recurrent document model and the sentence extractor, we used as regularization dropout with probability 0.5 on the LSTM input-to-hidden layers and the scoring layer. The depth of each LSTM module was 1. All LSTM parameters were randomly initialized over a uniform distribution within [-0.05, 0.05]. The word vectors were initialized with 150 dimensional pre-trained embeddings.[9]

Proper nouns pose a problem for embedding-based approaches, especially when these are rare

[5] A simpler model would use hard attention to select a sentence first and then a few words from it as a summary, but this would render the system non-differentiable for training. Although hard attention can be trained with the REINFORCE algorithm (Williams, 1992), it requires sampling of discrete actions and could lead to high variance.

[6] We empirically found that feeding the previous sentence-level attention vector as additional input to the LSTM would lead to small performance improvements. This is not shown in the equation.

[7] According to the DUC2002 guidelines `http://www-nlpir.nist.gov/projects/duc/guidelines/2002.html`, the generated summary should be within 100 words.

[8] The CNN-LSTM architecture is publicly available at `https://github.com/yoonkim/lstm-char-cnn`.

[9] We used the *word2vec* (Mikolov et al., 2013) skip-gram model with context window size 6, negative sampling size 10 and hierarchical softmax 1. The model was trained on the *Google 1-billion* word benchmark (Chelba et al., 2014).

or unknown (e.g., at test time). Rush et al. (2015) address this issue by adding a new set of features and a log-linear model component to their system. As our model enjoys the advantage of generation by extraction, we can force the model to inspect the context surrounding an entity and its relative position in the sentence in order to discover extractive patterns, placing less emphasis on the meaning representation of the entity itself. Specifically, we perform named entity recognition with the package provided by Hermann et al. (2015) and maintain a set of randomly initialized entity embeddings. During training, the index of the entities is permuted to introduce some noise but also robustness in the data. A similar data augmentation approach has been used for reading comprehension (Hermann et al., 2015).

A common problem with extractive methods based on sentence labeling is that there is no constraint on the number of sentences being selected at test time. We address this by reranking the positively labeled sentences with the probability scores obtained from the softmax layer (rather than the label itself). In other words, we are more interested in is the relative ranking of each sentence rather than their exact scores. This suggests that an alternative to training the network would be to employ a ranking-based objective or a *learning to rank* algorithm. However, we leave this to future work. We use the three sentences with the highest scores as the summary (also subject to the word or byte limit of the evaluation protocol).

Another issue relates to the word extraction model which is challenging to batch since each document possesses a distinct vocabulary. We sidestep this during training by performing negative sampling (Mikolov et al., 2013) which trims the vocabulary of different documents to the same length. At each decoding step the model is trained to differentiate the true target word from 20 noise samples. At test time we still loop through the words in the input document (and a stop-word list) to decide which word to output next.

System Comparisons We compared the output of our models to various summarization methods. These included the standard baseline of simply selecting the "leading" three sentences from each document as the summary. We also built a sentence extraction baseline classifier using logistic regression and human engineered features. The classifier was trained on the same datasets as our neural network models with the following features: sentence length, sentence position, number of entities in the sentence, sentence-to-sentence cohesion, and sentence-to-document relevance. Sentence-to-sentence cohesion was computed by calculating for every document sentence its embedding similarity with every other sentence in the same document. The feature was the normalized sum of these similarity scores. Sentence embeddings were obtained by averaging the constituent word embeddings. Sentence-to-document relevance was computed similarly. We calculated for each sentence its embedding similarity with the document (represented as bag-of-words), and normalized the score. The word embeddings used in this baseline are the same as the pre-trained ones used for our neural models.

In addition, we included a neural abstractive summarization baseline. This system has a similar architecture to our word extraction model except that it uses an open vocabulary during decoding. It can also be viewed as a hierarchical document-level extension of the abstractive sentence summarizer proposed by Rush et al. (2015). We trained this model with negative sampling to avoid the excessive computation of the normalization constant.

Finally, we compared our models to three previously published systems which have shown competitive performance on the DUC2002 single document summarization task. The first approach is the phrase-based extraction model of Woodsend and Lapata (2010). Their system learns to produce highlights from parsed input (phrase structure trees and dependency graphs); it selects salient phrases and recombines them subject to length, coverage, and grammar constraints enforced via integer linear programming (ILP). Like ours, this model is trained on document-highlight pairs, and produces telegraphic-style bullet points rather than full-blown summaries. The other two systems, TGRAPH (Parveen et al., 2015) and URANK (Wan, 2010), produce more typical summaries and represent the state of the art. TGRAPH is a graph-based sentence extraction model, where the graph is constructed from topic models and the optimization is performed by constrained ILP. URANK adopts a unified ranking system for both single- and multi-document summarization.

Evaluation We evaluated the quality of the summaries automatically using ROUGE (Lin and Hovy, 2003). We report unigram and bigram over-

DUC 2002	ROUGE-1	ROUGE-2	ROUGE-L
LEAD	43.6	21.0	40.2
LREG	43.8	20.7	40.3
ILP	45.4	21.3	42.8
NN-ABS	15.8	5.2	13.8
TGRAPH	48.1	**24.3**	—
URANK	**48.5**	21.5	—
NN-SE	47.4	23.0	**43.5**
NN-WE	27.0	7.9	22.8

DailyMail	ROUGE-1	ROUGE-2	ROUGE-L
LEAD	20.4	7.7	11.4
LREG	18.5	6.9	10.2
NN-ABS	7.8	1.7	7.1
NN-SE	**21.2**	**8.3**	**12.0**
NN-WE	15.7	6.4	9.8

Table 1: ROUGE evaluation (%) on the DUC-2002 and 500 samples from the DailyMail.

lap (ROUGE-1,2) as a means of assessing informativeness and the longest common subsequence (ROUGE-L) as a means of assessing fluency.

In addition, we evaluated the generated summaries by eliciting human judgments for 20 randomly sampled DUC 2002 test documents. Participants were presented with a news article and summaries generated by a list of systems. These include two neural network systems (sentence- and word-based extraction), the neural abstractive system described earlier, the lead baseline, the phrase-based ILP model[10] of Woodsend and Lapata (2010), and the human authored summary. Subjects were asked to rank the summaries from best to worst (with ties allowed) in order of informativeness (does the summary capture important information in the article?) and fluency (is the summary written in well-formed English?). We elicited human judgments using Amazon's Mechanical Turk crowdsourcing platform. Participants (self-reported native English speakers) saw 2 random articles per session. We collected 5 responses per document.

6 Results

Table 1 (top half) summarizes our results on the DUC 2002 test dataset using ROUGE. NN-SE represents our neural sentence extraction model, NN-WE our word extraction model, and NN-ABS the neural abstractive baseline. The table also includes results for the LEAD baseline, the logistic regression classifier (LREG), and three previously published systems (ILP, TGRAPH, and URANK).

[10]We are grateful to Kristian Woodsend for giving us access to the output of his system. Unfortunately, we do not have access to the output of TGRAPH or URANK for inclusion in the human evaluation.

Models	1^{st}	2^{nd}	3^{rd}	4^{th}	5^{th}	6^{th}	MeanR
LEAD	0.10	0.17	0.37	0.15	0.16	0.05	3.27
ILP	0.19	0.38	0.13	0.13	0.11	0.06	2.77
NN-SE	0.22	0.28	0.21	0.14	0.12	0.03	2.74

NN-ABS	0.00	0.01	0.05	0.16	0.23	0.54	5.24
Human	0.27	0.23	0.29	0.17	0.03	0.01	2.51

Table 2: Rankings (shown as proportions) and mean ranks given to systems by human participants (lower is better).

The NN-SE outperforms the LEAD and LREG baselines with a significant margin, while performing slightly better than the ILP model. This is an encouraging result since our model has only access to embedding features obtained from raw text. In comparison, LREG uses a set of manually selected features, while the ILP system takes advantage of syntactic information and extracts summaries subject to well-engineered linguistic constraints, which are not available to our models. Overall, our sentence extraction model achieves performance comparable to the state of the art without sophisticated constraint optimization (ILP, TGRAPH) or sentence ranking mechanisms (URANK). We visualize the sentence weights of the NN-SE model in the top half of Figure 4. As can be seen, the model is able to locate text portions which contribute most to the overall meaning of the document.

ROUGE scores for the word extraction model are less promising. This is somewhat expected given that ROUGE is *n*-gram based and not very well suited to measuring summaries which contain a significant amount of paraphrasing and may deviate from the reference even though they express similar meaning. However, a meaningful comparison can be carried out between NN-WE and NN-ABS which are similar in spirit. We observe that NN-WE consistently outperforms the purely abstractive model. As NN-WE generates summaries by picking words from the original document, decoding is easier for this model compared to NN-ABS which deals with an open vocabulary. The extraction-based generation approach is more robust for proper nouns and rare words, which pose a serious problem to open vocabulary mod-

Figure 4: Visualization of the summaries for a DailyMail article. The top half shows the relative attention weights given by the sentence extraction model. Darkness indicates sentence importance. The lower half shows the summary generated by the word extraction.

els. An example of the generated summaries for NN-WE is shown at the lower half of Figure 4.

Table 1 (lower half) also shows system results on the 500 DailyMail news articles (test set). In general, we observe similar trends to DUC 2002, with NN-SE performing the best in terms of all ROUGE metrics. Note that scores here are generally lower compared to DUC 2002. This is due to the fact that the gold standard summaries (aka highlights) tend to be more laconic and as a result involve a substantial amount of paraphrasing.

The results of our human evaluation study are shown in Table 2. Specifically, we show, proportionally, how often our participants ranked each system 1st, 2nd, and so on. Perhaps unsurprisingly, the human-written descriptions were considered best and ranked 1st 27% of the time, however closely followed by our NN-SE model which was ranked 1st 22% of the time. The ILP system was mostly ranked in 2nd place (38% of the time). The rest of the systems occupied lower ranks. We further converted the ranks to ratings on a scale of 1 to 6 (assigning ratings $6 \ldots 1$ to rank placements $1 \ldots 6$). This allowed us to perform Analysis of Variance (ANOVA) which revealed a reliable effect of system type. Specifically, post-hoc Tukey tests showed that NN-SE and ILP are significantly ($p < 0.01$) better than LEAD, NN-WE, and NN-ABS but do not differ significantly from each other or the human goldstandard.

7 Conclusions

In this work we presented a data-driven summarization framework based on an encoder-extractor architecture. We developed two classes of models based on sentence and word extraction. Our models can be trained on large scale datasets and learn informativeness features based on continuous representations without recourse to linguistic annotations. Two important ideas behind our work are the creation of hierarchical neural structures that reflect the nature of the summarization task and generation by extraction. The later effectively enables us to sidestep the difficulties of generating under a large vocabulary, essentially covering the entire dataset, with many low-frequency words and named entities.

Directions for future work are many and varied. One way to improve the word-based model would be to take structural information into account during generation, e.g., by combining it with a tree-based algorithm (Cohn and Lapata, 2009). It would also be interesting to apply the neural models presented here in a phrase-based setting similar to Lebret et al. (2015). A third direction would be to adopt an information theoretic perspective and devise a purely unsupervised approach that selects summary sentences and words so as to minimize information loss, a task possibly achievable with the dataset created in this work.

Acknowledgments

We would like to thank three anonymous reviewers and members of the ILCC at the School of Informatics for their valuable feedback. The support of the European Research Council under award number 681760 "Translating Multiple Modalities into Text" is gratefully acknowledged.

Abstract

Automatic negation scope detection is a task that has been tackled using different classifiers and heuristics. Most systems are however 1) highly-engineered, 2) English-specific, and 3) only tested on the same genre they were trained on. We start by addressing 1) and 2) using a neural network architecture. Results obtained on data from the *SEM2012 shared task on negation scope detection show that even a simple feed-forward neural network using word-embedding features alone, performs on par with earlier classifiers, with a bi-directional LSTM outperforming all of them. We then address 3) by means of a specially-designed synthetic test set; in doing so, we explore the problem of detecting the negation scope more in depth and show that performance suffers from genre effects and differs with the type of negation considered.

1 Introduction

Amongst different extra-propositional aspects of meaning, negation is one that has received a lot of attention in the NLP community. Previous work have focused in particular on automatically detecting the *scope of negation*, that is, given a negative instance, to identify which tokens are affected by negation (§2). As shown in (1), only the first clause is negated and therefore we mark *he* and *the car*, along with the predicate *was driving* as inside the scope, while leaving the other tokens outside.

(1) He was **not** driving the car and she left to go home.

In the BioMedical domain there is a long line of research around the topic (e.g. Velldal et al. (2012) and Prabhakaran and Boguraev (2015)), given the importance of recognizing negation for information extraction from medical records. In more general domains, efforts have been more limited and most of the work centered around the *SEM2012 shared task on automatically detecting negation (§3), despite the recent interest (e.g. machine translation (Wetzel and Bond, 2012; Fancellu and Webber, 2014; Fancellu and Webber, 2015)).

The systems submitted for this shared task, although reaching good overall performance are highly feature-engineered, with some relying on heuristics based on English (Read et al. (2012)) or on tools that are available for a limited number of languages (e.g. Basile et al. (2012), Packard et al. (2014)), which do not make them easily portable across languages. Moreover, the performance of these systems was only assessed on data of the same genre (stories from Conan Doyle's *Sherlock Holmes*) but there was no attempt to test the approach on data of different genre.

Given these shortcomings, we investigate whether neural network based sequence-to-sequence models (§ 4) are a valid alternative. The first advantage of neural networks-based methods for NLP is that we could perform classification by means of unsupervised word-embeddings features only, under the assumption that they also encode structural information previous system had to explicitly represent as features. If this assumption holds, another advantage of continuous representations is that, by using a bilingual word-embedding space, we would be able to transfer the model cross-lingually, obviating the problem of the lack of annotated data in other languages.

The paper makes the following contributions:

1. *Comparable or better performance*: We show that neural networks perform on par with previously developed classifiers, with a bi-directional LSTM outperforming them

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 495–504,
Berlin, Germany, August 7-12, 2016.

when tested on data from the same genre.

2. *Better understanding of the problem*: We analyze in more detail the difficulty of detecting negation scope by testing on data of different genre and find that the performance of word-embedding features is comparable to that of more fine-grained syntactic features.

3. *Creation of additional resources*: We create a *synthetic* test set of negative sentences extracted from Simple English Wikipedia (§ 5) and annotated according to the guidelines released during the *SEM2012 shared task (Morante et al., 2011), that we hope will guide future work in the field.

2 The task

Before formalizing the task, we begin by giving some definitions. A *negative sentence n* is defined as a vector of words $\langle w_1, w_2...w_n \rangle$ containing one or more negation **cues**, where the latter can be a word (e.g. *not*), a morpheme (e.g. *im*-patient) or a multi-word expression (e.g. *by no means, no longer*) inherently expressing negation.

A word is a **scope token** if included in the scope of a negation cue. Following Blanco and Moldovan (2011), in the *SEM2012 shared task the negation **scope** is understood as part of a knowledge representation focused around a negated event along with its related semantic roles and adjuncts (or its head in the case of a nominal event). This is exemplified in (2) (from Blanco and Moldovan (2011)) where the scope includes both the negated event *eat* along the subject *the cow*, the object *grass* and the PP *with a fork*.

(2) The cow did **n't** eat grass with a fork.[1]

Each cue defines its own *negation instance*, here defined as a tuple *I*(*n*,c) where $c \in \{1,0\}^{|n|}$ is a vector of length *n* s.t. $c_i = 1$ if w_i is part of the cue and 0 otherwise. Given *I* the goal of automatic scope detection is to predict a vector $s \in \{O,I\}^{|n|}$ s.t. s_i = I (inside of the scope) if w_i is in the scope of the cue or O (outside) otherwise.

In (3) for instance, there are two cues, *not* and *no longer*, each one defining a separate negation instance, *I1(n,c1)* and *I2(n,c2)*, and each with its own scope, *s1* and *s2*. In both (3a) and (3b), *n* = [I, do, not, love, you, and, you, are, no, longer, invited]; in (3a), the vector *c1* is 1 only at index 3 (w_2='not'), while in (3b) *c2* is 1 at position 9, 10 (where w_9 w_{10} = 'no longer'); finally the vectors *s1* and *s2* are I only at the indices of the words underlined and O anywhere else.

(3) a. I do **not** love you and you are no longer invited

b. I do not love you and you are **no longer** invited

There are the two main challenges involved in detecting the scope of negation: 1) a sentence can contain multiple instances of negation, sometimes nested and 2) scope can be discontinuous. As for 1), the classifier must correctly classify each word as being inside or outside the scope and assign each word to the correct scope; in (4) for instance, there are two negation cues and therefore two scopes, one spanning the entire sentence (3a.) and the other the subordinate only (3b.), with the latter being nested in the former (given that, according to the guidelines, if we negate the event in the main, we also negate its cause).

(4) a. I did **not** drive to school because my wife was not feeling well .[2]

b. I did not drive to school because my wife was **not** feeling well .

In (5), the classifier should instead be able to capture the long range dependency between the subject and its negated predicate, while excluding the positive VP in the middle.

(5) Naomi went to visit her parents to give them a special gift for their anniversary but **never** came back .

In the original task, the performance of the classifier is assessed in terms of precision, recall and F_1 measure over the number of words correctly classified as part of the scope (*scope tokens*) and over the number of scopes predicted that exactly

[1] In the *SEM2012 shared task, negation is not considered as a downward monotone function and definite expressions are included in its scope.

[2] One might object that the scope only spans over the subordinate given that it is the part of the scope most likely to be interpreted as false (*It is not the case that I drove to school because my wife was not at home, but for other reasons*). In the *SEM2012 shared task however this is defined separately as the *focus* of negation and considered as part of the scope. One reason to distinguish the two is the high ambiguity of the focus: one can imagine for instance that if the speaker stresses the words *to school* this will be most likely considered the focus and the statement interpreted as *It is not the case that I drive to school because my wife was not feeling well* (but I drove to the hospital instead).

match the gold scopes (*exact scope match*). As for latter, recall is a measure of accuracy since we score how many scopes we fully predict (true positives) over the total number of scopes in our test set (true positives and false negatives); precision takes instead into consideration false positives, that is those negation instances that are predicted as having a scope but in reality don't have any. This is the case of the interjection *No* (e.g. '**No**, leave her alone') that never take scope.

3 Previous work

Table 1 summarizes the performance of systems previously developed to resolve the scope of negation in non-Biomedical texts.

In general, supervised classifiers perform better than rule-based systems, although it is a combination of hand-crafted heuristics and SVM rankers to achieve the best performance. Regardless of the approach used, the syntactic structure (either constituent or dependency-based) of the sentence is often used to detect the scope of negation. This is because the position of the cue in the tree along with the projection of its parent/governor are strong indicators of scope boundaries. Moreover, given that during training we basically learn which syntactic patterns the scope are likely to span, it is also possible to hypothesize that this system should scale well to other genre/domain, as long as we can have a parse for the sentence; this however was never confirmed empirically. Although informative, these systems suffers form three main shortcomings: 1) they are highly-engineered (as in the case of Read et al. (2012)) and syntactic features add up to other PoS, word and lemma n-gram features, 2) they rely on the parser producing a correct parse and 3) they are English specific.

Other systems (Basile et al., 2012; Packard et al., 2014) tried to traverse a semantic representation instead. Packard et al. (2014) achieves the best results so far, using hand-crafted heuristics to traverse the MRS (Minimal Recursion Semantics) structures of negative sentences. If the semantic parser cannot create a reliable representation for a sentence, the system 'backs-off' to the hybrid model of Read et al. (2012), which uses syntactic information instead. This system suffers however from the same shortcomings mentioned above, in particular, given that MRS representation can only be built for a small set of languages.

4 Scope detection using Neural Networks

In this paper, we experiment with two different neural networks architecture: a one hidden layer **feed-forward neural network** and a **bi-directional LSTM** (Long Short Term Memory, BiLSTM below) model. We chose to 'start simple' from a feed-forward network to investigate whether even a simple model can reach good performance using word-embedding features only. We then turned to a BiLSTM because a better fit for the task. BiLSTM are sequential models that operate both in forward and backwards fashion; the backward pass is especially important in the case of negation scope detection, given that a scope token can appear in a string before the cue and it is therefore important that we see the latter first to classify the former. We opted in this case for LSTM over RNN cells given that their inner composition is able to better retain useful information when backpropagating the error.[4]

Both networks take as input a single negative instance $I(n,c)$. We represent each word $w_i \in n$ as a d-dimensional word-embedding vector $\mathbf{x} \in \mathbb{R}^d$ (d=50). In order to encode information about the cue, each word is also represented by a *cue*-embedding vector $\mathbf{c} \in \mathbb{R}^d$ of the same dimensionality of $\mathbf{x}$. $\mathbf{c}$ can only take two representations, *cue*, if c_i=1, or *notcue* otherwise. We also define $\mathbf{E}_w^{v \times d}$ as the word-embedding matrix, where v is the vocabulary size, and $\mathbf{E}_c^{2 \times d}$ as the cue-embedding matrix.

In the case of a feed-forward neural network, the input for each word $w_i \in n$ is the concatenation of its representation with the ones of its neighboring words in a context window of length l. This is because feed-forward networks treat the input units as separate and information about how words are arranged as sequences must be explicitly encoded in the input. We define these concatenations $\mathbf{x}_{conc}$ and $\mathbf{c}_{conc}$ as $\mathbf{x}_{w_{i-l}}...\mathbf{x}_{w_{i-1}}$; $\mathbf{x}_{w_i}$; $\mathbf{x}_{w_{i+1}}...\mathbf{x}_{w_i+l}$ and $\mathbf{c}_{w_{i-l}}...\mathbf{c}_{w_{i-1}}$; $\mathbf{c}_{w_i}$; $\mathbf{c}_{w_{i+1}}...\mathbf{c}_{w_{i+l}}$ respectively. We chose the value of l after analyzing the negation scopes in the dev set. We found that although the furthest scope tokens are 23 and 31 positions away from the cue on the left and the right respectively, 95% of the scope tokens fall in a window of 9 tokens to the left and 15 to the right, these two values being the window sizes we con-

[4] For more details on LSTM and related mathematical formulations, we refer to reader to Hochreiter and Schmidhuber (1997)

Table 1: Summary of previous work on automatic detection of negation scope.

sider for our input. The probability of a given input is then computed as follows:

$$\begin{aligned} \mathbf{h} &= \sigma(\mathbf{W}_x\mathbf{x}_{conc} + \mathbf{W}_c\mathbf{c}_{conc} + \mathbf{b}) \\ y &= g(\mathbf{W}_y\mathbf{h} + \mathbf{b}_y) \end{aligned} \tag{1}$$

where $\mathbf{W}$ and $\mathbf{b}$ the weight and biases matrices, $\mathbf{h}$ the hidden layer representation, σ the sigmoid activation function and g the softmax operation ($g(z_m) = e^{z_m} / \sum_k e^{z_k}$) to assign a probability to the input of belonging to either the inside (I) or outside (O) of the scope classes.

In the biLSTM, no concatenation is performed, given that the structure of the network is already sequential. The input to the network for each word w_i are the word-embedding vector $\mathbf{x}_{w_i}$ and the cue-embedding vector $\mathbf{c}_{w_i}$, where w_i constitutes a time step. The computation of the hidden layer at time t and the output can be represented as follows:

$$\begin{aligned} \mathbf{i}_t &= \sigma(\mathbf{W}_x^{(i)}\mathbf{x} + \mathbf{W}_c^{(i)}\mathbf{c} + \mathbf{W}_h^{(i)}\mathbf{h_{t-1}} + \mathbf{b}^{(i)}) \\ \mathbf{f}_t &= \sigma(\mathbf{W}_x^{(f)}\mathbf{x} + \mathbf{W}_c^{(f)}\mathbf{c} + \mathbf{W}_h^{(f)}\mathbf{h_{t-1}} + \mathbf{b}^{(f)}) \\ \mathbf{o}_t &= \sigma(\mathbf{W}_x^{(o)}\mathbf{x} + \mathbf{W}_c^{(o)}\mathbf{c} + \mathbf{W}_h^{(o)}\mathbf{h_{t-1}} + \mathbf{b}^{(o)}) \\ \tilde{\mathbf{c}}_t &= tanh(\mathbf{W}_x^{(c)}\mathbf{x} + \mathbf{W}_c^{(c)}\mathbf{c} + \mathbf{W}_h^{(c)}\mathbf{h_{t-1}} + \mathbf{b}^{(c)}) \\ \mathbf{c}_t &= \mathbf{f}_t \cdot \tilde{\mathbf{c}}_{t-1} + \mathbf{i}_t \cdot \tilde{\mathbf{c}}_t \\ \mathbf{h}_{back/forw} &= \mathbf{o}_t \cdot tanh(\mathbf{c}_t) \\ y_t &= g(\mathbf{W}_y(\mathbf{h}_{back}; \mathbf{h}_{forw}) + \mathbf{b}_y) \end{aligned} \tag{2}$$

where the $\mathbf{W}$s are the weight matrices, $\mathbf{h}_{t-1}$ the hidden layer state a time t-1, $\mathbf{i}_t$, $\mathbf{f}_t$, $\mathbf{o}_t$ the input, forget and the output gate at the time t and $\mathbf{h}_{back}$; $\mathbf{h}_{forw}$ the concatenation of the backward and forward hidden layers.

Finally, in both networks our training objective is to minimise, for each negative instance, the negative log likelihood *J(W,b)* of the correct predictions over gold labels:

$$\begin{aligned} J(W,b) = -\frac{1}{l}\sum_{i=1}^{l} & y^{(w_i)} \log h_\theta(x^{(w_i)}) \\ & + (1 - y^{(w_i)}) \log(1 - h_\theta(x^{(w_i)})) \end{aligned} \tag{3}$$

where l is the length of the sentence $n \in I$, $x^{(w_i)}$ the probability for the word w_i to belong to either the I or O class and $y^{(w_i)}$ its gold label.

An overview of both architectures is shown in Figure 1.

4.1 Experiments

Training, development and test set are a collection of stories from Conan Doyle's *Sherlock Holmes* annotated for cue and scope of negation and released in concomitance with the *SEM2012 shared task.[5] For each word, the correspondent lemma, POS tag and the constituent subtree it belongs to are also annotated. If a sentence contains multiple instances of negation, each is annotated separately.

Both training and testing is done on negative sentences only, i.e. those sentences with at least one cue annotated. Training and test size are of 848 and 235 sentences respectively. If a sentence contains multiple negation instances, we create as many copies as the number of instances. If the sentence contains a morphological cue (e.g. *im-patient*) we split it into affix (**im-**) and root (*patient*), and consider the former as cue and the latter as part of the scope.

Both neural network architectures are implemented using TensorFlow (Abadi et al., 2015) with a 200-units hidden layer (400 in total for two concatenated hidden layers in the BiLSTM), the Adam optimizer (Kingma and Ba, 2014) with a

[5]For the statistics regarding the data, we refer the reader to Morante and Blanco (2012).

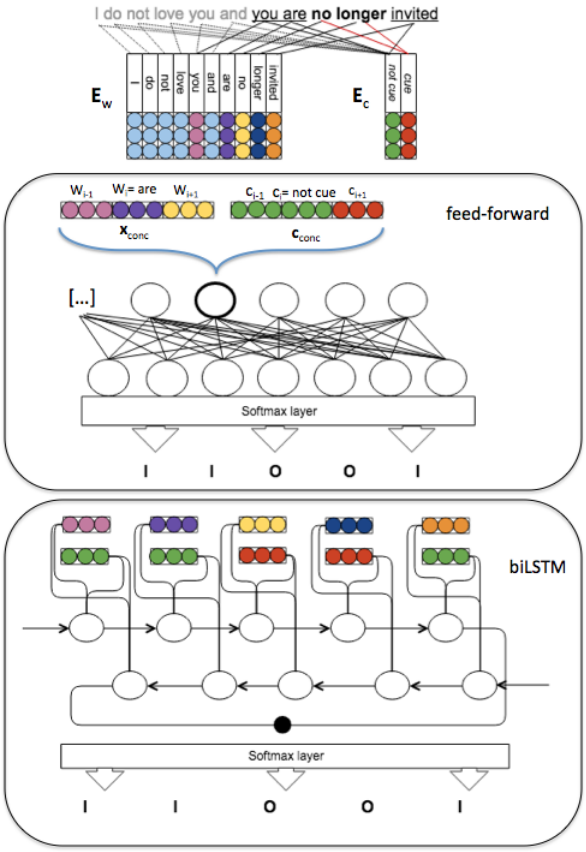

Figure 1: An example of scope detection using feed-forward and BiLSTM for the tokens '*you are* **no longer** *invited*' in the instance in ex. (3b).

starting learning rate of 0.0001, learning rate decay after 10 iterations without improvement and early stopping. In both cases we experimented with different settings:

1. **Simple baseline**: In order to understand how hard the task of negation scope detection is, we created a simple baseline by tagging as part of the scope all the tokens 4 words to the left and 6 to the right of the cue; these values were found to be the average span of the scope in either direction in the training data.

2. **Cue info (C)**: The word-embedding matrix is randomly initialised and updated relying on the training data only. Information about the cue is fed through another set of embedding vectors, as shown in 4. This resembles the 'Closed track' of the *SEM2012 shared task since no external resource is used.

3. **Cue info + external embeddings (E)**: This is the same as setting (2) except that the embeddings are pre-trained using external data. We experimented with both keeping the word-embedding matrix fixed and updating it during training but we found small or no difference between the two settings. To do this, we train a word-embedding matrix using Word2Vec (Mikolov et al., 2013) on 770 million tokens (for a total of 30 million sentences and 791028 types) from the 'One Billion Words Language Modelling' dataset [6] and the Sherlock Holmes data (5520 sentences) combined. The dataset was tokenized and morphological cues split into negation affix and root to match the Conan Doyle's data. In order to perform this split, we matched each word against an hand-crafted list of words containing affixal negation[7]; this method have an accuracy of 0.93 on the Conan Doyle test data.

4. **Adding PoS / Universal PoS information (PoS/uni PoS)**: This was mainly to assess whether we could get further improvement by adding additional information. For all the setting above, we also add an extra embedding input vector for the POS or Universal POS of each word w_i. As for the word and the cue embeddings, PoS-embedding information are fed to the hidden layer through a separate weight matrix. When pre-trained, the training data for the external PoS-embedding matrix is the same used for building the word embedding representation, except that in this case we feed the PoS / Universal PoS tag for each word. As in (3), we experimented with both updating the tag-embedding matrix and keeping it fixed but found again small or no difference between the two settings. In order to maintain consistency with the original data, we perform PoS tagging using the GENIA tagger (Tsuruoka et al., 2005)[8] and then map the resulting tags to universal POS tags.[9]

4.2 Results

The results for the scope detection task are shown in Table 2.

[6] Available at `https://code.google.com/archive/p/word2vec/`

[7] The list was courtesy of Ulf Hermjakob and Nathan Schneider.

[8] `https://github.com/saffsd/geniatagger`

[9] Mapping available at `https://github.com/slavpetrov/universal-pos-tags`

Results for both architecture when word-embedding features *only* are used (C and C + E) show that neural networks are a valid alternative for scope detection, with bi-directional LSTM being able to outperform all previously developed classifiers on both scope token recognition and exact scope matching. Moreover, a bi-directional LSTM shows similar performance to the hybrid system of Packard et al. (2014) (rule-based + SVM as a back-off) in absence of any hand-crafted heuristics.

It is also worth noticing that although pre-training the word-embedding and PoS-embedding matrices on external data leads to a slight improvement in performance, the performance of the systems using internal data only is already competitive; this is a particularly positive result considering that the training data is relatively small.

Finally, adding universal POS related information leads to a better performance in most cases. The fact that the best system is built using language-independent features only is an important result when considering the portability of the model across different languages.

4.3 Error analysis

In order to understand the kind of errors our best classifier makes, we performed an error analysis on the held-out set.

First, we investigate whether the per-instance prediction accuracy correlates with scope-related (length of the scope to the left, to the right and combined; maximum length of the gap in a discontinuous scope) and cue-related (type of cue -one-word, prefixal, suffixal, multiword-) variables. We also checked whether the neural network is biased towards the words it has seen in the training(for instance, if it has seen the same token always labeled as O it will then classify it as O). For our best biLSTM system, we found only weak to moderate negative correlations with the following variables:

- *length of the gap*, if the scope is discontinuous (r=-0.1783, p = 0.004);
- *overall scope length* (r=-0.3529, $p < 0.001$);
- *scope length to the left and to the right* (r=-0.3251 and -0.2659 respectively with $p < 0.001$)
- *presence of a prefixal cue* (r=-0.1781, p = 0.004)
- *presence of a multiword cue* (r=-0.1868, p = 0.0023)

meaning that the variables considered are not strong enough to be considered as error patterns.

For this reason we also manually analyzed the 96 negation scopes that the best biLSTM system predicted incorrectly and noticed several error patterns:

- in 5 cases, the scope should only span on the subordinate but end up including elements from the main. In (6) for instance, where the system prediction is reported in curly brackets, the BiLSTM ends up including the main predicate with its subject in the scope.

  (6) You felt so strongly about it that {I knew you could} **not** {think of Beecher without thinking of that also} .

- in 5 cases, the system makes an incorrect prediction in presence of the syntactic inversion, where a subordinate appears before the main clause; in (7) for instance, the system extends the prediction to the main clause when the scope should instead span the subordinate only.

  (7) But {if she does} **not** {wish to shield him she would give his name}

- in 8 cases, where two VPs, one positive and one negative, are coordinated, the system ends up including in the scope the positive VP as well, as shown in (8). We hypothesized this is due to the lack of such examples in the training set.

  (8) Ah, {you do} **n't** {know Sarah 's temper or you would wonder no more} .

As in Packard et al. (2014), we also noticed that in 15 cases, the gold annotations do not follow the guidelines; in the case of a negated adverb in particular, as shown in (9a) and (9b) the annotations do not seem to agree on whether consider as scope only the adverb or the entire clause around it.

b. [...] glaring help**less**ly at the frightful thing which was hunting him down.

5 Evaluation on synthetic data set

5.1 Methodology

One question left unanswered by previous work is whether the performance of scope detection classifiers is robust against data of a different genre and whether different types of negation lead to difference in performance. To answer this, we compare two of our systems with the only original submission to the *SEM2012 we found available (White, 2012)[10]. We decided to use both our best system, BiLSTM+C+UniPoS+E and a sub-optimal systems, BiLSTM+C+E to also assess the robustness of non-English specific features.

The synthetic test set here used is built on sentences extracted from Simple Wikipedia and manually annotated for cue and scope according to the annotation guidelines released in concomitance with the *SEM2012 shared task (Morante et al., 2011). We created 7 different subsets to test different types of negative sentences:

Simple: we randomly picked 50 positive sentences, containing only one predicate, no dates and no named entities, and we made them negative by adding a negation cue (*do* support or minor morphological changes were added when required). If more than a lexical negation cue fit in the context, we used them all by creating more than one negative counterpart, as shown in (10). The sentences were picked to contain different kind of predicates (verbal, existential, nominal, adjectival).

(10) a. Many people disagree on the topic

b. Many people do **not** disagree on the topic

c. Many people **never** disagree on the topic

Lexical: we randomly picked 10 sentences[11] for each **lexical** (i.e. one-word) cue in training data (these are *not*, *no*, *none*, *nobody*, *never*, *without*)

Prefixal: we randomly picked 10 sentences for each prefixal cue in the training data (*un-*, *im-*, *in-*, *dis-*, *ir-*)

Suffixal: we randomly picked 10 sentences for the suffixal cue *-less*.

Multi-word: we randomly picked 10 sentences for each multi-word cue (*neither...nor*,*no longer*,*by no means*).

Unseen: we include 10 sentences for each of the negative prefixes *a-* (e.g. *a*-cyclic), *ab-* (e.g. *ab*-normal) *non-* (e.g. *non*-Communist) that are not annotated as cue in the Conan Doyle corpus,

[10] In order for the results to be comparable, we feed White's system with the cues from the gold-standard instead of automatically detecting them.

[11] In some cases, we ended up with more than 10 examples for some cues given that some of the sentences we picked contained more than a negation instance.

Table 3: Results for the scope detection task on the synthetic test set.

to test whether the system can generalise the classification to unseen cues.[12]

5.2 Results

Table 3. shows the results for the comparison on the synthetic test set. The first thing worth noticing is that by using word-embedding features only it is possible to reach comparable performance with a classifier using syntactic features, with universal PoS generally contributing to a better performance; this is particularly evident in the *multi-word* and *lexical* sub-sets. In general, genre effects hinder both systems; however, considering that the training data is less than 1000 sentences, results are relatively good.

Performance gets worse when dealing with morphological cues and in particular in the case of our classifier, with suffixal cues; at a closer inspection however, the cause of such poor performance is attributable to a discrepancy between the annotation guidelines and the training data, already noted in §4.4. The guidelines state in fact that '*If the negated affix is attached to an adverb that is a complement of a verb, the negation scopes over the entire clause*'(Morante et al., 2011, p. 21) and we annotated suffixal negation in this way. However, 3 out of 4 examples of suffixal negation in adverbs in the training data (e.g. 9a.) mark the scope on the adverbial root only and that's what our classifiers learn to do.

Finally, it can be noticed that our system does worse at exact scope matching than the CRF classifier. This is because White (2012)'s CRF model is build on constituency-based features that will then predict scope tokens based on constituent boundaries (which, as we said, are good indicator of scope boundaries), while neural networks, basing the prediction only on word-embedding information, might extend the prediction over these boundaries or leave 'gaps' within.

6 Conclusion and Future Work

In this work, we investigated and confirmed that neural networks sequence-to-sequence models are a valid alternative for the task of detecting the scope of negation. In doing so we offer a detailed analysis of its performance on data of different genre and containing different types of negation, also in comparison with previous classifiers, and found that non-English specific continuous representation can perform batter than or on par with more fine-grained structural features.

Future work can be directed towards answering two main questions:

Can we improve the performance of our classifier? To do this, we are going to explore whether adding language-independent structural informa-

[12]The data, along with the code, is freely available at `https://github.com/ffancellu/NegNN`

tion (e.g. universal dependency information) can help the performance on exact scope matching.

Can we transfer our model to other languages? Most importantly, we are going to test the model using word-embedding features extracted from a bilingual embedding space.

Abstract

Most sentence embedding models typically represent each sentence only using word surface, which makes these models indiscriminative for ubiquitous homonymy and polysemy. In order to enhance representation capability of sentence, we employ conceptualization model to assign associated concepts for each sentence in the text corpus, and then learn conceptual sentence embedding (CSE). Hence, this semantic representation is more expressive than some widely-used text representation models such as latent topic model, especially for short-text. Moreover, we further extend CSE models by utilizing a local attention-based model that select relevant words within the context to make more efficient prediction. In the experiments, we evaluate the CSE models on two tasks, text classification and information retrieval. The experimental results show that the proposed models outperform typical sentence embed-ding models.

1 Introduction

Many natural language processing applications require the input text to be represented as a fixed-length feature, of which sentence representation is very important. Perhaps the most common fixed-length vector representation for texts is the bag-of-words or bag-of-n-grams (Harris, 1970). However, they suffer severely from data sparsity and high dimensionality, and have very little sense about the semantics of words or the distances between the words. Recently, in sentence representation and classification, deep neural network (DNN) approaches have achieved state-of-the-art results (Le and Mikolov, 2014; Liu et al., 2015; Palangi et al., 2015; Wieting et al., 2015). Despite of their usefulness, recent sentence embeddings face several challenges: (i) Most sentence embedding models represent each sentence only using word surface, which makes these models indiscriminative for ubiquitous polysemy; (ii) For short-text, however, neither parsing nor topic modeling works well because there are simply not enough signals in the input; (iii) Setting window size of context words is very difficult. To solve these problems, we must derive more semantic signals from the input sentence, e.g., concepts. Besides, we should assigned different attention for different contextual word, to enhance the influence of words that are relevant for each prediction.

This paper proposed Conceptual Sentence Embedding (CSE), an unsupervised framework that learns continuous distributed vector representations for sentence. Specially, by innovatively introducing concept information, this concept-level vector representations of sentence are learned to predict the surrounding words or target word in contexts. Our research is inspired by the recent work in learning vector representations of words using deep learning strategy (Mikolov et al., 2013a; Le and Mikolov, 2014). More precisely, we first obtain concept distribution of the sentence, and generate corresponding concept vector. Then we concatenate or average the sentence vector, contextual word vectors with concept vector of the sentence, and predict the target word in the given context. All of the sentence vectors and word vectors are trained by the stochastic gradient descent and backpropagation (Rumelhart et al., 1986). At prediction time, sentence vectors are inferred by fixing the word vectors and observed sentence vectors, and training the new sentence vector until convergence.

In parallel, the concept of attention has gained

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 505–515,
Berlin, Germany, August 7-12, 2016.

popularity recently in neural natural language processing researches, which allowing models to learn alignments between different modalities (Bahdanau et al., 2014; Bansal et al., 2014; Rush et al., 2015). In this work, we further propose the extensions to CSE, which adds an attention model that considers contextual words differently depending on the word type and its relative position to the predicted word. The main intuition behind the extended model is that prediction of a word is mainly dependent on certain words surrounding it.

In summary, the basic idea of CSE is that, we allow each word to have different embeddings under different concepts. Taking word apple into consideration, it may indicate a fruit under the concept *food*, and indicate an IT company under the concept *information technology*. Hence, concept information significantly contributes to the discriminative of sentence vector. Moreover, an important advantage of the proposed conceptual sentence embeddings is that they could be learned from unlabeled data. Another advantage is that we take the word order into account, in the same way of n-gram model, while bag-of-n-grams model would create a very high-dimensional representation that tends to generalize poorly.

To summarize, this work contributes on the following aspects: We integrate concepts and attention-based strategy into basic sentence embedding representation, and allow the resulting conceptual sentence embedding to model different meanings of a word under different concept. The experimental results on text classification task and information retrieval task demonstrate that this concept-level sentence representation is robust. The outline of the paper is as follows. Section 2 surveys related researches. Section 3 formally de-scribes the proposed model of conceptual sentence embedding. Corresponding experimental results are shown in Section 4. Finally, we conclude the paper.

2 Related Works

Conventionally, one-hot sentence representation has been widely used as the basis of bag-of-words (BOW) text model. However, it can-not take the semantic information into consideration. Recently, in sentence representation and classification, deep neural network approaches have achieved state-of-the-art results (Le and Mikolov, 2014; Liu et al., 2015; Ma et al., 2015; Palangi et al., 2015; Wieting et al., 2015), most of which are inspired by word embedding (Mikolov et al., 2013a). (Le and Mikolov, 2014) proposed the paragraph vector (PV) that learns fixed-length representations from variable-length pieces of texts. Their model represents each document by a dense vector which is trained to predict words in the document. However, their model depends only on word surface, ignoring semantic information such as topics or concepts. In this paper, we extent PV by introducing concept information.

Aiming at enhancing discriminativeness for ubiquitous polysemy, (Liu et al., 2015) employed latent topic models to assign topics for each word in the text corpus, and learn topical word embeddings (TWE) and sentence embeddings based on both words and their topics. Besides, to combine deep learning with linguistic structures, many syntax-based embedding algorithms have been proposed (Severyn et al., 2014; Wang et al., 2015b) to utilize long-distance dependencies. However, short-texts usually do not observe the syntax of a written language, nor do they contain enough signals for statistical inference (e.g., topic model). Therefore, neither parsing nor topic modeling works well because there are simply not enough signals in the input, and we must derive more semantic signals from the input, e.g., concepts, which have been demonstrated effective in knowledge representation (Wang et al., 2015c; Song et al., 2015). Shot-text conceptualization, is an interesting task to infer the most likely concepts for terms in the short-text, which could help better make sense of text data, and extend the texts with categorical or topical information (Song et al., 2011). Therefore, our models utilize short-text conceptualization algorithm to discriminate concept-level sentence senses and provide a good performance on short-texts.

Recently, attention model has been used to improve many neural natural language pro-cessing researches by selectively focusing on parts of the source data (Bahdanau et al., 2014; Bansal et al., 2014; Wang et al., 2015a). To the best of our knowledge, there has not been any other work exploring the use of attentional mechanism for sentence embeddings.

3 Conceptual Sentence Embedding

This paper proposes four conceptual sentence embedding models. The first one is based on continu-

ous bag-of-word model (denoted as **CSE-1**) which have not taken word order into consideration. To overcome this drawback, its extension model (denoted as **CSE-2**), which is based on Skip-Gram model, is proposed. Based on the basic conceptual sentence embedding models above, we obtain their variants (**aCSE-1** and **aCSE-2**) by introducing attention model.

3.1 CBOW Model & Skip-Gram Model

As inspiration of the proposed conceptual sentence embedding models, we start by discussing previous models for learning word vectors (Mikolov et al., 2013a; Mikolov et al., 2013b) firstly.

Let us overview the framework of Continuous Bag-of-Words (CBOW) firstly, which is shown in Figure 1(a). Each word is typically mapped to an unique vector, represented by a column in a word matrix $\mathbf{W} \in \Re^{d*|V|}$. Wherein, V denotes the word vocabulary and d is embedding dimension of word. The column is indexed by position of the word in V. The concatenation or average of the vectors, the context vector w_t, is then used as features for predicting the target word in the current context. Formally, Given a sentence $S = \{w_1, w_2, \ldots, w_l\}$, the objective of CBOW is to maximize the average log probability:

$$\mathcal{L}(S)=\frac{1}{(l-2k-2)}\sum_{t=k+1}^{l-k}\log Pr(w_t|w_{t-k},\cdots,w_{t+k}) \quad (1)$$

Wherein, k is the context windows size of target word w_t. The prediction task is typically done via a softmax function, as follows:

$$Pr(w_t|w_{t-k},\cdots,w_{t+k}) = \frac{e^{y_{w_t}}}{\sum_{w_i \in V} e^{y_{w_i}}} \quad (2)$$

Each of $y_(w_t)$ is an un-normalized log-probability for each target word w_t, as follows:

$$y_{w_t} = \mathbf{U}h(w_{t-k},\ldots,w_{t+k});\mathbf{W}) + b \quad (3)$$

Wherein, $\mathbf{U}$ and b are softmax parameters. And $h(\cdot)$ is constructed by a concatenation or average of word vectors $\{\mathbf{w}_{t-k},\ldots,\mathbf{w}_{t+k}\}$ extracted from word matrix $\mathbf{W}$ according to $\{w_{t-k},\ldots,w_{t+k}\}$. For illustration purposes, we utilize average here. On the condition of average, the context vector c_t is obtained by averaging the embeddings of each word, as follows:

$$\mathbf{c}_t = \frac{1}{2k}\sum_{-k\le c\le k, c\neq 0}\mathbf{w}_{t+c} \quad (4)$$

The framework of Skip-Gram (Figure 1(b)) aims to predict context words given a target word w_t in a sliding window, instead of predicting the current word based on its context. Formally, given a sentence $S = \{w_1, w_2, \ldots, w_l\}$, the objective of Skip-Gram is to maximize the following average log probability:

$$\mathcal{L}(S)=\frac{1}{(l-2k)}\sum_{t=k+1}^{l-k}\sum_{-k\le c\le k, c\neq 0}\log Pr(w_{t+c}|w_t) \quad (5)$$

Wherein, $\mathbf{w}_t$ and $\mathbf{w}_c$ are respectively the vector representations of the target word w_t and the context word w_c. Usually, during the training stage of CBOW and Skip-Gram: (i) in order to make the models efficient for learning, the techniques of hierarchical softmax and negative sampling are used to ensure the models efficient for learning (Morin and Bengio, 2005; Mikolov et al., 2013a); (ii) the word vectors are trained by using stochastic gradient descent where the gradient is obtained via backpropagation (Rumelhart et al., 1986). After the training stage converges, words with similar meaning are mapped to a similar position in the semantic vector space. e.g., 'powerful' and 'strong' are close to each other.

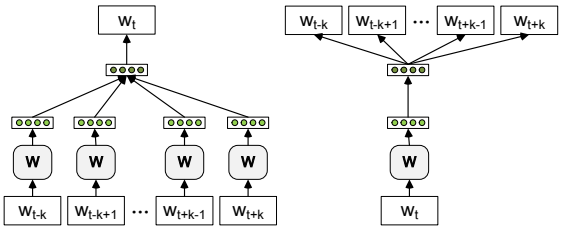

Figure 1: (a) CBOW model and (b) Skip-Gram model.

3.2 CSE based on CBOW Model

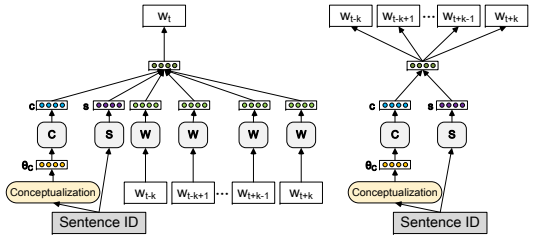
Intuitively, the proposed (attention-based) conceptual sentence embedding model for learning sentence vectors, is inspired by the methods for learning the word vectors. The inspiration is that, in researches of word embeddings: (i) The word vectors are asked to contribute to a prediction task about the target word or the surrounding words in the context; (ii) The word representation vectors are initialized randomly, however they could

finally capture precise semantics as an indirect result. Therefore, we will utilize this idea in our sentence vectors in a similar manner: The concept-associated sentence vectors are also asked to contribute to the prediction task of the target word or surrounding words in given contextual text windows. Furthermore, attention model will attribute different influence value to different contextual words.

We describe the first conceptual sentence embedding model, denoted as **CSE-1**, which is based on CBOW. In the framework of **CSE-1** (Figure 2(a)), each sentence, denoted by sentence ID, is mapped to a unique vector **s**, represented by a column in matrix **S**. And its concept distribution θ_C are generated from a knowledge-based text conceptualization algorithm (Wang et al., 2015c). Moreover, similar to word embedding methods, each word w_i is also mapped to a unique vector $\mathbf{w}_i$, represented by a column in matrix W. The surrounding words in contextual text window $\{w_{t-k}, \ldots, w_{t+k}\}$, sentence ID and concept distribution θ_C corresponding to this sentence are the inputs. Besides, **C** is a fixed linear operator similar to the one used in (Huang et al., 2013) that converts the concept distribution θ_C to a concept vector, denoted as **c**. Note that, this makes our model very different from (Le and Mikolov, 2014) where no concept information is used, and experimental results demonstrate the efficiency of introducing concept information. It is clear that **CSE-1** also does not take word order into consideration just like CBOW.

Afterward, the sentence vector **s**, surrounding word vectors $\{\mathbf{w}_{t-k}, \ldots, \mathbf{w}_{t+k}\}$ and the concept vector **c** are concatenated or averaged to predict the target word w_t in current context. In reality, the only change in this model compared to the word embedding method is in Eq. 3, where $h(\cdot)$ is constructed from not only **W** but also **C** and **S**. Note that, the sentence vector is shared across all contexts generated from the same sentence but not across sentences. Wherein, the contexts are fixed-length (length is $2k$) and sampled from a sliding window over the current sentence. However, the word matrix **W** is shared across sentences.

In summary, the procedure of **CSE-1** itself is described as follows. A probabilistic conceptualization algorithm (Wang et al., 2015c) is employed here to obtain the corresponding concepts about given sentence: Firstly, we preprosess and segment the given sentence into a set of words; Then, based on a probabilistic lexical knowledge-base Probase (Wu et al., 2012), the heterogeneous semantic graph for these words and their corresponding concepts are constructed (Figure 3 shows an example); Finally, we utilize a simple iterative process to identify the most likely mapping from words to concepts. After efforts above, we could conceptualize words in given sentence, and access the concepts and corresponding probabilities, which is the concept distribution θ_C mentioned before. Note that, the concept distribution yields an important influence on the entire framework of conceptual sentence embedding, by contributing greatly to the semantic representation.



(a) (b)

Figure 2: **CSE-1** model (a) and **CSE-2** model (b). Green circles indicate word embeddings, blue circles indicate concept embeddings, and purple circles indicate sentence embeddings. Besides, orange circles indicate concept distribution θ_C generated by knowledge-based text conceptualization algorithm.

During the training stage, we aim at obtaining word matrix **W**, sentence matrix **S**, and softmax weights $\{\mathbf{U}, b\}$ on already observed sentences. The techniques of hierarchical softmax and negative sampling are used to make the model efficient for learning. **W** and **S** are trained using stochastic gradient descent: At each step of stochastic gradient descent, we sample a fixed-length context from the given sentence, compute the error gradient which is obtained via backpropagation, and then use the gradient to update the parameters. During the inferring stage, we get sentence vectors for new sentences (unobserved before) by adding more columns in **S** and gradient descending on **S** while holding **W**, **U** and b fixed. Finally, we use **S** to make a prediction about multi-labels by using a standard classifier in output layer.

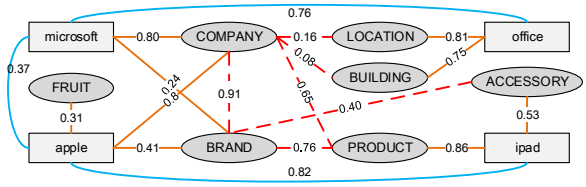


Figure 3: Semantic graph of example sentence microsoft unveils office for apples ipad. Rectangles indicate terms occurred in given sentence, and ellipses indicate concept defined in knowledge-base (e.g., Probase). Bule solid links indicate *isA* relationship between terms and concepts, and red dashed lines indicate correlation relationship between two concepts. Numerical values on the line is corresponding probabilities.

3.3 CSE based on Skip-Gram Model

The above method considers the combination of the sentence vector with the surrounding word vectors and concept vector to predict the target word in given text window. However, it loss information about word order somehow, just like CBOW. In fact, there exists another for modeling the prediction procedure: we could ignore the context words in the input, but force the model to predict words randomly sampled from the fix-length contexts in the output. As is shown in Figure 2 (b), only sentence vector **s** and concept vector **c** are used to predict the next word in a text window. That means, contextual words are no longer used as inputs, whereas they become what the output layer predict. Hence, this model is similar to the Skip-Gram model in word embedding (Mikolov et al., 2013b). In reality, what this means is that at each iteration of stochastic gradient descent, we sample a text window $\{w_{t-k}, \ldots, w_{t+k}\}$, then sample a random word from this text window and form a classification task given the sentence vector **s** and corresponding concept vector **c**.

We denote this sort of conceptual sentence embedding model as **CSE-2**. The scheme of **CSE-2** is similar to that of **CSE-1** as described above. In addition to being conceptually simple, **CSE-2** requires to store less data. We only need to store {**U**,b,**S**} as opposed to {**U**,b,**S**,**W**} in **CSE-1**.

3.4 CSE based on Attention Model

As mentioned above, setting a good value for contextual window size k is difficult. Because a larger value of k may introduce a degenerative behavior in the model, and more effort is spent predicting words that are conditioned on unrelated words, while a smaller value of k may lead to cases where the window size is not large enough include words that are semantically related (Bansal et al., 2014; Wang et al., 2015a). To solve these problems , we extend the proposed models by introducing attention model (Bahdanau et al., 2014; Rush et al., 2015), by allowing it to consider contextual words within the window in a non-uniform way. For illustration purposes, we extend **CSE-1** here with attention model. Following (Wang et al., 2015a), we rewrite Eq.(4) as follows:

$$\mathbf{c}_t = \frac{1}{2k} \sum_{-k \le c \le k, c \ne 0} a_{t+c}(w_{t+c}) \mathbf{w}_{t+c} \qquad (6)$$

Wherein we replace the average of the surrounding word vectors in Eq.(4) with a weighted sum of the these vectors. That means, each contextual word w_{t+c} is attributed a different attention level, representing how much the attention model believes whether it is important to look at in order to predict the target word w_t. The attention factor $a_i(w_i)$ for word w_i in position i is formulated as a softmax function over contextual words (Bahdanau et al., 2014), as follows:

$$a_i(w) = \frac{e^{d_{w,i}} + r_i}{\sum_{-k \le c \le k, c \ne 0} e^{d_{w,c}} + r_c} \qquad (7)$$

Wherein, $d_{w,i}$ is an element of matrix $\mathbf{D} \in \Re^{|V| * 2k}$, which is a set of parameters determining the importance of each word type in each relative position i (distance to the left/right of target word w_t). Moreover, r_i, an element of $\mathbf{R} \in \Re^{2k}$, is a bias, which is conditioned only on the relative position i. Note that, attention models have been reported expensive for large tables in terms of storage and performance (Bahdanau et al., 2014; Wang et al., 2015a). Nevertheless the computation consumption here is simple, and compute the attention of all words in the input requires $2k$ operations, as it simply requires retrieving on value from the lookup-matrix **D** for each word and one value from the bias vector **R** for each word in the context. Although this strategy may not be the best approach and there exist more elaborate attention models (Bahdanau et al., 2014; Luong et al., 2015), the proposed attention model is a proper balance of computational efficiency and complexity.

Thus, besides {**W**,**C**,**S**} in CSE models, **D** and **R** are added into parameter set which relates to

gradients of the loss function Eq.(1). All parameters are computed with backpropagation and updated after each training instance using a fixed learning rate. We denote the attention-based **CSE-1** model above as **aCSE-1**. With limitation of space, attention variant of **CSE-2**, denoted as **aCSE-2**, is not described here, however the principle is similar to **aCSE-1**.

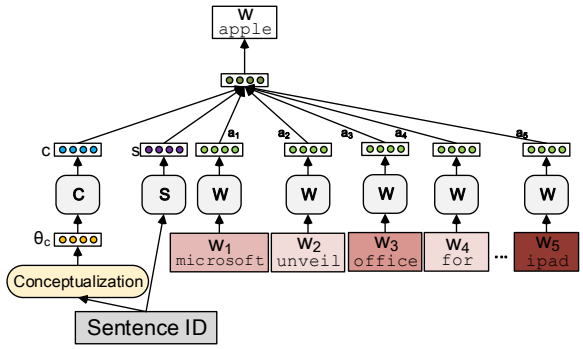

Figure 4: **aCSE-1** model. The illustration of example sentence 'mcrosoft unveils office for apple's ipad' for predicting word 'apple'.

Taking example 'microsoft unveils office for apple's ipad' into consideration. The prediction of the polysemy word 'apple' by **CSE-1** is shown in Figure 4, and darker cycle cell indicate higher attention value. We could observe that preposition word 'for' tend to be attributed very low attention, while context words, especially noun-words which contribute much to conceptualization (such as 'ipad', 'office', and 'microsoft') are attributed higher weights as these word own more predictive power. Wherein, 'ipad' is assigned the highest attention value as it close to the predicted word and co-occurs with it more frequently.

As described before, concept distribution θ_C yields a considerable influence on conceptual sentence embedding. This is because, each dimensionality of this distribution denotes the probability of the concept (topic or category) this sentence is respect to. In other words, the concept distribution is a solid semantic representation of the sentence. Nevertheless, the information in each dimensionality of sentence (or word) vector makes no sense. Hence, there exist a linear operator in **CSE-1**, **CSE-2**, **aCSE-1**, and **aCSE-2**, which transmit the concept distribution into word vector and sentence vector, as shown in Figure 2 and Figure 3.

4 Experiments and Results

In this section, we show experiments on two text understanding problems, text classification and information retrieval, to evaluate related models in several aspects. These tasks are always used to evaluate the performance of sentence embedding methods (Liu et al., 2015; Le and Mikolov, 2014). The source codes and datasets of this paper are publicly available[1].

4.1 Datasets

We utilize four datasets for training and evaluating. For text classification task, we use three datasets: **NewsTile**, **TREC** and **Twitter**. Dataset **Tweet11** is used for evaluation in information retrieval task. Moreover, we construct dataset **Wiki** to fully train topic model-based models.

NewsTitle: The news articles are extracted from a large news corpus, which contains about one million articles searched from Web pages. We organize volunteers to classify these news articles manually into topics according its article content (Song et al., 2015), and we select six topics: company, health, entertainment, food, politician, and sports. We randomly select 3,000 news articles in each topic, and only keep its title and its first one line of article. The average word count of titles is 9.41.

TREC: It is the corpus for question classification on TREC (Li and Roth, 2002), which is widely used as benchmark in text classification task. There are 5,952 sentences in the entire dataset, classified into the 6 categories as follows: person, abbreviation, entity, description, location and numeric.

Tweet11: This is the official tweet collections used in TREC Microblog Task 2011 and 2012 (Ounis et al., 2011; Soboroff et al., 2012). Using the official API, we crawled a set of local copies of the corpus. Our local Tweets11 collection has a sample of about 16 million tweets, and a set of 49 (TMB2011) and 60 (TMB2012) timestamped topics.

Twitter: This dataset is constructed by manually labeling the previous dataset Tweet11. Similar to dataset NewsTitle, we ask our volunteers to label these tweets. After manually labeling, the dataset contains 12,456 tweets which are in four

[1] http://hlipca.org/index.php/2014-12-09-02-55-58/2014-12-09-02-56-24/58-acse

categories: company, country, entertainment, and device. The average length of the tweets is 13.16 words. Because of its noise and sparsity, this social media dataset is very challenging for the comparative models.

Moreover, we also construct a Wikipedia dataset (denoted as **Wiki**) for training. We preprocess the Wikipedia articles[2] with the following rules. First, we remove the articles less than 100 words, as well as the articles less than 10 links. Then we remove all the category pages and disambiguation pages. Moreover, we move the content to the right redirection pages. Finally we obtain about 3.74 million Wikipedia articles for indexing and training.

4.2 Alternative Algorithms

We compare the proposed models with the following comparative algorithms.

BOW: It is a simple baseline which represents each sentence as bag-of-words, and uses TF-IDF scores (Salton and Mcgill, 1986) as features to generate sentence vector.

LDA: It represents each sentence as its topic distribution inferred by latent dirichlet allocation (Blei et al., 2003). We train this model in two ways: (i) on both Wikipedia articles and the evaluation datasets above, and (ii) only on the evaluation datasets. We report the better of the two.

PV: Paragraph Vector models are variable-length text embedding models, including the distributed memory model (**PV-DM**) and the distributed bag-of-words model (**PV-DBOW**). It has been reported to achieve the state-of-the-art performance on task of sentiment classification (Le and Mikolov, 2014), however it only utilizes word surface.

TWE: By taking advantage of topic model, it overcome ambiguity to some extent (Liu et al., 2015). Typically, TWE learn topic models on training set. It further learn topical word embeddings using the training set, then generate sentence embeddings for both training set and testing set. (Liu et al., 2015) proposed three models for topical word embedding, and we present the best results here. Besides, We also train TWE in two ways like **LDA**.

[2] `http://en.wikipedia.org/wiki/Wikipedia:Databasedown-load`

4.3 Experiment Setup

The details about parameter settings of the comparative algorithms are described in this section, respectively. For **TWE**, **CSE-1**, **CSE-2** and their attention variants **aCSE-1**, and **aCSE-2**, the structure of the hierarchical softmax is a binary Huffman tree (Mikolov et al., 2013a; Mikolov et al., 2013b), where short codes are assigned to frequent words. This is a good speedup trick because common words are accessed quickly (Le and Mikolov, 2014).We set the dimensions of sentence, word, topic and concept embeddings as 5,000, which is like the number of concept clusters in Probase (Wu et al., 2012; Wang et al., 2015c). Meanwhile, we have done many experiments on choosing the context window size (k). We perform experiments on increasing windows size from 3 to 11, and different size works differently on different dataset with different average length of short-texts. And we choose the result of windows size of 5 present here, because it performs best in almost datasets. Usually, in project layer, the sentence vector, the context vector and the concept vectors could be averaged or concatenated for combination to predict the next word in a context. We perform experiments following these two strategies respectively, and report the better of the two. In fact, the concatenation performs better since averaging different types of vectors may cause loss of information somehow.

For **BOW** and **LDA**, we remove stop words by using InQuery stop-word list. For **BOW**, we select top 50,000 words according to TF-IDF scores as features. For both **LDA** and **TWE**, in the text classification task, we set the topic number to be the cluster number or twice, and report the better of the two; while in the information retrieval task, we experimented with a varying number of topics from 100 to 500, which gives similar performance, and we report the final results of using 500 topics.

In summary, we use the sentence vectors generated by each algorithm as features and run a linear classifier using Liblinear (Fan et al., 2010) for evaluation.

4.4 Text Classification

In this section, we run the multi-class text classification experiments on the dataset **NewsTitle**, **Twitter**, and **TREC**. We report precision, recall and F-measure for comparison (as shown in Table 1). Statistical t-test are employed here. To de-

	NewsTitle			Twitter			TREC

Table 1: Evaluation results of multi-class text classification task.

cide whether the improvement by method A over method B is significant, the t-test calculates a value p based on the performance of A and B. The smaller p is, the more significant is the improvement. If the p is small enough ($p < 0.05$), we conclude that the improvement is statistically significant. In Table 1, the superscript α and β respectively denote statistically significant improvements over **TWE** and **PV-DM**.

Without regard to attention-based model firstly, we could conclude that **CSE-2** outperforms all the baselines significantly (expect for recall in **Twitter**). This fully indicates that the proposed model could capture more precise semantic information of sentence as compared to topic model-based models and other embedding models. Because the concepts we obtained contribute significantly to the semantic representation of sentence, meanwhile suffer slightly from texts noisy and sparsity. Moreover, as compared to **BOW**, **CSE-1** and **CSE-2** manage to reduce the feature space by 90 percent, while among them, **CSE-2** needs to store less data comparing with **CSE-1**. By introducing attention model, performances of CSE models are entirely promoted, as compared **aCSE-2** with original **CSE-2**, which demonstrates the advantage of attention model.

PV-DM and **PV-DBOW** are reported as the state-of-the-art model for sentence embedding. From the results we can also see that, the proposed model **CSE-2** and **aCSE-2** significantly outperforms **PV-DBOW**. As expected, **LDA** performs worst, even worse than **BOW**, because it is trained on very sparse short-texts (i.e., question and social media text), where there is no enough statistical information to infer word co-occurrence and word topics, and latent topic model suffer extremely from the sparsity of the short-text. Besides, the number of topics slightly impacts the performance of **LDA**. In future, we may conduct more experiments to explore genuine reasons. As described in section 3, **aCSE-2** (**CSE-2**) performs better than **aCSE-1** (**CSE-1**), because the former one take word order into consideration. Based on Skip-Gram similarly, **CSE-2** outperforms **TWE**. Although **TWE** aims at enhancing sentence representation by using topic model, neither parsing nor topic modeling would work well because short-texts lack enough signals for inference. Whats more, sentence embeedings are generated by simple aggregating over all topical word embeddings of each word in this sentence in **TWE**, which limits its capability of semantic representation.

Overall, nearly all the alternative algorithms perform worse on **Twitter**, especially **LDA** and **TWE**. This is mainly because that data in **Twitter** are more challenging for topic model as short-texts are noisy, sparse, and ambiguous. Although the training on larger corpus, i.e., way (i), contributes greatly to improving the performance of these topic-model based algorithms, they only have similar performance to **CSE-1** and could not transcend the attention-based variants. Certainly, we could also train **TWE** (even **LDA**) on a very larger corpus, and could expect a letter better results. However, training latent topic model on very large dataset is very slow, although many fast algorithms of topic models are available (Smola and Narayanamurthy, 2010; Ahmed et al., 2012). Whats more, from the complexity analysis, we could conclude that, compared with **PV**, **CSE** only need a little more space to store look-ups matrix **D**

and **R**; while compared with **CSE** and **PV**, **TWE** require more parameters to store more discriminative information for word embedding.

4.5 Information Retrieval

The information retrieval task is also utilized to evaluate the proposed models, and we want to examine whether a sentence should be retrieved given a query. Specially, we mainly focus on short-text retrieval by utilizing official tweet collection **Tweet11**, which is the benchmark dataset for microblog retrieval. We index all tweets in this collection by using Indri toolkit, and then perform a general relevance-pseudo feedback procedure, as follows: (i) Given a query, we firstly obtain associated tweets, which are before query issue time, via preliminary retrieval as feedback tweets. (ii) We generate the sentence representation vector of both original query and these feedback tweets by the alternative algorithms above. (iii) With efforts above, we compute cosine scores between query vector and each tweet vector to measure the semantic similarity between the query and candidate tweets, and then re-rank the feedback tweets with descending cosine scores.

We utilize the official metric for the TREC Microblog track, i.e., Precision at 30 (P@30), and Mean Average Precision (MAP), for evaluating the ranking performance of different algorithms. Experimental results for this task are shown in Table 2. Besides, we also operate a query-by-query analysis and conduct t-test to demonstrate the improvements on both metrics are statistically significant. In Table 2, the superscript α and β respectively denote statistically significant improvements over **TWE** and **PV-DM** ($p < 0.05$).

As shown in Table 2, the **CSE-2** significantly outperforms all these models, and exceeds the best baseline model (**TWE**) by 11.9% in MAP and 4.5% in P@30, which is a statistically significant improvement. Without regard to attention-based model firstly, such an improvement comes from the **CSE-2**'s ability to embed the contextual and semantic information of the sentences into a finite dimension vector. Topic model based algorithms (e.g., **LDA** and **TWE**) suffer extremely from the sparsity and noise of tweet collection. For the twitter data, since we are not able to find appropriate long texts, latent topic models are not performed.

We could observe that attention-based CSE model (**aCSE-1** and **aCSE-2**) improves over original CSE model (**CSE-1** and **CSE-2**). However, attention model promotes **CSE-1** significantly, while **aCSE-2** obtain similar results compared to **CSE-2**, indicating that attention model leads to small improvement for Skip-Gram based CSE model. We argue that it is because Skip-Gram itself gives less weight to the distant words by sampling less from those words, which is essentially similar to attention model somehow.

	TMB2011		TMB2012	
Model	**MAP**	**P@30**	**MAP**	**P@30**
BOW	0.304	0.412	0.321	0.494

Table 2: Results of information retrieval.

5 Conclusion

By inducing concept information, the proposed conceptual sentence embedding maintains and enhances the semantic information of sentence embedding. Furthermore, we extend the proposed models by introducing attention model, which allows it to consider contextual words within the window in a non-uniform way while maintaining the efficiency. We compare them with different algorithms, including bag-of-word models, topic model-based model and other state-of-the-art sentence embedding models. The experimental results demonstrate that the proposed method performs the best and shows improvement over the compared methods, especially for short-texts.

Abstract

Most current chatbot engines are designed to reply to user utterances based on existing utterance-response (or Q-R)[1] pairs. In this paper, we present DocChat, a novel information retrieval approach for chatbot engines that can leverage unstructured documents, instead of Q-R pairs, to respond to utterances. A learning to rank model with features designed at different levels of granularity is proposed to measure the relevance between utterances and responses directly. We evaluate our proposed approach in both English and Chinese: (i) For English, we evaluate DocChat on WikiQA and QASent, two answer sentence selection tasks, and compare it with state-of-the-art methods. Reasonable improvements and good adaptability are observed. (ii) For Chinese, we compare DocChat with XiaoIce[2], a famous chitchat engine in China, and side-by-side evaluation shows that DocChat is a perfect complement for chatbot engines using Q-R pairs as main source of responses.

1 Introduction

Building chatbot engines that can interact with humans with natural language is one of the most challenging problems in artificial intelligence. Along with the explosive growth of social media, like community question answering (CQA) websites (e.g., Yahoo Answers and WikiAnswers) and social media websites (e.g., Twitter and Weibo), the amount of utterance-response (or Q-R) pairs has experienced massive growth in recent years, and such a corpus greatly promotes the emergence of various data-driven chatbot approaches.

Instead of multiple rounds of conversation, we only consider a much simplified task, short text conversation (STC) in which the response $\mathcal{R}$ is a short text and only depends on the last user utterance $\mathcal{Q}$. Previous methods for the STC task mostly rely on Q-R pairs and fall into two categories: **Retrieval-based methods** (e.g., Ji et al., 2014). This type of methods first retrieve the most possible $\langle \hat{\mathcal{Q}}, \hat{\mathcal{R}} \rangle$ pair from a set of existing Q-R pairs, which best matches current utterance $\mathcal{Q}$ based on semantic matching models, then take $\hat{\mathcal{R}}$ as the response $\mathcal{R}$. One disadvantage of such a method is that, for many specific domains, collecting such Q-R pairs is intractable. **Generation based methods** (e.g., Shang et al., 2015). This type of methods usually uses an encoder-decoder framework which first encode $\mathcal{Q}$ as a vector representation, then feed this representation to decoder to generate response $\mathcal{R}$. Similar to retrieval-based methods, such approaches also depend on existing Q-R pairs as training data. Like other language generation tasks, such as machine translation and paraphrasing, the fluency and naturality of machine generated text is another drawback.

To overcome the issues mentioned above, we present a novel response retrieval approach, **DocChat**, to find responses based on unstructured documents. For each user utterance, instead of looking for the best Q-R pair or generating a word sequence based on language generation techniques, our method selects a sentence from given documents directly, by ranking all possible sentences based on features designed at different levels of granularity. On one hand, using documents rather than Q-R pairs greatly improve the adapt-

[*]Contribution during internship at Microsoft Research.

[1]For convenience sake, we denote all utterance-response pairs (either QA pairs or conversational exchanges from social media websites like Twitter) as Q-R pairs in this paper.

[2]http://www.msxiaoice.com

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 516–525,
Berlin, Germany, August 7-12, 2016.

ability of chatbot engines on different chatting topics. On the other hand, all responses come from existing documents, which guarantees their fluency and naturality. We also show promising results in experiments, on both QA and chatbot scenarios.

2 Task Description

Formally, given an utterance $\mathcal{Q}$ and a document set $\mathcal{D}$, the document-based chatbot engine retrieves response $\mathcal{R}$ based on the following three steps:

- *response retrieval*, which retrieves response candidates $\mathcal{C}$ from $\mathcal{D}$ based on $\mathcal{Q}$:

$$\mathcal{C} = Retrieve(\mathcal{Q}, \mathcal{D})$$

  Each $\mathcal{S} \in \mathcal{C}$ is a sentence existing in $\mathcal{D}$.

- *response ranking*, which ranks all response candidates in $\mathcal{C}$ and selects the most possible response candidate as $\hat{\mathcal{S}}$:

$$\hat{\mathcal{S}} = \arg\max_{\mathcal{S} \in \mathcal{C}} Rank(\mathcal{S}, \mathcal{Q})$$

- *response triggering*, which decides whether it is confident enough to response $\mathcal{Q}$ using $\hat{S}$:

$$\mathcal{I} = Trigger(\hat{\mathcal{S}}, \mathcal{Q})$$

  where $\mathcal{I}$ is a binary value. When $\mathcal{I}$ equals to $true$, let the response $\mathcal{R} = \hat{\mathcal{S}}$ and output $\mathcal{R}$; otherwise, output nothing.

In the following three sections, we will describe solutions of these three components one by one.

3 Response Retrieval

Given a user utterance $\mathcal{Q}$, the goal of response retrieval is to efficiently find a small number of sentences from $\mathcal{D}$, which have high possibility to contain suitable sentences as $\mathcal{Q}$'s response. Although it is not necessarily true that a good response always shares more words with a given utterance, this measurement is still helpful in finding possible response candidates (Ji et al., 2014).

In this paper, the BM25 term weighting formulas (Jones et al., 2000) is used to retrieve response candidates from documents. Given each document $\mathcal{D}_k \in \mathcal{D}$, we collect a set of sentence triples $\langle \mathcal{S}^{prev}, \mathcal{S}, \mathcal{S}^{next} \rangle$ from $\mathcal{D}_k$, where $\mathcal{S}$ denotes a sentence in $\mathcal{D}_k$, $\mathcal{S}^{prev}$ and $\mathcal{S}^{next}$ denote $\mathcal{S}$'s previous sentence and next sentence respectively. Two special tags, $\langle BOD \rangle$ and $\langle EOD \rangle$, are added at the beginning and end of each passage, to make sure that such sentence triples can be extracted for every sentence in the document. The reason for indexing each sentence together with its context sentences is intuitive: If a sentence within a document can respond to an utterance, then its context should be revelent to the utterance as well.

4 Response Ranking

Given a user utterance $\mathcal{Q}$ and a response candidate $\mathcal{S}$, the ranking function $Rank(\mathcal{S}, \mathcal{Q})$ is designed as an ensemble of individual matching features:

$$Rank(\mathcal{S}, \mathcal{Q}) = \sum_k \lambda_k \cdot h_k(\mathcal{S}, \mathcal{Q})$$

where $h_k(\cdot)$ denotes the k-th feature function, λ_k denotes $h_k(\cdot)$'s corresponding weight.

We design features at different levels of granularity to measure the relevance between S and Q, including *word-level*, *phrase-level*, *sentence-level*, *document-level*, *relation-level*, *type-level* and *topic-level*, which will be introduced below.

4.1 Word-level Feature

We define three word-level features in this work: (1) $h_{WM}(\mathcal{S}, \mathcal{Q})$ denotes a word matching feature that counts the number (weighted by the *IDF* value of each word in $\mathcal{S}$) of non-stopwords shared by $\mathcal{S}$ and $\mathcal{Q}$. (2) $h_{W2W}(\mathcal{S}, \mathcal{Q})$ denotes a word-to-word translation-based feature that calculates the IBM model 1 score (Brown et al., 1993) of $\mathcal{S}$ and $\mathcal{Q}$ based on word alignments trained on 'question-related question' pairs using GIZA++ (Och and Ney, 2003). (3) $h_{W2V}(\mathcal{S}, \mathcal{Q})$ denotes a word embedding-based feature that calculates the average cosine distance between word embeddings of all non-stopword pairs $\langle v_{\mathcal{S}_j}, v_{\mathcal{Q}_i} \rangle$. $v_{\mathcal{S}_j}$ represent the word vector of j^{th} word in $\mathcal{S}$ and $v_{\mathcal{Q}_j}$ represent the word vector of i^{th} word in $\mathcal{Q}$.

4.2 Phrase-level Feature

4.2.1 Paraphrase

We first describe how to extract phrase-level paraphrases from an existing SMT (statistical machine translation) phrase table.

$PT = \{\langle s_i, t_i, p(t_i|s_i), p(s_i|t_i) \rangle\}$[3] is a phrase table, which is extracted from a bilingual corpus, where s_i (or t_i) denotes a phrase, in source

[3]We omit lexical weights that are commonly used in phrase tables, as they are not useful in paraphrase extraction.

(or target) language, $p(t_i|s_i)$ (or $p(s_i|t_i)$) denotes the translation probability from s_i (or t_i) to t_i (or s_i). We follow Bannard and Callison-Burch (2005) to extract a paraphrase table $PP = \{\langle s_i, s_j, score(s_j; s_i)\rangle\}$. s_i and s_j denote two phrases in source language, $score(s_j; s_i)$ denotes a confidence score that s_i can be paraphrased to s_j, which is computed based on PT:

$$score(s_j; s_i) = \sum_t \{p(t|s_i) \cdot p(s_j|t)\}$$

The underlying idea of this approach is that, two source phrases that are aligned to the same target phrase trend to be paraphrased.

We then define a paraphrase-based feature as:

$$h_{PP}(\mathcal{S}, \mathcal{Q}) = \frac{\sum_{n=1}^{N} \frac{\sum_{j=0}^{|\mathcal{S}|-n} Count_{PP}(\mathcal{S}_j^{j+n-1}, \mathcal{Q})}{|\mathcal{S}|-n+1}}{N}$$

where $\mathcal{S}_j^{j+n-1}$ denotes the consecutive word sequence (or phrase) in $\mathcal{S}$, which starts from $\mathcal{S}_j$ and ends with $\mathcal{S}_{j+n-1}$, N denotes the maximum n-gram order (here is 3). $Count_{PP}(\mathcal{S}_j^{j+n-1}, \mathcal{Q})$ is computed based on the following rules:

- If $\mathcal{S}_j^{j+n-1} \in \mathcal{Q}$, then $Count_{PP}(\mathcal{S}_j^{j+n-1}, \mathcal{Q}) = 1$;
- Else, if $\langle \mathcal{S}_j^{j+n-1}, s, score(s; \mathcal{S}_j^{j+n-1})\rangle \in PP$ and $\mathcal{S}_j^{j+n-1}$'s paraphrase s occurs in $\mathcal{Q}$, then $Count_{PP}(\mathcal{S}_j^{j+n-1}, \mathcal{Q}) = score(s; \mathcal{S}_j^{j+n-1})$
- Else, $Count_{PP}(\mathcal{S}_j^{j+n-1}, \mathcal{Q}) = 0$.

4.2.2 Phrase-to-Phrase Translation

Similar to $h_{PP}(\mathcal{S}, \mathcal{Q})$, a phrase translation-based feature based on a phrase table PT is defined as:

$$h_{PT}(\mathcal{S}, \mathcal{Q}) = \frac{\sum_{n=1}^{N} \frac{\sum_{j=0}^{|\mathcal{S}|-n} Count_{PT}(\mathcal{S}_j^{j+n-1}, \mathcal{Q})}{|\mathcal{S}|-n+1}}{N}$$

where $Count_{PT}(\mathcal{S}_j^{j+n-1}, \mathcal{Q})$ is computed based on the following rules:

- If $\mathcal{S}_j^{j+n-1} \in \mathcal{Q}$, then $Count_{PT}(\mathcal{S}_j^{j+n-1}, \mathcal{Q}) = 1$;
- Else, if $\langle \mathcal{S}_j^{j+n-1}, s, p(\mathcal{S}_j^{j+n-1}|s), p(s|\mathcal{S}_j^{j+n-1})\rangle \in PT$ and $\mathcal{S}_j^{j+n-1}$'s translation $s \in \mathcal{Q}$, then $Count_{PT}(\mathcal{S}_j^{j+n-1}, \mathcal{Q}) = p(\mathcal{S}_j^{j+n-1}|s) \cdot p(s|\mathcal{S}_j^{j+n-1})$
- Else, $Count_{PT}(\mathcal{S}_j^{j+n-1}, \mathcal{Q}) = 0$

We train a phrase table based on 'question-answer' pairs crawled from community QA websites.

4.3 Sentence-level Feature

We first present an attention-based sentence embedding method based on a convolution neural network (CNN), whose input is a sentence pair and output is a sentence embedding pair. Two features will be introduced in Section 4.3.1 and 4.3.2, which are designed based on two sentence embedding models trained using different types of data.

In the input layer, given a sentence pair $\langle \mathcal{S}_X, \mathcal{S}_Y\rangle$, an attention matrix $\mathcal{A} \in R^{|\mathcal{S}_X|\times|\mathcal{S}_Y|}$ is generated based on pre-trained word embeddings of $\mathcal{S}_X$ and $\mathcal{S}_Y$, where each element $\mathcal{A}_{i,j} \in \mathcal{A}$ is computed as:

$$\mathcal{A}_{i,j} = cosine(v_i^{\mathcal{S}_X}, v_j^{\mathcal{S}_Y})$$

where $v_i^{\mathcal{S}_X}$ (or $v_j^{\mathcal{S}_Y}$) denotes the embedding vector of the i^{th} (or j^{th}) word in $\mathcal{S}_X$ (or $\mathcal{S}_Y$).

Then, column-wise and row-wise max-pooling are applied to $\mathcal{A}$ to generate two attention vectors $V^{\mathcal{S}_X} \in R^{|\mathcal{S}_X|}$ and $V^{\mathcal{S}_Y} \in R^{|\mathcal{S}_Y|}$, where the k^{th} elements of $V^{\mathcal{S}_X}$ and $V^{\mathcal{S}_Y}$ are computed as:

$$V_k^{\mathcal{S}_X} = \max_{1<l<|\mathcal{S}_Y|} \{\mathcal{A}_{k,l}\} \; and \; V_k^{\mathcal{S}_Y} = \max_{1<l<|\mathcal{S}_X|} \{\mathcal{A}_{l,k}\}$$

$V_k^{\mathcal{S}_X}$ (or $V_k^{\mathcal{S}_Y}$) can be interpreted as the *attention score* of the k^{th} word in $\mathcal{S}_X$ (or $\mathcal{S}_Y$) with regard to all words in $\mathcal{S}_Y$ (or $\mathcal{S}_X$).

Next, two *attention distributions* $D^{\mathcal{S}_X} \in R^{|\mathcal{S}_X|}$ and $D^{\mathcal{S}_Y} \in R^{|\mathcal{S}_Y|}$ are generated for $\mathcal{S}_X$ and $\mathcal{S}_Y$ based on $V^{\mathcal{S}_X}$ and $V^{\mathcal{S}_Y}$ respectively, where the k^{th} elements of $D^{\mathcal{S}_X}$ and $D^{\mathcal{S}_Y}$ are computed as:

$$D_k^{\mathcal{S}_X} = \frac{e^{V_k^{\mathcal{S}_X}}}{\sum_{l=1}^{|\mathcal{S}_X|} e^{V_l^{\mathcal{S}_X}}} \; and \; D_k^{\mathcal{S}_\mathcal{Y}} = \frac{e^{V_k^{\mathcal{S}_Y}}}{\sum_{l=1}^{|\mathcal{S}_Y|} e^{V_l^{\mathcal{S}_Y}}}$$

$D_k^{\mathcal{S}_\mathcal{X}}$ (or $D_k^{\mathcal{S}_\mathcal{Y}}$) can be interpreted as the *normalized attention score* of the k^{th} word in $\mathcal{S}_X$ (or $\mathcal{S}_Y$) with regard to all words in $\mathcal{S}_Y$ (or $\mathcal{S}_X$).

Last, we update each pre-trained word embedding $v_k^{\mathcal{S}_X}$ (or $v_k^{\mathcal{S}_Y}$) to $\hat{v}_k^{\mathcal{S}_X}$ (or $\hat{v}_k^{\mathcal{S}_Y}$), by multiplying every value in $v_k^{\mathcal{S}_X}$ (or $v_k^{\mathcal{S}_Y}$) with $D_k^{\mathcal{S}_X}$ (or $D_k^{\mathcal{S}_Y}$). The underlying intuition of updating pre-trained word embeddings is to *re-weight the importance of each word in $\mathcal{S}_X$ (or $\mathcal{S}_Y$) based on $\mathcal{S}_Y$ (or $\mathcal{S}_X$), instead of treating them in an equal manner.*

In the convolution layer, we first derive an input matrix $Z_{\mathcal{S}_X} = \{l_1, ..., l_{|\mathcal{S}_X|}\}$, where l_t is the concatenation of a sequence of $m = 2d-1$[4] updated word embeddings $[\hat{v}_{t-d}^{\mathcal{S}_X}, ..., \hat{v}_t^{\mathcal{S}_X}, ..., \hat{v}_{t+d}^{\mathcal{S}_X}]$, centralized in the t^{th} word in $\mathcal{S}_X$. Then, the convo-

[4] In this paper, m is set to 3.

lution layer performs sliding window-based feature extraction to project each vector representation $l_t \in Z_{\mathcal{S}_X}$ to a contextual feature vector $h_t^{\mathcal{S}_X}$:

$$h_t^{\mathcal{S}_X} = tanh(W_c \cdot l_t)$$

where W_c is the convolution matrix, $tanh(x) = \frac{1-e^{-2x}}{1+e^{-2x}}$ is the activation function. The same operation is performed to $\mathcal{S}_Y$ as well.

In the pooling layer, we aggregate local features extracted by the convolution layer from $\mathcal{S}_X$, and form a sentence-level global feature vector with a fixed size independent of the length of the input sentence. Here, *max-pooling* is used to force the network to retain the most useful local features by $l_p^{\mathcal{S}_X} = [v_1^{\mathcal{S}_X}, ..., v_K^{\mathcal{S}_X}]$, where:

$$v_i^{\mathcal{S}_X} = \max_{t=1,...,|\mathcal{S}_X|} \{h_t^{\mathcal{S}_X}(i)\}$$

$h_t^{\mathcal{S}_X}(i)$ denotes the i^{th} value in the vector $h_t^{\mathcal{S}_X}$. The same operation are performed to $\mathcal{S}_Y$ as well.

In the output layer, one more non-linear transformation is applied to $l_p^{\mathcal{S}_X}$:

$$y(\mathcal{S}_X) = tanh(W_s \cdot l_p^{\mathcal{S}_X})$$

W_s is the semantic projection matrix, $y(\mathcal{S}_X)$ is the final sentence embedding of $\mathcal{S}_X$. The same operation is performed to $\mathcal{S}_Y$ to obtain $y(\mathcal{S}_Y)$.

We train model parameters W_c and W_s by minimizing the following ranking loss function:

$$L = \max\{0, M - cosine(y(\mathcal{S}_X), y(\mathcal{S}_Y)) + cosine(y(\mathcal{S}_X), y(\mathcal{S}_Y^-))\}$$

where M is a constant, $\mathcal{S}_Y^-$ is a negative instance.

4.3.1 Causality Relationship Modeling

We train the first attention-based sentence embedding model based on a set of 'question-answer' pairs as input sentence pairs, and then design a causality relationship-based feature as:

$$h_{SCR}(\mathcal{S}, \mathcal{Q}) = cosine(y_{SCR}(\mathcal{S}), y_{SCR}(\mathcal{Q}))$$

$y_{SCR}(\mathcal{S})$ and $y_{SCR}(\mathcal{Q})$ denote the sentence embeddings of $\mathcal{S}$ and $\mathcal{Q}$ respectively. We expect this feature captures the *causality relationship* between questions and their corresponding answers, and works on *question-like utterances*.

4.3.2 Discourse Relationship Modeling

We train the second attention-based sentence embedding model based on a set of 'sentence-next sentence' pairs as input sentence pairs, and then design a discourse relationship-based feature as:

$$h_{SDR}(\mathcal{S}, \mathcal{Q}) = cosine(y_{SDR}(\mathcal{S}), y_{SDR}(\mathcal{Q}))$$

$y_{SDR}(\mathcal{S})$ and $y_{SDR}(\mathcal{Q})$ denote the sentence embeddings of $\mathcal{S}$ and $\mathcal{Q}$ respectively. We expect this feature learns and captures the *discourse relationship* between sentences and their next sentences, and works on *statement-like utterances*. Here, a large number of 'sentence-next sentence' pairs can be easily obtained from documents.

4.4 Document-level Feature

We take document-level information into consideration to measure the semantic similarity between $\mathcal{Q}$ and $\mathcal{S}$, and define two context features as:

$$h_{DM}(\mathcal{S}^*, \mathcal{Q}) = cosine(y_{SCR}(\mathcal{S}^*), y_{SCR}(\mathcal{Q}))$$

where $\mathcal{S}^*$ can be $\mathcal{S}^{prev}$ and $\mathcal{S}^{next}$ that denote previous and next sentences of $\mathcal{S}$ in the original document. The sentence embedding model trained based on 'question-answer' pairs (in Section 4.3.1) is directly used to generate context embeddings for $h_{DM}(\mathcal{S}^{prev}, \mathcal{Q})$ and $h_{DM}(\mathcal{S}^{next}, \mathcal{Q})$. So no further training data is needed for this feature.

4.5 Relation-level Feature

Given a structured knowledge base, such as Freebase[5], a single relation question $\mathcal{Q}$ (in natural language) with its answer can be first parsed into a fact formatted as $\langle e_{sbj}, rel, e_{obj} \rangle$, where e_{sbj} denotes a subject entity detected from the question, rel denotes the relationship expressed by the question, e_{obj} denotes an object entity found from the knowledge base based on e_{sbj} and rel. Then we can get $\langle \mathcal{Q}, rel \rangle$ pairs. This rel can help for modeling semantic relationships between $\mathcal{Q}$ and $\mathcal{R}$. For example, the Q-A pair $\langle$*What does Jimmy Neutron do? – inventor*$\rangle$ can be parsed into $\langle$*Jimmy Neutron, fictional_character_occupation, inventor*$\rangle$ where the rel is *fictional_character_occupation*.

Similar to Yih et al. (2014), We use $\langle \mathcal{Q}, rel \rangle$ pairs as training data, and learn a *rel*-CNN model, which can encode each question $\mathcal{Q}$ (or each relation rel) into a relation embedding. For a given question $\mathcal{Q}$, the corresponding relation rel^+ is

[5]http://www.freebase.com/

treated as a positive example, and randomly selected other relations are used as negative examples rel^-. The posterior probability of rel^+ given $\mathcal{Q}$ is computed as:

$$P(rel^+|\mathcal{Q}) = \frac{e^{cosine(y(rel^+),y(\mathcal{Q}))}}{\sum_{rel^-} e^{cosine(y(rel^-),y(\mathcal{Q}))}}$$

$y(rel)$ and $y(\mathcal{Q})$ denote relation embeddings of rel and $\mathcal{Q}$ based on *rel*-CNN. *rel*-CNN is trained by maximizing the log-posterior.

We then define a relation-based feature as:

$$h_{RE}(\mathcal{S}, \mathcal{Q}) = cosine(y_{RE}(\mathcal{Q}), y_{RE}(\mathcal{S}))$$

$y_{RE}(\mathcal{S})$ and $y_{RE}(\mathcal{Q})$ denote relation embeddings of $\mathcal{S}$ and $\mathcal{Q}$ respectively, coming from *rel*-CNN.

4.6 Type-level Feature

We extend each $\langle \mathcal{Q}, e_{sbj}, rel, e_{obj} \rangle$ in the SimpleQuestions data set to $\langle \mathcal{Q}, e_{sbj}, rel, e_{obj}, type \rangle$, where $type$ denotes the type name of e_{obj} based on Freebase. Thus, we obtain $\langle \mathcal{Q}, type \rangle$ pairs.

Similar to *rel*-CNN, we use $\langle \mathcal{Q}, type \rangle$ pairs to train another CNN model, denoted as *type*-CNN. Based on which, we define a type-based feature as:

$$h_{TE}(\mathcal{S}, \mathcal{Q}) = cosine(y_{TE}(\mathcal{Q}), y_{TE}(\mathcal{S}))$$

$y_{TE}(\mathcal{S})$ and $y_{TE}(\mathcal{Q})$ denote type embeddings of $\mathcal{S}$ and $\mathcal{Q}$ respectively, coming from *type*-CNN.

4.7 Topic-level Feature

4.7.1 Unsupervised Topic Model

As the assumption that Q-R pair should share similar topic distribution, We define an unsupervised topic model-based feature h_{UTM} as the average cosine distance between topic vectors of all non-stopword pairs $\langle v_{\mathcal{S}_j}, v_{\mathcal{Q}_i} \rangle$, where $v_w = [p(t_1|w), ..., p(t_N|w)]^T$ denotes the topic vector of a given word w. Given a corpus, various topic modeling methods, such as pLSI (probabilistic latent semantic indexing) and LDA (latent Dirichlet allocation), can be used to estimate $p(t_i|w)$, which denotes the probability that w belongs to a topic t_i.

4.7.2 Supervised Topic Model

One shortcoming of the unsupervised topic model is that, the topic size is pre-defined, which might not reflect the truth on a specific corpus. In this paper, we explore a supervised topic model approach as well, based on 'sentence-topic' pairs.

We crawl a large number of $\langle \mathcal{S}, topic \rangle$ pairs from Wikipedia documents, where $\mathcal{S}$ denotes a sentence, $topic$ denotes the content name of the section that $\mathcal{S}$ extracted from. Such content names are labeled by Wikipedia article editors, and can be found in the *Contents* fields.

Similar to *rel*-CNN and *type*-CNN, we use the $\langle \mathcal{S}, topic \rangle$ pairs to train another CNN model, denoted as *topic*-CNN. Based on which, we define a supervised topic model-based feature as:

$$h_{STM}(\mathcal{S}, \mathcal{Q}) = cosine(y_{STM}(\mathcal{S}), y_{STM}(\mathcal{Q}))$$

$y_{STM}(\mathcal{S})$ and $y_{STM}(\mathcal{Q})$ denote topic embeddings of $\mathcal{S}$ and $\mathcal{Q}$ respectively, coming from *topic*-CNN.

4.8 Learning to Ranking Model

We employ a regression-based learning to rank method (Nallapati, 2004) to train response ranking model, based on a set of labeled $\langle \mathcal{Q}, \mathcal{C} \rangle$ pairs, Feature weights in the ranking model are trained by SGD based on the training data that consists of a set of $\langle \mathcal{Q}, \mathcal{C} \rangle$ pairs, where $\mathcal{Q}$ denotes a user utterance and $\mathcal{C}$ denotes a set of response candidates. Each candidate $\mathcal{S}$ in $\mathcal{C}$ is labeled by $+$ or $-$, which indicates whether $\mathcal{S}$ is a suitable response of $\mathcal{Q}$ $(+)$, or not $(-)$.

As manually labeled data, such as WikiQA (Yang et al., 2015), needs expensive human annotation effort, we propose an automatic way to collect training data. First, 'question-answer' (or Q-A) pairs $\{Q_i, A_i\}_{i=1}^M$ are crawled from community QA websites. Q_i denotes a question. A_i denotes Q_i's answer, which includes one or more sentences $A_i = \{s_1, ..., s_K\}$. Then, we index answer sentences of all questions. Next, for each question Q_i, we run response retrieval to obtain answer sentence candidates $\mathcal{C}_i = \{s_1^{'}, ..., s_N^{'}\}$. Last, if we know the correct answer sentences of each question Q_i, we can then label each candidate in $\mathcal{C}_i$ as $+$ or $-$. In experiments, manually labeled data (WikiQA) is used in open domain question answering scenario, and automatically generated data is used in chatbot scenario.

5 Response Triggering

There are two types of utterances, *chit-chat utterances* and *informative utterances*. The former should be handled by chit-chat engines, and the latter is more suitable to our work, as documents usually contain formal and informative contents. Thus, we have to respond to informative utterances only. Response retrieval cannot always guarantee to return a candidate set that contains

at least one suitable response, but response ranking will output the best possible candidate all the time. So, we have to decide which responses are confident enough to be output, and which are not.

In this paper, we define *response triggering* as a function that decides whether a response candidate $\mathcal{S}$ has enough confidence to be output:

$$\begin{aligned}\mathcal{I} &= Trigger(\mathcal{S}, \mathcal{Q}) \\ &= \mathcal{I}_U(\mathcal{Q}) \wedge \mathcal{I}_{Rank}(\mathcal{S}, \mathcal{Q}) \wedge \mathcal{I}_R(\mathcal{S})\end{aligned}$$

where $Trigger(\mathcal{Q}, \mathcal{S})$ returns $true$, if and only if all its three sub-functions return $true$.

$\mathcal{I}_U(\mathcal{Q})$ returns $true$, if $\mathcal{Q}$ is an informative query. We collect and label chit-chat queries based on conversational exchanges from social media websites to train the classifier.

$\mathcal{I}_{Rank}(\mathcal{S}, \mathcal{Q})$ returns $true$, if the score $s(\mathcal{S}, \mathcal{Q})$ exceeds an empirical threshold τ:

$$s(\mathcal{S}, \mathcal{Q}) = \frac{1}{1 + e^{-\alpha \cdot Rank(\mathcal{S}, \mathcal{Q})}}$$

where α is the scaling factor that controls the distribution of $s(\cdot)$ smooth or sharp. Both α and τ are selected based on a separated development set.

$\mathcal{I}_R(\mathcal{S})$ returns $true$, if (i) the length of $\mathcal{S}$ is less than a pre-defined threshold, and (ii) $\mathcal{S}$ does not start with a phrase that expresses a progressive relation, such as *but also*, *besides*, *moreover* and etc., as the contents of sentences starting with such phrases usually depend on their context sentences, and they are not suitable for responses.

6 Related Work

For modeling dialogue. Previous works mainly focused on rule-based or learning-based approaches (Litman et al., 2000; Schatzmann et al., 2006; Williams and Young, 2007). These methods require efforts on designing rules or labeling data for training, which suffer the coverage issue.

For short text conversation. With the fast development of social media, such as microblog and CQA services, large scale conversation data and data-driven approaches become possible. Ritter et al. (2011) proposed an SMT based method, which treats response generation as a machine translation task. Shang et al. (2015) presented an RNN based method, which is trained based on a large number of single round conversation data. Grammatical and fluency problems are the biggest issue for such generation-based approaches. Retrieval-based methods selects the most suitable response to the current utterance from the large number of Q-R pairs. Ji et al. (2014) built a conversation system using learning to rank and semantic matching techniques. However, collecting enough Q-R pairs to build chatbots is often intractable for many domains. Compared to previous methods, DocChat learns internal relationships between utterances and responses based on statistical models at different levels of granularity, and relax the dependency on Q-R pairs as response sources. These make DocChat as a general response generation solution to chatbots, with high adaptation capability.

For answer sentence selection. Prior work in measuring the relevance between question and answer is mainly in word-level and syntactic-level (Wang and Manning, 2010; Heilman and Smith, 2010; Yih et al., 2013). Learning representation by neural network architecture (Yu et al., 2014; Wang and Nyberg, 2015; Severyn and Moschitti, 2015) has become a hot research topic to go beyond word-level or phrase-level methods. Compared to previous works we find that, (i) Large scale existing resources with noise have more advantages as training data. (ii) Knowledge-based semantic models can play important roles.

7 Experiments

7.1 Evaluation on QA (English)

Take into account response ranking task and answer selection task are similar, we first evaluate DocChat in a QA scenario as a simulation. Here, response ranking is treated as the *answer selection* task, and response triggering is treated as the *answer triggering* task.

7.1.1 Experiment Setup

We select *WikiQA*[6] as the evaluation data, as it is precisely constructed based on natural language questions and Wikipedia documents, which contains 2,118 'question-document' pairs in the training set, 296 'question-document' pairs in development set, and 633 'question-document' pairs in testing set. Each sentence in the document of a given question is labeled as 1 or 0, where 1 denotes the current sentence is a correct answer sentence, and 0 denotes the opposite meaning. Given a question, the task of WikiQA is to select answer sentences from all sentences in a question's corresponding document. The training data settings of response ranking features are described below.

[6] http://aka.ms/WikiQA

F_w denotes 3 word-level features, h_{WM}, h_{W2W} and h_{W2V}. For h_{W2W}, GIZA++ is used to train word alignments on 11.6M 'question-related question' pairs (Fader et al., 2013) crawled from WikiAnswers.[7]. For h_{W2V}, Word2Vec (Mikolov et al., 2013) is used to train word embedding on sentences from Wikipedia in English.

F_p denotes 2 phrase-level features, h_{PP} and h_{PT}. For h_{PP}, bilingual data[8] is used to extract a phrase-based translation table (Koehn et al., 2003), from which paraphrases are extracted (Section 4.2.1). For h_{PT}, GIZA++ trains word alignments on 4M 'question-answer' pairs[9] crawled from Yahoo Answers[10], and then a phrase table is extracted from word alignments using the *intersect-diag-grow* refinement.

F_s denotes 2 sentence-level features, h_{SCR} and h_{SDR}. For h_{SCR}, 4M 'question-answer' pairs (the same to h_{PT}) is used to train the CNN model. For h_{SDR}, we randomly select 0.5M 'sentence-next sentence' pairs from English Wikipedia.

F_d denotes document-level feature h_{DM}. Here, we didn't train a new model. Instead, we just reuse the CNN model used in h_{SCR}.

F_r and F_{ty} denote relation-level feature h_{RE} and type-level feature h_{TE}. Bordes et al. (2015) released the *SimpleQuestions* data set[11], which consists of 108,442 English questions. Each question (e.g., *What does Jimmy Neutron do?*) is written by human annotators based on a triple in Freebase which formatted as $\langle e_{sbj}, rel, e_{obj} \rangle$ (e.g., $\langle$*Jimmy Neutron, fictional_character_occupation, inventor*$\rangle$) Here, as described in Section 4.5 and 4.6, 'question-relation' pairs and 'question-type' pairs based upon *SimpleQuestions* data set are used to train h_{RE} and h_{TE}.

F_{to} denotes 2 topic-level features, h_{UTM} and h_{STM}. For h_{UTM}, we run LightLDA (Yuan et al., 2015) on sentences from English Wikipedia, where the topic is set to 1,000. For h_{STM}, 4M 'sentence-topic' pairs are extracted from English Wikipedia (Section 4.7.2), where the most frequent 25,000 content names are used as topics.

[7]http://wiki.answers.com

[8]We use 0.5M Chinese-English bilingual sentences in phrase table extraction, i.e., LDC2003E07, LDC2003E14, LDC2005T06, LDC2005T10, LDC2005E83, LDC2006E26, LDC2006E34, LDC2006E85 and LDC2006E92.

[9]For each question, we only select the first sentence in its answer to construct a 'question-answer' pair, as it contains more causality information than sentences in other positions.

(6)	DocChat+(2)	**70.08%**	**72.22%**

Table 2: Evaluation of AS task on WikiQA.

7.1.2 Results on Answer Selection (AS)

The performance of answer selection is evaluated by *Mean Average Precision (MAP)* and *Mean Reciprocal Rank (MRR)*. Among all 'question-document' pairs in WikiQA, only one-third of documents contain answer sentences to their corresponding questions. Similar to previous work, questions without correct answers in the candidate sentences are not taken into account.

We first evaluate the impact of features at each level, and show results in Table 1. F_w, F_p, and F_s perform best among all features, which makes sense, as they can capture lexical features. F_r and F_{ty} perform not very good, but make sense, as the training data (i.e. SimpleQuestions) are based on Freebase instead of Wikipedia. Interestingly, we find that F_{to} and F_d can achieve comparable results as well. We think the reason is that, their training data come from Wikipedia, which fit the WikiQA task very well.

We evaluate the quality of DocChat on WikiQA, and show results in Table 2. The first four rows in Table 2 represent four baseline methods, including: (1) Yih et al. (2013), which makes use of rich lexical semantic features; (2) Yang et al. (2015), which uses a bi-gram CNN model with average pooling; (3) Miao et al. (2015), which uses an enriched LSTM with a latent stochastic attention mechanism to model similarity between Q-R pairs; and (4) Yin et al. (2015), which adds the attention mechanism to the CNN architecture.

Table 2 shows that, without using WikiQA's training set (only development set for ranking weights), DocChat can achieve comparable per-

Methods	MAP	MRR
CNN$_{WikiQA}$	0.6575	0.7534
CNN$_{QASent}$	**0.6951**	0.7633
DocChat	0.6896	**0.7688**

Table 3: Evaluation of AS on QASent.

formance with state-of-the-art baselines. Furthermore, by combining the CNN model proposed by Yang et al. (2015) and trained on WikiQA training set, we achieve the best result on both metrics.

Compared to previous methods, we think DocChat has the following two advantages: First, our feature models depending on existing resources are readily available (such as Q-Q pairs, Q-A pairs, 'sentence-next sentence' pairs, and etc.), instead of requiring manually annotated data (such as WikiQA and QASent). Training of the response ranking model does need labeled data, but the size demanded is acceptable. Second, as the training data used in our approach come from open domain resources, we can expect a high adaptation capability and comparable results on other WikiQA-like tasks, as our models are task-independent.

To verify the second advantage, we evaluate DocChat on another answer selection data set, QASent (Wang et al., 2007), and list results in Table 3. CNN_{WikiQA} and CNN_{QASent} refer to the results of Yang et al. (2015)'s method, where the CNN models are trained on WikiQA's training set and QASent's training set respectively. All these three methods train feature weights using QASent's development set. Table 3 tells, DocChat outperforms CNN_{WikiQA} in terms of MAP and MRR, and achieves comparable results compared to CNN_{QASent}. The comparisons results show a good adaptation capability of DocChat.

Table 4 evaluates the contributions of features at different levels of granularity. To highlight the differences, we report the percent deviation by removing different features at the same level from DocChat. From Table 4 we can see that, 1) Each feature group is indispensable to DocChat; 2) Features at sentence-level are most important than other feature groups; 3) Compared to results in Table 1, combining all features can significantly promote the performance.

7.1.3 Evaluation of Answer Triggering (AT)

In both QA and chatbot, response triggering is important. Similar to Yang et al. (2015), we also evaluate answer triggering using Precision, Recall, and F1 score as metrics. We use the WikiQA development set to tune the scaling factor α and trigger threshold τ that are described in Section 5, where α is set to 0.9 and τ is set to 0.5.

Models	MAP	Change	MRR	Change
DocChat	68.25%		70.73%	
DocChat - F_w	66.06%	-2.19	67.99%	-2.74
DocChat - F_p	66.80%	-1.45	68.66%	-2.07
DocChat - F_s	65.49%	**-2.76**	67.27%	**-3.46**
DocChat - F_d	68.02%	-0.23	69.79%	-0.94
DocChat - F_r	67.00%	-1.25	69.07%	-1.66
DocChat - F_{ty}	67.09%	-1.16	69.28%	-1.45
DocChat - F_{to}	66.85%	-1.40	68.96%	-1.77

Table 4: Impacts of different feature groups.

Methods	Precision	Recall	F1
Yang et al. (2015)	28.34	35.80	31.64
DocChat	**28.95**	**44.44**	**35.06**

Table 5: Evaluation of AT on WikiQA.

Table 5 shows the evaluation results compare to Yang et al. (2015). We think the improvements come from the fact that our response ranking model are more discriminative, as more semantic-level features are leveraged.

7.2 Evaluation on Chatbot (Chinese)

XiaoIce is a famous Chinese chatbot engine, which can be found in many platforms including WeChat official accounts (like business pages on Facebook Messenger). The documents that each official account maintains and post to their followers can be easily obtained from the Web. Meanwhile, a WeChat official account can choose to authorize XiaoIce to respond to its followers' utterances. We design an interesting evaluation below to compare DocChat with XiaoIce, based on the publicly available documents.

7.2.1 Experiment Setup

For ranking features, 17M 'question-related questions' pairs crawled from Baidu Zhidao are used to train word alignments for h_{W2W}; sentences from Chinese Wikipedia are used to train word embeddings for h_{W2V} and a topic model for h_{UTM}; the same bilingual phrase table described in last experiment is also used to extract a Chinese paraphrase table for h_{PP} which use Chinese as the source language; 5M 'question-answer' pairs crawled from Baidu Zhidao are used for h_{PT}, h_{SCR} and h_{DM}; 0.5M 'sentence-next sentence' pairs from Chinese Wikipedia are used for h_{SDR}; 1.3M 'sentence-topic pairs' crawled from Chinese Wikipedia are used to train $topic-$CNN for

Utterance	Response
你知道北京的历史么？ (Do you know the history of Beijing?)	[XiaoIce Response]: 我的历史课学的不太好。 (I am not good at history class)
	[DocChat Response]:北京历史悠久，可以追溯到3000年前。 (Beijing is a historical city that can be traced back to 3,000 years ago.)

Table 6: XiaoIce response is more colloquial, as it comes from Q-R pairs; while DocChat response is more formal, as it comes from documents.

h_{STM}. As there is no knowledge base based labeled data for Chinese, we ignore relation-level feature h_{RE} and type-level feature h_{TE}.

For ranking weights, we generate 90,321 $\langle \mathcal{Q}, \mathcal{C} \rangle$ pairs based on Baidu Zhidao Q-A pairs by the automatic method described in Section 4.8. This data set is used to train the learning to rank model feature weights $\{\lambda_k\}$ by SGD.

For documents, we randomly select 10 WeChat official accounts, and index their documents separately. The average number of documents is 600.

Human annotators are asked to freely issue 100 queries to each official account to get XiaoIce response. Thus, we obtain 100 ⟨query, XiaoIce response⟩ pairs for each official account. We also send the same 100 queries of each official account to DocChat based on official account's corresponding document index, and obtain another 100 ⟨query, DocChat response⟩ pairs. Given these 1,000 ⟨query, XiaoIce response, DocChat response⟩ triples, we let human annotators do a side-by-side evaluation, by asking them which response is better for each query. Note that, the source of each response is masked during evaluation procedure. Table 6 gives an example.

7.2.2 DocChat v.s. XiaoIce

Table 7 shows the results. **Better** (or **Worse**) denotes a DocChat response is better (or worse) than a XiaoIce response, **Tie** denotes a DocChat response and a XiaoIce response are equally good or bad. From Table 7 we observe that: (1) 156 DocChat responses (58+47+51) out of 1,000 queries are triggered. The trigger rate of DocChat is 15.6%. We check un-triggered queries, and find most of them are chitchat, such as "hi", "hello", "who are you?". (2) Better cases are more than worse cases. Most queries in better cases are non-chitchat ones, and their contents are highly related to the domain of their corresponding WeChat official accounts. (3) Our proposed method is a perfect complement for chitchat engines on informative utterances. The reasons for bad cases are two-fold: First, a DocChat response overlaps with a query, but cannot actually response it. For this issue, we need to refine the capability of our response ranking model on measuring causality relationships. Second, we wrongly send a chitchat query to DocChat, as currently, we only use a white list of chitchat queries for chitchat/non-chitchat classification (Section 5).

	Better	Worse	Tie
Compare to XiaoIce	58	47	51

Table 7: Chatbot side-by-side evaluation.

8 Conclusion

This paper presents a response retrieval method for chatbot engines based on unstructured documents. We evaluate our method on both question answering and chatbot scenarios, and obtain promising results. We leave better triggering component and multiple rounds of conversation handling to be addressed in our future work.

Abstract

In conversation, speakers tend to "accommodate" or "align" to their partners, changing the style and substance of their communications to be more similar to their partners' utterances. We focus here on "linguistic alignment," changes in word choice based on others' choices. Although linguistic alignment is observed across many different contexts and its degree correlates with important social factors such as power and likability, its sources are still uncertain. We build on a recent probabilistic model of alignment, using it to separate out alignment attributable to words versus word categories. We model alignment in two contexts: telephone conversations and microblog replies. Our results show evidence of alignment, but it is primarily lexical rather than categorical. Furthermore, we find that discourse acts modulate alignment substantially. This evidence supports the view that alignment is shaped by strategic communicative processes related to the ongoing discourse.

1 Introduction

In conversation, people tend to adapt to one another across a broad range of behaviors. This adaptation behavior is collectively known as "communication accommodation" (Giles et al., 1991). Linguistic alignment, the use of similar words to a conversational partner, is one prominent form of accommodation. Alignment is found robustly across many settings, including in-person, computer-mediated, and web-based conversation (Danescu-Niculescu-Mizil et al., 2012; Giles et al., 1979; Niederhoffer and Pennebaker, 2002). In addition, the strength of alignment to conversational partners varies with relevant sociological factors, such as the power of the partners, their social network centrality, and their likability. Potentially, this alignment could be used to infer these factors in situations where they are difficult to observe directly.

Although linguistic alignment appears to reflect important social dynamics, the mechanisms underlying alignment are still not well-understood. One particular question is whether alignment is supported by relatively automatic priming mechanisms, or higher-level, discourse and communicative strategies. The Interactive Alignment Model proposes that conversational partners prime each other, causing alignment via the primed reuse of structures ranging from individual lexical items to syntactic abstractions (Pickering and Garrod, 2004). In contrast, Accommodation Theory emphasizes the relatively more communicative and strategic nature of alignment (Giles et al., 1991).

Relative to this theoretical landscape, a number of questions have emerged. First, does alignment occur at structural levels? If alignment is driven by interactive priming of structures, effects of alignment should be expected not only at the lexical level but also for structural elements or categories as well. In contrast, if alignment is primarily communicative, then alignment strength might differ and be greater for specific words that serve particular conversational or discourse functions in a particular situation.

Second, does alignment vary with conversational goals? If alignment is driven primarily by priming, it should be relatively consistent across different aspects of a discourse. In contrast, from a strategic or communicative perspective, alignment – in which preceding words and concepts are reused – must be balanced against a need to move the conversation forward by introducing new words and concepts. Thus, on a communica-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 526–536,
Berlin, Germany, August 7-12, 2016.

tive account, alignment should be modulated by the speaker's discourse act, reflecting whether the balance of the concern is convergence on a current focus or conveyal of new information.

Our goal in the current work is to investigate these questions. We make use of a recent probabilistic model of linguistic alignment, modifying it to operate robustly over corpora with highly varying distributional structures and to consider both lexical and category-based alignment. We use two corpora of spontaneous conversations, the Switchboard Corpus and a corpus of Twitter conversations, to perform two experiments. First, in both datasets we measure alignment across different levels of representation and find very limited evidence for category-level alignment. Second, we make use of annotations in Switchboard to measure alignment across different discourse acts, finding that the level of alignment depends on the discourse actions that are included in the analysis. Taken together, these findings are consistent with the idea that alignment arises from discourse-level, strategic processes that operate primarily over lexical items.

2 Previous Work

2.1 Why does alignment matter?

Linguistic alignment, like other kinds of accommodation, can be a critical part of achieving social goals. Performance in cooperative decision-making tasks is positively related to the participants' linguistic convergence (Fusaroli et al., 2012; Kacewicz et al., 2013). Romantically, match-making in speed dating and stability in established relationships have both been linked to increased alignment (Ireland et al., 2011). Alignment can also improve perceived persuasiveness, encouraging listeners to follow good health practices (Kline and Ceropski, 1984) or to leave larger tips (van Baaren et al., 2003).

Alignment is also important as an indicator of implicit sociological variables. Less powerful conversants generally accommodate to more to powerful conversants. Prominent examples include interviews and jury trials (Willemyns et al., 1997; Gnisci, 2005; Danescu-Niculescu-Mizil et al., 2012). A similar effect is found for network structure: speakers align more to more network-central speakers (Noble and Fernández, 2015). Additionally, factors such as gender, likability, respect, and attraction all interact with the magnitude of accommodation (Bilous and Krauss, 1988; Natale, 1975).

2.2 Sources of linguistic alignment

Despite the important outcomes associated with alignment, its sources are not clear. The most prominent strand of work on alignment has focused on the level of word categories, looking at how interlocutors change their frequency of using, for instance, pronouns or quantitative words (Danescu-Niculescu-Mizil et al., 2012; Ireland et al., 2011). These results show alignment effects at the category level, but it is in principle possible that these effects arose purely from alignment on individual words (and that conclusion would not be inconsistent with the interpretation of that work).

Syntactic alignment is one area in which theoretical predictions have been tested, though results have been somewhat equivocal. The Interactive Alignment Model has generally been taken to suggest that there should be cross-person priming of syntactic categories and structures (Pickering and Garrod, 2004). But while some studies have found support for syntactic priming (Gries, 2005; Dubey et al., 2005), others have found negative or null alignment (Healey et al., 2014; Reitter et al., 2006). In one particularly thorough study, Healey et al. (2014) found across two corpora that speakers syntactically *diverged* from their interlocutors once lexical alignment was accounted for.

Furthermore, positive alignment is generally regarded as a good conversational tactic, but there is clearly a limit to its virtues, at least when it comes to content words. Alignment is inherently backward-looking, while the general goal of a conversation is to exchange information that is not already known by both parties, an inherently forward-looking goal. Perhaps because of this, some recent work finding positive alignment has limited itself to "non-topical" word categories, which are less contentful (Danescu-Niculescu-Mizil et al., 2011; Doyle et al., 2016). And suggestively, alignment within a task-relevant syntactic category was a better predictor of decision-making performance than overall lexical alignment (Fusaroli et al., 2012).

In sum, although individual studies do bear on the sources of alignment, the picture is still not clear. Because most work on alignment has been done either on categories of words or aggregating

across the lexicon, we do not have a good sense of whether there are systematic differences in alignment at different levels of representation. A further complication is that there is no standard measure of alignment; we turn to this issue next.

2.3 Measures of alignment

The metrics used in previous work fall into two basic categories: distributional and conditional. Distributional methods such as Linguistic Style Matching (LSM) (Niederhoffer and Pennebaker, 2002; Ireland et al., 2011) or the Zelig Quotient (Jones et al., 2014) calculate the similarity between the conversation participants over their frequencies of word or word category use in all utterances within the conversation. In contrast, conditional metrics, such as Local Linguistic Alignment (LLA) (Fusaroli et al., 2012; Wang et al., 2014) and the metric used by Danescu-Nicolescu-Mizil et al. (2011), look at how a message conditions its reply, with alignment indicated by elevated word use in the reply when that word was in the preceding message.

While distributional methods have been popular, a major weakness of such methods is that they do not necessarily show true alignment, only similarity. A high level of distributional similarity does not imply that two conversational partners have aligned to one another, because they might instead have been similar to begin with. In contrast, conditional measures allow for stronger inferences about the temporal sequence of alignment (even though they cannot guarantee any causal interpretation). Thus, we focus here on conditional measures exclusively.

By-message conditional methods Several existing conditional methods have started from the simplified representation that messages either do or do not contain particular words ("markers"), irrespective of message length or marker count. (Danescu-Niculescu-Mizil et al., 2012; Doyle et al., 2016). We refer to these as "by-message" methods. Consider the following example of conditional alignment, using pronouns as the marker: Bob aligns to Alice if his replies are more likely to contain a pronoun when in response to a message from Alice that contains a pronoun.

	Bob's reply	
Alice's message	has pronoun	no pronoun
has pronoun	8	2
no pronoun	5	5

Here, Alice sends 10 messages that contain at least one pronoun, and 8 of Bob's replies contain at least one pronoun. But Alice also sends 10 messages that don't contain any pronouns, and only 5 of Bob's replies to these contain pronouns. This increased likelihood of a pronoun-containing reply to a pronoun-containing message is the conditional alignment.

Different models quantify this conditional alignment slightly differently. Danescu-Niculescu-Mizil et al. (2011) proposed a subtractive conditional probability model, where alignment is the difference between the likelihood of a pronoun-containing reply B to a pronoun-containing message A and the probability of a pronoun-containing reply to any message:

$$align_{SCP} = p(B|A) - p(B) \quad (1)$$

Doyle et al. (2016) showed that this measure can be affected by the overall frequency of the category being aligned on, though. To correct this issue, they proposed a Hierarchical Alignment Model (HAM), which defines alignment as a linear effect on the log-odds of a reply containing the relevant marker (e.g., a pronoun), similar to a linear predictor in a logistic regression.[1]

$$align_{HAM} \approx logit^{-1}(p(B|A)) - logit^{-1}(p(B|\neg A)) \quad (2)$$

These binary conditional methods depend on the assumption that all messages have similar, and small, numbers of words, however. The probability that a message contains at least one of any marker of interest is dependent on the message's length, so if messages vary substantially in their length, these alignment values can be at least noisy, if not biased. They are also not robust as messages increase in length, since the likelihood that a message contains any marker approaches 1 as message length increases.

By-word conditional methods A solution to the problem of variable message lengths is simply to shift from binarized data to count data. Instead of counting how many times Bob's replies contain at least one pronoun, we can count what proportion of his replies' word tokens are pronouns.

[1] Because the HAM estimated this quantity via Bayesian inference, the inferred alignment value depends on the prior and number of messages observed, so unlike the other measures, this equality is only approximate.

Some existing measures use a related quantity, the proportion of the preceding message that appears in its reply, to estimate alignment, notably Local Linguistic Alignment (LLA) (Fusaroli et al., 2012; Wang et al., 2014) and the lexical similarity (LS) measure of Healey et al. (2014). LLA is defined as the number of word tokens (w_i) that appear in both the message (M_a) and the reply (M_b), divided by the product of the total number of word tokens in the message and reply:

$$align_{LLA} = \frac{\sum_{w_i \in M_b} \delta(w_i \in M_a)}{length(M_a) length(M_b)} \quad (3)$$

These measures have an aspect of conditionality, as they only count words that appear in both the message and the reply. But they nevertheless fail to control for the baseline frequency of the initial marker, and hence may be biased in measurements across words or categories of different frequencies (Doyle et al., 2016). They also can be affected by reply length, as the maximum alignment estimate is only possible when the reply is shorter than the message.

All of these by-word conditional models treat the reply as a bag of words, without order information. The by-word models, including the WHAM model we propose, are agnostic about reply length effects, correcting for the artifactual length effects of by-message models, but assuming that all messages have similar alignment strengths independent of length. This is in contrast to models that explicitly model priming effects as decaying over time (Reitter et al., 2006; Reitter, 2008), which predict higher alignment in shorter replies. Future by-word alignment models could infer a discounting for words that occur later in the reply, similar to the beta value on the log-distance from the prime proposed in Reitter et al. (2006).

Our goal in this work is to create a model that combines the benefits of the existing by-message conditional models with the length-robustness of a by-word conditional method. We present WHAM, a modification of the HAM model that satisfies this goal.

3 The Word-Based Hierarchical Alignment Model (WHAM)

We propose the Word-Based Hierarchical Alignment Model (WHAM). Like HAM, WHAM assumes that word use in replies is shaped by whether the preceding message contained the marker of interest. But WHAM uses marker token frequencies within replies, so that a 40-word reply with two instances of the marker is represented differently from a 3-word reply containing one instance.

For each marker, WHAM treats each reply as a series of token-by-token independent draws from a binomial distribution. The binomial probability μ is dependent on whether the preceding message did (μ^{align}) or did not (μ^{base}) contain the marker, and the inferred alignment value is the difference between these probabilities in log-odds space (η^{align}). The graphical model is shown in Figure 1.

For a set of message-reply pairs between a speaker-replier dyad (a, b), we first separate the replies into two sets based on whether the preceding message contained the marker m (the "alignment" set) or not (the "baseline" set). All replies within a set are then aggregated in a single bag-of-words representation, with marker token counts $C^{align}_{m,a,b}$ and $C^{base}_{m,a,b}$, and total token counts $N^{base}_{m,a,b}$ and $N^{base}_{m,a,b}$, the observed variables on the far right of the model. Moving from right to left, these counts are assumed to come from binomial draws with probability $\mu^{align}_{m,a,b}$ or $\mu^{base}_{m,a,b}$. The μ values are generated from η values in log-odds space by an inverse-logit transform, similar to linear predictors in logistic regression.

The η^{base} variables are representations of the baseline frequency of a marker in log-odds space, and μ^{base} is simply a conversion of η^{base} to probability space, the equivalent of an intercept term in a logistic regression. η^{align} is an additive value, with $\mu^{align} = \text{logit}^{-1}(\eta^{base} + \eta^{align})$, the equivalent of a binary feature coefficient in a logistic regression. Alignment is then the change in log-odds of the replier using m above baseline usage, given that the initial message uses m.

The remainder of the model is a hierarchy of normal distributions that allow social and word category structure to be integrated into the analysis. In the present work, we have three levels in the hierarchy: category level, marker level,[2] and conversational dyad level. All of these normal distributions have identical standard deviations $\sigma^2 = .25$.[3] A $Cauchy(0, 2.5)$ distribution

[2] In the lexical and category-not-word alignment models, these markers are words within a category. The category alignment model does not include this level, since all words in a category are treated identically.

[3] This value was chosen as a good balance between rea-

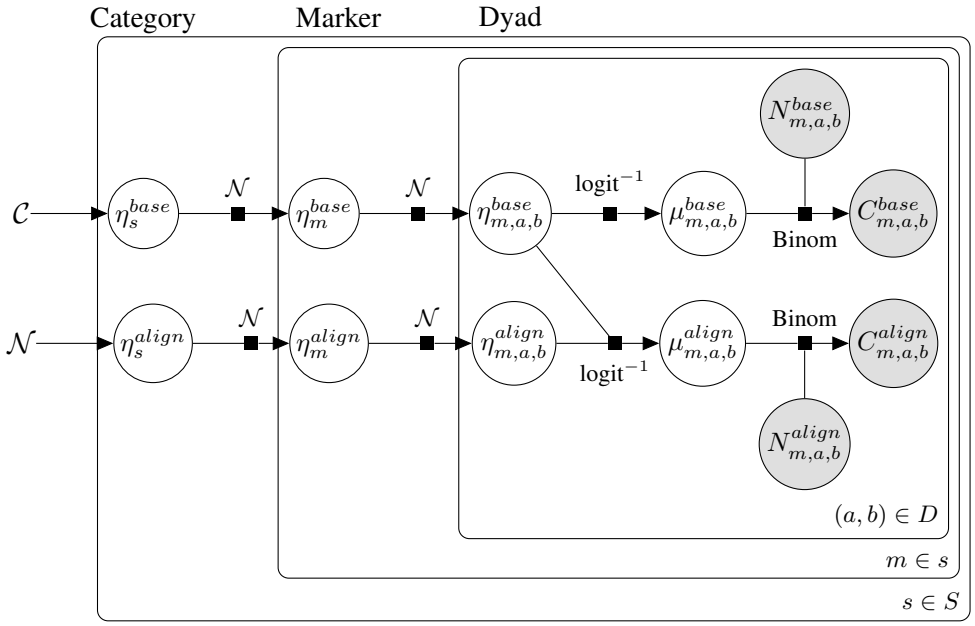

Figure 1: The Word-Based Hierarchical Alignment Model (WHAM). A chain of normal distributions generates a linear predictor η, which is converted into a probability μ for binomial draws of the words in each reply.

gives a relatively uninformative prior for the baseline marker frequency (Gelman et al., 2008). The alignment hierarchy is headed by a normal distribution centered at 0, biasing the model equally in favor of positive and negative alignments.

For our marker set, we adopt the Linguistic Inquiry and Word Count (LIWC) system to categorize words (Pennebaker et al., 2007). We use a set of 11 categories that have shown alignment effects in previous work (Danescu-Niculescu-Mizil et al., 2011). These can be loosely grouped into a set of five syntactic categories (articles, conjunctions, prepositions, pronouns, and quantifiers) and six conceptual categories (certainty, discrepancy, exclusion, inclusion, negation, and tentative). Categories and example elements are shown in Table 1. We manually lemmatized all words in each category. We implemented WHAM in RStan (Carpenter, 2015), with code available at `http://github.com/langcog/disc_align`.

Category	Examples	Size	Swbd Prob	Twit Prob
Article	*a, the*	2	.053	.047
Certainty	*always, never*	17	.014	.015
Conjunction	*but, and, though*	18	.077	.051
Discrepancy	*should, would*	21	.015	.019
Exclusive	*without, exclude*	77	.038	.028
Inclusive	*with, include*	57	.057	.028
Negation	*not, never*	12	.020	.023

3.1 Validating WHAM

A major goal of our by-word alignment model, WHAM, is to fix the length issues discussed in Section 2.3. We test WHAM and the by-message HAM model on simulated data, using a method similar to Simulation 2 in Doyle et al. (2016), to see how robust they are to different reply lengths. We generate 500 speaker-replier dyads, each exchanging an average of 5 message pairs (drawn from a geometric distribution). Each message pair consists of a message whose length in words is drawn from a uniform distribution $[1, 25]$, and a reply of length L. Because our goal is to test the effect of length on the models' performances, we create separate simulated datasets for different values of L, and see whether the model correctly estimates the alignment value η^{align}. Three independent simulations were run for each alignment-length pair. We present data here for a simulated

sonable parameter convergence (improved by smaller σ^2) and good model log-probability (improved by larger σ^2).

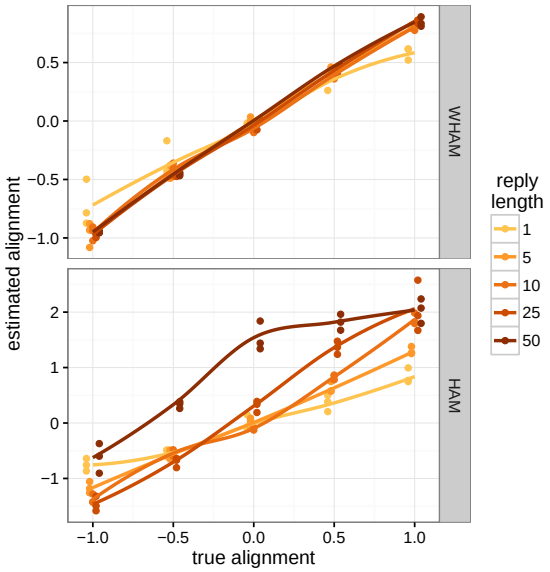

Figure 2: Actual versus estimated alignment on simulated data. Lines are loess-fit curves; colors represent the reply length in the simulation run. WHAM estimates alignment accurately regardless of reply length; HAM is highly affected by length.

word category with a baseline frequency of 0.1, around the middle of the attested category frequency range (see Table 1).

Figure 2 plots the true alignment value in the simulations against the model-estimated alignment values. Different colors represent different reply lengths L, ranging from single-word replies (light yellow) to 50-word replies (dark orange). The WHAM model shows consistently accurate alignment estimates over the range of simulated alignment values and reply lengths. The HAM model estimates the alignment far less accurately, and the reply length biases its estimates.

4 Data

Moving on to real data, we use two corpora for our experiments. The first is a collection of Twitter conversations collected by Doyle & Frank (2015) to examine information density in conversation. This corpus focuses on conversations within a set of 14 mostly distinct sub-communities on Twitter, and contains 63,673 conversation threads, covering 228,923 total tweets. We divide these conversations into message pairs, also called conversational turns, which are two consecutive tweets within a conversation thread. The second tweet is always in reply to the first (according to the Twitter API), although this does not necessarily mean that the content of the reply is a response to the preceding tweet. Retweets (including explicit retweets and some common manual retweet methods) were removed automatically. This processing leaves us with 122,693 message pairs, spanning 2,815 users. The tweets were parsed into word tokens using the Twokenizer (Owoputi et al., 2013).

The second corpus is the SwDA version of the Switchboard corpus (Godfrey et al., 1992; Jurafsky et al., 1997).[4] This corpus is a collection of transcribed telephone conversations, with each utterance labeled with the discourse act it is performing (e.g., statement of opinion, signal of non-understanding). It contains 221,616 total utterances in 1,155 conversations. We combine consecutive utterances by the same speaker without interruption from the listener into a single message and treat consecutive pairs of messages from different speakers as conversation turns, resulting in 110,615 message pairs.

5 Experiment 1: Lexical- and Category-Level Alignment

Our first experiment examines how alignment differs across the lexical and categorical levels. We use the WHAM framework to infer alignment on word and category counts, and also introduce a measure to estimate the influence of one word in a category on other words in its category, "category-not-word" alignment. We include this last type of alignment because it is possible that the category alignment effects in previous work are the result of lexical alignment on the individual words in the category, without any influence across words in the category. If categorical alignment is a real effect over and above lexical alignment, as an interactive-priming source for alignment would suggest, then the presence of a word in a message should not only increase the chance of seeing that word in the reply, but also other words in its category.

5.1 Category-not-word-alignment model

Assessing the amount of alignment triggered across words in a category (which we call "category-not-word alignment" or CNW) is not trivial, as there are a variety of interactions between lexical items within a category that can cause the lexical alignment to actually be less than

[4] Available courtesy of Christopher Potts at `http://compprag.christopherpotts.net/swda.html`.

	Reply		
Message	$\emptyset$	*he*	*she*
$\emptyset$	25	25	25
he	20	50	10
she	20	10	50

Table 2: A theoretical case where lexical alignment surpasses categorical alignment due to negative CNW between the words.

the category alignment. Table 2 illustrates this with a theoretical distribution over the pronouns *he* and *she*; one use of the pronoun *he* makes another use more likely (*A: Did he like the movie? B: Yeah, he loved it.*) while also reducing the likelihood of *she*, since the topic of conversation is now a male, and vice versa for *she*. For both *he* and *she*, the lexical alignment is approximately $logit^{-1}(p(B|A) - p(B|\neg A)) = logit^{-1}(\frac{50}{80} - \frac{25}{75}) \approx 1.2$, but categorical alignment is approximately $logit^{-1}(\frac{120}{160} - \frac{50}{75}) \approx 0.4$. On the other hand, the pronouns *you* and *I* might trigger each other more than themselves (*A: Did you like the movie? B: Yeah, I loved it.*).

The differences between lexical, categorical, and CNW alignment are also relevant to discussions of "lexical boosts" in the syntactic priming literature, an increased priming effect at the categorical level when there is lexical repetition. Lexicalist residual activation accounts (Pickering and Branigan, 1998) predict such a boost, while implicit learning accounts do not (Bock and Griffin, 2000; Chang et al., 2006). In the context of this experiment, such a lexical boost could make lexical and categorical alignment appear elevated and closer together, but would not have a substantial effect on CNW alignment.[5]

To investigate CNW alignment, we look at a subset of the data: for each word w, exclude all messages that contain a word from that category (S) that is not w. This limits the category alignment influence on the reply to the single word w. Then, instead of looking at how often w appears in the reply, we look at how often *all other words* in category S appear in the reply. The model then infers the influence of w on the other words in the category independent of their lexical alignment. Within the WHAM model, we change the count variables $C^{\cdot}$ and $N^{\cdot}$ so that C^{align} is the number of tokens of $\{S - w\}$ in replies to messages containing w but not $\{S - w\}$. C^{base} is then the number in replies to messages not containing any words in S. Similarly, N^{align} is the total token counts over replies containing w but not any other words in S, and N^{base} the total token counts over replies containing no words in S.

5.2 Methods

We conducted three sets of simulations, fitting the model with marker categories, individual words, and with the CNW scheme described above. In each, the model was fit with two chains of 200 iterations of the sampler for each dataset. We then extracted alignment estimates from each of the final 100 samples, and we report 95% highest posterior density intervals on η_S^{align}.

5.3 Results

Figure 3 shows the alignment on each marker category in the Twitter and Switchboard corpora. There were substantial differences in the overall rate of alignment between the corpora: Mean category alignment on Twitter was .19, while Switchboard category alignment was $-.051$. These differences may reflect the nature of the two discourse contexts: Replies on Twitter are composed while looking at the preceding message, encouraging the replier to take more account of the other tweeter's words, and a replier can draft and edit their reply to make it better fit the conversation. Messages on Switchboard, on the other hand, are evanescent, so a replier must compose a reply without looking back at the message, without editing, and in real-time. Differences in the discourse structure of these corpora may also be contributing, an effect we will consider in Experiment 2.

Despite the difference in reply construction in the two corpora, the results across levels of alignment were similar. Alignment was found primarily at the lexical – rather than the category – level. Lexical and category alignment were not significantly different from each other, but the strength of lexical alignment was significantly larger than the CNW alignment, according to a t-test over categories (Twitter: $t(10) = .21, p < .001$; Swbd: $t(10) = .12, p = .003$). CNW alignment was significantly negative on Switchboard ($t(10) = -.11, p = .01$) and not significantly different from zero on Twitter ($t(10) = .009, p = .79$).

[5]The categories being investigated in our work contain mostly non-topical, closed-class words, which have not exhibited lexical boosts in past research (Bock, 1989; Pickering and Branigan, 1998; Hartsuiker et al., 2008), but such boosting may be detectable in estimates on topical categories.

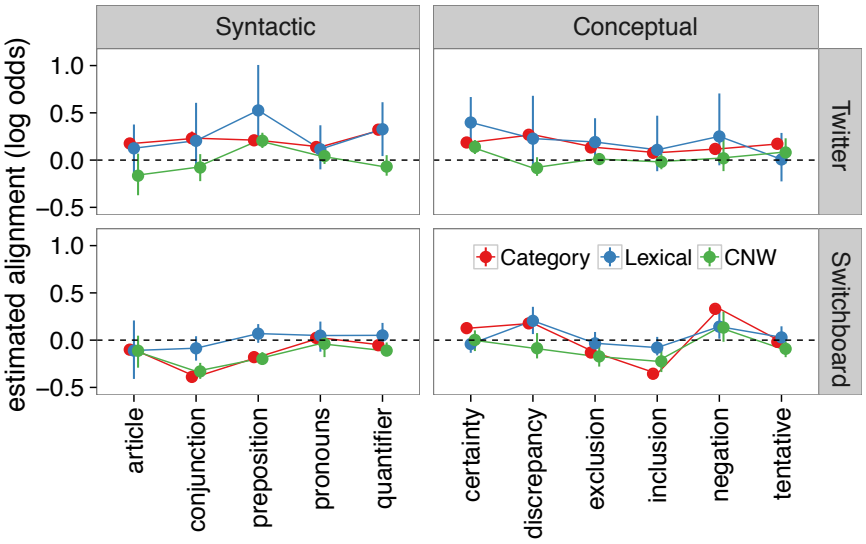

Figure 3: Categorical (red), lexical (blue), and CNW (green) alignments plotted by category, on the Twitter (left) and Switchboard (right) datasets. 95% HPD intervals from WHAM shown.

WHAM – unlike other previous measures – provides estimates of alignment that are unbiased by either marker frequency or message length, but we still observed modest alignment on Twitter, replicating previous work (Doyle et al., 2016; Danescu-Niculescu-Mizil et al., 2011). Alignment was smaller in Switchboard, and in both cases there were no category effects. Thus, the categorical alignment results may result primarily from lexical alignment, inconsistent with the predictions of interactive priming accounts of alignment.

6 Experiment 2: Discourse Acts and Alignment

Messages within a discourse can serve a very wide range of purposes. This variety has effects for both linguistic structure and the relationship to neighboring messages. For example, a simple yes/no question is likely to receive a short, constrained reply, while a statement of an opinion is more likely to yield a longer reply. In addition, different types of messages can either introduce new information to the conversation (e.g., statements, questions, offers) or look back at existing information (e.g., acknowledgments, reformulations, yes/no answers). We hypothesize that alignment will be substantially different depending on the discourse act, as speakers' conversational goals vary. Thus, our second experiment examines how alignment differs depending on discourse act.

We focus on a particular kind of discourse act, the backchannel (Yngve, 1970). Backchannels are extremely common in Switchboard, accounting for almost 20% of utterances, and include utterances such as single words signaling understanding or misunderstanding (*yeah, uh-huh, no*) or simple messages expressing empathy without trying to take a full conversational turn (*It must have been tough*). Backchannels are a particularly interesting case because their short and constrained nature makes it difficult to align on some categories (e.g., backchannels rarely contain quantifiers or prepositions), while the purpose of giving feedback to the speaker makes it important to align on others (e.g., matching the positive/negative tone or certainty of a speaker). In addition, backchannels are primarily restricted to spoken corpora. Twitter conversations contain far fewer backchannels than Switchboard, which may account for some of their alignment differences—especially as the results of this experiment suggest that backchannels reduce overall alignment.

6.1 Methods

We use the discourse-annotated Switchboard corpus to compare alignment in conversations containing backchannels with those whose backchannels have been removed. We make this comparison by creating a second corpus, removing every utterance classified as a backchannel from the corpus prior to parsing the utterances into conversation turns as before.

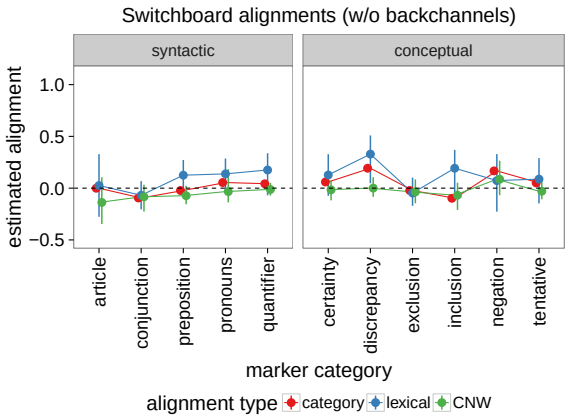

Figure 4: Categorical (red), lexical (blue), and CNW (green) alignments on the Switchboard dataset with backchannels removed. 95% HPD intervals from WHAM shown.

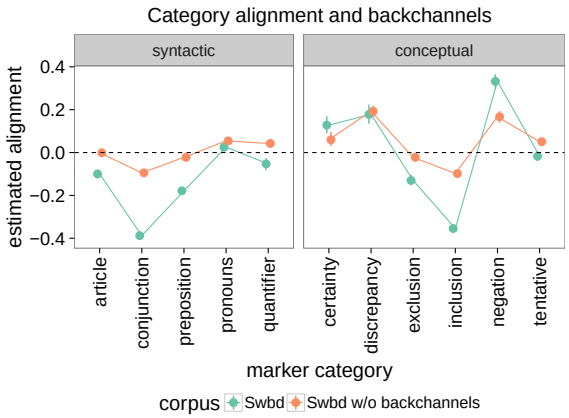

Figure 5: Comparing categorical alignment on the Switchboard dataset with and without backchannels. 95% HPD intervals from WHAM shown.

6.2 Results

Alignment values for the Switchboard corpus without backchannels are shown in Figure 4. As expected, alignment is on average higher without the backchannels ($p = .09$ for category, $p < .05$ for lexical and CNW), reflecting the constrained nature of backchannels. Lexical alignment is significantly higher than category alignment ($t(10) = -.08, p = .03$), consistent with the findings of Experiment 1. The mean category alignment without backchannels is .029.

Figure 5 compares the category alignments for the full Switchboard corpus (green) and Switchboard without backchannels (orange). Alignment on the full corpus is lower for all but two categories, exhibiting the reduced opportunity for alignment provided by backchannels. Syntactic category alignment is especially affected by backchannels, whose constrained forms provide very little ability to align syntactically.

Interestingly, the two categories that do show greater alignment when backchannels are included are certainty and negation. These categories are both important for backchannels; a negative backchannel is generally inappropriate in reply to a non-negative message, and similarly a confident backchannel would often be out of place in reply to an uncertain message. These influences of discourse acts on alignment are more consistent with a discourse-strategic origin for alignment than a priming-based account.

7 Discussion

Linguistic alignment is a prominent type of communicative accommodation, but its sources are unclear. We presented WHAM, a length-robust extension of a probabilistic alignment model. Using this model, we find evidence that linguistic alignment is primarily lexical, and that it is strongly affected by at least some aspects of the discourse goal of a message.

This combination of a primarily-lexical origin for linguistic alignment and its variation by word category and discourse act suggest that alignment is primarily a higher-level discourse strategy rather than a low-level priming-based mechanism. This set of results is consistent with both Accommodation Theory and the set of findings, reviewed above, that sociological factors affect the level of observed alignment. The effect of discourse acts on alignment further suggests that alignment is not a completely automatic process but rather one of many discourse strategies that speakers use to achieve their conversational goals.

Acknowledgments

We wish to thank Dan Yurovsky, Aaron Chuey, and Jake Prasad for their work on and discussion of earlier versions of the model, Herb Clark for discussions of potential effects of message length, and, of course, the reviewers. The authors were funded by NSF BCS 1528526, NSF BCS 1456077, and a grant from the Stanford Data Science Initiative.

Entropy Converges Between Dialogue Participants: Explanations from an Information-Theoretic Perspective

Abstract

The applicability of entropy rate constancy to dialogue is examined on two spoken dialogue corpora. The principle is found to hold; however, new entropy change patterns within the topic episodes of dialogue are described, which are different from written text. Speaker's dynamic roles as *topic initiators* and *topic responders* are associated with decreasing and increasing entropy, respectively, which results in local convergence between these speakers in each topic episode. This implies that the sentence entropy in dialogue is conditioned on different contexts determined by the speaker's roles. Explanations from the perspectives of grounding theory and interactive alignment are discussed, resulting in a novel, unified information-theoretic approach of dialogue.

1 Introduction

Information in written text and speech is strategically distributed. It has been claimed to be ordered such that the rate of information is not only close to the channel capacity, but also approximately constant (Genzel and Charniak, 2002, 2003; Jaeger, 2010); these results were developed within the framework of Information Theory (Shannon, 1948). In these studies, the per-word cross-entropy of a sentence is used to model the amount of information transmitted. Language is treated as a series of random variables of words.

Most existing work examined written text as opposed to speech. Spoken dialogue is different from written text in many ways. For example, dialogue contains more irregular or ungrammatical components, such as incomplete utterances, disfluencies etc. (Jurafsky and Martin, 2014, ch 12), which are "theoretically uninterested complexities that are unwanted" (Pickering and Garrod, 2004). Dialogue is also different from written text in high level discourse structure. The paragraphs in written text, which function as relatively standalone topic units, are constructed under the guidance of one consistent author. On the other hand, the constitution and transformation of topics in dialogue are more dynamic processes, which are the result of the joint activity from multiple speakers (Linell, 1998). In nature, written text is a monologue, while dialogue is a joint activity (Clark, 1996).

From the application perspective, investigating entropy in dialogue can help us better understand which speaker contributes the most information, and thus may potentially benefit tasks such as conversational roles identification (Traum, 2003) etc. From the theoretical perspective, we believe that such investigation will reveal some unique features of the formation of higher level discourse structure in dialogue that are different from written text, e.g., *topic episode* shifts, because previous studies have found the correlation between entropy decrease and potential topic shift in written text (Qian and Jaeger, 2011). Finally, entropy is closely related to predictability and processing demands, which has implications for cognitive aspects of communication.

The main purpose of this study is to characterize how lexical entropy changes in spoken language. We will focus on spontaneous dialogue of two speakers and carry out two steps of investigation. First, we examine the overall entropy patterns within dialogue as a whole context that does not differentiate speakers. Second, we zoom in to *topic episodes* within dialogue and explore how each of the two speakers' entropy develops. The goal of the second step is to account the complexity of topic shifts within spoken dialogues and to reach a more detailed understanding

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 537–546,
Berlin, Germany, August 7-12, 2016.

of human communication from an information-theoretic perspective. If topic shifts in dialogue do correlate with changes in entropy, how do they affect the two speakers, only one of whom typically initiates the topic shift, while another follows along? To answer this question, we use the transcribed text data from two well-developed corpora.

2 Related Work

2.1 The principle of entropy rate constancy

The *constancy rate principle* governing language generation in human communication was first proposed by Genzel and Charniak (2002). Inspired by ideas from Information Theory (Shannon, 1948), this principle asserts that people communicate (written or spoken) in a way that keeps the rate of information being transmitted approximately constant.

Genzel and Charniak (2002) provide evidence to support this principle by formulating the problem into Equation 1. They treat text as a sequence of random variables X_i, and X_i corresponds to the i th word in the corpus. They focus on the entropy of a word conditioned on its context, i.e., $X_i|X_1 = w_1, \ldots, X_{i-1} = w_{i-1}$, and decompose the context into two parts: the global context C_i that refers to all the words from preceding sentences, and the local context L_i that refers to all the preceding words within the same sentence as X_i. Thus, the conditioned entropy of X_i is also decomposed into two terms (see the right side of Equation 1): the local measure of entropy (first term), and the mutual information between the word and global context (second term).

$$H(X_i|C_i, L_i) = H(X_i|L_i) - I(X_i, C_i|L_i) \quad (1)$$

The constancy rate principle predicts that the left side of Equation 1 should be constant as i increases. Because $H(X_i|C_i, L_i)$ itself is difficult to estimate (because it is hard to define C_i mathematically), and that the mutual information turn $I(X_i, C_i|L_i)$ is known to increase with i, the whole problem becomes examining whether the local measure of entropy $H(X_i|L_i)$ also increases with i. Genzel and Charniak (2002) have confirmed this prediction by showing that $H(X_i|L_i)$ does increase with i within multiple genres of written text of different languages.

The constancy rate principle also leads to an interesting prediction about the relationship between entropy change and topic shift in text. Generally, a sentence that initiate a shift in topic will have lower mutual information between its context, because the previous context provides little information to the new topic. Thus, a topic shift corresponds to the drop of the mutual information term $I(X_i, C_i|L_i)$. Then in order to keep constancy of the left term as predicted by the principle, the entropy term needs to decrease when a topic shift happens. Genzel and Charniak (2003) verified this prediction by showing that paragraph-starting sentences have lower entropy than non-paragraph-starting ones, with the assumption that a new paragraph often indicates a topic shift in written text. More recently, latent topic modeling (Qian and Jaeger, 2011) showed that lower sentence entropy was associated with topic shifts.

Genzel and Charniak's work has been extended to integrate non-linguistic information into the principle. Doyle and Frank (2015) leveraged Twitter data to find further support to the constancy rate principle: the entropy of message gradually increases as the context builds up, and it sharply goes down when there is a sudden change in the non-linguistic context (Baseball world series news reports, Doyle and Frank, 2015). *Uniform Information Density* (UID) (Jaeger and Levy, 2006) extends the principle in a framework that governs how people manage the amount of information in language production, from lexical levels to all levels of linguistic representations, e.g., syntactic levels. Its core idea is that people avoid salient changes in the density of information (i.e., amount of information per amount of linguistic signal) by making specific linguistic choices under certain contexts (Jaeger, 2010).

2.2 Topic shift in dialogues

As a conversation unfolds, topic changes naturally happen when a current topic is exhausted or a new one occurs, which is referred to as *topic shift* in the field of *Conversation Analysis* (CA) (Ng and Bradac, 1993; Linell, 1998). In CA, the basic unit of topical structure analysis in dialogue is *episode*, which refers to a sequence of speech events that are "about" something specific in the world (Linell, 1998, ch 10, p 187). Here, to be precise, we use the term *topic episode*.

According to related theories in CA, the for-

Table 1: Basic statistics of corpora

Statistics	Switchboard	BNC
# of dialogues.	1126	1346
Avg # of turns in dialogue	109	52
Avg # of sentences in dialogue	141	70

mation of topic episode is a joint accomplishment from two speakers and a product of initiatives and responses (Linell, 1990). When establishing a new topic jointly, one speaker first produces an initiatory contribution that introduce a "candidate" topic, and the other speaker makes a response that shares his perspective on that (Linell, 1998). From the information theoretic point of view, the *initiator* of a new topic plays a role of introducing *novelty* or *surprisal* into the context, while the other speaker, the *responder*, is more of a *commenter* or *evaluator* of information, who does not contribute as much in terms of novelty.

Since previous studies have shown that the decrease of sentence entropy is correlated with topic shifts in written text (Genzel and Charniak, 2003; Qian and Jaeger, 2011), it is reasonable to expect the same effect to be present at the boundaries of topic episodes in dialogue. Furthermore, considering the *initiator* vs. *responder* discrepancy in speaker roles, we expect their entropy change patterns also to be different.

3 Overall Trend of Entropy in Dialogue

In this section we examine whether the overall entropy increase trend is present in dialogue text.

3.1 Corpus data

The Switchboard corpus (Godfrey et al., 1992) and the British National Corpus (BNC) (BNC, 2007) are used in this study. Switchboard contains 1126 dialogues by telephone between two native North-American English speakers in each dialogue. We use only a subset of BNC (spoken part) that contain spoken conversations with exactly two participants, so that the dialogue structures are consistent with Switchboard.

3.2 Computing Entropy of One Sentence

We use language model to estimate the sentence entropy, which is similar to Genzel and Charniak (2003)'s method. A sentence is considered as a sequence of words, $W = \{w_1, w_2, \ldots, w_n\}$, and its per-word entropy is estimated by:

$$H(w_1 \ldots w_n) = -\frac{1}{n} \sum_{w_i \in W} \log P(w_i | w_1 \ldots w_{i-1})$$

where $P(w_i|w_1 \ldots w_{i-1})$ is estimated using a trigram language model. The model is trained using Katz backoff (Katz, 1987) and Lidstone smoothing (Chen and Goodman, 1996).

For the two corpora respectively, we extract the first 100 sentences from each conversation, and apply a 10-fold cross-validation, i.e., dividing all the data into 10 folds. Then we choose each fold as the testing set, and compute the entropy of each sentence in it, using the language model trained against the rest of the folds.

3.3 Eliminating sentence length effects

Intuitively, longer sentences tend to convey more information than short ones. Thus, the per-word entropy of a sentence should be correlated with the sentence length, i.e., the number of words. This correlation is confirmed in our data by calculating the Pearson correlation between the per-word entropy and sentence length: For Switchboard, $r = 0.258, p < 0.001$; for BNC, $r = 0.088, p < 0.001$.

Sentence length is found to vary with its relative position in text (Keller, 2004). Thus, in order to truly examine the variation pattern of sentence entropy within dialogue, we need to eliminate the effect of sentence length from it. We calculate a *normalized entropy* that is independent of sentence length in the following way. (This method is used by Genzel and Charniak (2003) to get the length-independent *tree depth* and *branching factor* of sentence.) First, we compute $\bar{e}(n)$, the average per-word entropy of sentences of the same length n, for all lengths ($n = 1, 2, \ldots$) that have occurred

$$\bar{e}(n) = {}^{1}\!/_{|L(n)|} \sum\nolimits_{s \in L(n)} e(s)$$

where $e : S \rightarrow \mathbb{R}$ is the original per-word entropy of a sentence s, and $L(n) = s|l(s) = n$ is the set of sentences of length n. Then we compute the sentence-length adjusted entropy measure that we want by

$$e'(s) = \frac{e(s)}{\bar{e}(n)}$$

This normalized entropy measure sums up to 1, and is not sensitive to sentence length. In later part

of this paper, we demonstrate our results in both entropy and normalized entropy because the former is the direct measure of information content.

3.4 Results

We plot the per-word entropy and normalized entropy of sentence against its *global position*, which is the sentence position from the beginning of the dialogue (Figure 1). It can be seen that both measures increase with global position. BNC shows larger slope than Switchboard, and the latter has a flatter curve but sharper increase at the early stage of conversations.

To test the reliability of the observed increasing trend, we fit linear mixed-effect models using entropy and normalized entropy as response variables, and the global position of sentence as predictor (fixed effect), with a random intercept grouped by distinct dialogues. The `lme4` package in `R` is used (Bates et al., 2014). The results show that the fixed effects of global position are significant for both measures in both corpora: Entropy in Switchboard, $\beta = 4.2 \times 10^{-3},\ p < 0.001$; normalized entropy in Switchboard, $\beta = 5.9 \times 10^{-4},\ p < 0.001$; entropy in BNC, $\beta = 1.5 \times 10^{-2},\ p < 0.001$; normalized entropy in BNC, $\beta = 1.4 \times 10^{-3},\ p < 0.001$).

In particular, since the curves of Switchboard seem flat after a boost in the early phase (between 0 to 5 in global position), we fit extra models to examine whether the entropy increase for global positions larger than 10 is significant. The long-term changes are reliable, too: Entropy, $\beta = 3.4 \times 10^{-3},\ p < 0.001$; normalized entropy, $\beta = 5.1 \times 10^{-4},\ p < 0.001$.

In sum, we find increasing entropy over the course of the whole dialogue. These findings are consistent with previous findings on written text.

4 Topic Shift and Speaker Roles

Since the topic structure of dialogue differs from written text, it is our interest to investigate how this difference affects the sentence entropy patterns. First, we identify the boundaries of topic episodes, and examine the presence of entropy drop effect at the boundaries. Second, we differentiate the speakers' roles in initiating the topic episode, i.e., *initiator* vs. *responder*, and compare their entropy change patterns within the episode.

4.1 Topic segmentation

There are multiple computational frameworks for topic segmentation, such as the Bayesian model (Eisenstein and Barzilay, 2008), Hidden Markov model (Blei and Moreno, 2001), latent topic model (Blei et al., 2003) etc. Considering that performance is not the prior requirement in our task, and also to avoid being confounded by segmentation method that utilize entropy measure per se, we use a less sophisticated cohesion-based TextTiling algorithm (Hearst, 1997) to carry out topic segmentation.

TextTiling algorithm inserts boundaries into dialogue as a sequence of sentences. We treat the segments between those boundaries as topic episodes. For each episode within a dialogue, we assign it a unique *episode index*, indicating its relative position in the dialogue (e.g., from 1 to N for a dialogue that contains N episodes). For each sentence, we assign it a *within-episode position*, indicating its relative position within the topic episode.

In Figure 2 we plot the entropy (and normalized) of sentence against the within-episode positions, grouped by episode index. Due to the space limit, we only present the first 6 topic episodes and the first 10 sentences in each episode. It can be seen that entropy drops at the beginning of topic episode, and then increases within the episode.

To examine the reliability of the entropy increase within topic episodes, we fit linear mixed effect models using entropy (and normalized) as response variables, and the within-episode position of sentence as predictor (fixed effect), with a random intercept grouped by the unique episode index of each topic episode. We find a significant fixed effect of within-episode position on both measures for both corpora: Entropy in Switchboard, $\beta = 5.9 \times 10^{-4},\ p < 0.001$; normalized entropy in Switchboard, $\beta = 4.5 \times 10^{-3},\ p < 0.001$; entropy in BNC, $\beta = 2.5 \times 10^{-2},\ p < 0.001$; normalized entropy in BNC, $\beta = 3.0 \times 10^{-3},\ p < 0.001$.

Our results show that when we treat the sentences in dialogue indiscriminately, their entropy change patterns at topic boundaries are consistent with previous findings on written text.

4.2 Identifying topic initiating utterances

Having dialogue segmented into topic episodes, our next step is to identify each speaker's role in initiating the topic. According to the theories

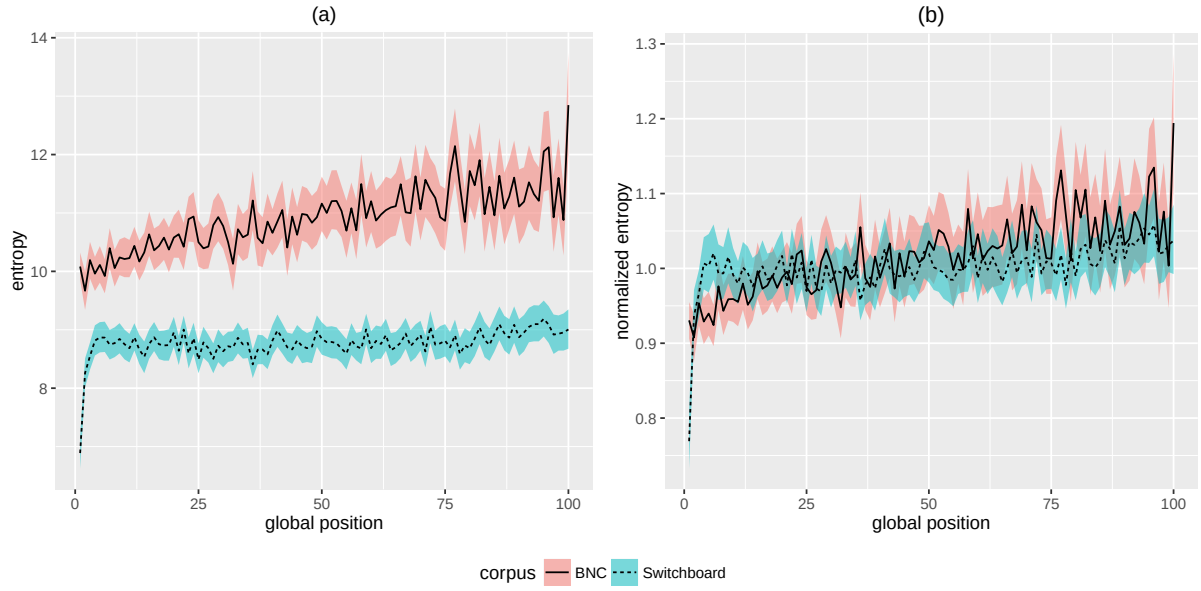

Figure 1: Entropy (a) and normalized entropy (b) against global position of sentences (from 1 to 100). Shadow area indicates 95% bootstrapped Confidence Interval.

reviewed in Section 2.2, the key to identify the speaker roles is to identify who produces the initiatory "candidate" topic. To be convenient, we use the term *topic initiating utterance* (TIU) to refer to the very first utterance produced by the *initiator* to bring up the new topic. Here, we give an empirical operational definition of TIU.

Since we treat dialogue as a series of sentences, and apply the TextTiling algorithm to insert topic boundaries indiscriminately (without differentiating whether adjacent sentences are from the same speaker or not), it results in two types of topic boundaries: *Within-turn* boundaries, the ones located in the middle of a turn (i.e., from one speaker). *Between-turn* boundaries, the ones located at the gap between two different turns (i.e., from two speakers). Our survey shows that in Switchboard 27.2% of the topic boundaries are within turns, and 72.8% are between turns. For BNC the two proportions are 41.2% and 58.8% respectively.

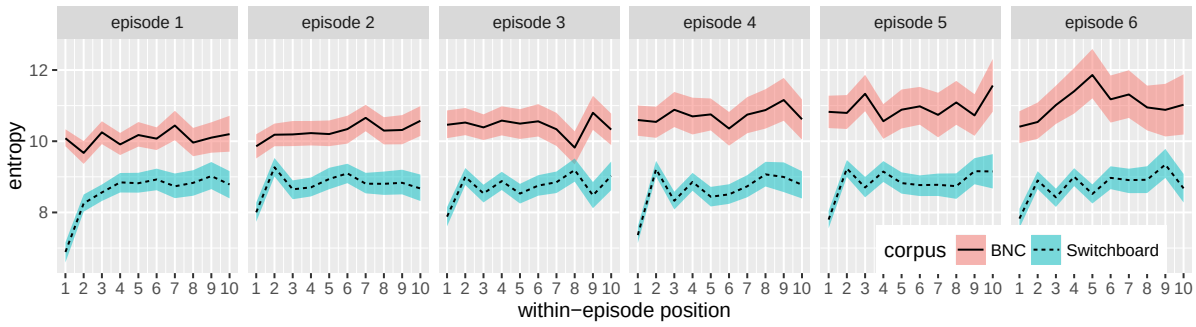
Intuitively, a within-turn topic boundary suggests that the speaker of the current turn is initiating the topic shift. On the other hand, a between-turn boundary suggests that the following speaker who first gives *substantial* contribution is more likely to be the initiator of the next topic. Following this intuition, for within-turn boundaries, we define TIU as the rest part of current turn after the boundary. For between-turn boundaries, we define TIU as the whole body of the next *relatively long* turn after the boundary, whose length is larger than N words. Note that the determination of threshold N is totally empirical, because our goal is to identify the most *probable* TIU, based on the intuition that longer sentences *tend* to contain more information, and thus are more likely to initiate a new topic. For the results shown later in this paper, we use $N = 5$, and our experiments draw similar results for $N \geq 5$. The operational definition of TIU is demonstrated in Figure 3.

4.3 The effect of topic initiator vs. responder

Based on the operational definition of topic initiating utterance (TIU), we distinguish the two speakers' roles in each topic segment: the author of TIU is the *initiator* of the current topic, while the other speaker is the *responder*.

Again, we plot the sentence entropy (and normalized) against the within-episode position respectively, this time, grouped by speaker roles (*initiator* vs. *responder*) in Figure 4. It can be seen that at the beginning of a topic, initiators have significantly higher entropy than responders. As the topic develops, the initiators' entropy decreases (Figure 4a) or stays relatively steady (Figure 4b), and the responder's entropy increases. Together they form a convergence trend within topic episode.

We use standard linear mixed models to examine the convergence trend observed, i.e., to test



(a) Entropy vs. within-episode position

(b) Normalized entropy vs. within-episode position

Figure 2: Entropy (a) and normalized entropy (b) against within-episode position grouped by episode index. The x-axis in each block indicates the within-episode position of sentence. The number 1 to 6 on top of the blocks are episode indexes. Shadow area indicates 95% bootstrapped Confidence Interval

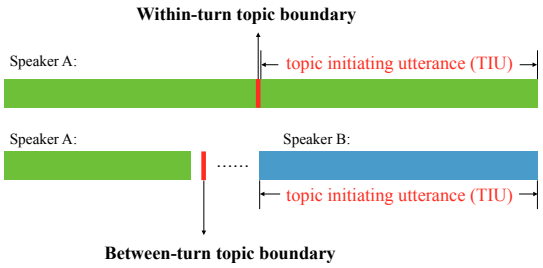


Figure 3: Operational definition of topic initiating utterances (TIUs). The red vertical bars indicate the topic boundaries placed using TextTiling. A complete horizontal bar of one color represents a turn from one speaker (green for speaker A and blue for speaker B). The upper line shows the case of within-turn topic boundary, and the lower line shows the case of between-turn topic boundary.

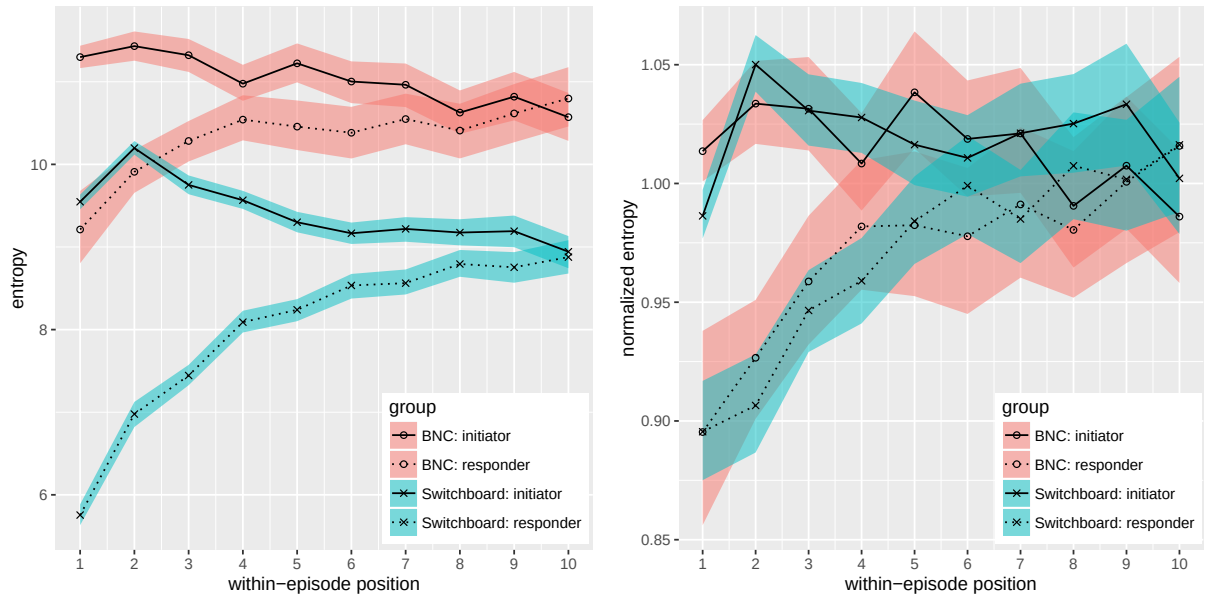
whether the initiators' entropy reliably decreases and whether the responders' entropy reliably increases. Models are fitted for initiators and responders respectively, using the entropy (and normalized) as response variables, and the within-episode position as predictor (fixed effect), with a random intercept grouped by the unique episode index. Our models show that for the entropy measure, the fixed effect of within-episode position is reliably negative for initiators (Switchboard, $\beta = -3.6 \times 10^{-2}$, $p < 0.001$; BNC, $\beta = -2.9 \times 10^{-2}$, $p < 0.05$) and reliably positive for responders (Switchboard, $\beta = 3.3 \times 10^{-1}$, $p < 0.001$; BNC, $\beta = 1.4 \times 10^{-1}$, $p < 0.001$). For the normalized entropy measure, the fixed effect of within-episode position is insignificant for initiators, which means there is neither increase nor decrease, and is reliably positive for responders (Switchboard, $\beta = 1.4 \times 10^{-2}$, $p < 0.001$; BNC, $\beta = 1.2 \times 10^{-2}$, $p < 0.001$). Thus, the convergence trend is confirmed.

The entropy change patterns of topic *initiators* (decrease or remain constant within topic episode) are inconsistent with previous findings that assert an entropy increase in written text (Genzel and



(a) (b)

Figure 4: Entropy (a) and normalized entropy (b) against within-episode position grouped by speaker roles (*topic initiator* vs. *topic responder*)

Charniak, 2002, 2003), which will be discussed in the next section.

5 Discussion

5.1 Summary

Our main contribution is that we find new entropy change patterns in dialogues that are different from those in written text. Specifically, when distinguishing the speakers' roles by topic *initiator* vs. *responder*, we see that the initiator's entropy decreases (or remain steady) whilst the responder's increases within a topic episode, and together they form a convergence pattern. The partial trend of entropy decrease in topic initiators seems to be contrary to the principle of entropy rate constancy, but as we will discuss next, it is actually an effect of the unique topic shift mechanism of dialogues that is different from written text, which does not violate the principle.

From an information theoretic perspective, we view dialogue as a process of information exchange, in which the interlocutors play the roles of information provider and receiver, interactively within each topic episode.

Beyond differences in speaker roles, we do observe that sentence entropy increases with its global position in the dialogue, which is consistent with written text data (Genzel and Charniak, 2002, 2003; Qian and Jaeger, 2011; Keller, 2004). Thus, overall speaking, spoken dialogue do follow the general principle of entropy rate constancy.

5.2 Dialogue as a process of information exchange

By combining topic segmentation techniques and fine-grained discourse analysis, we provide a new angle to view the big picture of human communication: the perspective of how information is distributed between different speakers.

One critical difference between written text and spoken text in conversation is that there is only one direct input source of information in the former, i.e., the author of the text, but for the latter, there are multiple direct input sources, i.e., the multiple speakers. That means, when language production is treated as a process of choosing proper words (or other representations) within a context, the definition of "context" is different between the two categories of text. In written language (see Equation 1 in Section 2), C_i, the global context of a word X_i, is assumed to be all the words in preceding sentences. This is a reasonable assumption, because when one author is writing a complete piece of text, he may organize information smoothly to keep the entropy rate constant. Within a dialogue, for any upcoming utterance, all preceding utterances together can be viewed as the *shared* context for the two speakers. To help us un-

derstand the nature of this shared context, we propose the following mental experiment. Suppose we, as researchers and "super-readers", observe the transcript of a dialogue between interlocutors A and B. To us, all utterances are based upon the context of previous ones, which is why we can observe consistent entropy increase within the whole dialogue (Figure 1 in Section 3). Also, to us, a new topic episode in dialogue is just like a new paragraph in written text, within which we can observe steady entropy increase without differentiating the utterances from the two speakers. By contrast, let's look at the context used by the two speakers. They will not necessarily leverage the preceding utterances as a coherent context. A *topic initiator* introduces new information from a context outside of the dialogue. Therefore the mutual information between the initiator's current sentence and the previous context is reduced, which causes the sentence entropy to start high before decreasing. On the other side, a *topic responder* relies much on the previous shared context (because he is not an active topic influencer). The responder is dynamically updating the context as the initiator pours new information into the mix. This causes the mutual information with the previous context to be high, and thus the sentence entropy start low before increasing again.

We think that the respective cognitive load in the topic responder imposed by following the other speaker in a new topic direction may be complemented by reduced information at the language level. This is, again, compatible with a cognitive communication framework that imposes a tendency to limit or keep constant overall information levels. It is also an example of extralinguistic information that causes complementary entropy changes in a speaker's language (cf., Doyle and Frank, 2015).

5.3 Dialogue as a process of building up common ground

Our findings can also be explained by a theory of *grounding* (Clark and Brennan, 1991; Clark, 1996) of communication. Dialogue can be seen as a joint activity during which multiple speakers contribute alternatively to build *common ground* (Clark and Brennan, 1991). Common ground can be understood as the mutual knowledge shared between interlocutors.

Clark (1996) proposes that joint activities have a number of characteristics: First, participants play different roles in the activity. Second, a major activity is usually comprised of sequences of subactivities, and the participants' role may differ from sub-activity to next. Third, to achieve the goal of the activity, it requires coordination between participants of different roles.

In our design, the local roles of *topic initiator* vs. *topic responder* correspond to roles suggested by the joint-activity theory. The initiator sets up the dominant goal of the sub-activity, i.e., developing a new *topic episode*, and the responder joins him or her in order to achieve the goal. The converging sentence entropy indicates that the mutual knowledge between them is accumulating, i.e., the common ground is being gradually built up. Once the goal is achieved, i.e., the current topic is fully developed, a new goal will emerge, and a new common ground needs to be built again, which is sometimes accompanied by a change in participants roles.

5.4 Convergence of linguistic behaviors

One mechanism that may lead to the convergence of sentence entropy may be the interactive alignment of linguistic features between speakers (Pickering and Garrod, 2004); repeating words and syntactic structure leads to increased similarity. The entropy-converging pattern also reflects the convergence of higher-level dialogical behavior, say, speakership occupancy; the discrepancy between the two speakers' roles gradually becomes smaller, i.e., the "speaker" becomes more of a "listener", and vice versa. A psychologist might treat the fragmented topic episodes in dialogues as the locus where interlocutors build temporarily shared understanding (Linell, 1998), through the process of "synchronization of two streams of consciousness" (Schutz, 1967).

6 Conclusion

In this study, we validate the principle of entropy rate constancy in spoken dialogue, using two common corpora. Besides the results that are consistent with previous findings on written text, we find new entropy change patterns unique to dialogue. Speakers that actively initiate a new topic tend to use language with higher entropy compared to the language of those who passively respond to the topic shift. These two speaker's respective entropy

levels converge as the topic develops. A model of this phenomenon may provide explanations from the perspectives of information exchange, common ground building, and the convergence of linguistic behaviors in general.

With this, we put forward what we think is a new perspective to analyzing dialogue. As much dialogue happens for the purpose of information exchange, loosely defined, it makes sense to apply information-theoretic models to the semantics as well as the form of speaker's messages. The quantitative approach taken here augments rather than supplants speech acts (Searle, 1976), identifying who leads the dialogic process by introducing topics and shifting them.

Furthermore, our approach actually provides a unified perspective of dialogue that combines Grounding theory (Clark and Brennan, 1991) and Interactive Alignment (Pickering and Garrod, 2004). These two models are often described as opposite; by applying each theory to the dialogic structure between and within topic episodes, we find both of them can explain our findings. The entropy measure of information content quantifies interlocutors' contributions to common ground and also allows us to show convergence patterns.

This unified information-theoretic perspective may eventually allow us to identify further systematic patterns of information exchange between dialogue participants. There is, of course, no reason to think that multi-party dialogue should work differently; we leave the empirical examination as an open task.

Abstract

To establish sophisticated dialogue systems, text planning needs to cope with congruent as well as incongruent interlocutor interests as given in everyday dialogues. Little attention has been given to this topic in text planning in contrast to dialogues that are fully aligned with anticipated user interests. When considering dialogues with congruent and incongruent interlocutor interests, dialogue partners are facing the constant challenge of finding a balance between cooperation and competition. We introduce the concept of fairness that operationalize an equal and adequate, i.e. equitable satisfaction of all interlocutors' interests. Focusing on Question-Answering (QA) settings, we describe an answer planning approach that support fair dialogues under congruent and incongruent interlocutor interests. Due to the fact that fairness is subjective per se, we present promising results from an empirical study (N=107) in which human subjects interacted with a QA system implementing the proposed approach.

1 Introduction

For building dialogue systems that cope with contradictions and individual interests of dialog partners, text planning is required to process incongruent and congruent interests of interlocutors. So far, research on dialogue systems focusses on supporting dialogues that are fully aligned with anticipated user interests, e.g., (Hovy, 1991; Grosz and Kraus, 1996; Moore and Paris, 1993; Lochbaum, 1998; Rich and Sidner, 1997), and, thus, maximizing cooperativeness (Bunt and Black, 2000, 191 p. 5). Few approaches exist that investigate text planning with pure conflict, e.g., (Jameson et al., 1994; Hadjinikolis et al., 2013; Black and Atkinson, 2011; Prakken, 2006). When considering dialogues with congruent as well as incongruent interlocutors interests, dialogue partners are facing the constant challenge of finding a balance between cooperation and competition (Parikh, 2010). We introduce the concept of *fairness* that operationalize an equal and adequate, i.e. equitable satisfaction of all interlocutors' interests (Oxford Dictionaries, 2016). Focusing on Question-Answering (QA) settings, we describe an answer planning approach that support fair dialogues under congruent and incongruent interests of interlocutors. Due to the fact that fairness is subjective per se, we present results from an empirical study in which human subjects interacted with a QA system in various dialogue settings.

When determining appropriate answers in text planning, approaches range from (1) wrong answer avoidance concepts technically checking the correctness of answers, e.g., Dong et al. (2011), and (2) opponent models in persuasion dialogues for choosing most suitable arguments, e.g., Hadjinikolis et al. (2013), to (3) the prediction of emotions of interlocutors to generate answers, e.g., Hasegawa et al. (2013). Here, related work is relevant that focuses on the determination of appropriate answers by processing concepts like users' intentions (e.g., Levelt (1993)), desires (e.g., Rao & Georgeff (1995)), preferences (e.g., Li et al. (2013)), objectives (e.g., Schelling (1960)) and goals (e.g., Traum et al. (2008)) which we will hereafter subsume under the term motives. *Motives* refer to objectives or situations that interlocutors would like to accomplish, e.g., to find the best price when shopping. According to the belief-desire-intention model, motives can be described as desires in the sense of a motivational state (Georgeff et al., 1998). Motives do not in-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 547–557,
Berlin, Germany, August 7-12, 2016.

volve the mandatory purpose of being recognizable by other participants; so they are equivalent with the concept of intentions in (Levelt, 1993). Regarding the processing of congruent and incongruent motives, existing approaches rather focus on motives of single interlocutors or on joint motives, e.g., Paquette (2012), Li et al. (2013). In the following, the aggregation of congruent and incongruent interlocutor motives in dialogues will be described as *mixed motives*.

In this work, we propose a model that formalizes answer planning as psychological game (Bjorndahl et al., 2013) embedded in text planning approaches (Mann and Thompson, 1986; Moore and Paris, 1993) for creating dialogues perceived as fair by all interlocutors. Since traditional formalization of motives by means of utility functions is not sufficient to handle complex interactions as given in the considered dialogue setting (Bjorndahl et al., 2013), psychological games enrich classical game settings with user models, i.e. in our case explicit representations of mixed motives. One appeal of the model is the consideration of answer planning as psychological game that lifts the process of finding appropriate answers from the short-term linguistic level to the long-term motive level in contrast to other approaches (van Deemter, 2009; Stevens et al., 2015). Interlocutors do not have preferences for answers, but try to satisfy motives. So, we assume that this approach enables a more sophisticated simulation of human behavior in mixed motive interactions as well as the establishment of "cooperativeness in response formulation" (Bunt and Black, 2000, p. 5) for creating dialogues perceived as fair. By exemplifying the model within a QA system as natural language sales assistant for conducting sales dialogues, we were able to evaluate the proposed approach in an empirical user study (N=107) in terms of perceived fairness of created dialogues with promising results.

2 Planning Answers given Mixed Motives

Adopting a computational pragmatics perspective, we intend to compute relevant linguistic aspects of answers based on contextual aspects given by mixed motives (Bunt and Black, 2000, p. 3). When searching for answers that support an equitable satisfaction of mixed motives during dialogue, Ω represents the solution space with potential answers. An objective function $f : \Omega \rightarrow \mathbb{R}$ assigns values to all answers $x \in \Omega$ for representing their potential in satisfying motives of interlocutor $i \in I$. Of course, all interlocutors I prefer answers x that satisfy best their motives; $x_{\mathrm{a}} \succ x_{\mathrm{b}} \Leftrightarrow f(x_{\mathrm{a}}) > f(x_{\mathrm{b}})$. So, the goal would be to find an answer $x \in \Omega$ with highest satisfaction of motives $f(x)$ of interlocutor $i \in I$ in the sense of an optimal solution x^*; i.e. $f(x^*) = max\{f(x)|x \in \Omega\}$. But, in order to achieve fair outcomes regarding an equitable, i.e. equal and adequate satisfaction of mixed motives, this definition is not sufficient. First, decision making takes places in the context of social dialogue interaction, i.e. answers have to be selected based on multiple objective functions since motives of all interlocutors $i \in I$ shall be satisfied; $f_{\mathrm{i}} : \Omega \rightarrow \mathbb{R}$. For capturing the aspect of equal motive satisfaction, the potential of answers has to be represented absolutely and relatively. In other words, the performance of an answer in satisfying motives of an interlocutor $i \in I$ is combined with its performance in satisfying motives of counterparts $-i \in I$; $max\{f_{\mathrm{i,\text{-}i}}(x)|x \in \Omega\}$. Second, the aforementioned conflict between cooperation and competition needs to be solved adequately. Since it is impossible to find an answer satisfying all motives of all interlocutors at any time in the dialogue, we search for a compromise in form of a solution i.e. an answer x^+ with a minimum quality s so that $f(x^+) \geq s$. Adopting the concept of satisficing by Simon (1956), an approach that attempts to find the best alternative available in contrast to optimal decision making, the goal is to find an answer $x \in \Omega$ with highest sufficient satisfaction of motives $f(x) \geq s$ of all interlocutors I in the sense of a satisficing solution x^+; i.e. $f(x^+) = max\{f_{\mathrm{i,\text{-}i}}(x) \geq s|x \in \Omega\}$.

3 Model for Planning Satisficing Answers

To capture these issues, we defined a model for planning satisficing answers in dialogues with mixed motives. In the considered setting, a user with motives poses questions to a QA system that takes the role of a proxy for indirect interlocutors, e.g., retailers in online shopping scenarios. The QA system adopts their motives and develops strategies to satisfy them. Adopted motives as well as user motives that are anticipated by the system represent mixed motives in the dialogue. Task of the system is to process these mixed mo-

tives with the objective to create a dialogue that is perceived as fair by all interlocutors after a finite number of question answer pairs. As full satisfaction of all motives of all interlocutors at any time in a mixed motive dialogue is not possible, the QA system has to find a compromise, i.e. it has to plan answers that satisfice mixed motives during dialogue. Let us start by describing an example dialogue between a customer and a retailer in a shopping scenario:

Q: *Is the range of this wifi router appropriate for a house with 3 floors?*

A: *In case of 3 floors, I would recommend an additional wifi repeater that got very good feedback by other customers. You can buy both router and repeater as a bundle with 15% discount.*

In this dialogue snippet, the customer intends to get comprehensive product information regarding the wifi router; the retailer also wants to satisfy informational needs of the customer to establish excellent services. Beyond these congruent motives, the retailer wants to increase revenue and to raise sales figures. A balance between mixed motives is found by giving information regarding the wifi router as well as preferences of other customers followed by a discounted bundle offer.

In order to implement this kind of behavior into dialogue systems, the model for planning satisficing answers separates linguistics from conceptual non-linguistic aspects (Traum and Larsson, 2003; Allen et al., 2001) and consists of three main modules: *linguistic module, mapper* and *mixed motive module* (cf. Fig. 1). The linguistic module takes care for handling user questions as input as well for generating answers as output. Essential components of the linguistic module are the linguistic intention model and flexible text planning technologies. For the latter, we apply text plans according to the Rhetorical Structure Theory (Mann and Thompson, 1986) in form of plan operators (Moore and Paris, 1993) for generating answers. Each plan operator consists of a single compulsive part, called nucleus, that is related with diverse optional text segments, mentioned as satellites. We assume that beside supporting the effect of the nucleus, satellites represent an opportunity to satisfice mixed motives during dialogue. Satellites are linked with entities of the linguistic intention model, means linguistic intentions that capture the intended effects, i.e. functions of satellites within answers (Grosz and Sidner, 1986). By means of second module - the mapper - linguistic intentions are mapped onto motives and vice versa (cf. Fig. 1). Therefore domain-specific knowledge about correlations between linguistic intentions and mixed motives is required that is induced by a domain configurator and has to be derived empirically. Last, the mixed motive module combines an explicit representation and situated processing of mixed motives (Cohen and Levesque, 1990) with a game-theoretical equilibrium approach (Nash, 1951) to establish a psychological game setting (Bjorndahl et al., 2013) (cf. Fig. 1). Our approach operates by assuming that interlocutors are rational. That means they act strategically and purposively in pursuit of their own motives that they try to maximally satisfy. Therefore, we assume that game theory is an adequate prospect to deliver the analytical tools for planning answers in the context of mixed motives. In game theory literature, equilibrium concepts are widely applied, e.g., Nash equilibrium (Nash, 1951). A Nash equilibrium is an outcome that holds because no involved actor has a rational incentive to deviate from it, i.e., the final result is "good enough" for all actors in the sense of a happy medium. Adapted to this work, this refers to a satisficing combination of motives at a particular time in the dialogue, that is good enough for planning an answer that supports equitable satisfaction of mixed motives.

3.1 Concepts

From a conceptual perspective, the model uses several core entities. First, we have players $p \in P$ that represent interlocutors I. Players have domain-specific motives m for participating in the dialogue. For each player $p \in P$, we assume a $MotiveSet$ that consists of individual motives, $IndM$, as well as of motives the player, i.e. the interlocutor anticipates from counterparts, $AntM$.

$$MotiveSet_{\mathrm{p}} = IndM_{\mathrm{p}} + AntM_{\text{-p}} \quad (1)$$

Mixed motives MM are represented by the non-redundant aggregation of $1 \ldots \mathrm{n}$ $MotiveSet$ of players $p \in P$ in the dialogue.

$$MM = \{MotiveSet_{\mathrm{p_1}} \ldots MotiveSet_{\mathrm{p_n}}\} \quad (2)$$

All motives $m \in MM$ are operationalized by means of real-valued weights for each player covered by a weight vector $\overrightarrow{Weight}_{\mathrm{m}}$. Motives are formed earlier and persist during dialogue, but

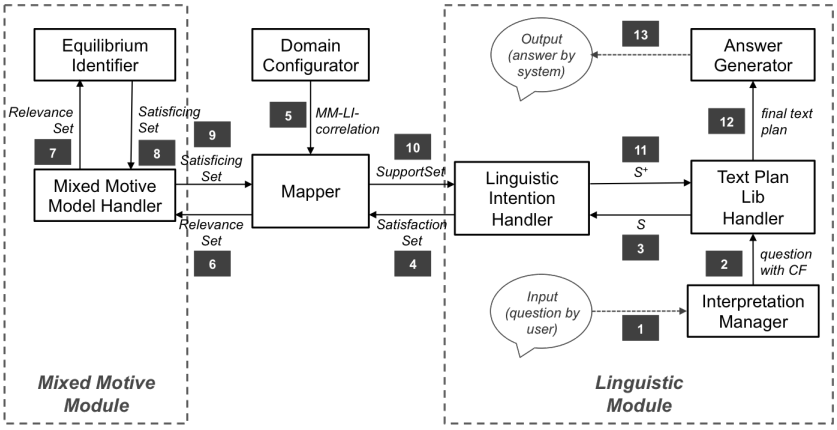

Figure 1: Model for planning satisficing answers in dialogues with mixed motives

players deliberate about weights of motives continuously (Bratman, 1987). The achievement and thereby satisfaction of motives is supported by linguistic intentions $li \in LI$ that are satisfied by satellites sat that are offered by plan operators and integrated into an answer. That means motives are achieved, if answers were given, that contributed to satisfaction of these motives.

3.2 Algorithm and example

For introducing the proposed approach, we will give an example course of satisficing answer planning starting with user question and ending with system answer. The description of the process will be supported by a model view marked with step numbers in Fig. 1 as well as by an algorithmic view in Alg. 1. In the example, we apply domain-specific knowledge that was derived empirically in the retailing domain. Although, in literature review, customer and retailer motives in sales dialogues were specified. Combinations of these motives were analyzed in simulated sales conversations between real retailers (N=3) and subjects acting as customers (N=12). Recorded as video files, conversations and identified motives were validated in a web-based user study (N=120) regarding their naturalness and relevance. Sales conversations were transcribed, aggregated to a text corpus and analyzed regarding question and answer structures. So, the domain-specific knowledge representation used in the example bases on results of this empirical analysis and covers all core model concepts introduced before: a mixed motive model with empirically derived default weights consisting of 19 customer and 4 retailer motives (cf. Tab. 1); 39 question and 33 answer schemata (McKeown, 1985), 31 plan operators (Moore and Paris, 1993), 21 satellites with 18 linguistic intentions (cf. Tab. 2) and 14 rhetorical relations (Hobbs, 1978; Hovy, 1993; Mann and Thompson, 1986), and exemplary product information.

Motive $m \in MM$	**Weight** $p_{\mathbf{a}}$	**Weight** $p_{\mathbf{b}}$
High level of reliability of product (m_{R})	1.90	1.00
Fair price of product (m_{FP})	0.70	0.00
Exclusive design of product (m_{ED})	0.53	1.00
Comprehensive product information (m_{CPI})	1.67	1.00
Improving customer relationship (m_{ICR})	0.00	4.00
Increase revenue (m_{IR})	4.00	4.00

Table 1: Extract of domain-specific mixed motive model with default weights for player (p_{a}) and player (p_{b}) representing customer and retailer

Imagine a sales conversation regarding consumer electronics between customer and retailer represented by player (p_{a}) and player (p_{b}). Sets of motives by players are equal regarding the motives included but differ in weights of individual and anticipated motives by players (cf. Tab. 1).

$$MM = MotiveSet_{\mathrm{p_a}} + MotiveSet_{\mathrm{p_b}} \quad (3)$$

$$MotiveSet_{\mathrm{p_a}} = IndM_{\mathrm{p_a}} + AntM_{\mathrm{p_b}}$$

$$MotiveSet_{\mathrm{p_b}} = IndM_{\mathrm{p_b}} + AntM_{\mathrm{p_a}}$$

The customer poses a question concerning products with a specific feature: *"How many tablets offer the wifi features 802.11A, 802.11B, 802.11G, 802.11n?"* Based on the identified question schema as well as the determined communicative function of the question, a dialogue system that instantiates the proposed model selects an appropriate plan operator (cf. Fig. 1, step 1 & 2).

Ling. Intention $li \in LI$	**supports** $m \in MM$	**Description**
Advantages (li_{A})	$\{m_{\text{ICR}}, m_{\text{FP}}, m_{\text{ED}}, m_{\text{IPD}}, m_{\text{R}}, m_{\text{HLS}}, m_{\text{ACB}}, m_{\text{SCD}}, m_{\text{I}}, m_{\text{HLP}}, m_{\text{PB}}, m_{\text{Q}}\}$	Integration of information about advantages of product(s) into answer
External_ Review (li_{ER})	$\{m_{\text{SI}}\}$	Presentation of customer reviews
My_Product (li_{MP})	$\{m_{\text{ICR}}, m_{\text{SP}}, m_{\text{R}}, m_{\text{HLC}}\}$	Mentioning products that could be interesting for customer
Functionality (li_{F})	$\{m_{\text{EU}}\}$	Extension of answer regarding product functions
Opinion (li_{O})	$\{m_{\text{HEM}}, m_{\text{SP}}, m_{\text{R}}, m_{\text{SI}}\}$	Integration of subjective (retailer) opinion into answer

Table 2: Extract of domain-specific linguistic intentions $li \in LI$ with supported motives and description

3.2.1 Definition of set S and determination of $SatisfactionSet$

In our case, a plan operator named NUMBER OF PRODUCTS is selected that offers an obligatory nucleus and a set S of four optional satellites (cf. Fig. 2):

$$S = \{sat_{\text{AAS}}, sat_{\text{VER}}, sat_{\text{DF}}, sat_{\text{EUP}}\} \quad (4)$$

Overall objective is to determine set S^{+} out of set S, that consists of satellites that - besides supporting the effect of the nucleus - contribute to satisficing mixes motives of customer and retailer during dialogue (cf. Alg. 1). According to (Grosz and Sidner, 1986; Moore and Paris, 1993), satellites are linked with linguistic intentions; i.e. they fulfill certain functions regarding the overall dialogue. Set S is sent to the linguistic intention handler that specifies the $SatisfactionSet$ (cf. Fig. 1, step 3 and Alg. 1, line 1-4). This set covers linguistic intentions that can be satisfied by satellites of set S (cf. Tab. 2):

$$SatisfactionSet = \{li_{\text{A}}, li_{\text{ER}}, li_{\text{F}}, li_{\text{MP}}\} \quad (5)$$

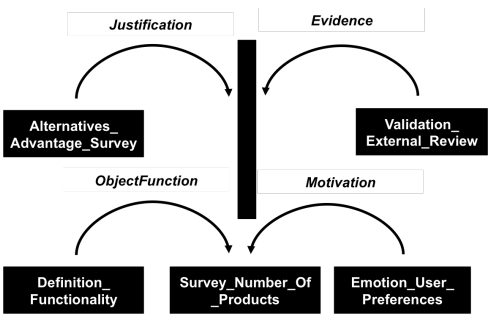

Figure 2: Plan operator NUMBER OF PRODUCTS

3.2.2 Mapping linguistic intentions onto mixed motives

Next, linguistic intentions have to be mapped onto motives. The m:n correlation between linguistic intentions and motives (Moore and Paris, 1993) is domain-specific, has to be specified empirically and is induced by the domain configurator (cf. Fig. 1, step 5). Each motive is supported by a set of linguistic intentions that contribute to the achievement of this motive (cf. Fig. 3). On the other hand, each linguistic intention can support the achievement of several motives. By processing

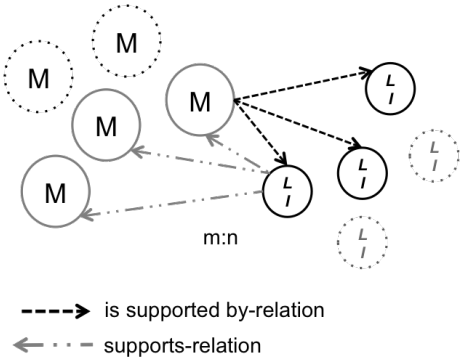

Figure 3: Correlations between motives (M) and linguistic intentions (LI)

the supports-relation between both concepts, the mapper specifies the $RelevanceSet$ based on the $SatisfactionSet$. The resulting $RelevanceSet$ represents all mixed motives relevant for planning the actual answer (cf. Alg. 1, line 5-8):

$$\begin{aligned} RelevanceSet = \{&m_{\text{Q}}, m_{\text{R}}, m_{\text{IPD}}, m_{\text{HCS}}, m_{\text{ACB}}, m_{\text{ICR}}, \\ &m_{\text{I}}, m_{\text{SCD}}, m_{\text{PB}}, m_{\text{EU}}, m_{\text{FP}}, m_{\text{ED}}, \\ &m_{\text{HLP}}, m_{\text{SI}}, m_{\text{SP}}, m_{\text{HLC}}\} \end{aligned} \quad (6)$$

3.2.3 Satisficing mixed motives

Having identified the $RelevanceSet$, we now intend to identify a satisficing combination of the involved motives. Therefore, the mapper sends the $RelevanceSet$ to the mixed motive model handler for specifying the $SatisficingSet$ that consists of motives that (1) are sufficiently interesting for all interlocutors (i.e. weighted positively), and (2) have preferably low conflict potential (i.e. small differences in player weights) (cf. Fig. 1, step 6). Satisficing mixed motives is considered as multi-player non-zero-sum game that is played for infinitely many rounds, more precisely pairs of user questions and system answers. In each round of the game, it has to be decided which motives

Algorithm 1 Determining set S^+ of satisficing satellites

Require: set of default satellites $S = \{sat_1 \dots sat_n\}$; set of players $P = \{p_1 \dots p_n\}$; set of mixed motives $MM = \{m_1 \dots m_n\}$; set of linguistic intentions $LI = \{li_1 \dots li_n\}$
Ensure: set of satisficing satellites $S^+ = \{sat_1 \dots sat_n\}$
1: Initialize $SatisfactionSet = \{li_1 \dots li_n \in LI | li.isSatisfiedBy(sat \in S)\}$
2: **for** $\forall sat \in S$ **do**
3: $SatisfactionSet \Leftarrow SatisfactionSet_{sat} \cup SatisfactionSet$
4: **end for**
5: Initialize $RelevanceSet = \{m_1 \dots m_n \in MM | m.isSupportedBy(li \in SatisfactionSet)\}$
6: **for** $\forall li \in SatisfactionSet$ **do**
7: $RelevanceSet \Leftarrow RelevanceSet_{li} \cup RelevanceSet$
8: **end for**
9: Determine $StrategySet \Leftarrow \mathcal{P}(RelevanceSet)$
10: Initialize $StrategyProfiles = \{\overrightarrow{s}_1 \dots \overrightarrow{s}_n\}$
11: **for** $\forall s \in StrategySet; \forall p \in P$ **do**
12: Calculate $LocalPayout(s)$
13: Define $\overrightarrow{s} = \{s_1 \dots s_n \in StrategySet | LocalPayout(s_p{}^* | s_{\text{-}p}) \geq LocalPayout(s_p | s_{\text{-}p})\}$
14: $StrategyProfiles.add(\overrightarrow{s})$
15: **end for**
16: **for** $\forall \overrightarrow{s} \in StrategyProfiles$ **do**
17: **if** $LocalPayout(s_p{}^* | s^*{}_{\text{-}p}) \geq LocalPayout(s_p | s^*{}_{\text{-}p})$ **then**
18: $\overrightarrow{s}^* \Leftarrow \overrightarrow{s}$
19: **end if**
20: **end for**
21: Determine $SatisficingSet = \{m_1 \dots m_n \in s \in \overrightarrow{s}^*\}$
22: **if** $SatisficingSet \neq \emptyset$ **then**
23: Initialize $SupportSet = \{li_1 \dots li_n \in LI | li.supports(m \in SatisficingSet)\}$
24: **for** $\forall m \in SatisficingSet$ **do**
25: $SupportSet \Leftarrow SupportSet_m \cup SupportSet$
26: **end for**
27: Return $S^+ = \{sat_1 \dots sat_n \in S | sat.satisfies(li \in SupportSet \cap SatisfactionSet)\}$
28: **else**
29: Return $S^+ = \{\emptyset\}$
30: **end if**

of the $RelevanceSet$ are selected as trigger for planning an answer that supports the creation of dialogues perceived as fair by all interlocutors. The equilibrium identifier specifies strategy sets $S_p = \{s_1 \dots s_n\}$ for all players P by generating the power set of the $RelevanceSet$ (cf. Fig. 1, step 7 and Alg. 1, line 9). Each of the 137 resulting strategies $s = \{m_1 \dots m_n\}$ represents a possible combination of motives or the empty set and is measured by a normalized local payout for each player based on weights of involved motives.

$$S_{p_a} = S_{p_b} = \{s_1 \dots s_{137}\}; s_{18} = \{m_Q, m_R\} \quad (7)$$

$$LocalPayout_{p_a,s_{18}} = 0.1280; LocalPayout_{p_b,s_{18}} = 0.0090$$

Strategy sets of players are identical regarding types of covered strategies, but differ in local payouts that can be expected by players when playing this strategy as shown in eq. (7). As players prefer those strategies that provide high local payouts, the equilibrium identifier identifies strategies $s^* \in S_p$ for each player that represent best answers regarding the behavior of counterparts $\overrightarrow{s_{\text{-}p}}$:

$$LocalPayout(s^*, \overrightarrow{s_{\text{-}p}}) \geq LocalPayout(s, \overrightarrow{s_{\text{-}p}}), \forall s \in S_p \quad (8)$$

Best answers of players in the sense of highest local payouts are aggregated to 17 strategy profiles, each a vector consisting of two strategies one for each player (cf. Alg. 1, line 10-15): $\overrightarrow{s} = \{s_x, s_y\}; s_x \in S_{p_a}, s_y \in S_{p_b}$.
Next, strategy profiles are selected that meet the Nash equilibrium condition, i.e. those strategy profiles exclusively cover strategies that represent mutual best answers of players (cf. Alg. 1, line 16-20):

$$LocalPayout(s^*, \overrightarrow{s_{\text{-}p}}^*) \geq LocalPayout(s, \overrightarrow{s_{\text{-}p}}^*) \quad (9)$$

$$\forall s \in \overrightarrow{s_1} \dots \overrightarrow{s_n}$$

In our example, we find two Nash equilibria. Those two strategy profiles represent best answers for the player p as well as the whole group of players P in the sense of a solution with minimum quality. No player has an incentive to deviate from those strategy profile because then its local payout would decrease. With $\overrightarrow{s} = \{s_{36}, s_{36}\}$, we select the non-pareto-dominant option for finding the strategy profile with the lowest difference in local payouts following the idea of the model to

create a balance between mixed motives. With each answer planning, players generate local payouts that are added during the course of dialogue to global payouts. Instead of gaining high global payouts, the objective of the model is to balance payouts of players during dialogue or to approximate them in case of drifting apart. We assume that similar global payouts of players can be regarded as evidence for satisficed mixed motives.
Based on the selected strategy profile, involved motives are aggregated to the $SatisficingSet = \{m_{\mathrm{R}}, m_{\mathrm{ICR}}\}$ that represents a combination of mixed motives that is satisficing for all players in this time in the dialogue (cf. Alg. 1, line 21).

3.2.4 Mapping mixed motives onto linguistic intentions

The resulting $SatisficingSet$ is forwarded to the mapper for mapping back motives onto linguistic intentions (cf. Fig. 1, step 8 & 9). In case, the $SatisficingSet$ covers zero motives, no mapping takes place, the process ends and none of the satellites in set S, cf. eq (4), will be considered in the actual answer planning. Otherwise, the mapper determines the set of supporting linguistic intentions by processing the inverse is-supported-by-relation between motives and linguistic intentions (cf. Alg. 1, line 22-30) (cf. Fig. 3). Comparing this set with the $SatisfactionSet$ (cf. eq. (5)), an intersection called $SupportSet$ is created that represents the set of linguistic intentions that will be satisfied in current answer planning:

$$SupportSet = \{li_{\mathrm{A}}, li_{\mathrm{MP}}\} \tag{10}$$

3.2.5 Determination of set S^+ and generation of answer

The linguistic intention handler determines the final set of satellites S^+ by analyzing 1:1 relations between linguistic intentions of the $SupportSet$ and satellites of the set S (cf. Fig. 1, step 10 and Alg. 1, line 27). The resulting set $S^+ = \{sat_{\mathrm{AAS}}, sat_{\mathrm{EUP}}\}$ consists of two satellites: *Alternatives_Advantages_Survey* (sat_{AAS}) and *Emotion_User_Preferences* (sat_{EUP}). The text plan lib handler adjusts the final text plan regarding the selected satellites before sending it to the answer generator (cf. Fig. 1, step 11 & 12). Last, the text plan provided by the plan operator NUMBER OF PRODUCTS is transformed into an answer. Thereby, answer schemata referenced by nucleus as well as satellites of set S^+ are instantiated (cf. Fig. 1, step 13):

Q: *"How many tablets offer the wifi features 802.11A, 802.11B, 802.11G, 802.11n?"*
A: *"*[$_{nuc}$ *The following tablets offer this feature: Sony SGPT122 Xperia.*] [$_{sat_{AAS}}$ *Due to its features, e.g., storage capacity: 32GB, Sony SGPT122 Xperia has some advantages compared to other products in this category.*] [$_{sat_{EUP}}$ *How about having a look at Sony SGPT122 Xperia by Sony?*]

3.2.6 Summary

In summary, satisficing answer planning is considered as a game consisting of four components $\langle P, S, F, A\rangle$: the set of players $P = \{p_{\mathrm{a}}, p_{\mathrm{b}}\}$, strategies of players $S = \{S_{\mathrm{p_a}}, S_{\mathrm{p_b}}\}$, objective functions of players $F = \{f_{\mathrm{p_a}}, f_{\mathrm{p_b}}\}$, and a state space $A = \{a^1 \dots a^{\mathrm{t}}\}$ that represents the rounds of the game, i.e. answers planned in the dialogue. The game starts in an initial state a^1. At a particular time t in the dialogue, the equilibrium identifier observes the state a^{t} characterized by P, S, and F and identifies best answers for all players; $s^{\mathrm{t}} \in S_{\mathrm{p}}; \forall p \in P$. Consequential, a strategy profile meeting the Nash equilibrium condition, $\overrightarrow{s}^{\mathrm{t}} = \{s^{\mathrm{t}}{}_{\mathrm{p_a}}, s^{\mathrm{t}}{}_{\mathrm{p_b}}\}$, is specified and resulting payouts are observed: $f(a^{\mathrm{t}}, \overrightarrow{s}^{\mathrm{t}}) \rightarrow LocalPayout \rightarrow \mathbb{R}$. The calculation of local payouts by means of objective functions $f \in F$ in state a^{t} does not depend solely on the selected strategy profile, but on results of former states in A, i.e. all answers planned in the dialogue until a^{t}. That means, infinite playing of the described non-zero-sum game $a^1, \overrightarrow{s}^1, \dots, a^{\mathrm{t}}, \overrightarrow{s}^{\mathrm{t}}, \dots$ generates a stream of payouts $f^1, f^2, \dots, f^{\mathrm{t}} = f(a^{\mathrm{t}}, \overrightarrow{s}^{\mathrm{t}})$. Besides relevant motives of the $RelevanceSet$, answer planning in state $a^{\mathrm{t+1}}$ is directly influenced by local payouts $f^{\mathrm{t}}(a^{\mathrm{t}}, \overrightarrow{s}^{\mathrm{t}})$ in a^{t} leading to a continuous deliberation of the mixed motive model during dialogue.

4 Implementation and Evaluation

Based on the proposed model (cf. Fig. 1), we implemented a German text-based QA system in form of a online shopping assistant (cf. Fig. 4)[1]. Users are able to construct questions term-by-term. Having tapped the last term of a question, the answer is given. The QA system uses the domain-specific knowledge representation mentioned in section 3.2 formalized in RDF[2].

[1] QA system was implemented as web application: http://redqueen.iss.uni-saarland.de/satin
[2] Resource Description Framework

Figure 4: Web-based QA system with posed question and given answer in German

4.1 Setting

To evaluate our approach, we conducted a user study with the implemented prototype in German that was set up as lab experiment. Goal of this study was to assess the perceived fairness and naturalness of the dialogue with the QA system as well as the extent of motive satisfaction of participants. For that purpose, four randomized groups were formed. Each group was characterized by a combination of motives by users (fair price of product (m_{FP}) or exclusive design of product (m_{ED})) and the QA system representing the retailer (increasing revenue (m_{IR}) or improving customer relationship (m_{ICR})) (cf. Tab. 3). These

		QA system	
	Motives	Increasing revenue (m_{IR})	Improving customer relationship (m_{ICR})
Users (N=107)	Fair price of product (m_{FP})	Mixed Motives Group #4	Mixed Motives Group #3
	Exclusive design of product (m_{ED})	Mixed Motives Group #2	Mixed Motives Group #1

Table 3: Groups and mixed motive combinations of user study

mixed motives were combined systematically by means of scenarios given to users and a manipulated mixed motive model of the QA system. Before interacting with the QA system that was embedded into a web-based questionnaire, participants had to opportunity to get to know the QA system and interacting with it for the first time (cf. Fig. 8). Participants were then asked to pose questions to the QA system and to evaluate generated answers against the background of their motive (e.g., m_{FP}) and the related scenario, e.g.:
"You are searching for a new tablet that shall be functional regarding standby and storage capacity. A fair price is important; no need for the latest innovation. You do not want to spend a lot of money for the new tablet. You are price conscious."
Participants were told to interact with the QA system as long as it needed to gain the information that was required by the scenario. Finally, seven-point Likert scales ranging from strongly disagree (1), neither (4) to strongly agree (7) were used to assess the perceived fairness of the dialogue, the naturalness of the dialogue and the motive satisfaction. Tab. 4 lists the questionnaire items for each of these constructs.

4.2 Results

In summary, 120 subjects participated in the experiment. A complete dataset from 107 participants (58,3% female) with an average age of 24.3 (SD=6.9) was considered for analysis. On average, interactions between participants (N=107) and the QA system covered 5.19 question answer pairs (cf. example dialogue in appendix A). 556 questions were posed by subjects; 35.07% of them were propositional questions (e.g., "Is product A up-to-date?"), 62.41% set questions (e.g., "Where is the difference between product A and product B?") and 2.52% choice questions (e.g., "Which product is better than product A?"), cf. Bunt et al. (2010).
Due to the fact that Cronbachs alpha values for all three multi-item constructs lie clearly above the recommended threshold of .70 (Nunnally, 1967),

Figure 5: Subject during interaction with QA system in user study

which indicates a good to excellent reliability of the scales, we calculated aggregated mean scores for each construct. The descriptive statistics of the three core constructs are presented in Tab. 4.

#	Construct	Item	Alpha	Aggregated scores (mean values of items)					Interpretation
				Mean	SD	one-sample t-test with test value 4			
						T	p	95% CI	
1	Perceived Naturalness of Dialogue	1. I perceived the sales dialogue with the shopping assistant as natural.	.847	4,05	1,19	0,41	0,686	-.18 - .27	Participants were undecided with respect to the naturalness of the dialogue with the QA system.
		2. I can imagine that this sales dialogue could have happened also in daily life.							
		3. I can remember a similar sales dialogue in my everyday life.							
		4. I can imagine to conduct a similar sales dialogue in my daily life.							
		5. I found that the sales dialogue with the shopping assistant was natural.							
		6. I could observe a similar sales dialogue in the past.							
2	Perceived Fairness of Dialogue	1. I found that the sales dialogue with the shopping assistant was pretty fair.	.947	5,17	1,20	10,10	0,000	.94 - 1.40	The dialogue was perceived as fair.
		2. The sales dialogue with the shopping assistant was particular equitably.							
		3.* I did not perceive the sales dialogue with the shopping assistant as being fair.							
		4.* To my understanding, the sales dialogue was not pretty equitably.							
3	Motive Satisfaction	1. I have achieved my motive in this sales dialogue.	.915	5,16	1,25	9,67	0,000	.93 - 1.40	Participants indicated that they were able to sufficiently satisfy their motives.
		2. I believe that I achieved my motive in this sales dialogue.							
		3. I was able to attain certain steps towards my motive in this sales dialogue.							
		4. * I was not able to attain my motive within the sales dialogue.							
* Reverse coded item									

Table 4: Descriptive statistics and results of one-sample t-tests for the empirical core constructs (N=107)

Additionally, results of one-sample t-tests are provided to evaluate whether the aggregated scores lie significantly above or below the neutral scale value of 4. Results indicate that the participants were undecided with respect to the "Perceived Naturalness of Dialogue" with the QA system. We assume that this is owed to the restricted QA setting since there were no significant differences among the four groups ($F(3,104) = 2.06$, $p = .11$) (cf. Tab. 3). However, the data support the conclusion that participants perceived the dialogue as fair and that they were able to sufficiently satisfy their motives. Assuming rather conflicting motives of subject and QA system as given for instance in group #4 in Tab. 3, it could be assumed that perceived fairness and motive satisfaction should be smaller than in rather congruent motive combinations as shown in group #1. Nonetheless, the mean value of the construct "Perceived Fairness of Dialogue" was 5.17 across all groups (significant above mean value 4) and there were no significant differences between the randomized groups ($F(3,104) = 1.59$, $p = .20$). Furthermore, "Motive Satisfaction" was rated with a mean value of 5.16 across all groups (significant above mean value 4) and again, there was not a significant effect of the group on motive satisfaction at the .05 level of significance ($F(3,104) = 2.33$, $p = .08$).
Overall, this indicates a positive evaluation of the QA system regarding its ability to generate satisficing answers despite of mixed motives of interlocutors.

5 Conclusion

We considered dialogues with congruent as well as incongruent interlocutor motives, where dialogue partners are facing the constant challenge of finding a balance between cooperation and competition. Despite of the overall presence of dialogues with such mixed motives in everyday life, little attention has been given to this topic in text planning in contrast to scrutinized dialogue systems that support dialogues fully aligned with anticipated user interests. Focusing on Question-Answering (QA) settings, we introduced a model that formalizes answer planning as psychological game embedded in text planning approaches for supporting fair dialogues under mixed motives. The model was exemplified within a QA sales assistant with domain-specific world knowledge for conducting sales dialogues. Due to the fact that fairness is subjective per se, we presented results from an empirical study (N=107) in which human subjects interacted with the QA system in various mixed motive settings. Results indicate a positive evaluation of the systems performance in planning answers that support fair dialogues despite of mixed motives of interlocutors.

A Example dialogue between user and QA system

In the following, an example dialogue between a user and the QA system consisting of four question answer pairs is given. Questions (Q) are segmentally constructed by the user. Answers (A) consisting of text, images, links to webpages and/or external product offers are generated by the QA system.

(1) Q: Which tablets are available in lower price range?

(2) A: In this price range, the following products are available: Lenovo Yoga. Compared to other products in this category, Lenovo Yoga offers advantages regarding its price of 198.99€. Currently, a lot of customers ask for Lenovo Yoga. Regarding the price-performance ratio, the product is absolutely recommended.

(3) Q: Is there a discount for Lenovo Yoga?

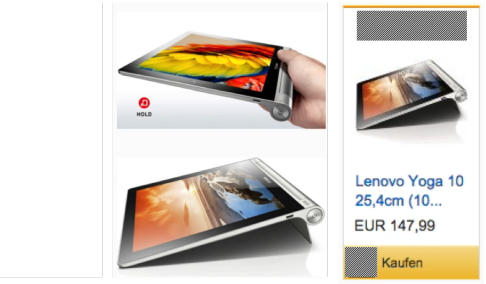
(4) A: For Lenovo Yoga, there is a discount of 1%. The total comes to 197.00€. Lenovo Yoga goes with Apple iPod Nano, Sony NWZ-E585B Walkman, Apple iPhone 5S and Apple iPhone 4S.

(5) Q: How many tablets offer a standby time of at least 18h?

(6) A: The following tablets offer this feature: Lenovo Yoga. How about having a look at Lenovo Yoga by Lenovo?

(7) Q: Are there any offers for Lenovo Yoga?

(8) A: You can order this product online, as you can see here:



A Sentence Interaction Network for Modeling Dependence between Sentences

Abstract

Modeling interactions between two sentences is crucial for a number of natural language processing tasks including Answer Selection, Dialogue Act Analysis, etc. While deep learning methods like Recurrent Neural Network or Convolutional Neural Network have been proved to be powerful for sentence modeling, prior studies paid less attention on interactions between sentences. In this work, we propose a Sentence Interaction Network (SIN) for modeling the complex interactions between two sentences. By introducing "interaction states" for word and phrase pairs, SIN is powerful and flexible in capturing sentence interactions for different tasks. We obtain significant improvements on Answer Selection and Dialogue Act Analysis without any feature engineering.

1 Introduction

There exist complex interactions between sentences in many natural language processing (NLP) tasks such as Answer Selection (Yu et al., 2014; Yin et al., 2015), Dialogue Act Analysis (Kalchbrenner and Blunsom, 2013), etc. For instance, given a question and two candidate answers below, though they are all talking about cats, only the first answer correctly answers the question about cats' appearance. It is important to appropriately model the relation between two sentences in such cases.

Q	*What do cats look like?*
A1	*Cats have large eyes and furry bodies.*
A2	*Cats like to play with boxes and bags.*

* Correspondence author

For sentence pair modeling, some methods first project the two sentences to fix-sized vectors separately without considering the interactions between them, and then fed the sentence vectors to other classifiers as features for a specific task (Kalchbrenner and Blunsom, 2013; Tai et al., 2015). Such methods suffer from being unable to encode context information during sentence embedding.

A more reasonable way to capture sentence interactions is to introduce some mechanisms to utilize information from both sentences at the same time. Some methods attempt to introduce an attention matrix which contains similarity scores between words and phrases to approach sentence interactions (Socher et al., 2011; Yin et al., 2015). While the meaning of words and phrases may drift from contexts to contexts, simple similarity scores may be too weak to capture the complex interactions, and a more powerful interaction mechanism is needed.

In this work, we propose a Sentence Interaction Network (SIN) focusing on modeling sentence interactions. The main idea behind this model is that each word in one sentence may potentially influence every word in another sentence in some degree (the word "influence" here may refer to "answer" or "match" in different tasks). So, we introduce a mechanism that allows information to flow from every word (or phrase) in one sentence to every word (or phrase) in another sentence. These "information flows" are real-valued vectors describing how words and phrases interact with each other, for example, a word (or phrase) in one sentence can modify the meaning of a word (or phrase) in another sentence through such "information flows".

Specifically, given two sentences s_1 and s_2, for every word x_t in s_1, we introduce a "candidate interaction state" for every word x_τ in s_2. This

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 558–567,
Berlin, Germany, August 7-12, 2016.

state is regarded as the "influence" of x_τ to x_t, and is actually the "information flow" from x_τ to x_t mentioned above. By summing over all the "candidate interaction states", we generate an "interaction state" for x_t, which represents the influence of the whole sentence s_2 to word x_t . When feeding the "interaction state" and the word embedding together into Recurrent Neural Network (with Long Short-Time Memory unit in our model), we obtain a sentence vector with context information encoded. We also add a convolution layer on the word embeddings so that interactions between phrases can also be modeled.

SIN is powerful and flexible for modeling sentence interactions in different tasks. First, the "interaction state" is a vector, compared with a single similarity score, it is able to encode more information for word or phrase interactions. Second, the interaction mechanism in SIN can be adapted to different functions for different tasks during training, such as "word meaning adjustment" for Dialogue Act Analysis or "Answering" for Answer Selection.

Our main contributions are as follows:

- We propose a Sentence Interaction Network (SIN) which utilizes a new mechanism to model sentence interactions.
- We add convolution layers to SIN, which improves the ability to model interactions between phrases.
- We obtain significant improvements on Answer Selection and Dialogue Act Analysis without any handcrafted features.

The rest of the paper is structured as follows: We survey related work in Section 2, introduce our method in Section 3, present the experiments in Section 4, and summarize our work in Section 5.

2 Related Work

Our work is mainly related to deep learning for sentence modeling and sentence pair modeling.

For sentence modeling, we have to first represent each word as a real-valued vector (Mikolov et al., 2010; Pennington et al., 2014) , and then compose word vectors into a sentence vector. Several methods have been proposed for sentence modeling. Recurrent Neural Network (RNN) (Elman, 1990; Mikolov et al., 2010) introduces a hidden state to represent contexts, and repeatedly feed the hidden state and word embeddings to the network to update the context representation. RNN suffers from gradient vanishing and exploding problems which limit the length of reachable context. RNN with Long Short-Time Memory Network unit (LSTM) (Hochreiter and Schmidhuber, 1997; Gers, 2001) solves such problems by introducing a "memory cell" and "gates" into the network. Recursive Neural Network (Socher et al., 2013; Qian et al., 2015) and LSTM over tree structures (Zhu et al., 2015; Tai et al., 2015) are able to utilize some syntactic information for sentence modeling. Kim (2014) proposed a Convolutional Neural Network (CNN) for sentence classification which models a sentence in multiple granularities.

For sentence pair modeling, a simple idea is to first project the sentences to two sentence vectors separately with sentence modeling methods, and then feed these two vectors into other classifiers for classification (Tai et al., 2015; Yu et al., 2014; Yang et al., 2015). The drawback of such methods is that separately modeling the two sentences is unable to capture the complex sentence interactions. Socher et al. (2011) model the two sentences with Recursive Neural Networks (Unfolding Recursive Autoencoders), and then feed similarity scores between words and phrases (syntax tree nodes) to a CNN with dynamic pooling to capture sentence interactions. Hu et al. (2014) first create an "interaction space" (matching score matrix) by feeding word and phrase pairs into a multilayer perceptron (MLP), and then apply CNN to such a space for interaction modeling. Yin et al. (2015) proposed an Attention based Convolutional Neural Network (ABCNN) for sentence pair modeling. ABCNN introduces an attention matrix between the convolution layers of the two sentences, and feed the matrix back to CNN to model sentence interactions. There are also some methods that make use of rich lexical semantic features for sentence pair modeling (Yih et al., 2013; Yang et al., 2015), but these methods can not be easily adapted to different tasks.

Our work is also related to context modeling. Hermann et al. (2015) proposed a LSTM-based method for reading comprehension. Their model is able to effectively utilize the context (given by a document) to answer questions. Ghosh et al. (2016) proposed a Contextual LSTM (CLSTM) which introduces a topic vector into LSTM for context modeling. The topic vector in CLSTM is

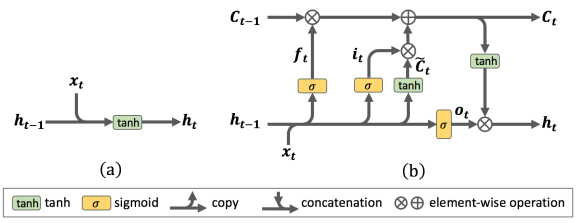

Figure 1: RNN (a) and LSTM (b) [1]

computed according to those already seen words, and therefore reflects the underlying topic of the current word.

3 Method

3.1 Background: RNN and LSTM

Recurrent Neural Network (RNN) (Elman, 1990; Mikolov et al., 2010), as depicted in Figure 1(a), is proposed for modeling long-distance dependence in a sequence. Its hidden layer is connected to itself so that previous information is considered in later times. RNN can be formalized as

$$h_t = f(W_x x_t + W_h h_{t-1} + b_h)$$

where x_t is the input at time step t and h_t is the hidden state. Though theoretically, RNN is able to capture dependence of arbitrary length, it tends to suffer from the gradient vanishing and exploding problems which limit the length of reachable context. In addition, an additive function of the previous hidden layer and the current input is too simple to describe the complex interactions within a sequence.

RNN with Long Short-Time Memory Network unit (LSTM, Figure 1(b)) (Hochreiter and Schmidhuber, 1997; Gers, 2001) solves such problems by introducing a "memory cell" and "gates" into the network. Each time step is associated with a subnet known as a memory block in which a "memory cell" stores the context information and "gates" control which information should be added or discarded or reserved. LSTM can be formalized as

$$\begin{aligned} f_t &= \sigma(W_f \cdot [x_t, h_{t-1}] + b_f) \\ i_t &= \sigma(W_i \cdot [x_t, h_{t-1}] + b_i) \\ \tilde{C}_t &= \tanh(W_C \cdot [x_t, h_{t-1}] + b_C) \\ C_t &= f_t * C_{t-1} + i_t * \tilde{C}_t \\ o_t &= \sigma(W_o \cdot [x_t, h_{t-1}] + b_o) \\ h_t &= o_t * \tanh(C_t) \end{aligned}$$

where $*$ means element-wise multiplication, f_t, i_t, o_t is the forget, input and output gate that control which information should be forgot, input and output, respectively. $\tilde{C}_t$ is the candidate information to be added to the memory cell state C_t. h_t is the hidden state which is regarded as a representation of the current time step with contexts.

In this work, we use LSTM with peephole connections, namely adding C_{t-1} to compute the forget gate f_t and the input gate i_t, and adding C_t to compute the output gate o_t.

3.2 Sentence Interaction Network (SIN)

Sentence Interaction Network (SIN, Figure 2) models the interactions between two sentences in two steps.

First, we use a LSTM (referred to as LSTM_1) to model the two sentences s_1 and s_2 separately, and the hidden states related to the t-th word in s_1 and the τ-th word in s_2 are denoted as $z_t^{(1)}$ and $z_\tau^{(2)}$ respectively. For simplicity, we will use the position (t, τ) to denote the corresponding words hereafter.

Second, we propose a new mechanism to model the interactions between s_1 and s_2 by allowing information to flow between them. Specifically, word t in s_1 may be potentially influenced by all words in s_2 in some degree. Thus, for word t in s_1, a candidate interaction state $\tilde{c}_{t\tau}^{(i)}$ and an input gate $i_{t\tau}^{(i)}$ are introduced for each word τ in s_2 as follows:

$$\begin{aligned} \tilde{c}_{t\tau}^{(i)} &= \tanh(W_c^{(i)} \cdot [z_t^{(1)}, z_\tau^{(2)}] + b_c^{(i)}) \\ i_{t\tau}^{(i)} &= \sigma(W_i^{(i)} \cdot [z_t^{(1)}, z_\tau^{(2)}] + b_i^{(i)}) \end{aligned}$$

here, the superscript "i" indicates "interaction". $W_c^{(i)}, W_i^{(i)}, b_c^{(i)}, b_i^{(i)}$ are model parameters. The interaction state $c_t^{(i)}$ for word t in s_1 can then be formalized as

$$c_t^{(i)} = \sum_{\tau=1}^{|s_2|} \tilde{c}_{t\tau}^{(i)} * i_{t\tau}^{(i)}$$

where $|s_2|$ is the length of sentence s_2, and $c_t^{(i)}$ can be viewed as the total interaction information received by word t in s_1 from sentence s_2. The interaction states of words in s_2 can be similarly

[1] This figure referred to http://colah.github.io/posts/2015-08-Understanding-LSTMs/

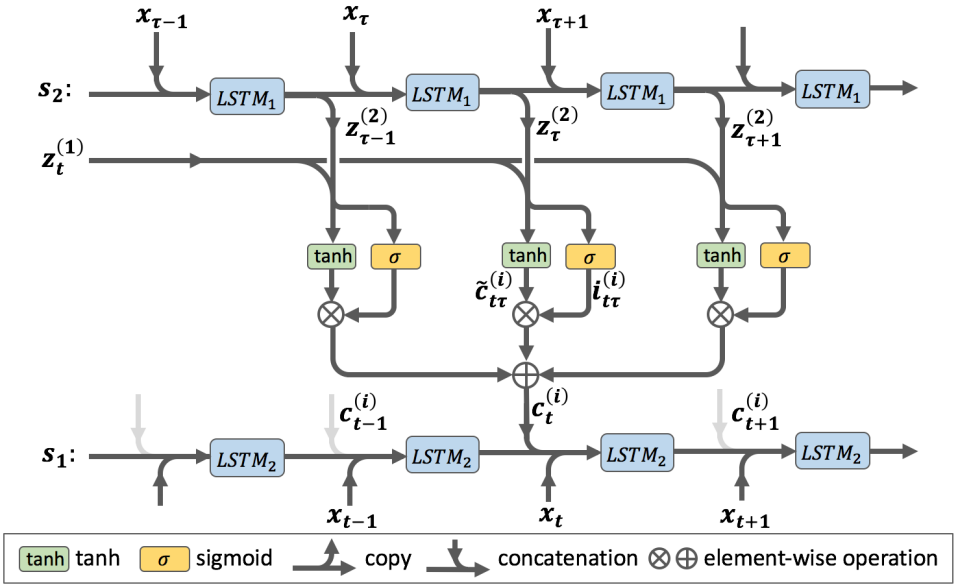

Figure 2: SIN for modeling sentence s_1 at timestep t. First, we model s_1 and s_2 separately with LSTM$_1$ and obtain the hidden states $z_t^{(1)}$ for s_1 and $z_\tau^{(2)}$ for s_2. Second, we compute interaction states based on these hidden states, and incorporate $c_t^{(i)}$ into LSTM$_2$. Information flows (interaction states) from s_1 to s_2 are not depicted here for simplicity.

computed by exchanging the position of $z_t^{(1)}$ and $z_\tau^{(2)}$ in $\tilde{c}_{t\tau}^{(i)}$ and $i_{t\tau}^{(i)}$ while sharing the model parameters.

We now introduce the interaction states into another LSTM (referred to as LSTM$_2$) to compute the sentence vectors. Therefore, information can flow between the two sentences through these states. For sentence s_1, at timestep t, we have

$$
\begin{aligned}
f_t &= \sigma(W_f \cdot [x_t, h_{t-1}, c_t^{(i)}, C_{t-1}] + b_f) \\
i_t &= \sigma(W_i \cdot [x_t, h_{t-1}, c_t^{(i)}, C_{t-1}] + b_i) \\
\tilde{C}_t &= \tanh(W_C \cdot [x_t, h_{t-1}, c_t^{(i)}] + b_C) \\
C_t &= f_t * C_{t-1} + i_t * \tilde{C}_t \\
o_t &= \sigma(W_o \cdot [x_t, h_{t-1}, c_t^{(i)}, C_t] + b_o) \\
h_t &= o_t * \tanh(C_t)
\end{aligned}
$$

By averaging all hidden states of LSTM$_2$, we obtain the sentence vector v_{s_1} of s_1, and the sentence vector v_{s_2} of s_2 can be computed similarly. v_{s_1} and v_{s_2} can then be used as features for different tasks.

In SIN, the candidate interaction state $\tilde{c}_{t\tau}^{(i)}$ represents the potential influence of word τ in s_2 to word t in s_1, and the related input gate $i_{t\tau}^{(i)}$ controls the degree of the influence. The element-wise multiplication $\tilde{c}_{t\tau}^{(i)} * i_{t\tau}^{(i)}$ is then the actual influence. By summing over all words in s_2, the interaction state $c_t^{(i)}$ gives the influence of the whole sentence s_2 to word t.

3.3 SIN with Convolution (SIN-CONV)

SIN is good at capturing the complex interactions of words in two sentences, but not strong enough for phrase interactions. Since convolutional neural network is widely and successfully used for modeling phrases, we add a convolution layer before SIN to model phrase interactions between two sentences.

Let $v_1, v_2, ..., v_{|s|}$ be the word embeddings of a sentence s, and let $c_i \in \mathbb{R}^{wd}, 1 \leq i \leq |s| - w + 1$, be the concatenation of $v_{i:i+w-1}$, where w is the window size. The representation p_i for phrase $v_{i:i+w-1}$ is computed as:

$$p_i = \tanh(F \cdot c_i + b)$$

where $F \in \mathbb{R}^{d \times wd}$ is the convolution filter, and d is the dimension of the word embeddings.

In SIN-CONV, we first use a convolution layer to obtain phrase representations for the two sentences s_1 and s_2, and the SIN interaction procedure is then applied to these phrase representations as before to model phrase interactions. The average of all hidden states are treated as sentence vectors $v_{s_1}^{cnn}$ and $v_{s_2}^{cnn}$. Thus, SIN-CONV is SIN with word vectors substituted by phrase vectors. The

two phrase-based sentence vectors are then fed to a classifier along with the two word-based sentence vectors together for classification.

The LSTM and interaction parameters are not shared between SIN and SIN-CONV.

4 Experiments

In this section, we test our model on two tasks: Answer Selection and Dialogue Act Analysis. Both tasks require to model interactions between sentences. We also conduct auxiliary experiments for analyzing the interaction mechanism in our SIN model.

4.1 Answer Selection

Selecting correct answers from a set of candidates for a given question is quite crucial for a number of NLP tasks including question-answering, natural language generation, information retrieval, etc. The key challenge for answer selection is to appropriately model the complex interactions between the question and the answer, and hence our SIN model is suitable for this task.

We treat Answer Selection as a classification task, namely to classify each question-answer pair as "correct" or "incorrect". Given a question-answer pair (q, a), after generating the question and answer vectors v_q and v_a using SIN, we feed them to a logistic regression layer to output a probability. And we maximize the following objective function:

$$p_\theta(q, a) = \sigma(W \cdot [v_q, v_a]) + b)$$
$$\mathcal{L} = \sum_{(q,a)} \hat{y}_{q,a} \log p_\theta(q, a) + (1 - \hat{y}_{q,a}) \log(1 - p_\theta(q, a))$$

where $\hat{y}_{q,a}$ is the true label for the question-answer pair (q, a) (1 for correct, 0 for incorrect). For SIN-CONV, the sentence vector v_q^{cnn} and v_a^{cnn} are also fed to the logistic regression layer.

During evaluation, we rank the answers of a question q according to the probability $p_\theta(q, a)$. The evaluation metrics are mean average precision (MAP) and mean reciprocal rank (MRR).

4.1.1 Dataset

The WikiQA[2](Yang et al., 2015) dataset is used for this task. Following Yin et al. (2015), we filtered out those questions that do not have any correct answers from the development and test set. Some statistics are shown in Table 1.

	Q	QA pair	A/Q	correct A/Q
Train	2,118	20,360	9.61	0.49
Dev	126	1,130	8.97	1.11
Test	243	2,351	9.67	1.21

Table 1: Statistics of WikiQA (Q=Question, A=Answer)

4.1.2 Setup

We use the 100-dimensional GloVe vectors[3] (Pennington et al., 2014) to initialize our word embeddings, and those words that do not appear in Glove vectors are treated as unknown. The dimension of all hidden states is set to 100 as well. The window size of the convolution layer is 2. To avoid overfitting, dropout is introduced to the sentence vectors, namely setting some dimensions of the sentence vectors to 0 with a probability p (0.5 in our experiment) randomly. No handcrafted features are used in our methods and the baselines.

Mini-batch Gradient Descent (30 question-answer pairs for each mini batch), with AdaDelta tuning learning rate, is used for model training. We update model parameters after every mini batch, check validation MAP and save model after every 10 batches. We run 10 epochs in total, and the model with highest validation MAP is treated as the optimal model, and we report the corresponding test MAP and MRR metrics.

4.1.3 Baselines

We compare our SIN and SIN-CONV model with 5 baselines listed below:

- LCLR: The model utilizes rich semantic and lexical features (Yih et al., 2013).
- PV: The cosine similarity score of paragraph vectors of the two sentences is used to rank answers (Le and Mikolov, 2014).
- CNN: Bigram CNN (Yu et al., 2014).
- ABCNN: Attention based CNN, no handcrafted features are used here (Yin et al., 2015).
- LSTM: The question and answer are modeled by a simple LSTM. Different from SIN, there is no interaction between sentences.

[2]http://aka.ms/WikiQA

[3]http://nlp.stanford.edu/projects/glove/

4.1.4 Results

Results are shown in Table 2. SIN performs much better than LSTM, PV and CNN, this justifies that the proposed interaction mechanism well captures the complex interactions between the question and the answer. But SIN performs slightly worse than ABCNN because it is not strong enough at modeling phrases. By introducing a simple convolution layer to improve its phrase-modeling ability, SIN-CONV outperforms all the other models.

For SIN-CONV, we do not observe much improvements by using larger convolution filters (window size ≥ 3) or stacking more convolution layers. The reason may be the fact that interactions between long phrases is relatively rare, and in addition, the QA pairs in the WikiQA dataset may be insufficient for training such a complex model with long convolution windows.

4.2 Dialogue Act Analysis

Dialogue acts (DA), such as *Statement, Yes-No-Question, Agreement*, indicate the sentence pragmatic role as well as the intention of the speakers (Williams, 2012). They are widely used in natural language generation (Wen et al., 2015), speech and meeting summarization (Murray et al., 2006; Murray et al., 2010), etc. In a dialogue, the DA of a sentence is highly relevant to the content of itself and the previous sentences. As a result, to model the interactions and long-range dependence between sentences in a dialogue is crucial for dialogue act analysis.

Given a dialogue (n sentences) $d = [s_1, s_2, ..., s_n]$, we first use a LSTM (LSTM_1) to model all the sentences independently. The hidden states of sentence s_i obtained at this step are used to compute the interaction states of sentence s_{i+1}, and SIN will generate a sentence vector v_{s_i} using another LSTM (LSTM_2) for each sentence s_i in the dialogue (see Section 3.2) . These sentence vectors can be used as features for dialogue act analysis. We refer to this method as SIN (or SIN-CONV for adding a convolution layer).

For dialogue act analysis, we add a softmax layer on the sentence vector v_{s_i} to predict the probability distribution:

$$p_\theta(y_j|v_{s_i}) = \frac{\exp(v_{s_i}^T \cdot w_j + b_j)}{\sum_k \exp(v_{s_i}^T \cdot w_k + b_k)}$$

[4]With extra handcrafted features, ABCNN's performance is: MAP(0.692), MRR(0.711).

Model	MAP	MRR
LCLR	0.599	0.609
PV	0.511	0.516
CNN	0.619	0.628
ABCNN	0.660	0.677
LSTM	0.634	0.648
SIN	0.657	0.672
SIN-CONV	**0.674**	**0.693**

Table 2: Results on answer selection[4].

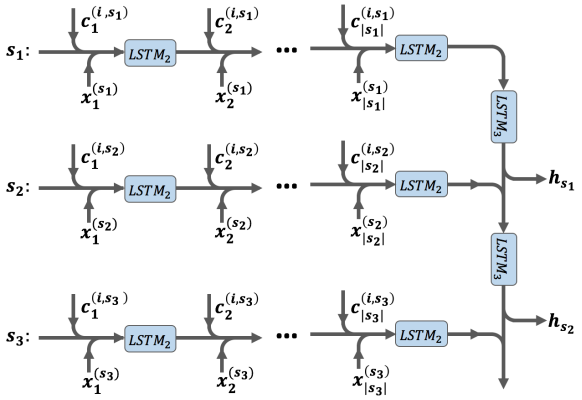

Figure 3: SIN-LD for dialogue act analysis. LSTM_1 is not shown here for simplicity. $x_t^{(s_j)}$ means word t in s_j, $c_t^{(i,s_j)}$ means the interaction state for word t in s_j.

where y_j is the j-th DA tag, w_j and b_j is the weight vector and bias corresponding to y_j. We maximize the following objective function:

$$\mathcal{L} = \sum_{d \in \mathcal{D}} \sum_{i=1}^{|d|} \log p_\theta(\hat{y}_{s_i}|v_{s_i})$$

where $\mathcal{D}$ is the training set, namely a set of dialogues, $|d|$ is the length of the dialogue, s_i is the i-th sentence in d, $\hat{y}_{s_i}$ is the true dialogue act label of s_i.

In order to capture long-range dependence in the dialogue, we can further join up the sentence vector v_{s_i} with another LSTM (LSTM_3). The hidden state h_{s_i} of LSTM_3 are treated as the final sentence vector, and the probability distribution is given by substituting v_{s_i} with h_{s_i} in $p_\theta(y_j|v_{s_i})$. We refer to this method as SIN-LD (or SIN-CONV-LD for adding a convolution layer), where LD means long-range dependence. Figure 3 shows the whole structure (LSTM_1 is not shown here for simplicity).

Dialogue Act	Example	Train(%)	Test(%)
Statement-non-Opinion	*Me, I'm in the legal department.*	37.0	31.5
Backchannel/Acknowledge	*Uh-huh.*	18.8	18.3
Statement-Opinion	*I think it's great*	12.8	17.2
Abandoned/Uninterpretable	*So,-*	7.6	8.6
Agreement/Accept	*That's exactly it.*	5.5	5.0
Appreciation	*I can imagine.*	2.4	1.8
Yes-No-Question	*Do you have to have any special training?*	2.3	2.0
Non-Verbal	*[Laughter], [Throat-clearing]*	1.8	2.3
Yes-Answers	*Yes.*	1.5	1.7
Conventional-closing	*Well, it's been nice talking to you.*	1.3	1.9
Other Labels(32)		9.1	9.8
Total number of sentences		196258	4186
Total number of dialogues		1115	19

Table 3: Dialogue act labels

4.2.1 Dataset

We use the Switch-board Dialogue Act (SwDA) corpus (Calhoun et al., 2010) in our experiments[5]. SwDA contains the transcripts of several people discussing a given topic on the telephone. There are 42 dialogue act tags in SwDA,[6] and we list the 10 most frequent tags in Table 3.

The same data split as in Stolcke et al. (2000) is used in our experiments. There are 1,115 dialogues in the training set and 19 dialogues in the test set[7]. We also randomly split the original training set as a new training set (1,085 dialogues) and a validation set (30 dialogues).

4.2.2 Setup

The setup is the same as that in Answer Selection except: (1) Only the most common 10,000 words are used, other words are all treated as unknown. (2) Each mini batch contains all sentences from 3 dialogues for Mini-batch Gradient Descent. (3) The evaluation metric is accuracy. (4) We run 30 epochs in total. (5) We use the last hidden state of LSTM_2 as sentence representation since the sentences here are much shorter compared with those in Answer Selection.

4.2.3 Baselines

We compare with the following baselines:

- unigram, bigram, trigram LM-HMM: HMM variants (Stolcke et al., 2000).
- RCNN: Recurrent Convolutional Neural Networks (Kalchbrenner and Blunsom, 2013). Sentences are first separately embedded with CNN, and then joined up with RNN.
- LSTM: All sentences are modeled separately by one LSTM. Different from SIN, there is no sentence interactions in this method.

Model	Accuracy(%)
unigram LM-HMM	68.2
bigram LM-HMM	70.6
trigram LM-HMM	71.0
RCNN	73.9
LSTM	72.8
SIN	74.8
SIN-CONV	75.1
SIN-LD	76.0
SIN-CONV-LD	**76.5**

Table 4: Accuracy on dialogue act analysis. Inter-annotator agreement is 84%.

4.2.4 Results

Results are shown in Table 4. HMM variants, RCNN and LSTM model the sentences separately during sentence embedding, and are unable to capture the sentence interactions. With our interaction mechanism, SIN outperforms LSTM, and proves that well modeling the interactions between sentences in a dialogue is important for dialogue act analysis. After introducing a convolution layer, SIN-CONV performs slightly better than SIN. SIN-LD and SIN-CONV-LD model the

[5] http://compprag.christopherpotts.net /swda.html.

[6] SwDA actually contains 43 tags in which "+" should not be treated as a valid tag since it means continuation of the previous sentence.

Table 5: A question-answer pair example.

long-range dependence in the dialogue with another LSTM, and obtain further improvements.

4.3 Interaction Mechanism Analysis

We investigate into the interaction states of SIN for Answer Selection to see how our proposed interaction mechanism works.

Given a question-answer pair in Table 5, for SIN, there is a candidate interaction state $\tilde{c}_{\tau t}^{(i)}$ and an input gate $i_{\tau t}^{(i)}$ from each word t in the question to each word τ in the answer. We investigate into the L_2-norm $||\tilde{c}_{\tau t}^{(i)} * i_{\tau t}^{(i)}||_2$ to see how words in the two sentences interact with each other. Note that we have linearly mapped the original L_2-norm value to $[0, 1]$ as follows:

$$f(x) = \frac{x - x_{min}}{x_{max} - x_{min}}$$

As depicted in Figure 4, we can see that the word *"what"* in the question has little impact to the answer through interactions. This is reasonable since *"what"* appears frequently in questions, and does not carry much information for answer selection[8]. On the contrary, the phrase *"creates a cloud"*, especially the word *"cloud"*, transmits much information through interactions to the answer, this conforms with human knowledge since we rely on these words to answer the question as well.

In the answer, interactions concentrate on the phrase *"a cloud is a visible mass of liquid droplets"* which seems to be a good and complete answer to the question. Although there are also other highly related words in the answer, they are almost ignored. The reason may be failing to model such a complex phrase (three relatively simple sentences joined by "or") or the existence of the previous phrase which is already a good answer.

This experiment clearly shows how the interaction mechanism works in SIN. Through interaction states, SIN is able to figure out what the question is asking about, namely to detect those highly informative words in the question, and which part in the answer can answer the question.

5 Conclusion and Future Work

In this work, we propose Sentence Interaction Network (SIN) which utilizes a new mechanism for modeling interactions between two sentences. We also introduce a convolution layer into SIN (SIN-CONV) to improve its phrase modeling ability so that phrase interactions can be handled. SIN is powerful and flexible to model sentence interactions for different tasks. Experiments show that the proposed interaction mechanism is effective, and we obtain significant improvements on Answer Selection and Dialogue Act Analysis without any handcrafted features.

Previous works have showed that it is important to utilize the syntactic structures for modeling sentences. We also find out that LSTM is sometimes unable to model complex phrases. So, we are going to extend SIN to tree-based SIN for sentence modeling as future work. Moreover, applying the models to other tasks, such as semantic relatedness measurement and paraphrase identification, would

[8]Our statements focus on the interaction, in a sense of *"answering" or "matching"*. Definitely, such words like "what" and "why" are very important for answering questions from the general QA perspective since they determine the type of answers.

also be interesting attempts.

Abstract

In this study, we introduce a non-deterministic method for referring expression generation. We describe two models that account for individual variation in the choice of referential form in automatically generated text: a Naive Bayes model and a Recurrent Neural Network. Both are evaluated using the VaREG corpus. Then we select the best performing model to generate referential forms in texts from the GREC-2.0 corpus and conduct an evaluation experiment in which humans judge the coherence and comprehensibility of the generated texts, comparing them both with the original references and those produced by a random baseline model.

1 Introduction

Automatic text generation is the process of converting non-linguistic data into coherent and comprehensible text (Reiter and Dale, 2000). In recent years, interest in text generation has substantially increased, due to the emergence of new applications such as "robot-journalism" (Clerwall, 2014). Even though computers these days are perfectly capable of automatically producing text, the results are arguably often rather rigid, always producing the same kind and style of text, which makes them somewhat "boring" to read, especially when reading multiple texts in succession.

Human-written texts, by contrast, do not suffer from this problem, presumably because human authors have an innate tendency to produce variation in their use of words and constructions. Indeed, psycholinguistic research has shown that when speakers produce referring expressions in comparable contexts, they non-deterministically vary both the form and the contents of their references (Dale and Viethen, 2010; Van Deemter et al., 2012). In this paper, we present and evaluate models of referring expression generation that mimic this human non-determinacy and show that this enables us to generate varied references in texts, which, in terms of coherence and comprehensibility, did not yield significant differences from human-produced references according to human judges.

In particular, in this study we focus on the choice of referential *form*, which is the first decision to be made by referring expression generation models (Reiter and Dale, 2000) and which determines whether a reference takes the form of a proper name, a pronoun, a definite description, etc. Several such models have been proposed (Reiter and Dale, 2000; Henschel et al., 2000; Callaway and Lester, 2002; Krahmer and Theune, 2002; Gupta and Bandopadhyay, 2009; Greenbacker and McCoy, 2009). However, all of these are fully deterministic, always choosing the same referential form in the same context.

The fact that these models are generally based on text corpora which have only one gold standard form per reference (the one produced by the original author) does not help either. When the corpus contains, say, a description at some point in the text, this does not mean that, for example, a proper name could not occur in that position as well (Yeh and Mellish, 1997; Ferreira et al., 2016). Generally, we just don't know. To counter this problem, a recent corpus, called VaREG, was developed in which 20 different writers were asked to produce references for a particular topic in a variety of texts, giving rise to a distribution over forms per reference (Ferreira et al., 2016). This gives us the possibility to distinguish situations where there is more or less agreement between writers in their choices of referential form. But it also enables a new paradigm for choosing referential forms,

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 568–577,
Berlin, Germany, August 7-12, 2016.

where instead of predicting the most likely referential form, we can in fact predict the frequency in which a reference assumes a specific form, allowing us to turn the choice of referential form into a non-deterministic probabilistic model.

In this study, we introduce two different models that take the individual variation into account for the choice of referential form, one based on Naive Bayes and one on Recurrent Neural Networks. Both are evaluated using the VaREG corpus. Furthermore, we use the best performing model to generate referential forms in texts from the GREC-2.0 corpus, based on the roulette-wheel generation process (Belz, 2008), and conduct an evaluation experiment in which humans judge the coherence and comprehensibility of the generated texts, comparing them both with the original references and those produced by a random baseline model.

2 Related Studies

Several models for the choice of referential form have been proposed in the literature. They can roughly be distinguished in two groups: rule-based and data-driven models.

Many rule-based models were created for pronominalization, i.e, to choose whether an object or person should be referred to using a pronoun or not. Reiter and Dale (2000) proposed one of the first rule-based models, which opts for a pronominal reference only if the referent was previously mentioned in the discourse and no mention to an entity of same gender can be found between the reference and its antecedent. Henschel et al. (2000) presented a pronominalization model based on recency, discourse status, syntactic position, parallelism and ambiguity. To decide among a pronoun or a definite description, Callaway and Lester (2002) also proposed a rule-based model which makes the choices based on information about the discourse, rhetorical structure, recency and distance. Krahmer and Theune (2002) extended the Incremental algorithm so that if a referent achieves a level of salience in the discourse (measured by a salience weight), a pronoun is used. Otherwise, a definite description is produced to distinguish the referent from the distractors.

Aiming to make choices similar to humans, some studies proposed machine learning models trained on human choices of referential form. The GREC project (Belz et al., 2010) motivated the development of many of those data-driven models. One of the project's shared tasks aimed to predict the form of the references to the main topics of texts taken from Wikipedia. Among the participants of the task, Gupta and Bandopadhyay (2009) presented a model that combined rules and a machine learning technique based on semantic and syntactic category, paragraph and sentence positions, and reference number. Similarly, Greenbacker and McCoy (2009) proposed a decision tree that, besides the features used in Gupta and Bandopadhyay (2009), was also based on recency and part-of-speech features. For more information on the GREC shared task, see Belz et al. (2010).

One limitation that these models all have in common is that they fail to model individual variation. According to their predictions, a reference will always assume the most likely referential form. For example, a model that takes into account syntactic position will always choose the same referential form for the subject of a sentence, while humans tend to vary in their choices of referential form. One of the reasons for this problem arises from the data these models are trained on. Most corpora only contain one referring expression per reference. Only the newly introduced VaREG corpus takes variation into account, containing 20 different expressions for each reference, allowing us to model distributions over referential slots.

3 The VaREG corpus

The VaREG corpus was collected for the study of individual variation in the choice of referential form (Ferreira et al., 2016). The corpus is based on a number of texts, which were presented to participants in such a way that all references to the main topic of the text had been replaced with gaps. Each participant was asked to fill each of those gaps with a referring expression for the topic.

The resulting corpus consists of 9,588 referring expressions, produced by 78 participants for 563 referential gaps - around 20 referring expressions per reference - in 36 English texts. The texts were equally distributed over 3 genres: news texts, reviews of commercial products and encyclopedic texts. The references were annotated according to their syntactic position (subject, object, etc.), referential status (new or old, in text, paragraph and sentence) and recency (number of words between previous reference to the same object or entity),

and the referring expressions of the participants were classified into 5 referential forms: proper names, pronouns, definite descriptions, demonstratives and empty references.

The analysis of the corpus revealed considerable variation among participants in their choices of referential forms. Various factors influenced the amount of variation that occurred. High amounts of variation, for example, were found in product reviews and also in the object position of sentences. Besides allowing us to distinguish between situations with relatively high and relatively low individual variation in choices of referential form, this corpus introduces a new paradigm for the development and evaluation of models for referential choice. Rather than predicting the most likely form of a reference, as is usually done, the new corpus allows us to develop a model that can predict the frequency with which a particular reference can assume different referential forms. In this study, we explore this possibility.

4 Models

We model the individual variation in the choice of referential form in the following way: each reference consists of a tuple (X, y), where X is the set of feature values that describes the reference and y is a distribution of referential forms that indicates the frequency (in proportion) in which X assumes each form. So given X, we expect to find a distribution $\hat{y}$ similar to y.

Table 1 depicts the features used to describe X. The influence of those discourse factors in the choice of referential form has been often studied in the literature. Concerning syntactic position, Brennan (1995) argued that references in the subject position of a sentence are more likely to be shorter than references in the the object position. In favor of status and recency, Chafe (1994) showed that references to previously mentioned referents in the discourse and ones that are close to their antecedents are more likely to be shorter than references to new referents or ones that are distant from their antecedents.

All features were defined categorically, including the recency. This latter is treated by describing if a reference's antecedent is 10 or less words away, between 11 and 20 words, between 21 and 30 words, between 31 and 40 words and more than 40 words away.

To predict a distribution $\hat{y}$ based on X, we propose two models: a Naive Bayes and a Recurrent Neural Network.

4.1 Naive Bayes

Given a set of referential forms F, the probability that a reference assumes a particular form $f \in F$ according to this model is given by:

$$P(f \mid X) \propto \frac{P(f) \prod_{x \in X} P(x \mid f)}{\sum_{f' \in F} P(f') \prod_{x \in X} P(x \mid f')} \quad (1)$$

To avoid zero probabilities, we used additive smoothing with $\alpha = 2e^{-308}$. So given a reference described by X, $\hat{y}$ is the distribution over F:

$$\hat{y} = \begin{bmatrix} P(f_1 \mid X) \\ ... \\ P(f_{|F|} \mid X) \end{bmatrix} \quad (2)$$

4.2 Recurrent Neural Network

Some referential theories support the idea that a referential form is chosen based on previous choices to the same referent. Arnold (1998) argued that subjects of a sentence are more likely to be later pronominalized, as well as references in parallel syntactic position with their antecedents. Chafe (1994) sustained that referents mentioned in recent clauses also tend to be pronominalized. Since Naive Bayes does not take into account the sequential nature of text, we use a Recurrent Neural Network (RNN) to be able to take context into account.

RNN is a powerful structure to handle sequences of data. It can map a sequence of references $(X_1, ..., X_t)$ to their referential forms distributions $(y_1, ..., y_t)$ based on the previous steps.

Our approach here is similar to the one presented by Mesnil et al. (2013). But instead of word continuous representations, a referential embedding is created for each combination of feature values in X. So given a reference X_t and a context window size win, the embeddings of the references $X_{t-win/2}^{t-1}$, X_t and $X_{t+1}^{t+win/2}$ are merged to form a representation e_t. This representation is used in equations 3 and 4 to find a distribution over the referential forms that X_t could assume.

$$h_t = sigmoid(W^{hx} e_t + W^{hh} h_{t-1}) \quad (3)$$

$$\hat{y}_t = softmax(W^{yh} h_t) \quad (4)$$

Feature	Description
Syntactic position	Subject, object or a genitive noun phrase in the sentence.
Referential Status	First mention to the referent (new) or not (old) at the level of text, paragraph and sentence.
Recency	Distance between a given reference and the last, previous reference to the same referent.

Table 1: Features used to describe the references.

We assume a sequence of tuples $\{(X_1, y_1)..., (X_t, y_t)\}$ as all the references to a referent throughout a text.

We trained our RNN using Backpropagation Through Time. To measure the error among y and $\hat{y}$, we use cross entropy as a cost function. The values for the remaining parameters of the RNN are introduced in Table 2. We chose them based on an ad-hoc analysis, where we searched for an optimal combination to obtain the best predictions.

5 Individual Variation Experiments

For each reference slot encountered in the VaREG corpus, we evaluated how well a model takes the individual variation into account in the choice of referential form by comparing its predicted distribution of referential forms ($\hat{y}$) with the real distribution (y). We performed this comparison through two experiments.

In the first, the models were trained and tested with VaREG corpus. In the second, we aimed to check to what extent the referring expressions from the GREC-2.0 corpus are similar in form to the referring expressions from VaREG corpus by training the models with the first corpus and testing with the second.

5.1 Method

4-fold-cross-validation was used to train the models in the first experiment. The number of folds was chosen based on the set-up of the VaREG corpus, which consists of 4 groups of texts. Given the structure of the corpus, we decided that training our model with 3 groups of texts and testing it on the held-out group was the most natural solution to avoid overfitting. Each fold has the same amount of texts per genre.

Unlike VaREG, GREC-2.0 corpus does not have a set of referring expressions for the exact same reference. So, in the second experiment, the referential form distributions y were defined globally by grouping the references by X and computing the frequency of each referential form.

We also re-annoted the GREC-2.0 corpus to make it compatible with the VaREG corpus. In particular, we added features for status and recency to the GREC-2.0 corpus and made the terminology consistent beween the two corpora[1]. Both the VaREG corpus and the re-annotated GREC-2.0 corpus are publicly available[2].

5.2 Metrics

For each reference, Jensen-Shannon divergence (Lin, 1991) was used to measure the similarity between y and $\hat{y}$:

$$JSD(y||\hat{y}) = \frac{1}{2}D(y||m) + \frac{1}{2}D(\hat{y}||m) \quad (5)$$

$$\text{where } m = \tfrac{1}{2}(y + \hat{y})$$

In this measure, D is the Kullback-Leibler divergence (Kullback, 1968). The Jensen-Shannon divergence ranges from 0 to 1, in which 0 indicates full convergence of the two distributions and 1 full divergence. Therefore, a lower number indicates a better individual variation modeling.

To check the behaviour of $\hat{y}$ based on y in each reference, the referential forms of both distributions were ranked and their relation were analysed with the Spearman's rank correlation coefficient. This measure ranges between -1 and 1, where -1 indicates a fully opposed behaviour among the variables and 1 the exact same behaviour among them. 0 indicates a non-linear correlation among the involved variables.

[1] Texts also used in VaREG had their references removed from the GREC-2.0 version used in here.

[2] http://ilk.uvt.nl/~tcastrof/acl2016

5.3 Baselines

We considered two baseline models in the experiments. The first, called *Random*, assumes $\hat{y}$ as a random distribution of forms for each reference.

The second model, called *ParagraphStatus*, always chooses a proper name when the reference is to a new topic in the paragraph (the distribution will assume the value 1 to the proper name form and 0 to the others), and a pronoun otherwise (value 1 to the pronoun form and 0 to the others).

5.4 Results

5.4.1 Cross-validation on VaREG corpus

Models	JSD	$\rho_{y,\hat{y}}$

Table 3: Average Jensen-Shannon divergence and Spearman's correlation coefficient of the models in Experiment 1.

Table 3 depicts the Jensen-Shannon divergence and Spearman's correlation coefficient of the models cross-validated on VaREG corpus. All our models outperformed the baselines.

Considering the models in which the references are described by only one kind of feature, it seems that the status features (+Status) are the ones that best contributed to model the individual variation in the choice of referential form, whereas the recency (+Recency) is the worst. Syntactic position is sandwiched among the previous two.

In the comparison within Naive Bayes and RNN models, the ones in which the references are described by syntactic position and referential status (+Syntax+Status−Recency) obtained the best results for both measures. Figure 1 depicts the average Jensen-Shannon divergences by genre of Naive Bayes and RNN models in which the references are described by this combination of features. Both models presented the best results in

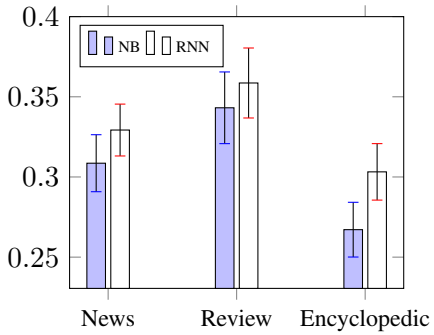

Figure 1: Jensen-Shannon divergence of NB+Syntax+Status−Recency (NB) and RNN+Syntax+Status−Recency (RNN) by genre in Experiment 1. Error bars represent 95% confidence intervals.

encyclopedic texts, and the worst in product reviews.

Although RNNs are able to model the individual variation in a reference based on its antecedents, they did not introduce significantly better results than Naive Bayes. In fact, NB+Syntax+Status−Recency is significantly better than RNN+Syntax+Status−Recency in modeling the individual variation in news (Wilcoxon $Z = 11574.5$, $p < 0.01$) and encyclopedic texts (Wilcoxon $Z = 4232.5$, $p < 0.001$).

5.4.2 Training on GREC-2.0 and evaluating on VaREG corpus

Models	JSD	$\rho_{y,\hat{y}}$
Random	0.63	-0.01
ParagraphStatus	0.43	0.66
NB+Syntax+Status−Recency	**0.36**	**0.67**
NB+Syntax+Status+Recency	0.37	0.64
RNN+Syntax+Status−Recency	0.37	0.62
RNN+Syntax+Status+Recency	0.37	0.64

Table 4: Average Jensen-Shannon divergence and Spearman's correlation coefficient of the models in Experiment 2.

Table 4 shows the results of models trained with GREC-2.0 and tested with VaREG corpus. These models are the two versions of Naive Bayes, and the two versions of RNN which were best evaluated in the previous experiment.

The results of this experiment follow the results of the previous one. Our models outperformed the baselines and NB+Syntax+Status−Recency was the model that obtained the best results for both measures.

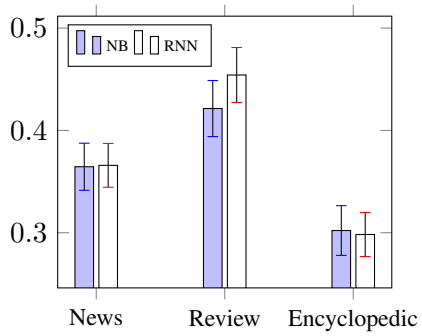

Figure 2: Average Jensen-Shannon divergence of NB+Syntax+Status−Recency (NB) and RNN+Syntax+Status-Recency (RNN) by genre in Experiment 2. Error bars represent 95% confidence intervals.

Figure 2 depicts the Jensen-Shannon divergence measures of models NB+Syntax+Status-Recency and RNN+Syntax+Status-Recency by text genre. As in the previous experiment, both Naive Bayes and RNN models best modeled the individual variation in encyclopedic texts. Moreover, there was not significant difference among NB+Syntax+Status-Recency and RNN+Syntax+Status-Recency in the three text genres.

In general, the models trained with VaREG corpus seemed to model the individual variation in the choice of referential form better than the models trained with GREC-2.0 corpus.

6 Coherence and comprehensibility of the texts

In this section, we investigate to what extent texts generated by our method, including variation of referential form, are judged coherent and comprehensible by readers. We do this by comparing texts from the GREC-2.0 corpus in which all references were (re)generated using our method, with the original text and with a variant that includes random variation of referential form.

6.1 Our model for choice of referential form

To generate the referring expressions for the topic of a given text of GREC-2.0, we first group all references by syntactic position and referential status values. Then for each group, we shuffle the references and choose their forms according to the distribution predicted by our best performing model (the NB+Syntax+Status−Recency trained on VaREG). The choice of referential forms follows the roulette-wheel generation process (Belz, 2008). This process entails that if a group has 5 references and our model predicts a distribution of 0.75 proper names and 0.25 pronouns, 4 references of the group will be proper names and 1 a pronoun.

This covers the selection of referential forms (deciding which form to use at which particular point in the text). To deal with their linguistic realisation, we implemented the following heuristics. For the cases in which a proper name reference is selected, we choose a realization depending on referential status. If the reference is the first mention to the topic in the text, the reference is realized with the topic's longest proper name. Otherwise, the reference is realized with its shortest proper name. For the cases in which a definite description is selected, but where the original GREC-2.0 corpus does not provide a description for the topic, we select the shortest predicate adjective of the first sentence of the text, immediately following the main verb. For instance, for the sentence *"Alan Mathison Turing was an English mathematician, logician, and cryptographer."*, the selected definite description would be "**The English mathematician**". In the cases where a reference should assume the form of a demonstrative, the definite article of the definite description is replaced by the demonstrative "this" (In the previous example, "**This English mathematician**").

6.2 Evaluation Method

We evaluated three versions of each text. The *Original* is the original text in the corpus, including the original referring expressions selected by the author. We compare this with a *Random* variant, which does include variation of referential forms, but selects them in a fully random way. Finally, in the third, *Generated* version, all references are generated according to the method outlined at Section 6.1. Table 5 depicts an example of text in the three versions.

In total, we make 3 versions of 9 pseudo-randomly selected texts (5 covering animate topics and 4 inanimate ones, varying in length) from the GREC-2.0 corpus, yielding 27 texts in total. These were distributed over 3 lists, such that each list contains one variant of each text, and there is an equal number of texts from the 3 conditions (*Original*, *Random*, *Generated*). In all texts, all

Version	Text
Original	**Spain**, officially the Kingdom of Spain, is a country located in Southern Europe, with two small exclaves in North Africa (both bordering Morocco). **Spain** is a democracy **which** is organized as a parliamentary monarchy. **It** is a developed country with the ninth-largest economy in the world. **It** is the largest of the three sovereign nations that make up the Iberian Peninsula–the others are Portugal and the microstate of Andorra.
Random	**It**, officially the Kingdom of Spain, is a country located in Southern Europe, with two small exclaves in North Africa (both bordering Morocco). **The country** is a democracy **that** is organized as a parliamentary monarchy. **It** is a developed country with the ninth-largest economy in the world. **This country** is the largest of the three sovereign nations that make up the Iberian Peninsula–the others are Portugal and the microstate of Andorra.
Generated	**Spain**, officially the Kingdom of Spain, is a country located in Southern Europe, with two small exclaves in North Africa (both bordering Morocco). **Spain** is a democracy **that** is organized as a parliamentary monarchy. **The country** is a developed country with the ninth-largest economy in the world. **It** is the largest of the three sovereign nations that make up the Iberian Peninsula–the others are Portugal and the microstate of Andorra.

Table 5: Example of text in the Original, Random and Generated version.

references to the topic were highlighted in yellow. The experiment was run on CrowdFlower and is publicly available[3].

The experiment was performed by 30 participants (10 per list). Their average age was 36 years, and 22 were female. All were proficient in English (the language of the experiment), 26 participants were native speakers. They were asked to rate each text in terms of how coherent and comprehensible they considered it, on a scale from 1 (Very Bad) to 5 (Very Good).

6.3 Results

Figure 3 depicts the average coherence and comprehensibility of the texts where their topics are described by the *Original*, *Random* and *Generated* approaches, respectively. Inspection of this Figure clearly shows that the *Random* texts are rated lower than both the *Original* and the *Generated* texts, and that the latter are rated very similarly on both dimensions.

This is confirmed by the statistical analysis. According to a Friedman test, there is statistically significant difference in the coherence ($\chi^2 = 11.79$, $p < 0.005$) and comprehensibility ($\chi^2 = 8.98$, $p = 0.01$) for the three kinds of texts. We then conducted a post hoc analysis with Wilcoxon signed-rank test corrected for multiple comparisons using the Bonferroni method, resulting in a significance level set at $p < 0.017$. Texts of the *Original* approach are statistically more coherent ($Z = 322$, $p < 0.017$) and comprehensible ($Z = 407.5$, $p < 0.017$) than texts of the *Random* one. Texts of the *Generated* approach are also statistically more coherent ($Z = 275$, $p < 0.017$), but not more comprehensible ($Z = 378$, $p < 0.05$) than texts of the *Random* one. Finally, and crucially, comparing *Original* and *Generated* texts revealed no significant differences for coherence ($Z = 540$, $p < 0.5$) nor for comprehensibility ($Z = 391.5$, $p < 0.5$).

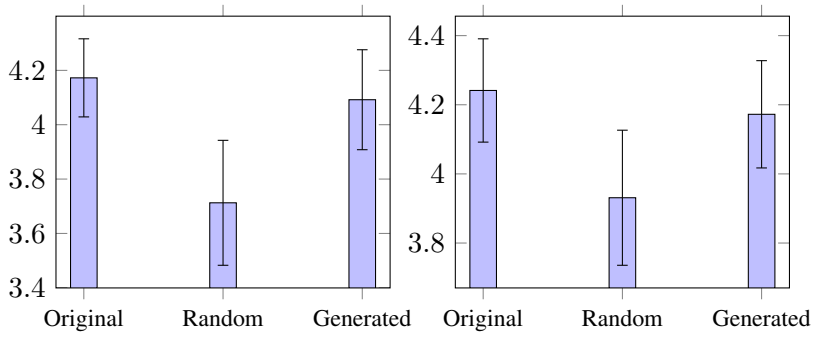
7 Discussion

In this paper we explored the possibilities of introducing more variation in automatically generated texts, by trying to model individual variation in the selection of referential form. We relied on a new corpus (VaREG (Ferreira et al., 2016)), which does not contain a single expression for each reference in a text, but rather a distribution of referential forms produced by 20 different people. In contrast to earlier models for referential choice which always deterministically choose the most likely form of a reference, we proposed a Naive Bayes and a Recurrent Neural Network model which aimed to predict the frequency distribution with which a reference can assume a specific referential form, based on discourse features including syntactic position, referential status and recency. Given a reference, we evaluated how well each different model could capture the individual variation found in the VaREG corpus by comparing its predicted distribution of referential forms with the real one in the corpus. We trained the models in two different ways: first using the VaREG, and second using the GREC-2.0 corpus. The Naive Bayes model, trained on VaREG corpus, in which the references were described by syntactic position and referential status features was the one that best modeled the individual variation in the choice of referential form.

Features Referential status features were the most helpful for modeling the individual variation in the choice of referential form. They were fol-



(a) Coherence (b) Comprehensibility

Figure 3: Average coherence (3a) and comprehensibility (3b) of the texts with the original, randomized and generated referring expressions. Error bars represent 95% confidence intervals.

lowed by the syntactic position feature. Both of these findings are consistent with the observations about human variation in the selection of referential forms, as discussed by Ferreira et al. (2016). This study argued that writers are more likely to vary in their choices when a reference is in the object position, and when it is an old mention in the text, but new in the sentence. Recency was not a helpful feature for our models, and this may be due to the way the feature was represented - i.e., as a categorical rather than a continuous feature. Moreover, the recency feature was measured in terms of words between the current reference and the most recent previous one to the same referent. Perhaps, it would be better to measure recency in terms of different discourse entities mentioned between two references to the same referent.

Genre In agreement with Ferreira et al. (2016), we also found that genre mattered. For modeling variation, our models performed best when applied to encyclopedic texts, and worst in product reviews, with news sandwiched in between.

Naive Bayes model vs. RNNs Although the RNNs were able to model individual variation in the choice of referential form to some extent, they did not perform significantly better than the Naive Bayes models, which might have to do with the relatively small dataset. However, we think the size of the corpus matches the relatively low complexity of the problem we address. In the most complex case (i.e., when a reference is described by its syntactic position, status and recency), an input can be represented in 120 different ways to predict a multinomial distribution of size 5 (number of referential forms). This complexity is much smaller than other problems typically modeled by RNNs. In text production, for instance, an input may be represented by thousands of words to predict a large multinomial distribution over a vocabulary (Sutskever et al., 2014). Additionally, it is important to stress that we actually have a real multinomial distribution to compare with the distribution predicted by the RNN in each situation. We observed that it is possible to compute more fine-grained error costs in our case, which makes the RNN converge faster when it is backpropagated. In sum, we believe that those two factors combined compensate for the size of the dataset. A possible explanation for the non-difference among the Naive Bayes model and RNNs is the use of the referential status features, which perhaps are already enough to model the relation among a reference and its antecedents.

VaREG corpus vs. GREC-2.0 corpus Interestingly, our proposed models yielded better performance when trained on the VaREG than on the GREC-2.0 corpus. This shows a difference among the referential choices of both corpora. We conjecture this difference is partly due to differences in text genres, since the VaREG corpus contains texts from three different genres, whereas the GREC-2.0 corpus only has encyclopedic texts. Earlier work has also highlighted the influence of text genre on the amount of individual variation in writers' choices for referential forms (Ferreira et al., 2016).

Coherence and comprehensibility In the second part of the study, we used the best performing model to generate referential forms in texts from the GREC-2.0 corpus, using a roulette-based model sampling from the predicted distributions over referential forms. We evaluated the texts gen-

erated in this way in an experiment in which humans were asked to judge the coherence and comprehensibility of the generated texts, comparing them both with the original references and those produced by a random baseline model. In terms of coherence and comprehensibility, we found that the texts in which the references were generated by our model were not significantly different than the human generated ones, and significantly better than the randomly generated ones. This shows that our solution does not only model the individual variation in the choice of referential form, but that this also does not negatively affect the quality of the texts. This is an important step towards developing new models for automatic text generation that are less predictable and more varied.

Abstract

How much is 131 million US dollars? To help readers put such numbers in context, we propose a new task of automatically generating short descriptions known as perspectives, e.g. "$131 million is about the cost to employ everyone in Texas over a lunch period". First, we collect a dataset of numeric mentions in news articles, where each mention is labeled with a set of rated perspectives. We then propose a system to generate these descriptions consisting of two steps: formula construction and description generation. In construction, we compose formulae from numeric facts in a knowledge base and rank the resulting formulas based on familiarity, numeric proximity and semantic compatibility. In generation, we convert a formula into natural language using a sequence-to-sequence recurrent neural network. Our system obtains a 15.2% F_1 improvement over a non-compositional baseline at formula construction and a 12.5 BLEU point improvement over a baseline description generation.

1 Introduction

When posed with a mention of a number, such as "Cristiano Ronaldo, the player who Madrid acquired for [...] a *$131 million*" (Figure 1), it is often difficult to comprehend the scale of large (or small) absolute values like *$131 million* (Paulos, 1988; Seife, 2010). Studies have shown that providing relative comparisons, or *perspectives*, such as "about the cost to employ everyone in Texas over a lunch period" significantly improves comprehension when measured in terms of memory retention or outlier detection (Barrio et al., 2016).

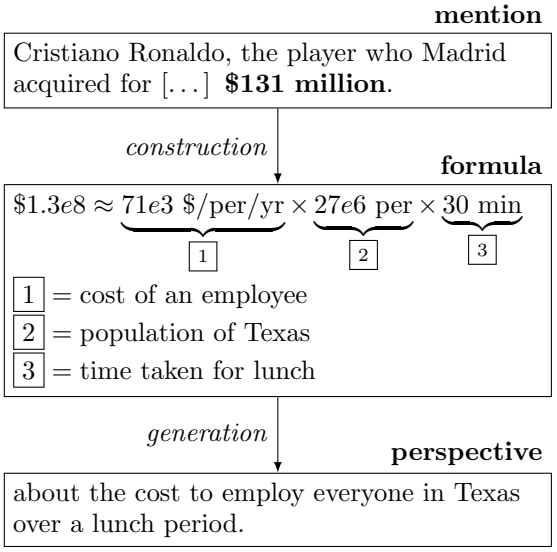

Figure 1: An overview of the perspective generation task: given a *numeric mention*, generate a short description (a *perspective*) that allows the reader to appreciate the scale of the mentioned number. In our system, we first construct a *formula* over facts in our knowledge base and then generate a description of that formula.

Previous work in the HCI community has relied on either manually generated perspectives (Barrio et al., 2016) or present a fact as is from a knowledge base (Chiacchieri, 2013). As a result, these approaches are limited to contexts in which a relevant perspective already exists.

In this paper, we generate perspectives by composing facts from a knowledge base. For example, we might describe *$100,000* to be "about twice the median income for a year", and describe *$5 million* to be the "about how much the average person makes over their lifetime". Leveraging compositionality allows us to achieve broad coverage of numbers from a relatively small collection of familiar facts, e.g. median income and a person's

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 578–587,
Berlin, Germany, August 7-12, 2016.

lifetime.

Using compositionality in perspectives is also concordant with our understanding of how people learn to appreciate scale. Jones and Taylor (2009) find that students learning to appreciate scale do so mainly by *anchoring* with familiar concepts, e.g. $50,000 is slightly less than the median income in the US, and by *unitization*, i.e. improvising a system of units that is more relatable, e.g. using the Earth as a measure of mass when describing the mass of Jupiter to be that of 97 Earths. Here, compositionality naturally unitizes the constituent facts: in the examples above, money was unitized in terms of median income, and time was unitized in a person's lifetime. Unitization and anchoring have also been proposed by Chevalier et al. (2013) as the basis of a design methodology for constructing visual perspectives called concrete scales.

When generating compositional perspectives, we must address two key challenges: constructing familiar, relevant and meaningful formulas and generating easy-to-understand descriptions or perspectives. We tackle the first challenge using an overgenerate-and-rank paradigm, selecting formulas using signals from familiarity, compositionality, numeric proximity and semantic similarity. We treat the second problem of generation as a translation problem and use a sequence-to-sequence recurrent neural network (RNN) to generate perspectives from a formula.

We evaluate individual components of our system quantitatively on a dataset collected using crowdsourcing. Our formula construction method improves on F_1 over a non-compositional baseline by about 17.8%. Our generation method improves over a simple baseline by 12.5 BLEU points.

2 Problem statement

The input to the *perspective generation* task is a sentence s containing a *numeric mention* x: a span of tokens within the sentence which describes a quantity with value $x.\text{value}$ and of unit $x.\text{unit}$. In Figure 1, the numeric mention x is "$131 million", $x.\text{value} = 1.31e8$ and $x.\text{unit} = \$$. The output is a description y that puts x in perspective.

We have access to a knowledge base $\mathcal{K}$ with numeric tuples $t = (t.\text{value}, t.\text{unit}, t.\text{description})$. Table 1 has a few examples of tuples in our knowledge base. Units (e.g. $/per/yr) are fractions composed either of fundamental units (length, area, volume, mass, time) or of ordinal units (e.g. cars, people, etc.).

Description	Value Unit
cost of an employee	71e3 $/year/person
population of Texas	27e3 person
number of employees at Google	57e3 person
average household size	2.54 person
time taken for a basketball game	60 minute
average lifetime for a person	79 year
a week	1 week
time taken for lunch	30 minute
cost of property in the Bay area	1e3 $/ft^2
area of a city block	10e3 m^2

Table 1: A subset of our knowledge base of numeric tuples. Tuples with fractional units (e.g. $/ft^2) can be combined with other tuples to create formulas.

The first step of our task, described in Section 4, is to construct a *formula* f over numeric tuples in $\mathcal{K}$ that has the same value and unit as the numeric mention x. A valid formula comprises of an arbitrary multiplier $f.m$ and a sequence of tuples $f.\text{tuples}$. The value of a formula, $f.\text{value}$, is simply the product of the multiplier and the values of the tuples, and the unit of the formula, $f.\text{unit}$, is the product of the units of the tuples. In Figure 1, the formula has a multiplier of 1 and is composed of tuples $\boxed{1}$, $\boxed{2}$ and $\boxed{3}$; it has a value of $1.3e8$ and a unit of $.

The second step of our task, described in Section 5, is to generate a *perspective* y, a short noun phrase that realizes f. Typically, the utterance will be formed using variations of the descriptions of the tuples in $f.\text{tuples}$.

3 Dataset construction

We break our data collection task into two steps, mirroring formula selection and description generation: first, we collect descriptions of formulas constructed exhaustively from our knowledge base (for generation), and then we use these descriptions to collect preferences for perspectives (for construction).

Collecting the knowledge base. We manually constructed a knowledge base with 142 tuples and 9 fundamental units[1] from the United States Bu-

[1]Namely, length, area, volume, time, weight, money, people, cars and guns. These units were chosen because they

reau of Statistics, the orders of magnitude topic on Wikipedia and other Wikipedia pages. The facts chosen are somewhat crude; for example, though "the cost of an employee" is a very context dependent quantity, we take its value to be the median cost for an employer in the United States, $71,000. Presenting facts at a coarse level of granularity makes them more familiar to the general reader while still being appropriate for perspective generation: the intention is to convey the right scale, not necessarily the precise quantity.

Collecting numeric mentions. We collected 53,946 sentences containing numeric mentions from the newswire section of LDC2011T07 using simple regular expression patterns like `$([0-9]+(,[0-9]+)*(.[0-9]+)? ((hundred)|(thousand)|(million)|(billion)|(trillion)))`. The values and units of the numeric mentions in each sentence were normalized and converted to fundamental units (e.g. from miles to length). We then randomly selected up to 200 mentions of each of the 9 types in bins with boundaries $10^{-3}, 1, 10^3, 10^6, 10^9, 10^{12}$ leading to 4,931 mentions that are stratified by unit and magnitude.[2] Finally, we chose mentions which could be described by at least one numeric expression, resulting in the 2,041 mentions that we use in our experiments (Figure 2). We note that there is a slight bias towards mentions of money and people because these are more common in the news corpus.

Generating formulas. Next, we exhaustively generate valid formulas from our knowledge base. We represent the knowledge base as a graph over units with vertices and edges annotated with tuples (Figure 3). Every vertex in this graph is labeled with a unit u and contains the set of tuples with this unit: $\{t \in \mathcal{K} : t.\text{unit} = u\}$. Additionally, for every vertex in the graph with a unit of the form u_1/u_2, where u_2 has no denominator, we add an edge from u_1/u_2 to u_1, annotated with all tuples of type u_2: in Figure 3 we add an edge from *money/person* to *money* annotated with the three person tuples in Table 1. The set of formulas with unit u is obtained by enumerating all paths in the graph which terminate at the vertex u. The multiplier of the formula is set so that the value of

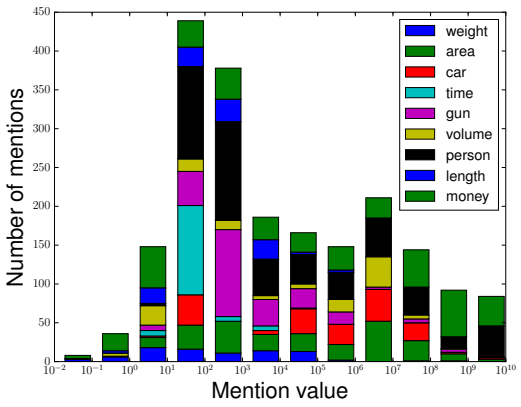

Figure 2: A histogram of the absolute values of numeric mentions by type. There are 100–300 mentions of each unit.

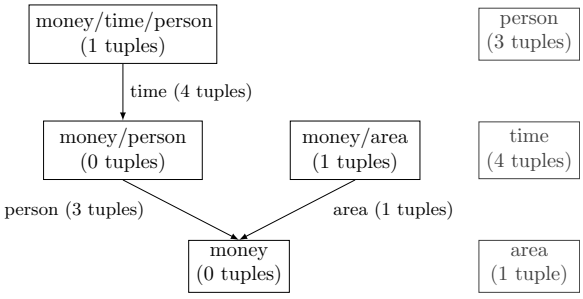

Figure 3: The graph over tuples generated from the knowledge base subset in Table 1.

the formula matches the value of the mention. For example, the formula in Figure 1 was constructed by traversing the graph from *money/time/person* to *money*: we start with a tuple in *money/time/person* (*cost of an employee*) and then multiply by a tuple with unit *time* (*time for lunch*) and then by unit *person* (*population of Texas*), thus traversing two edges to arrive at *money*.

Using the 142 tuples in our knowledge base, we generate a total of 1,124 formulas sans multiplier.

Collecting descriptions of formulas. The main goal of collecting descriptions of formulas is to train a language generation system, though these descriptions will also be useful while collecting training data for formula selection. For every unit in our knowledge base and every value in the set $\{10^{-7}, 10^{-6} \ldots, 10^{10}\}$, we generated all valid formulas. We further restricted this set to formulas with a multiplier between $1/100$ and 100, based on the rationale that human cognition of scale sharply drops beyond an order of magnitude (Tretter et al.,

were well represented in the corpus.

[2]Some types had fewer than 200 mentions for some bins.

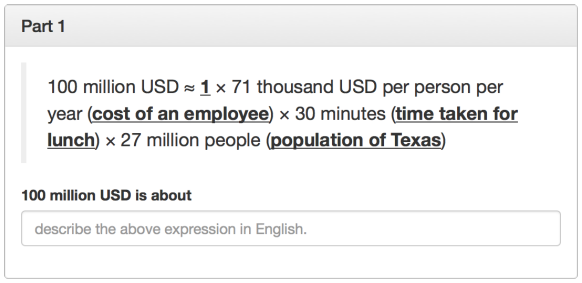

Figure 4: A screenshot of the crowdsourced task to generate natural language descriptions, or perspectives, from formulas.

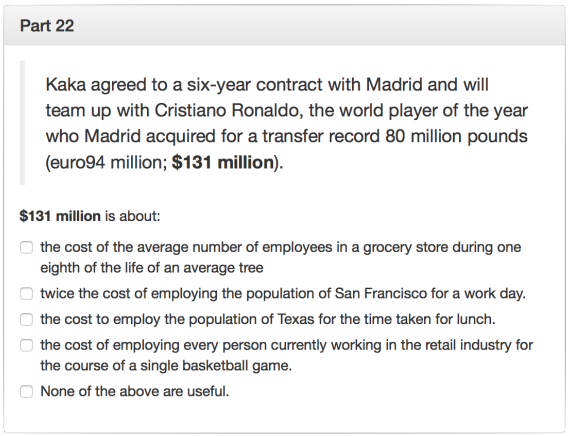

Figure 5: A screenshot of the crowdsourced task to identify which formulas are useful to crowdworkers in understanding the highlighted mentioned number.

2006). In total, 5000 formulas were presented to crowdworkers on Amazon Mechanical Turk, with a prompt asking them to rephrase the formula as an English expression (Figure 4).[3] We obtained 5–7 descriptions of each formula, leading to a total of 31,244 unique descriptions.

Collecting data on formula preference. Finally, given a numeric mention, we ask crowdworkers which perspectives from the description dataset they prefer. Note that formulas generated for a particular mention may differ in multiplier with a formula in the description dataset. We thus relax our constraints on factual accuracy while collecting this formula preference dataset: for each mention x, we choose a random perspective from the description dataset described above corresponding to a formula whose value is within a factor of 2 from the mention's value, $x.\text{value}$. A smaller factor led to too many mentions without a valid comparison, while a larger one led to blatant factual inaccuracies. The perspectives were partitioned into sets of four and displayed to crowdworkers along with a "None of the above" option with the following prompt: "We would like you to pick up to two of these descriptions that are useful in understanding the scale of the highlighted number" (Figure 5). A formula is rated to be useful by simple majority.[4]

Figure 6 provides a summary of the dataset collected, visualizing how many formulas are useful, controlling for the size of the formula. The exhaustive generation procedure produces a large number of spurious formulas like "20 × trash generated in the US × a minute × number of employees on Medicare". Nonetheless, compositional formulas are quite useful in the appropriate context; Table 2 presents some mentions with highly rated perspectives and formulas.

4 Formula selection

We now turn to the first half of our task: given a numeric mention x and a knowledge base $\mathcal{K}$, select a formula f over $\mathcal{K}$ with the same value and unit as the mention. It is easy to generate a very large number of formulas for any mention. For the example, "Cristiano Ronaldo, the player who Madrid acquired for [. . .] $131 million.", the small knowledge base in Table 1 can generate the 12 different formulas,[5] including the following:

1. 1 × the cost of an employee × the population of Texas × the time taken for lunch.
2. 400 × the cost of an employee × average household size × a week.
3. 1 × the cost of an employee × number of employees at Google × a week.
4. 1 × cost of property in the Bay Area × area of a city block.

Some of the formulas above are clearly worse than others: the key challenge is picking a formula that will lead to a meaningful and relevant perspective.

Criteria for ranking formulas. We posit the following principles to guide our choice in features (Table 3).

[3] Crowdworkers were paid $0.08 per description.

[4] Crowdworkers were paid $0.06 to vote on each set of perspectives.

[5] The full knowledge base described in Section 3 can generate 242 formulas with the unit money (sans multiplier).

Sentence	That's about ...	Formula
The Billings-based Stillwater Mining produced **601,000 ounces of platinum**.	4 times the weight of an elephant.	4 × weight of an elephant.
Authorities estimate there are about **60 million guns** in Yemen.	twice the gun ownership of the population of Texas	2 × gun ownership × population of Texas
Water is flowing into Taihu lake at a rate of **150 cubic meters** per second.	how much water would flow from a tap left on for a week.	rate of flow of water from tap × a week
The bank had held auctions, selling around **US$1 billion** worth of three-month bills.	half the cost of employing the population of Texas for a work day.	1/2 × cost of an employee × time taken for a work day × population of Texas
The government[s] have promised to rent about **1.2 million sq. feet**.	the area of forest logged in a single minute	90 × area of forest logged × a minute

Table 2: Examples of numeric mentions, perspectives and their corresponding formulas in the dataset. All the examples except the last one are rated to be useful by crowdworkers.

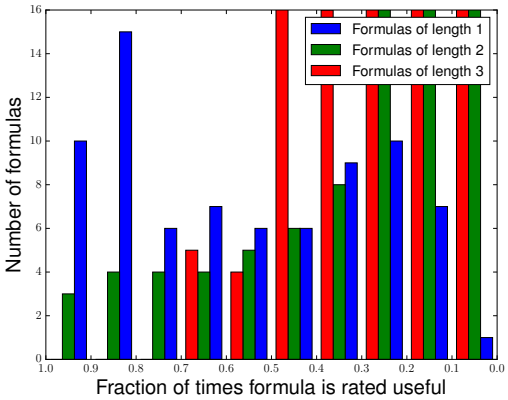

Figure 6: A histogram comparing formula length to ratings of usefulness (clipped for readability). Non-compositional perspectives with a single tuple are broadly useful. Useful compositional perspectives tend to be more context-specific than non-compositional ones, and many of the formulas that can be generated from the knowledge base are spurious.

Type	Features	#
Proximity	$\text{sign}(\log(f.m)), \lvert\log(f.m)\rvert$	1
Familiarity	$\mathbb{I}[t]$	142
Compatibility	$\mathbb{I}[t, t']$	20022
Similarity	$\text{wvec}(s)^\top$ $\text{wvec}(t.\text{description})$	1

Table 3: Feature templates used to score a formulas f and their counts (#), where $f.m$ is the formula's multiplier and $t, t' \in f.\text{tuples}$ are tuples in the formula.

Proximity: *A numeric perspective should be within an order of magnitude of the mentioned value*. Conception of scale quickly fails with quantities that exceed "human scales" (Tretter et al., 2006): numbers that are significantly away from $1/10$ and 10. We use this principle to prune formulas with multipliers not in the range $[1/100, 100]$ (e.g. example 2 above) and introduce features for numeric proximity.

Familiarity: *A numeric perspective should be composed of concepts familiar to the reader*. The most common technique cited by those who do well at scale cognition tests is reasoning in terms of familiar objects (Tretter et al., 2006; Jones and Taylor, 2009; Chevalier et al., 2013). Intuitively, the average American reader may not know exactly how many people are in Texas, but is familiar enough with the quantity to effectively reason using Texas' population as a unit. On the other hand, it is less likely that the same reader is familiar with even the concept of Angola's population.

Of course, because it is so personal, familiarity is difficult to capture. With additional information about the reader, e.g. their location, it is possible to personalize the chosen tuples (Kim et al., 2016). Without this information, we back off to a global preference on tuples by using indicator features for each tuple in the formula.

Formula	Score
Studies estimate **36,000 people** die on average each year from seasonal flu.	
1/4 × global death rate × a day	0.67
5 × death rate in the US × a day	0.64
1/3 × number of employees at Microsoft	0.60
Gazprom's exports to Europe [...] will total **60 billion cubic meters** ...	
oil produced by the US × average lifetime	0.78
average coffee consumption × population of the world × average lifetime	0.78
2 × average coffee consumption × population of Asia × average lifetime	0.73

Table 4: The top three examples outputted by the ranking system with the scores reported by the system.

Compatibility: Similarly, some tuple combinations are more natural ("median income × a month") while others are less so ("weight of a person × population of Texas"). We model compatibility between tuples in a formula using an indicator feature.

Similarity: *A numeric perspective should be relevant to the context*. Apart from helping with scale cognition, a perspective should also place the mentioned quantity in appropriate context: for example, NASA's budget of $17 billion could be described as 0.1% of the United States' budget or the amount of money it could cost to feed Los Angeles for a year. While both perspectives are appropriate, the former is more relevant than the latter.

We model context relevance using word vector similarity between the tuples of the formula and the sentence containing the mention as a proxy for semantic similarity. Word vectors for a sentence or tuple description are computed by taking the mean of the word vectors for every non-stop-word token. The word vectors at the token level are computed using word2vec (Mikolov et al., 2013).

Evaluation. We train a logistic regression classifier using the features described in Table 3 using the perspective ratings collected in Section 3. Recall that the formula for each perspective in the dataset is assigned a positive ("useful") label if it was labeled to be useful to the majority of the workers. Table 5a presents results on classifying formulas as useful with a feature ablation.[6]

Familiarity and compatibility are the most useful features when selecting formulas, each having a significant increase in F_1 over the proximity baseline. There are minor gains from combining these two features. On the other hand, semantic similarity does not affect performance relative to the baseline. We find that this is mainly due to the disproportionate number of unfamiliar formulas present in the dataset that drown out any signal. Table 4 presents two examples of the system's ranking of formulas.

5 Perspective generation

Our next goal is to generate natural language descriptions, also known as perspectives, given a formula. Our approach models the task as a sequence-to-sequence translation task from formulas to natural language. We first describe a rule-based baseline and then describe a recurrent neural network (RNN) with an attention-based copying mechanism (Jia and Liang, 2016).

Baseline. As a simple approach to generate perspectives, we just combine tuples in the formula with the neutral prepositions *of* and *for*, e.g. "1/5th *of* the cost of an employee *for* the population of Texas *for* the time taken for lunch."

Sequence-to-sequence RNN. We use formula-perspective pairs from the dataset to create a sequence-to-sequence task: the input is composed using the formula's multiplier and descriptions of its tuples connected with the symbol '*'; the output is the perspective (Figure 7).

Our system is based on the model described in Jia and Liang (2016). Given a sequence of input tokens ($\mathbf{x} = (x_i)$), the model computes a context-dependent vector ($\mathbf{b} = (b_i)$) for each token using a bidirectional RNN with LSTM units. We then generate the output sequence (y_j) left to right as follows. At each output position, we have a hidden state vector (s_j) which is used to produce an "attention" distribution ($\boldsymbol{\alpha}_j = (\alpha_{ji})$) over input tokens: $\alpha_{ji} = \mathrm{Attend}(s_j, b_i)$. This distribution is used to generate the output token and update the hidden state vector. To generate the token, we ei-

[6] Significance results are computed by the bootstrap test as described in Berg-Kirkpatrick et al. (2012) using the output of classifiers trained on the entire training set.

Feature set	Train			Dev		
	P	R	F_1	P	R	F_1
Proximity	56.4	48.7	52.2	56.3	48.8	52.3
Similarity	65.1	34.9	45.4	65.1	34.9	45.4
Familiarity*	70.5	63.5	66.8	69.6	62.9	66.1
Compatibility$^+$	66.9	**74.4**	70.4	65.4	**73.1**	69.0

(a) the formula construction system. Precision, Recall and F_1 are cross-validated on 10-folds. *significant F_1 versus P and S with $p < 0.01$. $^+$significant F_1 versus P, S and F with $p < 0.01$. †significant F_1 versus P, S, F and C with $p < 0.05$.

System	Train BLEU	Test BLEU
Baseline	65.00	57.32
RNN*	**81.50**	**69.79**

(b) the description generation system. *significant BLEU score versus the baseline with $p < 0.01$.

Table 5: Evaluation of perspective generation subsystems.

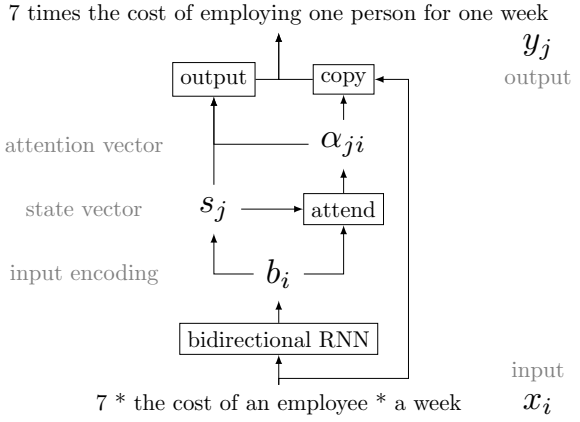

Figure 7: We model description generation as a sequence transduction task, with input as formulas (at bottom) and output as perspectives (at top). We use a RNN with an attention-based copying mechanism.

ther sample a word from the current state or copy a word from the input using attention. Allowing our model to copy from the input is helpful for our task, since many of the entities are repeated verbatim in both input and output. We refer the reader to Jia and Liang (2016) for more details.

Evaluation. We split the perspective description dataset into a training and test set such that no formula in the test set contains the same set of tuples as a formula in the training set.[7] Table 5b compares the performance of the baseline and sequence-to-sequence RNN using BLEU. The sequence-to-sequence RNN performs significantly better than the baseline, producing more natural rephrasings. Table 6 shows some output generated by the system (see Table 6).

6 Human evaluation

In addition to the automatic evaluations for each component of the system, we also ran an end-to-end human evaluation on an independent set of 211 mentions collected using the same methodology described in Section 3. Crowdworkers were asked to choose between perspectives generated by our full system (LR+RNN) and those generated by the baseline of picking the numerically closest tuple in the knowledge base (BASELINE). They could also indicate if either both or none of the shown perspectives appeared useful.[8]

Table 7 summarizes the results of the evaluation and an error analysis conducted by the authors. Errors were characterized as either being errors in generation (e.g. Table 6) or violations of the criteria in selecting good formulas described in Section 4 (Table 7c). The *other* category mostly contains cases where the output generated by LR+RNN appears reasonable by the above criteria but was not chosen by a majority of workers. A few of the mentions shown did not properly describe a numeric quantity, e.g. "... claimed responsibility for a *2009 gun* massacre ..." and were labeled *invalid mentions*. The most common error is the selection of a formula that is not contextually relevant to the mentioned text because no such

[7]Note that formulas with the same set of tuples can occur multiple times in the either the training or test set with different multipliers.

[8]Crowdworkers were paid $0.06 per to choose a perspective for each mention. Each mention and set of perspectives were presented to 5 crowdworkers.

Input formula	Generated perspective
7 × the cost of an employee × a week	7 times the cost of employing one person for one week
1/10 × the cost of an employee × the population of California × the time taken for a football game	one tenth the cost of an employee during a football game by the population of California
1 × coffee consumption × a minute × population of the world	the amount of coffee consumed in one minute on the world
6 × weight of a person × population of California	six times the weight of the people who is worth

Table 6: Examples of perspectives generated by the sequence-to-sequence RNN. The model is able to capture rephrasings of fact descriptions and reordering of the facts. However, it often confuses prepositions and, very rarely, can produce nonsensical utterances.

LR+RNN perspective rated useful?	BASELINE	#
Yes	Yes	31
Yes	No	63
No	Yes	61
No	No	56

(a) A summary of the number of times the perspective generated by LR+RNN or BASELINE was rated useful by a majority of crowdworkers.

Cause of error	#
Proximity	9
Familiarity	6
Compatibility	8
Similarity	49
Generation	24
Other	14
Invalid mention	7
Total	117

(b) An analysis of errors produced by LR+RNN when its perspectives were not rated useful. Errors caused by poor formula selection are further categorized by selection criteria violated.

Cat.	Mention
	LR+RNN perspective (*vs.* BASELINE)
Prox.	... ready to ship about **2,300 miles** across the Pacific to the mainland ...
	three times the distance from San Francisco to Los Angeles (*vs.* the distance from San Francisco to Dallas TX).
Sim.	China had disposed of about **100,000 tons** of CFCs" ...
	one fifth of the weight of garbage produced in the United States by the population of Texas in one week. (*vs.* the average food wasted every year).
Fam.	... the project could save New England ratepayers **$4.6 billion** in energy costs over 25 years.
	one eighth the cost of employing the population of Asia for one hour. (*vs.* the construction cost of The Cosmopolitan in Las Vegas.)
Comp.	Hominids started shaping stone tools about **2.6 million years** ago.
	5 times the total time taken to build the number of cars registered. (*vs.* 17000 times the average lifetime for a tree).

(c) Examples of errors categorized by the criteria defined in Section 4.

Table 7: Results of an end-to-end human evaluation of the output produced by our perspective generation system (LR+RNN) and a baseline (BASELINE) that picks the numerically closest tuple in the knowledge base for each mention.

	Mention	Perspective (that's about...)
+	In 2007, Turkmenistan exported **50 billion cubic meters** of gas to Russia.	the amount of oil produced by the US during a lifetime
+	It can carry up to 10 nuclear warheads and has a range of **8,000 km**.	the distance from San Francisco to Beijing
-	the **2.7 million square feet** that Mission Bay's largest developer is entitled to build	twice the area of forest logged in a minute
-	Las Vegas Sands claims the **10.5 million square feet** is the largest building in Asia.	one half of an area of an average farm

Table 8: Examples of perspectives generated by our system that frame the mentioned quantity to be larger or smaller (top to bottom) than initially the authors thought.

formula exists within the knowledge base (within an order of magnitude of the mentioned value): a larger knowledge base would significantly decrease these errors.

7 Related work and discussion

We have proposed a new task of perspective generation. Compositionality is the key ingredient of our approach, which allows us synthesize information across multiple sources of information. At the same time, compositionality also poses problems for both formula selection and description generation.

On the formula selection side, we must compose facts that make sense. For semantic compatibility between the mention and description, we have relied on simple word vectors (Mikolov et al., 2013), but more sophisticated forms of semantic relations on larger units of text might yield better results (Bowman et al., 2015).

On the description generation side, there is a long line of work in generating natural language descriptions of structured data or logical forms Wong and Mooney (2007); Chen and Mooney (2008); Lu and Ng (2012); Angeli et al. (2010). We lean on the recent developments of neural sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015). Our problem bears some similarity to the semantic parsing work of Wang et al. (2015), who connect generated canonical utterances (representing logical forms) to real utterances.

If we return to our initial goal of helping people understand numbers, there are two important directions to explore. First, we have used a small knowledge base, which limits the coverage of perspectives we can generate. Using Freebase (Bollacker et al., 2008) or even open information extraction (Fader et al., 2011) would dramatically increase the number of facts and therefore the scope of possible perspectives.

Second, while we have focused mostly on basic compatibility, it would be interesting to explore more deeply how the juxtaposition of facts affects framing. Table 8 presents several examples generated by our system that frame the mentioned quantities to be larger or smaller than the authors originally thought. We think perspective generation is an exciting setting to study aspects of numeric framing (Teigen, 2015).

Reproducibility All code, data, and experiments for this paper are available on the CodaLab platform at `https://worksheets.codalab.org/worksheets/0x243284b4d81d4590b46030cdd3b72633/`.

Abstract

Over the past decade, large-scale supervised learning corpora have enabled machine learning researchers to make substantial advances. However, to this date, there are no large-scale question-answer corpora available. In this paper we present the 30M Factoid Question-Answer Corpus, an enormous question-answer pair corpus produced by applying a novel neural network architecture on the knowledge base Freebase to transduce facts into natural language questions. The produced question-answer pairs are evaluated both by human evaluators and using automatic evaluation metrics, including well-established machine translation and sentence similarity metrics. Across all evaluation criteria the question-generation model outperforms the competing template-based baseline. Furthermore, when presented to human evaluators, the generated questions appear to be comparable in quality to real human-generated questions.

1 Introduction

A major obstacle for training question-answering (QA) systems has been due to the lack of labeled data. The question answering field has focused on building QA systems based on traditional information retrieval procedures (Lopez et al., 2011; Dumais et al., 2002; Voorhees and Tice, 2000). More recently, researchers have started to utilize large-scale knowledge bases (KBs) (Lopez et al., 2011), such as Freebase (Bollacker et al., 2008), WikiData (Vrandečić and Krötzsch, 2014) and Cyc (Lenat and Guha, 1989).[1] Bootstrapping QA systems with such structured knowledge is clearly beneficial, but it is unlikely alone to overcome the lack of labeled data. To take into account the rich and complex nature of human language, such as paraphrases and ambiguity, it would appear that labeled question and answer pairs are necessary. The need for such labeled pairs is even more critical for training neural network-based QA systems, where researchers until now have relied mainly on hand-crafted rules and heuristics to synthesize artificial QA corpora (Bordes et al., 2014; Bordes et al., 2015).

Motivated by these recent developments, in this paper we focus on generating questions based on the Freebase KB. We frame question generation as a transduction problem starting from a Freebase fact, represented by a triple consisting of a subject, a relationship and an object, which is trans-

[1] Freebase is now a part of WikiData.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 588–598,
Berlin, Germany, August 7-12, 2016.

duced into a question about the subject, where the object is the correct answer (Bordes et al., 2015). We propose several models, largely inspired by recent neural machine translation models (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015), and we use an approach similar to Luong et al. (2015) for dealing with the problem of rare-words. We evaluate the produced questions in a human-based experiment as well as with respect to automatic evaluation metrics, including the well-established machine translation metrics BLEU and METEOR and a sentence similarity metric. We find that the question-generation model outperforms the competing template-based baseline, and, when presented to untrained human evaluators, the produced questions appear to be indistinguishable from real human-generated questions. This suggests that the produced question-answer pairs are of high quality and therefore that they will be useful for training QA systems. Finally, we use the best performing model to construct a new factoid question-answer corpus – The 30M Factoid Question-Answer Corpus – which is made freely available to the research community.[2]

2 Related Work

Question generation has attracted interest in recent years with notable work by Rus et al. (2010), followed by the increasing interest from the Natural Language Generation (NLG) community. A simple rule-based approach was proposed in different studies as *wh-fronting* or *wh-inversion* (Kalady et al., 2010; Ali et al., 2010). This comes at the disadvantage of not making use of the semantic content of words apart from their syntactic role. The problem of determining the *question type* (e.g. that a *Where-question* should be triggered for locations), which requires knowledge of the category type of the elements involved in the sentence, has been addressed in two different ways: by using named entity recognizers (Mannem et al., 2010; Yao and Zhang, 2010) or semantic role labelers (Chen et al., 2009). In Curto et al. (2012) questions are split into classes according to their syntactic structure, prefix of the question and the category of the answer, and then a pattern is learned to generate questions for that class of questions. After the identification of key points, Chen et al. (2009) apply handcrafted-templates to generate questions framed in the right target expression by following the analysis of Graesser et al. (1992), who classify questions according to a taxonomy consisting of 18 categories.

The works discussed so far propose ways to map unstructured text to questions. This implies a two-step process: first, transform a text into a symbolic representation (e.g. a syntactic representation of the sentence), and second, transform the symbolic representation of the text into the question (Yao et al., 2012). On the other hand, going from a symbolic representation (structured information) to a question, as we will describe in the next section, only involves the second step. Closer to our approach is the work by Olney et al. (2012). They take triples as input, where the edge relation defines the question template and the head of the triple replaces the placeholder token in the selected question template. In the same spirit, Duma et al. (2013) generate short descriptions from triples by using templates defined by the relationship and replacing accordingly the placeholder tokens for the subject and object.

Our baseline is similar to that of Olney et al. (2012), where a set of relationship-specific templates are defined. These templates include placeholders to replace the string of the subject. The main difference with respect to their work is that our baseline does not explicitly define these templates. Instead, each relationship has as many templates as there are different ways of framing a question with that relationship in the training set. This yields more diverse and semantically richer questions by effectively taking advantage of the fact-question pairs, which Olney et al. did not have access to in their experiments.

Unlike the work by Berant and Liang (2014), which addresses the problem of deterministically generating a set of candidate logical forms with a canonical realization in natural language for each, our work addresses the inverse problem: given a logical form (fact) it outputs the associated question.

It should also be noted that recent work in question answering have used simpler rule-based and template-based approaches to generate synthetic questions to address the lack of question-answer pairs to train their models (Bordes et al., 2014; Bordes et al., 2015).

3 Task Definition

3.1 Knowledge Bases

In general, a KB can be viewed as a multi-relational graph, which consists of a set of nodes (entities) and a set of edges (relationships) linking nodes together. In Freebase (Bollacker et al., 2008) these relationships are directed and always connect exactly two entities. For example, in Freebase the two entities *fires_creek* and *nantahala_national_forest* are linked together by the relationship *contained_by*. Since the triple {*fires_creek*, *contained_by*, *nantahala_national_forest*} represents a complete and self-contained piece of information, it is also called a *fact* where *fires_creek* is the subject (head of the edge), *contained_by* is the relationship and *nantahala_national_forest* is the object (tail of the edge).

3.2 Transducing Facts to Questions

We aim to transduce a fact into a question, such that:

1. The question is concerned with the subject and relationship of the fact, and
2. The object of the fact represents a valid answer to the generated question.

We model this in a probabilistic framework as a directed graphical model:

$$P(Q|F) = \prod_{n=1}^{N} P(w_n|w_{<n}, F), \qquad (1)$$

where $F = (subject, relationship, object)$ represents the fact, $Q = (w_1, \ldots, w_N)$ represents the question as a sequence of tokens $w_1, \ldots, w_N$, and $w_{<n}$ represents all the tokens generated before token w_n. In particular, w_N represents the question mark symbol '?'.

3.3 Dataset

We use the SimpleQuestions dataset (Bordes et al., 2015) in order to train our models. This is by far the largest dataset of question-answer pairs created by humans based on a KB. It contains over 100K question-answer pairs created by users on Amazon Mechanical Turk[3] in English based on the Freebase KB. In order to create the questions, human participants were shown one whole Freebase fact at a time and they were asked to phrase a question such that the object of the presented fact becomes the answer of the question.[4] Consequently, both the subject and the relationship are explicitly given in each question. But indirectly characteristics of the object may also be given since the humans have an access to it as well. Often when phrasing a question the annotators tend to be more informative about the target object by giving specific information about it in the question produced. For example, in the question *What city is the American actress X from?* the city name given in the object informs the human participant that it was in America - information, which was not provided by either the subject or relationship of the fact. We have also observed that the questions are often ambiguous: that is, one can easily come up with several possible answers that may fit the specifications of the question. Table 1 shows statistics of the dataset.

Questions	Entities	Relationships	Words
108,442	131,684	1,837	∼77k

Table 1: Statistics of SimpleQuestions

4 Model

We propose to attack the problem with the models inspired by the recent success of neural machine translation models (Sutskever et al., 2014; Bahdanau et al., 2015). Intuitively, one can think of the transduction task as a "lossy translation" from structured knowledge (facts) to human language (questions in natural language), where certain aspects of the structured knowledge is intentionally left out (e.g. the name of the object). These models typically consist of two components: an encoder, which encodes the source phrase into one or several fixed-size vectors, and a decoder, which decodes the target phrase based on the results of the encoder.

4.1 Encoder

In contrast to the neural machine translation framework, our source language is not a proper language but instead a sequence of three variables making up a fact. We propose an encoder sub-model, which encodes each atom of the fact into an embedding. Each atom $\{s, r, o\}$, may

[3] www.mturk.com

[4] It is not necessary for the object to be the only answer, but it is required to be one of the possible answers.

stand for subject, relationship and object, respectively, of a fact $F = (s, r, o)$ is represented as a 1-of-K vector x_{atom}, whose embedding is obtained as $e_{\text{atom}} = E_{\text{in}} x_{\text{atom}}$, where $E_{\text{in}} \in \mathbb{R}^{D_{\text{Enc}} \times K}$ is the embedding matrix of the input vocabulary and K is the size of that vocabulary. The encoder transforms this embedding into $\text{Enc}(F)_{\text{atom}} \in \mathbb{R}^{H_{\text{Dec}}}$ as $\text{Enc}(F)_{\text{atom}} = W_{\text{Enc}} e_{\text{atom}}$, where $W_{\text{Enc}} \in \mathbb{R}^{H_{\text{Dec}} \times D_{\text{Enc}}}$.

This embedding matrix, E_{in}, could be another parameter of the model to be learned, however, as discussed later (see Section 4.3), we have learned it separately and beforehand with *TransE* (Bordes et al., 2013), a model aimed at modeling this kind of multi-relational data. We fix it and do not allow the encoder to tune it during training.

We call *fact embedding* $\text{Enc}(F) \in \mathbb{R}^{3H_{\text{Dec}}}$ the concatenation $[\text{Enc}(F)_s, \text{Enc}(F)_r, \text{Enc}(F)_o]$ of the atom embeddings, which is the input for the next module.

4.2 Decoder

For the decoder, we use a GRU recurrent neural network (RNN) (Cho et al., 2014) with an attention-mechanism (Bahdanau et al., 2015) on the encoder representation to generate the associated question Q to that fact F. Recently, it has been shown that the GRU RNN performs equally well across a range of tasks compared to other RNN architectures, such as the LSTM RNN (Greff et al., 2015). The hidden state of the decoder RNN is computed at each time step n as:

$$g_n^r = \sigma(W_r E_{out} w_{n-1} + C_r c(F, h_{n-1}) + U_r h_{n-1}) \quad (2)$$

$$g_n^u = \sigma(W_u E_{out} w_{n-1} + C_u c(F, h_{n-1}) + U_u h_{n-1}) \quad (3)$$

$$\tilde{h} = \tanh(W E_{out} w_{n-1} + C c(F, h_{n-1}) + U(g_n^r \circ h_{n-1})) \quad (4)$$

$$h_n = g_n^u \circ h_{n-1} + (1 - g_n^u) \circ \tilde{h}, \quad (5)$$

where σ is the sigmoid function, s.t. $\sigma(x) \in [0, 1]$, and the circle, $\circ$, represents element-wise multiplication. The initial state h_0 of this RNN is given by the output of a feedforward neural network fed with the fact embedding. The product $E_{out} w_n \in \mathbb{R}^{D_{\text{Dec}}}$ is the decoder embedding vector corresponding to the word w_n (coded as a 1-of-V vector, with V being the size of the output vocabulary), the variables $U_r, U_u, U, C_r, C_u, C \in \mathbb{R}^{H_{\text{Dec}} \times H_{\text{Dec}}}$, $W_r, W_u, W \in \mathbb{R}^{H_{\text{Dec}} \times D_{\text{Dec}}}$ are the parameters of the GRU and $c(F, h_{n-1})$ is the context vector (defined below Eq. 6). The vector g^r is called the *reset gate*, g^u as the *update gate* and $\tilde{h}$ the *candidate activation*. By adjusting g^r and g^u appropriately, the model is able to create linear *skip-connections* between distant hidden states, which in turn makes the credit assignment problem easier and the gradient signal stronger to earlier hidden states. Then, at each time step n the set of probabilities over word tokens is given by applying a softmax layer over $V_o \tanh(V_h h_n + V_w E_{out} w_{n-1} + V_c c(F, h_{n-1}))$, where $V_o \in \mathbb{R}^{V \times H_{\text{Dec}}}$, $V_h, V_c \in \mathbb{R}^{H_{\text{Dec}} \times H_{\text{Dec}}}$ and $V_w \in \mathbb{R}^{H_{\text{Dec}} \times D_{\text{Dec}}}$. Lastly, the function $c(F, h_{n-1})$ is computed using an attention-mechanism:

$$c(F, h_{n-1}) = \alpha_{\text{s},n-1} \text{Enc}(F)_{\text{s}} + \alpha_{\text{r},n-1} \text{Enc}(F)_{\text{r}} + \alpha_{\text{o},n-1} \text{Enc}(F)_{\text{o}}, \quad (6)$$

where $\alpha_{\text{s},n-1}, \alpha_{\text{r},n-1}, \alpha_{\text{r},n-1}$ are real-valued scalars, which weigh the contribution of the subject, relationship and object representations.

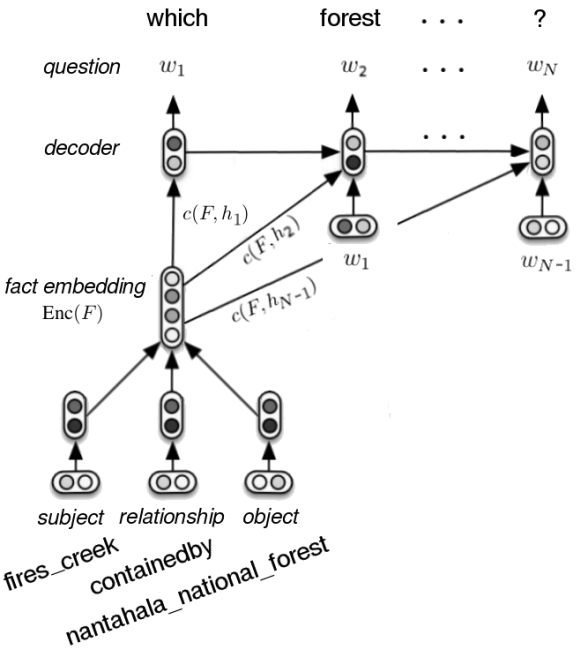

Figure 1: The computational graph of the question-generation model, where $\text{Enc}(F)$ is the fact embedding produced by the encoder model, and $c(F, h_{n-1})$ for $n = 1, \ldots, N$ is the fact representation weighed according to the attention-mechanism, which depends on both the fact F and the previous hidden state of the decoder RNN h_{n-1} . For the sake of simplicity, the attention-mechanism is not shown explicitly.

They correspond to the *attention* of the model, and are computed by applying a one-layer neural network with tanh-activation function on the encoder representations of the fact, Enc(F), and the previous hidden state of the RNN, h_{n-1}, followed by the sigmoid function to restrict the attention values to be between zero and one. The need for the attention-mechanism is motivated by the intuition that the model needs to attend to the subject only once during the generation process while attending to the relationship at all other times during the generation process. The model is illustrated in Figure 1.

4.3 Modeling the Source Language

A particular problem with the model presented above is related to the embeddings for the entities, relationships and tokens, which all have to be learned in one way or another. If we learn these naively on the SimpleQuestions training set, the model will perform poorly when it encounters previously unseen entities, relationships or tokens. Furthermore, the multi-relational graph defined by the facts in SimpleQuestions is extremely sparse, i.e. each node has very few edges to other nodes, as can be expected due to high ratio of unique entities over number of examples. Therefore, even for many of the entities in SimpleQuestions, the model may perform poorly if the embedding is learned solely based on the SimpleQuestions dataset alone.

On the source side, we can resolve this issue by initializing the subject, relationship and object embeddings to those learned by applying multi-relational embedding-based models to the knowledge base. Multi-relational embedding-based models (Bordes et al., 2011) have recently become popular to learn distributed vector embeddings for knowledge bases, and have shown to scale well and yield good performance. Due to its simplicity and good performance, we choose to use TransE (Bordes et al., 2013) to learn such embeddings. TransE is a translation-based model, whose energy function is trained to output low values when the fact expresses true information, i.e. a fact which exists in the knowledge base, and otherwise high values. Formally, the energy function is defined as $f(s, r, o) = ||e_s + e_r - e_o||_2$, where e_s, e_r and e_o are the real-valued embedding vectors for the subject, relationship and object of a fact. Further details are given by Bordes et al. (2013).

Embeddings for entities with few connections are easy to learn, yet the quality of these embeddings depends on how inter-connected they are. In the extreme case where the subject and object of a triple only appears once in the dataset, the learned embeddings of the subject and object will be semantically meaningless. This happens very often in SimpleQuestions, since only around 5% of the entities have more than 2 connections in the graph. Thus, by applying TransE directly over this set of triples, we would eventually end up with a layout of entities that does not contain clusters of semantically close concepts. In order to guarantee an effective semantic representation of the embeddings, we have to learn them together with additional triples extracted from the whole Freebase graph to complement the SimpleQuestions graph with relevant information for this task.

We need a coarse representation for the entities contained in SimpleQuestions, capturing the *basic* information, like the profession or nationality, the annotators tend to use when phrasing the questions, and accordingly we have ensured the embeddings contain this information by taking triples coming from the Freebase graph[5] regarding:

1. Category information: given by the *type/instance* relationship, this ensures that all the entities of the same semantic category are close to each other. Although one might think that the expected category of the subject/object could be inferred directly from the relationship, there are fine-grained differences in the expected types that be extracted only directly by observing this category information.

2. Geographical information: sometimes the annotators have included information about nationality (e.g. *Which French president...?*) or location (e.g. *Where in Germany...?*) of the subject and/or object. This information is given by the relationships *person/nationality* and *location/contained_by*. By including these facts in the learning, we ensure the existence of a fine-grained layout of the embeddings regarding this information within a same category.

Table 2: Examples of differences in the local structure of the vector space embeddings when adding more FB facts

3. Gender: similarly, sometimes annotators have included information about gender (e.g. *Which male audio engineer...*?). This information is given by the relationship *person/gender*.

To this end, we have included more than $300,000$ facts from Freebase in addition to the facts in SimpleQuestions for training. Table 2 shows the differences in the embeddings before and after adding additional facts for training the TransE representations.

4.4 Generating Questions

To resolve the problem of data sparsity and previously unseen words on the target side, we draw inspiration from the placeholders proposed for handling rare words in neural machine translation by Luong et al. (2015). For every question and answer pair, we search for words in the question which overlap with words in the subject string of the fact.[6] We heuristically estimate the sequence of most likely words in the question, which correspond to the subject string. These words are then replaced by the placeholder token *<placeholder>*. For example, given the fact {fires_creek, contained_by, nantahala_national_forest} the original question *Which forest is Fires Creek in?* is transformed into the question *Which forest is <placeholder>in?*. The model is trained on these modified questions, which means that model only has to learn decoder embeddings for tokens which are not in the subject string. At test time, after outputting a question, all placeholder tokens are replaced by the subject string and then the outputs are evaluated. We call this the Single-Placeholder (SP) model. The main difference with respect to that of Luong et al. (2015) is that we do not use placeholder tokens in the input language, because then the entities and relationships in the input would not be able to transmit semantic (e.g. topical) information to the decoder. If we had included placeholder tokens in the input language, the model would not be able to generate informative words regarding the subject in the question (e.g. it would be impossible for the model to learn that the subject *Paris* may be accompanied by the words *French city* when generating a question, because it would not see *Paris* but only a placeholder token).

A single placeholder token for all question types could unnecessarily limit the model. We therefore also experiment with another model, called the Multi-Placeholder (MP) model, which uses 60 different placeholder tokens such that the placeholder for a given question is chosen based on the subject category extracted from the relationship (e.g. contained_by is classified in the category location, and so the transformed question would be *Which forest is <location placeholder> in?*). This could make it easier for the model to learn to phrase questions about a diverse set of entities, but it also introduces additional parameters, since there are now 60 placeholder embeddings to be learned, and therefore the model may suffer from overfitting. This way of addressing the sparsity in the output reduces the vocabulary size to less than 7000 words.

4.5 Template-based Baseline

To compare our neural network models, we propose a (non-parametric) template-based baseline model, which makes use of the entire training set when generating a question. The baseline operates on questions modified with the placeholder as in the preceding section. Given a fact F as input, the baseline picks a candidate fact F_c in the training set at uniformly random, where F_c has the same relationship as F. Then the baseline considers the questions corresponding to F_c and as in the

[6] We use the tool difflib: `https://docs.python.org/2/library/difflib.html`.

SP model, in the final step the placeholder token in the question is replaced by the subject string of the fact F.

5 Experiments

5.1 Training Procedure

All neural network models were implemented in Theano (Theano Development Team, 2016). To train the neural network models, we optimized the log-likelihood using the first-order gradient-based optimization algorithm Adam (Kingma and Ba, 2015). To decide when to stop training we used early stopping with patience (Bengio, 2012) on the METEOR score obtained for the validation set. In all experiments, we use the default split of the SimpleQuestions dataset into training, validation and test sets.

We trained TransE embeddings with embedding dimensionality 200 for each subject, relationship and object. Based on preliminary experiments, for all neural network models we fixed the learning rate to 0.00025 and clipped parameter gradients with norms larger than 0.1. We further fixed the embedding dimensionality of words to be 200, and the hidden state of the decoder RNN to have dimensionality 600.

5.2 Evaluation

To investigate the performance of our models, we make use of both automatic evaluation metrics and human evaluators.

5.2.1 Automatic Evaluation Metrics

BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005) are two widely used evaluation metrics in statistical machine translation and automatic image-caption generation (Chen et al., 2015). Similar to statistical machine translation, where a phrase in the source language is mapped to a phrase in the target language, in this task a KB fact is mapped to a natural language question. Both tasks are highly constrained, e.g. the set of valid outputs is limited. This is true in particular for short phrases, such as one sentence questions. Furthermore, in both tasks, the majority of valid outputs are paraphrases of each other, which BLEU and METEOR have been designed to capture. We therefore believe that BLEU and METEOR constitute reasonable performance metrics for evaluating the generated questions.

Although we believe that METEOR and BLEU are reasonable evaluation metrics, they may have not recognize certain paraphrases, in particular paraphrases of entities. We therefore also make use of a sentence similarity metric, as proposed by Rus and Lintean (2012), which we will denote *Embedding Greedy* (Emb. Greedy). The metric makes use of a word similarity score, which in our experiments is the cosine similarity between two Word2Vec word embeddings (Mikolov et al., 2013).[7] The metric finds a (non-exclusive) alignment between words in the two questions, which maximizes the similarity between aligned words, and computes the sentence similarity as the mean over the word similarities between aligned words.

The results are shown in Table 3. Example questions produced by the model with multiple placeholders are shown in Table 4. The neural network models outperform the template-based baseline by a clear margin across all metrics. The template-based baseline is already a relatively strong model, because it makes use of a separate template for each relationship. Qualitatively the neural networks outperform the baseline model in cases where they are able to levage additional knowledge about the entities (see first, third and fifth example in Table 4). On the other hand, for rare relationships the baseline model appears to perform better, because it is able to produce a reasonable question if only a single example with the same relationship exists in the training set (see eighth example in Table 4). Given enough training data this suggests that neural networks are generally better at the question generation task compared to hand-crafted template-based procedures, and therefore that they may be useful for generating question answering corpora. Furthermore, it appears that the best performing models are the models where TransE are trained on the largest set of triples (TransE++). This set contains, apart from the supporting triples described in Section 4.3, triples involving entities which are highly connected to the entities found in the SimpleQuestions facts. In total, around 30 millions of facts, which have been used to generate the 30M Factoid Question-Answer Corpus. Lastly, it is not clear whether the model with a single placeholder or the model with multiple placeholders performs best. This motivates the following human study.

[7] We use the Word2Vec embeddings pretrained on the Google News Corpus: `https://code.google.com/p/word2vec/`.

Model	BLEU	METEOR	Emb. Greedy
Baseline	31.36	33.12	74.02
SP Triples	33.27	35.07	76.72
MP Triples	32.76	34.97	76.70
SP Triples TransE++	**33.32**	**35.38**	76.78
MP Triples TransE++	33.28	35.29	**77.01**

5.2.2 Human Evaluation Study

We carry out pairwise preference experiments on Amazon Mechanical Turk.

Initially, we considered carrying out separate experiments for measuring relevancy and fluency respectively, since this is common practice in machine translation. However, the relevancy of a question is determined solely by a single factor, i.e. the relationship, since by construction the subject is always in the question. Measuring relevancy is therefore not very useful in our task. To verify this we carried out an internal pairwise preference experiment with human subjects, who were repeatedly shown a fact and two questions and asked to select the most relevant question. We found that 93% of the questions generated by the MP Triples TransE++ model were either judged better or at least as good as the human generated questions w.r.t. relevancy. The remaining 7% questions of the MP Triples TransE++ model questions were also judged relevant questions, although less so compared to the human generated questions. In the next experiment, we therefore measure the holistic quality of the questions.

We setup experiments comparing: Human-Baseline (human and baseline questions), Human-MP (human and MP Triples TransE++ questions) and Baseline-MP (baseline and MP Triples TransE++ questions). We show human evaluators a fact along with two questions, one question from each model for the corresponding fact, and ask the them to choose the question which is most relevant to the fact and most natural. The human evaluator also has the option of not choosing either question. This is important if both questions are equally good or if neither of the questions make sense. At the beginning of each experiment, we show the human evaluators two examples of statements and a corresponding pair of questions, where we briefly explain the form of the statements and how questions relate to those statements. Following the introductory examples, we present the facts and cor-

Model A	Model B	Model A Preference (%)	Model B Preference (%)	Fleiss' kappa
Human	Baseline	$^{*}\mathbf{56.329 \pm 5.469}$	34.177 ± 5.230	0.242
Baseline	MP Triples TransE++	32.484 ± 5.180	$^{*}\mathbf{60.828 \pm 5.399}$	0.234
Human	MP Triples TransE++	38.652 ± 5.684	$\mathbf{51.418 \pm 5.833}$	0.182

Table 5: Pairwise human evaluation preferences computed across evaluators with 95% confidence intervals. The preferred model in each experiment is marked in bold font. An asterisk next to the preferred model indicates a statistically significance likelihood-ratio test, which shows that the model is preferred in at least half of the presented examples with 95% confidence. The name *MP Triples TransE++* indicates the model with multiple placeholders and TransE embeddings pretrained on a larger set of triples. The last column shows the Fleiss' kappa averaged across batches (HITs) with different evaluators and questions.

responding pair of questions one by one. To avoid presentation bias, we randomly shuffle the order of the examples and the order in which questions are shown by each model. During each experiment, we also show four check facts and corresponding check questions at random, which any attentive human annotator should be able to answer easily. We discard responses of human evaluators who fail any of these four checks.

The preference of each example is defined as the question which is preferred by the majority of the evaluators. Examples where neither of the two questions are preferred by the majority of the evaluators, i.e. when there is an equal number of evaluators who prefer each question, are assigned to a separate preference class called "comparable".[8]

The results are shown in Table 5. In total, 3,810 preferences were recorded by 63 independent human evaluators. The questions produced by each model model pair were evaluated in 5 batches (HITs). Each human evaluated 44-75 examples (facts and corresponding question pairs) in each batch and each example was evaluated by 3-5 evaluators. In agreement with the automatic evaluation metrics, the human evaluators strongly prefer either the human or the neural network model over the template-based baseline. Furthermore, it appears that humans cannot distinguish between the human-generated questions and the neural network questions, on average showing a preference towards the later over the former ones. We hypothesize this is because our model penalizes uncommon and unnatural ways to frame questionsand sometimes, includes specific information about the target object that the humans do not (see last example in Table 4). This confirms our earlier assertion, that the neural network questions can be used for building question answering systems.

[8]The probabilities for the "comparable" class in Table 5 can be computed in each row as 100 minus the third and fourth column in the table.

6 Conclusion

We propose new neural network models for mapping knowledge base facts into corresponding natural language questions. The neural networks combine ideas from recent neural network architectures for statistical machine translation, as well as multi-relational knowledge base embeddings for overcoming sparsity issues and placeholder techniques for handling rare words. The produced question and answer pairs are evaluated using automatic evaluation metrics, including BLEU, METEOR and sentence similarity, and are found to outperform a template-based baseline model. When evaluated by untrained human subjects, the question and answer pairs produced by our best performing neural network appears to be comparable in quality to real human-generated questions. Finally, we use our best performing neural network model to generate a corpus of 30M question and answer pairs, which we hope will enable future researchers to improve their question answering systems.

Abstract

Many language generation tasks require the production of text conditioned on both structured and unstructured inputs. We present a novel neural network architecture which generates an output sequence conditioned on an arbitrary number of input functions. Crucially, our approach allows both the choice of conditioning context and the granularity of generation, for example characters or tokens, to be marginalised, thus permitting scalable and effective training. Using this framework, we address the problem of generating programming code from a mixed natural language and structured specification. We create two new data sets for this paradigm derived from the collectible trading card games Magic the Gathering and Hearthstone. On these, and a third preexisting corpus, we demonstrate that marginalising multiple predictors allows our model to outperform strong benchmarks.

1 Introduction

The generation of both natural and formal languages often requires models conditioned on diverse predictors (Koehn et al., 2007; Wong and Mooney, 2006). Most models take the restrictive approach of employing a single predictor, such as a word softmax, to predict all tokens of the output sequence. To illustrate its limitation, suppose we wish to generate the answer to the question "Who wrote The Foundation?" as "The Foundation was written by Isaac Asimov". The generation of the words "Issac Asimov" and "The Foundation" from a word softmax trained on annotated data is unlikely to succeed as these words are sparse. A robust model might, for example, employ one predictor to copy "The Foundation" from the input, and a another one to find the answer "Issac Asimov" by searching through a database. However, training multiple predictors is in itself a challenging task, as no annotation exists regarding the predictor used to generate each output token. Furthermore, predictors generate segments of different granularity, as database queries can generate multiple tokens while a word softmax generates a single token. In this work we introduce *Latent Predictor Networks (LPNs)*, a novel neural architecture that fulfills these desiderata: at the core of the architecture is the exact computation of the marginal likelihood over latent predictors and generated segments allowing for scalable training.

Figure 1: Example MTG and HS cards.

We introduce a new corpus for the automatic generation of code for cards in Trading Card Games (TCGs), on which we validate our model [1]. TCGs, such as Magic the Gathering (MTG) and Hearthstone (HS), are games played between two players that build decks from an ever expanding pool of cards. Examples of such cards are shown in Figure 1. Each card is identified by its attributes

[1] Dataset available at https://deepmind.com/publications.html

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 599–609,
Berlin, Germany, August 7-12, 2016.

(e.g., name and cost) and has an effect that is described in a text box. Digital implementations of these games implement the game logic, which includes the card effects. This is attractive from a data extraction perspective as not only are the data annotations naturally generated, but we can also view the card as a specification communicated from a designer to a software engineer.

This dataset presents additional challenges to prior work in code generation (Wong and Mooney, 2006; Jones et al., 2012; Lei et al., 2013; Artzi et al., 2015; Quirk et al., 2015), including the handling of structured input—i.e. cards are composed by multiple sequences (e.g., name and description)—and attributes (e.g., attack and cost), and the length of the generated sequences. Thus, we propose an extension to attention-based neural models (Bahdanau et al., 2014) to attend over structured inputs. Finally, we propose a code compression method to reduce the size of the code without impacting the quality of the predictions.

Experiments performed on our new datasets, and a further pre-existing one, suggest that our extensions outperform strong benchmarks.

The paper is structured as follows: We first describe the data collection process (Section 2) and formally define our problem and our baseline method (Section 3). Then, we propose our extensions, namely, the structured attention mechanism (Section 4) and the LPN architecture (Section 5). We follow with the description of our code compression algorithm (Section 6). Our model is validated by comparing with multiple benchmarks (Section 7). Finally, we contextualize our findings with related work (Section 8) and present the conclusions of this work (Section 9).

2 Dataset Extraction

We obtain data from open source implementations of two different TCGs, MTG in Java[2] and HS in Python.[3] The statistics of the corpora are illustrated in Table 1. In both corpora, each card is implemented in a separate class file, which we strip of imports and comments. We categorize the content of each card into two different groups: *singular fields* that contain only one value; and *text fields*, which contain multiple words representing different units of meaning. In MTG, there are six singular fields (attack, defense, rarity, set, id, and health) and four text fields (cost, type, name, and description), whereas HS cards have eight singular fields (attack, health, cost and durability, rarity, type, race and class) and two text fields (name and description). Text fields are tokenized by splitting on whitespace and punctuation, with exceptions accounting for domain specific artifacts (e.g., Green mana is described as "{G}" in MTG). Empty fields are replaced with a "NIL" token.

	MTG	HS
Programming Language	Java	Python
Cards	13,297	665
Cards (Train)	11,969	533
Cards (Validation)	664	66
Cards (Test)	664	66
Singular Fields	6	4
Text Fields	8	2
Words In Description (Average)	21	7
Characters In Code (Average)	1,080	352

Table 1: Statistics of the two TCG datasets.

The code for the HS card in Figure 1 is shown in Figure 2. The effect of "drawing cards until the player has as many cards as the opponent" is implemented by computing the difference between the players' hands and invoking the draw method that number of times. This illustrates that the mapping between the description and the code is non-linear, as no information is given in the text regarding the specifics of the implementation.

```
class DivineFavor(SpellCard):
    def __init__(self):
        super().__init__("Divine Favor", 3,
    CHARACTER_CLASS.PALADIN, CARD_RARITY.RARE)

    def use(self, player, game):

3 Problem Definition

Given the description of a card x, our decoding problem is to find the code $\hat{y}$ so that:

$$\hat{y} = \underset{y}{\operatorname{argmax}} \log P(y \mid x) \quad (1)$$

Here $\log P(y \mid x)$ is estimated by a given model. We define $y = y_1..y_{|y|}$ as the sequence of characters of the code with length $|y|$. We index each input field with $k = 1..|x|$, where $|x|$ quantifies the

[2] github.com/magefree/mage/

[3] github.com/danielyule/hearthbreaker/

number of input fields. $|x_k|$ denotes the number of tokens in x_k and x_{ki} selects the i-th token.

4 Structured Attention

Background When $|x| = 1$, the attention model of Bahdanau et al. (2014) applies. Following the chain rule, $\log P(y|x) = \sum_{t=1..|y|} \log P(y_t|y_1..y_{t-1}, x)$, each token y_t is predicted conditioned on the previously generated sequence $y_1..y_{t-1}$ and input sequence $x_1 = x_{11}..x_{1|x_1|}$. Probability are estimated with a softmax over the vocabulary Y:

$$p(y_t|y_1..y_{t-1}, x_1) = \underset{y_t \in Y}{\text{softmax}}(\mathbf{h}_t) \quad (2)$$

where $\mathbf{h}_t$ is the Recurrent Neural Network (RNN) state at time stamp t, which is modeled as $g(\mathbf{y}_{t-1}, \mathbf{h}_{t-1}, \mathbf{z}_t)$. $g(\cdot)$ is a recurrent update function for generating the new state $\mathbf{h}_t$ based on the previous token $\mathbf{y}_{t-1}$, the previous state $\mathbf{h}_{t-1}$, and the input text representation $\mathbf{z}_t$. We implement g using a Long Short-Term Memory (LSTM) RNNs (Hochreiter and Schmidhuber, 1997).

The attention mechanism generates the representation of the input sequence $\mathbf{x} = x_{11}..x_{1|x_1|}$, and $\mathbf{z}_t$ is computed as the weighted sum $\mathbf{z}_t = \sum_{i=1..|x_1|} a_i h(x_{1i})$, where a_i is the attention coefficient obtained for token x_{1i} and h is a function that maps each x_{1i} to a continuous vector. In general, h is a function that projects x_{1i} by learning a lookup table, and then embedding contextual words by defining an RNN. Coefficients a_i are computed with a softmax over input tokens $x_{11}..x_{1|x_1|}$:

$$a_i = \underset{x_{1i} \in x}{\text{softmax}}\left(v(h(x_{1i}), \mathbf{h}_{t-1})\right) \quad (3)$$

Function v computes the affinity of each token x_{1i} and the current output context $\mathbf{h}_{t-1}$. A common implementation of v is to apply a linear projection from $h(x_{1i}) : \mathbf{h}_{t-1}$ (where : is the concatenation operation) into a fixed size vector, followed by a $\tanh$ and another linear projection.

Our Approach We extend the computation of $\mathbf{z}_t$ for cases when x corresponds to multiple fields. Figure 3 illustrates how the MTG card "Serra Angel" is encoded, assuming that there are two singular fields and one text field. We first encode each token x_{ki} using the C2W model described in Ling et al. (2015), which is a replacement for lookup tables where word representations are learned at the

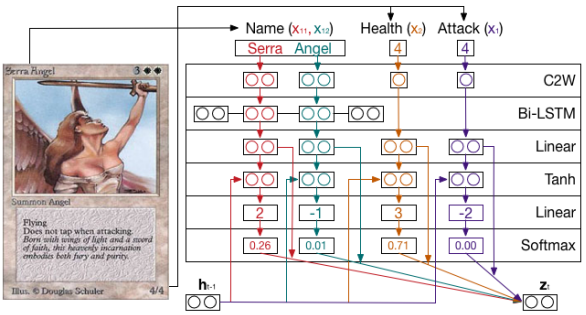

Figure 3: Illustration of the structured attention mechanism operating on a single time stamp t.

character level (cf. *C2W* row). A context-aware representation is built for words in the text fields using a bidirectional LSTM (cf. *Bi-LSTM* row). Computing attention over multiple input fields is problematic as each input field's vectors have different sizes and value ranges. Thus, we learn a linear projection mapping each input token x_{ki} to a vector with a common dimensionality and value range (cf. *Linear* row). Denoting this process as $f(x_{ki})$, we extend Equation 3 as:

$$a_{ki} = \underset{x_{ki} \in x}{\text{softmax}}(v(f(x_{ki}), \mathbf{h}_{t-1})) \quad (4)$$

Here a scalar coefficient a_{ki} is computed for each input token x_{ki} (cf. "Tanh", "Linear", and "Softmax" rows). Thus, the overall input representation $\mathbf{z}_t$ is computed as:

$$\mathbf{z}_t = \sum_{k=1..|x|, i=1..|x_k|} a_{ij} f(x_{ki}) \quad (5)$$

5 Latent Predictor Networks

Background In order to decode from x to y, many words must be copied into the code, such as the name of the card, the attack and the cost values. If we observe the HS card in Figure 1 and the respective code in Figure 2, we observe that the name "Divine Favor" must be copied into the class name and in the constructor, along with the cost of the card "3". As explained earlier, this problem is not specific to our task: for instance, in the dataset of Oda et al. (2015), a model must learn to map from `timeout = int ( timeout )` to "convert timeout into an integer.", where the name of the variable "timeout" must be copied into the output sequence. The same issue exists for proper nouns in machine translation

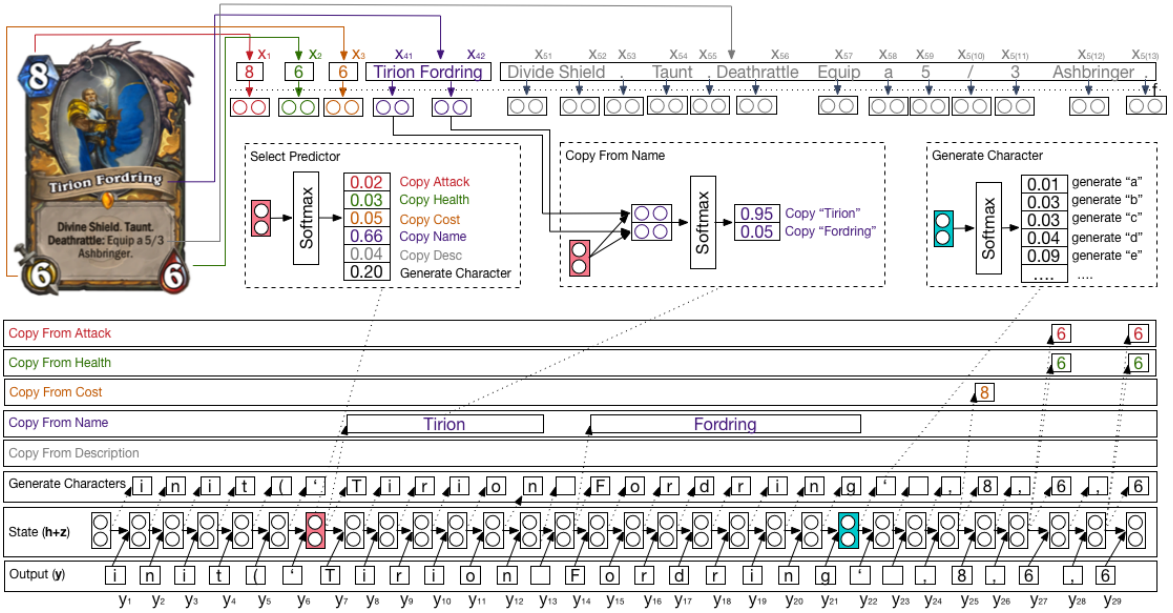

Figure 4: Generation process for the code `init('Tirion Fordring',8,6,6)` using LPNs.

which are typically copied from one language to the other. Pointer networks (Vinyals et al., 2015) address this by defining a probability distribution over a set of units that can be copied $c = c_1..c_{|c|}$. The probability of copying a unit c_i is modeled as:

$$p(c_i) = \underset{c_i \in c}{\text{softmax}}(v(h(c_i), \mathbf{q})) \quad (6)$$

As in the attention model (Equation 3), v is a function that computes the affinity between an embedded copyable unit $h(c_i)$ and an arbitrary vector $\mathbf{q}$.

Our Approach Combining pointer networks with a character-based softmax is in itself difficult as these generate segments of different granularity and there is no ground truth of which predictor to use at each time stamp. We now describe Latent Predictor Networks, which model the conditional probability $\log P(y|x)$ over the latent sequence of predictors used to generate y.

We assume that our model uses multiple predictors $r \in R$, where each r can generate multiple segments $s_t = y_t..y_{t+|s_t|-1}$ with arbitrary length $|s_t|$ at time stamp t. An example is illustrated in Figure 4, where we observe that to generate the code `init('Tirion Fordring',8,6,6)`, a pointer network can be used to generate the sequences y_7^{13}=`Tirion` and y_{14}^{22}=`Fordring` (cf. "Copy From Name" row). These sequences can also be generated using a character softmax (cf. "Generate Characters" row). The same applies to the generation of the attack, health and cost values as each of these predictors is an element in R. Thus, we define our objective function as a marginal log likelihood function over a latent variable ω:

$$\log P(y \mid x) = \log \sum_{\omega \in \bar{\omega}} P(y, \omega \mid x) \quad (7)$$

Formally, ω is a sequence of pairs r_t, s_t, where $r_t \in R$ denotes the predictor that is used at timestamp t and s_t the generated string. We decompose $P(y, \omega \mid x)$ as the product of the probabilities of segments s_t and predictors r_t:

$$P(y, \omega \mid x) = \prod_{r_t, s_t \in \omega} P(s_t, r_t \mid y_1..y_{t-1}, x) =$$

$$\prod_{r_t, s_t \in \omega} P(s_t \mid y_1..y_{t-1}, x, r_t) P(r_t \mid y_1..y_{t-1}, x)$$

where the generation of each segment is performed in two steps: select the predictor r_t with probability $P(r_t \mid y_1..y_{t-1}, x)$ and then generate s_t conditioned on predictor r_t with probability $\log P(s_t \mid y_1..y_{t-1}, x, r_t)$. The probability of each predictor is computed using a softmax over all predictors in R conditioned on the previous state $\mathbf{h_{t-1}}$ and the input representation $\mathbf{z}_t$ (cf. "Select Predictor" box). Then, the probability of generating the segment s_t depends on the predictor type. We define three types of predictors:

Character Generation Generate a single character from observed characters from the training data. Only one character is generated at each time stamp with probability given by Equation 2.

Copy Singular Field For singular fields only the field itself can be copied, for instance, the value of the attack and cost attributes or the type of card. The size of the generated segment is the number of characters in the copied field and the segment is generated with probability 1.

Copy Text Field For text fields, we allow each of the words x_{ki} within the field to be copied. The probability of copying a word is learned with a pointer network (cf. "Copy From Name" box), where $h(c_i)$ is set to the representation of the word $f(x_{ki})$ and $\mathbf{q}$ is the concatenation $\mathbf{h}_{t-1} : \mathbf{z}_t$ of the state and input vectors. This predictor generates a segment with the size of the copied word.

It is important to note that the state vector $\mathbf{h}_{t-1}$ is generated by building an RNN over the sequence of characters up until the time stamp $t-1$, i.e. the previous context $\mathbf{y}_{t-1}$ is encoded at the character level. This allows the number of possible states to remain tractable at training time.

5.1 Inference

At training time we use back-propagation to maximize the probability of observed code, according to Equation 7. Gradient computation must be performed with respect to each computed probability $P(r_t \mid y_1..y_{t-1}, x)$ and $P(s_t \mid y_1..y_{t-1}, x, r_t)$. The derivative $\frac{\partial \log P(y|x)}{\partial P(r_t|y_1..y_{t-1},x)}$ yields:

$$\frac{\partial \alpha_t P(r_t \mid y_1..y_{t-1}, x)\beta_{t,r_t} + \xi_{r_t}}{P(y \mid x)\partial P(r_t \mid y_1..y_{t-1}, x)} = \frac{\alpha_t \beta_{t,r_t}}{\alpha_{|y|+1}}$$

Here α_t denotes the cumulative probability of all values of ω up until time stamp t and $\alpha_{|y|+1}$ yields the marginal probability $P(y \mid x)$. $\beta_{t,r_t} = P(s_t \mid y_1..y_{t-1})\beta_{t+|s_t|-1}$ denotes the cumulative probability starting from predictor r_t at time stamp t, exclusive. This includes the probability of the generated segment $P(s_t \mid y_1..y_{t-1}, x, r_t)$ and the probability of all values of ω starting from timestamp $t+|s_t|-1$, that is, all possible sequences that generate segment y after segment s_t is produced. For completeness, ξ_r denotes the cumulative probabilities of all ω that do not include r_t. To illustrate this, we refer to Figure 4 and consider the timestamp $t = 14$, where the segment s_{14} =`Fordring` is generated. In this case, the cumulative probability α_{14} is the sum of the path that generates the sequence `init('Tirion` with characters alone, and the path that generates the word `Tirion` by copying from the input. β_{21} includes the probability of all paths that follow the generation of `Fordring`, which include $2\times3\times3$ different paths due to the three decision points that follow (e.g. generating 8 using a character softmax vs. copying from the cost). Finally, ξ_r refers to the path that generates `Fordring` character by character.

While the number of possible paths grows exponentially, α and β can be computed efficiently using the forward-backward algorithm for Semi-Markov models (Sarawagi and Cohen, 2005), where we associate $P(r_t \mid y_1..y_{t-1}, x)$ to edges and $P(s_t \mid y_1..y_{t-1}, x, r_t)$ to nodes in the Markov chain.

The derivative $\frac{\partial \log P(y|x)}{\partial P(s_t|y_1..y_{t-1},x,r_t)}$ can be computed using the same logic:

$$\frac{\partial \alpha_{t,s_t} P(s_t \mid y_1..y_{t-1}, x, r_t)\beta_{t+|s_t|-1} + \xi_{r_t}}{P(y \mid x)\partial P(s_t \mid y_1..y_{t-1}, x, r_t)} = \frac{\alpha_{t,r_t}\beta_{t+|s_t|-1}}{\alpha_{|y|+1}}$$

Once again, we denote $\alpha_{t,r_t} = \alpha_t P(r_t \mid y_1..y_{t-1}, x)$ as the cumulative probability of all values of ω that lead to s_t, exclusive.

An intuitive interpretation of the derivatives is that gradient updates will be stronger on probability chains that are more likely to generate the output sequence. For instance, if the model learns a good predictor to copy names, such as `Fordring`, other predictors that can also generate the same sequences, such as the character softmax will allocate less capacity to the generation of names, and focus on elements that they excel at (e.g. generation of keywords).

5.2 Decoding

Decoding is performed using a stack-based decoder with beam search. Each state S corresponds to a choice of predictor r_t and segment s_t at a given time stamp t. This state is scored as $V(S) = \log P(s_t \mid y_1..y_{t-1}, x, r_t) + \log P(r_t \mid y_1..y_{t-1}, x) + V(prev(S))$, where $prev(S)$ denotes the predecessor state of S. At each time stamp, the n states with the highest scores V are expanded, where n is the size of the beam. For each predictor r_t, each output s_t generates a new state. Finally, at each timestamp t, all states

which produce the same output up to that point are merged by summing their probabilities.

6 Code Compression

As the attention-based model traverses all input units at each generation step, generation becomes quite expensive for datasets such as MTG where the average card code contains 1,080 characters. While this is not the essential contribution in our paper, we propose a simple method to compress the code while maintaining the structure of the code, allowing us to train on datasets with longer code (e.g., MTG).

The idea behind that method is that many keywords in the programming language (e.g., `public` and `return`) as well as frequently used functions and classes (e.g., `Card`) can be learned without character level information. We exploit this by mapping such strings onto additional symbols X_i (e.g., `public class copy()` $\rightarrow$ "X_1 X_2 X_3()"). Formally, we seek the string $\hat{v}$ among all strings $V(max)$ up to length max that maximally reduces the size of the corpus:

$$\hat{v} = \underset{v \in V(max)}{\operatorname{argmax}} (len(v) - 1)C(v) \qquad (8)$$

where $C(v)$ is the number of occurrences of v in the training corpus and $len(v)$ its length. $(len(v) - 1)C(v)$ can be seen as the number of characters reduced by replacing v with a non-terminal symbol. To find $q(v)$ efficiently, we leverage the fact that $C(v) \leq C(v')$ if v contains v'. It follows that $(max - 1)C(v) \leq (max - 1)C(v')$, which means that the maximum compression obtainable for v at size max is always lower than that of v'. Thus, if we can find a $\bar{v}$ such that $(len(\bar{v}) - 1)C(\bar{v}) > (max - 1)C(v')$, that is $\bar{v}$ at the current size achieves a better compression rate than v' at the maximum length, then it follows that all sequences that contain v can be discarded as candidates. Based on this idea, our iterative search starts by obtaining the counts $C(v)$ for all segments of size $s = 2$, and computing the best scoring segment $\bar{v}$. Then, we build a list $L(s)$ of all segments that achieve a better compression rate than $\bar{v}$ at their maximum size. At size $s + 1$, only segments that contain a element in $L(s - 1)$ need to be considered, making the number of substrings to be tested to be tractable as s increases. The algorithm stops once s reaches max or the newly generated list $L(s)$ contains no elements.

Table 2: First 10 compressed units in MTG. We replaced newlines with ⇓ and spaces with _.

Once $\hat{v}$ is obtained, we replace all occurrences of $\hat{v}$ with a new non-terminal symbol. This process is repeated until a desired average size for the code is reached. While training is performed on the compressed code, the decoding will undergo an additional step, where the compressed code is restored by expanding the all X_i. Table 2 shows the first 10 replacements from the MTG dataset, reducing its average size from 1080 to 794.

7 Experiments

Datasets Tests are performed on the two datasets provided in this paper, described in Table 1. Additionally, to test the model's ability of generalize to other domains, we report results in the Django dataset (Oda et al., 2015), comprising of 16000 training, 1000 development and 1805 test annotations. Each data point consists of a line of Python code together with a manually created natural language description.

Neural Benchmarks We implement two standard neural networks, namely a sequence-to-sequence model (Sutskever et al., 2014) and an attention-based model (Bahdanau et al., 2014). The former is adapted to work with multiple input fields by concatenating them, while the latter uses our proposed attention model. These models are denoted as "Sequence" and "Attention".

Machine Translation Baselines Our problem can also be viewed in the framework of semantic parsing (Wong and Mooney, 2006; Lu et al., 2008; Jones et al., 2012; Artzi et al., 2015). Unfortunately, these approaches define strong assumptions regarding the grammar and structure of the output, which makes it difficult to generalize for other domains (Kwiatkowski et al., 2010). However, the work in Andreas et al. (2013) provides

evidence that using machine translation systems without committing to such assumptions can lead to results competitive with the systems described above. We follow the same approach and create a phrase-based (Koehn et al., 2007) model and a hierarchical model (or PCFG) (Chiang, 2007) as benchmarks for the work presented here. As these models are optimized to generate words, not characters, we implement a tokenizer that splits on all punctuation characters, except for the "_" character. We also facilitate the task by splitting CamelCase words (e.g., `class TirionFordring` → `class Tirion Fordring`). Otherwise all class names would not be generated correctly by these methods. We used the models implemented in Moses to generate these baselines using standard parameters, using IBM Alignment Model 4 for word alignments (Och and Ney, 2003), MERT for tuning (Sokolov and Yvon, 2011) and a 4-gram Kneser-Ney Smoothed language model (Heafield et al., 2013). These models will be denoted as "Phrase" and "Hierarchical", respectively.

Retrieval Baseline It was reported in (Quirk et al., 2015) that a simple retrieval method that outputs the most similar input for each sample, measured using Levenshtein Distance, leads to good results. We implement this baseline by computing the average Levenshtein Distance for each input field. This baseline is denoted "Retrieval".

Evaluation A typical metric is to compute the accuracy of whether the generated code exactly matches the reference code. This is informative as it gives an intuition of how many samples can be used without further human post-editing. However, it does not provide an illustration on the degree of closeness to achieving the correct code. Thus, we also test using BLEU-4 (Papineni et al., 2002) at the token level. There are clearly problems with these metrics. For instance, source code can be correct without matching the reference. The code in Figure 2, could have also been implemented by calling the `draw` function in an cycle that exists once both players have the same number of cards in their hands. Some tasks, such as the generation of queries (Zelle and Mooney, 1996), have overcome this problem by executing the query and checking if the result is the same as the annotation. However, we shall leave the study of these methologies for future work, as adapting these methods for our tasks is not trivial. For instance, the correctness cards with conditional (e.g. `if player has no cards, then draw a card`) or non-deterministc (e.g. `put a random card in your hand`) effects cannot be simply validated by running the code.

Setup The multiple input types (Figure 3) are hyper-parametrized as follows: The C2W model (cf. "C2W" row) used to obtain continuous vectors for word types uses character embeddings of size 100 and LSTM states of size 300, and generates vectors of size 300. We also report on results using word lookup tables of size 300, where we replace singletons with a special unknown token with probability 0.5 during training, which is then used for out-of-vocabulary words. For text fields, the context (cf. "Bi-LSTM" row) is encoded with a Bi-LSTM of size 300 for the forward and backward states. Finally, a linear layer maps the different input tokens into a common space with of size 300 (cf. "Linear" row). As for the attention model, we used an hidden layer of size 200 before applying the non-linearity (row "Tanh"). As for the decoder (Figure 4), we encode output characters with size 100 (cf. "output (y)" row), and an LSTM state of size 300 and an input representation of size 300 (cf. "State(h+z)" row). For each pointer network (e.g., "Copy From Name" box), the intersection between the input units and the state units are performed with a vector of size 200. Training is performed using mini-batches of 20 samples using AdaDelta (Zeiler, 2012) and we report results using the iteration with the highest BLEU score on the validation set (tested at intervals of 5000 mini-batches). Decoding is performed with a beam of 1000. As for compression, we performed a grid search over compressing the code from 0% to 80% of the original average length over intervals of 20% for the HS and Django datasets. On the MTG dataset, we are forced to compress the code up to 80% due to performance issues when training with extremely long sequences.

7.1 Results

Baseline Comparison Results are reported in Table 3. Regarding the retrieval results (cf. "Retrieval" row), we observe the best BLEU scores among the baselines in the card datasets (cf. "MTG" and "HS" columns). A key advantage of this method is that retrieving existing entities guarantees that the output is well formed, with no

syntactic errors such as producing a non-existent function call or generating incomplete code. As BLEU penalizes length mismatches, generating code that matches the length of the reference provides a large boost. The phrase-based translation model (cf. "Phrase" row) performs well in the Django (cf. "Django" column), where mapping from the input to the output is mostly monotonic, while the hierarchical model (cf. "Hierarchical" row) yields better performance on the card datasets as the concatenation of the input fields needs to be reordered extensively into the output sequence. Finally, the sequence-to-sequence model (cf. "Sequence" row) yields extremely low results, mainly due to the lack of capacity needed to memorize whole input and output sequences, while the attention based model (cf. "Attention" row) produces results on par with phrase-based systems. Finally, we observe that by including all the proposed components (cf. "Our System" row), we obtain significant improvements over all baselines in the three datasets and is the only one that obtains non-zero accuracies in the card datasets.

Component Comparison We present ablation results in order to analyze the contribution of each of our modifications. Removing the C2W model (cf. "– C2W" row) yields a small deterioration, as word lookup tables are more susceptible to sparsity. The only exception is in the HS dataset, where lookup tables perform better. We believe that this is because the small size of the training set does not provide enough evidence for the character model to scale to unknown words. Surprisingly, running our model compression code (cf. "– Compress" row) actually yields better results. Table 4 provides an illustration of the results for different compression rates. We obtain the best results with an 80% compression rate (cf. "BLEU Scores" block), while maximising the time each card is processed (cf. "Seconds Per Card" block). While the reason for this is uncertain, it is similar to the finding that language models that output characters tend to under-perform those that output words (Józefowicz et al., 2016). This applies when using the regular optimization process with a character softmax (cf. "Softmax" rows), but also when using the LPN (cf. "LPN" rows). We also note that the training speed of LPNs is not significantly lower as marginalization is performed with a dynamic program. Finally, a significant decrease is observed if we remove the pointer networks (cf. "– LPN" row). These improvements also generalize to sequence-to-sequence models (cf. "– Attention" row), as the scores are superior to the sequence-to-sequence benchmark (cf. "Sequence" row).

Result Analysis Examples of the code generated for two cards are illustrated in Figure 5. We obtain the segments that were copied by the pointer networks by computing the most likely predictor for those segments. We observe from the marked segments that the model effectively copies the attributes that match in the output, including the name of the card that must be collapsed. As expected, the majority of the errors originate from inaccuracies in the generation of the effect of the card. While it is encouraging to observe that a small percentage of the cards are generated correctly, it is worth mentioning that these are the result of many cards possessing similar effects. The "Madder Bomber" card is generated correctly as there is a similar card "Mad Bomber" in the training set, which implements the same effect, except that it deals 3 damage instead of 6. Yet, it is a promising result that the model was able to capture

this difference. However, in many cases, effects that radically differ from seen ones tend to be generated incorrectly. In the card "Preparation", we observe that while the properties of the card are generated correctly, the effect implements a unrelated one, with the exception of the value 3, which is correctly copied. Yet, interestingly, it still generates a valid effect, which sets a minion's attack to 3. Investigating better methods to accurately generate these effects will be object of further studies.

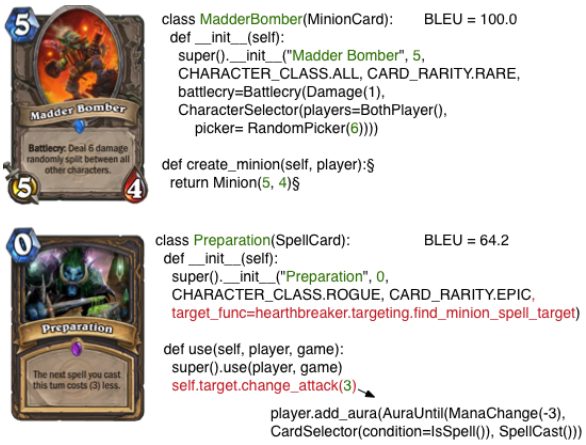

Figure 5: Examples of decoded cards from HS. Copied segments are marked in green and incorrect segments are marked in red.

8 Related Work

While we target widely used programming languages, namely, Java and Python, our work is related to studies on the generation of any executable code. These include generating regular expressions (Kushman and Barzilay, 2013), and the code for parsing input documents (Lei et al., 2013). Much research has also been invested in generating formal languages, such as database queries (Zelle and Mooney, 1996; Berant et al., 2013), agent specific language (Kate et al., 2005) or smart phone instructions (Le et al., 2013). Finally, mapping natural language into a sequence of actions for the generation of executable code (Branavan et al., 2009). Finally, a considerable effort in this task has focused on semantic parsing (Wong and Mooney, 2006; Jones et al., 2012; Lei et al., 2013; Artzi et al., 2015; Quirk et al., 2015). Recently proposed models focus on Combinatory Categorical Grammars (Kushman and Barzilay, 2013; Artzi et al., 2015), Bayesian Tree Transducers (Jones et al., 2012; Lei et al., 2013) and Probabilistic Context Free Grammars (Andreas et al., 2013). The work in natural language programming (Vadas and Curran, 2005; Manshadi et al., 2013), where users write lines of code from natural language, is also related to our work. Finally, the reverse mapping from code into natural language is explored in (Oda et al., 2015).

Character-based sequence-to-sequence models have previously been used to generate code from natural language in (Mou et al., 2015). Inspired by these works, LPNs provide a richer framework by employing attention models (Bahdanau et al., 2014), pointer networks (Vinyals et al., 2015) and character-based embeddings (Ling et al., 2015). Our formulation can also be seen as a generalization of Allamanis et al. (2016), who implement a special case where two predictors have the same granularity (a sub-token softmax and a pointer network). Finally, HMMs have been employed in neural models to marginalize over label sequences in (Collobert et al., 2011; Lample et al., 2016) by modeling transitions between labels.

9 Conclusion

We introduced a neural network architecture named *Latent Prediction Network*, which allows efficient marginalization over multiple predictors. Under this architecture, we propose a generative model for code generation that combines a character level softmax to generate language-specific tokens and multiple pointer networks to copy keywords from the input. Along with other extensions, namely structured attention and code compression, our model is applied on on both existing datasets and also on a newly created one with implementations of TCG game cards. Our experiments show that our model out-performs multiple benchmarks, which demonstrate the importance of combining different types of predictors.

Easy Things First: Installments Improve Referring Expression Generation for Objects in Photographs

Sina Zarrieß David Schlangen

first.last@uni-bielefeld.de

Abstract

Research on generating referring expressions has so far mostly focussed on "one-shot reference", where the aim is to generate a single, discriminating expression. In interactive settings, however, it is not uncommon for reference to be established in "installments", where referring information is offered piecewise until success has been confirmed. We show that this strategy can also be advantageous in technical systems that only have uncertain access to object attributes and categories. We train a recently introduced model of grounded word meaning on a data set of REs for objects in images and learn to predict semantically appropriate expressions. In a human evaluation, we observe that users are sensitive to inadequate object names - which unfortunately are not unlikely to be generated from low-level visual input. We propose a solution inspired from human task-oriented interaction and implement strategies for avoiding and repairing semantically inaccurate words. We enhance a word-based REG with context-aware, referential installments and find that they substantially improve the referential success of the system.

1 Introduction

A speaker who wants to refer to an object in a visual scene will try to produce a referring expression (RE) that (i) is semantically adequate, i.e. accurately describes the visual properties of the target referent, and (ii) is pragmatically and contextually appropriate, i.e. distinguishes the target from other objects in the scene but does not overload the listener with unnecessary information. Figure 1 illustrates this with two examples from a corpus of REs collected from human subjects for objects in images (Kazemzadeh et al., 2014).

Figure 1: Example images and REs from the ReferIt corpus (Kazemzadeh et al., 2014)

Research on referring expression generation (REG) has mostly focussed on (ii), modeling pragmatic adequacy in attribute selection tasks, using as input a fully specified, symbolic representation of the visual attributes of an object and its distractors in a scene (Dale and Reiter, 1995; Krahmer and Van Deemter, 2012).

In this paper, we follow a more recent trend (Kazemzadeh et al., 2014; Gkatzia et al., 2015) and investigate REG on real-world images. In this setting, a low-level visual representation of an image (a scene) segmented into regions (objects), including the region of the target referent, constitutes the input. This task is closely related to the recently very active field of image-to-text generation, where deep learning approaches have been used to directly map low-level visual input to natural language sentences, e.g. (Vinyals et al., 2015; Chen and Lawrence Zitnick, 2015; Devlin et al., 2015). Similarly, we propose to cast REG on images as a word selection task. Thus, we base this work on a model of perceptually grounded word meaning, which associates words with classifiers that predict their semantic appropriateness given

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 610–620,
Berlin, Germany, August 7-12, 2016.

the low-level visual features of an object (Kennington and Schlangen, 2015). As our first contribution, we train this model on the ReferIt corpus (Kazemzadeh et al., 2014) and define decoding mechanisms tailored to REG.

Large-scale recognition of objects and their attributes in images is still a non-trivial task. Consequently, REG systems now face the challenge of dealing with semantically inadequate expressions. For instance, in Figure 1, the system might not precisely distinguish between *man* or *woman* and generate an inadequate, confusing RE like *man in the middle*. Therefore, we focus on evaluating our system in an object identification task with users, in contrast to previous approaches to REG on images (Mao et al., 2015). In order to assess possible sources of misunderstanding more precisely, our set-up also introduces a restricted form of interaction: instead of measuring "one-shot" performance only, users have three trials for identifying a referent. In this set-up, we find that different parameter settings of the systems (e.g. their visual inputs) have a clear effect on the referential success rates, while automatic evaluation measures reflect the interactive effectiveness rather poorly.

Research on reference in human interaction has noticed that conversation partners try to minimize their joint effort and often prefer to present simple expressions that can be expanded on or repaired, if necessary (Clark and Wilkes-Gibbs, 1986). This strategy, called "referring in installments" is very effective for achieving common ground in task-oriented interaction (Fang et al., 2014) and is attested in dialogue data (Striegnitz et al., 2012). The connection between reference in installments on the one and the status of distractors and distinguishing expressions on the other hand is relatively unexplored, though it seems natural to combine the two perspectives (DeVault et al., 2005). Figure 1 shows an example for very a simple but highly effective expression - it mentions color as a salient and distinguishing property while avoiding a potentially unclear object name.

As our second contribution, we extend our probabilistic word selection model to work in a simple interactive installment component that tries to avoid semantically inadequate words as much as possible and only expands the expression in case of misunderstanding. We present an algorithm that generates these installments depending on the context, based on ideas from traditional REG algorithms like (Dale and Reiter, 1995). We find that a context-aware installment strategy greatly improves referential success as it helps to avoid and repair misunderstandings and offers a combined treatment of semantic and pragmatic adequacy.

2 Background

2.1 Approaches to REG

"One-shot REG" Foundational work in REG has investigated attribute selection algorithms (Dale and Reiter, 1995) that compute a *distinguishing* referring expression for an object in a visual scene, which is defined as a target object r, set of distractor objects $D = \{d_1, d_2, d_3, ...\}$ and a set of attributes $A = \{type, position, size, color, ...\}$. A manually specified database typically associates the target and distractors in D with atomic values for each attribute, cf. (Krahmer and Van Deemter, 2012). In this setting, an attribute $a_1 \in A$ is said to *rule out* a distractor object from D, if the target and distractor have different values. This is mostly based on the assumption that we have objects of particular types (e.g. people, furniture, etc.) and that the system has perfect knowledge about these object types and, consequently, about potential distractors of the target. This does not apply to REG on real-world images which, as we will show in this paper, triggers some new challenges and research questions for this field. Subsequent work has shown that human speakers do not necessarily produce minimally distinguishing expressions (van Deemter et al., 2006; Viethen and Dale, 2008; Koolen et al., 2011), and has tried to account for the wide range of factors - such as different speakers, modalities, object categories - that are related to attribute selection, cf. (Mitchell et al., 2010; Koolen and Krahmer, 2010; Clarke et al., 2013; Tarenskeen et al., 2015).

Task-oriented REG has looked at reference as a collaborative process where a speaker and a listener try to reach a common goal (Clark and Wilkes-Gibbs, 1986; Heeman and Hirst, 1995; DeVault et al., 2005). Given the real-time constraints of situated interaction, a speaker often has to start uttering before she has found the optimal expression, but at the same time, she can tailor, extend, adapt, revise or correct her referring expressions in case the listener signals that he did not understand. Thus, human speakers can flex-

ibly split and adapt their REs over several utterances during an interaction, a phenomenon called "reference in installments". In a corpus analysis of the S-GIVE domain, (Striegnitz et al., 2012) showed that installments are pervasive in human-human interaction in a task-oriented environment. However, while there has been research on goal-oriented and situated REG (Stoia et al., 2006; Kelleher and Kruijff, 2006; Striegnitz et al., 2011; Garoufi and Koller, 2013), installments have been rarely implemented and empirically tested in interactive systems. A noticeable exception is the work by Fang et al. (2014) who use reinforcement learning to induce an installment strategy that is targeted at robots that have uncertain knowledge about the objects in their environment. Using relatively simple computer-generated scenes and a standard representations of objects as sets of attributes, they learn a strategy that first guides the user to objects that the system can recognize with high confidence. Our work is targeted at more complex scenes in real-world images and large domains where no a priori knowledge about object types and their attributes is given. Mao et al. (2015) use a convolutional neural network and an LSTM to generate REs directly and on the same data sets as we do in this paper, but they only report automatic evaluation results.

2.2 The ReferIt corpus

We train and evaluate our system on the ReferIt data set collected by Kazemzadeh et al. (2014). The basis of the corpus is a collection of "20,000 still natural images taken from locations around the world" (Grubinger et al., 2006), which was augmented by Escalante et al. (2010) with segmentation masks identifying objects in the images (an average of 5 objects per image). This dataset also provides manual annotations of region labels and a vector of visual features for each region (e.g. region area, width, height, and color-related features). There are 256 types of objects (i.e. labels), out of which 140 labels are used for more than 50 regions (Escalante et al., 2010). Kazemzadeh et al. (2014) collected a large number of expressions referring to objects (for which segmentations exist) from these images (130k REs for 96k objects), using a game-based crowd-sourcing approach, and they have assembled an annotated test set.

2.3 The WAC model

Given a corpus of REs aligned with objects in images, we can train a model that predicts semantically appropriate words given the visual representation of an image region. We adopt the WAC ("words-as-classifiers") model (Kennington and Schlangen, 2015), which was originally used for reference resolution in situated dialogue. However, WAC is essentially a task-independent approach to predicting semantic appropriateness of words in visual contexts and can be flexibly combined with task-dependent decoding procedures.

The WAC model pairs each word w in its vocabulary V with an individual classifier that maps the low-level, real-valued visual properties of an object o to a semantic appropriateness score. In order to learn the meaning of e.g. the word *red*, the visual properties of all objects described as *red* in a corpus of REs are given as positive instances to a supervised (logistic regression) learner. Negative instances are randomly samples from the complementary set of utterances (e.g. not containing *red*).

We used this relatively simple model in our work, because first of all we wanted to test wether it scales from a controlled domain of typical reference game scenes (Kennington and Schlangen, 2015) to real-world images. Second, as compared to standard object recognisers that predict abstract image labels annotated in e.g. ImageNet (Deng et al., 2009), this model directly captures the relation between actual words used in REs and visual properties of the corresponding referents. Following (Schlangen et al., 2016), we can easily base our classifiers on such a high-performance convolutional neural network (Szegedy et al., 2015), by applying it on our images and extracting the final fully-connected layer before the classification layer (see Section 3.1).

3 Word-based REG for Image Objects

We describe a word selection model for REG on images, which reverses the decoding procedure of our reference resolution model (Kennington and Schlangen, 2015; Schlangen et al., 2016). The main question we pursue here is whether we can predict semantically adequate words for visually represented target objects in real-world images and achieve communicative success in a task-oriented evaluation.

3.1 A Basic Algorithm for REG with WAC

Given a visual representation of an object, we can apply all word classifiers from the vocabulary of our WAC model and obtain an appropriateness ranking over words. As these WAC scores do not reflect appropriateness in the linguistic context, i.e. the previously generated words, we combine them with simple language model (bigram) probabilities (LM) computed on our corpus. The combination of WAC and LM scores is used to rank our vocabulary with respect to appropriateness given the visual features of the target referent and linguistic context.

Algorithm 1 shows our implementation of the decoding step, a beam search that iteratively adds n words with the highest combined LM and WAC score to a its agenda and terminates after a prespecified number of maximum steps.

The algorithm takes the number of iterations as input, so it searches for the optimal RE given a fixed length. Deciding how many words have to be generated is very related to deciding how many attributes to include in more traditional REG. As a first approach, we have trained an additional regression classifier that predicts the length of the RE, given the number of objects in the scene and the visual properties of the target.

Algorithm 1 Baseline REG with WAC

function WORD-GEN($object, maxsteps, V$)
  $Agenda \leftarrow \{`start'\}$
  for $n \in 0..maxsteps$ **do**
    $Beam \leftarrow \emptyset$
    for $re \in Agenda$ **do**
      $w_{-1} \leftarrow$ LAST(re)
      for $w \in$ BIGRAMS(w_{-1}, V) **do**
        $s =$ WAC($w, object$) + LM(w, w_{-1})
        $re_{new} \leftarrow$ APPEND($re, word$)
        $Beam \leftarrow Beam \cup \{(re_{new}, s)\}$
      end for
    end for
    $Agenda \leftarrow$ K-BEST($Beam, k$)
  end for
  return K-BEST($Agenda, 1$)
end function

3.2 Experimental Set-up

Data We use the same test set as Kazemzadeh et al. (2014) that is divided into the 3 subsets, each containing 500 objects: "**Set A** contains objects randomly sampled from the entire dataset, **Set B** was sampled from the most frequently occurring object categories in the dataset, excluding the less interesting categories, **Set C** contains objects sampled from images that contain at least 2 objects of the same category, excluding the less interesting categories."[1] For each object, there are 3 human-generated reference REs. We train the WAC model on the set of images that are not contained in the test set, which amounts to 100384 REs.

The classifiers We use Schlangen et al. (2016)'s WAC model that is a trained on the REFERIT data (Kazemzadeh et al., 2014) based on the SAIAPR collection (Grubinger et al., 2006). We train binary logistic regression classifiers (with $\ell 1$ regularisation) for the 400 most frequent words from the training set.[2] During training, we only consider non-relational expressions, as words from relational expressions would introduce further noise. Each classifier is trained with the same balance of positive and negative examples, a fixed ratio of 1 positive to 7 negative. Additionally, we train a regression classifier that predicts the expected length of the RE given the visual features of the target object and the number of objects in the entire scene. We also train a simple bigram language model on the data.

Feature sets In this experiment, we manipulate the features sets of the underlying word classifiers. We train it on (i) a small set of 27 low-level visual features extracted and provided by Escalante et al. (2010), called SAIAPR features below, and (ii) a larger set of features automatically learned by a state-of-the-art convolutional neural network, "GoogLeNet" (Szegedy et al., 2015). We derive representations of our visual inputs with this CNN, that was trained on data from the ImageNet corpus (Deng et al., 2009), and extract the final fully-connected layer before the classification layer, to give us a 1024 dimensional representation of the region. We augment this with 7 features that encode information about the region relative to the image: the (relative) coordinates of two corners, its (relative) area, distance to the center, and orientation of the image. The full representation hence is a vector of 1031 features. The feature extraction for (ii) is described in more detail in (Schlangen et al., 2016). Generally, the SAIAPR features represent interpretable visual information on position, area, and color of an image region, they could be associated with particular visual attributes. This is not possible with the GoogLeNet features.

[1] Where objects mostly located in the background like 'sky', 'mountain' are considered to be less interesting.

[2] We used `scikit learn` (Pedregosa et al., 2011).

3.3 Automatic Evaluation

To the best of our knowledge, end-to-end REG performance has not been reported on the ReferIt data set before. Table 1 shows corpus-based BLEU and NIST measures calculated on the test set (using 3 references for each RE). The results indicate a minor gain of the GoogLeNet features. We also evaluate a version of the GoogLeNet-based system that instantiates the beam search with the gold length of the RE from the corpus (GoogLeNet$_{glen}$). This leads to a small improvement in BLEU and NIST, indicating that the length prediction is not a critical factor.

	BLEU		NIST	
	1-gram	2-gram	1-gram	2-gram
SAIAPR	0.33	0.19	1.5	1.7
GoogLeNet	0.35	0.21	1.9	2.3
GoogLeNet$_{glen}$	0.38	0.19	2.0	2.6

Table 1: Automatic evaluation for word-based REG systems

3.4 A Game-based Human Evaluation

Set-up In parallel to the reference game in (Kazemzadeh et al., 2014), we set up a game between a computer that generates REs and a human player who clicks on the location of the described object that he identifies based on the RE. After each click, the GUI presents some canned feedback and informs the player whether he clicked on the intended object. In case of an unsuccessful click, the player has two more trials. In the following, we report the success rates with respect to each trial and the different test sets. This set-up will trigger a certain amount of user guesses such that the success rates do not correspond perfectly to semantic accuracies. But it accounts for the increased difficulty as well as the interactive nature of the task. See Section 4.4 for an analysis of learning effects in this set-up and (Gatt et al., 2009; Belz and Hastie, 2014) for general discussion on REG and NLG evaluation.

	Success rate/ trial			Error
	1st	2nd	3rd	red.
SAIAPR	32.2	40.3	46.3	20.8
GoogLeNet	41.6	53.4	59.1	29.9
GoogLeNet$_{glen}$	37.6	51	58.7	33.8
human	90.6	94.6	98.3	81.9

Table 2: Human success and error reduction rates in object identification task, for different sets of visual features

For each player, we randomly sampled the games from the entire test set, but balanced the items so that they were equally distributed across the 3 test subsets A, B, C (see above) and the three systems. We also included human REs from the corpus. In total, we collected 1201 games played by 8 participants.

Results In Table 2, we report the cumulative success rates for the different systems across the different trials, i.e. the success rate in the 3rd trial corresponds to the overall proportion of successfully identified referents. First of all, this suggests that the differences in performance between the systems is much bigger in terms of their communicative effectiveness as in terms of the corpus-based measures (Table 1). Thus, on the one hand, the GoogLeNet features are clearly superior to SAIAPR, whereas differences between GoogLeNet and GoogLeNet$_{glen}$ are minor. Interestingly, the GoogLeNet features improve 1st trial as well as overall success, leading to a much better error reduction rate[3] in object identification between the first and third trial. This means that, here, humans are more likely to recover from misunderstandings and indicates that REs generated by the SAIAPR system are more semantically inadequate.

	Success rate (3rd trial)		
	Set A	Set B	Set C
SAIAPR	35.7	63.8	40.7
GoogLeNet	57	67.7	53.1
GoogLeNet$_{glen}$	50	74	53
human	99.1	99	96.5

Table 3: Human success rates for baseline REG systems trained on different visual feature sets

In Table 3, we report the overall success rates for the different test sets. All systems have a clearly higher performance on the B Set which contains the most frequent object types. Surprisingly, all systems have a largely comparable performance on Set A and C whereas only C contains images with distractors in the sense of traditional REG. This shows that describing objects which belong to an infrequent type in a semantically adequate way, which is necessary in Set A, is equally challenging as reaching pragmatic adequacy which is called for in Set C.

[3] Calculated as $(\#error_{1st} - \#error_{3rd})/\#error_{1st}$

3.5 Error Analysis

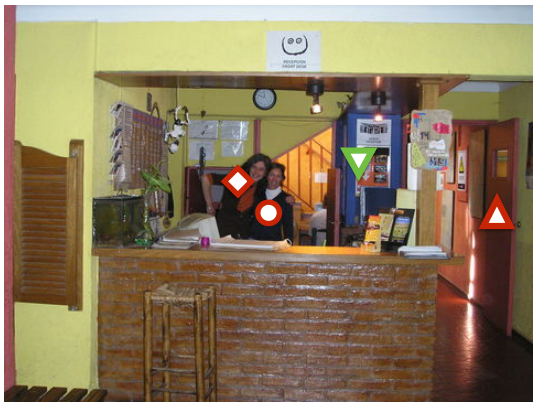
When users click on a distractor object instead of the intended referent in our object identification task, there can be several sources of misunderstanding. For instance, it is possible that the system produced REs that are interpretable but not specific and distinguishing enough to identify the target. It is also possible that the system selected words that are semantically inadequate such that the expression becomes completely misleading. We can get some insight into possible sources of misunderstanding by comparing the the clicked-on distractor objects to their intended target, using the object labels annotated for each image region (see Section 2.2).

The analysis of mismatches between the expected label of the target and the label of the object actually clicked on by the user reveals that many errors are due to semantic inadequacies and apparently severe interpretation failures: Looking at the total number of clicks on distractor objects, 80% are clicks on a distractor with a different label than the target.[4], e.g. the user clicked on a 'tree' instead of a 'man'. This is clear evidence for semantic inadequacies, suggesting that the systems often generate an inadequate noun for the object type. An example for such a label mismatch is shown in Figure 2 where the system generated "person" for referring to a "sign", such that the user first clicked on distractor objects that are persons.

Similarly, we can get some evidence about how users try to repair misunderstandings, by comparing a distractor clicked on in the first trial to another distractor clicked on in the subsequent second, or third trial. Interestingly, we find that users do not seem to be aware of the fact that the system does not always generate the correct noun and do not generally try to click on objects with a different label. Only in 39% of the unsuccessful second trials, users decided for a distractor object with a different label, even though the first click had been unsuccessful. For instance, in Figure 2, the user clicked on the other person in the image in the second trial, although this referent is clearly not on the right. This suggests that users do not easily revise their RE interpretation with respect to the intended type of referent.

Moreover, we can compare the different distractor clicks with respect to their spatial distance

[4]The percentage varies between saiapr (86%), GoogLeNet (71%)



re$_{generated}$: "person on the right"
re$_{human}$: "sign on the blue shelf in the back"

Figure 2: Example for an unsuccessful trial in object identification; first click: ◯, second click: ⋄, third click: △, target: ▽)

to the target. We find that after an unsuccessful first trial, users click on an object that has a greater distance to the target in 70% of the cases (as e.g. in Figure 2). This means that users often try to repair the misunderstanding with respect to the intended location, rather than with respect to the intended object type. Intuitively, this behaviour makes sense: a human speaker is more likely to confuse e.g. *left* and *right* than e.g. *man* and *tree*. From the perspective of the system this is a problematic situation: words like *left* and *right* are much easier to generate (based on simple positional features) than nouns like *man* and *tree*.

4 Towards interactive, contextual REG

In this Section, we extend our word-based REG to deal with semantic inadequacies. We take a first step towards interactive REG and implement installments, a pervasive strategy in human task-oriented interaction. The main idea is that the system should try to avoid semantically inadequate expressions wherever possible and, if misunderstanding occurs, try to react appropriately.

4.1 Procedure

When a speaker or system *refers in installments*, they do not need to generate an RE in one shot, but can start with an initial, simple RE that is extended or reformulated if this becomes necessary in the interaction, i.e. if the listener cannot identify the referent. This setting is a straightforward extension of our game-based evaluation in Section 3.4, where users had 3 trials for identifying a referent: instead of generating a single RE for the target

and presenting it in every trial, we now produce a triple (re_1, re_2, re_3), where re_1 will be used in the first trial, re_2 in the second trial, etc.

In this set-up, we want to investigate whether installments and reformulations help to avoid semantic inadequacies and improve referential success, i.e. whether a dynamic approach to REG compares favourably to the non-dynamic version of our system (see Section 3). This question is, however, closely linked to another, more intricate question: what is the best strategy to realize installments that, on the one hand, provide enough information so that a user can eventually identify the referent and, on the other hand, avoid misleading words? To date, even highly interactive systems do not generally treat installments, or if they do, only realise them via templates, e.g. (Stoia et al., 2006; Staudte et al., 2012; Garoufi and Koller, 2013; Dethlefs and Cuayáhuitl, 2015). As pointed out by Liu et al. (2012), data-driven approaches are not straightforward to set-up, due to the "mismatched perceptual basis" between a human listener and an REG system.

Based on the insights of our error analysis in Section 3.4, we will rely on a general installment strategy that is mostly targeted at avoiding semantically inadequate object names, and emphasizing the fact that location words generated by the system convey more reliable information. We have implemented two versions of this general strategy: (i) pattern-based installments that always avoid object names in their initial expression and dynamically extend this if necessary, (ii) context-dependent installments that condition the initial expression on the complexity of the scene and extend the initial expression accordingly, inspired by standard approaches to attribute selection in REG (Krahmer and Van Deemter, 2012). Thus, we do not test initial or reformulated expressions in isolation, but the strategy as a whole, which is similar to (Fang et al., 2014).

4.2 Pattern-based Installments

This system generates a triple of REs for each image, corresponding to the respective trials in the object identification task. The triple for pattern-based installments is defined as follows:

- re_1: a short RE that only contains location words, e.g. *bottom left*
- re_2: a longer RE that contains location words and an object name, e.g. *the car on the left*
- re_3: a reformulation of re_2 that hedges the object name and suggests an alternative object name, e.g. *vehicle or bottle on the left*

Figure 3(a) illustrates a case where this pattern is useful: the target is a horse, the biggest and most salient object in the image, which can be easily identified with a simple locative expression. As horses are not frequent in the training data, the system unfortunately generates *hat guy* as the most likely object name. This RE would be very misleading indeed if presented to a listener, as one of the distractors actually is a person with a hat.

Generation Procedure In order to generate the above installment triples with our REG system, we simply restrict the vocabulary of the underlying WAC-model. Thus, we divided the 400 word classifiers into the following subsets:

- V_1: 20 location words (manually defined)
- V_2: V_1 + 183 object names (extracted from annotated section of the ReferIt corpus)
- V_3: entire vocabulary

This basic installment-based system does not use V_3 (but see below). For generating the hedge of the object name in the third trial (re_3) we use the top-second and top-third word from the ranking that WAC produces over all object type words given the visual features of the target.

4.3 Context-dependent Installments

Our context-dependent installment strategy determines the initial RE (re_1) based on the surrounding scene and generates subsequent reformulations (re_2,re_3) accordingly.

Initial REs and Distractors As we do not have a symbolic representation of the distractor objects and their properties, we use the word-based REG system to decide whether an RE can be expected to be distinguishing for the target in the scene. This is similar to (Roy, 2002). Algorithm 2 shows the procedure for determining the initial RE (re_1). Same as before, we restrict the vocabulary of the underlying WAC model, e.g. to contain only location words. But now, we apply the word generation function to the target object and to all the other objects in the set of distractors (D). If the algorithm generates an identical chunk for the target and one of its distractors, it continues with a less restricted vocabulary and a longer expression. It terminates when it has found an RE that is optimal only for the target. This algorithm proceeds on the level of

chunks, instead of single words, as e.g. location is often described by several words (e.g. *bottom left*).

Algorithm 2 A Context-aware REG Algorithm

```
1: function INC-GEN(object, maxsteps, D, V)
2:     for n ∈ 2..maxsteps do
3:         V_n ← RESTRICT(V, n)
4:         re ← WORD-GEN(object, V_n)
5:         for d ∈ D do
6:             re_d ← WORD-GEN(d, V_n)
7:             if re_d = re then
8:                 break
9:             end if
10:        end for
11:        return re
12:    end for
13: end function
```

As we found that the linguistic quality degrades for longer REs, we limit the maximal RE length to 6 words. We obtain 3 types of initial REs predicted to be distinguishing for a target by Algorithm 2:

- ref_{loc}: 2 word RE, only location words (V_1), Figure 3(a)
- ref_{object}: 4 word RE, location words and object names (V_2), Figure 3(b)
- ref_{att}: 6 word RE, all attributes from the entire vocabulary (V_3), Figure 3(c)

On our test set, this produces distinguishing REs for all targets, except 4 cases for which we use an initial 6 word RE as well.

Reformulations We have several options for generating the reformulation REs (re_2,re_3) - e.g. hedging the object name, extending the RE with more words, removing potentially misleading words, etc. - which are more or less appropriate, depending on the initial RE predicted by Algorithm 2. Therefore, we implemented the following types of installment triples that dynamically extend or reduce the initial RE:

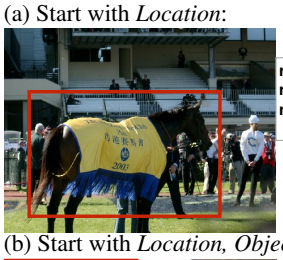
1. (ref_{loc}, ref_{object}, $ref_{object,hedge}$), this corresponds to the pattern in Section 4.2
2. (ref_{object}, $ref_{object,hedge}$,ref_{att})
3. (ref_{att}, $ref_{att,hedge}$,ref_{loc})

Figure 3 shows examples for each triple.

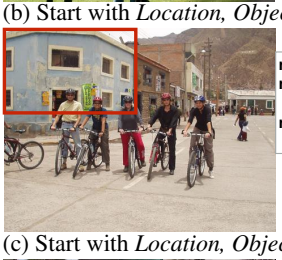
4.4 Human Evaluation

Set-up We use the task-oriented setup from Section 3.4 with 3 trials per image. But instead of presenting the same RE in each trial, the system now updates the phrases according to the RE triples described above. We have recruited 5 players and collected 1200 games, split equally between

(a) Start with *Location*:



(b) Start with *Location, Object Type*:



(c) Start with *Location, Object Type,Other*:

Figure 3: Examples for context-dependent installments

the pattern-based installment (Section 4.2) and the context-dependent installment strategy (Section 4.3). In this evaluation, we only use word classifiers trained on GoogLeNet features.

Results Table 4 shows that even the simple, pattern-based installment system improves the 1st trial success rate compared to the non-interactive baseline (the GoogLeNet-based system from Section 3) and is clearly superior with respect to its overall success and error reduction rate over trials. This suggests that a fair amount of target objects can be identified by users based on very simple, locative REs as semantically inadequate object names are avoided. Another important finding here is the high rate of error reduction during the 2nd and 3rd trial achieved by the installment-based system. In the non-interactive system, users did not have additional cues for repairing their misunderstanding and probably guessed other possible targets in individual, more or less systematic ways. Apparently, even simple strategies for extending and hedging the initially presented RE provide very helpful cues for repairing initial misunderstandings.

As we expected, the pattern-based installment system is clearly improved by our context-dependent approach to generating installments. This systems seems to strike a much better balance between generating simple expressions that avoid

	Success rate/ trial			Error
	1st	2nd	3rd	red.
No install.	41.6	53.4	59.1	29.9
Pattern install.	46.8	69.2	80.9	64.1
Contextual install.	50.5	74.9	86	71.71

Table 4: Human evaluation for installment-based REG systems

inadequate object names on the one and contextually appropriate expressions on the other hand. It improves the pattern-based installments in terms of 1st trial success rate and overall success and error reduction rate.

The finding that installment strategies should be combined with insights from traditional distractor-oriented REG is further corroborated when we compare the success rates on the different subsets of our test set, see Table 5. Thus, the performance of the context-dependent installment system is much more stable on the different subsets than the pattern-based system which has a clear dip in success rate on Set C, which contains target referents with distractors of the same object type. This result suggests that our approach to determine distinguishing REs based purely on predictions of word-based REG (Section 4.3) presents a viable solution for REG on images, where information on distractors is not directly assessable in the low-level representation of the scene.

	Success rate (3rd trial)		
	Set A	Set B	Set C
No install.	57	67.7	53.1
Pattern install.	80.8	84.3	77.5
Contextual install.	86	87.5	84.5

Table 5: Human evaluation on different test sets for installment-based REG systems

Finally, the graph in Figure 4 shows the average success rates over time and provides more evidence for the effectiveness of installments. We observe a clear learning effect in the non-interactive system, meaning that users faced unexpected interpretation problems due to inaccurate expressions, but adapted to the situation to some extent. In contrast, both installment systems have stable performance over time, which indicates that system behaviour is immediately understandable and predictable for human users.

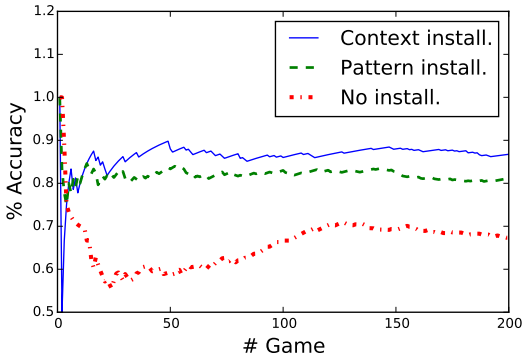


Figure 4: Participants' success rates in object identification over time

5 Discussion and Conclusion

We have presented an REG system that approaches the task as a word selection problem and circumvents manual specification of attributes in symbolic scene representations as required in traditional REG (Krahmer and Van Deemter, 2012), or manual specification of attribute-specific functions that map particular low-level visual features to attributes or words as in (Roy, 2002; Kazemzadeh et al., 2014). This knowledge-lean approach allows us to use automatically learned ConvNet features and obtain a promising baseline that predicts semantically appropriate words based on visual object representations.

We have argued and demonstrated that REG in more realistic settings greatly benefits from a task-oriented, interactive account and should explore principled strategies for repairing and avoiding misunderstandings due to semantically inaccurate REs. In order to achieves this, we have augmented our approach with some manually designed installment strategies. An obvious direction for future work is to automatically induce such a strategy, based on confidence measures that automatically predict the trust-worthiness of a word for an object.

Another extension that we have planned for future work is to implement relational expressions, similar to (Kennington and Schlangen, 2015). Based on relational expressions, we will be able to generate reformulations and installments tailored to the interaction with the user. For instance, a very natural option for installments is to relate the wrong target object clicked on by the user to the intended target, e.g. something like *to the left of that one, the bigger object*.

Abstract

Entity resolution is the task of linking each mention of an entity in text to the corresponding record in a knowledge base (KB). Coherence models for entity resolution encourage all referring expressions in a document to resolve to entities that are related in the KB. We explore attention-like mechanisms for coherence, where the evidence for each candidate is based on a small set of strong relations, rather than relations to all other entities in the document. The rationale is that document-wide support may simply not exist for non-salient entities, or entities not densely connected in the KB. Our proposed system outperforms state-of-the-art systems on the CoNLL 2003, TAC KBP 2010, 2011 and 2012 tasks.

1 Introduction

Entity resolution (ER) is the task of mapping mentions of entities in text to corresponding records in a knowledge base (KB) (Bunescu and Pasca, 2006; Cucerzan, 2007; Kulkarni et al., 2009; Dredze et al., 2010; Hoffart et al., 2011; Hachey et al., 2013). ER is a challenging problem because mentions are often ambiguous on their own, and can only be resolved given appropriate context. For example, the mention `Beirut` may refer to the capital of Lebanon, the band from New Mexico, or a drinking game (Figure 1). Names may also refer to entities that are not in the KB, a problem known as NIL *detection*.

Most ER systems consist of a *mention model*, a *context model*, and a *coherence model* (Milne and Witten, 2008; Cucerzan, 2007; Ratinov et al., 2011; Hoffart et al., 2011; Hachey et al., 2013). The mention model associates each entity with its possible textual representations (also known as aliases or surface forms). The context model helps resolve an ambiguous mention using textual features extracted from the surrounding context. The coherence model, the focus of this work, encourages all mentions to resolve to entities that are related to each other. Relations may be established via the KB, Web links, embeddings, or other resources.

Coherence models often define an objective function that includes local and pairwise candidate scores, where the pairwise scores correspond to some notion of coherence or relation strength.[1] Support for a candidate is typically aggregated over relations to all other entities in the document. One problem with this approach is that it may dilute evidence for entities that are not salient in the document, or not well-connected in the KB. Our work aims to address this issue.

We introduce a novel coherence model with an attention mechanism, where the score for each candidate only depends on a small subset of mentions. Attention has recently been used with considerable empirical success in tasks such as translation (Bahdanau et al., 2014) and image caption generation (Xu et al., 2015). We argue that attention is also desirable for collective ER due to the discussed imbalance in the number of relations for different entities.

Attention models typically have a single focus, implemented using the softmax function. Our model allows each candidate to focus on multiple mentions, and, to implement it, we introduce a novel smooth version of the multi-focus attention

[*] Currently at Tel Aviv University
[†] Currently at IIT Bombay

[1] An exception to this framework are topic models in which a topic may generate both entities and words, e.g., (Kataria et al., 2011; Han and Sun, 2012; Houlsby and Ciaramita, 2014).

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 621–631,
Berlin, Germany, August 7-12, 2016.

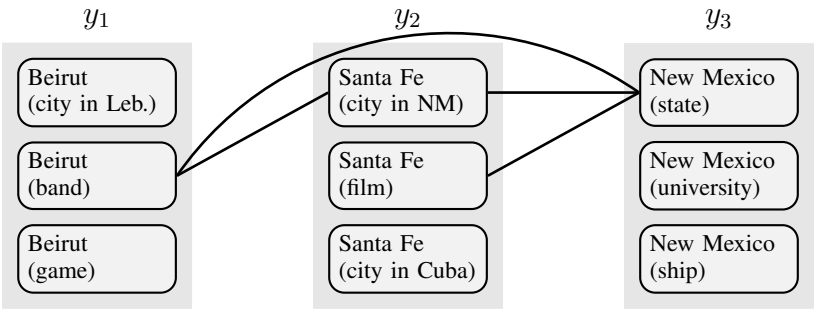

Figure 1: Illustration of the ER problem for three mentions "Beirut", "New Mexico" and "Santa Fe". each mention has three possible disambiguations. Edges link disambiguations that have Wikipedia links between their respective pages.

function, which generalizes soft-max.

Our system uses mention and context models similar to those of Lazic et al. (2015), along with our novel multi-focal attention model to enforce coherence, leading to significant performance improvements on CoNLL 2003 (Hoffart et al., 2011) and TAC KBP 2010–2012 tasks (Ji et al., 2010; Ji et al., 2011; Mayfield et al., 2012). In particular, we achieve a 20% relative reduction in error from Chisholm and Hachey (2015) on CoNLL, and a 22% error reduction from Cucerzan (2012) on TAC 2012. Our contributions thus consist of defining a novel multi-focal attention model and applying it successfully to an entity resolution system.

2 Definitions and notation

We are given a document with n mentions, where each mention i has a set of n_i candidate entities $\mathcal{C}_i = \{c_{i,1}, ..., c_{i,n_i}\}$. The goal is to assign a label $y_i \in \mathcal{C}_i$ to each mention.

Similarly to previous work, our approach to disambiguation relies on local and pairwise candidate scores, which we denote by $s_i(y_i)$ and $s_{ij}(y_i, y_j)$ respectively. The local score is based only on local evidence, such as the mention phrase and textual features, while the pairwise score is based on the relatedness of the two candidates. In Sections 3.2 and 3.3 we discuss how these scores may be parameterized and learned. Many systems (Cucerzan, 2007; Milne and Witten, 2008; Kulkarni et al., 2009) simply hardwire pairwise scores.

Coherence models typically attempt to maximize a *global* objective function that assigns a score to each complete labeling $\mathbf{y} = (y_1, \ldots, y_n)$. An example of such a function is the sum of all singleton and pairwise scores for each label:[2]

$$g(\mathbf{y}) = \sum_i s_i(y_i) + \sum_i \sum_{j:j \neq i} s_{ij}(y_i, y_j). \quad (1)$$

One disadvantage of this approach is that maximizing g corresponds to finding the MAP assignment of a general pairwise Markov random field, and is hence NP hard for the general case (Wainwright and Jordan, 2008). Another limitation is that non-salient entities may be related to very few other entities mentioned in the document, and summing over all mentions may dilute the evidence for such entities. In this paper we explore alternative objectives, relying on attention and tractable inference.

3 Attention model

We now describe our multi-focal attention model. We first introduce the inference approach and optimization objective, and then provide details on how scores are calculated and learned.

3.1 Inference

As noted earlier, the global score function in Eq. (1) is hard to maximize. Here we simplify inference by decomposing the task over mentions, which makes it easy to integrate attention in terms of both inference and learning.

3.1.1 Star model

We start by considering a simple attention-free model in which inference is tractable, which we call a *star model*. For a particular mention i, the star model is a graphical model that contains y_i,

[2] The scores usually depend not only on the labels, but also on the input text. We omit this dependence for brevity.

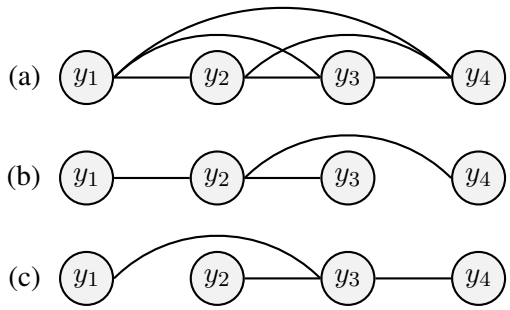

Figure 2: (a) The complete graph corresponding to Eq. (1). (b) A star shaped subgraph corresponding to y_2. This will be used to obtaining the label y_2. (c) The star graph for y_3.

all interactions between y_i and other labels, and no other interactions, as illustrated in Fig. 2.

While the star graph centered at i contains up to n variables, we will only use it to infer the label of mention i. Let $q_{ij}(y_i)$ be the support for label y_i from mention j, defined as follows:

$$q_{ij}(y_i) = \max_{y_j} s_{ij}(y_i, y_j) + s_j(y_j), \qquad (2)$$

and we also define $q_{ii}(y_i) = -\infty$ to simplify notation for later. We define the following score function for mention i:

$$f_i(y_i) = s_i(y_i) + \sum_{j:j\neq i} q_{ij}(y_i) \qquad (3)$$

and predict the label $y_i = \arg\max_y f_i(y)$.

Due to the structure of the star graph, inference is easy and can be done in $O(nC^2)$, where C is the maximum number of candidates. A similar decomposition has previously been used in the context of approximate learning for structured prediction (Sontag et al., 2011). Note that we do not view this approach as an approximation to the global problem, but rather as our inference procedure.

3.1.2 Adding attention

The score function in Eq. (3) aggregates pairwise scores for each label y_i over all mentions. In this section, we restrict this to only consider K mentions with the strongest relations to y_i.[3] Let $\text{amx}_K(\mathbf{z})$ be the sum of the largest K values in the vector $\mathbf{z} = (z_1, \ldots, z_n)$. For each label y_i, we redefine the score function to be

$$f_i(y_i) = s_i(y_i) + \text{amx}_K(\mathbf{q}_i(y_i)), \qquad (4)$$

where $\mathbf{q}_i(y_i) = (q_{i1}(y_i), \ldots, q_{in}(y_i))$ and $q_{ij}(y_i)$ is as defined in Eq. (2). The inference rule is again $y_i = \arg\max_y f_i(y)$, and the computational cost is $O(nC^2 + n \log n)$ since sorting is required.[4]

3.1.3 Soft attention

Previous work on attention has shown that it is advantageous to use a soft form of attention, where the level of attention is not zero or one, but can rather take intermediate values. Existing attention models focus on a single object, such as a single word (Bahdanau et al., 2014) or a single image window (Xu et al., 2015). In such models, it is natural to change the max function in the attention operator to a soft-max. In our case, the attention beam contains K elements, and we require a different notion of a soft-max, which we develop below.

To obtain a soft version of the function $\text{amx}_K(\mathbf{z})$, we first use an alternative definition. Denote by $\mathcal{S}$ the set $\mathbf{u} = (u_1, \ldots, u_n)$ such that $0 \leq u_i \leq 1$ and $\sum_i u_i = K$. Then $\text{amx}_K(\mathbf{z})$ is equivalent to the optimization problem:

$$\max_{\cdot \mathbf{u} \in \mathcal{S}} \mathbf{z} \cdot \mathbf{u} \qquad (5)$$

The optimization problem above is a linear program, whose solution is the sum of top K elements of $\mathbf{z}$ as required. This follows since the optimal u_i can easily be shown to attain only integral values.

Given this optimization view of $\text{amx}_K(\mathbf{z})$ it is natural to smooth it (Nesterov, 2005) by adding a non-linearity to the optimization. Since the variables are non-negative, one possible choice is an entropy-like regularizer. We shall see that this choice results in a closed form solution, and also recovers the standard soft-max case for $K = 1$. Consider the optimization problem:

$$\text{smx}_K(\mathbf{z}) = \max_{\mathbf{u}\in\mathcal{S}} \sum_i z_i u_i - \beta^{-1} \sum_i u_i \log u_i, \qquad (6)$$

where β is a tuned hyperparameter.[5] The following proposition provides a closed form solution for smx_K, as well as its gradient.

Proposition 3.1. *Assume w.l.o.g. that* $\mathbf{z}$ *is sorted such that* $z_1 \geq \ldots \geq z_n$. *Denote by* R *the maximum index* $r \in \{1, \ldots, K-1\}$ *such that:*

$$z_r \geq \beta^{-1} \log \frac{\sum_{j=r+1}^{n} \exp(\beta z_j)}{K - r} \qquad (7)$$

[3] It is possible to relax this to allow *up to* K relations, but we focus on exactly K for simplicity.

[4] Note that if $K < \log n$, we spend only nK instead of $n \log n$ time.

[5] Note that $-\sum_i u_i \log u_i$ is different from the entropy function since variables u_i sum to K and not to 1.

If this doesn't hold for any r, set $R = 0$. Then:

$$smx_K(\mathbf{z}) = \sum_{j=1}^{R} z_j + \frac{K-R}{\beta} \log \frac{\sum_{j=R+1}^{n} \exp(\beta z_j)}{K-R} \tag{8}$$

The function $smx_K(\mathbf{z})$ is differentiable with a gradient $\boldsymbol{v}$ given by:

$$v_i = \left\{ \begin{array}{ll} 1 & 1 \le i \le R \\ (K-R)\frac{\exp(\beta z_i)}{\sum_{j=R+1}^{n} \exp(\beta z_j)} & R < i \le n \end{array} \right\} \tag{9}$$

Proof is provided in the appendix.

As noted, $K = 1$ recovers the standard soft-max function.[6] As $\beta \to \infty$, smx_K will approach the sum of the top K elements as expected. For finite β we have a soft version of amx_K.

Our soft attention based model will therefore consider the soft-variant of Eq. (4):

$$f_i(y_i) = s_i(y_i) + \text{smx}_K(\mathbf{q}_i(y_i)) \,, \tag{10}$$

and maximize $f(y_i)$ to obtain the label.

3.2 Score parameterization

Thus far we assumed the singleton and pairwise scores were given. We next discuss how to parameterize and learn these scores. As in other structured prediction work, we will assume that the scores are functions of the features of the input x and labels. Specifically, denote a set of singleton features for mention i and label y_i by $\boldsymbol{\phi}_i^s(x, y_i) \in \mathbb{R}^{n_s}$ and a set of pairwise features for mentions i and j and their labels by $\boldsymbol{\phi}_{ij}^p(x, y_i, y_j) \in \mathbb{R}^{n_p}$. Then the model has two sets of weights $\boldsymbol{w}_s$ and $\boldsymbol{w}_p$ and the scores are obtained as a linear combination of the features. Namely:[7]

$$\begin{aligned} s_i(y_i; \boldsymbol{w}_s) &= \boldsymbol{w}_s \cdot \boldsymbol{\phi}_i^s(x, y_i) \\ s_{ij}(y_i, y_j; \boldsymbol{w}_p) &= \boldsymbol{w}_p \cdot \boldsymbol{\phi}_{ij}^p(x, y_i, y_j) \,, \end{aligned}$$

where we have explicitly denoted the dependence of the scores on the weight vectors. See Sec. 6.2.2 for details on how the features are chosen. It is of course possible to consider non-linear alternatives for the score function, as in recent deep learning parsing models (Chen and Manning, 2014; Weiss et al., 2015), but we focus on the linear case for simplicity.

3.3 Parameter learning

The parameters $\boldsymbol{w}_s, \boldsymbol{w}_p$ are learned from labeled data, as explained next. Since inference decomposes over mentions, we use a simple hinge loss for each mention. Denote by y_i^* the ground truth label for mention i, and let $\mathbf{s}_i(y_i) \equiv (s_{i1}(y_i), \ldots, s_{in}(y_i))$. Then the hinge loss for mention i is:

$$\begin{aligned} L_i \;=\; & \max_{y_i} [s_i(y_i) + \text{smx}_K(\mathbf{s}_i(y_i)) \\ & - s_i(y_i^*) - \text{smx}_K(\mathbf{s}_i(y_i^*)) + \Delta(y_i, y_i^*)] \end{aligned}$$

where $\Delta(y_i, y_i^*)$ is zero if $y_i = y_i^*$ and one otherwise. If there are unlabeled mentions in the training data, we add those to the star graph, and maximize over the unknown labels in the positive and negative part of the hinge loss. The overall loss is simply the sum of losses for all the mentions, plus ℓ_2 regularization over $\boldsymbol{w}_s, \boldsymbol{w}_p$. We minimize the loss using AdaGrad (Duchi et al., 2011) with learning rate $\eta = 0.1$.

4 Single-link model

To motivate our modeling choices of using multi-focal attention and decomposed inference, we additionally consider a simple baseline model with single-focus attention and global inference. In this approach, which we name *single-link*, each mention i attends to exactly one other mention that maximizes the pairwise relation score. The corresponding objective can be written as

$$g^{SL}(\mathbf{y}) = \sum_i \left(s_i(y_i) + \max_j s_{ij}(y_i, y_j) \right) \tag{11}$$

where $s_{ij}(y_i, y_j) = -\infty$ if there is no relation between y_i and y_j, and we set $s_{ii}(y_i, y_i) = 0$.

While exact inference in this model remains intractable, we can find approximate solutions using max-sum belief propagation (Kschischang et al., 2001). As a reminder, max-sum is an iterative algorithm for MAP inference which can be described in terms of messages sent from model factors $g_a(\mathbf{y}_a)$ to each of their variables $y \in \mathbf{y}_a$. At convergence, each variable is assigned to the value that maximizes *belief* $b(y)$, defined as the sum of incoming messages. The message updates

[6] When we refer to the *soft-max function*, we mean the function $\beta^{-1} \log \sum \exp(\beta a_i)$, which is an often used differentiable convex upper bound of the max function (e.g., see (Gimpel and Smith, 2010)). Soft-max sometimes also refers to the activation function $\frac{\exp(a_i)}{\sum_j \exp(a_j)}$. The latter is in fact the gradient of the former (for $\beta = 1$).

[7] We again omit the dependence of the scores on the input x for brevity.

have the following form:

$$\mu_{g_a \to Y}(y) = \max_{\mathbf{y}_a \backslash y} \left[g_a(\mathbf{y}_a) + \sum_{j \neq i} q_j^{\backslash a}(y_j) \right] \quad (12)$$

where $q_j^{\backslash a}(y_j)$ is the sum of all messages to y_j except the one from factor g_a. While the single-link model contains high-order factors over n variables, computing the messages from these factors is tractable and requires sorting.

5 Related work

Ji (2016) and Ling et al. (2015) provide summaries of recent ER research. Here we review work related to the three main facets of our approach.

5.1 Coherence scores

Several systems (Milne and Witten, 2008; Kulkarni et al., 2009; Hoffart et al., 2011) use the "Milne and Witten" measure for relatedness between a pair of entities, which is based on the number of Wikipedia articles citing each entity page, and the number of articles citing both; Cucerzan (2007) has also relied on the Wikipedia category structure. Internal links from one entity page to another in Wikipedia also provide direct evidence of relatedness between them. Another (possibly more noisy) source of information are Web pages containing links (Singh et al., 2012) to Wikipedia pages of both entities. Such links have been used in several recent systems (Cheng and Roth, 2013; Chisholm and Hachey, 2015). Yamada et al. (2016) train embedding vectors for entities, and use them to define similarities.

5.2 Collective inference for ER

Optimizing most global coherence objectives is intractable. Milne and Witten (2008) and Ferragina and Scaiella (2010) decompose the problem over mentions and select the candidate that maximizes their relatedness score, which includes relations to all other mentions. Hoffart et al. (2011) use an iterative heuristic to remove unpromising mention-entity edges. Cucerzan (2007) creates a relation vector for each candidate, and disambiguates each entity to the candidate whose vector is most similar to the aggregate (which includes both correct and incorrect labels). Cheng and Roth (2013) use an integer linear program solver and Kulkarni et al. (2009) use a convex relaxation. Ratinov et al. (2011) use relation scores as features in a ranking SVM. Belief propagation without attention has been used by Ganea et al. (2015). Personalized PageRank (PPR) (Jeh and Widom, 2003) is another tractable alternative, adopted by several recent systems (Han and Sun, 2011; He et al., 2013; Alhelbawy and Gaizauskas, 2014; Pershina et al., 2015). Laplacian smoothing (Huang et al., 2014) is closely related.

5.3 Attention models

Attention models have shown great promise in several applications, including machine translation (Bahdanau et al., 2014) and image caption generation (Xu et al., 2015). We address a new application of attention, and introduce a significantly different attention mechanism, which allows each variable to focus on *multiple* objects. We develop a novel smooth version of the multi-focus attention function, which generalizes the single focus softmax-function. While some existing entity resolution systems (Jin et al., 2014; Lazic et al., 2015) may be viewed as having attention mechanisms, these are intended for single textual features and not readily extensible to structured inference.

6 Experiments

6.1 Evaluation data

CoNLL: The CoNLL dataset (Hoffart et al., 2011) contains 1393 articles with about 34K mentions, and the standard performance metric is mention-averaged accuracy. The documents are partitioned into train, test-a and test-b. Like most authors, we report performance on the 231 test-b documents with 4483 linkable mentions.

TAC KBP: The TAC KBP 2010, 2011, and 2012 evaluation datasets (Ji et al., 2010; Ji et al., 2011; Mayfield et al., 2012) include 2250, 2250, and 2226 mentions respectively, of which roughly half are linkable to the reference KB. The competition evaluation includes NIL entities; participants are required to cluster NIL mentions across documents so that all mentions of each unknown entity are assigned a unique identifier. For these datasets, we report in-KB accuracy, overall accuracy (with all NILs in one cluster), and the competition metric $B^{3+}F_1$ which evaluates NIL clustering.

6.2 Experimental setup

6.2.1 KB and entity aliases

Our KB is derived from the Wikipedia subset of Freebase (Bollacker et al., 2008), with about 4M

entities. To obtain our mention prior (the probability of candidate entities given a mention), we collect alias counts from Wikipedia page titles (including redirects and disambiguation pages), Freebase aliases, and Wikipedia anchor text. 99.31% of CoNLL test-b mentions are covered by the KB, and 96.19% include the gold entity in the candidates.

We optionally use the mapping from aliases to candidate entities released by Hoffart et al. (2011), obtained by extending the "means" tables of YAGO (Hoffart et al., 2013). When released, it had 100% mention and gold recall on CoNLL, i.e. every annotated mention could be mapped to at least one entity, and the set of entities included the gold entity. However, changes in canonical Wikipedia URLs, accented characters and unicode usually result in mention losses over time, as not all URLs can be mapped to the KB (Hasibi et al., 2016, Sec. 4).

For CoNLL only, we experiment with a third alias-entity mapping derived from Hoffart et al. (2011) by Pershina et al. (2015); we call it "HP". It is not known how candidates were pruned, but it has high recall and very low ambiguity: only 12.6 on CoNLL test-b, compared to 22.34 in our KB and 65.9 in YAGO. Unsurprisingly, using only this source of aliases results in high accuracy on CoNLL (Pershina et al., 2015; Yamada et al., 2016).

Table 1 lists the statistics of the three alias-entity mappings and some of their combinations on the CoNLL test-b dataset. Table 2 provides the same statistics on the TAC KBP datasets (restricted to non-NIL mentions) for the of the YAGO+KB alias-entity mapping.

Alias map	Mention recall	Gold recall	Uniq. %	Avg. ambig.
KB	99.31	96.19	17.93	22.3
YAGO	97.17	96.30	15.50	65.9
+KB	99.84	99.51	16.28	73.6
HP	99.87	99.84	17.98	12.6
+KB	99.87	99.87	16.40	28.7
All	99.87	99.87	15.37	78.7

Table 1: Alias-entity map statistics on CoNLL test-b, 4483 gold mentions. Mention recall is the percentage of mentions with at least one known entity; gold recall is the percentage of mentions where the gold entity was included in the candidates. Unique aliases map to exactly one entity. The last column shows the number of candidates averaged over test-b mentions.

Dataset	Mention recall	Gold recall	Uniq. %	Avg. ambig.
TAC 2010	98.14	93.04	22.45	45.34
TAC 2011	98.40	89.23	27.82	49.13
TAC 2012	97.36	87.83	20.00	68.93

Table 2: YAGO+KB alias-entity map statistics on the TAC KBP datasets, restricted to non-NIL mentions.

6.2.2 Local and pairwise scores

Our baseline system is similar in design and accuracy to Plato (Lazic et al., 2015). Given the referent phrase m_i and textual context features $\mathbf{b}_i$, it computes the probability of a candidate entity as $p_i(c) \propto p(c|m_i)p(\mathbf{b}_i|c)$. The system resolves mentions independently and does not have an explicit coherence model; however, it does capture some coherence information indirectly as referent phrases are included as string context features. We experiment with several versions of the mention prior $p(c|m_i)$ as described in the previous section.

Scores for single-link model: In the single-link model, we simply set the local score for mention i and candidate c to $s_i(c) = \ln \frac{p_i(c)}{1-p_i(c)}$, so that likely candidates get positive scores. We set the pairwise score between two candidates heuristically to $s_{ij}(y_i, y_j) = \ln o(y_i, y_j) + 2.3$, where $o(y_i, y_j)$ is the number of outlinks from the Wikipedia page of y_i to the page of y_j. We consider up to three candidates for each mention for CONLL, and ten for TAC; if the baseline probability of the top candidate exceeds 0.9, we only consider the top candidate. Including more candidates did not make a difference in performance, as additional candidates had low baseline scores and were almost never chosen in practice.

Scores for attention model: Local features $\boldsymbol{\phi}_i^s(x, y_i)$ for the attention model are derived from $p_i(c)$. As the attention models have no probabilistic interpretation, we inject as features $\log p_i(c)$ and $\log(1 - p_i(c))$. We set $\log 0 = 0$ by convention, and handle the case where $\log$ is undefined by introducing two additional binary indicator features for $p_i(c) = 0$ and $p_i(c) = 1$.

Edge features $\boldsymbol{\phi}_{ij}^p$ are set based on three sources of information: (1) number of Freebase relations

between y_i and y_j, (2) number of hyperlinks between Wikipedia pages of y_i and y_j (in either direction), and (3) number of mentions of y_i on the Wikipedia page of y_j and vice versa, after annotating Wikipedia with our baseline resolver. We cap each count to five and encode it using five binary indicator features, where the j^{th} feature is set to 1 if the count is j and 0 otherwise. Additionally, for each count c we add a feature $\log(1+c)$. We also added a binary feature which is one if $y_i = y_j$.

We train the scores for the attention model on the 946 CoNLL train documents for CoNLL, and on the TAC 2009 evaluation and TAC 2010 training documents for TAC.

6.3 Results

CoNLL: Table 3 compares our models to recent competitive systems on CoNLL test-b in terms of mention-averaged (micro) accuracy. We also note the alias-entity map used in each system, as the corresponding gold recall is an upper bound on accuracy, and alias ambiguity determines the difficulty of the task. Therefore performance is not strictly comparable between maps.

Our baseline is slightly better than Lazic et al. (2015), but degrades after adding YAGO aliases which increase ambiguity. The attention model provides a substantial gain over the baseline, and outperforms Chisholm and Hachey (2015) by 2.3% in absolute accuracy.

The extremely low ambiguity (Tab. 1) of the HP alias mapping, coupled with guaranteed gold recall, makes the task too easy to be considered a realistic benchmark. Although we match Pershina et al. (2015) using KB+HP, for completeness, we provide the performance of our system with candidate entities restricted to those in HP (KB+HP*), but this is not equivalent to using only HP during training and inference. With KB+HP*, we outperform Pershina et al. (2015), and are competitive with recent unpublished work by Yamada et al. (2016), which uses entity and word embeddings. Including embeddings as features in our system may lead to further gains.

TAC KBP: Table 4 shows our results for the TAC KBP 2010, 2011, and 2012 evaluation datasets, where we used the KB+YAGO entity-alias map for all our experiments. To compute NIL clusters required for $B^3 + F_1$, we simply rely on the fact that our KB is larger than the TAC reference KB, similarly to previous work. We assign a unique NIL label to all mentions of an entity that is in our KB but not in TAC. For mentions that cannot be linked to our KB, we simply use the mention string as the NIL identifier. Once again, our attention models improve the performance over the baseline system in nearly all experiments, with multi-focus attention outperforming single-link. Compared to prior work, we achieve competitive performance on TAC 2010 and the best results to date on TAC 2011 and TAC 2012.

Table 5 shows two examples from the TAC 2011 dataset in which our multi-focus attention model improves over the baseline, along with the focus mentions in the document.

6.4 Effect of K and β on attention

We set the size of the multi-focus attention beam K based on accuracy on CoNLL test-a (for CoNLL) and training accuracy (for TAC). Fig. 3 shows the effect of K on the performance on CoNLL test-a dataset. Performance peaks for $K = 6$, with a sharp decrease after $K = 10$. This validates our central premise: all-pairs label coupling may hurt accuracy.

In Sec. 3.1.3 we proposed an extension of softmax smoothing to the K attention case. In our

experiments we cross-validated over a wide range of β values, including $\beta = \infty$ which corresponds to taking the exact sum of K largest values. We found that the optimal value in most cases was large: $\beta = 10, 100$, or even ∞. This suggests that a *hard* attention model, where exactly K mentions are picked is adequate in the current settings.

7 Conclusion

We have described an attention-based approach to collective entity resolution, motivated by the observation that a non-salient entity in a long document may only have relations to a small subset of other entities. We explored two approaches to attention: a multi-focus attention model with tractable inference decomposed over mentions, and a single-focus model with global inference implemented using belief propagation. Our empirical results show that the methods results in significant performance gains across several benchmarks.

Experiments in varying the size of the attention beam K in the star-shaped model suggest that multi-focus attention is beneficial. It is of course possible to extend the global single-link model to the multi-focus case, by modifying the model factors and resulting messages. However, the simplicity of the star-shaped model, its empirical effectiveness, and ease of learning parameters make it an attractive approach for easily incorporating attention into existing resolution models. The model can also readily be applied to other structured prediction problems in language processing, such as selecting antecedents in coreference resolution.

Deep learning has recently been used in mutliple NLP applications, including parsing (Chen and Manning, 2014) and translation (Bahdanau et al., 2014). Learning the local and pairwise scores in our model using a deep architecture rather than a linear model would likely lead to performance improvements. The star-shaped model is particularly amenable to this architecture, as it can be implemented via a feed-forward sequence of operations (including sorting, which can be implemented with soft-max gates).

Finally, one may consider a more elaborate model in which attention depends on the current state of the system; for example, the state can summarize the mention context. The dynamics of the underlying state can be modeled by recurrent neural networks or LSTMs (Bahdanau et al., 2014).

In conclusion, we have shown that attention is an effective mechanism for improving entity resolution models, and that it can be implemented via a simple inference mechanism, where model parameters can be easily learned.

8 Proof of Proposition 3.1

Begin with the optimization problem in Eq. (6). Introduce the following Lagrange multipliers: λ for the $\sum_i u_i = K$ constraint, and $\alpha_i \geq 0$ for the $u_i \leq 1$ constraint. We can ignore the $u_i \geq 0$ constraint, as it will turn out to be satisfied. Denote

Sentence with mention	Entity	Attn. focus mentions
Caroline has dropped her name from consideration for the seat that Hillary has left vacant.	base: Caroline (given name) attn: Caroline Kennedy	Democratic Party New York Robert Kennedy
Chris Johnson had just 13 tackles last season, and the Raiders currently have have 11 defensive backs on their roster.	base: Chris Johnson (running back) attn: Chris Johnson (cornerback)	Oakland Raiders Oakland Raiders Oakland Raiders

Table 5: Examples of gains by our algorithm, showing the resolved mention, the entities it resolves to in the baseline and the attention models, and the mentions in the document that are attended to (here $K = 3$). In the first example, the baseline labels the mention "Caroline" as the given name, whereas the attention model attends to mentions that identify it as the diplomat Caroline Kennedy. In the second example, both models resolve "Chris Johnson" to football players, but the attention model finds the correct one by attending to three mentions of his former team, the Oakland Raiders.

the corresponding Lagrangian by $L(\mathbf{u}, \lambda, \alpha)$. We will show the result by using the dual $g(\lambda, \alpha) = \max_{\mathbf{u}} L(\mathbf{u}, \lambda, \alpha)$ and the fact that the solution of Eq. (6) is $\min_{\lambda,\alpha} g(\lambda, \alpha)$.

Maximizing L with respect to u_i yields:

$$u_i = e^{\beta z_i - 1 + \beta\lambda - \beta\alpha_i} \tag{13}$$

From this we can obtain the convex dual $g(\lambda, \alpha)$, and after minimizing over λ we arrive at:

$$g(\alpha) = K\beta^{-1} \log \frac{\sum_i e^{\beta z_i - \beta\alpha_i}}{K} + \sum_i \alpha_i \tag{14}$$

Next, we maximize the above with respect to $\alpha \geq 0$. Introduce Lagrange multipliers γ_i for the constraint $\alpha_i \geq 0$ and the corresponding Lagrangian $\bar{L}(\alpha, \gamma)$. We propose a solution for α, γ and show that it satisfies the KKT conditions. Minimizing $\bar{L}$ wrt α we can characterize the optimal γ as:

$$\gamma_i = -K \frac{e^{\beta z_i - \beta\alpha_i}}{\sum_i e^{\beta z_i - \beta\alpha_i}} + 1 \tag{15}$$

Set α_i as follows:

$$\alpha_i = \begin{cases} z_i - \frac{1}{\beta} \log \frac{\sum_{i=R+1}^{n} e^{\beta z_i}}{K-R} & 1 \leq i \leq R \\ 0 & R < i \leq n \end{cases} \tag{16}$$

It can now be confirmed that the α, γ from Equations 16 and 15 satisfy the KKT conditions. Plugging the α value into $g(\alpha)$ yields the solution in the proposition. Differentiability follows from Nesterov (2005) and the gradient is u_i in Eq. (13).

Which Coreference Evaluation Metric Do You Trust? A Proposal for a Link-based Entity Aware Metric

Nafise Sadat Moosavi and **Michael Strube**

Abstract

Interpretability and discriminative power are the two most basic requirements for an evaluation metric. In this paper, we report the *mention identification effect* in the B^3, *CEAF*, and *BLANC* coreference evaluation metrics that makes it impossible to interpret their results properly. The only metric which is insensitive to this flaw is *MUC*, which, however, is known to be the least discriminative metric. It is a known fact that none of the current metrics are reliable. The common practice for ranking coreference resolvers is to use the average of three different metrics. However, one cannot expect to obtain a reliable score by averaging three unreliable metrics. We propose LEA, a Link-based Entity-Aware evaluation metric that is designed to overcome the shortcomings of the current evaluation metrics. *LEA* is available as branch `LEA-scorer` in the reference implementation of the official CoNLL scorer.

1 Introduction

There exists a variety of models (e.g. pairwise, entity-based, and ranking) and feature sets (e.g. string match, lexical, syntactic, and semantic) to be used in coreference resolution. There is no known formal way to prove which coreference model is superior to the others and which set of features is more beneficial/less useful in coreference resolution. The only way to compare different models, features or implementations of coreference resolvers is to compare the values of the existing coreference resolution evaluation metrics. By comparing the evaluation scores, we determine which system performs best, which model suits coreference resolution better, and which feature set is useful for improving the recall or precision of a coreference resolver. Therefore, evaluation metrics play an important role in the advancement of the underlying technology. It is imperative for the evaluation metrics to be reliable. However, it is not a trivial task to score output entities with various kinds of coreference errors.

Several evaluation metrics have been introduced for coreference resolution (Vilain et al., 1995; Bagga and Baldwin, 1998; Luo, 2005; Recasens and Hovy, 2011; Tuggener, 2014). Metrics that are being used widely are *MUC* (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), *CEAF* (Luo, 2005), and *BLANC* (Recasens and Hovy, 2011). There are known flaws for each of these metrics. Besides, the agreement between all these metrics is relatively low (Holen, 2013), and it is not clear which metric is the most reliable. The CoNLL-2011/2012 shared tasks (Pradhan et al., 2011; Pradhan et al., 2012) ranked participating systems using an *average* of three metrics, i.e. *MUC*, B^3, and *CEAF*, following a proposal by (Denis and Baldridge, 2009a). Averaging three unreliable scores does not result in a reliable one. Besides, when an average score is used for comparisons, it is not possible to analyse recall and precision to determine which output is more precise and which one covers more coreference information. This is indeed a requirement for coreference resolvers to be used in end-tasks. Therefore, averaging individual metrics is nothing but a compromise.

As mentioned by Luo (2005), interpretability and discriminative power are two basic requirements for a reasonable evaluation metric. In regard to the *interpretability* requirement a high score should indicate that the vast majority of coreference relations and entities are detected correctly. Similarly, a system that resolves none of the coreference relations or entities should get a zero score.

Table 1: Counterintuitive values of B^3, CEAF and BLANC recall and precision.

An evaluation metric should also be *discriminative*. It should be able to discriminate between good and bad coreference decisions. In this paper, we report on a drawback for *B^3*, *CEAF*, and *BLANC* which violates the interpretability requirement. We also show that this flaw invalidates the recall/precision analysis of coreference outputs based on these three metrics. We then review the current evaluation metrics with their known flaws to explain why we cannot trust them and need a new reliable one. Finally, we propose *LEA*, a Link-based Entity Aware evaluation metric that is designed to overcome problems of the existing metrics. We have begun the process of integrating the *LEA* metric in the official CoNLL scorer[1] so as to continue the progress made in recent years to produce replicable evaluation metrics. In order to use the *LEA* metric, there is no additional requirement than that of the CoNLL scorer v8.01 [2].

2 The Mention Identification Effect

All the proposed evaluation metrics for coreference resolution use recall, precision and F_1 for reporting the performance of a coreference resolver. Recall is an indicator of the fraction of correct coreference information, i.e. coreference links or entities, that is resolved. Precision is an indicator of the fraction of resolved coreference information that is correct. F_1 is the weighted harmonic mean of recall and precision.

While we usually use F_1 for comparing coreference resolution systems, it is also important for the corresponding recall and precision values to be interpretable and discriminative. Coreference resolution is not an end-task itself but it is an important step toward text understanding. Depending on the task, recall or precision may be more important. For example, as Stuckhardt (2003) argues, a coreference resolver needs high precision to meet the specific requirements of text summarization and question answering.

In this section, we show that the recall and precision of the *B^3*, *CEAF* and *BLANC* metrics are neither interpretable nor reliable. We choose the output of the state-of-the-art coreference resolver of Wiseman et al. (2015) on the CoNLL 2012 English test set as the base output. The CoNLL 2012 English test set contains 222 documents (comprising 348 partially annotated sections). This test set contains 19,764 coreferring mentions that belong to 4,532 different entities.

In Table 1, *Base* represents the scores of (Wiseman et al., 2015) on the CoNLL 2012 test set. All reported scores in this paper are computed by the official CoNLL scorer v8.01 (Pradhan et al., 2014).

Assume $M_{k,r}$ is the set of mentions that exists in both key and response entities. Let $L_k(m)$ and $L_r(m)$ be the set of coreference links of mention m in the key and response entities, respectively. Mention m is an incorrectly resolved mention if $m \in M_{k,r}$ and $L_k(m) \cap L_r(m) = \emptyset$. Therefore, m is a coreferent mention that has at least one coreference link in the response entities. However, none of its detected coreference links in the response entities are correct.

By removing the incorrectly resolved mentions, the response entities will become more precise. The precision improves because the wrong links that are related to the incorrectly resolved mentions have been removed. Besides, the recall will not change because no correct coreference relations or entities have been added or removed.

We make the *Base* output more precise by removing all 1075 incorrectly resolved mentions from the response entities. The score for this more precise output is shown as *More precise* in Table 1. As can be seen, (1) recall changes for all the metrics except for *MUC*; (2) both *$CEAF_e$* recall and precision significantly decrease; and (3) *BLANC* recall notably decreases so that F_1 drops significantly in comparison to *Base*.

On the other hand, adding completely incorrect

[1] Currently available as branch `LEA-scorer` in `https://github.com/conll/reference-coreference-scorers`.

[2] *LEA* scores will be obtained by running the command `perl scorer.pl lea goldFile systemFile`.

entities to the response entities should not affect the recall and it should decrease the precision.

Assume $M_{d,k,\bar{r}}$ is the set of mentions of document d that exists in the key entities but is missing from the response entities. We can add completely incorrect entities to the *Base* output as follows: (1) By linking $m_1 \in M_{d,k,\bar{r}}$ to mention $m_2 \in M_{d,k,\bar{r}}$ that is non-coreferent with m_1. All the new wrong entities are of size two (*Less precise*^{a}). (2) By linking $m_1 \in M_{d,k,\bar{r}}$ to all mentions of $M_{d,k,\bar{r}}$ that are non-coreferent with m_1. In this case the new entities are larger but their number is smaller (*Less precise*^{b}). The number of new entities is 1350 and 283 for the first and second case, respectively. As can be seen from the results of Table 1, (1) recall changes for all metrics except for *MUC*; and (2) the B^3, *CEAF* and *BLANC* scores improve significantly over those of *Base* when the output is doubtlessly worse.

These experiments show that B^3, *CEAF* and *BLANC* are not reliable for recall-precision analysis. We refer to the problem that is causing these contradictory results as the **mention identification effect**.

3 Reasons for the Unreliable Results

In this section, we briefly give an overview of the common evaluation metrics for coreference resolution. We also discuss the shortcomings of each metric, including the **mention identification effect**, that may lead to counterintuitive and unreliable results. In all metrics, K is the key entity set and R is the response entity set.

3.1 MUC

MUC is the earliest systematic coreference evaluation metric and is introduced by Vilain et al. (1995). *MUC* is a link-based metric. It computes recall based on the minimum number of missing links in the response entities in comparison to the key entities. *MUC* recall is defined as:

$$\text{Recall} = \frac{\sum_{k_i \in K}(|k_i| - |p(k_i)|)}{\sum_{k_i \in K}(|k_i| - 1)}$$

where $p(k_i)$ is the set of partitions that is created by intersecting k_i with the corresponding response entities. *MUC* precision is computed by switching the role of the key and response entities.

It is not trivial to determine which evaluation metric discriminates coreference responses best. However, *MUC* is known to be the **least discriminative** coreference resolution metric (Bagga and Baldwin, 1998; Luo, 2005; Recasens and Hovy, 2011). The *MUC* evaluation is only based on the minimum number of missing/extra links in the response compared to the key entities. For instance, *MUC* does not differentiate whether an extra link merges two singletons or the two most prominent entities of the text. However, the latter error does more damage than the first one.

Another major problem with *MUC* is that it has an **incorrect preference in ranking** coreference outputs. *MUC* favors the outputs in which entities are over-merged (Luo, 2005). For instance, if we link all the key mentions of the CoNLL 2012 test set into a single response entity, the corresponding *MUC* scores, i.e. Recall=100, Precision=78.44 and F_1=87.91, will be all higher than those of the state-of-the-art system (*Base* in Table 1).

3.2 BCUBED

The B^3 score is introduced by Bagga and Baldwin (1998). B^3 is a mention-based metric, i.e., the overall recall/precision is computed based on the recall/precision of the individual mentions. For each mention m in the key entities, B^3 recall considers the fraction of the correct mentions that are included in the response entity of m. B^3 recall is computed as follows:

$$\text{Recall} = \frac{\sum_{k_i \in K} \sum_{r_j \in R} \frac{|k_i \cap r_j|^2}{|k_i|}}{\sum_{k_i \in K} |k_i|}$$

Similar to MUC, B^3 precision is computed by switching the role of the key and response entities.

The **mention identification effect** arises in B^3, because B^3 uses mentions instead of coreference relations to evaluate the response entities. Therefore, if a mention exists in a response entity, it is considered as a resolved mention regardless of whether it has a correct coreference relation in the response entity.

Luo (2005) argues that B^3 leads to **counter-intuitive results for boundary cases**: (1) consider a system that makes no decision and leaves every key mention as a singleton. B^3 precision for this system is 100%. However, not all of the recognized system entities (i.e. singletons), or the detected coreference relations (i.e. every mention only coreferent with itself) are correct; (2) consider a system that merges all key mentions into a single entity. B^3 recall for this system is 100%.

Luo (2005) interprets this recall as counterintuitive because the key entities have not been found in the response. The intuitiveness or counterintuitiveness of this recall value depends on the evaluator's point of view. From one point of view, all of the key mentions, that are supposed to be in the same entity, are indeed in the same entity.

Finally, as discussed by Luo and Pradhan (2016), B^3 cannot properly handle **repeated mentions in the response entities**. If a gold mention is repeated in several response entities, B^3 receives credit for all the repetitions. The repeated response mentions issue is not an imaginary problem (Luo and Pradhan, 2016). It can happen if system mentions are read from a parse tree where an NP node has a single child, a pronoun, and where both the nodes are considered as candidate mentions.

3.3 CEAF

The *CEAF* metric is introduced by Luo (2005). *CEAF*'s main assumption is that each key entity should only be mapped to one reference entity, and vice versa. *CEAF* uses a similarity measure (ϕ) to evaluate the similarity of two entities. It uses the Kuhn-Munkres algorithm to find the best one-to-one mapping of the key to the response entities (g^*) using the given similarity measure. Assuming K^* is the set of key entities that is included in the optimal mapping, recall is computed as:

$$\text{Recall} = \frac{\sum_{k_i \in K^*} \phi(k_i, g^*(k_i))}{\sum_{k_i \in K} \phi(k_i, k_i)} \qquad (1)$$

For computing *CEAF* precision, the denominator of Equation 1 is changed to $\sum_{R_i \in R} \phi(r_i, r_i)$. Based on ϕ, there are two variants of CEAF: (1) mention-based *CEAF* (*CEAF*$_m$), which computes the similarity as the number of common mentions between two entities, i.e. $\phi(k_i, r_j) = |k_i \cap r_j|$; and (2) entity-based *CEAF* (*CEAF*$_e$), in which $\phi(k_i, r_j) = \frac{2 \times |k_i \cap r_j|}{|k_i| + |r_j|}$. The denominator of Equation 1 for *CEAF*$_e$ is the number of key entities.

Similar to B^3, the **mention identification effect** of *CEAF* is caused by both similarity measures of *CEAF* using the number of common mentions between two entities, i.e. $|k_i \cap r_j|$. In this way, even if the two mapped entities (k_i and r_j) have only one mention in common, *CEAF*$_m$ rewards recall and precision by $\frac{1}{\sum_{k_i} |k_i|}$ and $\frac{1}{\sum_{r_j} |r_j|}$, respectively. *CEAF*$_e$ rewards recall and precision by $\frac{2}{(|k_i| + |r_j|) \times |K|}$ and $\frac{2}{(|k_i| + |r_j|) \times |R|}$, respectively. If instead of the number of common mentions, we would use the number of common coreference links between two entities in both *CEAF*$_m$ and *CEAF*$_e$ similarity measures, this problem would be solved. However, even if we handle the mention identification effect by using coreference relations rather than mentions in the similarity measures, *CEAF* may still result in counterintuitive results. As mentioned by Denis and Baldridge (2009b), *CEAF* **ignores all correct decisions of unaligned response entities** that may lead to unreliable results. In order to illustrate this, we use a sample text from the CoNLL 2012 development set as an example (Figure 1). Gold mentions are enclosed in square brackets. Mentions with the same text are marked with different indices. The indices in parentheses denote to which key entity the mentions belong Consider cr_1 and cr_2 in Table 2, which are different responses for entity (1) of Figure 1. cr_1 resolves many coreference relations of entity (1). However, it misses that *they*$_1$ could refer to an entity which is already referred to by 'it'. Therefore cr_1 produces two entities instead of one because of this missing relation. On the other hand, cr_2 only recognizes half of the correct coreference relations of entity (1).

As can be seen from Table 3, CEAF prefers cr_2 over cr_1 even though cr_1 makes more correct decisions. CEAF only selects one of the output entities of cr_1 for giving credit to the correct decisions.

[The American administration]$_{(1)}$ committed a fatal mistake when [it$_1$]$_{(1)}$ [executed]$_{(2)}$ [this man]$_{(3)}$, in a way for which [it$_2$]$_{(1)}$ will pay a hefty price in the near future. [[His$_1$]$_{(3)}$ survival]$_{(4)}$ would have benefited [it$_3$]$_{(1)}$ much more than [[his$_2$]$_{(3)}$ execution]$_{(2)}$ if [they$_1$]$_{(1)}$ understood politics as [they$_2$]$_{(1)}$ should, because [[his$_3$]$_{(3)}$ survival]$_{(4)}$ could have been a card to threaten [the sectarians]$_{(5)}$ and keep [them$_1$]$_{(5)}$ as servants to [them$_1$]$_{(1)}$ and [their]$_{(1)}$ schemes.

Figure 1: Sample text from CoNLL 2012.

	Response entities
cr_1	r_1={the American administration, it$_1$, it$_2$, it$_3$} , r_2={they$_1$, they$_2$, them, their}
cr_2	r_1={the American administration, it$_1$, it$_2$, it$_3$}

Table 2: Different system outputs for Figure 1.

	MUC	B^3	CEAF$_m$	CEAF$_e$	BLANC
cr_1	92.30	66.66	50.00	44.44	60.00
cr_2	60.00	40.00	66.66	66.66	32.29

Table 3: F_1 scores for Table 2's response entities.

The other response entity is only used for penalizing the precision of cr_1. This counterintuitive result is only because of the stringent constraint of CEAF that the mapping of key to response entities should be one-to-one.

Another problem with *CEAF*$_e$, mentioned by Stoyanov et al. (2009), is that it **weights entities equally regardless of their sizes**. The system that does not detect entity (1), the most prominent entity of Figure 1, gets the same score as that of a system which does not detect entity (4) of size 2.

3.4 BLANC

BLANC (Recasens and Hovy, 2011; Luo et al., 2014) is a link-based metric that adapts the Rand index (Rand, 1971) to coreference resolution evaluation. Let C_k and C_r be the sets of coreference links in the key and response entities, respectively. Assume N_k and N_r are the sets of non-coreference links in the key and response entities, respectively. Recall and precision of coreference links are computed as:

$$R_c = \frac{|C_k \cap C_r|}{|C_k|}, \quad P_c = \frac{|C_k \cap C_r|}{|C_r|}$$

Recall and precision of non-coreference links are computed as:

$$R_n = \frac{|N_k \cap N_r|}{|N_k|}, \quad P_n = \frac{|N_k \cap N_r|}{|N_r|}$$

BLANC recall and precision are computed by averaging the recall and precision of coreference and non-coreference links, e.g. Recall$= \frac{R_c+R_n}{2}$.

The *BLANC* measure is the newest but the least popular metric for evaluating coreference resolvers. Because of considering non-coreferent relations, the **mention identification effect** affects *BLANC* most strongly. When the number of gold mentions that exist in the response entities is larger, the number of detected non-coreference links will also get larger. Therefore, it results in higher values for *BLANC* recall and precision ignoring whether those gold mentions are resolved.

4 LEA

In this section, we present our new evaluation metric, namely the Link-Based Entity-Aware metric (*LEA*). *LEA* is designed to overcome the shortcomings of the current evaluation metrics.

For each entity, *LEA* considers how important the entity is and how well it is resolved. Therefore, *LEA* evaluates a set of entities as follows:

$$\frac{\sum_{e_i \in E}(importance(e_i) \times resolution\text{-}score(e_i))}{\sum_{e_k \in E} importance(e_k)}$$

We consider the size of an entity as a measure of importance, i.e. $importance(e) = |e|$. Therefore, the more prominent entities of the text get higher importance values. However, according to the end-task or domain used, one can choose other importance measures based on factors besides e_i's size, e.g. e_i's entity type or e_i's mention types. For example, as suggested by Holen (2013), each mention carries different information values, and considering this information could benefit the quantitative evaluation of coreference resolution. The $importance$ measure of *LEA* is the appropriate place to incorporate this kind of information.

Entity e with n mentions has $link(e) = n \times (n-1)/2$ unique coreference links. The resolution score of key entity k_i is computed as the fraction of correctly resolved coreference links of k_i:

$$resolution\text{-}score(k_i) = \sum_{r_j \in R} \frac{link(k_i \cap r_j)}{link(k_i)}$$

For each k_i, *LEA* checks all the response entities to see whether they are partial matches for k_i. r_j is a partial match for k_i, if it contains at least one of the coreference links of k_i. Thus, if a response entity only contains one mention of k_i, it is not a partial mapping of k_i.

Having the definitions of $importance$ and $resolution\text{-}score$, *LEA* recall is computed as:

$$\text{Recall} = \frac{\sum_{k_i \in K}(|k_i| \times \sum_{r_j \in R} \frac{link(k_i \cap r_j)}{link(k_i)})}{\sum_{k_z \in K} |k_z|}$$

LEA precision is computed by switching the role of the key and response entities:

$$\text{Precision} = \frac{\sum_{r_i \in R}(|r_i| \times \sum_{k_j \in K} \frac{link(r_i \cap k_j)}{link(r_i)})}{\sum_{r_z \in R} |r_z|}$$

LEA handles singletons by self-links. A self-link is a link connecting a mention to itself. Self-links indicate that a mention is only coreferent with itself and not with other mentions. By considering self-links, the number of links in a singleton is one. If entity k_i is a singleton, $link(k_i \cap r_j)$ is one only if r_j is a singleton and contains the same mention as k_i.

In summary, *LEA* is a link-based metric with the following properties:

– *LEA* takes into account all coreference links instead of only extra/missing links. Therefore, it has more discriminative power than MUC.
– *LEA* evaluates resolved coreference relations instead of resolved mentions. *LEA* also does not rely on non-coreferent links in order to detect entity structures or singletons. Therefore, the **mention identification effect** does not apply to *LEA* recall and precision. As a result, one can trust *LEA* recall or precision.
– *LEA* allows one-to-many mappings of entities. Unlike *CEAF*, all correct coreference relations are rewarded by *LEA*. More splits (or similarly merges) in entity k_i result in a smaller $\sum_{r_j \in R} link(k_i \cap r_j)$. Therefore, splitting (merging) of an entity in several entities will be penalized implicitly in $resolution\text{-}score$.
– *LEA* takes the importance of missing/extra entities into account. Therefore, unlike $CEAF_e$, it differentiates between the outputs missing the most prominent and the smallest entities.
– *LEA* considers resolved coreference relations instead of resolved mentions. Therefore, the existence of repeated mentions in different response entities is not troublesome for *LEA*.

5 An Illustrative Example

In this section, we use the example from Pradhan et al. (2014) to show the process of computing the LEA scores. In this example, $K = \{k_1 = \{a, b, c\}, k_2 = \{d, e, f, g\}\}$ is the set of key entities and $R = \{r_1 = \{a, b\}, r_2 = \{c, d\}, r_3 = \{f, g, h, i\}\}$ is the set of response entities.

Here we assume that $importance$ corresponds to entity size. Hence, $importance(k_1) = 3$ and $importance(k_2) = 4$. The sets of coreference links in k_1 and k_2 are $\{ab, ac, bc\}$ and $\{de, df, dg, ef, eg, fg\}$, respectively. Therefore, $link(k_1) = 3$ and $link(k_2) = 6$. ab is the only common link between k_1 and r_1. There are no common links between k_1 and the two other response entities. Similarly, k_2 has one common link with r_3 and it has no common links with r_1 or r_2. Therefore, $resolution\text{-}score(k_1) = \frac{1+0+0}{3}$ and $resolution\text{-}score(k_2) = \frac{0+0+1}{6}$. As a result *LEA* recall is computed as:

$$\frac{\sum importance(k_i) \times resolution\text{-}score(k_i)}{\sum importance(k_j)} = \frac{3 \times \frac{1}{3} + 4 \times \frac{1}{6}}{3+4} \approx 0.24$$

By changing the roles of key and response entities, *LEA* precision is computed as:

$$\frac{2 \times \frac{1+0}{1} + 2 \times \frac{0+0}{1} + 4 \times \frac{0+1}{6}}{2+2+4} \approx 0.33$$

6 Evaluation on Real Data

Table 4 shows the scores of the state-of-the-art coreference resolvers developed by Wiseman et al. (2015), Martschat and Strube (2015), and Peng et al. (2015). Clark and Manning (2015)'s resolver is also among the state-of-the-art systems but we did not have access to their output. Considering the average score of *MUC*, B^3, and $CEAF_e$, *Martschat*, and *Peng* perform equally. However, according to *LEA*, *Martschat* performs significantly better based on an approximate randomization test (Noreen, 1989). $CEAF_e$ also agrees with *LEA* for this ranking. However, $CEAF_e$ recall and precision are similar for *Peng* while based on *LEA*, *Peng*'s precision is marginally better than recall.

In addition to the state-of-the-art systems, we report the scores of boundary cases in the CoNLL 2012 test set in Table 4: (1) *sys-sing*: all system mentions as singletons; and (2) *sys-1ent*: all system mentions in a single entity.

Table 5 presents the evaluations of the participating systems in the CoNLL 2012 shared task (closed task with predicted mentions). The rankings are specified in parentheses. For the *LEA* rankings we also perform a significance test. The systems without significant differences have the same ranking. The main difference between the rankings of *avg.* and *LEA* is the rank of *xu*. Based on *LEA*, *xu* is significantly better than *chen* and *chunyuang*, while *avg.* ranks these two above *xu*. The recall values of *chen* and *chunyuang* for mention identification are 75.08 and 75.23, which are higher than those of the best performing systems, i.e 72.75 for *fernandes*, and 74.23 for *martschat*. *chen* and *chunyuang* include 1850 and 1735 gold mentions in their outputs that have not a single correct coreference link. On the other hand, the number of these gold mentions in *xu* is 757. Therefore, these different rankings could be a direct result of the **mention identification effect**.

Overall, using one reliable metric instead of an average score benefits us in two additional ways: (1) we can perform a significance test to check whether there is a meaningful difference, and (2) the recall and precision values are meaningful.

	MUC			B^3			$CEAF_e$			CoNLL	LEA

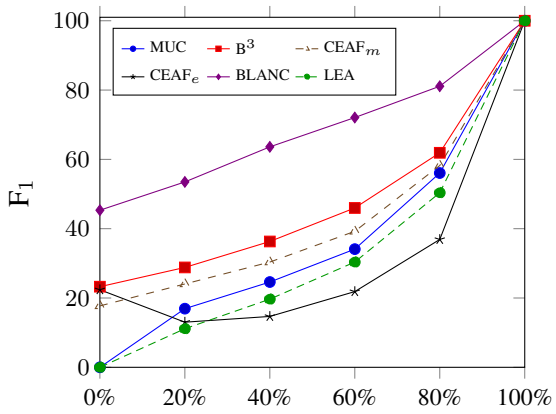

Figure 3: Resolved coreference links ratio in the presence of incorrect links.

7 Analysis

In this section we analyze the behavior of the evaluation metrics based on various coreference resolution errors. The set of key entities in all experiments contains: one entity of size 20, two entities of size 10, three entities of size 5, one entity of size 4, and ten entities of size 2.

7.1 Correct Links

We analyze different metrics based on the ratio of correctly resolved coreference links: (1) without wrong coreference links (Figure 2), and (2) with wrong coreference links (Figure 3). In the experiments of Figure 2, only mentions that are correctly resolved exist in the response. In Figure 3, apart from the mentions that are resolved correctly, other mentions are linked to at least one non-coreferent mention. Therefore, mention detection F_1 is always 100%.

The following observations can be drawn from these experiments: (1) *MUC* and *LEA* are the only measures which give a zero score to the response that contains no correct coreference relations; (2) in our experiments, $CEAF_e$ shows an unreasonable drop when the correct link ratio changes from 0% to 20%; and (3), in Figure 2, the *BLANC*

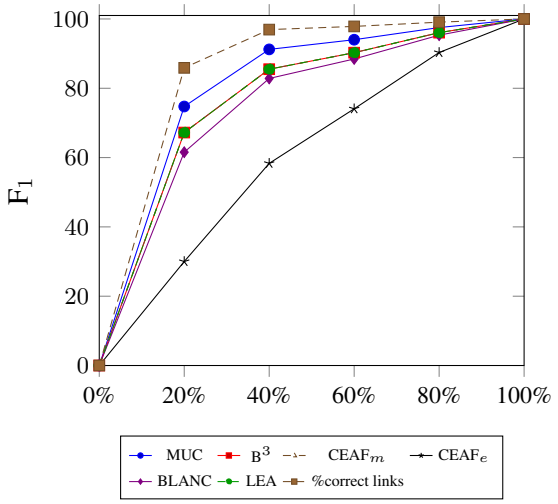

Figure 4: Resolving entities in decreasing order. F_1 of B^3, CEAF, and LEA are the same.

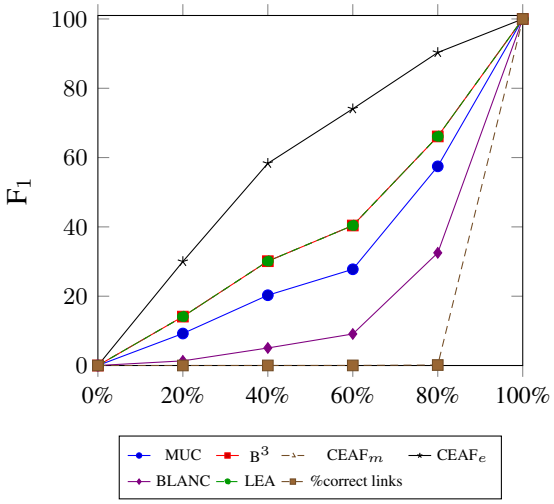

Figure 5: Resolving entities in increasing order. F_1 of B^3, CEAF, and LEA are the same.

F_1 values are less than or equal to those of B^3 and *LEA*. However, in Figure 3 that contains both coreferent and non-coreferent links, *BLANC* F_1 is at least 20% higher than that of other metrics.

7.2 Correct Entities

Apart from the correctly resolved links, a coreference metric should also take into account the resolved entities. In this section, we analyze the coreference resolution metrics based on the number and the size of the correctly resolved entities. In these experiments, each entity is either resolved completely, or all of its mentions are absent from the response. In Figure 4, the key entities are added to the response in decreasing order of their size. Figure 5 shows the experiments in which the entities are resolved in increasing order. The ratio of the correctly resolved coreference links is shown in both figures.

We can observe the following points from Figure 4 and Figure 5: (1) $CEAF_e$ results in the same F_1 values regardless of the size of entities that are resolved or are missing; (2) B^3, $CEAF_m$ and *LEA* result in the same F_1 values; and (3) *BLANC* is very sensitive to the total number of links.

7.3 Splitting/Merging Entities

The effect of splitting a single entity into two or more entities is studied in Figure 6. The overall effect of merging entities would be similar to that of splitting if the roles of the key and response entities change. In each experiment, only one key entity is split in a way that no singletons are created. For example, 18-2 in the horizontal axis indicates

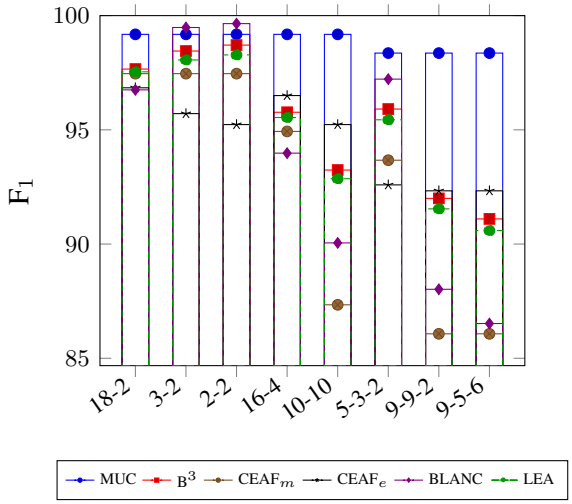

Figure 6: Effect of splitting entities.

that an entity of size 20 is split into two entities of size 18 and 2.

The following observations can be drawn from Figure 6: (1) *MUC* only recognizes the number of splits regardless of the size of entities; (2) $CEAF_e$ does not differentiate 2-2 from 10-10, and 9-9-2 from 9-5-6; and (3) the highest disagreement is for ranking different numbers of splits in entities with different sizes, i.e., B^3: 18-2>5-3-2>16-4, *BLANC*: 5-3-2>18-2>16-4, *CEAF*: 18-2>16-4>5-3-2, and *LEA*: 18-2>16-4>5-3-2. These are the cases that are even for humans hard to rank.

7.4 Extra/Missing Mentions

Figure 7 shows the effect of extra mentions, i.e. mentions that are not included in any key entity. If we change the roles of the key and response enti-

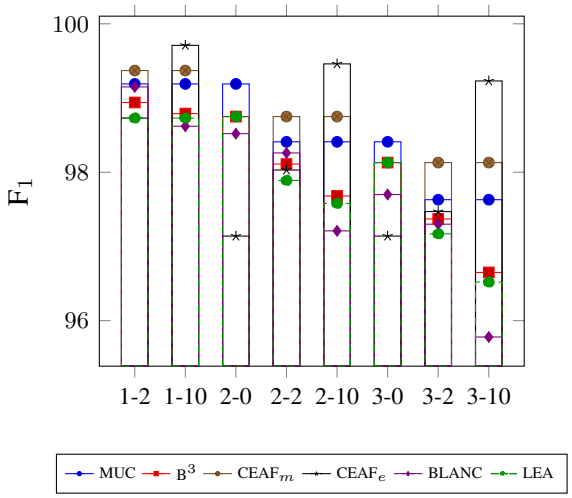

Figure 7: Effect of extra mentions.

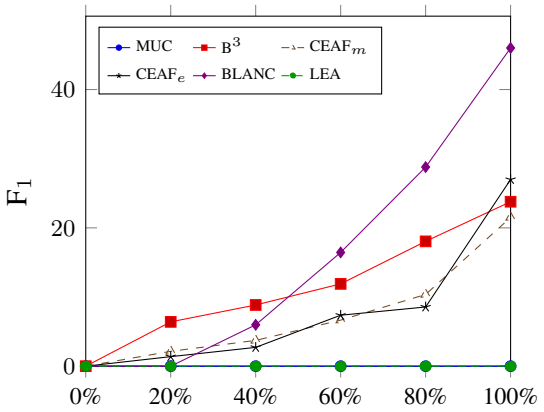

Figure 8: Effect of mention identification.

ties, the overall effect of missing mentions would be similar. In the horizontal axis, the first number shows the number of extra mentions. The second number shows the size of the entity to which extra mentions are added. A zero entity size indicates the extra mentions are linked together.

The following points are worth noting from the results of Figure 7: (1) *MUC* and $CEAF_m$ are the least discriminative metrics when the system output includes extra mentions; (2) except for $CEAF_e$, other metrics rank 3-10 as the worst output;(3) $CEAF_e$ recognizes both 2-0 and 3-0 as the worst outputs. However, in these outputs the extra mentions are linked together and therefore no incorrect information is added to the correctly resolved entities; and (4) *LEA* is the only metric that recognizes error 2-0 is less harmful than 1-2 or 1-10. However, *LEA* does not discriminate the different outputs in which only one extra mention is added to an entity. If k extra mentions are added to an entity of size n, the corresponding resolution error multiplied by the importance of the response entity is $(n+k) \times (1 - \frac{n \times (n-1)}{(n+k) \times (n+k-1)})$. If $k = 1$, this equation is 2 regardless of n's value.

7.5 Mention Identification

The **mention identification effect** is shown in Figure 8. In all experiments, the number of correct coreference links is *zero*. The horizontal axis shows the mention identification accuracy in the system output. The F_1 of B^3, *CEAF* and *BLANC* in these experiments clearly contrast the interpretability requirement. A coreference resolver with a non-zero score should have resolved some of the coreference relations.

8 Conclusions

Current coreference resolution evaluation metrics have flaws which make them unreliable for comparing coreference resolvers. There is also a low agreement between the rankings of different metrics. The current solution is to use an average value of different metrics for comparisons. Averaging unreliable scores does not result in a reliable one. Indeed, recall and precision comparisons of coreference resolvers are not possible based on an average score. We first report the **mention identification effect** on B^3, *CEAF* and *BLANC* which causes these metrics to report misleading values. The only metric that is resistant to the mention identification effect is the least discriminative one, i.e. *MUC*. We introduce *LEA*, the Link-based Entity-Aware metric, as a new evaluation metric for coreference resolution. *LEA* is a simple intuitive metric that overcomes the drawbacks of the current metrics. It can be easily adapted for entity evaluation in different domains or applications in which entities with various attributes are of different importance.

Acknowledgments

The authors would like to thank Sameer Pradhan, Mark-Christoph Müller, Mohsen Mesgar and Sebastian Martschat for their helpful comments. We would also like to thank Sam Wiseman and Haoruo Peng for providing us with their coreference system outputs. This work has been funded by the Klaus Tschira Foundation, Heidelberg, Germany. The first author has been supported by a Heidelberg Institute for Theoretical Studies PhD. scholarship.

Abstract

A long-standing challenge in coreference resolution has been the incorporation of entity-level information – features defined over clusters of mentions instead of mention pairs. We present a neural network based coreference system that produces high-dimensional vector representations for pairs of coreference clusters. Using these representations, our system learns when combining clusters is desirable. We train the system with a learning-to-search algorithm that teaches it which local decisions (cluster merges) will lead to a high-scoring final coreference partition. The system substantially outperforms the current state-of-the-art on the English and Chinese portions of the CoNLL 2012 Shared Task dataset despite using few hand-engineered features.

1 Introduction

Coreference resolution, the task of identifying which mentions in a text refer to the same real-world entity, is fundamentally a clustering problem. However, many recent state-of-the-art coreference systems operate solely by linking pairs of mentions together (Durrett and Klein, 2013; Martschat and Strube, 2015; Wiseman et al., 2015).

An alternative approach is to use agglomerative clustering, treating each mention as a singleton cluster at the outset and then repeatedly merging clusters of mentions deemed to be referring to the same entity. Such systems can take advantage of entity-level information, i.e., features between clusters of mentions instead of between just two mentions. As an example for why this is useful, it is clear that the clusters {*Bill Clinton*} and {*Clinton*, *she*} are not referring to the same entity, but it is ambiguous whether the pair of mentions *Bill Clinton* and *Clinton* are coreferent.

Previous work has incorporated entity-level information through features that capture hard constraints like having gender or number agreement between clusters (Raghunathan et al., 2010; Durrett et al., 2013). In this work, we instead train a deep neural network to build distributed representations of pairs of coreference clusters. This captures entity-level information with a large number of learned, continuous features instead of a small number of hand-crafted categorical ones.

Using the cluster-pair representations, our network learns when combining two coreference clusters is desirable. At test time it builds up coreference clusters incrementally, starting with each mention in its own cluster and then merging a pair of clusters each step. It makes these decisions with a novel easy-first cluster-ranking procedure that combines the strengths of cluster-ranking (Rahman and Ng, 2011) and easy-first (Stoyanov and Eisner, 2012) coreference algorithms.

Training incremental coreference systems is challenging because the coreference decisions facing a model depend on previous decisions it has already made. We address this by using a learning-to-search algorithm inspired by SEARN (Daumé III et al., 2009) to train our neural network. This approach allows the model to learn which action (a cluster merge) available from the current state (a partially completed coreference clustering) will eventually lead to a high-scoring coreference partition.

Our system uses little manual feature engineering, which means it is easily extended to multiple languages. We evaluate our system on the English and Chinese portions of the CoNLL 2012 Shared Task dataset. The cluster-ranking model significantly outperforms a mention-ranking model that

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 643–653,
Berlin, Germany, August 7-12, 2016.

does not use entity-level information. We also show that using an easy-first strategy improves the performance of the cluster-ranking model. Our final system achieves CoNLL F_1 scores of 65.29 for English and 63.66 for Chinese, substantially outperforming other state-of-the-art systems.[1]

2 System Architecture

Our cluster-ranking model is a single neural network that learns which coreference cluster merges are desirable. However, it is helpful to think of the network as being composed of distinct subnetworks. The *mention-pair encoder* produces distributed representations for pairs of mentions by passing relevant features through a feedforward neural network. The *cluster-pair encoder* produces distributed representations for pairs of clusters by applying a pooling operation over the representations of relevant mention pairs, i.e., pairs where one mention is in each cluster. The *cluster-ranking model* then scores pairs of clusters by passing their representations through a single neural network layer.

We also train a *mention-ranking model* that scores pairs of mentions by passing their representations through a single neural network layer. Its parameters are used to initialize the cluster-ranking model, and the scores it produces are used to prune which candidate cluster merges the cluster-ranking model considers, allowing the cluster-ranking model to run much faster. The system architecture is summarized in Figure 1.

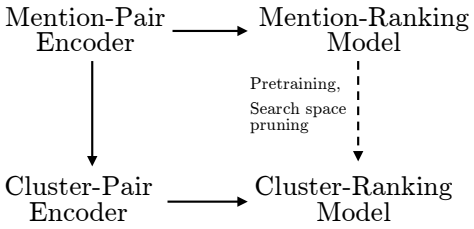

Figure 1: System architecture. Solid arrows indicate one neural network is used as a component of the other; the dashed arrow indicates other dependencies.

3 Building Representations

In this section, we describe the neural networks producing distributed representations of pairs of mentions and pairs of coreference clusters. We assume that a set of mentions has already been extracted from each document using a method such as the one in Raghunathan et al. (2010).

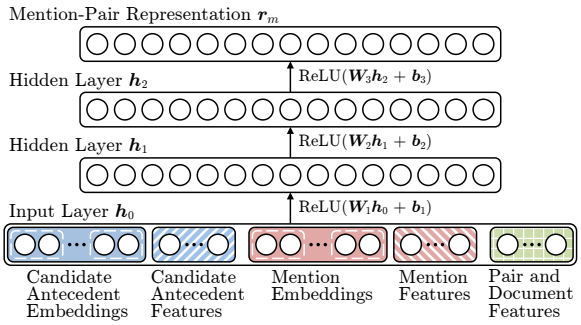

Figure 2: Mention-pair encoder.

3.1 Mention-Pair Encoder

Given a mention m and candidate antecedent a, the mention-pair encoder produces a distributed representation of the pair $\boldsymbol{r}_m(a, m) \in \mathbb{R}^d$ with a feedforward neural network, which is shown in Figure 2. The candidate antecedent may be any mention that occurs before m in the document or NA, indicating that m has no antecedent. We also experimented with models based on Long Short-Term Memory recurrent neural networks (Hochreiter and Schmidhuber, 1997), but found these to perform slightly worse when used in an end-to-end coreference system due to heavy overfitting to the training data.

Input Layer. For each mention, the model extracts various words and groups of words that are fed into the neural network. Each word is represented by a vector $\boldsymbol{w}_i \in \mathbb{R}^{d_w}$. Each group of words is represented by the average of the vectors of each word in the group. For each mention and pair of mentions, a small number of binary features and distance features are also extracted. Distances and mention lengths are binned into one of the buckets $[0, 1, 2, 3, 4, 5\text{-}7, 8\text{-}15, 16\text{-}31, 32\text{-}63, 64+]$ and then encoded in a one-hot vector in addition to being included as continuous features. The full set of features is as follows:

Embedding Features: Word embeddings of the head word, dependency parent, first word, last word, two preceding words, and two following words of the mention. Averaged word embeddings of the five preceding words, five following

[1] Code and trained models are available at `https://github.com/clarkkev/deep-coref`.

words, all words in the mention, all words in the mention's sentence, and all words in the mention's document.

Additional Mention Features: The type of the mention (pronoun, nominal, proper, or list), the mention's position (index of the mention divided by the number of mentions in the document), whether the mentions is contained in another mention, and the length of the mention in words.

Document Genre: The genre of the mention's document (broadcast news, newswire, web data, etc.).

Distance Features: The distance between the mentions in sentences, the distance between the mentions in intervening mentions, and whether the mentions overlap.

Speaker Features: Whether the mentions have the same speaker and whether one mention is the other mention's speaker as determined by string matching rules from Raghunathan et al. (2010).

String Matching Features: Head match, exact string match, and partial string match.

The vectors for all of these features are concatenated to produce an I-dimensional vector $\boldsymbol{h}_0$, the input to the neural network. If $a = \text{NA}$, the features defined over mention pairs are not included. For this case, we train a separate network with an identical architecture to the pair network except for the input layer to produce anaphoricity scores.

Our set of hand-engineered features is much smaller than the dozens of complex features typically used in coreference systems. However, we found these features were crucial for getting good model performance. See Section 6.1 for a feature ablation study.

Hidden Layers. The input gets passed through three hidden layers of rectified linear (ReLU) units (Nair and Hinton, 2010). Each unit in a hidden layer is fully connected to the previous layer:

$$\boldsymbol{h}_i(a, m) = \max(0, \boldsymbol{W}_i \boldsymbol{h}_{i-1}(a, m) + \boldsymbol{b}_i)$$

where $\boldsymbol{W}_1$ is a $M_1 \times I$ weight matrix, $\boldsymbol{W}_2$ is a $M_2 \times M_1$ matrix, and $\boldsymbol{W}_3$ is a $d \times M_2$ matrix.

The output of the last hidden layer is the vector representation for the mention pair: $\boldsymbol{r}_m(a, m) = \boldsymbol{h}_3(a, m)$.

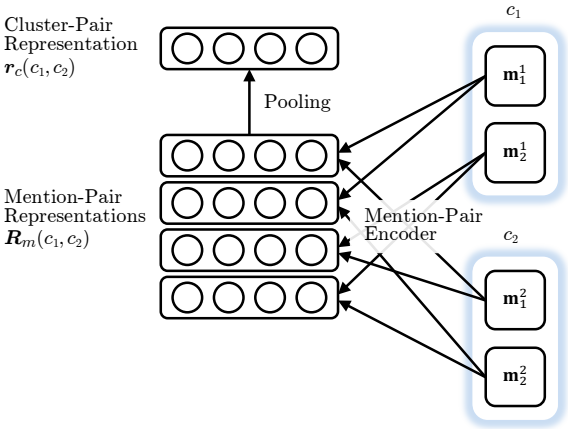

Figure 3: Cluster-pair encoder.

3.2 Cluster-Pair Encoder

Given two clusters of mentions $c_i = \{m_1^i, m_2^i, ..., m_{|c_i|}^i\}$ and $c_j = \{m_1^j, m_2^j, ..., m_{|c_j|}^j\}$, the cluster-pair encoder produces a distributed representation $\boldsymbol{r}_c(c_i, c_j) \in \mathbb{R}^{2d}$. The architecture of the encoder is summarized in Figure 3.

The cluster-pair encoder first combines the information contained in the matrix of mention-pair representations $\boldsymbol{R}_m(c_i, c_j) = [\boldsymbol{r}_m(m_1^i, m_1^j), \boldsymbol{r}_m(m_1^i, m_2^j), ..., \boldsymbol{r}_m(m_{|c_i|}^i, m_{|c_j|}^j)]$ to produce $\boldsymbol{r}_c(c_i, c_j)$. This is done by applying a pooling operation. In particular it concatenates the results of max-pooling and average-pooling, which we found to be slightly more effective than using either one alone:

$$\boldsymbol{r}_c(c_i, c_j)_k = \begin{cases} \max\{\boldsymbol{R}_m(c_i, c_j)_{k,\cdot}\} & \text{for } 0 \le k < d \\ \text{avg}\{\boldsymbol{R}_m(c_i, c_j)_{k-d,\cdot}\} & \text{for } d \le k < 2d \end{cases}$$

4 Mention-Ranking Model

Rather than training a cluster-ranking model from scratch, we first train a mention-ranking model that assigns each mention its highest scoring candidate antecedent. There are two key advantages of doing this. First, it serves as pretraining for the cluster-ranking model; in particular the mention-ranking model learns effective weights for the mention-pair encoder. Second, the scores produced by the mention-ranking model are used to provide a measure of which coreference decisions are easy (allowing for an easy-first clustering strategy) and which decisions are clearly wrong (these decisions can be pruned away, significantly reducing the search space of the cluster-ranking model).

The mention-ranking model assigns a score $s_m(a, m)$ to a mention m and candidate an-

tecedent a representing their compatibility for coreference. This is produced by applying a single fully connected layer of size one to the representation $\boldsymbol{r}_m(a, m)$ produced by the mention-pair encoder:

$$s_m(a, m) = \boldsymbol{W}_m \boldsymbol{r}_m(a, m) + b_m$$

where $\boldsymbol{W}_m$ is a $1 \times d$ weight matrix. At test time, the mention-ranking model links each mention with its highest scoring candidate antecedent.

Training Objective. We train the mention-ranking model with the slack-rescaled max-margin training objective from Wiseman et al. (2015), which encourages separation between the highest scoring true and false antecedents of the current mention. Suppose the training set consists of N mentions $m_1, m_2, ..., m_N$. Let $\mathcal{A}(m_i)$ denote the set of candidate antecedents of a mention m_i (i.e., mentions preceding m_i and NA), and $\mathcal{T}(m_i)$ denote the set of true antecedents of m_i (i.e., mentions preceding m_i that are coreferent with it or $\{\text{NA}\}$ if m_i has no antecedent). Let $\hat{t}_i$ be the highest scoring true antecedent of mention m_i:

$$\hat{t}_i = \operatorname*{argmax}_{t \in \mathcal{T}(m_i)} s_m(t, m_i)$$

Then the loss is given by

$$\sum_{i=1}^{N} \max_{a \in \mathcal{A}(m_i)} \Delta(a, m_i)(1 + s_m(a, m_i) - s_m(\hat{t}_i, m_i))$$

where $\Delta(a, m_i)$ is the mistake-specific cost function

$$\Delta(a, m_i) = \begin{cases} \alpha_{\text{FN}} & \text{if } a = \text{NA} \ \wedge \mathcal{T}(m_i) \neq \{\text{NA}\} \\ \alpha_{\text{FA}} & \text{if } a \neq \text{NA} \ \wedge \mathcal{T}(m_i) = \{\text{NA}\} \\ \alpha_{\text{WL}} & \text{if } a \neq \text{NA} \ \wedge a \notin \mathcal{T}(m_i) \\ 0 & \text{if } a \in \mathcal{T}(m_i) \end{cases}$$

for "false new," "false anaphoric," "wrong link," and correct coreference decisions. The different error penalties allow the system to be tuned for coreference evaluation metrics by biasing it towards making more or fewer coreference links.

Finding Effective Error Penalties. We fix $\alpha_{\text{WL}} = 1.0$ and search for α_{FA} and α_{FN} out of $\{0.1, 0.2, ..., 1.5\}$ with a variant of grid search. Each new trial uses the unexplored set of hyperparameters that has the closest Manhattan distance to the best setting found so far on the dev set. We stopped the search when all immediate neighbors (within 0.1 distance) of the best setting had been explored. We found $(\alpha_{\text{FN}}, \alpha_{\text{FA}}, \alpha_{\text{WL}}) = (0.8, 0.4, 1.0)$ to be best for English and $(\alpha_{\text{FN}}, \alpha_{\text{FA}}, \alpha_{\text{WL}}) = (0.7, 0.4, 1.0)$ to be best for Chinese on the CoNLL 2012 data. We attribute our smaller false new cost from the one used by Wiseman et al. (they set $\alpha_{\text{FN}} = 1.2$) to using more precise mention detection, which results in fewer links to NA.

Training Details. We initialized our word embeddings with 50 dimensional ones produced by `word2vec` (Mikolov et al., 2013) on the Gigaword corpus for English and 64 dimensional ones provided by Polyglot (Al-Rfou et al., 2013) for Chinese. Averaged word embeddings were held fixed during training while the embeddings used for single words were updated. We set our hidden layer sizes to $M_1 = 1000, M_2 = d$ = 500 and minimized the training objective using RMSProp (Hinton and Tieleman, 2012). To regularize the network, we applied L2 regularization to the model weights and dropout (Hinton et al., 2012) with a rate of 0.5 on the word embeddings and the output of each hidden layer.

Pretraining. As in Wiseman et al. (2015), we found that pretraining is crucial for the mention-ranking model's success. We pretrained the network in two stages, minimizing the following objectives from Clark and Manning (2015):

All-Pairs Classification

$$-\sum_{i=1}^{N}[\sum_{t \in \mathcal{T}(m_i)} \log p(t, m_i) + \sum_{f \in \mathcal{F}(m_i)} \log(1 - p(f, m_i))]$$

Top-Pairs Classification

$$-\sum_{i=1}^{N}[\max_{t \in \mathcal{T}(m_i)} \log p(t, m_i) + \min_{f \in \mathcal{F}(m_i)} \log(1 - p(f, m_i))]$$

Where $\mathcal{F}(m_i)$ is the set of false antecedents for m_i and $p(a, m_i) = \textit{sigmoid}(s(a, m_i))$. The top pairs objective is a middle ground between the all-pairs classification and mention ranking objectives: it only processes high-scoring mentions, but is probabilistic rather than max-margin. We first pretrained the network with all-pairs classification for 150 epochs and then with top-pairs classification for 50 epochs. See Section 6.1 for experiments on

the two-stage pretraining.

5 Cluster-Ranking Model

Although a strong coreference system on its own, the mention-ranking model has the disadvantage of only considering local information between pairs of mentions, so it cannot consolidate information at the entity-level. We address this problem by training a cluster-ranking model that scores pairs of clusters instead of pairs of mentions.

Given two clusters of mentions c_i and c_j, the cluster-ranking model produces a score $s_c(c_i, c_j)$ representing their compatibility for coreference. This is produced by applying a single fully connected layer of size one to the representation $\boldsymbol{r}_c(c_i, c_j)$ produced by the cluster-pair encoder:

$$s_c(c_i, c_j) = \boldsymbol{W}_c \boldsymbol{r}_c(c_i, c_j) + b_c$$

where $\boldsymbol{W}_c$ is a $1 \times 2d$ weight matrix. Our cluster-ranking approach also uses a measure of anaphoricity, or how likely it is for a mention m to have an antecedent. This is defined as

$$s_{\text{NA}}(m) = \boldsymbol{W}_{\text{NA}} \boldsymbol{r}_m(\text{NA}, m) + b_{\text{NA}}$$

where $\boldsymbol{W}_{\text{NA}}$ is a $1 \times d$ matrix.

5.1 Cluster-Ranking Policy Network

At test time, the cluster ranker iterates through every mention in the document, merging the current mention's cluster with a preceding one or performing no action. We view this procedure as a sequential decision process where at each step the algorithm observes the current state x and performs some action u.

Specifically, we define a state $x = (C, m)$ to consist of $C = \{c_1, c_2, ...\}$, the set of existing coreference clusters, and m, the current mention being considered. At a start state, each cluster in C contains a single mention. Let $c_m \in C$ be the cluster containing m and $\mathcal{A}(m)$ be a set of candidate antecedents for m: mentions occurring previously in the document. Then the available actions $U(x)$ from x are

- MERGE$[c_m, c]$, where c is a cluster containing a mention in $\mathcal{A}(m)$. This combines c_m and c into a single coreference cluster.
- PASS. This leaves the clustering unchanged.

After determining the new clustering C' based on the existing clustering C and action u, we consider another mention m' to get the next state $x' = (C', m')$.

Using the scoring functions s_c and s_{NA}, we define a policy network π that assigns a probability distribution over $U(x)$ as follows:

$$\pi(\text{MERGE}[c_m, c]|x) \propto e^{s_c(c_m, c)}$$
$$\pi(\text{PASS}|x) \propto e^{s_{\text{NA}}(m)}$$

During inference, π is executed by taking the highest-scoring (most probable) action at each step.

5.2 Easy-First Cluster Ranking

The last detail needed is the ordering in which to consider mentions. Cluster-ranking models in prior work order the mentions according to their positions in the document, processing them left-to-right (Rahman and Ng, 2011; Ma et al., 2014). However, we instead sort the mentions in descending order by their highest scoring candidate coreference link according to the mention-ranking model. This causes inference to occur in an easy-first fashion where hard decisions are delayed until more information is available. Easy-first orderings have been shown to improve the performance of other incremental coreference strategies (Raghunathan et al., 2010; Stoyanov and Eisner, 2012) because they reduce the problem of errors compounding as the algorithm runs.

We also find it beneficial to prune the set of candidate antecedents $\mathcal{A}(m)$ for each mention m. Rather than using all previously occurring mentions as candidate antecedents, we only include high-scoring ones, which greatly reduces the size of the search space. This allows for much faster learning and inference; we are able to remove over 95% of candidate actions with no decrease in the model's performance. For both of these two preprocessing steps, we use $s(a, m) - s(\text{NA}, m)$ as the score of a coreference link between a and m.

5.3 Deep Learning to Search

We face a sequential prediction problem where future observations (visited states) depend on previous actions. This is challenging because it violates the common i.i.d. assumption made in machine learning. Learning-to-search algorithms are effective for this sort of problem, and have been applied successfully to coreference resolution (Daumé III and Marcu, 2005; Clark and Manning, 2015) as

Algorithm 1 Deep Learning to Search

for $i = 1$ **to** num_epochs **do**
  Initialize the current training set $\Gamma = \emptyset$
  for each example $(x, y) \in \mathcal{D}$ **do**
    Run the policy π to completion from start state x to obtain a trajectory of states $\{x_1, x_2, ..., x_n\}$
    for each state x_i in the trajectory **do**
      for each possible action $u \in U(x_i)$ **do**
        Execute u on x_i and then run the reference policy π^{ref} until reaching an end state e
        Assign u a cost by computing the loss on the end state: $l(u) = \mathcal{L}(e, y)$
      end for
      Add the state x_i and associated costs l to Γ
    end for
  end for
  Update π with gradient descent, minimizing $\sum_{(x,l)\in\Gamma} \sum_{u\in U(x)} \pi(u|x)l(u)$.
end for

well as other structured prediction tasks in natural language processing (Daumé III et al., 2014; Chang et al., 2015a).

We train the cluster-ranking model using a learning-to-search algorithm inspired by SEARN (Daumé III et al., 2009), which is described in Algorithm 1. The algorithm takes as input a dataset $\mathcal{D}$ of start states x (in our case documents with each mention in its own singleton coreference cluster) and structured labels y (in our case gold coreference clusters). Its goal is to train the policy π so when it executes from x, reaching a final state e, the resulting loss $\mathcal{L}(e, y)$ is small. We use the negative of the B^3 coreference metric for this loss (Bagga and Baldwin, 1998). Although our system evaluation also includes the MUC (Vilain et al., 1995) and CEAF_{ϕ_4} (Luo, 2005) metrics, we do not incorporate them into the loss because MUC has the flaw of treating all errors equally and CEAF_{ϕ_4} is slow to compute.

For each example $(x, y) \in \mathcal{D}$, the algorithm obtains a trajectory of states $x_1, x_2, ..., x_n$ visited by the current policy by running it to completion (i.e., repeatedly taking the highest scoring action until reaching an end state) from the start state x. This exposes the model to states at train time similar to the ones it will face at test time, allowing it to learn how to cope with mistakes.

Given a state x in a trajectory, the algorithm then assigns a cost $l(u)$ to each action $u \in U(x)$ by executing the action, "rolling out" from the resulting state with a reference policy π^{ref} until reaching an end state e, and computing the resulting loss $\mathcal{L}(e, y)$. This rolling out procedure allows the model to learn how a local action will affect the final score, which cannot be otherwise computed because coreference evaluation metrics do not decompose over cluster merges. The policy network is then trained to minimize the risk associated with taking each action: $\sum_{u\in U(x)} \pi(u|x)l(u)$.

Reference policies typically refer to the gold labels to find actions that are likely to be beneficial. Our reference policy π^{ref} takes the action that increases the B^3 score the most each step, breaking ties randomly. It is generally recommended to use a stochastic mixture of the reference policy and the current learned policy during rollouts when the reference policy is not optimal (Chang et al., 2015b). However, we find only using the reference policy (which is close to optimal) to be much more efficient because it does not require neural network computations and is deterministic, which means the costs of actions can be cached.

Training details. We update π using RMSProp and apply dropout with a rate of 0.5 to the input layer. For most experiments, we initialize the mention-pair encoder component of the cluster-ranking model with the learned weights from the mention-ranking model, which we find to greatly improve performance (see Section 6.2).

Runtime. The full cluster-ranking system runs end-to-end in slightly under 1 second per document on the English test set when using a GPU (including scoring all pairs of mentions with the mention-ranking model for search-space pruning). This means the bottleneck for the overall system is the syntactic parsing required for mention detection (around 4 seconds per document).

Model	English F_1	Chinese F_1

– MATCHING	–2.07	–3.44

Table 1: CoNLL F_1 scores of the mention-ranking model on the dev sets without mention, document genre, distance, speaker, and string matching hand-engineered features.

6 Experiments and Results

Experimental Setup. We run experiments on the English and Chinese portions of the CoNLL 2012 Shared Task data (Pradhan et al., 2012). The models are evaluated using three of the most popular coreference metrics: MUC, B^3, and Entity-based CEAF ($CEAF_{\phi_4}$). We generally report the average F_1 score (CoNLL F_1) of the three, which is common practice in coreference evaluation. We used the most recent version of the CoNLL scorer (version 8.01), which implements the original definitions of the metrics.

Mention Detection. Our experiments were run using system-produced predicted mentions. We used the rule-based mention detection algorithm from Raghunathan et al. (2010), which first extracts pronouns and maximal NP projections as candidate mentions and then filters this set with rules that remove spurious mentions such as numeric entities and pleonastic *it* pronouns.

6.1 Mention-Ranking Model Experiments

Feature Ablations. We performed a feature ablation study to determine the importance of the hand-engineered features included in our model. The results are shown in Table 1. We find the small number of non-embedding features substantially improves model performance, especially the distance and string matching features. This is unsurprising, as the additional features are not easily captured by word embeddings and historically such features have been very important in coreference resolvers (Bengtson and Roth, 2008).

The Importance of Pretraining. We evaluate the benefit of the two-step pretraining for the mention-ranking model and report results in Table 2. Consistent with Wiseman et al. (2015), we find pretraining to greatly improve the model's accuracy. We note in particular that the model benefits from using both pretraining steps from Section 4, which more smoothly transitions the model from a mention-pair classification objective that is easy to optimize to a max-margin objective better suited for a ranking task.

All-Pairs	Top-Pairs	English F_1	Chinese F_1

– EASY-FIRST	–0.15	–0.12
– L2S	–0.32	–0.25

Table 3: CoNLL F_1 scores of the cluster-ranking model on the dev sets with various ablations. – PRETRAINING: initializing model parameters randomly instead of from the mention-ranking model, – EASY-FIRST: iterating through mentions in order of occurrence instead of according to their highest scoring candidate coreference link, – L2S: training on a fixed trajectory of correct actions instead of using learning to search.

6.2 Cluster-Ranking Model Experiments

We evaluate the importance of three key details of the cluster ranker: initializing it with the mention-ranking model's weights, using an easy-first ordering of mentions, and using learning to search. The results are shown in Table 3.

Pretrained Weights. We compare initializing the cluster-ranking model randomly with initializing it with the weights learned by the mention-ranking model. Using pretrained weights greatly improves performance. We believe the cluster-ranking model has difficulty learning effective weights from scratch due to noise in the signal coming from cluster-level decisions (an overall bad cluster merge may still involve a few cor-

rect pairwise links) and the smaller amount of data used to train the cluster-ranking model (many possible actions are pruned away during preprocessing). We believe the score would be even lower without search-space pruning, which stops the model from considering many bad actions.

Easy-First Cluster Ranking. We compare the effectiveness of easy-first cluster-ranking with the commonly used left-to-right approach. Using a left-to-right strategy simply requires changing the preprocessing step ordering the mentions so mentions are sorted by their position in the document instead of their highest scoring coreference link according to the mention-ranking model. We find the easy-first approach slightly outperforms using a left-to-right ordering of mentions. We believe this is because delaying hard decisions until later reduces the problem of early mistakes causing later decisions to be made incorrectly.

Learning to Search. We also compare learning to search with the simpler approach of training the model on a trajectory of gold coreference decisions (i.e., training on a fixed cost-sensitive classification dataset). Using this approach significantly decreases performance. We attribute this to the model not learning how to deal with mistakes when it only sees correct decisions during training.

6.3 Capturing Semantic Similarity

Using semantic information to improve coreference accuracy has had mixed in results in previous research, and has been called an "uphill battle" in coreference resolution (Durrett and Klein, 2013). However, word embeddings are well known for being effective at capturing semantic relatedness, and we show here that neural network coreference models can take advantage of this.

Perhaps the case where semantic similarity is most important is in linking nominals with no head match (e.g., "the nation" and "the country"). We compare the performance of our neural network model with our earlier statistical system (Clark and Manning, 2015) at classifying mention pairs of this type as being coreferent or not. The neural network shows substantial improvement (18.9 F_1 vs. 10.7 F_1) on this task compared to the more modest improvement it gets at classifying any pair of mentions as coreferent (68.7 F_1 vs. 66.1 F_1). Some example wins are shown in Table 4. These types of coreference links are quite rare in the CoNLL data (about 1.2% of the positive coreference links in the test set), so the improvement does not significantly contribute to the final system's score, but it does suggest progress on this difficult type of coreference problem.

Antecedent	Anaphor
the country's leftist rebels	the guerrillas
the company	the New York firm
the suicide bombing	the attack
the gun	the rifle
the U.S. carrier	the ship

Table 4: Examples of nominal coreferences with no head match that the neural model gets correct, but the system from Clark and Manning (2015) gets incorrect.

6.4 Final System Performance

In Table 5 we compare the results of our system with state-of-the-art approaches for English and Chinese. Our mention-ranking model surpasses all previous systems. We attribute its improvement over the neural mention ranker from Wiseman et al. (2015) to our model using a deeper neural network, pretrained word embeddings, and more sophisticated pretraining.

The cluster-ranking model improves results further across both languages and all evaluation metrics, demonstrating the utility of incorporating entity-level information. The improvement is largest in CEAF_{ϕ_4}, which is encouraging because CEAF_{ϕ_4} is the most recently proposed metric, designed to correct flaws in the other two (Luo, 2005). We believe entity-level information is particularly useful for preventing bad merges between large clusters (see Figure 4 for an example). However, it is worth noting that in practice the much more complicated cluster-ranking model brings only fairly modest gains in performance.

7 Related Work

There has been extensive work on machine learning approaches to coreference resolution (Soon et al., 2001; Ng and Cardie, 2002), with mention-ranking models being particularly popular (Denis and Baldridge, 2007; Durrett and Klein, 2013; Björkelund and Kuhn, 2014).

We train a neural mention-ranking model inspired by Wiseman et al. (2015) as a starting point, but then use it to pretrain a cluster-ranking model that benefits from entity-level information. Wise-

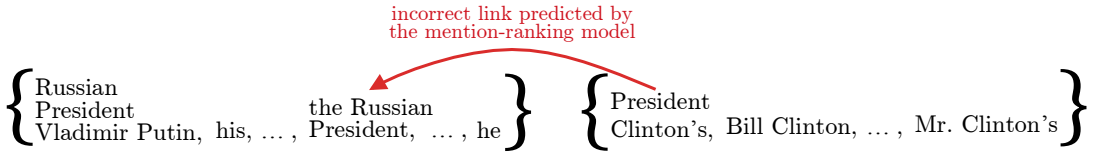

Figure 4: Thanks to entity-level information, the cluster-ranking model correctly declines to merge these two large clusters when running on the test set. However, the mention-ranking model incorrectly links *the Russian President* and *President Clinton's*, which greatly reduces the final precision score.

man et al. (2016) extend their mention-ranking model by incorporating entity-level information produced by a recurrent neural network running over the candidate antecedent-cluster. However, this is an augmentation to a mention-ranking model, and not fundamentally a clustering model as our cluster ranker is.

Entity-level information has also been incorporated in coreference systems using joint inference (McCallum and Wellner, 2003; Poon and Domingos, 2008; Haghighi and Klein, 2010) and systems that build up coreference clusters incrementally (Luo et al., 2004; Yang et al., 2008; Raghunathan et al., 2010). We take the latter approach, and in particular combine the cluster-ranking (Rahman and Ng, 2011; Ma et al., 2014) and easy-first (Stoyanov and Eisner, 2012; Clark and Manning, 2015) clustering strategies. These prior systems all express entity-level information in the form of hand-engineered features and constraints instead of entity-level distributed representations that are learned from data.

We train our system using a learning-to-search algorithm similar to SEARN (Daumé III et al., 2009). Learning-to-search style algorithms have been employed to train coreference resolvers on trajectories of decisions similar to those that would be seen at test-time by Daumé et al. (2005), Ma et al. (2014), and Clark and Manning (2015). Other works use structured perceptron models for the same purpose (Stoyanov and Eisner, 2012; Fernandes et al., 2012; Björkelund and Kuhn, 2014).

8 Conclusion

We have presented a coreference system that captures entity-level information with distributed representations of coreference cluster pairs. These learned, dense, high-dimensional feature vectors provide our cluster-ranking coreference model with a strong ability to distinguish beneficial cluster merges from harmful ones. The model is trained with a learning-to-search algorithm that allows it to learn how local decisions will affect the final coreference score. We evaluate our system on the English and Chinese portions of the CoNLL 2012 Shared Task and report a substantial improvement over the current state-of-the-art.

Effects of Creativity and Cluster Tightness on Short Text Clustering Performance

Abstract

Properties of corpora, such as the diversity of vocabulary and how tightly related texts cluster together, impact the best way to cluster short texts. We examine several such properties in a variety of corpora and track their effects on various combinations of similarity metrics and clustering algorithms. We show that semantic similarity metrics outperform traditional n-gram and dependency similarity metrics for k-means clustering of a linguistically creative dataset, but do not help with less creative texts. Yet the choice of similarity metric interacts with the choice of clustering method. We find that graph-based clustering methods perform well on tightly clustered data but poorly on loosely clustered data. Semantic similarity metrics generate loosely clustered output even when applied to a tightly clustered dataset. Thus, the best performing clustering systems could not use semantic metrics.

1 Introduction

Corpora of collective discourse—texts generated by multiple authors in response to the same stimulus—have varying properties depending on the stimulus and goals of the authors. For instance, when multiple puzzle-composers write crossword puzzle clues for the same word, they will try to write creative, unique clues to make the puzzle interesting and challenging; clues for "star" could be "Paparazzi's target" or "Sky light." In contrast, people writing a descriptive caption for a photograph can adopt a less creative style. Corpora may also differ on how similar texts within a particular class are to one another, compared to how similar they are to texts from other classes. For example, entries in a cartoon captioning contest that all relate to the same cartoon may vary widely in subject, while crossword clues for the same word would likely be more tightly clustered.

This paper studies how such text properties affect the best method of clustering short texts. Choosing how to cluster texts involves two major decisions: choosing a similarity metric to determine which texts are alike, and choosing a clustering method to group those texts. We hypothesize that creativity may drive authors to express the same concept in a wide variety of ways, leading to data that can benefit from different similarity metrics than less creative texts. At the same time, we hypothesize that tightly clustered datasets—datasets where each text is much more similar to texts in its cluster than to texts from other clusters—can be clustered by powerful graph-based methods such as Markov Clustering (MCL) and Louvain, which may fail on more loosely clustered data. This paper explores the interaction of these effects.

Recently, distributional semantics has been popular and successful for measuring text similarity (Socher et al., 2011; Cheng and Kartsaklis, 2015; He et al., 2015; Kenter and de Rijke, 2015; Kusner et al., 2015; Ma et al., 2015; Tai et al., 2015; Wang et al., 2015). Word embeddings represent similar words in similar locations in vector space: "cat" is closer to "feline" than to "bird." It would be natural to expect such semantics-based approaches to be useful for clustering, particularly for corpora where authors have tried to express similar ideas in unique ways. And indeed, this paper will show that, depending on the choice of clustering method, semantics-based similarity

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 654–665,
Berlin, Germany, August 7-12, 2016.

measures such as summed word embeddings and deep neural networks can have an advantage over more traditional similarity metrics, such as n-gram counts, n-gram tf-idf vectors, and dependency tree kernels, when applied to creative texts.

However, unlike in most text similarity tasks, in clustering the choice of similarity metric interacts with both the choice of clustering method and the properties of the text. Graph-based clustering techniques can be quite effective in clustering short texts (Rangrej et al., 2011), yet this paper will show that they are sensitive to how tightly clustered the data is. Moreover, the tightness of clusters in a dataset is a property of both the underlying data and the similarity metric. We show that when the underlying data can be clustered tightly enough to use powerful graph-based clustering methods, using semantics-based similarity metrics actually creates a disadvantage compared to methods that rely on the surface form of the text, because semantic metrics reduce tightness.

The remainder of this paper is organized as follows. Section 2 summarizes related work. Section 3 describes four datasets of short texts. In Section 4, we describe the similarity metrics and clustering methods used in our experiments, as well as the evaluation measures. Section 5 shows that semantics-based similarity metrics have some advantage when clustering short texts from the most creative dataset, but ultimately do not perform the best when graph-based clustering is an option. In Section 6, we demonstrate the powerful effect that tightness of clusters has on the best combination of similarity metric and clustering method for a given dataset. Finally, Section 7 draws conclusions.

2 Related Work

The most similar work to the present paper is Shrestha et al. (2012), which acknowledged that the similarity metric and the clustering method could both contribute to clustering results. It compared four similarity methods and also tested four clustering methods. Unlike the present work, it did not consider distributional semantics-based similarity measures or similarity measures that incorporated deep learning. In addition, it reported that the characteristics of the corpora "overshadow[ed] the effect of the similarity measures," making it difficult to conclude that there were any significant differences between the similarity measures.

Several papers address the choice of similarity metric for short text clustering without varying the clustering method. Yan et al. (2012) proposed an alternative term weighting scheme to use in place of tf-idf when clustering using non-negative matrix factorization. King et al. (2013) used the cosine similarity between feature vectors that included context word and part-of-speech features and spelling features and applied Louvain clustering to the resulting graph. Xu et al. (2015) used a convolutional neural network to represent short texts and found that, when used with the k-means clustering algorithm, this deep semantic representation outperformed tf-idf, Laplacian eigenmaps, and average embeddings for clustering.

Other papers focused on choosing the best clustering method for short texts, but kept the similarity metric constant. Rangrej et al. (2011) compared k-means, singular value decomposition, and affinity propagation for tweets, finding affinity propagation the most effective, using tf-idf with cosine similarity or Jaccard for a similarity measure. Errecalde et al. (2010) describe an AntTree-based clustering method. They used the cosine similarity of tf-idf vectors as well. Yin (2013) also use the cosine similarity of tf-idf vectors for a two-stage clustering algorithm for tweets.

One common strategy for short text clustering has been to take advantage of outside sources of knowledge (Banerjee et al., 2007; Wang et al., 2009a; Petersen and Poon, 2011; Rosa et al., 2011; Wang et al., 2014). The present work relies only on the texts themselves, not external information.

3 Datasets

Collective discourse (Qazvinian and Radev, 2011; King et al., 2013) involves multiple writers generating texts in response to the same stimulus. In a corpus of texts relating to several stimuli, it may be desirable to cluster according to which stimulus each text relates to—for instance, grouping all of the news headlines about the same event together. Here, we consider texts triggered by several types of stimuli: photographs that need descriptive captions, cartoons that need humorous captions, and crossword answers that need original clues. Each need shapes the properties of the texts.

Pascal and Flickr Captions. The Pascal Captions dataset (hereinafter PAS) and the 8K ImageFlickr dataset (Rashtchian et al., 2010) are sets of captions solicited from Mechanical Turkers for photographs from Flickr and from the Pat-

tern Analysis, Statistical Modeling, and Computational Learning (PASCAL) Visual Object Classes Challenge (Everingham et al., 2010).

PAS includes twenty categories of images (e.g., dogs, as in Example (1)) and 4998 captions. Each category has fifty images with approximately five captions for each image. We use the category as the gold standard cluster. The 8K ImageFlickr set includes 38,390 captions for 7663 photographs; we treat the image a caption is associated with as the gold standard cluster. To keep dataset sizes comparable, we use a randomly selected subset of 5000 captions (998 clusters) from ImageFlickr (hereinafter FLK).

(1)

"a man walking a small dog on a very wavy beach"
"A person in a large black coats walks a white dog on the beach through rough waves."
"Walking a dog on the edge of the ocean"

This task did not encourage creativity; instructions said to "describe the image in one complete but simple sentence." This could lead to sentences within a cluster being rather similar to each other. However, because photographs may contain overlapping elements—for instance, a photograph in the "bus" category of PAS might also show cars, while a photograph in the "cars" category could also contain a bus—texts in one cluster can also be quite similar to texts from other clusters. Thus, these datasets should not be very tightly clustered.

***New Yorker* Cartoon Captions**. *The New Yorker* magazine has a weekly competition in which readers submit possible captions for a captionless cartoon (Example (2)) (Radev et al., 2015). We use the cartoon each caption is associated with as its gold standard cluster.

The complete dataset includes over 1.9 million captions for 366 cartoons. For this work, we use a total of 5000 captions from 20 randomly selected cartoons as the "TOON" dataset.

(2)

"Objection, Your Honor! Alleged killer whale."
"My client maintains that the penguin had a gun!"
"I demand a change of venue to a maritime court!"

Since caption writers seek to stand out from the crowd, we expect high creativity. This may encourage a more varied vocabulary than the FLK and PAS captions that merely describe the image. We also expect wide variation in the meanings of captions for the same cartoon, due to the different joke senses submitted for each, leading to low intra-cluster similarity. Moreover, some users may submit the same caption for more than one cartoon, so we can expect surprisingly high inter-cluster similarity despite the wide variation in cartoon prompt images. We therefore do not expect TOON to be tightly clustered.

Crossword Clues. A dataset of particularly creative texts is comprised of crossword clues.[1] We use the clues as texts and the answer words as their gold standard cluster; all of the clues in Example (3) belong to the "toe" cluster.

(3) Part of the foot
Little piggy
tic-tac-___
The third O of OOO

The complete crossword clues dataset includes 1.7M different clues corresponding to 174,638 unique answers. The "CLUE" dataset includes 5000 clues corresponding to 20 unique answers selected by randomly choosing answers that have 250 or more unique clues, and then randomly choosing 250 of those clues for each answer.

Since words repeat, crossword authors must be creative to come up with clues that will not bore cruciverbalists. CLUE should thus contain many alternative phrasings for essentially the same idea. At the same time, there is likely to be relatively little overlap between clues for different answers, so CLUE should be tightly clustered.

4 Method

Here we describe the similarity metrics and clustering methods, as well as evaluation measures.

4.1 Similarity Metrics

We hypothesize that creative texts with wide vocabularies will benefit from similarity metrics based on semantic representation of the text, rather than its surface form. We therefore compare three metrics that rely on surface forms of words—n-gram count vectors, tf-idf vectors, and dependency tree segment counts—to three semantic ones—summed Word2Vec embeddings, LSTM autoencoders, and skip-thought vectors. In each case, we represent texts as vectors and find their cosine similarities; if cosine similarity can be negative, we add one and normalize by two to ensure similarity in the range [0, 1].

N-Gram Counts. First we consider n-gram count vectors. We use three variations: (1) unigrams, (2) unigrams and bigrams, and (3) unigrams, bigrams, and trigrams.

N-Gram tf-idf. We also consider weighting n-grams by tf-idf, as calculated by sklearn (Pedregosa et al., 2011).

Dependency Counts. Grammatical information has been found to be useful in text, particularly short text, similarity. (Liu and Gildea, 2005; Zhang et al., 2005; Wang et al., 2009b; Heilman and Smith, 2010; Tian et al., 2010; Šarić et al., 2012; Tai et al., 2015). To leverage this information, previous work has used dependency kernels (Tian et al., 2010), which measure similarity by the fraction of identical dependency parse segments between two sentences. Here, we accomplish the same effect using a count vector for each sentence, with the dependency parse segments as the vocabulary. We define the set of segments for a dependency parse to consist of, for each word, the word, its parent, and the dependency relation that connects them as shown in Example (4).

(4) Part of shoe
- a. Segment 1: (part, ROOT, nsubj)
- b. Segment 2: (of, part, prep)
- c. Segment 3: (shoe, of, pobj)

Word2Vec. For each word, we obtain, if possible, a vector learned via Word2Vec (Mikolov et al., 2013) from the Google News corpus.[2] We represent a sentence as the normalized sum of its word vectors.

LSTM Autoencoder. We use Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) to build another semantics-based sentence representation. We train an LSTM autoencoder consisting of an encoder network and a decoder network. The encoder reads the input sentence and produces a single vector as the hidden state at the last time step. The decoder takes this hidden state vector as input and attempts to reconstruct the original sentence. The LSTM autoencoder is trained to minimize the reconstruction loss. After training, we extract the hidden state at the last time step of encoder as the vector representation for a sentence. We use 300-dimensional word2vec vectors pretrained on GoogleNews and generate 300-dimensional hidden vectors. LSTM autoencoders are separately trained for each dataset with 20% for validation.

Skip-thoughts (Kiros et al., 2015) trains encoder-decoder Recurrent Neural Networks (RNN) without supervision to predict the next and the previous sentences given the current sentence. The pretrained skip-thought model computes vectors as sentence representations.

4.2 Clustering Methods

We explore five clustering methods: k-means, spectral, affinity propagation, Louvain, and MCL.

K-means is a popular and straightforward clustering algorithm (Berkhin, 2006) that takes a parameter k, the number of clusters, and uses an expectation-maximization approach to find k centroids in the data. In the expectation phase points are assigned to their nearest cluster centroid. In the maximization phase the centroids of are recomputed for each cluster of assigned points. K-means is not a graph-based clustering algorithm, but rather operates in a vector space.

Spectral clustering (Donath and Hoffman, 1973; Shi and Malik, 2000; Ng et al., 2001) is a graph-based clustering approach that finds the graph Laplacian of a similarity matrix, builds a matrix of the first k eigenvectors of the Laplacian, and then applies further clustering to this matrix. The method can be viewed as an approximation of a normalized min-cuts algorithm or of a random walks approach. We use the default implementation provided by sklearn, which applies a Gaussian kernel to determine the graph Laplacian and uses

[2] https://code.google.com/archive/p/word2vec/

k-means for the subsequent clustering step.

Affinity propagation finds exemplars for each cluster and then assigns nodes to a cluster based on these exemplars (Frey and Dueck, 2007). This involves updating two matrices R and A, respectively representing the responsibility and availability of each node. A high value for $R_{(i,k)}$ indicates that node x_i would be a good exemplar for cluster k. A high value for $A_{(i,k)}$ indicates that node x_i is likely to belong to cluster k. We use the default implementation provided by sklearn.

Louvain initializes each node to be its own cluster, then greedily maximizes modularity (Section 6.1) by iteratively merging clusters that are highly interconnected (Blondel et al., 2008).

Markov Cluster Algorithm (MCL) simulates flow on a network via random walk (Van Dongen, 2000). The sequence of nodes is represented via a Markov chain. By applying inflation to the transition matrix, the algorithm can maintain the cluster structure pronounced in the transition matrix of this random walk—a structure that would otherwise disappear over time.[3]

4.3 Evaluation Methods

Adjusted Rand Index We use the sklearn implementation of the Adjusted Rand Index (ARI)[4] (Hubert and Arabie, 1985):

$$\text{ARI} = \frac{RI - \text{Expected RI}}{\max RI - \text{Expected RI}} \quad (1)$$

where RI is the Rand Index,

$$RI = \frac{TP + TN}{TP + FP + FN + TN} \quad (2)$$

TP is the number of true positives, TN is true negatives, and FP and FN are false positives and false negatives, respectively. The Rand Index ranges from 0 to 1. ARI adjusts the Rand Index for chance, so that the score ranges from -1 to 1. Random labeling will achieve an ARI score close to 0; perfect labeling achieves an ARI of 1.

Purity is a score in the $[0, 1]$ range that indicates to what extent sentences in the same predicted cluster actually belong to the same cluster. Given $\Omega = \{\omega_1, \omega_2, ..., \omega_K\}$, the predicted clusters, $C = \{c_1, c_2, ..., c_J\}$, the true clusters, and N, the number of examples, purity is

$$\text{Purity}(\Omega, C) = \frac{1}{N} \sum_{k \in K} \max_{j \in J} |\omega_k \cap c_j| \quad (3)$$

[3]We use the implementation from `http://micans.org/mcl/` with inflation=2.0.

[4]Equivalent to Cohen's Kappa (Warrens, 2008).

Normalized Mutual Information (NMI). We use the sklearn implementation of NMI:

$$NMI(\Omega, C) = \frac{MI(\Omega, C)}{\sqrt{H(C) \cdot H(\Omega)}} \quad (4)$$

The numerator is the mutual information (MI) of predicted cluster labels Ω and true cluster labels C. MI describes how much knowing what the predicted clusters are increases knowledge about what the actual classes are. Using marginal entropy ($H(x)$), NMI normalizes MI so that it ranges from 0 to 1. If C and Ω are identical—that is, if the clusters are perfect—NMI will be 1.

5 Vocabulary Width

5.1 Descriptive Statistics for Vocabulary Width

We predict that creative texts have a wider vocabulary than functional texts. We use two measures to reflect this wide vocabulary: the type/token ratio in the dataset (TTR), and that ratio normalized by the mean length of a text in the dataset.

TTR is an obvious estimate of the width of the vocabulary of a corpus. However, all other things being equal, a corpus of many very short texts triggered by the same stimulus would have more repeated words, proportional to the total number of tokens in the corpus, than would a corpus of a smaller number of longer texts. We might therefore normalize the ratio of types to tokens by dividing by the mean length of a text in the dataset, leading to the normalized type-to-token ratio (NTTR) and TTR values shown in Table 1.

	CLUE	TOON	PAS	FLK
TTR	0.1680	0.1064	0.0625	0.0561
NTTR	0.0377	0.0086	0.0058	0.0047

Table 1: Vocabulary properties of each dataset

FLK, PAS, and CLUE conform to expectations. The creative CLUE has TTR more than double that of the more functional PAS and FLK. The effect is more pronounced using NTTR. Surprisingly, TOON falls closer to the PAS and FLK end of the spectrum, suggesting that vocabulary width does not capture the creativity in the captioning competition; perhaps the creativity of cartoon captions is about expressing different ideas, rather than finding unique ways to express the same idea. For the experiments based on vocabulary width, we therefore compare PAS and CLUE.

5.2 Experiments

We hypothesize that if a dataset uses a wide variety of words to express the same ideas, similarity metrics that rely on the surface form of the sentence will be at a disadvantage compared to similarity metrics based in distributional semantics. Thus, word2vec, LSTM autoencoders, and skip-thoughts ought to perform better than the n-gram-based methods and dependency count method when applied to CLUE, but should enjoy no advantage when applied to PAS.

We begin by comparing the performance of all similarity metrics on PAS and CLUE, using k-means for clustering. We then also examine their performance with MCL.

5.3 Results and Discussion

Table 2 compares the performance of all similarity metrics on PAS and CLUE using k-means and MCL. Using k-means on PAS, the unigram tf-idf similarity metric gives the strongest performance for purity and NMI and came in a close second for ARI. LSTM slightly outperformed the other similarity metrics on ARI, but had middle-of-the-road results on the other evaluations. Overall, the semantics-based similarity metrics gave reasonable but not exceptional ARI and purity results, but were at the low end on NMI. This is consistent with our hypothesis that when authors are not trying to express creativity by using a wider vocabulary, surface-based similarity metrics suffice.

For k-means on CLUE, the picture is quite different: the semantics-based similarity metrics markedly outperformed any other similarity metric on ARI. LSTM also provides the best purity score, followed by skip-thought. The semantics-based metrics do not stand out for NMI, though. Based on these results, we conclude that semantics-based measures provide a significant advantage over traditional similarity metrics when using k-means on the wide-vocabulary, creative CLUE.

When clustering with MCL, however, the semantics-based methods perform exceptionally poorly on both datasets. Interestingly, the n-gram-based similarity metrics performed very well when paired with MCL on CLUE—outperforming the best of the k-means scores—while the same metrics performed terribly with MCL on PAS.

We hypothesize that the semantics-based similarity metrics produce less tightly clustered data than the surface-form-based metrics do, and that this may make clustering difficult for some graph-based clustering methods. The next section describes how we test this hypothesis.

6 Tightness of Clusters

6.1 Descriptive Statistics for Tightness

Two pieces contribute to cluster tightness: the dataset itself and the choice of similarity metric. To illustrate, we represent each text with the vector for its similarity metric—for instance, the sum of its word2vec vectors or the unigram tf-idf vector—and reduce it to two dimensions using linear discriminant analysis. We plot five randomly selected gold standard clusters. Plots for unigram tf-idf and word2vec representations of PAS and CLUE are shown in Figures 1 and 2. These support the intuition that semantics-based similarity metrics are not as tightly clustered as n-gram-based metrics. Note also that the CLUE unigram tf-idf clusters appear tighter than the PAS unigram tf-idf clusters.

To quantify this, we compute modularity (Newman, 2004; Newman, 2006):[5]

$$Q = \frac{1}{2m} \sum_{ij} \left(A_{ij} - \frac{k_i k_j}{2m} \right) \delta(c_i, c_j) \quad (5)$$

A_{ij} is the edge weight between nodes i and j. $\delta(c_i, c_j)$ indicates whether i and j belong to the same cluster. m is the number of edges. k_i is the degree of vertex i, so $\frac{k_i k_j}{2m}$ is the expected number of edges between i and j in a random graph. Thus, modularity is highest when nodes in a cluster are highly interconnected, but sparsely connected to nodes in different clusters. We use this statistic in an unconventional way, determining the modularity of the golden clusters.

Table 3 shows the modularities for all four datasets using the unigram, trigram, unigram tf-idf, trigram tf-idf, dependency, word2vec, and skipthoughts similarity metrics. As suggested by Figures 1 and 2, the CLUE surface-form-based similarities have the highest modularity by far. The surface-form-based similarities for all datasets have much higher modularity than any of the semantics-based similarities; indeed, the

[5]Newman (2010) notes that modularity for even a perfectly mixed network generally cannot be 1 and describes a normalized modularity formula. We calculated both normalized and non-normalized modularity and found the pattern of results to be the same, so we report only modularity.

Table 2: A comparison of all similarity metrics on PAS and CLUE datasets, clustered using k-means and MCL. For all evaluations, higher scores are better.

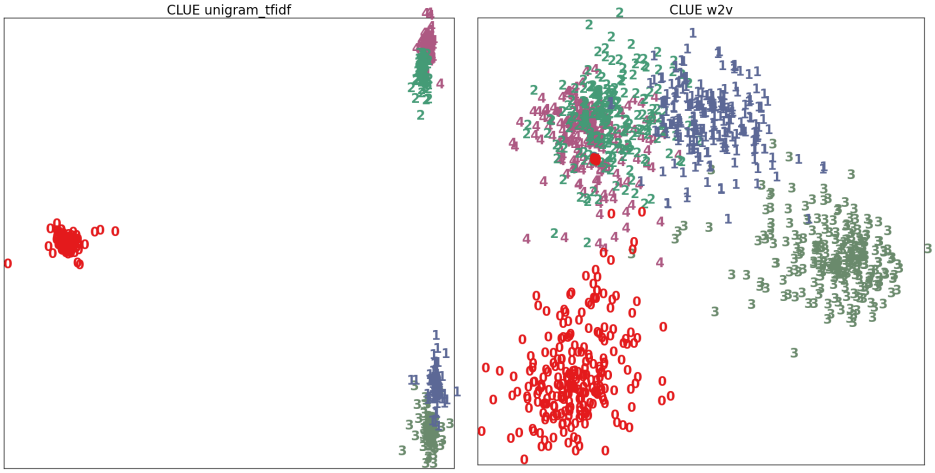

Figure 1: Plots of unigram tf-idf (left) and word2vec (right) vectors representing five randomly selected clusters of CLUE: clues for words "ets," "stay," "yes," "easel," and "aha."

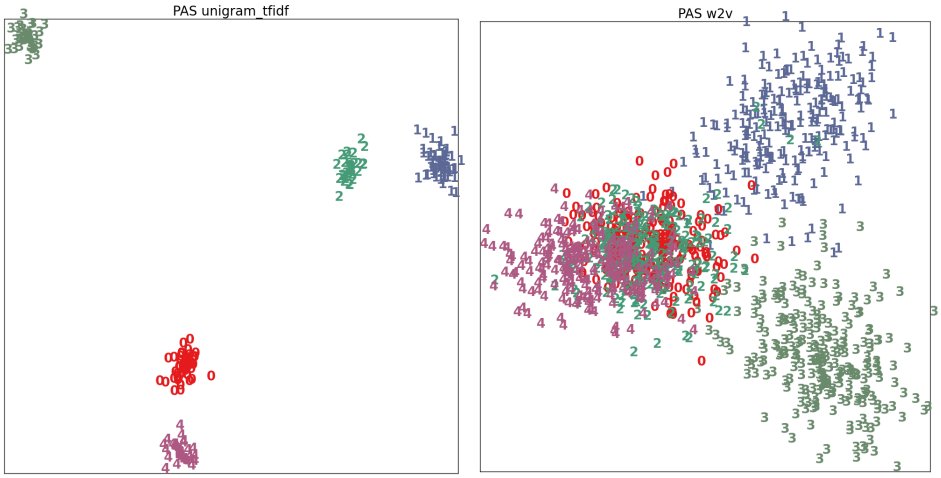

Figure 2: Plots of unigram tf-idf (left) and word2vec (right) vectors representing five randomly selected clusters of PAS: images containing "bus," "boat," "car," "bird," and "motorbike."

semantics-based similarities rarely have modularity much higher than zero. Thus, we conclude both that CLUE is more tightly clustered than the other datasets and that surface-form-based measures yield tighter clusters than semantics-based measures.

CLUE's tight clustering could be due in part to its particularly short texts. Additionally, it might reflect the semantics of the dataset: words that the clues hint at may be less similar to one another than the categories in PAS are to each other. For instance, some images in PAS's "bus" category include cars, and vice-versa.

The difference between semantics-based and surface-form similarity metrics likely arises from the fact that similarity of a word pair is a yes-or-

Metric	PAS	Clues	TOON	FLK

Table 3: Modularity for all datasets

no question to surface-form-based metrics, but a question of degree to semantics-based ones. According to semantics-based methods, "cat" is more similar to "feline" than it is to "dog," but more similar to "dog" than to "motorcycle." This creates some similarity between texts from different clusters, blurring the lines between them. Thus, "The man walks his dog" and "A woman with a cat" are entirely dissimilar according to surface form methods, but not according to the semantics-based measures. Even if the nodes in a cluster are highly interconnected, if the connections between nodes in different clusters are too strong, modularity will be low.

To determine whether cluster tightness influences the best clustering method, we tested all clustering methods on all four datasets using unigram, trigram, unigram tf-idf, trigram tf-idf, word2vec, and skipthought similarity metrics.

6.2 Results and Discussion

As can be seen in Figure 3, the best ARI results by a large margin were those on the tightly clustered CLUE. Louvain, which provides the best ARI for CLUE, and MCL, which provides the second best, both performed most strongly when paired with the surface-form-based similarity metrics (n-gram counts, tf-idf, and dependency count), which had high modularity relative to the semantics-based metrics. Although CLUE also differs from the other datasets in that it has the shortest mean text length, text length by itself cannot explain the observed differences in performance, since the pattern of graph-based clustering methods working best with modular data is consistent within each dataset as well as between datasets.

CLUE is also the only dataset where the semantics-based similarity metrics performed exceptionally well with any of the clustering methods. Recall from Table 1 that CLUE had a markedly wider vocabulary than any other dataset. This further supports our findings in Section 5.3 regarding how creativity affects the usefulness of semantics-based similarity metrics.

FLK, which had the lowest modularity, cannot be clustered by the spectral, Louvain, or MCL algorithms. K-means provides the strongest performance, followed by affinity propagation.

TOON has the worst ARI results. Its best-performing clustering methods are the graph-based Louvain and MCL methods. Both perform well only when paired with the most modular similarity metrics. Louvain seems less sensitive to modularity than MCL does. MCL's best performance by far for TOON is when it is paired with trigram tf-idf, which also had the highest modularity; its performance when paired with the lower-modularity similarity metrics rapidly falls away. In contrast, Louvain fares reasonably well with the lower n-gram tf-idfs, which also had lower modularity than trigram tf-idf.

Louvain and MCL follow a similar pattern on PAS: both perform at their peak on the most modular similarity metric (dependency), but Louvain handles slightly less modular similarity metrics nearly as well as the most modular one, while MCL quickly falters.

K-means' performance is not correlated with modularity. This makes sense, as k-means is the only non-graph-based method. Methods like MCL, which is based on a random walk, may be stymied by too many highly-weighted paths between clusters; the random walk can too easily reach a different neighborhood from where it started. But k-means relies on how close texts are to centroids, not to other texts, and so would be less affected.

The fact that k-means nevertheless performs poorly on TOON suggests that this dataset may be particularly difficult to cluster. An interesting test would be to measure inter-annotator agreement on TOON.

7 Conclusions and Future Work

This work has shown that creativity can influence the best way to cluster text. When using k-means to cluster a dataset where authors tried to be creative, similarity metrics utilizing distri-

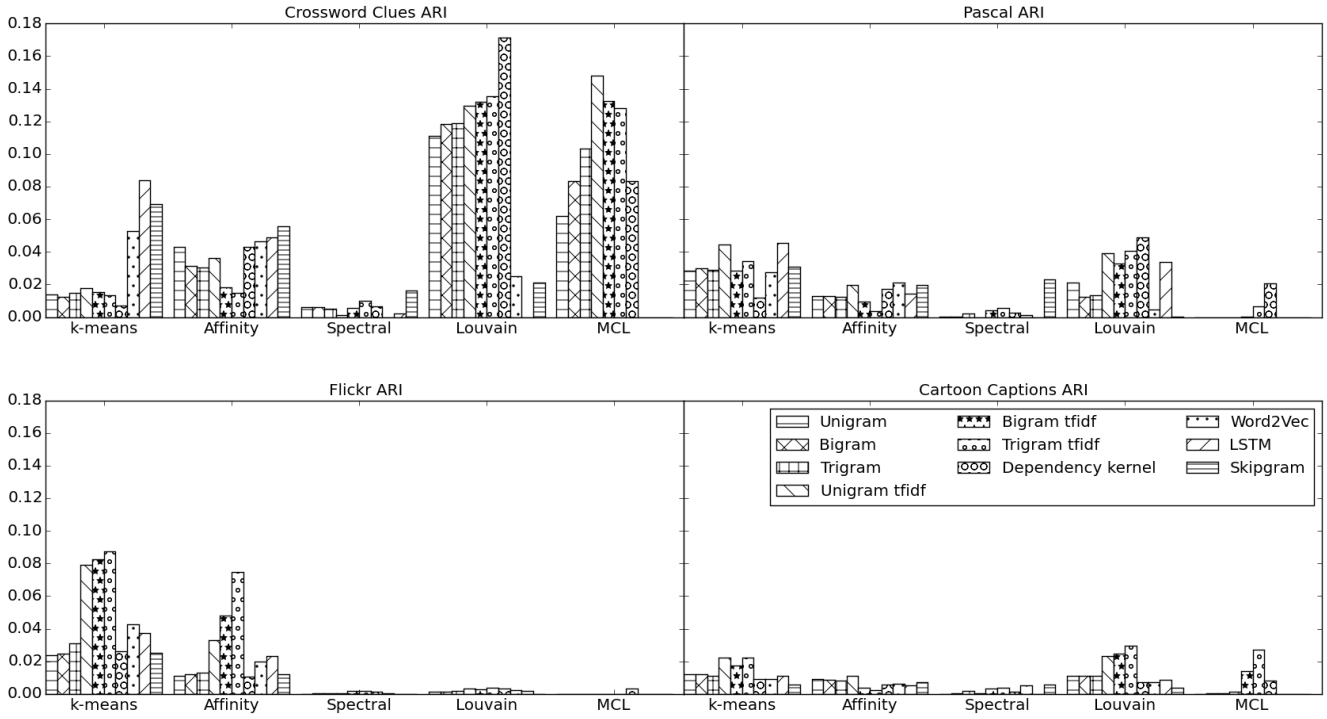

Figure 3: All similarity metrics and all clustering methods for the four datasets.

butional semantics outperformed those that relied on surface forms. We also showed that semantics-based methods do not provide a notable advantage when applying k-means to less creative datasets. Since traditional similarity metrics are often faster to calculate, use of slower semantics-based methods should be limited to creative datasets.

Unlike most work on clustering short texts, we examined how the similarity metric interacts with the clustering method. Even for a creative dataset, if the underlying data is tightly clustered, the use of semantics-based similarity measures can actually hurt performance. Traditional metrics applied to such tightly clustered data generate more modular output that enables the use of sophisticated, graph-based clustering methods such as MCL and Louvain. When either the underlying data or the similarity metrics applied to it produce loose clusters with low modularity, the sophisticated graph clustering algorithms fail, and we must fall back on simpler methods.

Future work can manipulate datasets' text properties to confirm that a specific property is the cause of observed differences in clustering. Such work should alter the datasets TTR and NTTR while holding mean length of texts constant. A pilot effort to use word embeddings to alter the variety of vocabulary in a dataset has so far not succeeded, but future experiments altering vocabulary width or modularity of a dataset and finding that the modified dataset behaved like natural datasets with the same properties could increase confidence in causality. Future work can also explore finer clusters within these datasets, such as clustering CLUE by word sense of the answers and TOON by joke sense.

These results are a first step towards determining the best way to cluster a new dataset based on properties of the text. Future work will explore further how the goals of short text authors translate into measurable properties of the texts they write, and how measuring those properties can help predict which similarity metrics and clustering methods will combine to provide the best performance.

Abstract

Word embedding maps words into a low-dimensional continuous embedding space by exploiting the local word collocation patterns in a small context window. On the other hand, topic modeling maps documents onto a low-dimensional topic space, by utilizing the global word collocation patterns in the same document. These two types of patterns are complementary. In this paper, we propose a generative topic embedding model to combine the two types of patterns. In our model, topics are represented by embedding vectors, and are shared across documents. The probability of each word is influenced by both its local context and its topic. A variational inference method yields the topic embeddings as well as the topic mixing proportions for each document. Jointly they represent the document in a low-dimensional continuous space. In two document classification tasks, our method performs better than eight existing methods, with fewer features. In addition, we illustrate with an example that our method can generate coherent topics even based on only one document.

1 Introduction

Representing documents as fixed-length feature vectors is important for many document processing algorithms. Traditionally documents are represented as a bag-of-words (BOW) vectors. However, this simple representation suffers from being high-dimensional and highly sparse, and loses semantic relatedness across the vector dimensions.

Word Embedding methods have been demonstrated to be an effective way to represent words as continuous vectors in a low-dimensional embedding space (Bengio et al., 2003; Mikolov et al., 2013; Pennington et al., 2014; Levy et al., 2015). The learned embedding for a word encodes its semantic/syntactic relatedness with other words, by utilizing local word collocation patterns. In each method, one core component is the *embedding link function*, which predicts a word's distribution given its context words, parameterized by their embeddings.

When it comes to documents, we wish to find a method to encode their overall semantics. Given the embeddings of each word in a document, we can imagine the document as a "bag-of-vectors". Related words in the document point in similar directions, forming *semantic clusters*. The centroid of a semantic cluster corresponds to the most representative embedding of this cluster of words, referred to as the *semantic centroids*. We could use these semantic centroids and the number of words around them to represent a document.

In addition, for a set of documents in a particular domain, some semantic clusters may appear in many documents. By learning collocation patterns across the documents, the derived semantic centroids could be more topical and less noisy.

Topic Models, represented by Latent Dirichlet Allocation (LDA) (Blei et al., 2003), are able to group words into topics according to their collocation patterns across documents. When the corpus is large enough, such patterns reflect their semantic relatedness, hence topic models can discover coherent topics. The probability of a word is governed by its latent topic, which is modeled as a categorical distribution in LDA. Typically, only a small number of topics are present in each document, and only a small number of words have high probability in each topic. This intuition motivated Blei et al. (2003) to regularize the topic distributions with Dirichlet priors.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 666–675,
Berlin, Germany, August 7-12, 2016.

Semantic centroids have the same nature as topics in LDA, except that the former exist in the embedding space. This similarity drives us to seek the common semantic centroids with a model similar to LDA. We extend a generative word embedding model PSDVec (Li et al., 2015), by incorporating topics into it. The new model is named TopicVec. In TopicVec, an embedding link function models the word distribution in a topic, in place of the categorical distribution in LDA. The advantage of the link function is that the semantic relatedness is already encoded as the *cosine* distance in the embedding space. Similar to LDA, we regularize the topic distributions with Dirichlet priors. A variational inference algorithm is derived. The learning process derives *topic embeddings* in the same embedding space of words. These topic embeddings aim to approximate the underlying semantic centroids.

To evaluate how well TopicVec represents documents, we performed two document classification tasks against eight existing topic modeling or document representation methods. Two setups of TopicVec outperformed all other methods on two tasks, respectively, with fewer features. In addition, we demonstrate that TopicVec can derive coherent topics based only on *one* document, which is not possible for topic models.

The source code of our implementation is available at https://github.com/askerlee/topicvec.

2 Related Work

Li et al. (2015) proposed a generative word embedding method PSDVec, which is the precursor of TopicVec. PSDVec assumes that the conditional distribution of a word given its context words can be factorized approximately into independent log-bilinear terms. In addition, the word embeddings and regression residuals are regularized by Gaussian priors, reducing their chance of overfitting. The model inference is approached by an efficient Eigendecomposition and blockwise-regression method (Li et al., 2016b). TopicVec differs from PSDVec in that in the conditional distribution of a word, it is not only influenced by its context words, but also by a topic, which is an embedding vector indexed by a latent variable drawn from a Dirichlet-Multinomial distribution.

Hinton and Salakhutdinov (2009) proposed to model topics as a certain number of binary hidden variables, which interact with all words in the document through weighted connections. Larochelle and Lauly (2012) assigned each word a unique topic vector, which is a summarization of the context of the current word.

Huang et al. (2012) proposed to incorporate global (document-level) semantic information to help the learning of word embeddings. The global embedding is simply a weighted average of the embeddings of words in the document.

Le and Mikolov (2014) proposed Paragraph Vector. It assumes each piece of text has a latent paragraph vector, which influences the distributions of all words in this text, in the same way as a latent word. It can be viewed as a special case of TopicVec, with the topic number set to 1. Typically, however, a document consists of multiple semantic centroids, and the limitation of only one topic may lead to underfitting.

Nguyen et al. (2015) proposed Latent Feature Topic Modeling (LFTM), which extends LDA to incorporate word embeddings as latent features. The topic is modeled as a mixture of the conventional categorical distribution and an embedding link function. The coupling between these two components makes the inference difficult. They designed a Gibbs sampler for model inference. Their implementation[1] is slow and infeasible when applied to a large corpous.

Liu et al. (2015) proposed Topical Word Embedding (TWE), which combines word embedding with LDA in a simple and effective way. They train word embeddings and a topic model separately on the same corpus, and then average the embeddings of words in the same topic to get the embedding of this topic. The topic embedding is concatenated with the word embedding to form the topical word embedding of a word. In the end, the topical word embeddings of all words in a document are averaged to be the embedding of the document. This method performs well on our two classification tasks. Weaknesses of TWE include: 1) the way to combine the results of word embedding and LDA lacks statistical foundations; 2) the LDA module requires a large corpus to derive semantically coherent topics.

Das et al. (2015) proposed Gaussian LDA. It uses pre-trained word embeddings. It assumes that words in a topic are random samples from a multivariate Gaussian distribution with the topic embedding as the mean. Hence the probability that a

$\boldsymbol{\phi}_i$	Mixing proportions of topics in doc d_i

Table 1: Table of notations

word belongs to a topic is determined by the Euclidean distance between the word embedding and the topic embedding. This assumption might be improper as the Euclidean distance is not an optimal measure of semantic relatedness between two embeddings[2].

3 Notations and Definitions

Throughout this paper, we use uppercase bold letters such as $\boldsymbol{S}, \boldsymbol{V}$ to denote a matrix or set, lowercase bold letters such as $\boldsymbol{v}_{w_i}$ to denote a vector, a normal uppercase letter such as N, W to denote a scalar constant, and a normal lowercase letter as s_i, w_i to denote a scalar variable.

Table 1 lists the notations in this paper.

In a document, a sequence of words is referred to as a *text window*, denoted by $w_i, \cdots, w_{i+l}$, or $w_i{:}w_{i+l}$. A text window of chosen size c before a word w_i defines the *context* of w_i as $w_{i-c}, \cdots, w_{i-1}$. Here w_i is referred to as the *focus word*. Each context word w_{i-j} and the focus word w_i comprise a bigram w_{i-j}, w_i.

We assume each word in a document is semantically similar to a *topic embedding*. Topic embeddings reside in the same N-dimensional space as word embeddings. When it is clear from context, topic embeddings are often referred to as *topic*s. Each document has K candidate topics, arranged in the matrix form $\boldsymbol{T}_i = (\boldsymbol{t}_{i1} \cdots \boldsymbol{t}_{iK})$, referred to as the *topic matrix*. Specifically, we fix $\boldsymbol{t}_{i1} = \boldsymbol{0}$, referring to it as the *null topic*.

In a document d_i, each word w_{ij} is assigned to a topic indexed by $z_{ij} \in \{1, \cdots, K\}$. Geometrically this means the embedding $\boldsymbol{v}_{w_{ij}}$ tends to align with the direction of $\boldsymbol{t}_{i,z_{ij}}$. Each topic $\boldsymbol{t}_{ik}$ has a document-specific prior probability to be assigned to a word, denoted as $\phi_{ik} = P(k|d_i)$. The vector $\boldsymbol{\phi}_i = (\phi_{i1}, \cdots, \phi_{iK})$ is referred to as the *mixing proportions* of these topics in document d_i.

[2]Almost all modern word embedding methods adopt the exponentiated cosine similarity as the link function, hence the cosine similarity may be assumed to be a better estimate of the semantic relatedness between embeddings derived from these methods.

4 Link Function of Topic Embedding

In this section, we formulate the distribution of a word given its context words and topic, in the form of a link function.

The core of most word embedding methods is a *link function* that connects the embeddings of a focus word and its context words, to define the distribution of the focus word. Li et al. (2015) proposed the following link function:

$$\begin{aligned} &P(w_c \mid w_0 : w_{c-1}) \\ \approx &P(w_c) \exp\Big\{ \boldsymbol{v}_{w_c}^\top \sum_{l=0}^{c-1} \boldsymbol{v}_{w_l} + \sum_{l=0}^{c-1} a_{w_l w_c} \Big\}. \quad (1) \end{aligned}$$

Here $a_{w_l w_c}$ is referred as the bigram residual, indicating the non-linear part not captured by $\boldsymbol{v}_{w_c}^\top \boldsymbol{v}_{w_l}$. It is essentially the logarithm of the normalizing constant of a softmax term. Some literature, e.g. (Pennington et al., 2014), refers to such a term as a bias term.

(1) is based on the assumption that the conditional distribution $P(w_c \mid w_0 : w_{c-1})$ can be factorized approximately into independent log-bilinear terms, each corresponding to a context word. This approximation leads to an efficient and effective word embedding algorithm *PSDVec* (Li et al., 2015). We follow this assumption, and propose to incorporate the topic of w_c in a way like a latent word. In particular, in addition to the context words, the corresponding embedding $\boldsymbol{t}_{ik}$ is included as a new log-bilinear term that influences the distribution of w_c. Hence we obtain the following extended link function:

$$\begin{aligned} &P(w_c \mid w_0{:}w_{c-1}, z_c, d_i) \approx P(w_c) \cdot \\ &\exp\Big\{ \boldsymbol{v}_{w_c}^\top \Big(\sum_{l=0}^{c-1} \boldsymbol{v}_{w_l} + \boldsymbol{t}_{z_c} \Big) + \sum_{l=0}^{c-1} a_{w_l w_c} + r_{z_c} \Big\}, \quad (2) \end{aligned}$$

where d_i is the current document, and r_{z_c} is the logarithm of the normalizing constant, named the *topic residual*. Note that the topic embeddings $\boldsymbol{t}_{z_c}$ may be specific to d_i. For simplicity of notation, we drop the document index in $\boldsymbol{t}_{z_c}$. To restrict the impact of topics and avoid overfitting, we constrain the magnitudes of all topic embeddings, so that they are always within a hyperball of radius γ.

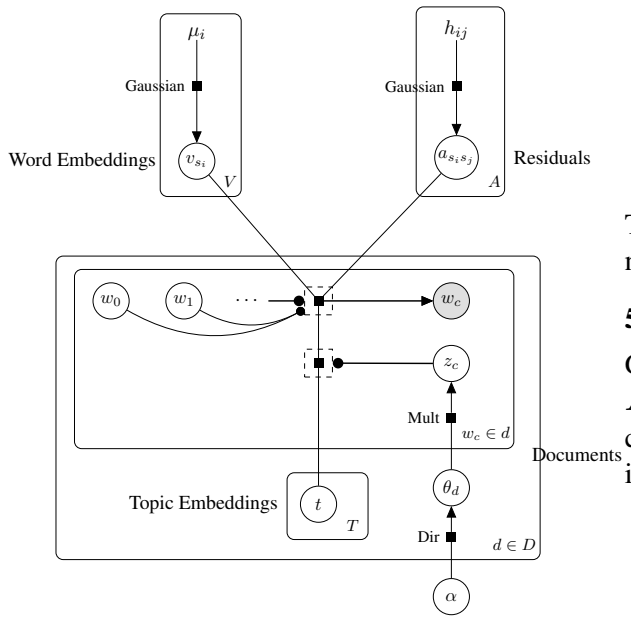

Figure 1: Graphical representation of TopicVec.

It is infeasible to compute the exact value of the topic residual r_k. We approximate it by the context size $c = 0$. Then (2) becomes:

$$P(w_c \mid k, d_i) = P(w_c) \exp\left\{\boldsymbol{v}_{w_c}^\top \boldsymbol{t}_k + r_k\right\}. \quad (3)$$

It is required that $\sum_{w_c \in \boldsymbol{S}} P(w_c \mid k) = 1$ to make (3) a distribution. It follows that

$$r_k = -\log\Big(\sum_{s_j \in \boldsymbol{S}} P(s_j) \exp\{\boldsymbol{v}_{s_j}^\top \boldsymbol{t}_k\}\Big). \quad (4)$$

(4) can be expressed in the matrix form:

$$\boldsymbol{r} = -\log(\boldsymbol{u} \exp\{\boldsymbol{V}^\top \boldsymbol{T}\}), \quad (5)$$

where $\boldsymbol{u}$ is the row vector of unigram probabilities.

5 Generative Process and Likelihood

The generative process of words in documents can be regarded as a hybrid of LDA and PSDVec. Analogous to PSDVec, the word embedding $\boldsymbol{v}_{s_i}$ and residual $a_{s_i s_j}$ are drawn from respective Gaussians. For the sake of clarity, we ignore their generation steps, and focus on the topic embeddings. The remaining generative process is as follows:

1. For the k-th topic, draw a topic embedding uniformly from a hyperball of radius γ, i.e. $\boldsymbol{t}_k \sim \text{Unif}(B_\gamma)$;
2. For each document d_i:
   (a) Draw the mixing proportions $\boldsymbol{\phi}_i$ from the Dirichlet prior $\text{Dir}(\boldsymbol{\alpha})$;
   (b) For the j-th word:
      i. Draw topic assignment z_{ij} from the categorical distribution $\text{Cat}(\boldsymbol{\phi}_i)$;
      ii. Draw word w_{ij} from $\boldsymbol{S}$ according to $P(w_{ij} \mid w_{i,j-c}{:}w_{i,j-1}, z_{ij}, d_i)$.

The above generative process is presented in plate notation in Figure (1).

5.1 Likelihood Function

Given the embeddings $\boldsymbol{V}$, the bigram residuals $\boldsymbol{A}$, the topics $\boldsymbol{T}_i$ and the hyperparameter $\boldsymbol{\alpha}$, the complete-data likelihood of a single document d_i is:

$$\begin{aligned}
&p(d_i, \boldsymbol{Z}_i, \boldsymbol{\phi}_i | \boldsymbol{\alpha}, \boldsymbol{V}, \boldsymbol{A}, \boldsymbol{T}_i) \\
=&p(\boldsymbol{\phi}_i|\boldsymbol{\alpha}) p(\boldsymbol{Z}_i|\boldsymbol{\phi}_i) p(d_i|\boldsymbol{V}, \boldsymbol{A}, \boldsymbol{T}_i, \boldsymbol{Z}_i) \\
=&\frac{\Gamma(\sum_{k=1}^K \alpha_k)}{\prod_{k=1}^K \Gamma(\alpha_k)} \prod_{j=1}^K \phi_{ij}^{\alpha_j - 1} \cdot \prod_{j=1}^{L_i} \Bigg(\phi_{i,z_{ij}} P(w_{ij}) \\
&\cdot \exp\Bigg\{ \boldsymbol{v}_{w_{ij}}^\top \Big(\sum_{l=j-c}^{j-1} \boldsymbol{v}_{w_{il}} + \boldsymbol{t}_{z_{ij}} \Big) \\
&+ \sum_{l=j-c}^{j-1} a_{w_{il} w_{ij}} + r_{i,z_{ij}} \Bigg\} \Bigg),
\end{aligned} \quad (6)$$

where $\boldsymbol{Z}_i = (z_{i1}, \cdots, z_{iL_i})$, and $\Gamma(\cdot)$ is the Gamma function.

Let $\boldsymbol{Z}, \boldsymbol{T}, \boldsymbol{\phi}$ denote the collection of all the document-specific $\{\boldsymbol{Z}_i\}_{i=1}^M, \{\boldsymbol{T}_i\}_{i=1}^M, \{\boldsymbol{\phi}_i\}_{i=1}^M$, respectively. Then the complete-data likelihood of the whole corpus is:

$$\begin{aligned}
&p(\boldsymbol{D}, \boldsymbol{A}, \boldsymbol{V}, \boldsymbol{Z}, \boldsymbol{T}, \boldsymbol{\phi} | \boldsymbol{\alpha}, \gamma, \boldsymbol{\mu}) \\
=&\prod_{i=1}^W P(\boldsymbol{v}_{s_i}; \mu_i) \prod_{i,j=1}^{W,W} P(a_{s_i s_j}; f(h_{ij})) \prod_k^K \text{Unif}(B_\gamma) \\
&\cdot \prod_{i=1}^M \{p(\boldsymbol{\phi}_i|\boldsymbol{\alpha}) p(\boldsymbol{Z}_i|\boldsymbol{\phi}_i) p(d_i|\boldsymbol{V}, \boldsymbol{A}, \boldsymbol{T}_i, \boldsymbol{Z}_i)\} \\
=&\frac{1}{\mathcal{Z}(\boldsymbol{H}, \boldsymbol{\mu}) U_\gamma^K} \exp\{-\sum_{i,j=1}^{W,W} f(h_{i,j}) a_{s_i s_j}^2 - \sum_{i=1}^W \mu_i \|\boldsymbol{v}_{s_i}\|^2\} \\
&\cdot \prod_{i=1}^M \Bigg\{ \frac{\Gamma(\sum_{k=1}^K \alpha_k)}{\prod_{k=1}^K \Gamma(\alpha_k)} \prod_{j=1}^K \phi_{ij}^{\alpha_j - 1} \cdot \prod_{j=1}^{L_i} \Bigg(\phi_{i,z_{ij}} P(w_{ij}) \\
&\cdot \exp\Big\{ \boldsymbol{v}_{w_{ij}}^\top \Big(\sum_{l=j-c}^{j-1} \boldsymbol{v}_{w_{il}} + \boldsymbol{t}_{z_{ij}} \Big) + \sum_{l=j-c}^{j-1} a_{w_{il} w_{ij}} + r_{i,z_{ij}} \Big\} \Bigg) \Bigg\},
\end{aligned} \quad (7)$$

where $P(\boldsymbol{v}_{s_i}; \mu_i)$ and $P(a_{s_i s_j}; f(h_{ij}))$ are the two Gaussian priors as defined in (Li et al., 2015).

Following the convention in (Li et al., 2015), $h_{ij}, \boldsymbol{H}$ are empirical bigram probabilities, $\boldsymbol{\mu}$ are the embedding magnitude penalty coefficients, and $\mathcal{Z}(\boldsymbol{H}, \boldsymbol{\mu})$ is the normalizing constant for word embeddings. U_γ is the volume of the hyperball of radius γ.

Taking the logarithm of both sides, we obtain

$$\begin{aligned}
&\log p(\boldsymbol{D}, \boldsymbol{A}, \boldsymbol{V}, \boldsymbol{Z}, \boldsymbol{T}, \boldsymbol{\phi} | \boldsymbol{\alpha}, \gamma, \boldsymbol{\mu}) \\
=&C_0 - \log \mathcal{Z}(\boldsymbol{H}, \boldsymbol{\mu}) - \|\boldsymbol{A}\|^2_{f(\boldsymbol{H})} - \sum_{i=1}^{W} \mu_i \|\boldsymbol{v}_{s_i}\|^2 \\
+&\sum_{i=1}^{M} \Bigg\{ \sum_{k=1}^{K} \log \phi_{ik} (m_{ik} + \alpha_k - 1) + \sum_{j=1}^{L_i} \Bigg(r_{i,z_{ij}} \\
+&\boldsymbol{v}_{w_{ij}}^\top \Big(\sum_{l=j-c}^{j-1} \boldsymbol{v}_{w_{il}} + \boldsymbol{t}_{z_{ij}} \Big) + \sum_{l=j-c}^{j-1} a_{w_{il} w_{ij}} \Bigg) \Bigg\}, \quad (8)
\end{aligned}$$

where $m_{ik} = \sum_{j=1}^{L_i} \delta(z_{ij} = k)$ counts the number of words assigned with the k-th topic in d_i, $C_0 = M \log \frac{\Gamma(\sum_{k=1}^{K} \alpha_k)}{\prod_{k=1}^{K} \Gamma(\alpha_k)} + \sum_{i,j=1}^{M,L_i} \log P(w_{ij}) - K \log U_\gamma$ is constant given the hyperparameters.

6 Variational Inference Algorithm

6.1 Learning Objective and Process

Given the hyperparameters $\boldsymbol{\alpha}, \gamma, \boldsymbol{\mu}$, the learning objective is to find the embeddings $\boldsymbol{V}$, the topics $\boldsymbol{T}$, and the word-topic and document-topic distributions $p(\boldsymbol{Z}_i, \boldsymbol{\phi}_i | d_i, \boldsymbol{A}, \boldsymbol{V}, \boldsymbol{T})$. Here the hyperparameters $\boldsymbol{\alpha}, \gamma, \boldsymbol{\mu}$ are kept constant, and we make them implicit in the distribution notations.

However, the coupling between $\boldsymbol{A}, \boldsymbol{V}$ and $\boldsymbol{T}, \boldsymbol{Z}, \boldsymbol{\phi}$ makes it inefficient to optimize them simultaneously. To get around this difficulty, we learn word embeddings and topic embeddings separately. Specifically, the learning process is divided into two stages:

1. In the first stage, considering that the topics have a relatively small impact to word distributions and the impact might be "averaged out" across different documents, we simplify the model by ignoring topics temporarily. Then the model falls back to the original PSDVec. The optimal solution $\boldsymbol{V}^*, \boldsymbol{A}^*$ is obtained accordingly;
2. In the second stage, we treat $\boldsymbol{V}^*, \boldsymbol{A}^*$ as constant, plug it into the likelihood function, and find the corresponding optimal $\boldsymbol{T}^*, p(\boldsymbol{Z}, \boldsymbol{\phi} | \boldsymbol{D}, \boldsymbol{A}^*, \boldsymbol{V}^*, \boldsymbol{T}^*)$ of the full model. As in LDA, this posterior is analytically intractable, and we use a simpler variational distribution $q(\boldsymbol{Z}, \boldsymbol{\phi})$ to approximate it.

6.2 Mean-Field Approximation and Variational GEM Algorithm

In this stage, we fix $\boldsymbol{V} = \boldsymbol{V}^*, \boldsymbol{A} = \boldsymbol{A}^*$, and seek the optimal $\boldsymbol{T}^*, p(\boldsymbol{Z}, \boldsymbol{\phi} | \boldsymbol{D}, \boldsymbol{A}^*, \boldsymbol{V}^*, \boldsymbol{T}^*)$. As $\boldsymbol{V}^*, \boldsymbol{A}^*$ are constant, we also make them implicit in the following expressions.

For an arbitrary variational distribution $q(\boldsymbol{Z}, \boldsymbol{\phi})$, the following equalities hold

$$\begin{aligned}
&E_q \log \left[\frac{p(\boldsymbol{D}, \boldsymbol{Z}, \boldsymbol{\phi} | \boldsymbol{T})}{q(\boldsymbol{Z}, \boldsymbol{\phi})} \right] \\
=&E_q \left[\log p(\boldsymbol{D}, \boldsymbol{Z}, \boldsymbol{\phi} | \boldsymbol{T}) \right] + \mathcal{H}(q) \\
=&\log p(\boldsymbol{D} | \boldsymbol{T}) - \mathrm{KL}(q || p), \quad (9)
\end{aligned}$$

where $p = p(\boldsymbol{Z}, \boldsymbol{\phi} | \boldsymbol{D}, \boldsymbol{T})$, $\mathcal{H}(q)$ is the entropy of q. This implies

$$\begin{aligned}
&\mathrm{KL}(q || p) \\
=&\log p(\boldsymbol{D} | \boldsymbol{T}) - \Big(E_q \left[\log p(\boldsymbol{D}, \boldsymbol{Z}, \boldsymbol{\phi} | \boldsymbol{T}) \right] + \mathcal{H}(q) \Big) \\
=&\log p(\boldsymbol{D} | \boldsymbol{T}) - \mathcal{L}(q, \boldsymbol{T}). \quad (10)
\end{aligned}$$

In (10), $E_q \left[\log p(\boldsymbol{D}, \boldsymbol{Z}, \boldsymbol{\phi} | \boldsymbol{T}) \right] + \mathcal{H}(q)$ is usually referred to as the *variational free energy* $\mathcal{L}(q, \boldsymbol{T})$, which is a lower bound of $\log p(\boldsymbol{D} | \boldsymbol{T})$. Directly maximizing $\log p(\boldsymbol{D} | \boldsymbol{T})$ w.r.t. $\boldsymbol{T}$ is intractable due to the hidden variables $\boldsymbol{Z}, \boldsymbol{\phi}$, so we maximize its lower bound $\mathcal{L}(q, \boldsymbol{T})$ instead. We adopt a mean-field approximation of the true posterior as the variational distribution, and use a variational algorithm to find $q^*, \boldsymbol{T}^*$ maximizing $\mathcal{L}(q, \boldsymbol{T})$.

The following variational distribution is used:

$$\begin{aligned}
&q(\boldsymbol{Z}, \boldsymbol{\phi}; \boldsymbol{\pi}, \boldsymbol{\theta}) = q(\boldsymbol{\phi}; \boldsymbol{\theta}) q(\boldsymbol{Z}; \boldsymbol{\pi}) \\
=&\prod_{i=1}^{M} \left\{ \mathrm{Dir}(\boldsymbol{\phi}_i; \boldsymbol{\theta}_i) \prod_{j=1}^{L_i} \mathrm{Cat}(z_{ij}; \boldsymbol{\pi}_{ij}) \right\}. \quad (11)
\end{aligned}$$

We can obtain (Li et al., 2016a)

$$\begin{aligned}
&\mathcal{L}(q, \boldsymbol{T}) \\
=&\sum_{i=1}^{M} \Bigg\{ \sum_{k=1}^{K} \Big(\sum_{j=1}^{L_i} \pi_{ij}^k + \alpha_k - 1 \Big) \Big(\psi(\theta_{ik}) - \psi(\theta_{i0}) \Big) \\
&+ \mathrm{Tr}(\boldsymbol{T}_i^\top \sum_{j=1}^{L_i} \boldsymbol{v}_{w_{ij}} \boldsymbol{\pi}_{ij}^\top) + \boldsymbol{r}_i^\top \sum_{j=1}^{L_i} \boldsymbol{\pi}_{ij} \Bigg\} \\
&+ \mathcal{H}(q) + C_1, \quad (12)
\end{aligned}$$

where $\boldsymbol{T}_i$ is the topic matrix of the i-th document, and $\boldsymbol{r}_i$ is the vector constructed by concatenating all the topic residuals r_{ik}. $C_1 = C_0 - \log \mathcal{Z}(\boldsymbol{H}, \boldsymbol{\mu}) - \|\boldsymbol{A}\|^2_{f(\boldsymbol{H})} - \sum_{i=1}^{W} \mu_i \|\boldsymbol{v}_{s_i}\|^2 + \sum_{i,j=1}^{M,L_i} \Big(\boldsymbol{v}_{w_{ij}}^\top \sum_{k=j-c}^{j-1} \boldsymbol{v}_{w_{ik}} + \sum_{k=j-c}^{j-1} a_{w_{ik} w_{ij}} \Big)$ is constant.

We proceed to optimize (12) with a Generalized Expectation-Maximization (GEM) algorithm w.r.t. q and $\boldsymbol{T}$ as follows:

1. Initialize all the topics $\boldsymbol{T}_i = \boldsymbol{0}$, and correspondingly their residuals $\boldsymbol{r}_i = \boldsymbol{0}$;
2. Iterate over the following two steps until convergence. In the l-th step:
   (a) Let the topics and residuals be $\boldsymbol{T} = \boldsymbol{T}^{(l-1)}, \boldsymbol{r} = \boldsymbol{r}^{(l-1)}$, find $q^{(l)}(\boldsymbol{Z}, \boldsymbol{\phi})$ that maximizes $\mathcal{L}(q, \boldsymbol{T}^{(l-1)})$. This is the Expectation step (E-step). In this step, $\log p(\boldsymbol{D}|\boldsymbol{T})$ is constant. Then the q that maximizes $\mathcal{L}(q, \boldsymbol{T}^{(l)})$ will minimize $\mathrm{KL}(q||p)$, i.e. such a q is the closest variational distribution to p measured by KL-divergence;
   (b) Given the variational distribution $q^{(l)}(\boldsymbol{Z}, \boldsymbol{\phi})$, find $\boldsymbol{T}^{(l)}, \boldsymbol{r}^{(l)}$ that improve $\mathcal{L}(q^{(l)}, \boldsymbol{T})$, using Gradient descent method. This is the generalized Maximization step (M-step). In this step, $\boldsymbol{\pi}, \boldsymbol{\theta}, \mathcal{H}(q)$ are constant.

6.2.1 Update Equations of $\boldsymbol{\pi}, \boldsymbol{\theta}$ in E-Step

In the E-step, $\boldsymbol{T} = \boldsymbol{T}^{(l-1)}, \boldsymbol{r} = \boldsymbol{r}^{(l-1)}$ are constant. Taking the derivative of $\mathcal{L}(q, \boldsymbol{T}^{(l-1)})$ w.r.t. π_{ij}^k and θ_{ik}, respectively, we can obtain the optimal solutions (Li et al., 2016a) at:

$$\pi_{ij}^k \propto \exp\{\psi(\theta_{ik}) + \boldsymbol{v}_{w_{ij}}^\top \boldsymbol{t}_{ik} + r_{ik}\}. \tag{13}$$

$$\theta_{ik} = \sum_{j=1}^{L_i} \pi_{ij}^k + \alpha_k. \tag{14}$$

6.2.2 Update Equation of $\boldsymbol{T}_i$ in M-Step

In the Generalized M-step, $\boldsymbol{\pi} = \boldsymbol{\pi}^{(l)}, \boldsymbol{\theta} = \boldsymbol{\theta}^{(l)}$ are constant. For notational simplicity, we drop their superscripts (l).

To update $\boldsymbol{T}_i$, we first take the derivative of (12) w.r.t. $\boldsymbol{T}_i$, and then take the Gradient Descent method.

The derivative is obtained as (Li et al., 2016a):

$$\frac{\partial \mathcal{L}(q^{(l)}, \boldsymbol{T})}{\partial \boldsymbol{T}_i} = \sum_{j=1}^{L_i} \boldsymbol{v}_{w_{ij}} \boldsymbol{\pi}_{ij}^\top + \sum_{k=1}^{K} \bar{m}_{ik} \frac{\partial r_{ik}}{\partial \boldsymbol{T}_i}, \tag{15}$$

where $\bar{m}_{ik} = \sum_{j=1}^{L_i} \pi_{ij}^k = E[m_{ik}]$, the sum of the variational probabilities of each word being assigned to the k-th topic in the i-th document. $\frac{\partial r_{ik}}{\partial \boldsymbol{T}_i}$ is a gradient matrix, whose j-th column is $\frac{\partial r_{ik}}{\partial \boldsymbol{t}_{ij}}$.

Remind that $r_{ik} = -\log\Big(E_{P(s)}[\exp\{\boldsymbol{v}_s^\top \boldsymbol{t}_{ik}\}]\Big)$. When $j \neq k$, it is easy to verify that $\frac{\partial r_{ik}}{\partial \boldsymbol{t}_{ij}} = \boldsymbol{0}$. When $j = k$, we have

$$\begin{aligned} \frac{\partial r_{ik}}{\partial \boldsymbol{t}_{ik}} &= e^{-r_{ik}} \cdot E_{P(s)}[\exp\{\boldsymbol{v}_s^\top \boldsymbol{t}_{ik}\} \boldsymbol{v}_s] \\ &= e^{-r_{ik}} \cdot \sum_{s \in W} \exp\{\boldsymbol{v}_s^\top \boldsymbol{t}_{ik}\} P(s) \boldsymbol{v}_s \\ &= e^{-r_{ik}} \cdot \exp\{\boldsymbol{t}_{ik}^\top \boldsymbol{V}\} (\boldsymbol{u} \circ \boldsymbol{V}), \end{aligned} \tag{16}$$

where $\boldsymbol{u} \circ \boldsymbol{V}$ is to multiply each column of $\boldsymbol{V}$ with $\boldsymbol{u}$ element-by-element.

Therefore $\frac{\partial r_{ik}}{\partial \boldsymbol{T}_i} = (\boldsymbol{0}, \cdots \frac{\partial r_{ik}}{\partial \boldsymbol{t}_{ik}}, \cdots, \boldsymbol{0})$. Plugging it into (15), we obtain

$$\frac{\partial \mathcal{L}(q^{(l)}, \boldsymbol{T})}{\partial \boldsymbol{T}_i} = \sum_{j=1}^{L_i} \boldsymbol{v}_{w_{ij}} \boldsymbol{\pi}_{ij}^\top + (\bar{m}_{i1} \frac{\partial r_{i1}}{\partial \boldsymbol{t}_{i1}}, \cdots, \bar{m}_{iK} \frac{\partial r_{iK}}{\partial \boldsymbol{t}_{iK}}).$$

We proceed to optimize $\boldsymbol{T}_i$ with a gradient descent method:

$$\boldsymbol{T}_i^{(l)} = \boldsymbol{T}^{(l-1)} + \lambda(l, L_i) \frac{\partial \mathcal{L}(q^{(l)}, \boldsymbol{T})}{\partial \boldsymbol{T}_i},$$

where $\lambda(l, L_i) = \frac{L_0 \lambda_0}{l \cdot \max\{L_i, L_0\}}$ is the learning rate function, L_0 is a pre-specified document length threshold, and λ_0 is the initial learning rate. As the magnitude of $\frac{\partial \mathcal{L}(q^{(l)}, \boldsymbol{T})}{\partial \boldsymbol{T}_i}$ is approximately proportional to the document length L_i, to avoid the step size becoming too big a on a long document, if $L_i > L_0$, we normalize it by L_i.

To satisfy the constraint that $\|\boldsymbol{t}_{ik}^{(l)}\| \leq \gamma$, when $\boldsymbol{t}_{ik}^{(l)} > \gamma$, we normalize it by $\gamma / \|\boldsymbol{t}_{ik}^{(l)}\|$.

After we obtain the new $\boldsymbol{T}$, we update $\boldsymbol{r}_i^{(m)}$ using (5).

Sometimes, especially in the initial few iterations, due to the excessively big step size of the gradient descent, $\mathcal{L}(q, \boldsymbol{T})$ may decrease after the update of $\boldsymbol{T}$. Nonetheless the general direction of $\mathcal{L}(q, \boldsymbol{T})$ is increasing.

6.3 Sharing of Topics across Documents

In principle we could use one set of topics across the whole corpus, or choose different topics for different subsets of documents. One could choose a way to best utilize cross-document information.

For instance, when the document category information is available, we could make the documents in each category share their respective set

of topics, so that M categories correspond to M sets of topics. In the learning algorithm, only the update of π_{ij}^k needs to be changed to cater for this situation: when the k-th topic is relevant to the document i, we update π_{ij}^k using (13); otherwise $\pi_{ij}^k = 0$.

An identifiability problem may arise when we split topic embeddings according to document subsets. In different topic groups, some highly similar redundant topics may be learned. If we project documents into the topic space, portions of documents in the same topic in different documents may be projected onto different dimensions of the topic space, and similar documents may eventually be projected into very different topic proportion vectors. In this situation, directly using the projected topic proportion vectors could cause problems in unsupervised tasks such as clustering. A simple solution to this problem would be to compute the pairwise similarities between topic embeddings, and consider these similarities when computing the similarity between two projected topic proportion vectors. Two similar documents will then still receive a high similarity score.

7 Experimental Results

To investigate the quality of document representation of our TopicVec model, we compared its performance against eight topic modeling or document representation methods in two document classification tasks. Moreover, to show the topic coherence of TopicVec on a single document, we present the top words in top topics learned on a news article.

7.1 Document Classification Evaluation

7.1.1 Experimental Setup

Compared Methods Two setups of TopicVec were evaluated:

- **TopicVec**: the topic proportions learned by TopicVec;
- **TV+WV**: the topic proportions, concatenated with the mean word embedding of the document (same as the MeanWV below).

We compare the performance of our methods against eight methods, including three topic modeling methods, three continuous document representation methods, and the conventional bag-of-words (**BOW**) method. The count vector of BOW is unweighted.

The topic modeling methods include:

- **LDA**: the vanilla LDA (Blei et al., 2003) in the gensim library[3];
- **sLDA**: Supervised Topic Model[4] (McAuliffe and Blei, 2008), which improves the predictive performance of LDA by modeling class labels;
- **LFTM**: Latent Feature Topic Modeling[5] (Nguyen et al., 2015).

The document-topic proportions of topic modeling methods were used as their document representation.

The document representation methods are:

- **Doc2Vec**: Paragraph Vector (Le and Mikolov, 2014) in the gensim library[6].
- **TWE**: Topical Word Embedding[7] (Liu et al., 2015), which represents a document by concatenating average topic embedding and average word embedding, similar to our TV+WV;
- **GaussianLDA**: Gaussian LDA[8] (Das et al., 2015), which assumes that words in a topic are random samples from a multivariate Gaussian distribution with the mean as the topic embedding. Similar to TopicVec, we derived the posterior topic proportions as the features of each document;
- **MeanWV**: The mean word embedding of the document.

Datasets We used two standard document classification corpora: the 20 Newsgroups[9] and the ApteMod version of the Reuters-21578 corpus[10]. The two corpora are referred to as the **20News** and **Reuters** in the following.

20News contains about 20,000 newsgroup documents evenly partitioned into 20 different categories. Reuters contains 10,788 documents, where each document is assigned to one or more categories. For the evaluation of document classification, documents appearing in two or more categories were removed. The numbers of documents in the categories of Reuters are highly imbalanced, and we only selected the largest 10 categories, leaving us with 8,025 documents in total.

[8] https://github.com/rajarshd/Gaussian_LDA
[9] http://qwone.com/~jason/20Newsgroups/
[10] http://www.nltk.org/book/ch02.html

The same preprocessing steps were applied to all methods: words were lowercased; stop words and words out of the word embedding vocabulary (which means that they are extremely rare) were removed.

Experimental Settings TopicVec used the word embeddings trained using PSDVec on a March 2015 Wikipedia snapshot. It contains the most frequent 180,000 words. The dimensionality of word embeddings and topic embeddings was 500. The hyperparameters were $\boldsymbol{\alpha} = (0.1, \cdots, 0.1), \gamma = 5$. For 20news and Reuters, we specified 15 and 12 topics in each category on the training set, respectively. The first topic in each category was always set to null. The learned topic embeddings were combined to form the whole topic set, where redundant null topics in different categories were removed, leaving us with 281 topics for 20News and 111 topics for Reuters. The initial learning rate was set to 0.1. After 100 GEM iterations on each dataset, the topic embeddings were obtained. Then the posterior document-topic distributions of the test sets were derived by performing one E-step given the topic embeddings trained on the training set.

LFTM includes two models: LF-LDA and LF-DMM. We chose the better performing LF-LDA to evaluate. TWE includes three models, and we chose the best performing TWE-1 to compare.

LDA, sLDA, LFTM and TWE used the specified 50 topics on Reuters, as this is the optimal topic number according to (Lu et al., 2011). On the larger 20news dataset, they used the specified 100 topics. Other hyperparameters of all compared methods were left at their default values.

GaussianLDA was specified 100 topics on 20news and 70 topics on Reuters. As each sampling iteration took over 2 hours, we only had time for 100 sampling iterations.

For each method, after obtaining the document representations of the training and test sets, we trained an ℓ-1 regularized linear SVM one-vs-all classifier on the training set using the scikit-learn library[11]. We then evaluated its predictive performance on the test set.

Evaluation metrics Considering that the largest few categories dominate Reuters, we adopted macro-averaged precision, recall and F1 measures as the evaluation metrics, to avoid the average results being dominated by the performance of the top categories.

[1]Combined features of TopicVec topic proportions and MeanWV.

Table 2: Performance on multi-class text classification. Best score is in boldface.

Avg. Features	BOW	MeanWV	TWE	TopicVec	TV+WV
20News	50381	500	800	281	781
Reuters	17989	500	800	111	611

Table 3: Number of features of the five best performing methods.

Evaluation Results Table 2 presents the performance of the different methods on the two classification tasks. The highest scores were highlighted with boldface. It can be seen that TV+WV and TopicVec obtained the best performance on the two tasks, respectively. With only topic proportions as features, TopicVec performed slightly better than BOW, MeanWV and TWE, and significantly outperformed four other methods. The number of features it used was much lower than BOW, MeanWV and TWE (Table 3).

GaussianLDA performed considerably inferior to all other methods. After checking the generated topic embeddings manually, we found that the embeddings for different topics are highly similar to each other. Hence the posterior topic proportions were almost uniform and non-discriminative. In addition, on the two datasets, even the fastest Alias sampling in (Das et al., 2015) took over 2 hours for one iteration and 10 days for the whole 100 iterations. In contrast, our method finished the 100 EM iterations in 2 hours.

Figure 2: Topic Cloud of the pharmaceutical company acquisition news.

7.2 Qualitative Assessment of Topics Derived from a Single Document

Topic models need a large set of documents to extract coherent topics. Hence, methods depending on topic models, such as TWE, are subject to this limitation. In contrast, TopicVec can extract coherent topics and obtain document representations even when only one document is provided as input.

To illustrate this feature, we ran TopicVec on a New York Times news article about a pharmaceutical company acquisition[12], and obtained 20 topics.

Figure 2 presents the most relevant words in the top-6 topics as a *topic cloud*. We first calculated the relevance between a word and a topic as the frequency-weighted cosine similarity of their embeddings. Then the most relevant words were selected to represent each topic. The sizes of the topic slices are proportional to the topic proportions, and the font sizes of individual words are proportional to their relevance to the topics. Among these top-6 topics, the largest and smallest topic proportions are 26.7% and 9.9%, respectively.

As shown in Figure 2, words in obtained topics were generally coherent, although the topics were only derived from a single document. The reason is that TopicVec takes advantage of the rich semantic information encoded in word embeddings, which were pretrained on a large corpus.

The topic coherence suggests that the derived topic embeddings were approximately the semantic centroids of the document. This capacity may aid applications such as document retrieval, where a "compressed representation" of the query document is helpful.

8 Conclusions and Future Work

In this paper, we proposed TopicVec, a generative model combining word embedding and LDA, with the aim of exploiting the word collocation patterns both at the level of the local context and the global document. Experiments show that TopicVec can learn high-quality document representations, even given only one document.

In our classification tasks we only explored the use of topic proportions of a document as its representation. However, jointly representing a document by topic proportions and topic embeddings would be more accurate. Efficient algorithms for this task have been proposed (Kusner et al., 2015).

Our method has potential applications in various scenarios, such as document retrieval, classification, clustering and summarization.

Abstract

News reader comments found in many on-line news websites are typically massive in amount. We investigate the task of **C**ultural-common **T**opic **D**etection (CTD), which is aimed at discovering common discussion topics from news reader comments written in different languages. We propose a new probabilistic graphical model called MCTA which can cope with the language gap and capture the common semantics in different languages. We also develop a partially collapsed Gibbs sampler which effectively incorporates the term translation relationship into the detection of cultural-common topics for model parameter learning. Experimental results show improvements over the state-of-the-art model.

1 Introduction

Nowadays the rapid development of information and communication technology enables more and more people around the world to engage in the movement of globalization. One effect of globalization is to facilitate greater connections between people bringing cultures closer than before. This also contributes to the convergence of some elements of different cultures (Melluish, 2014). For example, there is a growing tendency of people watching the same movie, listening to the same music, and reading the news about the same event. This kind of cultural homogenization brings the emergence of commonality of some aspects of different cultures worldwide. It would be beneficial to identify such common aspects among cultures. For example, it can provide some insights for global market and international business (Cavusgil et al., 2014).

Many news websites from different regions in the world report significant events which are of interests to people from different continents. These websites also allow readers around the world to give their comments in their own languages. The volume of comments is often enormous especially for popular events. In a news website, readers from a particular culture background tend to write comments in their own preferred languages. For some important or global events, we observe that readers from different cultures, via different languages, express common discussion topics. For instance, on March 8 2014, Malaysia Airlines Flight MH370, carrying 227 passengers and 12 crew members, disappeared. Upon the happening of this event, many news articles around the world reported it and many readers from different continents commented on this event. Through analyzing the reader comments manually, we observe that both English-speaking and Chinese-speaking readers expressed in their corresponding languages their desire for praying for the MH370 flight. This is an example of a **cultural-common** discussion topic. Identifying such cultural-common topics automatically can facilitate better understanding and organization of the common concerns or interests of readers with different language background. Such technology can be deployed for developing various applications. One application is to build a reader comment digest system that can organize comments by cultural-common discussion topics and rank the topics by popularity. This provides a functionality of analyzing the common focus of readers from different cultures on a particular event. An example of such application is shown in Figure 3. Under each event, reader comments are grouped by cultural-common topics.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 676–685,
Berlin, Germany, August 7-12, 2016.

In this paper, we investigate the task of **C**ultural-common **T**opic **D**etection (CTD) on multilingual news reader comments. Reader comments about a global event, written in different languages, from different news websites around the world exist in massive amount. The main goal of this task is to discover cultural-common discussion topics from raw multilingual news reader comments for a news event. One challenge is that the discussion topics are unknown. Another challenge is related to the language gap issue. Precisely, the words of reader comments in different languages are composed of different terms in their corresponding languages. Such language gap issue poses a great deal of challenge for identifying cultural-common discussion topics in multilingual news comments settings.

One recent work done by Prasojo et al. (2015) is to organize news reader comments around entities and aspects discussed by readers. Such organization of reader comments cannot handle the identification of common discussion topics. On the other hand, the Muto model proposed by Boyd-Graber and Blei (2009) can extract common topics from multilingual documents. This model merely outputs cross-lingual topics of matching word pairs. One example of such kind of topic contains key terms of word pairs such as "plane:飞机 ocean:海洋 ...". The assumption of one-to-one mapping of words has some drawbacks. One drawback is that the correspondence of identified common topics is restricted to the vocabulary level. Another drawback is that the one-to-one mapping of words cannot fit the original word occurrences well. For example, the English term "plane" appears in the English documents frequently while the Chinese translation "飞机" appears less. It is not reasonable that "plane" and "飞机" share the same probability mass in common topics. Another closely related existing work is the PCLSA model proposed by Zhang et al. (2010). PCLSA employs a mixture of English words and Chinese words to represent common topics. It incorporates bilingual constraints into the Probabilistic Latent Semantic Analysis (PLSA) model (Hofmann, 2001) and assumes that word pairs in the dictionary share similar probability in a common topic. However, similar to one-to-one mapping of words, such bilingual constraints cannot handle well the original word co-occurrence in each language resulting in a degradation of the coherence and interpretability of common topics.

We propose a new probabilistic graphical model which is able to detect cultural-common topics from multilingual news reader comments in an unsupervised manner. In principle, no labeled data is needed. In this paper, we focus on dealing with two languages, namely, English and Chinese news reader comments. Different from prior works, we design a technique based on auxiliary distributions which incorporates word distributions from the other language and can capture the common semantics on the topic level. We develop a partially collapsed Gibbs sampler which decouples the inference of topic distribution and word distribution. We also incorporate the term translation relationship, derived from a bilingual dictionary, into the detection of cultural-common topics for model parameter learning.

We have prepared a data set by collecting English and Chinese reader comments from different regions reflecting different culture. Our experimental results are encouraging showing improvements over the state-of-the-art model.

2 Related Work

Prasojo et al. (2015) and Biyani et al. (2015) organized news reader comments via identified entities or aspects. Such kind of organization via entities or aspects cannot capture common topics discussed by readers. Digesting merely based on entities fails to work in multilingual settings due to the fact that the common entities have distinct mentions in different languages.

Zhai et al. (2004) discovered common topics from comparable texts via a PLSA based mixture model. Paul and Girju (2009) proposed a Mixed-Collection Topic Model for finding common topics from different collections. Despite the fact that the above models can find a kind of common topic, they only deal with a single language setting without considering the language gap.

Some works discover common latent topics from multilingual corpora. For aligned corpora, they assume that the topic distribution in each document is the same (Vulić et al., 2011; Vulić and Moens, 2014; Erosheva et al., 2004; Fukumasu et al., 2012; Mimno et al., 2009; Ni et al., 2009; Zhang et al., 2013; Peng et al., 2014). However, aligned corpora are often unavailable for most domains. For unaligned corpora, cross-lingual topic models use some language resources, such

as a bilingual dictionary or a bilingual knowledge base to bridge the language gap (Boyd-Graber and Blei, 2009; Zhang et al., 2010; Jagarlamudi and Daumé III, 2010). As mentioned above, the goals of Boyd-Graber and Blei (2009) as well as Jagarlamud and Daumé (2010) focus on mining the correspondence of topics at the vocabulary level, which are different from that of Zhang et al. (2010) and ours. The model in Zhang et al. (2010) adds the constraints of word translation pairs into PLSA. These constraints cannot handle the original word co-occurrences well. In contrast, we consider the language gap by incorporating word distributions from the other language, capturing the common semantics on the topic level. Moreover, we use a fully Bayesian paradigm with a prior distribution.

Some existing topic methods conduct cross-lingual sentiment analysis (Lu et al., 2011; Guo et al., 2010; Lin et al., 2014; Boyd-Graber and Resnik, 2010). These models are not suitable for our CTD task because they mainly detect common elements related to product aspects. Moreover some works focus more on detecting sentiments.

3 Our Proposed Model

3.1 Model Description

The problem definition of the CTD task is described as follows. For a particular event, both English and Chinese news reader comments are collected from different regions reflecting different culture. The set of English comments is denoted by $\mathcal{E}$ and the set of Chinese comments is denoted by $\mathcal{C}$. The goal of the CTD task is to extract cultural-common topics $k \in \{1, 2, \ldots, K\}$ from $\mathcal{E}$ and $\mathcal{C}$. The set of multilingual news reader comments of each event are processed within the same event.

Our proposed model is called **M**ultilingual **C**ultural-common **T**opic **A**nalysis (MCTA) which is based on graphical model paradigm as depicted in Figure 1. The plate on the right represents cultural-common topics. Each cultural-common topic k is represented by an English word distribution φ_k^e over English vocabulary Λ^e and a Chinese word distribution φ_k^c over Chinese vocabulary Λ^c. We make use of a bilingual dictionary, which is composed of many-to-many word translations among English and Chinese words. To capture common semantics of multilingual news reader comments, we design two auxiliary distributions η_e, with dimension Λ^e, and η_c, with dimension Λ^c, to help the generation of φ_k^e and φ_k^c. Precisely, we generate η_e and η_c from the Dirichlet prior distributions $Dir(\beta \cdot \mathbf{1}_{|\Lambda^e|})$ and $Dir(\beta \cdot \mathbf{1}_{|\Lambda^c|})$ respectively, where $\mathbf{1}_D$ denotes a D-dimensional vector whose components are 1. Then we draw φ_k^e from the mixture of η_k^e and the translation of η_k^c. It is formulated as:

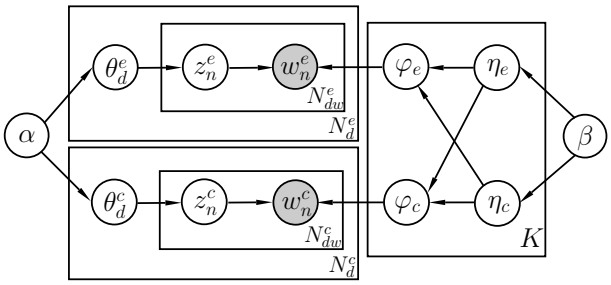

Figure 1: Our proposed graphical model

$$\varphi_k^e \propto \lambda(\eta_k^c)^T \mathbf{M}^{c \to e} + (1-\lambda)\eta_k^e \quad \text{where} \quad \eta^e, \eta^c \sim Dir(\beta) \tag{1}$$

where $\lambda \in (0, 1)$ is a parameter which balances the nature of original topics and transferred information from the other language. $\mathbf{M}^{c \to e}$ is a mapping $|\Lambda^c| \times |\Lambda^e|$ matrix from Λ^c to Λ^e. Each element $M_{ij}^{c \to e}$ is the mapping occurrence probability of the English term w_j^e given the Chinese term w_i^c in the set of news reader comments. This probability is calculated as:

$$M_{ij}^{c \to e} = \frac{C(w_j^e) + 1}{|T(w_i^c)| + \sum_{w^e \in T(w_i^c)} C(w^e)} \tag{2}$$

where $C(w_j^e)$ is the count of w_j^e in all news reader comments and $T(w_i^c)$ is the set of English translations of w_i^c found in the bilingual dictionary. The "add-one" smoothing is adopted. Note that the sum of each row is equal to 1. Using the same principle, we can derive φ_k^c which can be formulated as:

$$\varphi_k^c \propto \lambda(\eta_k^e)^T M^{e \to c} + (1-\lambda)\eta_k^c \quad \text{where} \quad \eta^e, \eta^c \sim Dir(\beta) \tag{3}$$

As a result, the incorporation of η_k^e and η_k^c on the topic level encourages the word distribution φ_k^e and φ_k^c to share common semantic components of reader comments in different languages.

The upper left plate in Figure 1 represents English reader comments. N_d^e denotes the number of English reader comments and N_{dw}^e denotes

the number of words in the English comment d^e. Each English reader comment d^e is characterized by a K-dimensional topic membership vector θ_d^e, which is assumed to be generated by the prior $Dir(\alpha \cdot \mathbf{1}_K)$. For each word w_n^e in an English comment d^e, we generate the topic z_e^n from θ_d^e. We generate the word w_n^e from the corresponding distribution φ_k^e.

The bottom left plate in Figure 1 represents Chinese reader comments. Similarly, we generate the topic distribution θ_d^c from the prior $Dir(\alpha \cdot \mathbf{1}_K)$. The topic z_c^n of each word w_n^c in a Chinese comment d^c is generated from θ_d^c. We generate word w_n^c from the corresponding distribution φ_k^c.

The generative process is formally depicted as:

- For each topic $k \in \mathcal{K}$
  - choose auxiliary distributions $\eta_k^e \sim Dir(\beta \cdot \mathbf{1}_{|\Lambda^e|})$ and $\eta_k^c \sim Dir(\beta \cdot \mathbf{1}_{|\Lambda^c|})$
  - choose English word distribution φ_k^e and φ_k^c using Eq. 1 and Eq. 3 respectively.
- For each English comment $d^e \in \mathcal{E}$, choose $\theta_d^e \sim Dir(\alpha \cdot \mathbf{1}_K)$
  - For each position n in d^e
    - draw $z_n^e \sim$ Multi(θ_d^e)
    - draw $w_n^e \sim$ Multi(φ_k^e)
- For each Chinese comment $d^c \in \mathcal{C}$, choose $\theta_d^c \sim Dir(\alpha \cdot \mathbf{1}_K)$
  - For each position n in d^c
    - draw $z_n^c \sim$ Multi(θ_d^c)
    - draw $w_n^c \sim$ Multi(φ_k^c)

Note that for simplicity, we present our model on the bilingual setting of Chinese and English. It can be extended to multilingual setting via introducing auxiliary distributions for each language. Each topic word distribution for each language is generated by the convex combination of all the auxiliary distributions.

3.2 Posterior Inference

In order to decouple the inference of z_n and φ_k for each language, we develop a partially collapsed Gibbs method which just discards θ_d^e and θ_d^c. Given φ_k^e, we sample the new assignments of the topic z_{di}^e in English news reader comments d^e with the following conditional probability:

$$P(z_{di}^e = k|\mathbf{z}^{e,\neg i}, W^e, \alpha, \varphi_k^e) \propto (N_{dk}^{e,\neg i} + \alpha_k) \times \varphi_k^e \tag{4}$$

where $\mathbf{z}^{e,\neg i}$ denotes the topic assignments except the assignment of the ith word. N_{dk}^e is the number of words in English document d^e whose topics are assigned to k. Similarly, we sample z_{di}^c with the following equation:

$$P(z_{di}^c = k|\mathbf{z}^{c,\neg i}, W^c, \alpha, \varphi_k^c) \propto (N_{dk}^{c,\neg i} + \alpha_k) \times \varphi_k^c \tag{5}$$

Given the topic assignments, the probability of the entire comment set can be:

$$p(W|\mathbf{z}, \varphi_k^e, \varphi_k^c) = \prod_{w \in \Lambda^e} (\varphi_{kw}^e)^{N_{kw}^e} \times \prod_{w \in \Lambda^c} (\varphi_{kw}^c)^{N_{kw}^c} \tag{6}$$

where N_{kw}^e is the number of words w in English news reader comments assigned to the topic k and N_{kw}^c is the number of words w in Chinese news reader comments assigned to the topic k.

Using Eq. 6, we can obtain the posterior likelihood related to η_k^e and η_k^c:

$$\begin{aligned}\mathcal{L}_{MAP} = & \\ & \sum_{w_i \in \Lambda^e} N_{kw_i}^e \log(\lambda \sum_{w_j \in \Lambda^c} M_{ji}^{c \to e} \eta_{kw_j}^c + (1-\lambda)\eta_{kw_i}^e) \\ & + \sum_{w_i \in \Lambda^c} N_{kw_i}^c \log(\lambda \sum_{w_j \in \Lambda^e} M_{ji}^{e \to c} \eta_{kw_j}^e + (1-\lambda)\eta_{kw_i}^c) \\ & + \sum_{w_i \in \Lambda^e} (\beta - 1) \log \eta_{kw_i}^e + \sum_{w_i \in \Lambda^c} (\beta - 1) \log \eta_{kw_i}^c\end{aligned} \tag{7}$$

We optimize Eq. 7 under the constraints of $\sum_{w_i \in \Lambda^e} \eta_{kw_i}^e = 1$ and $\sum_{w_i \in \Lambda^c} \eta_{kw_i}^c = 1$. Using the fixed-point method, we obtain the update

Algorithm 1 Partially Collapsed Gibbs Sampling for MCTA

```
Initialize z, φ_k^e, φ_k^c, η_k^e, η_k^c

            draw z_n^e using Eq. 4
        end for
    end for
    for each Chinese comment d in C do
        for each word w_n^c in d do
            draw z_n^c using Eq. 5.
        end for
    end for
    Update η_k^e, η_k^c by Eq. 8 and Eq. 9
    Update φ_k^e, φ_k^c according to Eq. 1 and Eq. 3
end for
Output θ_dk by Eq. 10
```

equations of $\eta^e_{kw_t}$ and $\eta^c_{kw_t}$ shown in Eq. 8 and Eq. 9.

$$\eta^e_{kw_t} \propto [\frac{(1-\lambda)N^e_{kw_t}}{\lambda \sum_{w_j \in \Lambda^c} M^{c\to e}_{jt} \eta^c_{kw_j} + (1-\lambda)\eta^e_{kw_t}} + \sum_{w_i \in \Lambda^c} \frac{\lambda N^c_{kw_i} M^{e\to c}_{ti}}{\lambda \sum_{w_j \in \Lambda^e} M^{e\to c}_{ji} \eta^e_{kw_j} + (1-\lambda)\eta^c_{kw_i}}]\eta^e_{kw_t} + \beta \tag{8}$$

$$\eta^c_{kw_t} \propto [\frac{(1-\lambda)N^c_{kw_t}}{\lambda \sum_{w_j \in \Lambda^e} M^{e\to c}_{jt} \eta^e_{kw_j} + (1-\lambda)\eta^c_{kw_t}} + \sum_{w_i \in \Lambda^e} \frac{\lambda N^e_{kw_i} M^{c\to e}_{ti}}{\lambda \sum_{w_j \in \Lambda^c} M^{c\to e}_{ji} \eta^c_{kw_j} + (1-\lambda)\eta^e_{kw_i}}]\eta^c_{kw_t} + \beta \tag{9}$$

Moreover, the posterior estimates for the topic distribution θ_d can be computed as follows.

$$\theta_{dk} = \frac{N_{dk} + \alpha}{\sum_{k \in \mathcal{K}} N_{dk} + K\alpha} \tag{10}$$

The whole detailed algorithm is depicted in Algorithm 1. When $\lambda = 0$, the updated equations of η^e_k and η^c_k can be simplified as:

$$\begin{aligned} \eta^e_{kw_t} &\propto N^e_{kw_t} + \beta \\ \eta^c_{kw_t} &\propto N^c_{kw_t} + \beta \end{aligned} \tag{11}$$

Then we have:

$$\begin{aligned} \varphi^e_k &\sim Dir(N^e_{kw_1} + \beta, N^e_{kw_2} + \beta, \dots) \\ \varphi^c_k &\sim Dir(N^c_{kw_1} + \beta, N^c_{kw_2} + \beta, \dots) \end{aligned} \tag{12}$$

Therefore, the algorithm degrades to a Gibbs sampler of LDA.

4 Experiments

4.1 Data Set and Preprocessing

We have prepared a data set by collecting English and Chinese comments from different regions reflecting different culture for some significant events as depicted in Table 1. The English reader comments are collected from Yahoo[1] and the Chinese reader comments are collected from Sina News[2]. We first remove news reader comments whose length is less than 5 words. We remove the punctuations and the stop words. For English comments, we also stem each word to its root form using Porter Stemmer (Porter, 1980). For the Chinese reader comments, we use the Jieba package[3] to segment and remove Chinese stop words. We utilize an English-Chinese dictionary from MDBG[4].

Event	Title	#English comments	#Chinese comments
1	MH370 flight accident	8608	5223
2	ISIS in Iraq	6341	3263
3	Ebola occurs	2974	1622
4	Taiwan Crashed Plane	6780	2648
5	iphone6 publish	5837	4352
6	Shooting of Michael Brown	17547	3693
7	Charlie Hebdo shooting	1845	551
8	Shanghai stampede	3824	3175
9	Lee Kuan Yew death	2418	1534
10	AIIB foundation	7221	3198

Table 1: The statistics for the data set

4.2 Comparative Methods

The PCLSA model proposed by Zhang et al. (2010) can be regarded as the state-of-the-art model for detecting latent common topics from multilingual text documents. We implemented PCLSA as one of the comparative methods in our experiments.

Another comparative model used in the experiment is LDA (Blei et al., 2003), which can generate K English topics and K Chinese topics from English and Chinese reader comments respectively. Then we translate Chinese topics into English topics and use symmetric KL divergence to align translated Chinese topics with original English topics. Each aligned topic pair is regarded as a cultural-common topic.

4.3 Experiment Settings

For each event, we partitioned the comments into a subset of 90% for the graphical model parameter estimation. The remaining 10% is used as a holdout data for the evaluation of the *CCP* metric as discussed in Section 4.4.1. We repeated the runs five times. For each run, we randomly split the comments to obtain the holdout data. As a result, we have five runs for our method as well as comparative methods. We make use of the holdout data of one event, namely the event "MH370

Flight Accident", to estimate the number of topics K for all models and λ in Eq. 1 for our model. The setting of K is described in Section 4.4.3. We set $\lambda = 0.5$ after tuning. For hyper-parameters, we set α to 0.5 and β to 0.01. When performing our Gibbs algorithm, we set the maximum iteration number as 1000, and the burn-in sweeps as 100.

4.4 Cultural-common Topic Evaluation

We conduct quantitative experiments to evaluate how well our MCTA model can discover cultural-common topics.

4.4.1 Evaluation Metrics

We use two metrics to evaluate the topic quality. The first metric is the "cross-collection perplexity" measure denoted as *CCP* which is similar to the one used in Zhang et al. (2010). The *CCP* of high quality cultural-common topics should be lower than those topics which are not shared by the English and Chinese reader comments. The calculation of *CCP* consists of two steps: *1)* For each $k \in \mathcal{K}$, we translate φ_k^e into Chinese word distribution $T(\varphi_k^e)$ and translate φ_k^c English word distribution $T(\varphi_k^c)$. To translate φ_k^e and φ_k^c, we look up the bilingual dictionary and conduct word-to-word translation. If one word has several translations, we distribute its probability mass equally to each English translation. *2)* We use $T(\varphi_k^e)$ to fit the holdout Chinese comments $\mathcal{C}$ and $T(\varphi_k^c)$ to fit the holdout English comments $\mathcal{E}$ using Eq. 13 (Blei et al., 2003). Eq. 13 depicts the calculation of *CCP*. The lower the *CCP* value is, the better the performance is.

$$
\begin{aligned}
&CCP = \\
&\frac{1}{2}\exp\{-\frac{\sum_{d\in\mathcal{E}}\sum_{w\in d}\sum_{k\in\mathcal{K}}\log p(k|\theta_d)p(w|T(\varphi_k^c))}{\sum_{d\in\mathcal{E}} N_d^e}\}+ \\
&\frac{1}{2}\exp\{-\frac{\sum_{d\in\mathcal{C}}\sum_{w\in d}\sum_{k\in\mathcal{K}}\log p(k|\theta_d)p(w|T(\varphi_k^e))}{\sum_{d\in\mathcal{C}} N_d^c}\}
\end{aligned}
\tag{13}
$$

For each detected common topic, we wish to evaluate the degree of commonality. We design another metric called "topic commonality distance" denoted by *TCD*. We first evaluate the KL-divergence between the English topic and translated Chinese topic. We also evaluate the KL-divergence between the Chinese topic and translated English topic. Then *TCD* is computed as the average sum of the two KL-divergences. The lower the *TCD* measure is, the better the topic is.

Event	LDA	PCLSA	MCTA
1	1963.57	1842.24	1784.05
2	1940.03	1831.55	1756.92
3	1958.09	1905.43	1808.01
4	1916.49	1847.16	1775.32
5	1901.44	1797.92	1744.07
6	1916.70	1853.66	1786.77
7	1945.22	1897.15	1824.10
8	1942.29	1862.14	1749.43
9	1943.53	1856.70	1739.66
10	1866.23	1815.44	1749.49
avg.	1929.36	1850.94	**1771.78**

Table 2: Topic quality evaluation as measured by *CCP*

The topic detected by PCLSA is a mixture of English and Chinese words. We obtain English representation and Chinese representation of the topic by the conditional probabilities as given in Eq. 14.

$$
\begin{aligned}
p(w^e|\varphi_k^e) &= \frac{p(w^e|\varphi_k)}{\sum_{w\in\Lambda^e} p(w|\varphi_k)} \\
p(w^c|\varphi_k^c) &= \frac{p(w^c|\varphi_k)}{\sum_{w\in\Lambda^c} p(w|\varphi_k)}
\end{aligned}
\tag{14}
$$

4.4.2 Experimental Results

The average *CCP* values of the three models are shown in Table 2. Our MCTA model achieves the best performance compared with PCLSA and LDA. Both MCTA and PCLSA achieve a better *CCP* than LDA because they can bridge the language gap in the multilingual news reader comments to some extent. Compared with PCLSA, our MCTA model demonstrates a 4.2% improvement. Our MCTA model provides a better characterization of the collections. One reason is that our MCTA model learns the word distribution of cultural-common topics using an effective topic modeling with a prior Dirichlet distribution. It is similar to the advantage of LDA over PLSA. Moreover, the bilingual constraints in PCLSA cannot handle the original natural word co-occurrence well in each language. In contrast, MCTA represents cultural-common topics as a mixture of the original topics and the translated topics, which capture the comment semantics more effectively.

The average *TCD* of three models are shown in Table 3. Our MCTA outperforms the two comparative methods. The cultural-common topics iden-

Table 4: Topic coherence evaluation

tified by MCTA have better topic commonality because our MCTA model can capture the common semantics between news reader comments in different languages.

4.4.3 Determining Number of Topics

As mentioned in Section 4.3, we use the hold-out data of one event to determine K. For each $\lambda \in \{0.2, 0.5, 0.8\}$, we vary K in the range of $[5, 200]$. Figure 2 depicts the effect of K on the cross-collection perplexity as measured by *CCP*. We can see that *CCP* decreases with the increase of the number of topics. Moreover, through manual inspection we observed that when K is 30 or more, even though *CCP* decreases, the topics will be repeated. Similar observations for the number of topics can be found in Paul and Girju (2009). Therefore, we set $K = 30$. We can also see that our model is not very sensitive to the balance parameter λ.

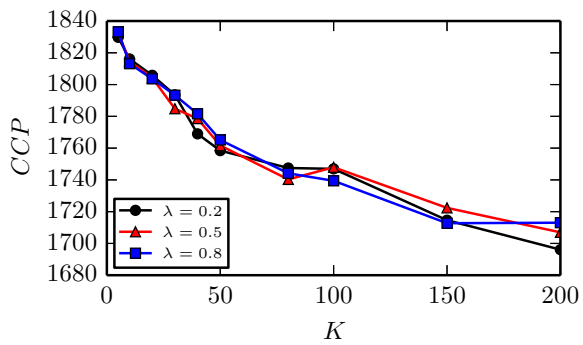

Figure 2: The effect of K

4.5 Topic Coherence Evaluation

We also evaluate the coherence of topics generated by PCLSA and MCTA, which indicates the interpretability of topics. Following Newman et al. (2010), we use a pointwise mutual information (PMI) score to measure the topic coherence. We compute the average PMI score of top 20 topic word pairs using Eq. 15. Newman et al. (2010) observed that it is important to use an external data set to evaluate PMI. Therefore, we use a 20-word sliding window in Wikipedia (Shaoul, 2010) to identify the co-occurrence of word pairs.

$$PMI(w_i, w_j) = \log \frac{P(w_i, w_j)}{P(w_i)P(w_j)} \qquad (15)$$

The experimental results are shown in Table 4. We can see that our MCTA model generally improves the coherence of the learned topics compared with PCLSA. The word-to-word bilingual constraints in PCLSA are not as effective. On the other hand, our MTCA model incorporates the bilingual translations using auxiliary distributions which incorporate word distributions from the other language on the topic level and can capture common semantics of multilingual reader comments.

5 Application and Case Study

We present an application for news comment digest and show some examples of detected cultural-common discussion topics in Figure 3. Under each event, the system can group reader comments into cultural-common discussion topics which can capture common concerns of readers in different languages. For each common topic, it shows top ranked words and corresponding reader comments

Figure 3: Some sample common discussion topics of some events

according to θ^e_{dk} and θ^c_{dk}. Considering the event "MH370 Flight accident", it shows two of the detected cultural-common topics. The first one indicates that readers pray for the family in the accident and the second one is related to the search of the crashed plane. For the common topic about praying for the family, we can see that the topics contain both English words and Chinese words which are very relevant and share common semantics of "family" and "hope". Moreover, the corresponding English and Chinese reader comments, both of which mention the family in the accident, illustrate a high coherent common discussion topic. Similarly for the second common topic, there are common semantics between English and Chinese top ranked words about the search of the crashed plane. Some of the English comments and Chinese comments mention the query of the position of the crashed plane. Interesting common topics are also generated for other events, such as the common topic of religion for the event "ISIS in Iraq" and the topic of economic organization for the event "AIIB foundation".

6 Conclusions

We investigate the task of cultural-common discussion topic detection from multilingual news reader comments. To tackle the task, we develop a new model called MCTA which can cope with the language gap and extract coherent cultural-common topics from multilingual news reader comments. We also develop a partially collapsed Gibbs sampler which incorporates the term translation relationship into the detection of cultural-common topics effectively for model parameter learning.

Abstract

Document collections often have links between documents—citations, hyperlinks, or revisions—and which links are added is often based on topical similarity. To model these intuitions, we introduce a new topic model for documents situated within a network structure, integrating latent blocks of documents with a max-margin learning criterion for link prediction using topic- and word-level features. Experiments on a scientific paper dataset and collection of webpages show that, by more robustly exploiting the rich link structure within a document network, our model improves link prediction, topic quality, and block distributions.

1 Introduction

Documents often appear within a network structure: social media mentions, retweets, and follower relationships; Web pages by hyperlinks; scientific papers by citations. Network structure interacts with the topics in the text, in that documents linked in a network are more likely to have similar topic distributions. For instance, a citation link between two papers suggests that they are about a similar field, and a mentioning link between two social media users often indicates common interests. Conversely, documents' similar topic distributions can suggest links between them. For example, topic model (Blei et al., 2003, LDA) and block detection papers (Holland et al., 1983) are relevant to our research, so we cite them. Similarly, if a social media user A finds another user B with shared interests, then A is more likely to follow B.

Our approach is part of a natural progression of network modeling in which models integrate more information in more sophisticated ways. Some past methods only consider the network itself (Kim and Leskovec, 2012; Liben-Nowell and Kleinberg, 2007), which loses the rich information in text. In other cases, methods take both links and text into account (Chaturvedi et al., 2012), but they are modeled separately, not jointly, limiting the model's ability to capture interactions between the two. The *relational topic model* (Chang and Blei, 2010, RTM) goes further, jointly modeling topics and links, but it considers only pairwise document relationships, failing to capture network structure at the level of groups or *blocks* of documents.

We propose a new joint model that makes fuller use of the rich link structure within a document network. Specifically, our model embeds the *weighted stochastic block model* (Aicher et al., 2014, WSBM) to identify blocks in which documents are densely connected. WSBM basically categorizes each item in a network probabilistically as belonging to one of L blocks, by reviewing its connections with each block. Our model can be viewed as a principled probabilistic extension of Yang et al. (2015), who identify blocks in a document network deterministically as *strongly connected components* (SCC). Like them, we assign a distinct Dirichlet prior to each block to capture its topical commonalities. Jointly, a linear regression model with a discriminative, max-margin objective function (Zhu et al., 2012; Zhu et al., 2014) is trained to reconstruct the links, taking into account the features of documents' topic and word distributions (Nguyen et al., 2013), block assignments, and inter-block link rates.

We validate our approach on a scientific paper abstract dataset and collection of webpages, with citation links and hyperlinks respectively, to predict links among previously unseen documents and from those new documents to training documents. Embedding the WSBM in a network/topic

Berlin, Germany, August 7-12, 2016.

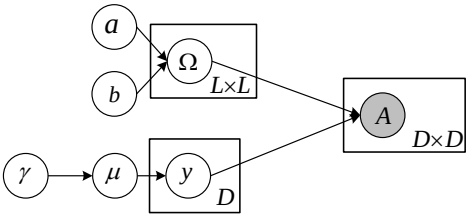

Figure 1: Weighted Stochastic Block Model

model leads to substantial improvements in link prediction over previous models; it also improves block detection and topic interpretability. The key advantage in embedding WSBM is its flexibility and robustness in the face of noisy links. Our results also lend additional support for using max-margin learning for a "downstream" supervised topic model (McAuliffe and Blei, 2008), and that predictions from lexical as well as topic features improves performance (Nguyen et al., 2013).

The rest of this paper is organized as follows. Section 2 introduces two previous link-modeling methods, WSBM and RTM. Section 3 presents our methods to incorporate block priors in topic modeling and include various features in link prediction, as well as the aggregated discriminative topic model whose posterior inference is introduced in Section 4. In Section 5 we show how our model can improve link prediction and (often) improve topic coherence.

2 Dealing with Links

2.1 Weighted Stochastic Block Model

WSBM (Aicher et al., 2014) is a generalized *stochastic block model* (Holland et al., 1983; Wang and Wong, 1987, SBM) and predicts non-negative integer-weight links, instead of binary-weight links. A block is a collection of documents which are densely connected with each other but sparsely connected with documents in other blocks. WSBM assumes that a document belongs to exactly one block. A link connecting two documents in blocks l and l' has a weight generated from a Poisson distribution with parameters $\Omega_{l,l'}$ which has a Gamma prior with parameters a and b, as Figure 1 shows.

The whole generative process is:

1. For each pair of blocks $(l, l') \in \{1, \dots, L\}^2$
   (a) Draw inter-block link rate $\Omega_{l,l'} \sim \text{Gamma}(a, b)$
2. Draw block distribution $\boldsymbol{\mu} \sim \text{Dir}(\gamma)$
3. For each document $d \in \{1, \dots, D\}$
   (a) Draw block assignment $y_d \sim \text{Mult}(\boldsymbol{\mu})$
4. For each link $(d, d') \in \{1, \dots, D\}^2$
   (a) Draw link weight $A_{d,d'} \sim \text{Poisson}(\Omega_{y_d, y_{d'}})$

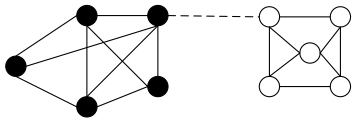

Figure 2: SCC can be distracted by spurious links connecting two groups, while WSBM maintains the distinction.

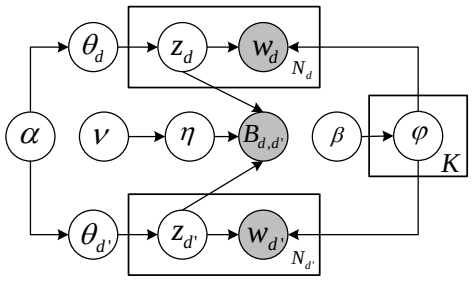

Figure 3: A Two-document Segment of RTM

WSBM is a probabilistic block detection algorithm and more robust than some deterministic algorithms like SCC, which is vulnerable to noisy links. For instance, we would intuitively say Figure 2 has two blocks—as denoted by coloring—whether or not the dashed link exists. If the dashed link does not exist, both WSBM and SCC can identify two blocks. However, if the dashed link does exist, SCC will return only one big block that contains all nodes, while WSBM still keeps the nodes in two reasonable blocks.

2.2 Relational Topic Model

RTM (Chang and Blei, 2010) is a downstream model that generates documents and links simultaneously (Figure 3). Its generative process is:

1. For each topic $k \in \{1, \dots, K\}$
   (a) Draw word distribution $\boldsymbol{\phi_k} \sim \text{Dir}(\beta)$
   (b) Draw topic regression parameter $\eta_k \sim \mathcal{N}(0, \nu^2)$
2. For each document $d \in \{1, \dots, D\}$
   (a) Draw topic distribution $\boldsymbol{\theta_d} \sim \text{Dir}(\alpha)$
   (b) For each token $t_{d,n}$ in document d
      i. Draw topic assignment $z_{d,n} \sim \text{Mult}(\boldsymbol{\theta_d})$
      ii. Draw word $w_{d,n} \sim \text{Mult}(\boldsymbol{\phi}_{\boldsymbol{z_{d,n}}})$
3. For each explicit link (d, d')
   (a) Draw link weight $B_{d,d'} \sim \Psi(\cdot \mid \boldsymbol{z_d}, \boldsymbol{z_{d'}}, \boldsymbol{\eta})$

In the inference process, the updating of topic assignments is guided by links so that linked documents are more likely to have similar topic distributions. Meanwhile, the linear regression (whose

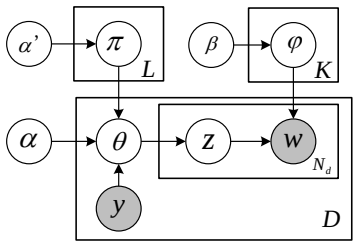

Figure 4: Graphical Model of BP-LDA

output is fed into link probability function Ψ) is updated to maximize the network likelihood using current topic assignments.

3 Discriminative Topic Model with Block Prior and Various Features

Our model is able to identify blocks from the network with an embedded WSBM, extract topic patterns of each block as prior knowledge, and use all this information to reconstruct the links.

3.1 LDA with Block Priors (BP-LDA)

As argued in the introduction, linked documents are likely to have similar topic distributions, which can be generalized to documents in the same block. Inspired by this intuition and the block assignment we obtain in the previous section, we want to extract some prior knowledge from these blocks. Thus we propose an LDA with block priors, hence BP-LDA, as shown in Figure 4, which has the following generative process:

1. For each topic $k \in \{1, \dots, K\}$
   (a) Draw word distribution $\boldsymbol{\phi_k} \sim \text{Dir}(\beta)$
2. For each block $l \in \{1, \dots, L\}$
   (a) Draw topic distribution $\boldsymbol{\pi_l} \sim \text{Dir}(\alpha')$
3. For each document $d \in \{1, \dots, D\}$
   (a) Draw topic distribution $\boldsymbol{\theta_d} \sim \text{Dir}(\alpha \boldsymbol{\pi_{y_d}})$
   (b) For each token $t_{d,n}$ in document d
      i. Draw topic assignment $z_{d,n} \sim \text{Mult}(\boldsymbol{\theta_d})$
      ii. Draw word $w_{d,n} \sim \text{Mult}(\boldsymbol{\phi_{z_{d,n}}})$

Unlike conventional LDA, which uses an uninformative topic prior, BP-LDA puts a Dirichlet prior $\boldsymbol{\pi}$ on each block to capture the block's topic distribution and use it as an informative prior when drawing each document's topic distribution. In other words, a document's topic distribution—i.e., what the document is about—is not just informed by the words present in the document but the broader context of its network neighborhood.

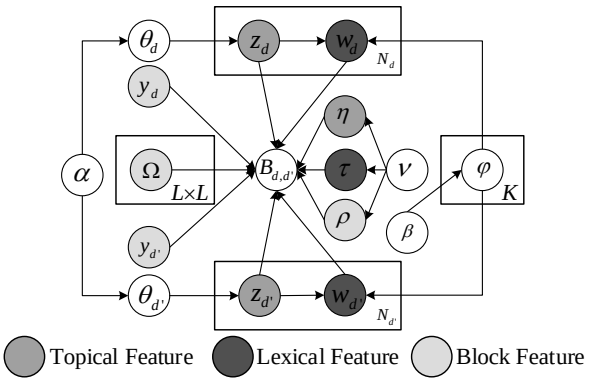

Figure 5: A two-document segment of VF-RTM. Various features are denoted by grayscale. $B_{d,d'}$ is observed, but we keep it in white background to avoid confusion.

3.2 RTM with Various Features (VF-RTM)

Building on Chang and Blei (2010), we want to generate the links between documents based on various features, hence VF-RTM. In addition to topic distributions, VF-RTM also includes documents' word distributions (Nguyen et al., 2013) and the link rate of two documents' assigned blocks, with the intent that these additional features improve link generation. VF-RTM involves the relationship between a pair of documents, so it is difficult to show the whole model; therefore Figure 5 illustrates with a two-document segment. The generative process is:

1. For each pair of blocks $(l, l') \in \{1, \dots, L\}^2$
   (a) Draw block regression parameter $\rho_{l,l'} \sim \mathcal{N}(0, \nu^2)$
2. For each topic $k \in \{1, \dots, K\}$
   (a) Draw word distribution $\boldsymbol{\phi_k} \sim \text{Dir}(\beta)$
   (b) Draw topic regression parameter $\eta_k \sim \mathcal{N}(0, \nu^2)$
3. For each word $v \in \{1, \dots, V\}$
   (a) Draw lexical regression parameter $\tau_v \sim \mathcal{N}(0, \nu^2)$
4. For each document $d \in \{1, \dots, D\}$
   (a) Draw topic distribution $\boldsymbol{\theta_d} \sim \text{Dir}(\alpha)$
   (b) For each token $t_{d,n}$ in document d
      i. Draw topic assignment $z_{d,n} \sim \text{Mult}(\boldsymbol{\theta_d})$
      ii. Draw word $w_{d,n} \sim \text{Mult}(\boldsymbol{\phi_{z_{d,n}}})$
5. For each explicit link (d, d')
   (a) Draw link weight $B_{d,d'} \sim \Psi(\cdot \mid y_d, y_{d'}, \boldsymbol{\Omega}, \boldsymbol{z_d}, \boldsymbol{z_{d'}}, \boldsymbol{w_d}, \boldsymbol{w_{d'}}, \boldsymbol{\eta}, \boldsymbol{\tau}, \boldsymbol{\rho})$

Links are generated by a link probability function Ψ which takes the regression value $R_{d,d'}$ of documents d and d' as an argument. Assuming documents d and d' belong to blocks l and l' respectively, $R_{d,d'}$ is

$$R_{d,d'} = \boldsymbol{\eta}^{\mathrm{T}}(\overline{\boldsymbol{z}}_d \circ \overline{\boldsymbol{z}}_{d'}) + \boldsymbol{\tau}^{\mathrm{T}}(\overline{\boldsymbol{w}}_d \circ \overline{\boldsymbol{w}}_{d'}) + \rho_{l,l'}\Omega_{l,l'}, \quad (1)$$

where $\overline{\boldsymbol{z}}_d$ is a K-length vector with each element $\overline{z}_{d,k} = \frac{1}{N_d}\sum_n \mathbb{1}(z_{d,n} = k)$; $\overline{\boldsymbol{w}}_d$ is a V-length vector with each element $\overline{w}_{d,v} = \frac{1}{N_d}\sum_n \mathbb{1}(w_{d,n} = v)$; $\circ$ denotes the Hadamard (element-wise) product;[1] $\boldsymbol{\eta}$, $\boldsymbol{\tau}$, and $\boldsymbol{\rho}$ are the weight vectors and matrix for topic-based, lexical-based and rate-based predictions, respectively.

A common choice of Ψ is a sigmoid (Chang and Blei, 2010). However, we instead use hinge loss so that VF-RTM can use the max-margin principle, making more effective use of side information when inferring topic assignments (Zhu et al., 2012). Using hinge loss, the probability that documents d and d' are linked is

$$\Pr(B_{d,d'}) = \exp(-2\max(0, \zeta_{d,d'})), \quad (2)$$

where $\zeta_{d,d'} = 1 - B_{d,d'}R_{d,d'}$. Positive and negative link weights are denoted by 1 and -1, respectively, in contrast to sigmoid loss.

3.3 Aggregated Model

Finally, we put all the pieces together and propose LBH-RTM: RTM with lexical weights (L), block priors (B), and hinge loss (H). Its graphical model is given in Figure 6.

1. For each pair of blocks $(l, l') \in \{1, \dots, L\}^2$
   (a) Draw inter-block link rate $\Omega_{l,l'} \sim \text{Gamma}(a, b)$
   (b) Draw block regression parameter $\rho_{l,l'} \sim \mathcal{N}(0, \nu^2)$
2. Draw block distribution $\boldsymbol{\mu} \sim \text{Dir}(\gamma)$
3. For each block $l \in \{1, \dots, L\}$
   (a) Draw topic distribution $\boldsymbol{\pi_l} \sim \text{Dir}(\alpha')$
4. For each topic $k \in \{1, \dots, K\}$
   (a) Draw word distribution $\boldsymbol{\phi_k} \sim \text{Dir}(\beta)$
   (b) Draw topic regression parameter $\eta_k \sim \mathcal{N}(0, \nu^2)$
5. For each word $v \in \{1, \dots, V\}$
   (a) Draw lexical regression parameter $\tau_v \sim \mathcal{N}(0, \nu^2)$
6. For each document $d \in \{1, \dots, D\}$
   (a) Draw block assignment $y_d \sim \text{Mult}(\boldsymbol{\mu})$
   (b) Draw topic distribution $\boldsymbol{\theta_d} \sim \text{Dir}(\alpha \boldsymbol{\pi}_{\boldsymbol{y_d}})$
   (c) For each token $t_{d,n}$ in document d
      i. Draw topic assignment $z_{d,n} \sim \text{Mult}(\boldsymbol{\theta_d})$
      ii. Draw word $w_{d,n} \sim \text{Mult}(\boldsymbol{\phi}_{\boldsymbol{z_{d,n}}})$
7. For each link $(d, d') \in \{1, \dots, D\}^2$
   (a) Draw link weight $A_{d,d'} \sim \text{Poisson}(\Omega_{y_d, y_{d'}})$
8. For each explicit link (d, d')
   (a) Draw link weight $B_{d,d'} \sim \Psi(\cdot \mid y_d, y_{d'}, \boldsymbol{\Omega}, \boldsymbol{z_d}, \boldsymbol{z_{d'}}, \boldsymbol{w_d}, \boldsymbol{w_{d'}}, \boldsymbol{\eta}, \boldsymbol{\tau}, \boldsymbol{\rho})$

$\boldsymbol{A}$ and $\boldsymbol{B}$ are assumed independent in the model, but they can be derived from the same set of links in practice.

[1] As Chang and Blei (2010) point out, the Hadamard product is able to capture similarity between hidden topic representations of two documents.

Algorithm 1 Sampling Process

```
1:  Set λ = 1 and initialize topic assignments
2:  for m = 1 to M do
3:      Optimize η, τ, and ρ using L-BFGS
4:      for d = 1 to D do
5:          Draw block assignment y_d
6:          for each token n do
7:              Draw a topic assignment z_{d,n}
8:          end for
9:          for each explicit link (d, d') do
10:             Draw λ^{-1}_{d,d'} (and then λ_{d,d'})
11:         end for
12:     end for
13: end for
```

Link set $\boldsymbol{A}$ is primarily used to find blocks, so it treats all links *deterministically*. In other words, the links observed in the input are considered explicit positive links, while the unobserved links are considered explicit negative links, in contrast to the implicit links in $\boldsymbol{B}$.

In terms of link set $\boldsymbol{B}$, while it adopts all explicit positive links from the input, it *does not deny* the existence of unobserved links, or implicit negative links. Thus $\boldsymbol{B}$ consists of only explicit positive links. However, to avoid overfitting, we sample some implicit links and add them to $\boldsymbol{B}$ as explicit negative links.

4 Posterior Inference

Posterior inference (Algorithm 1) consists of the sampling of topic and block assignments and the optimization of weight vectors and matrix.[2] We add an auxiliary variable $\boldsymbol{\lambda}$ for hinge loss (see Section 4.2), so the updating of $\boldsymbol{\lambda}$ is not necessary when using sigmoid loss.

The sampling procedure is an iterative process after initialization (Line 1). In each iteration, we first optimize the weight vectors and matrix (Line 3) before updating documents' block assignments (Line 5) and topic assignments (Line 7). When using hinge loss, the auxiliary variable $\boldsymbol{\lambda}$ for every explicit link needs to be updated (Line 10).

4.1 Sampling Block Assignments

Block assignment sampling is done by Gibbs sampling, using the block assignments and links in $\boldsymbol{A}$

[2] More details about sampling procedures and equations in this section (including the sampling and optimization equations using sigmoid loss) are available in the supplementary material.

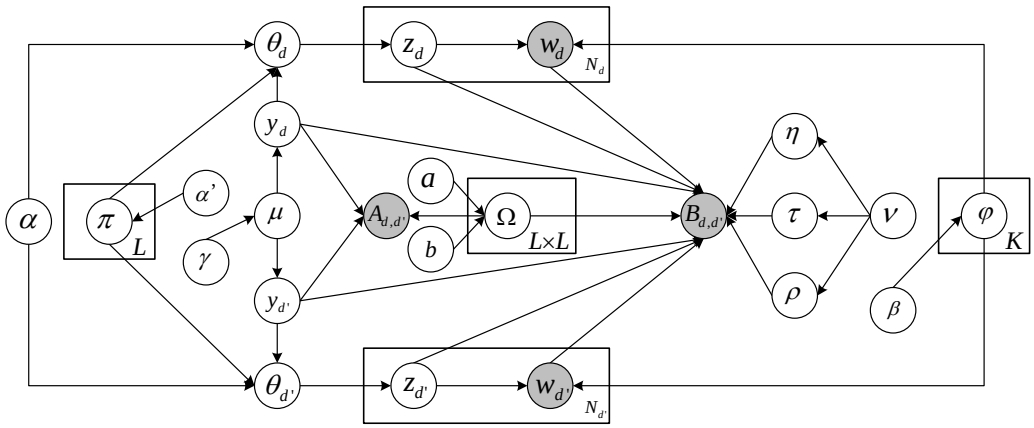

Figure 6: The graphical model of LBH-RTM for two documents, in which a weighted stochastic block model is embedded (γ, μ, y, a, b, $\boldsymbol{\Omega}$, and $\boldsymbol{A}$). Each document's topic distribution has an informative prior $\boldsymbol{\pi}$. The model predicts links between documents ($\boldsymbol{B}$) based on topics ($\boldsymbol{z}$), words ($\boldsymbol{w}$), and inter-block link rates ($\boldsymbol{\Omega}$), using a max-margin objective.

excluding document d and its related links.[3] The probability that d is assigned to block l is

$$\Pr(y_d = l \mid \boldsymbol{A}_{-d}, \boldsymbol{y}_{-d}, a, b, \gamma) \propto \left(N_l^{-d} + \gamma\right) \times \prod_{l'} \frac{\left(S_e^{-d}(l,l') + b\right)^{S_w^{-d}(l,l')+a}}{\left(S_e^{-d}(l,l') + b + S_e(d,l')\right)^{S_w^{-d}(l,l')+a+S_w(d,l')}} \prod_{i=0}^{S_w(d,l')-1} \left(S_w^{-d}(l,l') + a + i\right), \quad (3)$$

where N_l is the number of documents assigned to block l; $^{-d}$ denotes that the count excludes document d; $S_w(d,l)$ and $S_w(l,l')$ are the sums of link weights from document d to block l and from block l to block l', respectively:

$$S_w(d,l) = \sum_{d':y_{d'}=l} A_{d,d'} \quad (4)$$

$$S_w(l,l') = \sum_{d:y_d=l} S_w(d,l'). \quad (5)$$

$S_e(d,l)$ is the number of possible links from document d to l (i.e., assuming document d connects to every document in block l), which equals N_l. The number of possible links from block l to l' is $S_e(l,l')$ (i.e., assuming every document in block l connects to every document in block l'):

$$S_e(l,l') = \begin{cases} N_l \times N_{l'} & l \neq l' \\ \frac{1}{2} N_l(N_l - 1) & l = l'. \end{cases} \quad (6)$$

If we rearrange the terms of Equation 3 and put the terms which have $S_w(d,l')$ together, the value of $S_w(d,l')$ increases (i.e., document d is more densely connected with documents in block l'), the probability of assigning d to block l decreases exponentially. Thus if d is more densely connected with block l and sparsely connected with other blocks, it is more likely to be assigned to block l.

4.2 Sampling Topic Assignments

Following Polson and Scott (2011), by introducing an auxiliary variable $\lambda_{d,d'}$, the conditional probability of assigning $t_{d,n}$, the n-th token in document d, to topic k is

$$\Pr(z_{d,n} = k \mid \boldsymbol{z}_{-d,n}, \boldsymbol{w}_{-d,n}, w_{d,n} = v, y_d = l) \propto \left(N_{d,k}^{-d,n} + \alpha \pi_{l,k}^{-d,n}\right) \frac{N_{k,v}^{-d,n} + \beta}{N_{k,\cdot}^{-d,n} + V\beta} \prod_{d'} \exp\left(-\frac{(\zeta_{d,d'} + \lambda_{d,d'})^2}{2\lambda_{d,d'}}\right), \quad (7)$$

where $N_{d,k}$ is the number of tokens in document d that are assigned to topic k; $N_{k,v}$ denotes the count of word v assigned to topic k; Marginal counts are denoted by $\cdot$; $^{-d,n}$ denotes that the count excludes $t_{d,n}$; d' denotes all documents that have explicit links with document d. The block topic prior $\pi_{l,k}^{-d,n}$ is estimated based on the maximal path assumption (Cowans, 2006; Wallach, 2008):

$$\pi_{l,k}^{-d,n} = \frac{\sum_{d':y_{d'}=l} N_{d',k}^{-d,n} + \alpha'}{\sum_{d':y_{d'}=l} N_{d',\cdot}^{-d,n} + K\alpha'}. \quad (8)$$

the link prediction argument $\zeta_{d,d'}$ is

$$\zeta_{d,d'} = 1 - B_{d,d'}\left(\frac{\eta_k}{N_{d,\cdot}} \frac{N_{d',k}}{N_{d',\cdot}} + R_{d,d'}^{-d,n}\right). \quad (9)$$

[3] These equations deal with undirected edges, but they can be adapted for directed edges. See supplementary material.

where

$$R_{d,d'}^{-d,n} = \sum_{k=1}^{K} \eta_k \frac{N_{d,k}^{-d,n}}{N_{d,\cdot}} \frac{N_{d',k}}{N_{d',\cdot}} + \sum_{v=1}^{V} \tau_v \frac{N_{d,v}}{N_{d,\cdot}} \frac{N_{d',v}}{N_{d',\cdot}} + \rho_{y_d, y_{d'}} \Omega_{y_d, y_{d'}}. \quad (10)$$

Looking at the first term of Equation 7, the probability of assigning $t_{d,n}$ to topic k depends not only on its own topic distribution, but also the topic distribution of the block it belongs to. The links also matter: Equation 9 gives us the intuition that a topic which could increase the likelihood of links is more likely to be selected, which forms an interaction between topics and the link graph—the links are guiding the topic sampling while updating topic assignments is maximizing the likelihood of the link graph.

4.3 Parameter Optimization

While topic assignments are updated iteratively, the weight vectors and matrix $\boldsymbol{\eta}$, $\boldsymbol{\tau}$, and $\boldsymbol{\rho}$ are optimized in each global iteration over the whole corpus using L-BFGS (Liu and Nocedal, 1989). It takes the likelihood of generating $\boldsymbol{B}$ using $\boldsymbol{\eta}$, $\boldsymbol{\tau}$, $\boldsymbol{\rho}$, and current topic and block assignments as the objective function, and optimizes it using the partial derivatives with respect to every weight vector/matrix element.

The log likelihood of $\boldsymbol{B}$ using hinge loss is

$$\mathcal{L}(\boldsymbol{B}) \propto -\sum_{d,d'} \frac{R_{d,d'}^2 - 2(1+\lambda_{d,d'}) B_{d,d'} R_{d,d'}}{2\lambda_{d,d'}} - \sum_{k=1}^{K} \frac{\eta_k^2}{2\nu^2} - \sum_{v=1}^{V} \frac{\tau_v^2}{2\nu^2} - \sum_{l=1}^{L} \sum_{l'=1}^{L} \frac{\rho_{l,l'}^2}{2\nu^2}. \quad (11)$$

We also need to update the auxiliary variable $\lambda_{d,d'}$. Since the likelihood of $\lambda_{d,d'}$ follows a generalized inverse Gaussian distribution $\mathrm{GIG}\left(\lambda_{d,d'}; \frac{1}{2}, 1, \zeta_{d,d'}^2\right)$, we sample its reciprocal $\lambda_{d,d'}^{-1}$ from an inverse Gaussian distribution as

$$\Pr\left(\lambda_{d,d'}^{-1} \mid \boldsymbol{z}, \boldsymbol{w}, \boldsymbol{\eta}, \boldsymbol{\tau}, \boldsymbol{\rho}\right) = \mathrm{IG}\left(\lambda_{d,d'}^{-1}; \frac{1}{|\zeta_{d,d'}|}, 1\right). \quad (12)$$

5 Experimental Results

We evaluate using the two datasets. The first one is CORA dataset (McCallum et al., 2000). After removing stopwords and words that appear in fewer than ten documents, as well as documents with no words or links, our vocabulary has 1,240 unique words. The corpus has 2,362 computer science paper abstracts with 4,231 citation links.

LBH-RTM	**360.38**	**111.79**

Table 1: Predictive Link Rank Results

The second dataset is WEBKB. It is already preprocessed and has 1,703 unique words in vocabulary. The corpus has 877 web pages with 1,608 hyperlinks.

We treat all links as undirected. Both datasets are split into 5 folds, each further split into a development and test set with approximately the same size when used for evaluation.

5.1 Link Prediction Results

In this section, we evaluate LBH-RTM and its variations on link prediction tasks using *predictive link rank* (PLR). A document's PLR is the average rank of the documents to which it has explicit positive links, among all documents, so lower PLR is better.

Following the experiment setup in Chang and Blei (2010), we train the models on the training set and predict citation links within held-out documents as well as from held-out documents to training documents. We tune two important parameters—α and negative edge ratio (the ratio of the number of sampled negative links to the number of explicit positive links)—on the development set and apply the trained model which performs the best on the development set to the test set.[4] The cross validation results are given in Table 1, where models are differently equipped with lexical weights (L), WSBM prior (B), SCC prior (C), hinge loss (H), and sigmoid loss (S).[5] Link prediction generally improves with incremental application of prior knowledge and more sophisticated learning techniques.

The embedded WSBM brings around 6.5% and 10.2% improvement over RTM in PLR on the

[4] We also tune the number of blocks for embedded WSBM and set it to 35 (CORA) and 20 (WEBKB). The block topic priors are not applied on unseen documents, since we don't have available links.

[5] The values of RTM are different from the result reported by Chang and Blei (2010), because we re-preprocessed the CORA dataset and used different parameters.

CORA and WEBKB datasets, respectively. This indicates that the blocks identified by WSBM are reasonable and consistent with reality. The lexical weights also help link prediction (LBS-RTM), though less for BS-RTM. This is understandable since word distributions are much sparser and do not make as significant a contribution as topic distributions. Finally, hinge loss improves PLR substantially (LBH-RTM), about 14.1% and 21.1% improvement over RTM on the CORA and WEBKB datasets respectively, demonstrating the effectiveness of max-margin learning.

The only difference between LCH-RTM and LBH-RTM is the block detection algorithm. However, their link prediction performance is poles apart—LCH-RTM even fails to outperform RTM. This implies that the quality of blocks identified by SCC is not as good as WSBM, which we also illustrate in Section 5.4.

5.2 Illustrative Example

We illustrate our model's behavior qualitatively by looking at two abstracts, Koplon and Sontag (1997) and Albertini and Sontag (1992) from the CORA dataset, designated K and A for short.

Paper K studies the application of Fourier-type activation functions in fully recurrent neural networks. Paper A shows that if two neural networks have equal behaviors as "black boxes", they must have the same number of neurons and the same weights (except sign reversals).

From the titles and abstracts, we can easily find that both of them are about *neural networks* (NN). They both contain words like *neural*, *neuron*, *network*, *recurrent*, *activation*, and *nonlinear*, which corresponds to the topic with words *neural*, *network*, *train*, *learn*, *function*, *recurrent*, etc. There is a citation between K and A. The ranking of this link improves as the model gets more sophisticated (Table 2), except LCH-RTM, which is consistent with our PLR results.

In Figure 7, we also show the proportions of topics that dominate the two documents according to the various models. There are multiple topics dominating K and A according to RTM (Figure 7(a)). As the model gets more sophisticated, the NN topic proportion gets higher. Finally, only the NN topic dominates the two documents when LBH-RTM is applied (Figure 7(e)).

LCH-RTM gives the highest proportion to the NN topic (Figure 7(b)). However, the NN topic splits into two topics and the proportions are not assigned to the same topic, which greatly brings down the link prediction performance. The splitting of the NN topic also happens in other models (Figure 7(a) and 7(d)), but they assign proportions to the same topic(s). Further comparing with LBH-RTM, the blocks detected by SCC are not improving the modeling of topics and links—some documents that should be in two different blocks are assigned to the same one, as we will show in Section 5.4.

Model	Rank of the Link
RTM	1,265
LCH-RTM	1,385
BS-RTM	635
LBS-RTM	132
LBH-RTM	**106**

Table 2: PLR of the citation link between example documents K and A (described in Section 5.2)

Model	FET		LLR	
	CORA	WEBKB	CORA	WEBKB
RTM	0.1330	0.1312	3.001	6.055
LCH-RTM	0.1418	0.1678	3.071	6.577
BS-RTM	0.1415	0.1950	3.033	6.418
LBS-RTM	0.1342	0.1963	2.984	6.212
LBH-RTM	**0.1453**	**0.2628**	**3.105**	**6.669**

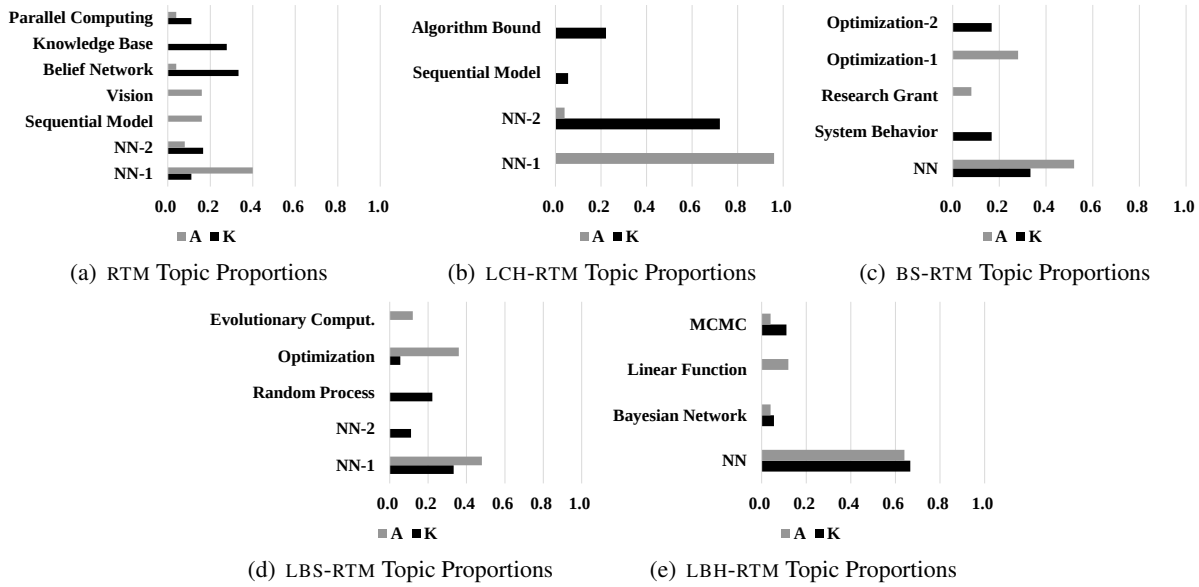
Table 3: Average Association Scores of Topics

5.3 Topic Quality Results

We use an automatic coherence detection method (Lau et al., 2014) to evaluate topic quality. Specifically, for each topic, we pick out the top n words and compute the average association score of each pair of words, based on the held-out documents in development and test sets.

We choose $n = 25$ and use *Fisher's exact test* (Upton, 1992, FET) and *log likelihood ratio* (Moore, 2004, LLR) as the association measures (Table 3). The main advantage of these measures is that they are robust even when the reference corpus is not large.

Coherence improves with WSBM and max-margin learning, but drops a little when adding lexical weights except the FET score on the WEBKB dataset, because lexical weights are intended to improve link prediction performance, not topic quality. Topic quality of LBH-RTM is also better than that of LCH-RTM, suggesting that WSBM benefits topic quality more than SCC.



(a) RTM Topic Proportions (b) LCH-RTM Topic Proportions (c) BS-RTM Topic Proportions

(d) LBS-RTM Topic Proportions (e) LBH-RTM Topic Proportions

Figure 7: Topic proportions given by various models on our two illustrative documents (K and A, described in described in Section 5.2). As the model gets more sophisticated, the NN topic proportion gets higher and finally dominates the two documents when LBH-RTM is applied. Though LCH-RTM gives the highest proportion to the NN topic, it splits the NN topic into two and does not assign the proportions to the same one.

Block	1	2
#Nodes	42	84
#Links in the Block	55	142
#Links across Blocks	2	

Table 4: Statistics of Blocks 1 (learning theory) and 2 (Bayes nets), which are merged in SCC.

5.4 Block Analysis

In this section, we illustrate the effectiveness of the embedded WSBM over SCC.[6] As we have argued, WSBM is able to separate two internally densely-connected blocks even if there are few links connecting them, while SCC tends to merge them in this case. As an example, we focus on two blocks in the CORA dataset identified by WSBM, designated Blocks 1 and 2. Some statistics are given in Table 4. The two blocks are very sparsely connected, but comparatively quite densely connected inside either block. The two blocks' topic distributions also reveal their differences: abstracts in Block 1 mainly focus on learning theory (*learn*, *algorithm*, *bound*, *result*, etc.) and MCMC (*markov*, *chain*, *distribution*, *converge*, etc.). Abstracts in Block 2, however, have higher weights on Bayesian networks (*network*, *model*, *learn*, *bayesian*, etc.) and Bayesian estimation (*estimate*, *bayesian*, *parameter*, *analysis*, etc.), which differs from Block 1's emphasis. Because of the two inter-block links, SCC merges the two blocks into one, which makes the block topic distribution unclear and misleads the sampler. WSBM, on the other hand, keeps the two blocks separate, which generates a high-quality prior for the sampler.

[6] We omit the comparison of WSBM with other models, because this has been done by Aicher et al. (2014). In addition, WSBM is a probabilistic method while SCC is deterministic. They are not comparable quantitatively, so we compare them qualitatively.

6 Related Work

Topic models are widely used in information retrieval (Wei and Croft, 2006), word sense disambiguation (Boyd-Graber et al., 2007), dialogue segmentation (Purver et al., 2006), and collaborative filtering (Marlin, 2003).

Topic models can be extended in either *upstream* or *downstream* way. *Upstream* models generate topics conditioned on supervisory information (Daumé III, 2009; Mimno and McCallum, 2012; Li and Perona, 2005). *Downstream* models, on the contrary, generates topics and supervisory data simultaneously, which turns unsupervised topic models to (semi-)supervised ones. Supervisory data, like labels of documents and links between documents, can be generated from either a maximum likelihood estimation approach (McAuliffe and Blei, 2008; Chang and

Blei, 2010; Boyd-Graber and Resnik, 2010) or a maximum entropy discrimination approach (Zhu et al., 2012; Yang et al., 2015).

In block detection literature, stochastic block model (Holland et al., 1983; Wang and Wong, 1987, SBM) is one of the most basic generative models dealing with binary-weighted edges. SBM assumes that each node belongs to only one block and each link exists with a probability that depends on the block assignments of its connecting nodes. It has been generalized for degree-correction (Karrer and Newman, 2011), bipartite structure (Larremore et al., 2014), and categorial values (Guimerà and Sales-Pardo, 2013), as well as nonnegative integer-weight network (Aicher et al., 2014, WSBM).

Our model combines both topic model and block detection in a unified framework. It takes text, links, and the interaction between text and links into account simultaneously, contrast to the methods that only consider graph structure (Kim and Leskovec, 2012; Liben-Nowell and Kleinberg, 2007) or separate text and links (Chaturvedi et al., 2012).

7 Conclusions and Future Work

We introduce LBH-RTM, a discriminative topic model that jointly models topics and document links, detecting blocks in the document network probabilistically by embedding the weighted stochastic block model, rather via connected-components as in previous models. A separate Dirichlet prior for each block captures its topic preferences, serving as an informed prior when inferring documents' topic distributions. Max-margin learning learns to predict links from documents' topic and word distributions and block assignments.

Our model better captures the connections and content of paper abstracts, as measured by predictive link rank and topic quality. LBH-RTM yields topics with better coherence, though not all techniques contribute to the improvement. We support our quantitative results with qualitative analysis looking at a pair of example documents and at a pair of blocks, highlighting the robustness of embedded WSBM over blocks defined as SCC.

As next steps, we plan to explore model variations to support a wider range of use cases. For example, although we have presented a version of the model defined using undirected binary weight edges in the experiment, it would be straightforward to adapt to model both directed/undirected and binary/nonnegative real weight edges. We are also interested in modeling changing topics and vocabularies (Blei and Lafferty, 2006; Zhai and Boyd-Graber, 2013). In the spirit of treating links probabilistically, we plan to explore application of the model in suggesting links that do not exist but should, for example in discovering missed citations, marking social dynamics (Nguyen et al., 2014), and identifying topically related content in multilingual networks of documents (Hu et al., 2014).

Abstract

Sentiment Analysis (SA) is an active research area nowadays due to the tremendous interest in aggregating and evaluating opinions being disseminated by users on the Web. SA of English has been thoroughly researched; however research on SA of Arabic has just flourished. Twitter is considered a powerful tool for disseminating information and a rich resource for opinionated text containing views on many different topics. In this paper we attempt to bridge a gap in Arabic SA of Twitter which is the lack of sentiment lexicons that are tailored for the informal language of Twitter. We generate two lexicons extracted from a large dataset of tweets using two approaches and evaluate their use in a simple lexicon based method. The evaluation is performed on internal and external datasets. The performance of these automatically generated lexicons was very promising, albeit the simple method used for classification. The best F-score obtained was 89.58% on the internal dataset and 63.1-64.7% on the external datasets.

1 Introduction

The past decade has witnessed the proliferation of social media websites which has led to the production of vast amounts of unstructured text on the Web. This text can be characterized as objective, i.e. containing facts, or subjective i.e. containing opinions and sentiments about entities. Sentiment Analysis (SA) is the research field that is concerned with identifying opinions in text and classifying them as positive, negative or neutral. SA of English has been thoroughly researched; however research on SA of Arabic has just flourished.

Arabic is ranked fourth among languages on the web although it is the fastest growing language on the web among other languages (Internet World Stats, 2015). Arabic is a morphologically rich language where one lemma can have hundreds of surface forms; this complicates the tasks of SA. Moreover, the Arabic language has many variants. The formal language is called Modern Standard Arabic (MSA) and the spoken language differs in different Arabic countries producing numerous Arabic dialects sometimes called informal Arabic or colloquial Arabic. The language used in social media is known to be highly dialectal (Darwish and Magdy, 2014). Dialects differ from MSA phonologically, morphologically and syntactically and they do not have standard orthographies (Habash, 2010). Consequently, resources built for MSA cannot be adapted to dialects very well.

The informal language used in social media and in Twitter in particular makes the SA of tweets a challenging task. The language on social media is known to contain slang, nonstandard spellings and evolves by time. As such sentiment lexicons that are built from standard dictionaries cannot adequately capture the informal language in social media text. Therefore, in this paper we propose to generate Arabic sentiment lexicons that are tweet-specific i.e. generated from tweets. We present two approaches to generating Arabic sentiment lexicons from a large dataset of 2.2 million tweets. The lexicons are evaluated on three datasets, one internal dataset extracted from the larger dataset of tweets and two external datasets from the literature on Arabic SA. Moreover, the lexicons are compared to an external Arabic lexicon generated also from tweets. A simple lexicon-based method is used to evaluate the lexicons.

This paper is organized as follows: Section 2 reviews the related work on sentiment lexicon generation. Section 3 describes the details of the datasets used to generate the lexicons and how they were collected. Section 4 presents the approaches used to generate the lexicons. Section 5 details the experimental setup while Section 6 presents and analyzes the results. Finally, we

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 697–705,
Berlin, Germany, August 7-12, 2016.

conclude the paper and present potential future work in Section 7.

2 Related Work

Words that convey positive or negative sentiment are fundamental for sentiment analysis. Compiling a list of these words is what is referred to as **sentiment lexicon generation**. There are three approaches to generate a sentiment lexicon (Liu, 2012): *manual approach, dictionary-based approach, and corpus-based approach*. The **manual approach** is usually not done alone since it is time consuming and labor intensive. It is used however, in conjunction with automated approaches to check the correction of the resulting lexicons from these approaches. In this section we review popular English and Arabic sentiment lexicons in the literature.

2.1 English Sentiment Lexicons

In the **dictionary based approach** as the name implies a dictionary is used by utilizing the synonym and antonym lists that are associated with dictionary words. The technique starts with a small set of sentiment words as seeds with known positive or negative orientations. The seed words are looked up in the dictionary then their synonyms and antonyms are added to the seed set and a new iteration starts. The process ends when no new words are found. A manual inspection is usually done after the process ends to correct errors. A majority of studies under this approach used the WordNet with different approaches for expanding the list such as distance-based measures (Kamps, 2004; Williams and Anand, 2009) and graph-based methods (Blair-Goldensohn et al., 2008; Rao and Ravichandran, 2009). Pioneering work in this approach is the construction of SentiWordNet by (Esuli and Sebastiani, 2005). Initially, they started with a set of positive seeds and a set of negative seeds then expanded the sets using the synonym and antonym relations in WordNet. This formed a training set which they used in a supervised learning classifier and applied it to all the glosses in WordNet, the process is run iteratively. Then in a following attempt (Esuli and Sebastiani, 2006), a committee of classifiers based on the previous method were used to build SentiWordNet which contains terms that are associated with three scores for objectivity, positivity and negativity, where the sum of the scores is 1. The latest version is SentiWordNet 3.0 (Baccianella et al., 2010).

As for **corpus-based approaches**, the words of the lexicon are extracted from the corpus using a seed list of known sentiment words and different approaches to find words of similar or opposite polarity. One of the earliest work in this approach was that of (Hatzivassiloglou and McKeown, 1997), where they utilized connectives e.g. and, but, etc. between adjectives in a corpus to learn new sentiment words not in the seed list. Turney, (2002); Turney and Littman, (2002) used the once popular AltaVista search engine to find the sentiment of a certain word through calculating the association strength between the word and a set of positive words minus the association strength between the word and a set of negative words. The association strength was measured using Pointwise-Mutual Information (PMI). The result is the sentiment score of the word, if it is positive this means the word is strongly associated with positive polarity and as such its polarity will be positive and if it is negative the word's polarity will be negative. The magnitude indicates the sentiment intensity of the word. We used PMI to generate one of the lexicons in this paper.

After the emergence of sentiment analysis as an evolving research field, several lexicons were constructed according to the approaches mentioned above. In the Bing Liu's lexicon (Hu and Liu, 2004), which falls under the dictionary-based method, the WordNet was exploited to infer the semantic orientation of adjectives extracted from customer reviews. The lexicon only provides the prior polarity of words: positive or negative, the sentiment intensity of the words was not calculated. Another popular sentiment lexicon is the MPQA subjectivity lexicon (Wilson et al., 2005) which was constructed by manually annotating the subjective expressions in the MPQA corpus. The words were annotated with four tags: positive, negative, both and neutral then further classified as strong or weak to denote intensity. We use these two lexicons in the generation of the other lexicon in this paper.

With the proliferation of social media websites, the need for lexicons that can capture the peculiarities of social medial language emerges. As such, many solutions for sentiment analysis of social media and Twitter in particular initiate by developing sentiment lexicons that are extracted from Twitter (Tang et al., 2014; Kiritchenko et al., 2014).

2.2 Arabic Sentiment Lexicons

Generating sentiment lexicons for Arabic has gained the interest of the research community lately. Consequently, we found several efforts for generating these lexicons. A recent effort to build a large scale multi-genre multi dialect Arabic sentiment lexicon was proposed by (Abdul-Mageed and Diab, 2014). However, it covers only two dialects: Egyptian and Levantine and is not yet fully applied to SSA tasks. Badaro et al., (2014) constructed ArSenL, a large scale Arabic sentiment lexicon. They relied on four resources to create ArSenL: English WordNet (EWN), Arabic WordNet (AWN), English SentiWordNet (ESWN), and SAMA (Standard Arabic Morphological Analyzer). Two approaches were followed producing two different lexicons: the first approach used AWN, by mapping AWN entries into ESWN using existing offsets thus producing ArSenL-AWN. The second approach utilizes SAMA's English glosses by finding the highest overlapping synsets between these glosses and ESWN thus producing ArSenL-Eng. Hence ArSenL is the union of these two lexicons. Although this lexicon can be considered as the largest Arabic sentiment lexicon developed to date, it is unfortunate that it only has MSA entries and no dialect words and is not developed from a social media context which could affect the accuracy when applied on social media text.

Following the example of ArSenL, the lexicon SLSA (Sentiment Lexicon for Standard Arabic) (Eskander and Rambow, 2015) was constructed by linking the lexicon of an Arabic morphological analyzer Aramorph with SentiWordNet. Although the approach is very similar to ArSenL, since both use SentiWordNet to obtain the scores of words, the linking algorithm used to link the glosses in Aramorph with those in SentiWordNet is different. SLSA starts by linking every entry in Aramorph with SentiWordNet if the one-gloss word and POS match. Intrinsic and extrinsic evaluations were performed by comparing SLSA and ArSenL which demonstrated the superiority of SLSA. Nevertheless, SLSA like ArSenL does not include dialect words and cannot accurately analyze social media text.

Mohammad et al., (2015), generated three Arabic lexicons from Twitter. Three datasets were collected from Twitter: the first was tweets that contained the emoticons:":)" and ":(", the second was tweets that contained a seed list of positive and negative Arabic words as hashtags and the third was also from tweets that contained Arabic positive and negative words as hashtags but these were dialectal words. Then using PMI three lexicons were generated from these datasets: Arabic Emoticon Lexicon, Arabic Hashtag Lexicon and Dialectal Arabic Hashtag Lexicon. Our approach in generating one of the lexicons is very similar and thus we use one of their lexicons in the experiments to compare with our lexicons. The best performing lexicon was the Dialectal Arabic Hashtag Lexicon therefore we use it in this paper to compare and evaluate our lexicons.

3 Dataset Collection

We followed the approaches in previous work on SA of English Twitter to collect the datasets. As in (Go et al., 2009; Pak and Paroubek, 2010) we utilized emoticons as noisy labels to construct the first dataset EMO-TWEET. Tweets containing the emoticons: ":)" and ":(" and the rule "lang:ar" (to retrieve Arabic tweets only) were collected during November and December 2015. The total number of Tweets collected is shown in Table 1.

Davidov et al., (2010) and Kiritchenko et al., (2014) used hashtags of sentiment words such as #good and #bad to create corpora of positive and negative tweets, we adopted a similar method to theirs. Initially, we tried collecting tweets that contain Arabic sentiment words with hashtags but the search results were too low. We designated this result to a cultural difference in using hashtags between the western and eastern societies. Arabs do not use hashtags in this way. Accordingly we opted to use the sentiment words as keywords without the hashtag sign and the number of search results was substantial. Tweets containing 10 Arabic words having positive polarity and 10 Arabic words having negative polarity were collected during January 2016. The keywords are in Table 2 and the number of tweets collected in Table1. These results constitute our second dataset KEY-TWEET.

Retweets, tweets containing URLs or media and tweets containing non-Arabic words were all excluded from the dataset. The reason for excluding tweets with URLs and media is that we found that most of the tweets that contain URLS and media were spam. We also noticed that although we had specified in the search query that the fetched tweets should be in Arabic "lang:ar" some of the tweets were in English and other languages. So we had to add a filter to eliminate tweets with non-Arabic characters.

In total, the number of collected tweets was around 6.3 million Arabic tweets in a time span of three months. After filtration and cleaning of

the tweets, the remaining were 2.2 million tweets.

	EMO-TWEET		*KEY-TWEET*	
	Positive Emoticon :)	*Negative Emoticon :(*	*Positive keywords*	*Negative keywords*
Total number of tweets collected	2,245,054	1,272,352	1,823,517	1,000,212
After cleaning and filtering	1,033,393	407,828	447,170	337,535
Number of Tokens	12,739,308	5,082,070	9,058,412	7,135,331

Table 2: Positive and negative keywords used to collect tweets.

4 Lexicon Generation

Two sentiment lexicons were extracted from the datasets of tweets using two different approaches. We call the first **AraSenTi-Trans** and the second **AraSenTi-PMI**. The approaches are presented in the following subsections.

4.1 AraSenTi-Trans

The datasets of tweets were processed using the MADAMIRA tool (Pasha et al., 2014). MADAMIRA is a recent effort by Pasha et al. (2014) that combines some of the best aspects of two previous systems used for Arabic NLP: MADA-Morphological Analysis and Disambiguation of Arabic (Habash and Rambow, 2005; Roth et al., 2008; Habash et al., 2009; Habash et al., 2013) and AMIRA (Diab et al., 2007). MADAMIRA, on the other hand, improves on these two systems with a solution that is more robust, portable, extensible, and faster.

The MADAMIRA tool identifies words into three types: ARABIC, NO_ANALYSIS and NON_ARABIC. This feature was used to eliminate tweets containing non-Arabic words and to distinguish MSA words from dialect words as NO_ANALYSIS words can be identified as dialect words or misspelled words or new words made up by tweepers (twitter users). According to the POS tags provided by MADAMIRA, we extracted only nouns, adjectives, adverbs, verbs and negation particles in an effort to eliminate unwanted stop words.

Then we utilized two popular English sentiment lexicons that were used in previous work on English and Arabic sentiment analysis: the Liu lexicon (Hu and Liu, 2004) and the MPQA lexicon (Wilson et al., 2005).

Most previous papers on Arabic SA that used these lexicons just translated them into Arabic, yet we tried a different approach. MADAMIRA provides an English gloss for each word identified as ARABIC, the gloss could be one, two or three words. We used this gloss to compare with the Liu lexicon and MPQA lexicon using the following heuristics:

- If all the word's glosses are positive in both lexicons or found in one lexicon as positive and do not exist in the other lexicon: classify as positive.
- If all the word's glosses are negative in both lexicons or found in one lexicon as negative and do not exist in the other: classify as negative.
- If the word's glosses have different polarities in the lexicons or are (both) in MPQA: add to both list.
- Else: all remaining words are classified as neutral.

Although this approach could contain some errors, a manual check can be performed to clean up. The manual cleanup is time consuming but it is a one-time effort that requires only a few days (Liu, 2012). Accordingly we gave the automati-

cally generated lists of positive, negative, both, and neutral words to two Arabic native speakers to review and correct the errors. We found that 5% of the neutral words were incorrectly misclassified as neutral while they were sentiment bearing words. Also 10% of the positive words were misclassified as negative, and 15% of the negative words were misclassified as positive. The lists were corrected accordingly. We can conclude that using translated English lexicons does not always give us accurate classification of polarity. This result could be due to mistranslations or cultural differences in classifying sentiment as demonstrated by (Mohammad et al., 2015; Mobarz et al., 2014; Duwairi, 2015). Accordingly, we propose a different approach to generating another lexicon in the following section.

4.2 AraSenti-PMI

The second lexicon was also generated from the dataset of tweets but through calculating the pointwise mutual information (PMI) measure for all words in the positive and negative datasets of tweets. The PMI is a measure of the strength of association between two words in a corpus, i.e. the probability of the two words to co-occur in the corpus (Church and Hanks, 1990). It has been adapted in sentiment analysis as a measure of the frequency of a word occurring in positive text to the frequency of the same word occurring in negative text. Turney, (2002); Turney and Littman, (2002) was the first work that proposed to use this measure in sentiment analysis. They used the once popular AltaVista search engine to find the sentiment of a certain word through calculating the PMI between the word and a set of positive words minus the PMI between the word and a set of negative words. Other works that used PMI to generate sentiment lexicons can be found in (Kiritchenko et al., 2014; Mohammad et al., 2015).

The frequencies of the words in the positive and negative datasets of tweets were calculated respectively then the PMI was calculated for each as follows:

$$PMI(w, pos) = \log_2 \frac{freq(w,pos)*N}{freq(w)*freq(pos)} \quad (1)$$

where *freq(w,pos)* is the frequency of the word *w* in the positive tweets, *freq(w)* is the frequency of the word *w* in the dataset, *freq(pos)* is the total number of tokens in the positive tweets and *N* is the total number of tokens in the dataset. The PMI of the word associated with negative tweets is calculated in the same way *PMI(w,neg).* The sentiment score for word *w* will be:

$$Sentiment\ Score(w)=PMI(w,pos)-PMI(w,neg) \quad (2)$$

This was calculated for all words that occurred in the dataset five times or more, the reason for this is that the PMI is a poor estimator of low-frequency words (Kiritchenko et al., 2014), so words occurring less than 5 times were excluded. Also for words that are found in the set of positive tweets but not in the set of negative tweets or vice versa, Equation 2 would give us a sentiment score of ∞, which would highly affect the calculation of the sentiment of the whole tweet. Since the absence of a word from the negative dataset does not require that the word's sentiment is positive or vice versa; as such we calculated the sentiment score of such words as in Equation 1, *PMI(w,pos)* for words occurring only in the positive tweets and *PMI(w,neg)* for words occurring only in the negative tweets.

4.3 Lexicons Coverage

The number of positive and negative entries in each of the lexicons is shown in Table 3. The details of the lexicon of (Mohammad et al., 2015) are also shown since this lexicon will be used in the experiments in the following section for evaluation and comparison purposes. Mohammad et al., (2015) generated three lexicons, however they demonstrated that the Dialectal Arabic Hashtag Lexicon (DAHL) gave the best results and accordingly we use this lexicon in the experiments in this paper. From Table 3, we can see the high coverage of the generated lexicons AraSenti-Trans and AraSenti-PMI when compared to DAHL. In addition we manually examined the three lexicons of (Mohammad et al., 2015) and found that they were not cleaned. They contained non-Arabic words and hashtags that do not convey sentiment. This put a question mark on the validity of the lexicons and the number of entries reported. Our datasets were cleaned from non-Arabic words and punctuation, so the generated lexicons all contain valid Arabic words.

Lexicon	*Positive*	*Negative*	*Total*
AraSenti-Trans	59,525	71,817	131,342
AraSenti-PMI	56,938	37,023	93,961
DAHL	11,947	8,179	20,126

Table 3: Details of the generated lexicons and the lexicon they will be compared to.

5 Evaluation

To evaluate the performance of the tweet-specific lexicons, we performed a set of experiments using a simple lexicon-based approach, hence no training and/or tuning is required. We performed a two-way classification on the datasets (positive or negative). We leave the problem of three and four way classification (positive, negative, neutral, mixed) for future work. We evaluated the generated lexicons on a dataset of 10,133 tweets extracted from the larger datasets of tweets EMO-TWEET and KEY-TWEET. The tweets were manually annotated by three annotators that are Arabic native speakers. The conflict between annotators was resolved by majority voting. We will call this dataset AraSenTi-Tweet. We also evaluated the generated lexicons on two external datasets of tweets: ASTD by (Nabil et al., 2015) and RR by (Refaee and Rieser, 2014). We extracted only the tweets that were labeled as positive or negative from these datasets. The details of all the datasets used in the experiments are illustrated in Table 4. We plan to release the dataset and the generated lexicons for the public.

Dataset	*Positive*	*Negative*	*Total*
AraSenti-Tweet	4329	5804	10133
ASTD	797	1682	2479
RR	876	1941	2817

Table 4: Datasets used in the evaluation of the generated lexicons.

Negation significantly affects the sentiment of its scope and consequently affects the evaluation of the lexicons. Accordingly, we propose to evaluate the generated lexicons in two settings: with and without negation handling. We also compare the performance of the generated lexicons with a lexicon that was generated in a very similar approach to one of the lexicons.

Since the datasets are unbalanced, we will report the performance measures of the macro-averaged F-score (F_{avg}), precision (P) and recall (R) of the positive and negative classes as follows:

$$P = TP/(TP+FP) \quad (3)$$

$$R = TP/(TP+FN) \quad (4)$$

$$F = 2*PR/P+R \quad (5)$$

where in the case of the positive class: TP is the number of positive tweets classified correctly as positive (true positive), FP is the number of negative tweets falsely classified as positive (false positive), and FN is the number of positive tweets falsely classified as negative (false negatives). The same holds for the negative class. Then the F-score is calculated as:

$$F_{avg} = \frac{F_{pos}+F_{neg}}{2} \quad (6)$$

5.1 Setup A: No Negation Handling

For the **AraSenTi-Trans** lexicon, we use the simple method of counting the number of positive and negative words in the tweet and whichever is the greatest denotes the sentiment of the tweet. The results of applying this method on the different datasets are illustrated in Table 5.

As for the **AraSenTi-PMI** lexicon, the sentiment score of all words in the tweet were summed up. The natural threshold to classify the data into positive or negative would be zero, since positive scores denote positive sentiment and negative scores denote negative sentiment. However, according to (Kiritchenko et al., 2014) other thresholds could give better results. Consequently, we experimented with the value of this threshold. We set it to 0, 0.5,and 1 and found that the best results were obtained when setting the threshold to 1. As such if the sum of the sentiment scores of the words in a tweet is greater than one, then the tweet is classified as positive, otherwise the tweet is classified as negative.

5.2 Setup B:Negation Handling

We also experimented with handling negation in the tweet, by compiling a list of negation particles found in the tweets and checking if the tweet contains a negation particle or not.

For the **AraSenTi-Trans** lexicon, if the tweet contains a negation particle and a positive word, we do not increment the positive word counter. However, for tweets containing negative words and negation particles we found that not incrementing the negative word counter degraded the accuracy, so we opted to increment the negative word counter even if a negation particle is found in the tweet.

Moreover, we experimented with adjusting the score of negation particles in the **AraSenTi-PMI** lexicon. After several experiments, we found that adjusting the score of the negation particles to -1 was the setting that gave the best performance.

6 Discussion and Results

The results of the first experimental setup for the two generated lexicons AraSenti-Trans and AraSenti-PMI are presented in Table 5. For the RR dataset and AraSenti-Tweet dataset, the superiority of the AraSenti-PMI lexicon is evident. The F_{avg} of applying the AraSenti-PMI lexicon on the RR dataset is 63.6% while the F_{avg} of applying the AraSenti-PMI lexicon on the AraSenti-Tweet dataset is 88.92%. As for the ASTD dataset, applying the AraSenti-Trans lexicon gave better results with an F_{avg} of 59.8%.

In Table 6, the results of the lexicon-based method with negation handling are presented. The results of using the DAHL lexicon on the same datasets are also reported for comparison.

First of all, the effect of negation handling on performance is significant, with increases of (1-4%) on all datasets. Although the two lexicons AraSenti-Trans and AraSenti-PMI handled negation differently but the increase for every dataset was almost the same: the ASTD dataset +4%, the RR dataset +1% and the AraSenti-Tweet dataset +2% and +1% respectively.

When comparing the performance of the generated lexicons AraSenti-Trans and AraSenti-PMI with the DAHL lexicon, we find that our lexicons presented better classification results on all datasets.

Finally, although the two lexicons were extracted from the same dataset, we find that their performance varied on the different datasets. The best performance for the ASTD dataset was when the AraSenti-Trans lexicon was used. However, the best performance for the RR and AraSenti-Tweet datasets was when the AraSenti-PMI lexicon was used. Moreover, albeit the simple lexicon-based method used in the evaluation, we find that the performance is encouraging. Several enhancements could be made such as incorporating Arabic valence shifters and certain linguistic rules to handle them.

	Lexicon									
DataSet	AraSenti-Trans					AraSenti-PMI				
	Positve		Negative		F_{avg}	Positve		Negative		F_{avg}
	P	R	P	R		P	R	P	R

7 Conclusion

In this paper, two large-scale Arabic sentiment lexicons were generated from a large dataset of Arabic tweets. The significance of these lexicons lies in their ability to capture the idiosyncratic nature of social media text. Moreover, their high coverage suggests the possibility of using them in different genres such as product reviews. This is a possible future research direction.

The performance of the lexicons on external datasets also suggests their ability to be used in classifying new datasets. However, there is much room for improvement given the simple method

used in evaluation. This simple lexicon-based method could be further enhanced by incorporating Arabic valence shifters and certain linguistic rules to handle them. We also plan to make the classification multi-way: positive, negative, neutral and mixed.

Abstract

This paper proposes an unsupervised approach for segmenting a multi-author document into authorial components. The key novelty is that we utilize the sequential patterns hidden among document elements when determining their authorships. For this purpose, we adopt Hidden Markov Model (HMM) and construct a sequential probabilistic model to capture the dependencies of sequential sentences and their authorships. An unsupervised learning method is developed to initialize the HMM parameters. Experimental results on benchmark datasets have demonstrated the significant benefit of our idea and our approach has outperformed the state-of-the-arts on all tests. As an example of its applications, the proposed approach is applied for attributing authorship of a document and has also shown promising results.

1 Introduction

Authorship analysis is a process of inspecting documents in order to extract authorial information about these documents. It is considered as a general concept that embraces several types of authorship subjects, including *authorship verification*, *plagiarism detection* and *author attribution*. Authorship verification (Brocardo et al., 2013; Potha and Stamatatos, 2014) decides whether a given document is written by a specific author. Plagiarism detection (Stein et al., 2011; Kestemont et al., 2011) seeks to expose the similarity between two texts. However, it is unable to determine if they are written by the same author. In author attribution (Juola, 2006; Savoy, 2015), a real author of an anonymous document is predicted using labeled documents of a set of candidate authors.

Another significant subject in authorship analysis, which has received comparatively less attention from research community, is *authorship-based document decomposition* (ABDD). This subject is to group the sentences of a multi-author document to different classes, of which each contains the sentences written by only one author. Many applications can take advantage of such a subject, especially those in forensic investigation, which aim to determine the authorship of sentences in a multi-author document. Furthermore, this kind of subject is beneficial for detecting plagiarism in a document and defining contributions of authors in a multi-author document for commercial purpose. ABDD can also be applied to identify which source (regarded as an 'author' in this paper) a part of a document is copied from when the document is formed by taking contents from various sources.

In despite of the benefits of ABDD, there has been little research reported on this subject. Koppel et al. (2011) are the first researchers who implemented an unsupervised approach for ABDD. However, their approach is restricted to Hebrew documents only. The authors of Akiva and Koppel (2013) addressed the drawbacks of the above approach by proposing a generic unsupervised approach for ABDD. Their approach utilized distance measurements to increase the precision and accuracy of clustering and classification phases, respectively. The accuracy of their approach is highly dependent on the number of au-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 706–714,
Berlin, Germany, August 7-12, 2016.

thors. When the number of authors increases, the accuracy of the approach is significantly dropped. Giannella (2015) presented an improved approach for ABDD when the number of authors of the document is known or unknown. In his approach, a Bayesian segmentation algorithm is applied, which is followed by a segment clustering algorithm. However, the author tested his approach by using only documents with a few transitions among authors. Furthermore, the accuracy of the approach is very sensitive to the setting of its parameters. In Aldebei et al. (2015), the authors presented an unsupervised approach ABDD by exploiting the differences in the posterior probabilities of a Naive-Bayesian model in order to increase the precision and the classification accuracy, and to be less dependent on the number of authors in comparing with the approach in Akiva and Koppel (2013). Their work was tested on documents with up to 400 transitions among authors and the accuracy of their approach was not sensitive to the setting of parameters, in contrast with the approach in Giannella (2015). However, the performance of their approach greatly depends on a threshold, of which the optimal value for an individual document is not easy to find.

Some other works have focused on segmenting a document into components according to their topics. For applications where the topics of documents are unavailable, these topic-based solutions will fail. In this paper, the ABDD approach is independent of documents' topics.

All of the existing works have assumed that the observations (i.e., sentences) are independent and identically distributed (i.i.d.). No consideration has been given to the contextual information between the observations. However, in some cases, the i.i.d. assumption is deemed as a poor one (Rogovschi et al., 2010). In this paper, we will relax this assumption and consider sentences of a document as a sequence of observations. We make use of the contextual information hidden between sentences in order to identify the authorship of each sentence in a document. In other words, the authorships of the "previous" and "subsequent" sentences have relationships with the authorship of the current sentence. Therefore, in this paper, a well-known sequential model, Hidden Markov Model (HMM), is used for modelling the sequential patterns of the document in order to describe the authorship relationships.

The contributions of this article are summarized as follows.

1. We capture the dependencies between consecutive elements in a document to identify different authorial components and construct an HMM for classification. It is for the first time the sequential patterns hidden among document elements is considered for such a problem.

2. To build and learn the HMM model, an unsupervised learning method is first proposed to estimate its initial parameters, and it does not require any information of authors or document's context other than how many authors have contributed to write the document.

3. Different from the approach in Aldebei et al. (2015), the proposed unsupervised approach no longer relies on any predetermined threshold for ABDD.

4. Comprehensive experiments are conducted to demonstrate the superior performance of our ideas on both widely-used artificial benchmark datasets and an authentic scientific document. As an example of its applications, the proposed approach is also applied for attributing authorship on a popular dataset. The proposed approach can not only correctly determine the author of a disputed document but also provide a way for measuring the confidence level of the authorship decision for the first time.

The rest of this article is organised as follows. Section 2 reviews the HMM. Section 3 presents the details of our proposed approach, including the processes for initialization and learning of HMM parameters, and the Viterbi decoding process for classification. Experiments are conducted in Section 4, followed by the conclusion in Section 5.

2 Overview of HMM

In this paper, we adopt the widely used sequential model, the Hidden Markov Model (HMM) (Eddy, 1996), to classify sentences of a multi-author document according to their authorship. The HMM is a probabilistic

model which describes the statistical dependency between a sequence of observations $O = \{o_1, o_2, \cdots, o_T\}$ and a sequence of hidden states $Q = \{q_1, q_2, \cdots, q_T\}$. The observations can either be discrete variables, where each o_i takes a value from a set of M symbols $W = \{w_1, \cdots, w_M\}$, or be continuous variables. On the other hand, each q_i takes one possible value from a set of N symbols, $S = \{s_1, \cdots, s_N\}$.

The behaviour of the HMM can be determined by three parameters shown as follows.

1. Initial state probabilities $\boldsymbol{\pi} = \{\pi_1, \cdots, \pi_N\}$, where $\pi_n = p(q_1 = s_n)$ and $s_n \in S$, for $n = 1, 2, \cdots, N$.

2. Emission probabilities $\boldsymbol{B}$, where each emission probability $b_n(o_t) = p(o_t|q_t = s_n)$, for $t = 1, 2, \cdots, T$ and $n = 1, 2, \cdots, N$.

3. State transition probabilities $\boldsymbol{A}$. It is assumed that the state transition probability has a time-homogeneous property, i.e., it is independent of the time t. Therefore, a probability $p(q_t = s_l|q_{t-1} = s_n)$ can be represented as a_{nl}, for $t = 1, 2, \cdots, T$ and $l, n = 1, 2, \cdots, N$.

3 The Proposed Approach

The ABDD proposed in this paper can be formulated as follows. Given a multi-author document C, written by N co-authors, it is assumed that each sentence in the document is written by one of the N co-authors. Furthermore, each co-author has written long successive sequences of sentences in the document. The number of authors N is known beforehand, while typically no information about the document contexts and co-authors is available. Our objective is to define the sentences of the document that are written by each co-author.

Our approach consists of three steps shown as follows.

1. Estimate the initial values of the HMM parameters $\{\boldsymbol{\pi}, \boldsymbol{B}, \boldsymbol{A}\}$ with a novel unsupervised learning method.

2. Learn the values of the HMM parameters using the $Baum - Welch$ algorithm (Baum, 1972; Bilmes and others, 1998).

3. Apply the $Viterbi$ algorithm (Forney Jr, 1973) to find the most likely authorship of each sentence.

3.1 Initialization

In our approach, we assume that we do not know anything about the document C and the authors, except the number of co-authors of the document (i.e., N). This approach applies an HMM in order to classify each sentence in document C into a class corresponding to its co-author. The step (see Sub-section 3.2) for learning of HMM parameters $\{\boldsymbol{\pi}, \boldsymbol{B}, \boldsymbol{A}\}$ is heavily dependent on the initial values of these parameters (Wu, 1983; Xu and Jordan, 1996; Huda et al., 2006). Therefore, a good initial estimation of the HMM parameters can help achieve a higher classification accuracy.

We take advantage of the sequential information of data and propose an unsupervised approach to estimate the initial values of the HMM parameters. The detailed steps of this approach are shown as follows.

1. The document C is divided into *segments*. Each segment has 30 successive sentences, where the i^{th} segment comprises the i^{th} 30 successive sentences of the document. This will produce s segments, where $s =$ Ceiling($|C|/30$) with $|C|$ representing the total number of sentences in the document. The number of sentences in each segment (i.e., 30) is chosen in such a way that each segment is long enough for representing a particular author's writing style, and also the division of the document gives an adequate number of segments in order to be used later for estimating the initial values of HMM parameters.

2. We select the words appearing in the document for more than two times. This produces a set of D words. For each segment, create a D-dimensional vector where the i^{th} element in the vector is one (zero) if the i^{th} element in the selected word set does (not) appear in the segment. Therefore, s binary D-dimensional vectors are generated, and the set of these vectors is denoted by $X = \{x_1, \cdots, x_s\}$.

3. A multivariate Gaussian Mixture Models (GMMs) (McLachlan and Peel, 2004) is used to cluster the D-dimensional vectors X into N components denoted by $\{s_1, s_2, \cdots, s_N\}$. Note that the number of components is equal to the number of co-authors of the document. Based on the GMMs, each vector, x_i, gets a label representing the Gaussian component that this vector x_i is assigned to, for $i = 1, 2, \cdots, s$.

4. Again, we represent each segment as a binary vector using a new feature set containing all words appearing in the document for at least once. Assuming the number of elements in the new feature set is D', s binary D'-dimensional vectors are generated, and the set of these vectors is denoted by $X' = \{x'_1, \cdots, x'_s\}$. Each vector x'_i will have the same label of vector x_i, for $i = 1, 2, \cdots, s$.

5. We construct a Hidden Markov model with a sequence of observations O' and its corresponding sequence of hidden states Q'. In this model, O' represents the resulted segment vectors X' of the previous step. Formally, observation o'_i, is the i^{th} binary D'-dimensional vector x'_i, that represents the i^{th} segment of document C. In contrast, Q' represents the corresponding authors of the observation sequence O'. Each q'_i symbolizes the most likely author of observation o'_i. According to Steps 3 and 4 of this sub-section, each x'_i representing o'_i takes one label from a set of N elements, and the label represents its state, for $i = 1, 2, \cdots, s$.

By assigning the most likely states to all hidden states (i.e., $q'_i, i = 1, 2, \cdots, s$), the state transition probabilities $\boldsymbol{A}$ are estimated.

As long as there is only one sequence of states in our model, the initial probability of each state is defined as the fraction of times that the state appears in the sequence Q', so $\pi_n = \frac{Count(q'=s_n)}{Count(q')}$, for $n = 1, 2, \cdots, N$.

6. Given the sequence X', and the set of all possible values of labels, the conditional probability of feature f_k in X' given a label s_n, $p(f_k|s_n)$, is computed, for $k = 1, 2, \cdots, D'$ and $n = 1, 2, \cdots, N$.

7. The document C is partitioned into sentences. Let $z = |C|$ represent the number of sentences in the document. We represent each sentence as a binary feature vector using the same feature set used in Step 4. Therefore, z binary D'-dimensional vectors, denoted by $O = \{o_1, \cdots, o_z\}$, are generated. By using the conditional probabilities resulted in Step 6, the initial values of $\boldsymbol{B}$ are computed as $p(o_i|s_n) = \prod_{k=1}^{D'} o_i^{f_k} p(f_k|s_n)$, where $o_i^{f_k}$ represents the value of feature f_k in sentence vector o_i, for $i = 1, 2, \cdots, z$ and $n = 1, 2, \cdots, N$.

In this approach, we use *add-one smoothing* (Martin and Jurafsky, 2000) for avoiding zero probabilities of $\boldsymbol{A}$ and $\boldsymbol{B}$. Furthermore, we take the logarithm function of the probability in order to simplify its calculations.

The initial values of the $\boldsymbol{A}$, $\boldsymbol{B}$ and $\boldsymbol{\pi}$ are now available. In next sub-section, the learning process of these parameter values is performed.

3.2 Learning HMM

After estimating the initial values for the parameters of HMM, we now find the parameter values that maximize likelihood of the observed data sequence (i.e., sentence sequence). The learning process of the HMM parameter values is performed as follows.

1. Construct a Hidden Markov model with a sequence of observations, O, and a corresponding sequence of hidden states, Q. In this model, O represents the resulted sentence vectors (Step 7 in the previous Sub-section). Formally, the observation o_i, is the i^{th} binary D'-dimensional vector and it represents the i^{th} sentence of document C. In contrast, Q represents the corresponding authors of observation sequence O. Each q_i symbolizes the most likelihood author of observation o_i, for $i = 1, 2, \cdots, z$

2. The Baum-Welch algorithm is applied to learn the HMM parameter values. The algorithm, also known as the $forward-backward$ algorithm (Rabiner, 1989), has two steps, i.e., *E-step* and *M-step*. The *E-step* finds the expected author sequence (Q) of the observation sequence (O), and the *M-step* updates the HMM parameter values according to the state assignments. The learning procedure starts with the initial values of HMM parameters, and then the cycle of these two steps continues until a convergence is achieved in $\boldsymbol{\pi}$, $\boldsymbol{B}$ and $\boldsymbol{A}$.

The learned HMM parameter values will be used in the next sub-section in order to find the best sequence of authors for the given sentences.

3.3 Viterbi Decoding

For a Hidden Markov model, there are more than one sequence of states in generating the observation sequence. The Viterbi decoding algorithm (Forney Jr, 1973) is used to determine the best sequence of states for generat-

ing observation sequence. Therefore, by using the Hidden Markov model that is constructed in previous sub-section and the learned HMM parameter values, the Viterbi decoding algorithm is applied to find the best sequence of authors for the given sentences.

4 Experiments

In this section, we demonstrate the performance of our proposed approach by conducting experiments on benchmark datasets as well as one authentic document. Furthermore, an application on authorship attribution is presented using another popular dataset.

4.1 Datasets

Three benchmark corpora widely used for authorship analysis are used to evaluate our approach. Furthermore, an authentic document is also examined.

The first corpus consists of five Biblical books written by Ezekiel, Isaiah, Jeremiah, Proverbs and Job, respectively. All of these books are written in Hebrew. The five books belong to two types of literature genres. The first three books are related to prophecy literature and the other two books are related to a wisdom literature.

The second corpus consists of blogs written by the Nobel Prize-winning economist Gary S. Becker and the renowned jurist and legal scholar Richard A. Posner. This corpus, which is titled "The Becker-Posner Blogs" (`www.becker-posner-blog.com`), contains 690 blogs. On average, each blog has 39 sentences talking about particular topic. The Becker-Posner Blogs dataset, which is considered as a very important dataset for authorship analysis, provides a good benchmark for testing the proposed approach in a document where the topics of authors are not distinguishable. For more challenging documents, Giannella (2015) has manually selected six single-topic documents from Becker-Posner blogs. Each document is a combination of Becker and Posner blogs that are talking about only one topic. The six merged documents with their topics and number of sentences of each alternative author are shown in Table 1.

Topics	Author order and number of sentences per author
Tenure (Ten)	Posner(73), Becker(36), Posner(33), Becker(19)
Senate Filibuster (SF)	Posner(39), Becker(36), Posner(28), Becker(24)
Tort Reform (TR)	Posner(29), Becker(31), Posner(24)
Profiling (Pro)	Becker(35), Posner(19), Becker(21)
Microfinance (Mic)	Posner(51), Becker(37), Posner(44), Becker(33)
Traffic Congestion (TC)	Becker(57), Posner(33), Becker(20)

Table 1: The 6 merged single-topic documents of Becker-Posner blogs.

The third corpus is a group of New York Times articles of four columnists. The articles are subjected to different topics. In our experiments, all possible multi-author documents of articles of these columnists are created. Therefore, this corpus permits us to examine the performance of our approach in documents written by more than two authors.

The fourth corpus is a very early draft of a scientific article co-authored by two PhD students each being assigned a task to write some full sections of the paper. We employ this corpus in order to evaluate the performance of our approach on an authentic document. For this purpose, we have disregarded its titles, author names, references, figures and tables. After that, we get 313 sentences which are written by two authors, where Author 1 has written 131 sentences and Author 2 has written 182 sentences.

4.2 Results on Document Decomposition

The performance of the proposed approach is evaluated through a set of comparisons with four state-of-the-art approaches on the four aforementioned datasets.

The experiments on the first three datasets, excluding the six single-topic documents, are applied using a set of artificially merged multi-author documents. These documents are created by using the same method that has been used by Aldebei et al. (2015). This method aims to combine a group of documents of N authors into a single merged document. Each of these documents is written by only one author. The merged document process starts by selecting a random author from an author set. Then, the first r successive and unchosen sentences from the documents of the selected author are gleaned, and are merged with the first r successive and unchosen sentences from the documents of another randomly selected au-

thor. This process is repeated till all sentences of authors' documents are gleaned. The value of r of each transition is selected randomly from a uniform distribution varying from 1 to V. Furthermore, we follow Aldebei et al. (2015) method and assign the value of 200 to V.

Bible Books

We utilize the bible books of five authors and create artificial documents by merging books of any two possible authors. This produces 10 multi-author documents of which four have the same type of literature and six have different type of literature. Table 2 shows the comparisons of classification accuracies of these 10 documents by using our approach and the approaches developed by Koppel et al. (2011), Akiva and Koppel (2013)-500CommonWords, Akiva and Koppel (2013)-SynonymSet and Aldebei et al. (2015).

	Doc.	1	2	3	4	5
Different	Eze-Job	85.8%	98.9%	95.0%	99.0%	99.4%
	Eze-Prov	77.0%	99.0%	91.0%	98.0%	98.8%
	Isa-Prov	71.0%	95.0%	85.0%	98.0%	98.7%
	Isa-Job	83.0%	98.8%	89.0%	99.0%	99.4%
	Jer-Job	87.2%	98.2%	93.0%	98.0%	98.5%
	Jer-Prov	72.2%	97.0%	75.0%	99.0%	99.5%
	Overall	***79.4%***	***97.8%***	***88.0%***	***98.5%***	***99.1%***
Same	Job-Prov	85.0%	94.0%	82.0%	95.0%	98.2%
	Isa-Jer	72.0%	66.9%	82.9%	71.0%	72.1%
	Isa-Eze	79.0%	80.0%	88.0%	83.0%	83.2%
	Jer-Eze	82.0%	97.0%	96.0%	97.0%	97.3%
	Overall	***79.5%***	***84.5%***	***87.2%***	***86.5%***	***87.7%***

Table 2: Classification accuracies of merged documents of different literature or the same literature bible books using the approaches of 1- Koppel et al. (2011), 2- Akiva and Koppel (2013)-500CommonWords, 3- Akiva and Koppel (2013)-SynonymSet, 4- Aldebei et al. (2015) and 5- our approach.

As shown in Table 2, the results of our approach are very promising. The overall classification accuracies of documents of the same literature or different literature are better than the other four state-of-the-art approaches.

In our approach, we have proposed an unsupervised method to estimate the initial values of the HMM parameters (i.e., $\boldsymbol{\pi}$, $\boldsymbol{B}$ and $\boldsymbol{A}$) using segments. Actually, the initial values of the HMM parameters are sensitive factors to the convergence and accuracy of the learning process. Most of the previous works using HMM have estimated these values by clustering the original data, i.e., they have clustered sentences rather than segments. Figure 1 compares the results of using segments with the results of using sentences for estimating the initial parameters of HMM in the proposed approach for the 10 merged Bible documents in terms of the accuracy results and number of iterations till convergence, respectively. From Figures 1, one can notice that the accuracy results obtained by using segments for estimating the initial HMM parameters are significantly higher than using sentences for all merged documents. Furthermore, the number of iterations required for convergence for each merged document using segments is significantly smaller than using sentences.

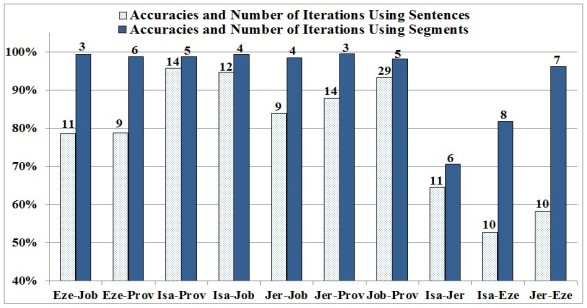

Figure 1: Comparisons between using segments and using sentences in the unsupervised method for estimating the initial values of the HMM of our approach in terms of accuracy (representd as the cylinders) and number of iterations required for convergence (represented as the numbers above cylinders) using the 10 merged Bible documents.

Becker-Posner Blogs (Controlling for Topics)

In our experiments, we represent Becker-Posner blogs in two different terms. The first term is as in Aldebei et al. (2015) and Akiva and Koppel (2013) approaches, where the whole blogs are exploited to create one merged document. The resulted merged document contains 26,922 sentences and more than 240 switches between the two authors. We obtain an accuracy of 96.72% when testing our approach in the merged document. The obtained result of such type of document, which does not have topic indications to differentiate between authors, is delightful. The first set of cylinders labelled "Becker-Posner" in Figure 2 shows the comparisons of classification accuracies of our approach and the approaches of Akiva and Koppel (2013) and Aldebei et al.

(2015) when the whole blogs are used to create one merged document. As shown in Figure 2, our approach yields better classification accuracy than the other two approaches.

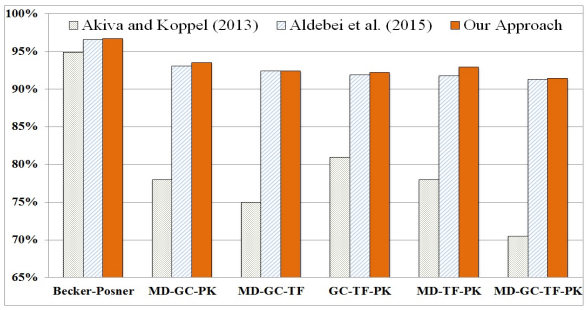

Figure 2: Classification accuracy comparisons between our approach and the approaches presented in Akiva and Koppel (2013) and Aldebei et al. (2015) in Becker-Posner documents, and documents created by three or four *New York Times* columnists (TF = Thomas Friedman, PK = Paul Krugman, MD = Maureeen Dowd, GC = Gail Collins).

The second term is as in the approach of Giannella (2015), where six merged single-topic documents are formed. Due to comparatively shorter lengths of these documents, the number of resulted segments that are used for the unsupervised learning in Sub-section 3.1 is clearly not sufficient. Therefore, instead of splitting each document into segments of 30 sentences length each, we split it into segments of 10 sentences length each. Figure 3 shows the classification accuracies of the six documents using our approach and the approach presented in Giannella (2015). It is observed that our proposed approach has achieved higher classification accuracy than Giannella (2015) in all of the six documents.

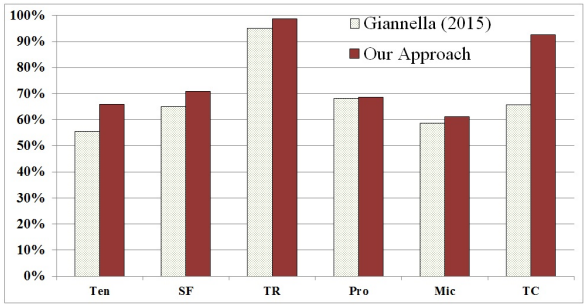

Figure 3: Classification accuracy comparisons between our approach and the approach presented in (Giannella, 2015) in the six single-topic documents of Becker-Posner blogs.

New York Times Articles (N > 2)

We perform our approach on *New York Times* articles. For this corpus, the experiments can be classified into three groups. The first group is for those merged documents that are created by combining articles of any pair of the four authors. The six resulted documents have on average more than 250 switches between authors. The classification accuracies of these documents are between 93.9% and 96.3%. It is notable that the results are very satisfactory for all documents. For comparisons, the classification accuracies of the same documents using the approach presented in Aldebei et al. (2015) range from 93.3% to 96.1%. Furthermore, some of these documents have produced an accuracy lower than 89.0% using the approach of Akiva and Koppel (2013).

The second group is for those merged documents that are created by combining articles of any three of the four authors. The four resulted documents have on average more than 350 switches among the authors. The third group is for the document that are created by combining articles of all four columnists. The resulted merged document has 46,851 sentences and more than 510 switches among authors. Figure 2 shows the accuracies of the five resulted documents regarding the experiments of the last two groups. Furthermore, it shows the comparisons of our approach and the approaches presented in Aldebei et al. (2015) and Akiva and Koppel (2013). It is noteworthy that the accuracies of our approach are better than the other two approaches in all of the five documents.

Authentic Document

In order to demonstrate that our proposed approach is applicable on genuine documents as well, we have applied the approach on first draft of a scientific paper written by two Ph.D. students (Author 1 and Author 2) in our research group. Each student was assigned a task to write some full sections of the paper. Author 1 has contributed 41.9% of the document and Author 2 contributed 58.1%. Table 3 shows the number of correctly assigned sentences of each author and the classification accuracy resulted using the proposed approach. Table 3 also displays the authors' contributions predicted using our approach. As

Author	Classification Accuracy	Predicted Contribution
1	98.5%	47.6%
2	89.0%	52.4%
Accuracy	**93.0%**	

Table 3: The classification accuracies and predicted contributions of the two authors of the scientific paper using the proposed approach.

shown in Table 3, the proposed approach has achieved an overall accuracy of 93.0% for the authentic document.

4.3 Results on Authorship Attribution

One of the applications that can take advantage of the proposed approach is the authorship attribution (i.e., determining a real author of an anonymous document given a set of labeled documents of candidate authors). The *Federalist Papers* dataset have been employed in order to examine the performance of our approach for this application. This dataset is considered as a benchmark in authorship attribution task and has been used in many studies related to this task (Juola, 2006; Savoy, 2013; Savoy, 2015). The *Federalist Papers* consist of 85 articles published anonymously between 1787 and 1788 by Alexander Hamilton, James Madison and John Jay to persuade the citizens of the State of New York to ratify the Constitution. Of the 85 articles, 51 of them were written by Hamilton, 14 were written by Madison and 5 were written by Jay. Furthermore, 3 more articles were written jointly by Hamilton and Madison. The other 12 articles (i.e., articles 49-58 and 62-63), the famous "anonymous articles", have been alleged to be written by Hamilton or Madison.

To predict a real author of the 12 anonymous articles, we use the first five undisputed articles of both authors, Hamilton and Madison. Note that we ignore the articles of Jay because the anonymous articles are alleged to be written by Hamilton or Madison. The five articles of Hamilton (articles 1 and 6-9) are combined with the five articles of Madison (articles 10, 14 and 37-39) in a single merged document where all the articles of Hamilton are inserted into the first part of the merged document and all the articles of Madison are inserted into the second part of the merged document. The merged document has 10 undisputed articles covering eight different topics (i.e., each author has four different topics). Before applying the authorship attribution on the 12 anonymous articles, we have tested our approach on the resulted merged document and an accuracy of 95.2% is achieved in this document. Note that, the authorial components in this document are not thematically notable.

For authorship attribution of the 12 anonymous articles, we add one anonymous article each time on the middle of the merged document, i.e., between Hamilton articles part and Madison articles part. Then, we apply our approach on the resulted document, which has 11 articles, to determine to which part the sentences of the anonymous article are classified to be sectences of Hamilton or Madison. As the ground truth for our experiments, all of these 12 articles can be deemed to have been written by Madison becuase the results of all recent state-of-the-art studies testing on these articles on authorship attribution have classified the articles to Madison's. Consistent with the state-of-the-art approaches, these 12 anonymous articles are also correctly classified to be Madison's using the proposed approach. Actually, all sentences of articles 50,52-58 and 62-63 are classified as Madison's sentences, and 81% of the sentences of article 49 and 80% of article 51 are classified as Madison's sentences. These percentages can be deemed as the confidence levels (i.e., 80% conferdence for articles 49, 81% for 51, and 100% confidences for all other articles) in making our conclusion of the authorship contributions.

5 Conclusions

We have developed an unsupervised approach for decomposing a multi-author document based on authorship. Different from the state-of-the-art approaches, we have innovatively made use of the sequential information hidden among document elements. For this purpose, we have used HMM and constructed a sequential probabilistic model, which is used to find the best sequence of authors that represents the sentences of the document. An unsupervised learning method has also been developed to estimate the initial parameter values of HMM. Comparative experiments conducted on benchmark datasets have demonstrated the effectiveness of our ideas with superior perfor-

mance achieved on both artificial and authentic documents. An application of the proposed approach on authorship attribution has also achieved perfect results of 100% accuracies together with confidence measurement for the first time.

Abstract

Automated Text Scoring (ATS) provides a cost-effective and consistent alternative to human marking. However, in order to achieve good performance, the predictive features of the system need to be manually engineered by human experts. We introduce a model that forms word representations by learning the extent to which specific words contribute to the text's score. Using Long-Short Term Memory networks to represent the meaning of texts, we demonstrate that a fully automated framework is able to achieve excellent results over similar approaches. In an attempt to make our results more interpretable, and inspired by recent advances in visualizing neural networks, we introduce a novel method for identifying the regions of the text that the model has found more discriminative.

1 Introduction

Automated Text Scoring (ATS) refers to the set of statistical and natural language processing techniques used to automatically score a text on a marking scale. The advantages of ATS systems have been established since Project Essay Grade (PEG) (Page, 1967; Page, 1968), one of the earliest systems whose development was largely motivated by the prospect of reducing labour-intensive marking activities. In addition to providing a cost-effective and efficient approach to large-scale grading of (extended) text, such systems ensure a consistent application of marking criteria, therefore facilitating equity in scoring.

There is a large body of literature with regards to ATS systems of text produced by non-native English-language learners (Page, 1968; Attali and Burstein, 2006; Rudner and Liang, 2002; Elliot, 2003; Landauer et al., 2003; Briscoe et al., 2010; Yannakoudakis et al., 2011; Sakaguchi et al., 2015, among others), overviews of which can be found in various studies (Williamson, 2009; Dikli, 2006; Shermis and Hammer, 2012). Implicitly or explicitly, previous work has primarily treated text scoring as a supervised text classification task, and has utilized a large selection of techniques, ranging from the use of syntactic parsers, via vectorial semantics combined with dimensionality reduction, to generative and discriminative machine learning.

As multiple factors influence the quality of texts, ATS systems typically exploit a large range of textual features that correspond to different properties of text, such as grammar, vocabulary, style, topic relevance, and discourse coherence and cohesion. In addition to lexical and part-of-speech (POS) $n$grams, linguistically deeper features such as types of syntactic constructions, grammatical relations and measures of sentence complexity are among some of the properties that form an ATS system's internal marking criteria. The final representation of a text typically consists of a vector of features that have been manually selected and tuned to predict a score on a marking scale.

Although current approaches to scoring, such as regression and ranking, have been shown to achieve performance that is indistinguishable from that of human examiners, there is substantial manual effort involved in reaching these results on different domains, genres, prompts and so forth. Linguistic features intended to capture the aspects of writing to be assessed are hand-selected and tuned for specific domains. In order to perform well on different data, separate models with distinct feature sets are typically tuned.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 715–725,
Berlin, Germany, August 7-12, 2016.

Prompted by recent advances in deep learning and the ability of such systems to surpass state-of-the-art models in similar areas (Tang, 2015; Tai et al., 2015), we propose the use of recurrent neural network models for ATS. Multi-layer neural networks are known for automatically learning useful features from data, with lower layers learning basic feature detectors and upper levels learning more high-level abstract features (Lee et al., 2009). Additionally, recurrent neural networks are well-suited for modeling the compositionality of language and have been shown to perform very well on the task of language modeling (Mikolov et al., 2011; Chelba et al., 2013). We therefore propose to apply these network structures to the task of scoring, in order to both improve the performance of ATS systems and learn the required feature representations for each dataset automatically, without the need for manual tuning. More specifically, we focus on predicting a holistic score for extended-response writing items.[1]

However, automated models are not a panacea, and their deployment depends largely on the ability to examine their characteristics, whether they measure what is intended to be measured, and whether their internal marking criteria can be interpreted in a meaningful and useful way. The deep architecture of neural network models, however, makes it rather difficult to identify and extract those properties of text that the network has identified as discriminative. Therefore, we also describe a preliminary method for visualizing the information the model is exploiting when assigning a specific score to an input text.

2 Related Work

In this section, we describe a number of the more influential and/or recent approaches in automated text scoring of non-native English-learner writing.

Project Essay Grade (Page, 1967; Page, 1968; Page, 2003) is one of the earliest automated scoring systems, predicting a score using linear regression over vectors of textual features considered to be proxies of writing quality. Intelligent Essay Assessor (Landauer et al., 2003) uses Latent Semantic Analysis to compute the semantic similarity between texts at specific grade points and a test text, which is assigned a score based on the ones in the training set to which it is most similar. Lonsdale and Strong-Krause (2003) use the Link Grammar parser (Sleator and Templerley, 1995) to analyse and score texts based on the average sentence-level scores calculated from the parser's cost vector.

The Bayesian Essay Test Scoring sYstem (Rudner and Liang, 2002) investigates multinomial and Bernoulli Naive Bayes models to classify texts based on shallow content and style features. e-Rater (Attali and Burstein, 2006), developed by the Educational Testing Service, was one of the first systems to be deployed for operational scoring in high-stakes assessments. The model uses a number of different features, including aspects of grammar, vocabulary and style (among others), whose weights are fitted to a marking scheme by regression.

Chen et al. (2010) use a voting algorithm and address text scoring within a weakly supervised bag-of-words framework. Yannakoudakis et al. (2011) extract deep linguistic features and employ a discriminative learning-to-rank model that outperforms regression.

Recently, McNamara et al. (2015) used a hierachical classification approach to scoring, utilizing linguistic, semantic and rhetorical features, among others. Farra et al. (2015) utilize variants of logistic and linear regression and develop models that score persuasive essays based on features extracted from opinion expressions and topical elements.

There have also been attempts to incorporate more diverse features to text scoring models. Klebanov and Flor (2013) demonstrate that essay scoring performance is improved by adding to the model information about percentages of highly associated, mildly associated and dis-associated pairs of words that co-exist in a given text. Somasundaran et al. (2014) exploit lexical chains and their interaction with discourse elements for evaluating the quality of persuasive essays with respect to discourse coherence. Crossley et al. (2015) identify student attributes, such as standardized test scores, as predictive of writing success and use them in conjunction with textual features to develop essay scoring models.

In 2012, Kaggle,[2] sponsored by the Hewlett Foundation, hosted the Automated Student Assessment Prize (ASAP) contest, aiming to demon-

[1] The task is also referred to as Automated Essay Scoring. Throughout this paper, we use the terms *text* and *essay* (scoring) interchangeably.

[2] http://www.kaggle.com/c/asap-aes/

strate the capabilities of automated text scoring systems (Shermis, 2015). The dataset released consists of around twenty thousand texts (60% of which are marked), produced by middle-school English-speaking students, which we use as part of our experiments to develop our models.

3 Models

3.1 C&W Embeddings

Collobert and Weston (2008) and Collobert et al. (2011) introduce a neural network architecture (Fig. 1a) that learns a distributed representation for each word w in a corpus based on its local context. Concretely, suppose we want to learn a representation for some target word w_t found in an n-sized sequence of words $\mathcal{S} = (w_1, \ldots, w_t, \ldots, w_n)$ based on the other words which exist in the same sequence ($\forall w_i \in \mathcal{S} \,|\, w_i \neq w_t$). In order to derive this representation, the model learns to discriminate between $\mathcal{S}$ and some 'noisy' counterpart $\mathcal{S}'$ in which the target word w_t has been substituted for a randomly sampled word from the vocabulary: $\mathcal{S}' = (w_1, \ldots, w_c, \ldots, w_n \,|\, w_c \sim \mathcal{V})$. In this way, every word w is more predictive of its local context than any other random word in the corpus.

Every word in $\mathcal{V}$ is mapped to a real-valued vector in Ω via a mapping function $C(\cdot)$ such that $C(w_i) = \langle \mathbf{M}_{\star i} \rangle$, where $\mathbf{M} \in \mathbb{R}^{D \times |\mathcal{V}|}$ is the embedding matrix and $\langle \mathbf{M}_{\star i} \rangle$ is the ith column of $\mathbf{M}$. The network takes $\mathcal{S}$ as input by concatenating the vectors of the words found in it; $\mathbf{s}_t = \langle C(w_1)^\intercal \| \ldots \| C(w_t)^\intercal \| \ldots \| C(w_n)^\intercal \rangle \in \mathbb{R}^{nD}$. Similarly, $\mathcal{S}'$ is formed by substituting $C(w_t)$ for $C(w_c) \sim \mathbf{M} \,|\, w_c \neq w_t$.

The input vector is then passed through a hard $\tanh$ layer defined as,

$$htanh(x) = \begin{cases} -1 & x < -1 \\ x & -1 \leqslant x \leqslant 1 \\ 1 & x > 1 \end{cases} \quad (1)$$

which feeds a single linear unit in the output layer. The function that is computed by the network is ultimately given by (4):

$$\mathbf{s}_t = \langle \mathbf{M}_{\star 1}^\intercal \| \ldots \| \mathbf{M}_{\star t}^\intercal \| \ldots \| \mathbf{M}_{\star n}^\intercal \rangle^\intercal \quad (2)$$

$$\mathbf{i} = \sigma(\mathbf{W}_{hi}\mathbf{s}_t + \mathbf{b}_h) \quad (3)$$

$$f(\mathbf{s}_t) = \mathbf{W}_{oh}\mathbf{i} + \mathbf{b}_o \quad (4)$$

$$f(\mathbf{s}), \mathbf{b}_o \in \mathbb{R}^1$$
$$\mathbf{W}_{oh} \in \mathbb{R}^{H \times 1}$$
$$\mathbf{W}_{hi} \in \mathbb{R}^{D \times H}$$
$$\mathbf{s} \in \mathbb{R}^D$$
$$\mathbf{b}_o \in \mathbb{R}^H$$

where $\mathbf{M}, \mathbf{W}_{oh}, \mathbf{W}_{hi}, \mathbf{b}_o, \mathbf{b}_h$ are learnable parameters, D, H are hyperparameters controlling the size of the input and the hidden layer, respectively; σ is the application of an element-wise non-linear function ($htanh$ in this case).

The model learns word embeddings by ranking the activation of the true sequence $\mathcal{S}$ higher than the activation of its 'noisy' counterpart $\mathcal{S}'$. The objective of the model then becomes to minimize the hinge loss which ensures that the activations of the original and 'noisy' $n$grams will differ by at least 1:

$$loss_{context}(target,\ corrupt) = [1 - f(\mathbf{s}_t) + f(\mathbf{s}_{ck})]_+,\ \forall k \in \mathbb{Z}^E \quad (5)$$

where E is another hyperparameter controlling the number of 'noisy' sequences we give along with the correct sequence (Mikolov et al., 2013; Gutmann and Hyvärinen, 2012).

3.2 Augmented C&W model

Following Tang (2015), we extend the previous model to capture not only the local linguistic environment of each word, but also how each word contributes to the overall score of the essay. The aim here is to construct representations which, along with the linguistic information given by the linear order of the words in each sentence, are able to capture *usage* information. Words such as *is, are, to, at* which appear with any essay score are considered to be *under*-informative in the sense that they will activate equally both on high and low scoring essays. Informative words, on the other hand, are the ones which would have an impact on the essay score (e.g., spelling mistakes).

In order to capture those *score-specific word embeddings* (SSWEs), we extend (4) by adding a further linear unit in the output layer that performs linear regression, predicting the essay score. Using (2), the activations of the network (presented in Fig. 1b) are given by:

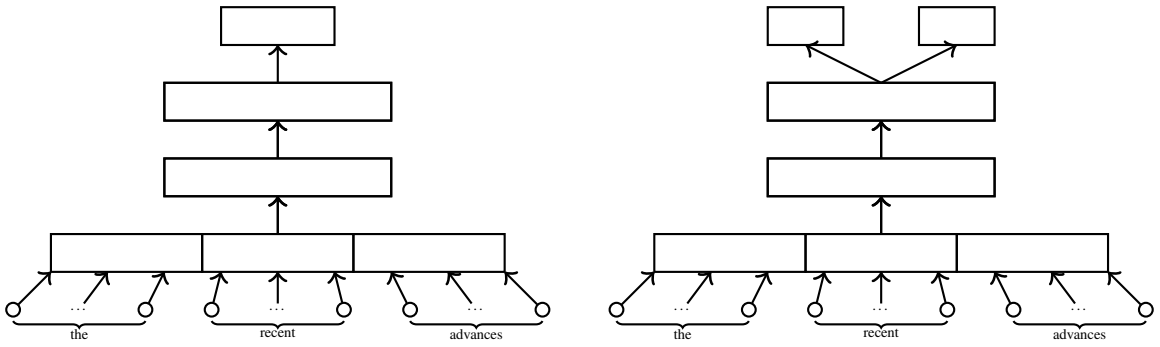

Figure 1: Architecture of the original C&W model (left) and of our extended version (right).

$$f_{ss}(\mathbf{s}) = \mathbf{W}_{oh_1}\mathbf{i} + \mathbf{b}_{o_1} \quad (6)$$

$$f_{context}(\mathbf{s}) = \mathbf{W}_{oh_2}\mathbf{i} + \mathbf{b}_{o_2} \quad (7)$$

$$f_{ss}(\mathbf{s}) \in [\min(score), \max(score)]$$
$$\mathbf{b}_{o_1} \in \mathbb{R}^1$$
$$\mathbf{W}_{oh_1} \in \mathbb{R}^{1\times H}$$

The error we minimize for f_{ss} (where ss stands for *score specific*) is the *mean squared error* between the predicted $\hat{y}$ and the actual essay score y:

$$loss_{score}(\mathbf{s}) = \frac{1}{N}\sum_{i=1}^{N}(\hat{y}_i - y_i)^2 \quad (8)$$

From (5) and (8) we compute the overall loss function as a weighted linear combination of the two loss functions (9), back-propagating the error gradients to the embedding matrix $\mathbf{M}$:

$$loss_{overall}(\mathbf{s}) = \begin{array}{c}\alpha \cdot loss_{context}(\mathbf{s}, \mathbf{s}') \\ + (1-\alpha)\cdot loss_{score}(\mathbf{s})\end{array} \quad (9)$$

where α is the hyper-parameter determining how the two error functions should be weighted. α values closer to 0 will place more weight on the score-specific aspect of the embeddings, whereas values closer to 1 will favour the contextual information.

Fig. 2 shows the advantage of using SSWEs in the present setting. Based solely on the information provided by the linguistic environment, words such as *computer* and *laptop* are going to be placed together with their mis-spelled counterparts *copmuter* and *labtop* (Fig. 2a). This, however, does not reflect the fact that the mis-spelled words tend to appear in lower scoring essays. Using SSWEs, the correctly spelled words are pulled apart in the vector space from the incorrectly spelled ones, retaining, however, the information that *labtop* and *copmuter* are still contextually related (Fig. 2b).

3.3 Long-Short Term Memory Network

We use the SSWEs obtained by our model to derive continuous representations for each essay. We treat each essay as a sequence of tokens and explore the use of uni- and bi-directional (Graves, 2012) Long-Short Term Memory networks (LSTMs) (Hochreiter and Schmidhuber, 1997) in order to embed these sequences in a vector of fixed size. Both uni- and bi-directional LSTMs have been effectively used for embedding long sequences (Hermann et al., 2015). LSTMs are a kind of recurrent neural network (RNN) architecture in which the output at time t is conditioned on the input $\mathbf{s}$ both at time t and at time $t-1$:

$$\mathbf{y}_t = \mathbf{W}_{yh}\mathbf{h}_t + \mathbf{b}_y \quad (10)$$

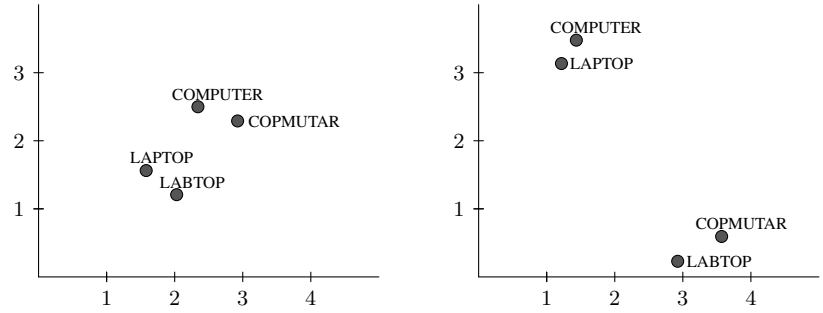
$$\mathbf{h}_t = \mathcal{H}(\mathbf{W}_{hs}\mathbf{s}_t + \mathbf{W}_{hh}\mathbf{h}_{t-1} + \mathbf{b}_h) \quad (11)$$

where $\mathbf{s}_t$ is the input at time t, and $\mathcal{H}$ is usually an element-wise application of a non-linear function. In LSTMs, $\mathcal{H}$ is substituted for a composite function defining $\mathbf{h}_t$ as:

$$\mathbf{i}_t = \begin{array}{c}\sigma(\mathbf{W}_{is}\mathbf{s}_t + \mathbf{W}_{ih}\mathbf{h}_{t-1} + \\ \mathbf{W}_{ic}\mathbf{c}_{t-1} + \mathbf{b}_i)\end{array} \quad (12)$$

$$\mathbf{f}_t = \begin{array}{c}\sigma(\mathbf{W}_{fs}\mathbf{s}_t + \mathbf{W}_{fh}\mathbf{h}_{t-1} + \\ \mathbf{W}_{fc}\mathbf{c}_{t-1} + \mathbf{b}_f)\end{array} \quad (13)$$

$$\mathbf{c}_t = \begin{array}{c}\mathbf{i}_t \odot g(\mathbf{W}_{cs}\mathbf{s}_t + \mathbf{W}_{ch}\mathbf{h}_{t-1} + \mathbf{b}_c) + \\ \mathbf{f}_t \odot \mathbf{c}_{t-1}\end{array} \quad (14)$$



(a) Standard neural embeddings

(b) Score-specific word embeddings

Figure 2: Comparison between standard and score-specific word embeddings. By virtue of appearing in similar environments, standard neural embeddings will place the correct and the incorrect spelling closer in the vector space. However, since the mistakes are found in lower scoring essays, SSWEs are able to discriminate between the correct and the incorrect versions without loss in contextual meaning.

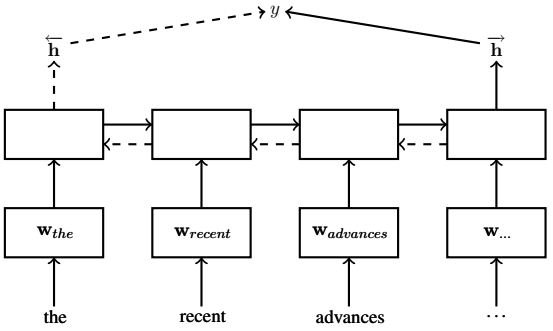


Figure 3: A single-layer *Long Short Term Memory* (LSTM) network. The word vectors $\mathbf{w}_i$ enter the input layer one at a time. The hidden layer that has been formed at the last timestep is used to predict the essay score using linear regression. We also explore the use of bi-directional LSTMs (dashed arrows). For 'deeper' representations, we can stack more LSTM layers after the hidden layer shown here.

$$\mathbf{o}_t = \sigma(\mathbf{W}_{os}\mathbf{s}_t + \mathbf{W}_{oh}\mathbf{h}_{t-1} + \mathbf{W}_{oc}\mathbf{c}_t + \mathbf{b}_o) \quad (15)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot h(\mathbf{c}_t) \quad (16)$$

where g, σ and h are element-wise non-linear functions such as the *logistic sigmoid* ($\frac{1}{1+e^{-x}}$) and the *hyperbolic tangent* ($\frac{e^{2z}-1}{e^{2z}+1}$); $\odot$ is the Hadamard product; $\mathbf{W}, \mathbf{b}$ are the learned weights and biases respectively; and *i*, *f*, *o* and *c* are the input, forget, output gates and the cell activation vectors respectively.

Training the LSTM in a uni-directional manner (i.e., from left to right) might leave out important information about the sentence. For example, our interpretation of a word at some point t_i might be different once we know the word at t_{i+5}. An effective way to get around this issue has been to train the LSTM in a bidirectional manner. This requires doing both a forward and a backward pass of the sequence (i.e., feeding the words from left to right and from right to left). The hidden layer element in (10) can therefore be re-written as the concatenation of the forward and backward hidden vectors:

$$\mathbf{y}_t = \mathbf{W}_{yh} \begin{pmatrix} \overleftarrow{\mathbf{h}}_t^\intercal \\ \overrightarrow{\mathbf{h}}_t^\intercal \end{pmatrix} + \mathbf{b}_y \quad (17)$$

We feed the embedding of each *word* found in each essay to the LSTM one at a time, zero-padding shorter sequences. We form D-dimensional *essay* embeddings by taking the activation of the LSTM layer at the timestep where the last word of the essay was presented to the network. In the case of bi-directional LSTMs, the two independent passes of the essay (from left to right and from right to left) are concatenated together to predict the essay score. These essay embeddings are then fed to a linear unit in the output layer which predicts the essay score (Fig. 3). We use the *mean square error* between the predicted and the gold score as our loss function, and optimize with RMSprop (Dauphin et al., 2015), propagating the errors back to the *word* embeddings.[3]

[3]The maximum time for jointly training a particular SSWE + LSTM combination took about 55–60 hours on an Amazon EC2 g2.2xlarge instance (average time was 27–30 hours).

3.4 Other Baselines

We train a Support Vector Regression model (see Section 4), which is one of the most widely used approaches in text scoring. We parse the data using the RASP parser (Briscoe et al., 2006) and extract a number of different features for assessing the quality of the essays. More specifically, we use character and part-of-speech unigrams, bigrams and trigrams; word unigrams, bigrams and trigrams where we replace open-class words with their POS; and the distribution of common nouns, prepositions, and coordinators. Additionally, we extract and use as features the rules from the phrase-structure tree based on the top parse for each sentence, as well as an estimate of the error rate based on manually-derived error rules.

Ngrams are weighted using *tf–idf*, while the rest are count-based and scaled so that all features have approximately the same order of magnitude. The final input vectors are unit-normalized to account for varying text-length biases.

Further to the above, we also explore the use of the Distributed Memory Model of Paragraph Vectors (PV-DM) proposed by Le and Mikolov (2014), as a means to directly obtain essay embeddings. PV-DM takes as input word vectors which make up $n$gram sequences and uses those to predict the next word in the sequence. A feature of PV-DM, however, is that each 'paragraph' is assigned a unique vector which is used in the prediction. This vector, therefore, acts as a 'memory', retaining information from all contexts that have appeared in this paragraph. Paragraph vectors are then fed to a linear regression model to obtain essay scores (we refer to this model as `doc2vec`).

Additionally, we explore the effect of our score-specific method for learning word embeddings, when compared against three different kinds of word embeddings:

- `word2vec` embeddings (Mikolov et al., 2013) trained on our training set (see Section 4).
- Publicly available `word2vec` embeddings (Mikolov et al., 2013) pre-trained on the Google News corpus (ca. 100 billion words), which have been very effective in capturing solely contextual information.
- Embeddings that are constructed on the fly by the LSTM, by propagating the errors from its hidden layer back to the embedding matrix (i.e., we do not provide any pre-trained word embeddings).[4]

4 Dataset

The Kaggle dataset contains 12.976 essays ranging from 150 to 550 words each, marked by two raters (Cohen's $\kappa = 0.86$). The essays were written by students ranging from Grade 7 to Grade 10, comprising eight distinct sets elicited by eight different prompts, each with distinct marking criteria and score range.[5] For our experiments, we use the resolved combined score between the two raters, which is calculated as the average between the two raters' scores (if the scores are close), or is determined by a third expert (if the scores are far apart). Currently, the state-of-the-art on this dataset has achieved a Cohen's $\kappa = 0.81$ (using quadratic weights). However, the test set was released without the gold score annotations, rendering any comparisons futile, and we are therefore restricted in splitting the given training set to create a new test set.

The sets where divided as follows: 80% of the entire dataset was reserved for training/validation, and 20% for testing. 80% of the training/validation subset was used for actual training, while the remaining 20% for validation (in absolute terms for the entire dataset: 64% training, 16% validation, 20% testing). To facilitate future work, we release the ids of the validation and test set essays we used in our experiments, in addition to our source code and various hyperparameter values.[6]

5 Experiments

5.1 Results

The hyperparameters for our model were as follows: sizes of the layers H, D, the learning rate η, the window size n, the number of 'noisy' sequences E and the weighting factor α. Also the hyperparameters of the LSTM were the size of the LSTM layer D_{LSTM} as well as the dropout rate r.

[4] Another option would be to use standard C&W embeddings; however, this is equivalent to using `SSWE`s with $\alpha = 1$, which we found to produce low results.

[5] Five prompts employed a holistic scoring rubric, one was scored with a two-trait rubric, and two were scored with a multi-trait rubric, but reported as a holistic score (Shermis and Hammer, 2012).

[6] The code, by-model hyperparameter configurations and the IDs of the testing set are available at `https://github.com/dimalik/ats/`.

Model	Spearman's ρ	Pearson r	RMSE	Cohen's κ
doc2vec	0.62	0.63	4.43	0.85
SVM	0.78	0.77	8.85	0.75
LSTM	0.59	0.60	6.8	0.54
BLSTM	0.7	0.5	7.32	0.36
Two-layer LSTM	0.58	0.55	7.16	0.46
Two-layer BLSTM	0.68	0.52	7.31	0.48
word2vec + LSTM	0.68	0.77	5.39	0.76
word2vec + BLSTM	0.75	0.86	4.34	0.85
word2vec + Two-layer LSTM	0.76	0.71	6.02	0.69
word2vec + Two-layer BLSTM	0.78	0.83	4.79	0.82
$\text{word2vec}_{\text{pre-trained}}$ + Two-layer BLSTM	0.79	0.91	3.2	0.92
SSWE + LSTM	0.8	0.94	2.9	0.94
SSWE + BLSTM	0.8	0.92	3.21	0.95
SSWE + Two-layer LSTM	0.82	0.93	3	0.94
SSWE + Two-layer BLSTM	**0.91**	**0.96**	**2.4**	**0.96**

Table 1: Results of the different models on the Kaggle dataset. All resulting vectors were trained using linear regression. We optimized the parameters using a separate validation set (see text) and report the results on the test set.

Since the search space would be massive for grid search, the best hyperparameters were determined using Bayesian Optimization (Snoek et al., 2012). In this context, the performance of our models in the validation set is modeled as a sample from a Gaussian process (GP) by constructing a probabilistic model for the error function and then exploiting this model to make decisions about where to next evaluate the function. The hyperparameters for our baselines were also determined using the same methodology.

All models are trained on our training set (see Section 4), except the one prefixed '$\text{word2vec}_{\text{pre-trained}}$' which uses pre-trained embeddings on the Google News Corpus. We report the Spearman's rank correlation coefficient ρ, Pearson's product-moment correlation coefficient r, and the root mean square error (RMSE) between the predicted scores and the gold standard on our test set, which are considered more appropriate metrics for evaluating essay scoring systems (Yannakoudakis and Cummins, 2015). However, we also report Cohen's κ with quadratic weights, which was the evaluation metric used in the Kaggle competition. Performance of the models is shown in Table 1.

In terms of correlation, SVMs produce competitive results ($\rho = 0.78$ and $r = 0.77$), outperforming doc2vec, LSTM and BLSTM, as well as their deep counterparts. As described above, the SVM model has rich linguistic knowledge and consists of hand-picked features which have achieved excellent performance in similar tasks (Yannakoudakis et al., 2011). However, in terms of RMSE, it is among the lowest performing models (8.85), together with 'BLSTM' and 'Two-layer BLSTM'. Deep models in combination with word2vec (i.e., 'word2vec + Two-layer LSTM' and 'word2vec + Two-layer BLSTM') and SVMs are comparable in terms of r and ρ, though not in terms of RMSE, where the former produce better results, with RMSE improving by half (4.79). doc2vec also produces competitive RMSE results (4.43), though correlation is much lower ($\rho = 0.62$ and $r = 0.63$).

The two BLSTMs trained with word2vec embeddings are among the most competitive models in terms of correlation and outperform all the models, except the ones using pre-trained embeddings and SSWEs. Increasing the number of hidden layers and/or adding bi-directionality does not always improve performance, but it clearly helps in this case and performance improves compared to their uni-directional counterparts.

Using pre-trained word embeddings improves the results further. More specifically, we found '$\text{word2vec}_{\text{pre-trained}}$ + Two-layer BLSTM' to be the best configuration, increasing correlation to 0.79 ρ and 0.91 r, and reducing RMSE to 3.2. We note however that this is not an entirely

fair comparison as these are trained on a much larger corpus than our training set (which we use to train our models). Nevertheless, when we use our SSWEs models we are able to outperform '$\texttt{word2vec}_{\text{pre-trained}}$ + Two-layer BLSTM', even though our embeddings are trained on fewer data points. More specifically, our best model ('SSWE + Two-layer BLSTM') improves correlation to $\rho = 0.91$ and $r = 0.96$, as well as RMSE to 2.4, giving a maximum increase of around 10% in correlation. Given the results of the pre-trained model, we believe that the performance of our best SSWE model will further improve should more training data be given to it.[7]

5.2 Discussion

Our SSWE + LSTM approach having no prior knowledge of the grammar of the language or the domain of the text, is able to score the essays in a very human-like way, outperforming other state-of-the-art systems. Furthermore, while we tuned the models' hyperparameters on a separate validation set, we did not perform any further preprocessing of the text other than simple tokenization.

In the essay scoring literature, text length tends to be a strong predictor of the overall score. In order to investigate any possible effects of essay length, we also calculate the correlation between the gold scores and the length of the essays. We find that the correlations on the test set are relatively low ($r = 0.3, \rho = 0.44$), and therefore conclude that there are no such strong effects.

As described above, we used Bayesian Optimization to find optimal hyperparameter configurations in fewer steps than in regular grid search. Using this approach, the optimization model showed some clear preferences for some parameters which were associated with better scoring models:[8] the number of 'noisy' sequences E, the weighting factor α and the size of the LSTM layer D_{LSTM}. The optimal α value was consistently set to 0.1, which shows that our SSWE approach was necessary to capture the *usage* of the words. Performance dropped considerably as α increased (less weight on SSWEs and more on the contextual aspect). When using $\alpha = 1$, which is equivalent to using the basic C&W model, we found that performance was considerably lower (e.g., correlation dropped to $\rho = 0.15$).

The number of 'noisy' sequences was set to 200, which was the highest possible setting we considered, although this might be related more to the size of the corpus (see Mikolov et al. (2013) for a similar discussion) rather than to our approach. Finally, the optimal value for D_{LSTM} was 10 (the lowest value investigated), which again may be corpus-dependent.

6 Visualizing the black box

In this section, inspired by recent advances in (de-) convolutional neural networks in computer vision (Simonyan et al., 2013) and text summarization (Denil et al., 2014), we introduce a novel method of generating interpretable visualizations of the network's performance. In the present context, this is particularly important as one advantage of the manual methods discussed in § 2 is that we are able to know on what grounds the model made its decisions and which features are most discriminative.

At the outset, our goal is to assess the 'quality' of our word vectors. By 'quality' we mean the level to which a word appearing in a particular context would prove to be problematic for the network's prediction. In order to identify 'high' and 'low' quality vectors, we perform a single pass of an essay from left to right and let the LSTM make its score prediction. Normally, we would provide the gold scores and adjust the network weights based on the error gradients. Instead, we provide the network with a *pseudo-score* by taking the maximum score this specific essay can take[9] and provide this as the 'gold' score. If the word vector is of 'high' quality (i.e., associated with higher scoring texts), then there is going to be little adjustment to the weights in order to predict the highest score possible. Conversely, providing the minimum possible score (here 0), we can assess how 'bad' our word vectors are. Vectors which require minimal adjustment to reach the lowest score are considered of 'lower' quality. Note that since we do a complete pass over the network (without doing any weight updates), the vector quality is going to be *essay dependent*.

[7] Our approach outperforms all the other models in terms of Cohen's κ too.

[8] For the best scoring model the hyperparameters were as follows: $D = 200, H = 100, \eta = 1e-7, n = 9, E = 200, \alpha = 0.1, D_{LSTM} = 10, r = 0.5$.

[9] Note the in the Kaggle dataset essays from different essay sets have different maximum scores. Here we take as $\tilde{y}_{\max}$ the essay set maximum rather than the global maximum.

. . . way to show that Saeng is a determined . . .
. . . sometimes I do . Being patience is being . . .
. . . which leaves the reader satisfied . . .
. . . is in this picture the cyclist is riding a dry and area which could mean that it is very and the looks to be going down hill there looks to be a lot of turns . . .
. . . The only reason im putting this in my own way is because know one is patient in my family . . . .
. . . Whether they are building hand-eye coordination , researching a country , or family and friends through @CAPS3 , @CAPS2 , @CAPS6 the internet is highly and I hope you feel the same way .

Table 2: Several example visualizations created by our LSTM. The full text of the essay is shown in black and the 'quality' of the word vectors appears in color on a range from dark red (low quality) to dark green (high quality).

Concretely, using the network function $f(\mathbf{x})$ as computed by Eq. (12) – (17), we can approximate the loss induced by feeding the *pseudo-scores* by taking the *magnitude* of each error vector (18) – (19). Since $\lim_{\|\mathbf{w}\|_2 \to 0} \hat{y} = y$, this magnitude should tell us how much an embedding needs to change in order to achieve the gold score (here pseudo-score). In the case where we provide the minimum as a *pseudo-score*, a $\|\mathbf{w}\|_2$ value closer to zero would indicate an incorrectly used word. For the results reported here, we combine the magnitudes produced from giving the maximum and minimum *pseudo-scores* into a single score, computed as $L(\tilde{y}_{\max}, f(\mathbf{x})) - L(\tilde{y}_{\min}, f(\mathbf{x}))$, where:

$$L(\tilde{y}, f(\mathbf{x})) \approx \|\mathbf{w}\|_2 \tag{18}$$

$$\mathbf{w} = \nabla L(\mathbf{x}) \triangleq \left.\frac{\partial L}{\partial \mathbf{x}}\right|_{(\tilde{y}, f(\mathbf{x}))} \tag{19}$$

where $\|\mathbf{w}\|_2$ is the vector Euclidean norm $\mathbf{w} = \sqrt{\sum_{i=1}^{N} w_i^2}$; $L(\cdot)$ is the *mean squared error* as in Eq. (8); and $\tilde{y}$ is the essay *pseudo-score*.

We show some examples of this visualization procedure in Table 2. The model is capable of providing positive feedback. Correctly placed punctuation or long-distance dependencies (as in Sentence 6 *are . . . researching*) are particularly favoured by the model. Conversely, the model does not deal well with proper names, but is able to cope with POS mistakes (e.g., *Being patience* or *the internet is highly and . . .*). However, as seen in Sentence 3 the model is not perfect and returns a false negative in the case of *satisfied*.

One potential drawback of this approach is that the gradients are calculated only after the end of the essay. This means that if a word appears multiple times within an essay, sometimes correctly and sometimes incorrectly, the model would not be able to distinguish between them. Two possible solutions to this problem are to either provide the gold score at each timestep which results into a very computationally expensive endeavour, or to feed sentences or phrases of smaller size for which the scoring would be more consistent.[10]

7 Conclusion

In this paper, we introduced a deep neural network model capable of representing both local contextual and usage information as encapsulated by essay scoring. This model yields *score-specific word embeddings* used later by a recurrent neural network in order to form essay representations.

We have shown that this kind of architecture is able to surpass similar state-of-the-art systems, as well as systems based on manual feature engineering which have achieved results close to the upper bound in past work. We also introduced a novel way of exploring the basis of the network's internal scoring criteria, and showed that such models are interpretable and can be further exploited to provide useful feedback to the author.

[10] We note that the same visualization technique can be used to show the 'goodness' of phrases/sentences. Within the phrase setting, after feeding the last word of the phrase to the network, the LSTM layer will contain the phrase embedding. Then, we can assess the 'goodness' of this embedding by evaluating the error gradients after predicting the highest/lowest score.

Abstract

Digital personal assistants are becoming both more common and more useful. The major NLP challenge for personal assistants is machine understanding: translating natural language user commands into an executable representation. This paper focuses on understanding rules written as If-Then statements, though the techniques should be portable to other semantic parsing tasks. We view understanding as structure prediction and show improved models using both conventional techniques and neural network models. We also discuss various ways to improve generalization and reduce overfitting: synthetic training data from paraphrase, grammar combinations, feature selection and ensembles of multiple systems. An ensemble of these techniques achieves a new state of the art result with 8% accuracy improvement.

1 Introduction

The ability to instruct computers using natural language clearly allows novice users to better use modern information technology. Work in semantic parsing has explored mapping natural language to some formal domain-specific programming languages such as database queries (Woods, 1977; Zelle and Mooney, 1996; Berant et al., 2013; Andreas et al., 2016; Yin et al., 2016), commands to robots (Kate et al., 2005), operating systems (Branavan et al., 2009), and spreadsheets (Gulwani and Marron, 2014). This paper explores the use of neural network models (NN) and conventional models for semantic parsing. Recently approaches using neural networks have shown great improvements in a number of areas such as parsing (Vinyals et al., 2015), machine translation (Devlin et al., 2014), and image captioning (Karpathy and Fei-Fei, 2015). We are among the first to apply neural network methods to semantic parsing tasks (Grefenstette et al., 2014; Dong and Lapata, 2016).

There are several benchmark datasets for semantic parsing, the most well known of which is Geoquery (Zelle and Mooney, 1996). We target an If-Then dataset (Quirk et al., 2015) for several reasons. First, it is both directly applicable to the end-user task of training personal digital assistants. Second, the training data, drawn from the site `http://ifttt.com`, is comparatively quite large, containing nearly 100,000 recipe-description pairs. That said, it is several orders of magnitude smaller than the data for other tasks where neural networks have been successful. Machine translation datasets, for instance, may contain billions of tokens. NN methods appear "data-hungry". They require larger datasets to outperform sparse linear approaches with careful feature engineering, as evidenced in work on syntactic parsing (Vinyals et al., 2015). This makes it interesting to compare NN models with conventional models on this dataset.

As in most prior semantic parsing attempts, we model natural language understanding as a structure prediction problem. Each modeling decision predicts some small component of the target structure, conditioned on the whole input and all prior decisions. Because this is a real-world task, the vocabulary is large and varied, with many words appearing only rarely. Overfitting is a clear danger. We explore several methods to improve generalization. A classic method is to apply feature selection. Synthetic data generated by paraphrasing helps augment the data available. Adjusting the conditional structure of our model also makes sense, as does creating ensembles of the best performing approaches.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 726–736,
Berlin, Germany, August 7-12, 2016.

An ensemble of the resulting systems achieves a new state-of-the-art result, with an absolute improvement of 8% in accuracy. We compare the performance of a neural network model with logistic regression, and explore in detail the contribution of each of them, and why the logistic regression is performing better than the neural network.

2 Related Work

2.1 Semantic Parsing

Semantic parsing is the task of translating natural language to a meaning representation language that the machine can execute. Various semantic parsing tasks have been proposed before, including querying a database (Zelle and Mooney, 1996), following navigation instructions (Chen, 2012), translating to Abstract Meaning Representation (AMR) (Artzi et al., 2015), as well as the If-Then task we explore. Meaning representation languages vary with the task. In database queries, the meaning representation language is either the native query language (e.g. SQL or Prolog), or some alternative that can be deterministically transformed into the native query language. To follow navigation instructions, the meaning representation language is comprised of sequences of valid actions: turn left, turn right, move forward, etc. For parsing If-Then rules, the meaning representation is an abstract syntax tree (AST) in a very simple language. Each root node expands into a "trigger" and "action" pair. These nodes in turn expand into a set of supported triggers and actions. We model these trees as an (almost) context free grammar[1] that generates valid If-Then tasks.

A number of semantic parsing approaches have been proposed, but most fit into the following broad divisions. First, approaches driven by Combinatory Categorical Grammar (CCG) have proven successful at several semantic parsing tasks. This approach is attractive in that it simultaneously provides syntactic and semantic parses of a natural language utterance. Syntactic structure helps constrain and guide semantic interpretation. CCG relies heavily on a *lexicon* that specifies both the syntactic category and formal semantics of each lexical item in the language. In many instantiations, the lexicon is learned from the training data (Zettlemoyer and Collins, 2005) and grounds directly in the meaning representation.

Another approach is to view the semantic parsing task as a machine translation task, where the source language is natural language commands and the target language is the meaning representation. Several approaches have applied standard machine translation techniques to semantic parsing (Wong and Mooney, 2006; Andreas et al., 2013; Ratnaparkhi, 1999) with successful results.

More recently, neural network approaches have been developed for semantic parsing, and especially for querying a database. A neural network is trained to translate the query and the database into some continuous representation then use it to answer the query (Andreas et al., 2016; Yin et al., 2016).

2.2 If-Then dataset

We use a semantic parsing dataset collected from `http://ifttt.com`, first introduced in Quirk et al. (2015). This website publishes a large set of *recipes* in the form of If-Then rules. Each recipe was authored by a website user to automate simple tasks. For instance, a recipe could send you a message every time you are tagged on a picture on Facebook. From a natural language standpoint, the most interesting part of this data is that alongside each recipe, there is a short natural language description intended to name or advertise the task. This provides a naturalistic albeit often noisy source of parallel data for training semantic parsing systems. Some of these descriptions faithfully represent the program. Others are underspecified or suggestive, with many details of the recipe are not uniquely specified or omitted altogether. The task is to predict the correct If-Then code given a natural language description.

As for the code, If-Then statements follow the format

```
If TriggerChannel.
       TriggerFunction (args)
Then ActionChannel.
       ActionFunction (args)
```

Every If-Then statement has exactly one *trigger* and one *action*. Each trigger and action consist of both a *channel* and a *function*. The channel represents a connection to a service, website, or device

[1] Information at the leaves of the action may use parameters drawn from the trigger. For instance, consider a rule that says "text me the daily weather report." The trigger is a new weather report, and the action is to send an SMS. The contents of that SMS are generated by the trigger, which is no longer context free.

(e.g., Facebook, Android, or ESPN) and provides a set of functions relevant to that channel. Finally, each of these functions may take a number of arguments: to receive a trigger when it becomes sunny, we need to specify the location to watch. The resulting dataset after cleaning and separation contains 77,495 training recipes, 5,171 development recipes and 4,294 testing recipes.

2.3 Semantic parsing for If-Then rules

Both CCG and MT-inspired approaches assume a fairly strong correspondence between the words in the natural language request and the concepts in the meaning representation. That is, most words in the description should correspond to some concept in the code, and most concepts in the code should correspond to some word in the description. However, prior work on this dataset (Quirk et al., 2015) found that this strong correspondence is often missing. The descriptions may mention only the most crucial or interesting concepts; the remainder of the meaning representation must be inferred from context. The best performing methods focused primarily on generating well-formed meaning representations, conditioning their decisions on the source language.

Quirk et al. (2015) proposed two models that rely on a grammar to generate all valid ASTs. The first model learns a simple classifier for each production in the grammar, treating the sentence as a bag of features. No alignment between the language and meaning representation is assumed. The second method attempts to learn a correspondence between the language and the code, jointly learning to select the correct productions in the meaning representation grammar. Although the latter approach is more appealing from a modeling standpoint, empirically it doesn't perform substantially better than the alignment-free model. Furthermore the alignment-free model is much simpler to implement and optimize. Therefore, we build upon the alignment-free approach.

2.4 Neural Networks

Neural network approaches have recently made great strides in several natural language processing tasks, including machine translation and dependency parsing. Partially these gains are due to better generalization ability. Until recently, the NLP community leaned heavily on feature-rich approaches that allow models to learn complex relationships from data. However, important features, such as indicator features for words and phrases, were often very sparse. Furthermore, the best systems often relied on manually-induced feature combinations (Bohnet, 2010). Multi-layer neural networks have several advantages. Words (or, more generally, features) are first embedded into a continuous space where similar features land in nearby locations; this helps lead to lexical generalization. The additional hidden layers can model feature interactions in complex ways, obviating the need for manual feature template induction. Feed-forward neural networks with relatively simple structure have shown great gains in both dependency parsing (Chen and Manning, 2014) and machine translation (Devlin et al., 2014) without the need for complex feature templates and large models. Our NN models here are inspired by these effective approaches.

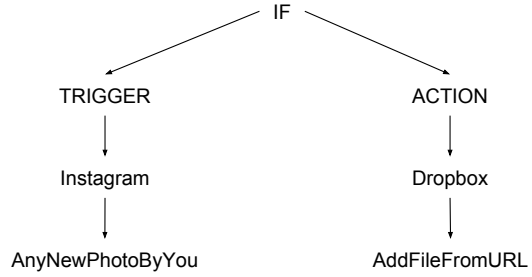

Figure 1: Derivation tree of If-Then statement of the recipe *Autosave your Instagram photos to Dropbox*. Arguments of the functions AnyNewPhotoByYou and AddFileFromURL are ignored.

3 Approach

We next describe the details of how If-Then recipes are constructed given natural language descriptions. As in prior work, we treat semantic parsing as a structure prediction task. First we describe the structure and features of the model, then expand on the details of inference.

3.1 Grammar

Along the lines of Quirk et al. (2015), we build a context-free grammar baseline. This grammar generates only well-formed meaning representations. In the case of this dataset, meaning representations always consist of a root production with two children: a trigger and an action. Both trigger and action first generate a channel, then a function matching that action. Optionally we may also generate the arguments of these functions; we do not

evaluate these selections as they are often idiosyncratic and specific to the user. For example, the recipe *Autosave your Instagram photos to Dropbox* has the following meaning representation:

```
IF Instagram.AnyNewPhotoByYou
THEN Dropbox.AddFileFromURL (
  FileURL={SourceUrl},
  FileName={Caption},
  DropboxFolderPath=IFTTT/Instagram
)
```

If we ignore the function arguments, the resulting meaning representation is:

```
IF Instagram.AnyNewPhotoByYou
THEN Dropbox.AddFileFromURL
```

This examples shows also that most of the function arguments are not crucial for the representation of the If-Then statement.[2]

The grammar we use has productions corresponding to every channel and every function. Figure 1 shows an example derivation tree D. This grammar consists of 892 productions: 128 trigger channels, 487 trigger functions, 99 action channels and 178 action functions.[3]

3.2 Model

Our goal is to learn a model of derivation trees D given a natural sentences S. To predict the derivation for a sentence, we seek the derivation D with maximum probability given the sentence $P(D|S)$.

For the purposes of modeling, we prefer to work with sequences rather than trees. Given a derivation tree D, we transform it into a sequence of productions $R(D) = r_1, \ldots, r_n$ by a top-down, left-to-right tree traversal: r_1 is the top-most production, and r_n is the bottom right production. The sentence S is represented as a set of features $f(S)$.

The derivation score $P(D|S)$ is a function of the productions of D and those features $f(S)$:

$$P(D|S) = \prod_{r_i \in R(D)} P(r_i|r_1, \ldots, r_{i-1}, f(S)) \quad (1)$$

The score of a derivation tree given the sentence is the product of probabilities of its productions.

[2]Arguments are still important for a few If-Then recipes. For instance, in *If there is snow tomorrow send a notification*, "snow" is an argument to the function Tomorrow'sForecastCallsFor. We are not handling such cases in this work.

[3]For this task, it is possible to model the programs as a 4-tuple, but using the grammar approach allows us to port the same technique to other semantic parsing tasks.

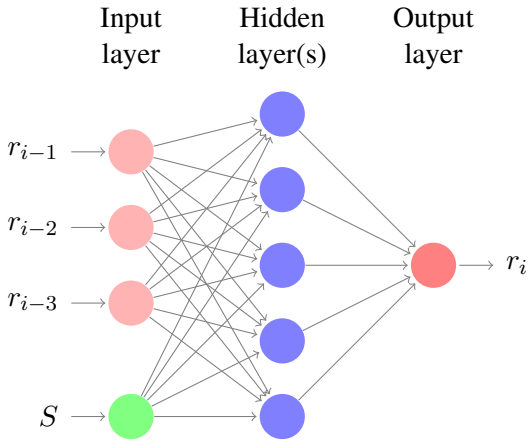

Figure 2: Architecture of the feed-forward neural networks used in this paper. When predicting rule r_i, the prior rules and the whole sentence are used as input. Separate parameters are learned for each position i.

The probability of selecting production r_i given the sentence S is dependent on the features of the sentence as well as the previous productions $r_1, \ldots, r_{i-1}$; namely, all those productions that are above and to the left of the current production. Conditioning on previous productions helps predicting the next one because it captures the conditional dependencies between the productions of the derivation tree, an improvement over prior work (Quirk et al., 2015). In particular, we can model which combinations of triggers and actions are more compatible, both function and channel.

3.3 Training

To learn the derivation score $P(D|S)$, we need to learn probability of productions $P(r_i|r_1, \ldots, r_{i-1}, f(S))$. We learn this probability using a multiclass classifier where the output classes are the possible productions in the grammar. The classifier is trained to predict the next production given previous productions and the sentence features.

Each sentence S is represented with a sparse feature vector $f(S)$. We used a simple set of features: word unigrams and bigrams, character trigrams, and Brown clusters (Liang, 2005). Each sentence is represented as a large sparse k-hot vector, where k is the number of features representing S, $|f(S)|$. We use a simple one-hot representation of prior rules.

For training, we explored two approaches: a standard logistic regression classifier, and a feed

forward neural network classifier. [4] As for network structure, we evaluated models with either one or two 200-dimensional hidden layers (with sigmoid activation function) followed by a softmax output layer to produce a probability for each production. We tried more than two hidden layers and larger hidden layer size, but the results were similar or worse likely because training becomes more difficult. Figure 2 shows the architecture of the network we use. For training, we used a variant of stochastic gradient descent called RMSprop (Dauphin et al., 2015) that adjusts the learning rate for each parameter adaptively, along with a global learning rate of 1^{-3}. The minibatch size was 100, with dropout regularization for hidden layers at 0.5 along with an L2 regularizer with weight 0.005. Each of these parameters were tuned on the validation set, though we found learning to be robust to minor variations in these parameters. All of the neural networks were implemented with Theanets (Johnson, 2015).

Note that history features $r_1, \ldots, r_{i-1}$ in classifier training are always correct. The model is akin to a MEMM, rather than a CRF. We make this simplifying assumption for tractability, like many neural network approaches (Devlin et al., 2014).

3.4 Inference

When, at test time, we are given a new sentence, we would like to infer its most probable derivation tree D. Classifiers trained as in the prior section give probability distributions over productions given the sentence and all prior productions $P(r_i|r_1, \ldots, r_{i-1}, f(S))$. Were the distribution to be context free, we could rely on algorithms similar to Earley parsing (Earley, 1970) to find the max derivation. However, the dependency on prior productions breaks the context free assumption. Therefore, we resort to approximate inference, namely beam search. Each partial hypothesis is grouped into a beam based on the number of productions it contains; we use a beam width of 8, and search for the highest scoring hypothesis.

4 Improving generalization

The data set we use for training and testing is primarily English but contains a broad vocabulary as well as many sentences from other languages such as Chinese, Arabic, and Russian. Thus, a seemingly large dataset of nearly eighty thousand examples is likely to suffer from overfitting. In this section, we discuss a few attempts to improve generalization in the sparse data setting.

4.1 Synthetic data using paraphrases

Arguably the best, though most expensive, way to reduce overfitting is to collect more training data. In our case, the training data available is limited and difficult to create. We propose to augment the training data in an automatic though potentially noisy way by generating synthetic training pairs.

The main idea is that two semantically equivalent sentences should have the same meaning representation. Given an existing training pair, replacing the pair's linguistic description with a paraphrase leads to a new synthetic training pair. For example, a recipe like *Autosave your Instagram **photos** to Dropbox* can be paraphrased to *Autosave your Instagram **pictures** to Dropbox* while retaining the meaning representation:

```
IF Instagram.AnyNewPhotoByYou
THEN Dropbox.AddFileFromURL.
```

We first explore paraphrases using WordNet synonyms. Every word in the sentence can be replaced by one of its synonyms that is picked randomly (a word is a synonym of itself). For words with multiple senses, we group all synonyms of all senses, then retain only those synonyms already in the vocabulary of the training data. This has two advantages. First, we do not increase the vocabulary size and therefore avoid overfitting. Second, this acts as a simple form of word sense disambiguation. This adds around 50,000 additional training examples.

Next, we consider augmenting the data using the Paraphrase Database (Ganitkevitch et al., 2013). Each original description is converted into a lattice. The original word at each position is left in place with a constant score. For each word or phrase in the description found PPDB, we add one arc for each paraphrase, parameterized by the PPDB score of that phrase. The resulting lattice represents many possible paraphrases of the input. We select at most 10 diverse paths through this lattice using the method of Gimpel et al. (2013).[5] This adds around 470,000 training examples.

[4] We tried the sequence-to-sequence model with LSTMs (Sutskever et al., 2014) to map word sequence to the derivation tree productions, but the results were always lower than the feed forward network. This is probably because of the lack of enough training data.

[5] We use a trigram language model, and a weight of 4.

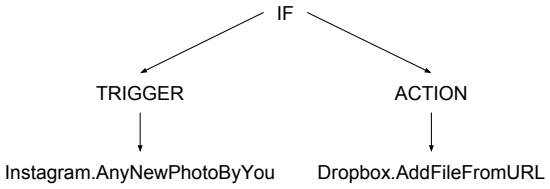

Figure 3: Derivation tree of IFTTT statement of the recipe *Autosave your Instagram photos to Dropbox* using the second grammar.

4.2 Alternative grammar formulation

We rely on a grammar to generate all valid meaning representations and learn models over the productions of this grammar. Different factorizations of the grammar lead to different model distributions. Our primary grammar is described in Section 3.1. A second, alternate grammar formulation has fewer levels but more productions: it combines the channel and function into a single production, in both the trigger and the action. Figure 3 shows an example derivation tree using this grammar. The size of this grammar is 780 productions (552 triggers + 228 actions).

An advantage of this grammar is that it cannot assign probability mass to invalid ASTs, where the function is not applicaable to the channel. On the other hand, this grammar likely does not generalize as well as the first grammar. The first grammar effectively has much more data about each channel, which likely improves accuracy. Function predictions can condition on hopefully accurate channel predictions. It can also benefit from the fact that some function names are shared among channels. From that perspective, the second grammar has fewer training instances for each outcome.

4.3 Feature selection

The training set contains approximately 77K training examples, yet the number of distinct features types (word unigrams and bigrams, character trigrams, Brown clusters) is approximately 230K. Only 80K features occur in the training set more than once. This ratio suggests overfitting may be a major issue.Feature selection likely can improve these issues. We used only simple count cutoffs, including only features that occur in the training set more than once and more than twice. Including features that occur more than once led to improvements in practice.

4.4 Ensemble

Finally, we explore improving generalization by building ensembles of multiple systems. Even if systems overfit, they likely overfit in different ways. When systems agree, they are likely to agree on the correct answer. Combining their results will suffer less from overfitting. We use simple majority voting as an ensemble strategy, resolving ties in an arbitrary but deterministic way.

5 Evaluation

We evaluate the performance of the systems by providing the model with descriptions unseen during training. Free parameters of the models were tuned using the development set. The separation of data into training, development, and test follows Quirk et al. (2015). Two evaluation metrics are used: accuracy on just channel selection and accuracy of both channel and function.

Two major families of approaches are considered: a baseline logistic regression classifier from scikit-learn (Pedregosa et al., 2011), as well as a feed-forward neural network. We explore a number of variations, including feature selection and grammar formulation.

5.1 Comparison systems

Our default system was described in section 3, not including improvements from section 4 unless otherwise noted. The grammar uses the primary formulation from section 3.1. Neural network models use a single hidden layer by default; we also explore two hidden layers.

We evaluate two approaches for generating synthetic data. The first approach, leaning primarily on WordNet to generate up to one paraphrase for each instance, is labeled WN. The second approach using Paraphrase Database to generate up to ten paraphrases is labeled PPDB.

The Alternate grammar line uses the section 4.2 grammar, and otherwise default configurations (no synthetic data, single hidden layer for NN).

Feature selection again uses the default configuration, but uses only those features that occurred more than once in the training data.

Finally we explore ensembles of all approaches. First, we combine all variations within the same model family; next, we bring all systems together. To evaluate the impact of individual systems, we also present results with specific systems removed.

System	Channel accuracy		Full tree accuracy	
	NN	LR	NN	LR
Quirk et al. (2015) w/o alignment	-	46.30	-	33.00
Quirk et al. (2015) with alignment	-	47.40	-	34.50
Default configurations	52.93	53.73	39.66	41.87
Two hidden layers	46.81	-	32.77	-
No hidden layers	50.05	-	38.47	-
Synthetic data (WN)	52.45	53.68	38.64	41.55

Alternate grammar	50.09	52.42	39.10	41.15
Feature selection	52.91	53.31	39.29	41.34
Ensemble of systems above	53.98	53.73	41.06	41.85
Ensemble NN + LR	54.31		**42.55**	
Ensemble NN + LR (w/o alternate grammar)	**54.38**		41.90	
Ensemble NN + LR (w/o synthetic data)	53.98		42.41	

Table 1: Accuracy of the Neural Network (NN) and Logistic Regression (LR) implementations of our system with various configurations. Channel-only and full tree (channel+function) accuracies are listed.

5.2 Results

Table 1 shows the accuracy of each evaluated system, and Table 2 explores system performance on important subsets of the data. The first columns present accuracy of just the channel, and the last columns present the channel and the function together (the full derivation). We achieve new state-of-the-art results, showing a 7% absolute improvement on the channel-only accuracy and 8% absolute improvement on the full derivation tree in the most difficult condition.

5.3 Discussion

Partly these improved results are driven by better features. Adding more robust representations of the input (e.g. Brown clusters) and conditioning on prior structure of the tree leads to more consistent and coherent trees.

One key observation is that the logistic regression classifier consistently outperforms the neural network, though by a small margin. We suspect two main causes: optimization difficulties and training size. To compare the optimization algorithms, Table 1 shows the result of a neural network with no hidden layers, which is effectively identical to a logistic regression model. Stochastic gradient descent used to train the neural network did not perform as well as the LIBLINEAR (Fan et al., 2008) solver used to train the logistic regression, because the loss function was not optimized as well. Optimization problems are even more likely with hidden layers, since the objective is no longer convex.

Second, the training data is small by neural network standards. Prior attempts to use neural networks for parsing required larger amounts of training data to exceed the state-of-the-art. Non-linear models are able to capture regularities that linear models cannot, but may require more training data to do so. Table 1 shows that a network with a single hidden layer outperforms a one with two hidden layers. This additional hidden layer seems to make learning harder (even with layer-wise pretraining). We also ran an additional experiment, limiting both NN and LR to use word unigram features, and varying the vocabulary size by frequency thresholding; the results are in table 3. LR models were more effective when all features were present, likely due to their convex objective and simple regularization. NN models, on the other hand, actually outperform LR models when limited to more common vocabulary items. Given more data, NN could likely find representations that outperformed manual feature engineering.

Although we only considered feed-forward nerual networks, results on recurrent architectures Dong and Lapata (2016) are in accordance with our findings. Their LSTM-based approach does not achieve great gains on this data set because: "*user curated descriptions are often of low quality, and thus align very loosely to their corresponding ASTs*". Even though this training set is larger than other semantic parsing datasets, the vocabulary, sentence structures, and even languages here are much more diverse, which make it difficult for the NN to learn useful representations. Dong and Lapata (2016) tried to reduce the impact of this problem by evaluating only on the English sub-

	Channel	Full tree
All: 4,294 recipes		
posclass	47.4	34.5
D&L	—	—
NN	52.9	39.7
LR	53.7	41.9
Ensemble	**54.3**	**42.6**
oracleturk	48.8	37.8
Omit non-English: 3,744 recipes		
posclass	50.0	36.9
D&L	54.3	39.2
NN	55.1	41.2
LR	56.0	44.3
Ensemble	**56.8**	**44.5**

NN	88.0	74.3
LR	88.8	**82.5**
Ensemble	**89.1**	82.2
oracleturk	100.0	100.0

Table 2: System comparisons on various subsets of the data. Following Quirk et al. (2015), we also evaluation on illustrative subsets. "posclass" represents the best system from prior work. D&L is the best-performing system from Dong and Lapata (2016). NN and LR are the single best neural network, logistic regression models, and Ensemble is the combination of all systems. "oracleturk" represents cases where at least one turker agreed with the gold standard.

set of the data. Interestingly, our carefully built feed-forward networks outperform their approach in almost every subset.

Although the neural network with one hidden layer does not outperform logistic regression in a feature rich setting, it makes substantially different predictions. An ensemble of their outputs achieves better accuracy than either system individually.

Our techniques for improving generalization do not improve individual systems. Yet when all techniques are combined in an ensemble, the resulting predictions are better. Furthermore, an ensemble without the synthetic data or without the alternate grammar has lower accuracy: each technique contributes to the final result.

System	Full tree accuracy	
	NN	LR
All words	35.79	37.03
Count ≥ 2	37.01	36.91
Count ≥ 3	37.07	36.59

Table 3: Accuracy of NN and LR limited to word unigram features, with three vocabulary sizes: all words, words occurring at least twice in the training data (13,971 words), and those occurring at least three times in the training data (8,974 words).

5.4 Comparison of logistic regression and neural network approaches

We performed a detailed exploration of the cases where either the LR model was correct and the NN model was wrong, or vice versa. Table 4 breaks these errors into a number of cases:

- **Swapped trigger and action**. Here the system misinterpreted a rule, swapping the trigger for the action. An example NN swap was "Backup Pinboard entries to diigo"; an example LR swap was "Like a photo on tumblr and upload it to your flickr photostream ."
- **Duplicated**. In this case, the system used the same channel for both trigger and action, despite clear evidence in the language. For instance, the LR model incorrectly used Facebook as both the trigger and channel in this recipe: "New photo on Facebook addec to my Pryv". The NN model correctly identified Pryv as the target channel, despite the typo in the recipe.
- **Missed word cue**. In many cases there was a clear "cue word" in the language that should have forced a correct channel, but the model picked the wrong one. For instance, in "tweet # stared youtube video", the trigger should be starred YouTube videos, but the NN model incorrectly selected feeds.
- **Missed multi-word cue**. Sometimes the cue was a multi-word phrase, such as "One Drive". The NN model tended to miss these cues.
- **Missed inference**. In certain cases the cue was more of a loose inference. Words such as "payment" and "refund" should tend to

Error type	NN errors	LR errors
Swapped trigger and action	4	4
Duplicated	3	4
Missed word cue	8	8
Missed multi-word cue	2	0
Missed inference	8	0
Related channel	5	8
Grand Total	30	24

Table 4: Count of error cases by type for NN and LR models, in their default configurations. This table only counts those instances in the most clean set (where three or more turkers agree with the gold program) where exactly one system made an error.

refer to triggers from the Square payment provider; the NN seemed to struggle on these cases.

- **Related channel**. Often the true channel is very difficult to pick: should the system use iOS location or Android location? NN models seemed to do better on these cases, perhaps picking up on some latent cues in the data that were not immediately evident to the authors.

In general, a slightly more powerful NN model with access to more relevant data might overcome some of the issues above.

We also explored correlations with errors and a number of other criteria, such as text length and frequency of the channels and functions, but found no substantial differences. In general, the remaining errors are often plausible given the noisy input.

6 Future Work

We have achieved a new state-of-the-art on this dataset, though derivation tree accuracy remains low, around 42%. While some errors are caused by training data noise and others are due to noisy test instances, there is still room for improvement.

We believe synthetic data is a promising direction. Initial attempts show small improvements; better results may be within reach given more tuning. This may enable gains with recurrent architectures (e.g., LSTMs).

The networks here rely primarily on word-based features. Character-based models have resulted in improved syntactic parsing results (Ballesteros et al., 2015). We believe that noisy data such as the If-Then corpus would benefit from character modelings, since the models could be more robust to spelling errors and variations.

Another important future work direction is to model the arguments of the If-Then statements. However, that requires segmenting the arguments into those that are general across all users, and those that are specific to the recipe's author. Likely this would require further annotation of the data.

7 Conclusion

In this paper, we address a semantic parsing task, namely translating sentences to If-Then statements. We model the task as structure prediction, and show improved models using both neural networks and logistic regression. We also discussed various ways to improve generalization and reduce overfitting, including adding synthetic training data by paraphrasing sentences, using multiple grammars, applying feature selection and ensembling multiple systems. We achieve a new state-of-the-art with 8% absolute accuracy improvement.

Abstract

We introduce the Treebank of Learner English (TLE), the first publicly available syntactic treebank for English as a Second Language (ESL). The TLE provides manually annotated POS tags and Universal Dependency (UD) trees for 5,124 sentences from the Cambridge First Certificate in English (FCE) corpus. The UD annotations are tied to a pre-existing error annotation of the FCE, whereby full syntactic analyses are provided for both the original and error corrected versions of each sentence. Further on, we delineate ESL annotation guidelines that allow for consistent syntactic treatment of ungrammatical English. Finally, we benchmark POS tagging and dependency parsing performance on the TLE dataset and measure the effect of grammatical errors on parsing accuracy. We envision the treebank to support a wide range of linguistic and computational research on second language acquisition as well as automatic processing of ungrammatical language[1].

1 Introduction

The majority of the English text available worldwide is generated by non-native speakers (Crystal, 2003). Such texts introduce a variety of challenges, most notably grammatical errors, and are of paramount importance for the scientific study of language acquisition as well as for NLP. Despite the ubiquity of non-native English, there is currently no publicly available syntactic treebank for English as a Second Language (ESL).

To address this shortcoming, we present the Treebank of Learner English (TLE), a first of its kind resource for non-native English, containing 5,124 sentences manually annotated with POS tags and dependency trees. The TLE sentences are drawn from the FCE dataset (Yannakoudakis et al., 2011), and authored by English learners from 10 different native language backgrounds. The treebank uses the Universal Dependencies (UD) formalism (De Marneffe et al., 2014; Nivre et al., 2016), which provides a unified annotation framework across different languages and is geared towards multilingual NLP (McDonald et al., 2013). This characteristic allows our treebank to support computational analysis of ESL using not only English based but also multilingual approaches which seek to relate ESL phenomena to native language syntax.

While the annotation inventory and guidelines are defined by the English UD formalism, we build on previous work in learner language analysis (Dıaz-Negrillo et al., 2010; Dickinson and Ragheb, 2013) to formulate an additional set of annotation conventions aiming at a uniform treatment of ungrammatical learner language. Our annotation scheme uses a two-layer analysis, whereby a distinct syntactic annotation is provided for the *original* and the *corrected* version of each sentence. This approach is enabled by a pre-existing error annotation of the FCE (Nicholls, 2003) which is used to generate an error corrected variant of the dataset. Our inter-annotator agreement results provide evidence for the ability of the annotation scheme to support consistent annotation of ungrammatical structures.

[1]The treebank is available at universaldependencies.org. The annotation manual used in this project and a graphical query engine are available at esltreebank.org.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 737–746,
Berlin, Germany, August 7-12, 2016.

Finally, a corpus that is annotated with both grammatical errors and syntactic dependencies paves the way for empirical investigation of the relation between grammaticality and syntax. Understanding this relation is vital for improving tagging and parsing performance on learner language (Geertzen et al., 2013), syntax based grammatical error correction (Tetreault et al., 2010; Ng et al., 2014), and many other fundamental challenges in NLP. In this work, we take the first step in this direction by benchmarking tagging and parsing accuracy on our dataset under different training regimes, and obtaining several estimates for the impact of grammatical errors on these tasks.

To summarize, this paper presents three contributions. First, we introduce the first large scale syntactic treebank for ESL, manually annotated with POS tags and universal dependencies. Second, we describe a linguistically motivated annotation scheme for ungrammatical learner English and provide empirical support for its consistency via inter-annotator agreement analysis. Third, we benchmark a state of the art parser on our dataset and estimate the influence of grammatical errors on the accuracy of automatic POS tagging and dependency parsing.

The remainder of this paper is structured as follows. We start by presenting an overview of the treebank in section 2. In sections 3 and 4 we provide background information on the annotation project, and review the main annotation stages leading to the current form of the dataset. The ESL annotation guidelines are summarized in section 5. Inter-annotator agreement analysis is presented in section 6, followed by parsing experiments in section 7. Finally, we review related work in section 8 and present the conclusion in section 9.

2 Treebank Overview

The TLE currently contains 5,124 sentences (97,681 tokens) with POS tag and dependency annotations in the English Universal Dependencies (UD) formalism (De Marneffe et al., 2014; Nivre et al., 2016). The sentences were obtained from the FCE corpus (Yannakoudakis et al., 2011), a collection of upper intermediate English learner essays, containing error annotations with 75 error categories (Nicholls, 2003). Sentence level segmentation was performed using an adaptation of the NLTK sentence tokenizer[2]. Under-segmented sentences were split further manually. Word level tokenization was generated using the Stanford PTB word tokenizer[3].

The treebank represents learners with 10 different native language backgrounds: Chinese, French, German, Italian, Japanese, Korean, Portuguese, Spanish, Russian and Turkish. For every native language, we randomly sampled 500 automatically segmented sentences, under the constraint that selected sentences have to contain at least one grammatical error that is not punctuation or spelling.

The TLE annotations are provided in two versions. The first version is the *original sentence* authored by the learner, containing grammatical errors. The second, *corrected sentence* version, is a grammatical variant of the original sentence, generated by correcting all the grammatical errors in the sentence according to the manual error annotation provided in the FCE dataset. The resulting corrected sentences constitute a parallel corpus of standard English. Table 1 presents basic statistics of both versions of the annotated sentences.

	original	corrected
sentences	5,124	5,124
tokens	97,681	98,976
sentence length	19.06 (std 9.47)	19.32 (std 9.59)
errors per sentence	2.67 (std 1.9)	-
authors	924	
native languages	10	

Table 1: Statistics of the TLE. Standard deviations are denoted in parenthesis.

To avoid potential annotation biases, the annotations of the treebank were created manually *from scratch*, without utilizing any automatic annotation tools. To further assure annotation quality, each annotated sentence was reviewed by two additional annotators. To the best of our knowledge, TLE is the first large scale English treebank constructed in a completely manual fashion.

3 Annotator Training

The treebank was annotated by six students, five undergraduates and one graduate. Among the undergraduates, three are linguistics majors and two are engineering majors with a linguistic minor. The graduate student is a linguist specializing in syntax. An additional graduate student in NLP participated in the final debugging of the dataset.

[2]http://www.nltk.org/api/nltk.tokenize.html

[3]http://nlp.stanford.edu/software/tokenizer.shtml

Prior to annotating the treebank sentences, the annotators were trained for about 8 weeks. During the training, the annotators attended tutorials on dependency grammars, and learned the English UD guidelines[4], the Penn Treebank POS guidelines (Santorini, 1990), the grammatical error annotation scheme of the FCE (Nicholls, 2003), as well as the ESL guidelines described in section 5 and in the annotation manual.

Furthermore, the annotators completed six annotation exercises, in which they were required to annotate POS tags and dependencies for practice sentences from scratch. The exercises were done individually, and were followed by group meetings in which annotation disagreements were discussed and resolved. Each of the first three exercises consisted of 20 sentences from the UD gold standard for English, the English Web Treebank (EWT) (Silveira et al., 2014). The remaining three exercises contained 20-30 ESL sentences from the FCE. Many of the ESL guidelines were introduced or refined based on the disagreements in the ESL practice exercises and the subsequent group discussions. Several additional guidelines were introduced in the course of the annotation process.

During the training period, the annotators also learned to use a search tool that enables formulating queries over word and POS tag sequences as regular expressions and obtaining their annotation statistics in the EWT. After experimenting with both textual and graphical interfaces for performing the annotations, we converged on a simple text based format described in section 4.1, where the annotations were filled in using a spreadsheet or a text editor, and tested with a script for detecting annotation typos. The annotators continued to meet and discuss annotation issues on a weekly basis throughout the entire duration of the project.

4 Annotation Procedure

The formation of the treebank was carried out in four steps: annotation, review, disagreement resolution and targeted debugging.

4.1 Annotation

In the first stage, the annotators were given sentences for annotation from scratch. We use a CoNLL based textual template in which each word is annotated in a separate line. Each line contains 6 columns, the first of which has the word index (IND) and the second the word itself (WORD). The remaining four columns had to be filled in with a Universal POS tag (UPOS), a Penn Treebank POS tag (POS), a head word index (HIND) and a dependency relation (REL) according to version 1 of the English UD guidelines.

The annotation section of the sentence is preceded by a metadata header. The first field in this header, denoted with SENT, contains the FCE error coded version of the sentence. The annotators were instructed to verify the error annotation, and add new error annotations if needed. Corrections to the sentence segmentation are specified in the SEGMENT field[5]. Further down, the field TYPO is designated for literal annotation of spelling errors and ill formed words that happen to form valid words (see section 5.2).

The example below presents a pre-annotated original sentence given to an annotator.

```
#SENT=That time I had to sleep in <ns type=
"MD"><c>a</c></ns> tent.
#SEGMENT=
#TYPO=

#IND   WORD    UPOS    POS     HIND    REL
1      That
2      time
3      I
4      had
5      to
6      sleep
7      in
8      tent
9      .
```

Upon completion of the original sentence, the annotators proceeded to annotate the corrected sentence version. To reduce annotation time, annotators used a script that copies over annotations from the original sentence and updates head indices of tokens that appear in both sentence versions. Head indices and relation labels were filled in only if the head word of the token appeared in both the original and corrected sentence versions. Tokens with automatically filled annotations included an additional # sign in a seventh column of each word's annotation. The # signs had to be removed, and the corresponding annotations either approved or changed as appropriate. Tokens that did not appear in the original sentence version were annotated from scratch.

[4]http://universaldependencies.org/#en

[5]The released version of the treebank splits the sentences according to the markings in the SEGMENT field when those apply both to the original and corrected versions of the sentence. Resulting segments without grammatical errors in the original version are currently discarded.

4.2 Review

All annotated sentences were randomly assigned to a second annotator (henceforth *reviewer*), in a double blind manner. The reviewer's task was to mark all the annotations that they would have annotated differently. To assist the review process, we compiled a list of common annotation errors, available in the released annotation manual.

The annotations were reviewed using an *active* editing scheme in which an explicit action was required for all the existing annotations. The scheme was introduced to prevent reviewers from overlooking annotation issues due to passive approval. Specifically, an additional # sign was added at the seventh column of each token's annotation. The reviewer then had to either "sign off" on the existing annotation by erasing the # sign, or provide an alternative annotation following the # sign.

4.3 Disagreement Resolution

In the final stage of the annotation process all annotator-reviewer disagreements were resolved by a third annotator (henceforth *judge*), whose main task was to decide in favor of the annotator or the reviewer. Similarly to the review process, the judging task was carried out in a double blind manner. Judges were allowed to resolve annotator-reviewer disagreements with a third alternative, as well as introduce new corrections for annotation issues overlooked by the reviewers.

Another task performed by the judges was to mark acceptable *alternative annotations* for ambiguous structures determined through review disagreements or otherwise present in the sentence. These annotations were specified in an additional metadata field called AMBIGUITY. The ambiguity markings are provided along with the resolved version of the annotations.

4.4 Final Debugging

After applying the resolutions produced by the judges, we queried the corpus with debugging tests for specific linguistics constructions. This additional testing phase further reduced the number of annotation errors and inconsistencies in the treebank. Including the training period, the treebank creation lasted over a year, with an aggregate of more than 2,000 annotation hours.

5 Annotation Scheme for ESL

Our annotations use the existing inventory of English UD POS tags and dependency relations, and follow the standard UD annotation guidelines for English. However, these guidelines were formulated with grammatical usage of English in mind and do not cover non canonical syntactic structures arising due to grammatical errors[6]. To encourage consistent and linguistically motivated annotation of such structures, we formulated a complementary set of ESL annotation guidelines.

Our ESL annotation guidelines follow the general principle of *literal reading*, which emphasizes syntactic analysis according to the observed language usage. This strategy continues a line of work in SLA which advocates for centering analysis of learner language around morpho-syntactic surface evidence (Ragheb and Dickinson, 2012; Dickinson and Ragheb, 2013). Similarly to our framework, which includes a parallel annotation of corrected sentences, such strategies are often presented in the context of multi-layer annotation schemes that also account for error corrected sentence forms (Hirschmann et al., 2007; Dıaz-Negrillo et al., 2010; Rosen et al., 2014).

Deploying a strategy of literal annotation within UD, a formalism which enforces cross-linguistic consistency of annotations, will enable meaningful comparisons between non-canonical structures in English and canonical structures in the author's native language. As a result, a key novel characteristic of our treebank is its ability to support cross-lingual studies of learner language.

5.1 Literal Annotation

With respect to POS tagging, literal annotation implies adhering as much as possible to the observed morphological forms of the words. Syntactically, argument structure is annotated according to the usage of the word rather than its typical distribution in the relevant context. The following list of conventions defines the notion of literal reading for some of the common non canonical structures associated with grammatical errors.

Argument Structure

Extraneous prepositions We annotate all nominal dependents introduced by extraneous prepositions

[6]The English UD guidelines do address several issues encountered in informal genres, such as the relation "goeswith", which is used for fragmented words resulting from typos.

as nominal modifiers. In the following sentence, "him" is marked as a nominal modifier (*nmod*) instead of an indirect object (*iobj*) of "give".

```
#SENT=...I had to give <ns type="UT"><i>to</i> </ns>
him water...
...
21      I          PRON      PRP      22      nsubj
22      had        VERB      VBD      5       parataxis
23      to         PART      TO       24      mark
24      give       VERB      VB       22      xcomp
25      to         ADP       IN       26      case
26      him        PRON      PRP      24      nmod
27      water      NOUN      NN       24      dobj
...
```

Omitted prepositions We treat nominal dependents of a predicate that are lacking a preposition as arguments rather than nominal modifiers. In the example below, "money" is marked as a direct object (*dobj*) instead of a nominal modifier (*nmod*) of "ask". As "you" functions in this context as a second argument of "ask", it is annotated as an indirect object (*iobj*) instead of a direct object (*dobj*).

```
#SENT=...I have to ask you <ns type="MT">
<c>for</c></ns> the money <ns type= "RT">
<i>of</i><c>for</c></ns> the tickets back.
...
12      I          PRON      PRP      13      nsubj
13      have       VERB      VBP      2       conj
14      to         PART      TO       15      mark
15      ask        VERB      VB       13      xcomp
16      you        PRON      PRP      15      iobj
17      the        DET       DT       18      det
18      money      NOUN      NN       15      dobj
19      of         ADP       IN       21      case
20      the        DET       DT       21      det
21      tickets    NOUN      NNS      18      nmod
22      back       ADV       RB       15      advmod
23      .          PUNCT     .        2       punct
```

Tense

Cases of erroneous tense usage are annotated according to the morphological tense of the verb. For example, below we annotate "shopping" with present participle VBG, while the correction "shop" is annotated in the corrected version of the sentence as VBP.

```
#SENT=...when you <ns type="TV"><i>shopping</i>
<c>shop</c></ns>...
...
4       when       ADV       WRB      6       advmod
5       you        PRON      PRP      6       nsubj
6       shopping   VERB      VBG      12      advcl
...
```

Word Formation

Erroneous word formations that are contextually plausible and can be assigned with a PTB tag are annotated literally. In the following example, "stuffs" is handled as a plural count noun.

```
#SENT=...into fashionable <ns type="CN">
<i>stuffs</i><c>stuff</c></ns>...
...
7       into       ADP       IN       9       case
8       fashionable ADJ      JJ       9       amod
9       stuffs     NOUN      NNS      2       ccomp
...
```

Similarly, in the example below we annotate "necessaryiest" as a superlative.

```
#SENT=The necessaryiest things...
1       The            DET       DT       3       det
2       necessaryiest  ADJ       JJS      3       amod
3       things         NOUN      NNS      0       root
...
```

5.2 Exceptions to Literal Annotation

Although our general annotation strategy for ESL follows literal sentence readings, several types of word formation errors make such readings uninformative or impossible, essentially forcing certain words to be annotated using some degree of interpretation (Rosén and De Smedt, 2010). We hence annotate the following cases in the original sentence according to an interpretation of an intended word meaning, obtained from the FCE error correction.

Spelling

Spelling errors are annotated according to the correctly spelled version of the word. To support error analysis of automatic annotation tools, misspelled words that happen to form valid words are annotated in the metadata field TYPO for POS tags with respect to the most common usage of the misspelled word form. In the example below, the TYPO field contains the typical POS annotation of "where", which is clearly unintended in the context of the sentence.

```
#SENT=...we <ns type="SX"><i>where</i>
<c>were</c></ns> invited to visit...
#TYPO=5 ADV WRB
...
4       we         PRON      PRP      6       nsubjpass
5       where      AUX       VBD      6       auxpass
6       invited    VERB      VBN      0       root
7       to         PART      TO       8       mark
8       visit      VERB      VB       6       xcomp
...
```

Word Formation

Erroneous word formations that cannot be assigned with an existing PTB tag are annotated with respect to the correct word form.

```
#SENT=I am <ns type="IV"><i>writting</i>
<c>writing</c></ns>...
1       I          PRON      PRP      3       nsubj
2       am         AUX       VBP      3       aux
3       writting   VERB      VBG      0       root
...
```

In particular, ill formed adjectives that have a plural suffix receive a standard adjectival POS tag. When applicable, such cases also receive an additional marking for unnecessary agreement in the error annotation using the attribute "ua".

```
#SENT=...<ns type="IJ" ua=true>
<i>interestings</i><c>interesting</c></ns> things...
```

```
...
6       interestings  ADJ     JJ      7       amod
7       things        NOUN    NNS     3 dobj
...
```

Wrong word formations that result in a valid, but contextually implausible word form are also annotated according to the word correction. In the example below, the nominal form "sale" is likely to be an unintended result of an ill formed verb. Similarly to spelling errors that result in valid words, we mark the typical literal POS annotation in the TYPO metadata field.

```
#SENT=...they do not <ns type="DV"><i>sale</i>
<c>sell</c></ns> them...
#TYPO=15 NOUN NN

...
12      they        PRON    PRP     15      nsubj
13      do          AUX     VBP     15      aux
14      not         PART    RB      15      neg
15      sale        VERB    VB      0       root
16      them        PRON    PRP     15      dobj
...
```

Taken together, our ESL conventions cover many of the annotation challenges related to grammatical errors present in the TLE. In addition to the presented overview, the complete manual of ESL guidelines used by the annotators is publicly available. The manual contains further details on our annotation scheme, additional annotation guidelines and a list of common annotation errors. We plan to extend and refine these guidelines in future releases of the treebank.

6 Editing Agreement

We utilize our two step review process to estimate agreement rates between annotators[7]. We measure agreement as the fraction of annotation tokens approved by the editor. Table 2 presents the agreement between annotators and reviewers, as well as the agreement between reviewers and the judges. Agreement measurements are provided for both the original the corrected versions of the dataset.

Overall, the results indicate a high agreement rate in the two editing tasks. Importantly, the gap between the agreement on the original and corrected sentences is small. Note that this result is obtained despite the introduction of several ESL annotation guidelines in the course of the annotation process, which inevitably increased the number of edits related to grammatical errors. We interpret this outcome as evidence for the effectiveness of the ESL annotation scheme in supporting consistent annotations of learner language.

[7]All experimental results on agreement and parsing exclude punctuation tokens.

Annotator-Reviewer	UPOS	POS	HIND	REL
original	98.83	98.35	97.74	96.98
corrected	99.02	98.61	97.97	97.20
Reviewer-Judge				
original	99.72	99.68	99.37	99.15
corrected	99.80	99.77	99.45	99.28

Table 2: Inter-annotator agreement on the entire TLE corpus. Agreement is measured as the fraction of tokens that remain unchanged after an editing round. The four evaluation columns correspond to universal POS tags, PTB POS tags, unlabeled attachment, and dependency labels. Cohen's Kappa scores (Cohen, 1960) for POS tags and dependency labels in all evaluation conditions are above 0.96.

7 Parsing Experiments

The TLE enables studying parsing for learner language and exploring relationships between grammatical errors and parsing performance. Here, we present parsing benchmarks on our dataset, and provide several estimates for the extent to which grammatical errors degrade the quality of automatic POS tagging and dependency parsing.

Our first experiment measures tagging and parsing accuracy on the TLE and approximates the global impact of grammatical errors on automatic annotation via performance comparison between the original and error corrected sentence versions. In this, and subsequent experiments, we utilize version 2.2 of the Turbo tagger and Turbo parser (Martins et al., 2013), state of the art tools for statistical POS tagging and dependency parsing.

Table 3 presents tagging and parsing results on a test set of 500 TLE sentences (9,591 original tokens, 9,700 corrected tokens). Results are provided for three different training regimes. The first regime uses the training portion of version 1.3 of the EWT, the UD English treebank, containing 12,543 sentences (204,586 tokens). The second training mode uses 4,124 training sentences (78,541 original tokens, 79,581 corrected tokens) from the TLE corpus. In the third setup we combine these two training corpora. The remaining 500 TLE sentences (9,549 original tokens, 9,695 corrected tokens) are allocated to a development set, not used in this experiment. Parsing of the test sentences was performed on predicted POS tags.

The EWT training regime, which uses out of domain texts written in standard English, provides the lowest performance on all the evaluation met-

Test set	Train Set	UPOS	POS	UAS	LA	LAS
TLE_{orig}	EWT	91.87	94.28	86.51	88.07	81.44
TLE_{corr}	EWT	92.9	95.17	88.37	89.74	83.8
TLE_{orig}	TLE_{orig}	95.88	94.94	87.71	89.26	83.4
TLE_{corr}	TLE_{corr}	96.92	95.17	89.69	90.92	85.64
TLE_{orig}	EWT+TLE_{orig}	93.33	95.77	90.3	91.09	86.27
TLE_{corr}	EWT+TLE_{corr}	94.27	96.48	92.15	92.54	88.3

Table 3: Tagging and parsing results on a test set of 500 sentences from the TLE corpus. EWT is the English UD treebank. TLE_{orig} are original sentences from the TLE. TLE_{corr} are the corresponding error corrected sentences.

rics. An additional factor which negatively affects performance in this regime are systematic differences in the EWT annotation of possessive pronouns, expletives and names compared to the UD guidelines, which are utilized in the TLE. In particular, the EWT annotates possessive pronoun UPOS as PRON rather than DET, which leads the UPOS results in this setup to be lower than the PTB POS results. Improved results are obtained using the TLE training data, which, despite its smaller size, is closer in genre and syntactic characteristics to the TLE test set. The strongest PTB POS tagging and parsing results are obtained by combining the EWT with the TLE training data, yielding 95.77 POS accuracy and a UAS of 90.3 on the original version of the TLE test set.

The dual annotation of sentences in their original and error corrected forms enables estimating the impact of grammatical errors on tagging and parsing by examining the performance gaps between the two sentence versions. Averaged across the three training conditions, the POS tagging accuracy on the original sentences is lower than the accuracy on the sentence corrections by 1.0 UPOS and 0.61 POS. Parsing performance degrades by 1.9 UAS, 1.59 LA and 2.21 LAS.

To further elucidate the influence of grammatical errors on parsing quality, table 4 compares performance on tokens in the original sentences appearing inside grammatical error tags to those appearing outside such tags. Although grammatical errors may lead to tagging and parsing errors with respect to any element in the sentence, we expect erroneous tokens to be more challenging to analyze compared to grammatical tokens.

This comparison indeed reveals a substantial difference between the two types of tokens, with an average gap of 5.0 UPOS, 6.65 POS, 4.67 UAS, 6.56 LA and 7.39 LAS. Note that differently from

Tokens	Train Set	UPOS	POS	UAS	LA	LAS
Ungrammatical	EWT	87.97	88.61	82.66	82.66	74.93
Grammatical	EWT	92.62	95.37	87.26	89.11	82.7
Ungrammatical	TLE_{orig}	90.76	88.68	83.81	83.31	77.22
Grammatical	TLE_{orig}	96.86	96.14	88.46	90.41	84.59
Ungrammatical	EWT+TLE_{orig}	89.76	90.97	86.32	85.96	80.37
Grammatical	EWT+TLE_{orig}	94.02	96.7	91.07	92.08	87.41

Table 4: Tagging and parsing results on the original version of the TLE test set for tokens marked with grammatical errors (Ungrammatical) and tokens not marked for errors (Grammatical).

the global measurements in the first experiment, this analysis, which focuses on the local impact of remove/replace errors, suggests a stronger effect of grammatical errors on the dependency labels than on the dependency structure.

Finally, we measure tagging and parsing performance relative to the fraction of sentence tokens marked with grammatical errors. Similarly to the previous experiment, this analysis focuses on remove/replace rather than insert errors.

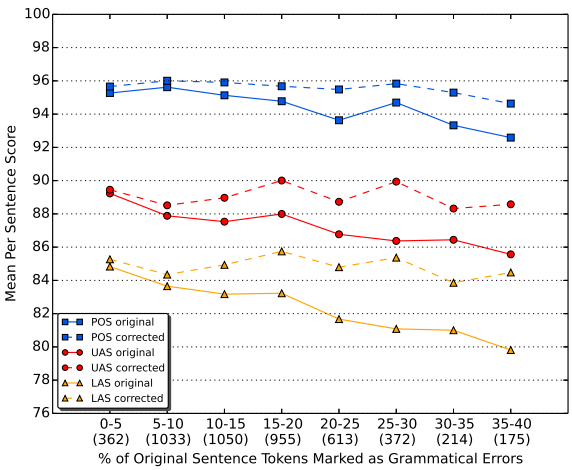

Figure 1: Mean per sentence POS accuracy, UAS and LAS of the Turbo tagger and Turbo parser, as a function of the percentage of original sentence tokens marked with grammatical errors. The tagger and the parser are trained on the EWT corpus, and tested on all 5,124 sentences of the TLE. Points connected by continuous lines denote performance on the original TLE sentences. Points connected by dashed lines denote performance on the corresponding error corrected sentences. The number of sentences whose errors fall within each percentage range appears in parenthesis.

Figure 1 presents the average sentential performance as a function of the percentage of tokens in the original sentence marked with grammati-

cal errors. In this experiment, we train the parser on the EWT training set and test on the entire TLE corpus. Performance curves are presented for POS, UAS and LAS on the original and error corrected versions of the annotations. We observe that while the performance on the corrected sentences is close to constant, original sentence performance is decreasing as the percentage of the erroneous tokens in the sentence grows.

Overall, our results suggest a negative, albeit limited effect of grammatical errors on parsing. This outcome contrasts a study by Geertzen et al. (2013) which reported a larger performance gap of 7.6 UAS and 8.8 LAS between sentences with and without grammatical errors. We believe that our analysis provides a more accurate estimate of this impact, as it controls for both sentence content and sentence length. The latter factor is crucial, since it correlates positively with the number of grammatical errors in the sentence, and negatively with parsing accuracy.

8 Related Work

Previous studies on learner language proposed several annotation schemes for both POS tags and syntax (Hirschmann et al., 2007; Dıaz-Negrillo et al., 2010; Dickinson and Ragheb, 2013; Rosen et al., 2014). The unifying theme in these proposals is a multi-layered analysis aiming to decouple the observed language usage from conventional structures in the foreign language.

In the context of ESL, Dıaz et al. (2010) propose three parallel POS tag annotations for the *lexical*, *morphological* and *distributional* forms of each word. In our work, we adopt the distinction between morphological word forms, which roughly correspond to our literal word readings, and distributional forms as the error corrected words. However, we account for morphological forms only when these constitute valid existing PTB POS tags and are contextually plausible. Furthermore, while the internal structure of invalid word forms is an interesting object of investigation, we believe that it is more suitable for annotation as word features rather than POS tags. Our treebank supports the addition of such features to the existing annotations.

The work of Ragheb and Dickinson (2009; 2012; 2013) proposes ESL annotation guidelines for POS tags and syntactic dependencies based on the CHILDES annotation framework. This approach, called "morphosyntactic dependencies" is related to our annotation scheme in its focus on surface structures. Differently from this proposal, our annotations are grounded in a parallel annotation of grammatical errors and include an additional layer of analysis for the corrected forms. Moreover, we refrain from introducing new syntactic categories and dependency relations specific to ESL, thereby supporting computational treatment of ESL using existing resources for standard English. At the same time, we utilize a multilingual formalism which, in conjunction with our literal annotation strategy, facilitates linking the annotations to native language syntax.

While the above mentioned studies focus on annotation guidelines, attention has also been drawn to the topic of parsing in the learner language domain. However, due to the shortage of syntactic resources for ESL, much of the work in this area resorted to using surrogates for learner data. For example, in Foster (2007) and Foster et al. (2008) parsing experiments are carried out on synthetic learner-like data, that was created by automatic insertion of grammatical errors to well formed English text. In Cahill et al. (2014) a treebank of secondary level native students texts was used to approximate learner text in order to evaluate a parser that utilizes unlabeled learner data.

Syntactic annotations for ESL were previously developed by Nagata et al. (2011), who annotate an English learner corpus with POS tags and shallow syntactic parses. Our work departs from shallow syntax to full syntactic analysis, and provides annotations on a significantly larger scale. Furthermore, differently from this annotation effort, our treebank covers a wide range of learner native languages. An additional syntactic dataset for ESL, currently not available publicly, are 1,000 sentences from the EFCamDat dataset (Geertzen et al., 2013), annotated with Stanford dependencies (De Marneffe and Manning, 2008). This dataset was used to measure the impact of grammatical errors on parsing by comparing performance on sentences with grammatical errors to error free sentences. The TLE enables a more direct way of estimating the magnitude of this performance gap by comparing performance on the same sentences in their original and error corrected versions. Our comparison suggests that the effect of grammatical errors on parsing is smaller that the one reported in this study.

9 Conclusion

We present the first large scale treebank of learner language, manually annotated and double-reviewed for POS tags and universal dependencies. The annotation is accompanied by a linguistically motivated framework for handling syntactic structures associated with grammatical errors. Finally, we benchmark automatic tagging and parsing on our corpus, and measure the effect of grammatical errors on tagging and parsing quality. The treebank will support empirical study of learner syntax in NLP, corpus linguistics and second language acquisition.

Extracting token-level signals of syntactic processing from fMRI - with an application to PoS induction

Joachim Bingel Maria Barrett Anders Søgaard

Abstract

Neuro-imaging studies on reading different parts of speech (PoS) report somewhat mixed results, yet some of them indicate different activations with different PoS. This paper addresses the difficulty of using fMRI to discriminate between linguistic tokens in reading of running text because of low temporal resolution. We show that once we solve this problem, fMRI data contains a signal of PoS distinctions to the extent that it improves PoS induction with error reductions of more than 4%.

1 Introduction

A few recent studies have tried to extract morphosyntactic signals from measurements of human sentence processing and used this information to improve NLP models. Klerke et al. (2016), for example, used eye-tracking recordings to regularize a sentence compression model. More related to this work, Barrett et al. (2016) recently used eye-tracking recordings to induce PoS models. However, a weakness of eye-tracking data is that while eye movement surely does reflect the temporal aspect of cognitive processing, it is only a proxy of the latter and does not directly represent which processes take place in the brain.

A recent neuro-imaging study suggests that concrete nouns and verbs elicit different brain signatures in the frontocentral cortex, and that concrete and abstract nouns elicit different brain activation patterns (Moseley and Pulvermüller, 2014). Also, for example, concrete verbs activate motor and premotor cortex more strongly than concrete nouns, and concrete nouns activate inferior frontal areas more strongly than concrete verbs. A decade earlier, Tyler et al. (2004) showed that the left inferior frontal gyrus was more strongly activated in processing regularly inflected verbs compared to regularly inflected nouns.

Such studies suggest that different parts of our brains are activated when reading different parts of speech (PoS). This would in turn mean that neuro-images of readers carry information about the grammatical structure of what they read. In other words, neuro-imaging provides a partial, noisy annotation of the data with respect to morphosyntactic category.

Say neuro-imaging data of readers was readily available. Would it be of any use to, for example, engineers interested in PoS taggers for low-resource languages? This is far from obvious. In fact, it is well-known that neuro-imaging data from reading is noisy, in part because the reading signal is not always very distinguishable (Tagamets et al., 2000), and also because the content of what we read may elicit certain activation in brain regions e.g. related to sensory processing (Boulenger et al., 2006; González et al., 2006).

Other researchers such as Borowsky et al. (2013) have also questioned that there are differences, claiming to show that the majority of activation is shared between nouns and verbs – including in regions suggested by previous researchers as unique to either nouns or verbs. Berlingeri et al. (2008) argue that only verbs could be associated with unique regions, not nouns.

In this paper we nevertheless explore this question. The paper should be seen as a proof of concept that interesting linguistic signals can be extracted from brain imaging data, and an attempt to show that learning NLP models from such data could be a way of pushing the boundaries of both fields.

Contributions (a) We present a novel technique for extracting syntactic processing signal at the token level from neuro-imaging data that is charac-

terized by low temporal resolution. (b) We demonstrate that the fMRI data improves performance of a type-constrained, second order hidden Markov model for PoS induction. Our model leads to an error reduction of more than 4% in tagging accuracy despite very little training data, which to the best of our knowledge is the first positive result on weakly supervised part-of-speech induction from fMRI data in the literature.

2 fMRI

Functional Magnetic Resonance Imaging (fMRI) is a technology for spatial visualization of brain activity. It measures the changes in oxygenation of the blood in the brain, often by use of the blood oxygenation level-dependent contrast (Ogawa et al., 1992), which correlates with neural activity. While the spatial resolution of fMRI is very high, its temporal resolution is low compared to other brain imaging technologies like EEG, which usually returns millisecond records of brain activity, but on the contrary have low spatial resolution. The temporal resolution of fMRI is usually between 0.5Hz and 1Hz. fMRI data contains representations of neural activity of millimeter-sized cubes called *voxels*.

The high spatial resolution may enable us to detect fine differences in brain activation patterns, such as between processing nouns and verbs, but the low temporal resolution is a real challenge when the different tokens are processed serially and quickly after each other, as is the case in reading.

Another inherent challenge when working with fMRI data is the lag between the the reaction to a stimulus and the point when it becomes visible through fMRI. This lag is called the *hemodynamic response latency*. While we know from brain imaging technologies with higher temporal resolution that the neural response to a stimuli happens within milliseconds, it only shows in fMRI data after a certain period of time, which further blurs the low temporal dimension of serial fMRI recordings. This latency has been studied as long as fMRI technology itself. It depends on the blood vessels and varies between e.g. voxels, brain regions, subjects, and tasks. A meta study of the hemodynamic response report latencies between 4 and 14 seconds in healthy adults, though latencies above 11 seconds are less typically reported (Handwerker et al., 2012). According to Handwerker et al. (2012), the precise response shape for a given stimulus and voxel region is hard to predict and remains a challenge when modeling temporal aspects of fMRI data.

Figure 1 visualizes the neural activations in different brain regions as a reaction to the type of information that is processed during reading. See Price (2012) for a thorough review of fMRI language studies.

Wehbe et al. (2014) presented a novel approach to fMRI studies of linguistic processing by studying a more naturalistic reading scenario, and modeling the entire process of reading and story understanding. They used data from 8 subjects reading contextualized, running text: a chapter from a *Harry Potter* book. The central benefit of this approach is that it allows studies of complex text processing closer to a real-life reading experience. Wehbe et al. (2014) used this data to train a comprehensive, generative model that—given a text passage—could predict the fMRI-recorded activity during the reading of this passage. Using the same data, our goal is to model a specific aspect of the story understanding process, i.e. the grammatical processing of words.

3 Data

3.1 Textual data

We use the available fMRI recordings from Wehbe et al. (2014), where 8 adult, native English speakers read chapter 9 from *Harry Potter and the Sorcerer's Stone* in English. The textual data as provided in the data set does not explicitly mark sentence boundaries, neither is punctuation sep-

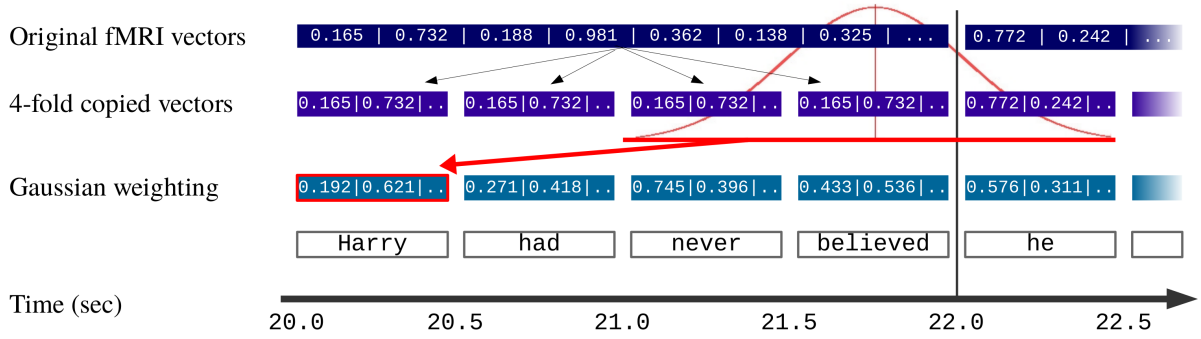

Figure 2: Computation of token-level fMRI vectors from the original fMRI data for the first token "Harry" while accounting for hemodynamic response latency using a Gaussian sliding window over a certain time window (indicated by red horizontal line). The final fMRI vector for "Harry" (red box) is computed as specified in Equation 1. In this example, the time stamp t for the token is $20s$ and the time window stretches from $t + 1s$ to $t + 2.5s$.

arated from the tokens at the end of clauses and sentences. As the temporal alignment between tokens and fMRI recordings (see below) forbids us to detach punctuation marks from their preceding tokens and introduce them as new tokens, we opt to remove all punctuation from the data. In the same process, we use simple heuristics to detect sentence boundaries. Finally, we correct errors in sentence splitting manually.

The chapter counts 4,898 tokens (excluding punctuation) and 1,411 types in 408 sentences.

3.2 fMRI data

The fMRI data from the same data set is available as high-dimensional vectors of flattened third-order tensors, in which each component represents the blood-oxygen-level dependent contrast for a certain voxel in the three-dimensional fMRI image. The resolution of the image is at $3 \times 3 \times 3$ mm, such that the brain activity for the eight subjects is represented by approximately 31,400 voxels on average (standard deviation is 3,607) depending on the size of their brain.

This data is recorded every two seconds during the reading process, in which each token is consecutively displayed for 0.5 seconds on a screen inside the fMRI scanner. Prior to reading, the subjects are asked to focus on a cross displayed at the center of the screen in a warm-up phase of 20 seconds. The chapter is divided into four blocks, separated by additional concentration phases of 20 seconds. Furthermore, paragraphs are separated by a 0.5-seconds display of a cross at the center of the screen.

As mentioned in the preceding section, punctuation marks were not displayed separately, but instead attached to the preceding token. This is arguably motivated through the attempt to create a reading scenario that is as natural as possible within the limitations of an fMRI recording. In similar fashion, contractions such as *don't* or *he's* were represented as one token, just as they appear in the original text.

In order to make the data feasible for our HMM approach (see Section 4), we apply Principal Component Analysis (PCA) to the high-dimensional fMRI vectors. We initially tune the number of principal components, which we describe in Section 5.

3.2.1 Computing token-level fMRI vectors

As outlined above, the time resolution of the fMRI recordings means that every block of four consecutive tokens is time-aligned with a single fMRI image. Naturally, this shared representation of consecutive tokens complicates any language learning at the token level. Furthermore, the hemodynamic response latency inherent to fMRI recordings entails that the image recorded while reading a certain token most probably does not give any clues about the mental state elicited by this stimulus.

We therefore face the dual challenge of

1. inferring token-level information from supra-token recordings, and

2. identifying the lag after which the perceptual effects of reading a given token are visible.

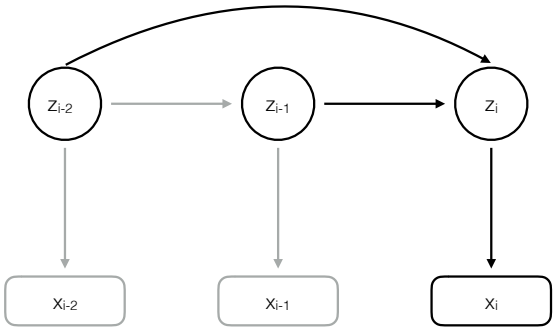

Figure 3: Second-order HMM incorporating transitional probabilities from first and second-degree preceding states.

We address this problem through the following procedure that we illustrate in Figure 2. First, we copy the number of fMRI recordings fourfold, such that every fMRI vector is aligned to exactly one token (excluding the vectors that are recorded while no token was displayed). The representation for a given token is then computed as a weighted average over all fMRI vectors that lie within a certain time window in relation to the token in question. Two consecutive tokens that originally lie within the same block of four thus receive different representations, provided that the window is large enough to transcend the border between two blocks.

The fMRI representation for the token at time stamp t is given by

$$v_t = \frac{1}{|V|} \sum_{k=1}^{|V|} V_k \cdot w_k \tag{1}$$

where V is the series of fMRI vectors within the time window $[t+s, t+e]$, and w is a Gaussian window of $|V|$ points, with a standard deviation of 1. In factoring the Gaussian weight vector into the equation, we lend less weight to the fMRI recordings at the outset and at the end of the time window specified through s (start) and e (end).

4 Model

We use a second-order hidden Markov model (HMM) with Wiktionary-derived type constraints (Li et al., 2012) as our baseline for weakly supervised PoS induction. We use the original implementation by Li et al. (2012). The model is a type-constrained, second order version of the first-order featurized HMM previously introduced by Berg-Kirkpatrick et al. (2010).

In each state z_i, a PoS HMM generates a sequence of words by consecutively generating word emissions x_i and successor states z_{i+1}. The emission probabilities and state transition probabilities are multinomial distributions over words and PoS. The joint probability of a word sequence and a tag sequence is

$$P_\theta(x, z) = P_\theta(z_1) \prod_{i=1} P_\theta(x_i|z_i) \prod_{i=2} P_\theta(z_i|z_{i-1}) \tag{2}$$

Following Berg-Kirkpatrick et al. (2010), the model calculates the probability distribution θ that parameterizes the emission probabilities as the output of a maximum entropy model, which enables unsupervised learning with a rich set of features. We thus let

$$\theta_{x_i,z_i} = \frac{\exp(\mathbf{w}^\intercal \mathbf{f}(x_i, z_i))}{\sum_{x'} \exp(\mathbf{w}^\intercal \mathbf{f}(x', z_i))} \tag{3}$$

where $\mathbf{w}$ is a weight vector and $\mathbf{f}(x_i, z_i)$ is a feature function that will, in our case, consider the fMRI vectors v_t that we computed in section 3.2.1 and a number of basic features that we adopt from the original model (Li et al., 2012). See Section 5 for details.

In addition, we use a second-order HMM, first introduced for PoS tagging in Thede and Harper (1999), in which transitional probabilities are also considered for second-degree subsequent states (cf. figure 3). Here, the joint probability becomes

$$\begin{aligned} P_\theta(x, z) = {} & P_\theta(z_1) P_\theta(x_1|z_1) P_\theta(z_2|z_1) \\ & \prod_{i=2} P_\theta(x_i|z_i) \prod_{i=3} P_\theta(z_i|z_{i-2}, z_{i-1}) \end{aligned} \tag{4}$$

In order to optimize the HMM (including the weight vector $\mathbf{w}$), the model uses the EM algorithm as applied for feature-rich, locally normalized models introduced in Berg-Kirkpatrick et al. (2010), with the important modification that we use type constraints in the E-step, following Li et al. (2012). Specifically, for each state z_i, the emission probability $P(x_i|z_i)$ is initialized randomly for every word type associated with z_i in our tag dictionary (the type constraints). This weakly supervised setup allows us to predict the actual PoS tags instead of abstract states. The M-step is solved using L-BFGS (Liu and Nocedal, 1989)

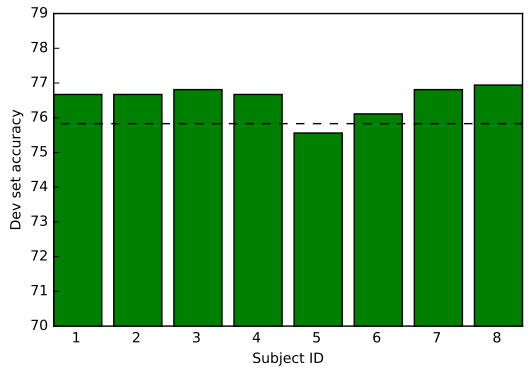

Figure 4: Accuracy on the development set for the different subjects when trained and tested on fMRI data from only this one subject. Dashed line is the development set baseline. Only in one out of eight cases does adding fMRI features lead to worse performance.

EM-HMM Parameters We use the same setting as Li et al. (2012) for the number of EM iterations, fixing this parameter to 30 for all experiments.

5 Experiments

Experimental setup From the neuro-imaging dataset described above, we use 41 sentences (720 tokens) as a development set and 41 sentences (529 tokens) as a test set, and the remaining 326 sentences (corresponding to 80%) for training our model.

Basic features The basic features of all the models (except when explicitly stated otherwise) are based on seven features that we adopt from Li et al. (2012), capturing word form, hyphenation, suffix patterns, capitalization and digits in the token.

Wiktionary Of the 1,411 word types in the corpus, we find that 1,381 (97.84%) are covered by the Wiktionary dump made available by Li et al. (2012),[1] which we use as our type constraints when inducing our models.

5.1 Part-of-speech annotation

Though Wehbe et al. (2014) also provide syntactic information, these are automatic parses that are not suitable for the evaluation of our model. The development and test data are therefore manually annotated for universal part-of-speech tags (Petrov et al., 2011) by two linguistically trained annotators. The development set was annotated by both annotators, who reached an inter-annotator agreement of 0.926 in accuracy and 0.928 in weighted F_1. For the final development and test data, disagreements were resolved by the annotators.

5.2 Non-fMRI baselines

Our first baseline is a second-order HMM with type constraints from Wiktionary; this in all respects the model proposed by Liu et al. (2012), except trained on our small Harry Potter corpus. In a second baseline model, we also incorporate 300-dimensional GloVe word embeddings trained on Wikipedia and the Gigaword corpus (Pennington et al., 2014). We also test a version of the baseline without the basic features to get an estimate of the contribution of this aspect of the setup.

5.3 Token-level fMRI

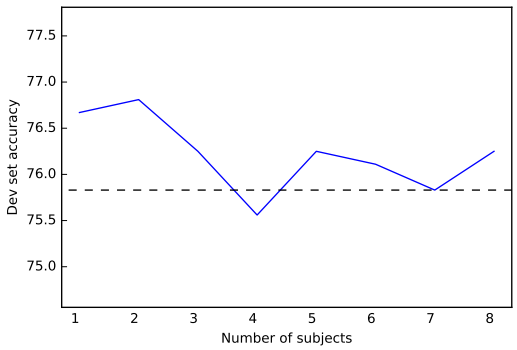
We run a series of experiments with token-level fMRI vectors that we obtain as described in Section 3.2.1. Initially, we train separate models for each of the eight individual subjects, whose performance on the development data are illustrated in Figure 4.

5.3.1 Tuning hyperparameters

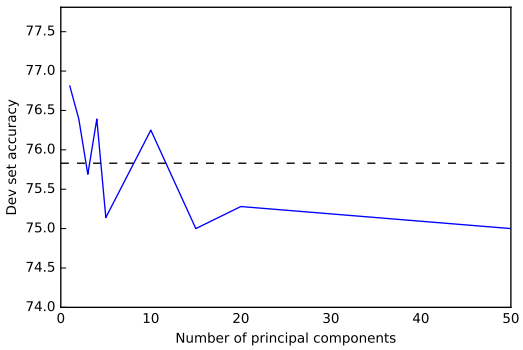
We tune the following hyperparameters on the token-level development set in the following order: the number of subjects to use, the number of principal components per subject, and the time window. For the earlier tuning processes we fix the later hyperparameters to values we consider reasonable, but once we have tuned a hyperparameter, we use the best value from this tuning process for later tuning steps. The initial values are: 10 principal components and a time window of $[t + 0s, t + 6s]$.

Number of subjects To reduce the chance of overfitting, we use fMRI data from several readers in our model. The data from Wehbe et al. (2014) would in theory allow us to average the three-dimensional image space for any number of readers, but this is not feasible if only for the difference in brain sizes between the subjects. It is not feasible, either, to average over the eigenvectors that we obtain from PCA, as the eigenvectors between subjects do not share the same (or any concrete) feature space. We therefore concatenate

[1] https://code.google.com/archive/p/wikily-supervised-pos-tagger/



(a) Learning curve for increasing number of subjects in the model. Fixed hyper-parameters: 10 principal components and a time window of $[t + 0s, t + 6s]$.



(b) Learning curve for increasing number of principal components per subject in the model. Number of principal components $\in \{1, 2, 3, 4, 5, 10, 15, 20, 50\}$ Fixed hyper-parameters: 8 subjects, a time window of $[t + 0s, t + 6s]$.

Figure 5: Exploring two individual hyper-parameters of the model on development set. Dashed lines indicate the development set baseline.

the eigenvectors that we obtain for different subjects, such that the feature vectors grow in length as the number of included subjects increases.

As Figure 5a shows, exploring an increasing number of subjects in the model does not seem to a have consistent effect on development set accuracy. However, we expect an increased robustness from a model that incorporates a greater number of subjects. In all following experiments we therefore use data from all eight readers, but we would also expect a model with fewer subjects to perform reasonably.

Principal components Fixing the number of subjects to eight, we then perform experiments to determine the number of principal components per subject to consider in our model, whose results are visualized in Figure 5b. We observe the first eigenvectors carry a strong signal, while a great number of principal components tends to water down the signal and lead to worse performance. We choose to continue using 10 dimensions in all further experiments.

Time window for token vectors We next run experiments to determine the optimal time window for the computation of the token vectors, using different combinations of start and end times in relation to the token time stamps, but keeping the number of subjects and principal components constant at eight and ten, respectively. These experiments yield three different time windows with an equally good performance on the development set: $[t - 4s, t + 10s]$, $[t + 2s, t + 8s]$ and $[t + 0s, t + 6s]$. Note that due to the Gaussian weighting the centre of the interval gets more weight than the edges and that $[t-4s, t+10s]$ and $[t+0s, t+6s]$ have the same centre, $t+3$. While $[t+2s, t+8s]$ and $[t+0, t+6]$ align better with psycholinguistic expectations, $[t - 4s, t + 10s]$ makes our model less prone to overfitting. We therefore select the model averaging over the largest time window.

5.4 Type-level fMRI aggregates

Next, we aggregate token vectors to compute their type-level averages, in an effort to explore to which degree neural activity is dependent on the read word type rather than the concrete grammatical environment, and whether this can allow our model to draw conclusions about the grammatical class of a token. We compute the type-level aggregates as the component-wise arithmetic mean of the token vectors that we extract using the parameter settings optimized above. Note, however, that out of the 4,898 tokens in the text, 823 (16.9%) occur only once.

6 Results

Table 1 reports the results that we obtain with our final hyper-parameter settings, which are as follows:

Number of subjects	8
Principal components	10
Start of time window	$t - 4s$
End of time window	$t + 10s$

The results show that our model leads to a consid-

	Accuracy
Baseline (Li et al., 2012)	69.57
Baseline+GloVe	69.38
Baseline w/o basic feats	55.53
fMRI (token-level) w/o basic feats	56.99
fMRI (type-level)	70.32
fMRI (token-level)	**70.89**
Error reduction over baseline	04.34

Table 1: Tagging accuracy on test data for the different models. The fMRI model is significantly better than the baseline ($p = 0.014$, Bootstrap).

Class	Prec.	Rec.	F_1	± BL

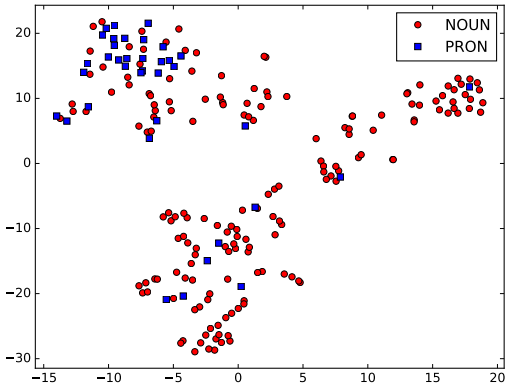
Table 2: Test data tagging performance by part-of-speech class for the best fMRI model. The rightmost column displays the difference in F_1 compared to the baseline model.

erable error reduction over the baseline model as well as the embeddings-enriched baseline model. It also outperforms the model which uses type-level averages over the fMRI recordings. Leaving out the basic features hurts performance, but even without the basic features the fMRI data can reduce error with 3.28% on the test set. In Table 2 we present the performance on the individual PoS classes under our best model.

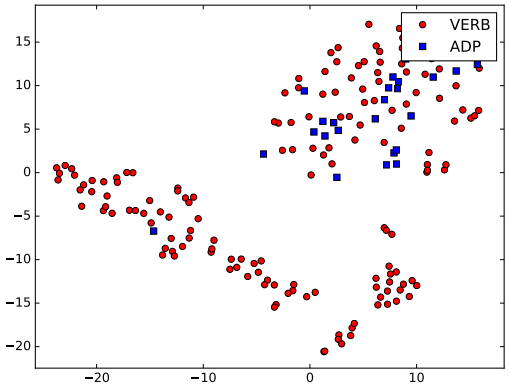
7 Analysis and Discussion

7.1 What's in the fMRI vectors?

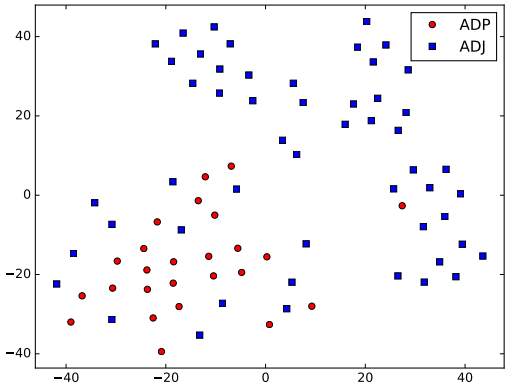
t-SNE (Van der Maaten and Hinton, 2008) is a powerful supervised dimensionality reduction tool for visualizing high-dimensional data in two-dimensional space using Stochastic Neighbor Embedding. In Figure 6, we visualize pairs of PoS classes of the test data in a two-dimensional re-



(a) NOUN and PRON



(b) VERB and ADP



(c) ADP and ADJ

Figure 6: Selected t-SNE visualizations of fMRI vectors for all tokens of a class of the test set. The visualizations show that datapoints of a PoS class tend to cluster in the fMRI vector space.

duction of the embedding space obtained when using the settings of the best fMRI model. The fact that we can discriminate reasonably well between, e.g., nouns and pronouns, verbs and adpositions, as well as adpositions and adjectives on the basis of fMRI data is to the best of our knowledge a new finding.

7.2 Discussion of the results

We showed that by careful model tuning and design it is possible to extract a signal of grammatical processing in the brain from fMRI. The figures that we present in Table 1 reflect, to our knowledge, the first successful results in inferring grammatical function at the token level from fMRI data. Our best model, which we train on the ten principal components from the fMRI recordings of eight readers, achieves an error reduction of over 4% despite a very small amount of training data. We find that our best model uses a very wide window of fMRI recordings to compute the representations for individual tokens, considering all recordings from 4 seconds before the token is displayed until 10 seconds after the token is displayed. Our best explanation for why the incorporation of preceding fMRI measurements is beneficial to our model, is that the grammatical function of a token may be predictable from a reader's cognitive state while reading preceding tokens. However, note that the measurements at the far ends of the time window only factor into the token vector to a small degree as a consequence of the Gaussian weighting. Our experiments further suggest that using token-level information instead of type-level features, such as word embeddings or type averages of fMRI vectors, is helpful for PoS induction that already is type-constrained.

Recently, Huth et al. (2016) found that semantically related words are processed in the same area of the brain. Open questions for future work include whether there is a bigger potential for using fMRI data for semantic rather than syntactic NLP tasks, and whether the signal we find mainly stems from semantic processing differences.

8 Conclusion

This paper presents the first experiments inducing part of speech from fMRI reading data. Cognitive psychologists have debated whether grammatical differences lead to different brain activation patterns. Somewhat surprisingly, we find that the fMRI data contains a strong signal, enabling a 4% error reduction over a state-of-the-art unsupervised PoS tagger. While our approach may not be readily applicable for developing NLP models today, we believe that the presented results may inspire NLP researchers to consider learning models from combinations of linguistic resources and auxiliary, behavioral data that reflects human cognition.

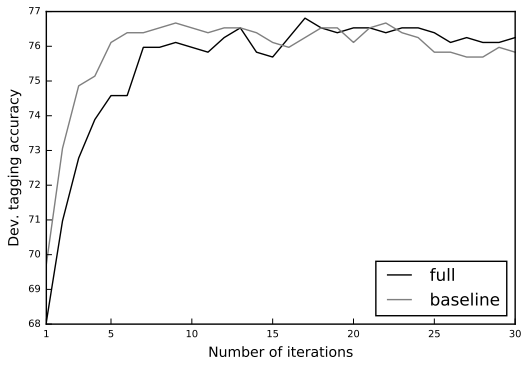


Figure 7: Learning curve of tagging accuracy on the development set as a function of different number of EM iterations for baseline model and the full model for iteration numbers $\in [1, 30]$. Fixed hyper-parameters: 8 subjects, 10 principal components, and a time window of $t - 4s$ to $t + 10s$

Abstract

Relation classification is an important semantic processing task in the field of natural language processing (NLP). In this paper, we present a novel model BRCNN to classify the relation of two entities in a sentence. Some state-of-the-art systems concentrate on modeling the shortest dependency path (SDP) between two entities leveraging convolutional or recurrent neural networks. We further explore how to make full use of the dependency relations information in the SDP, by combining convolutional neural networks and two-channel recurrent neural networks with long short term memory (LSTM) units. We propose a bidirectional architecture to learn relation representations with directional information along the SDP forwards and backwards at the same time, which benefits classifying the direction of relations. Experimental results show that our method outperforms the state-of-the-art approaches on the SemEval-2010 Task 8 dataset.

1 Introduction

Relation classification aims to classify the semantic relations between two entities in a sentence. For instance, in the sentence "The $[\text{burst}]_{e_1}$ has been caused by water hammer $[\text{pressure}]_{e_2}$", entities *burst* and *pressure* are of relation Cause-Effect(e_2, e_1). Relation classification plays a key role in robust knowledge extraction, and has become a hot research topic in recent years.

Nowadays, deep learning techniques have made significant improvement in relation classification, compared with traditional relation classification approaches focusing on designing effective features (Rink and Harabagiu, 2010) or kernels (Zelenko et al., 2003; Bunescu and Mooney, 2005) Although traditional approaches are able to exploit the symbolic structures in sentences, they still suffer from the difficulty to generalize over the unseen words. Some recent works learn features automatically based on neural networks (NN), employing continuous representations of words (word embeddings). The NN research for relation classification has centered around two main network architectures: convolutional neural networks and recursive/recurrent neural networks. Convolutional neural network aims to generalize the local and consecutive context of the relation mentions, while recurrent neural networks adaptively accumulate the context information in the whole sentence via memory units, thereby encoding the global and possibly unconsecutive patterns for relation classification. Socher et al. (2012) learned compositional vector representations of sentences with a recursive neural network. Kazuma et al. (2013) proposed a simple customizaition of recursive neural networks. Zeng et al. (2014) proposed a convolutional neural network with position embeddings.

Recently, more attentions have been paid to modeling the shortest dependency path (SDP) of sentences. Liu et al. (2015) developed a dependency-based neural network, in which a convolutional neural network has been used to capture features on the shortest path and a recursive neural network is designed to model subtrees. Xu et al. (2015b) applied long short term memory (LSTM) based recurrent neural networks (RNNs) along the shortest dependency path. However, SDP is a special structure in which every two neighbor words are separated by a dependency relations. Previous works treated dependency relations in the same

Realtion	Shortest Dependency Path
Cause-Effect(e_2,e_1)	burst ←nsubjpass— caused —prep→ by —pobj→ pressure
Cause-Effect(e_1,e_2)	pressure ←pobj— by ←prep— caused —nsubjpass→ burst

Figure 1: The shortest dependency path representation for an example sentence from SemEval-08.

way as words or some syntactic features like part-of-speech (POS) tags, because of the limitations of convolutional neural networks and recurrent neural networks. Our first contribution is that we propose a recurrent convolutional neural network (RCNN) to encode the global pattern in SDP utilizing a two-channel LSTM based recurrent neural network and capture local features of every two neighbor words linked by a dependency relation utilizing a convolution layer.

We further observe that the relationship between two entities are directed. For instance, Figure 1 shows that the shortest path of the sentence "The [burst]$_{e_1}$ has been caused by water hammer [pressure]$_{e_2}$." corresponds to relation Cause-Effect(e_2, e_1). The SDP of the sentence also corresponds to relation Cause-Effect(e_2, e_1), where e_1 refers to the entity at front end of SDP and e_2 refers to the entity at back end of SDP, and the inverse SDP corresponds to relation Cause-Effect(e_1, e_2). Previous work (Xu et al., 2015b) simply transforms a (K+1)-relation task into a $(2K + 1)$ classification task, where 1 is the *Other* relation and K is the number of directed relations. Besides, the recurrent neural network is a biased model, where later inputs are more dominant than earlier inputs. It could reduce the effectiveness when it is used to capture the semantics of a whole shortest dependency path, because key components could appear anywhere in a SDP rather than the end.

Our second contribution is that we propose a bidirectional recurrent convolutional neural networks (BRCNN) to learn representations with bidirectional information along the SDP forwards and backwards at the same time, which also strengthen the ability to classifying directions of relationships between entities. Experimental results show that the bidirectional mechanism significantly improves the performance.

We evaluate our method on the SemEval-2010 relation classification task, and achieve a state-of-the-art F_1-score of 86.3%.

2 The Proposed Method

In this section, we describe our method in detail. Subsection 2.1 provides an overall picture of our BCRNN model. Subsection 2.2 presents the rationale of using SDPs and some characteristics of SDP. Subsection 2.3 describes the two-channel recurrent neural network, and bidirectional recurrent convolutional neural network is introduced in Subsection 2.4. Finally, we present our training objective in Subsection 2.5.

2.1 Framework

Our BCRNN model is used to learn representations with bidirectional information along the SDP forwards and backwards at the same time. Figure 2 depicts the overall architecture of the BRCNN model.

Given a sentence and its dependency tree, we build our neural network on its SDP extracted from the tree. Along the SDP, two recurrent neural networks with long short term memory units are applied to learn hidden representations of words and dependency relations respectively. A convolution layer is applied to capture local features from hidden representations of every two neighbor words and the dependency relations between them. A max pooling layer thereafter gathers information from local features of the SDP or the inverse SDP. We have a $softmax$ output layer after pooling layer for classification in the unidirectional model RCNN.

On the basis of RCNN model, we build a bidirectional architecture BRCNN taking the SDP and the inverse SDP of a sentence as input. During the training stage of a (K+1)-relation task,

two fine-grained $softmax$ classifiers of RCNNs do a $(2K + 1)$-class classification respectively. The pooling layers of two RCNNs are concatenated and a coarse-grained $softmax$ output layer is followed to do a $(K + 1)$-class classification. The final (2K+1)-class distribution is the combination of two (2K+1)-class distributions provided by fine-grained classifiers respectively during the testing stage.

2.2 The Shortest Dependency Path

If e_1 and e_2 are two entities mentioned in the same sentence such that they are observed to be in a relationship R, the shortest path between e_1 and e_2 condenses most illuminating information for the relationship $R(e_1, e_2)$. It is because (1) if entities e_1 and e_2 are arguments of the same predicate, the shortest path between them will pass through the predicate; (2) if e_1 and e_2 belong to different predicate-argument structures that share a common argument, the shortest path will pass through this argument.

Bunescu and Mooney (2005) first used shortest dependency paths between two entities to capture the predicate-argument sequences, which provided strong evidence for relation classification. Xu et al. (2015b) captured information from the sub-paths separated by the common ancestor node of two entities in the shortest paths. However, the shortest dependency path between two entities is usually short (~4 on average) , and the common ancestor of some SDPs is e_1 or e_2, which leads to imbalance of two sub-paths.

We observe that, in the shortest dependency path, each two neighbor words w_a and w_b are linked by a dependency relation r_{ab}. The dependency relations between a governing word and its children make a difference in meaning. Besides, if we inverse the shortest dependency path, it corresponds to the same relationship with an opposite direction. For example , in Figure 1, the shortest path is composed of some sub-structure like "$burst \xrightarrow{nsubjpass} caused$". Following the above intuition, we design a bidirectional recurrent convolutional neural network, which can capture features from the local substructures and inversely at the same time.

2.3 Two-Channel Recurrent Neural Network with Long Short Term Memory Units

The recurrent neural network is suitable for modeling sequential data, as it keeps hidden state vector h, which changes with input data at each step accordingly. We make use of words and dependency relations along the SDP for relations classification (Figure 2). We call them *channels* as these information sources do not interact during recurrent propagation. Each word and dependency relation in a given sentence is mapped to a real-valued vector by looking up in a embedding table. The embeddings of words are trained on a large corpus unsupervisedly and are thought to be able to capture their syntactic and semantic information, and the embeddings of dependency relations are initialized randomly.

The hidden state h_t, for the t-th input is a function of its previous state h_{t-1} and the embedding x_t of current input. Traditional recurrent networks have a basic interaction, that is, the input is linearly transformed by a weight matrix and nonlinearly squashed by an activation function. Formally, we have

$$h_t = f(W_{in} \cdot x_t + W_{rec} \cdot h_{t-1} + b_h) \qquad (1)$$

where W_{in} and W_{rec} are weight matrices for the input and recurrent connections, respectively. b_h is a bias term for the hidden state vector, and f a non-linear activation function.

It was difficult to train RNNs to capture long-term dependencies because the gradients tend to either vanish or explode. Therefore, some more sophisticated activation function with gating units were designed. Long short term memory units are proposed in Hochreiter and Schmidhuber (1997) to overcome this problem. The main idea is to introduce an adaptive gating mechanism, which decides the degree to which LSTM units keep the previous state and memorize the extracted features of the current data input. Many LSTM variants have been proposed. We adopt in our method a variant introduced by Zaremba and Sutskever (2014). Concretely, the LSTM-based recurrent neural network comprises four components: an input gate i_t, a forget gate f_t, an output gate o_t, and a memory cell c_t.

First, we compute the values for i_t, the input gate, and g_t the candidate value for the states of

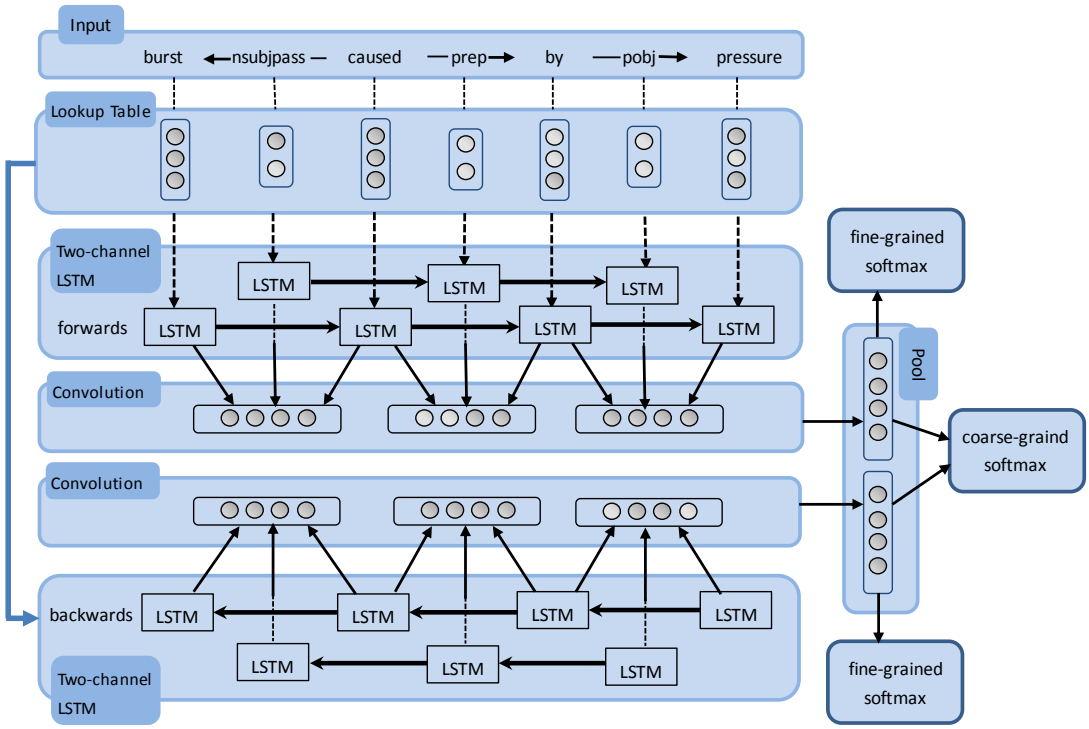

Figure 2: The overall architecture of BRCNN. Two-Channel recurrent neural networks with LSTM units pick up information along the shortest dependency path, and inversely at the same time. Convolution layers are applied to extract local features from the dependency units.

the memory cells at time t:

$$i_t = \sigma(W_i \cdot x_t + U_i \cdot h_{t-1} + b_i) \quad (2)$$

$$g_t = tanh(W_c \cdot x_t + U_c \cdot h_{t-1} + b_c) \quad (3)$$

Second, we compute the value for f_t, the activations of the memory cells' forget gates at time t:

$$f_t = \sigma(W_f \cdot x_t + U_f \cdot h_{t-1} + b_f) \quad (4)$$

Given the value of the input gate activations i_t, the forget gate activation f_t and the candidate state value g_t, we can compute c_t the memory cells' new state at time t:

$$c_t = i_t \otimes g_t + f_t \otimes c_{t-1} \quad (5)$$

With the new state of the memory cells, we can compute the value of their output gates and, subsequently, their outputs:

$$o_t = \sigma(W_o \cdot x_t + U_o \cdot h_{t-1} + b_o) \quad (6)$$

$$h_t = o_t \otimes tanh(c_t) \quad (7)$$

In the above equations, σ denotes a sigmoid function; $\otimes$ denotes element-wise multiplication.

2.4 Bidirectional Recurrent Convolutional Neural Network

We observe that a governing word w_a and its children w_b are linked by a dependency relation r_{ab}, which makes a difference in meaning. For example, "*kills* $\xrightarrow{nsubj}$ *it*" is distinct from "*kills* $\xrightarrow{dobj}$ *it*". The shortest dependency path is composed of many substructures like "$w_a \xrightarrow{r_{ab}} w_b$", which are hereinafter referred to as "*dependency unit*". Hidden states of words and dependency relations in the SDP are obtained, utilizing two-channel recurrent neural network. The hidden states of w_a, w_b and r_{ab} are h_a, h_b and h'_{ab}, and the hidden state of the dependency unit d_{ab} is $[h_a \oplus h'_{ab} \oplus h_b]$, where $\oplus$ denotes concatenate operation. Local features L_{ab} for the dependency unit d_{ab} can be extracted, utilizing a convolution layer upon the two-channel recurrent neural network . Formally, we have

$$L_{ab} = f(W_{con} \cdot [h_a \oplus h'_{ab} \oplus h_b] + b_{con}) \quad (8)$$

where W_{con} is the weight matrix for the convolution layer and b_{con} is a bias term for the hidden state vector. f is a non-linear activation function(*tanh* is used in our model). A pooling layer thereafter gather global information G from

local features of dependency units, which is defined as

$$G = \max_{d=1}^{D} L_d \tag{9}$$

where the max function is an element-wise function, and D is the number of dependency units in the SDP.

The advantage of two-channel recurrent neural network is the ability to better capture the contextual information, adaptively accumulating the context information the whole path via memory units. However, the recurrent neural network is a biased model, where later inputs are more dominant than earlier inputs. It could reduce the effectiveness when it is used to capture features for relation classification, for the entities are located at both ends of SDP and key components could appear anywhere in a SDP rather than at the end. We tackle the problem with Bidirectional Convolutional Recurrent Neural Network.

On the basis of observation, we make a hypothesis that SDP is a symmetrical structure. For example, if there is a forward shortest path $\overrightarrow{S}$ which corresponds to relation $R_x(e_1, e_2)$, the backward shortest path $\overleftarrow{S}$ can be obtained by inversing $\overrightarrow{S}$, and $\overleftarrow{S}$ corresponds to $R_x(e_2, e_1)$, and both $\overrightarrow{S}$ and $\overleftarrow{S}$ correspond to relation R_x.

As shown in Figure 2, two RCNNs pick up information along $\overrightarrow{S}$ and $\overleftarrow{S}$, obtaining global representations $\overrightarrow{G}$ and $\overleftarrow{G}$. A representation with bidirectional information is obtained by concatenating $\overrightarrow{G}$ and $\overleftarrow{G}$. A coarse-grained $softmax$ classifier is used to predict a (K+1)-class distribution y. Formally,

$$y = softmax(W_c \cdot [\overleftarrow{G} \oplus \overrightarrow{G}] + b_c) \tag{10}$$

Where W_c is the transformation matrix and b_c is the bias vector. Coarse-grained classifier makes use of representation with bidirectional information ignoring the direction of relations, which learns the inherent correlation between the same directed relations with opposite directions, such as $R_x(e_1, e_2)$ and $R_x(e_2, e_1)$.

Two fine-grained $softmax$ classifiers are applied to $\overrightarrow{G}$ and $\overleftarrow{G}$ with linear transformation to give the (2K+1)-class distribution $\overrightarrow{y}$ and $\overleftarrow{y}$ respectively. Formally,

$$\overrightarrow{y} = softmax(W_f \cdot \overrightarrow{G} + b_f) \tag{11}$$

$$\overleftarrow{y} = softmax(W_f \cdot \overleftarrow{G} + b_f) \tag{12}$$

where W_f is the transformation matrix and b_f is the bias vector. Classifying $\overrightarrow{S}$ and $\overleftarrow{S}$ respecitvely at the same time can strengthen the model ability to judge the direction of relations.

2.5 Training Objective

The $(K + 1)$-class $softmax$ classifier is used to estimate probability that $\overrightarrow{S}$ and $\overleftarrow{S}$ are of relation R . The two $(2K + 1)$-class $softmax$ classifiers are used to estimate the probability that $\overrightarrow{S}$ and $\overleftarrow{S}$ are of relation $\overrightarrow{R}$ and $\overleftarrow{R}$ respectively. For a single data sample, the training objective is the penalized cross-entropy of three classifiers, given by

$$\begin{aligned} J = &\sum_{i=1}^{2K+1} \overrightarrow{t}_i \log \overrightarrow{y}_i + \sum_{i=1}^{2K+1} \overleftarrow{t}_i \log \overleftarrow{y}_i \\ &+ \sum_{i=1}^{K} t_i \log y_i + \lambda \cdot \|\theta\|^2 \end{aligned} \tag{13}$$

where $t \in \mathbb{R}^{K+1}$, $\overrightarrow{t}$ and $\overleftarrow{t} \in \mathbb{R}^{2K+1}$, indicating the one-hot represented ground truth. y, $\overrightarrow{y}$ and $\overleftarrow{y}$ are the estimated probabilities for each class described in section 2.4. θ is the set of model parameters to be learned, and λ is a regularization coefficient.

For decoding (predicting the relation of an unseen sample), the bidirectional model provides the (2K+1)-class distribution $\overrightarrow{y}$ and $\overleftarrow{y}$. The final (2K+1)-class distribution y_{test} becomes the combination of $\overrightarrow{y}$ and $\overleftarrow{y}$. Formally,

$$y_{test} = \alpha \cdot \overrightarrow{y} + (1 - \alpha) \cdot z(\overleftarrow{y}) \tag{14}$$

where α is the fraction of the composition of distributions, which is set to the value 0.65 according to the performance on validation dataset. During the implementation of BRCNN, elements in two class distributions at the same position are not corresponding, e.g. Cause-Effect(e_1, e_2) in $\overrightarrow{y}$ should correspond to Cause-Effect(e_2, e_1) in $\overleftarrow{y}$. We apply a function z to transform $\overleftarrow{y}$ to a corresponding forward distribution like $\overrightarrow{y}$.

3 Experiments

3.1 Dataset

We evaluated our BRCNN model on the SemEval-2010 Task 8 dataset, which is an established benchmark for relation classification (Hendrickx et al., 2010). The dataset contains 8000 sentences for training, and 2717 for testing. We split 800 samples out of the training set for validation.

Classifier	Additional Information	F_1
SVM (Rink and Harabagiu, 2010)	POS, WordNet, Prefixes and other morphological features, dependency parse, Levin classed, PropBank, FanmeNet, NomLex-Plus, Google *n*-gram, paraphrases, TextRunner	82.2
RNN (Socher et al., 2011)	Word embeddings	74.8

	+ negative sampling from NYT dataset	85.6
BRCNN (Our Model)	Word embeddings	85.4
	+ POS, NER, WordNet embeddings	**86.3**

Table 1: Comparison of relation classification systems.

The dataset has (K+1)=10 distinguished relations, as follows.

- Cause-Effect
- Component-Whole
- Content-Container
- Entity-Destination
- Entity-Origin
- Message-Topic
- Member-Collection
- Instrument-Agency
- Product-Agency
- Other

The former K=9 relations are directed, whereas the Other class is undirected, we have (2K+1)=19 different classes for 10 relations. All baseline systems and our model use the official macro-averaged F_1-score to evaluate model performance. This official measurement excludes the Other relation.

3.2 Hyperparameter Settings

In our experiment, word embeddings were 200-dimensional as used in (Yu et al., 2014), trained on Gigaword with word2vec (Mikolov et al., 2013). Embeddings of relation are 50-dimensional and initialized randomly. The hidden layers in each channel had the same number of units as their embeddings (200 or 50). The convolution layer was 200-dimensional. The above values were chosen according to the performance on the validation dataset.

As we can see in Figure 1, dependency relation r "$\xrightarrow{prep}$" in $\overrightarrow{S}$ becomes r^{-1} "$\xleftarrow{prep}$" in $\overleftarrow{S}$. Experiment results show that, the performance of BRCNN is improved if r and r^{-1} correspond to different relations embeddings rather than a same embedding. We notice that dependency relations contain much fewer symbols than the words contained in the vocabulary, and we initialize the embeddings of dependency relations randomly for they can be adequately tuned during supervised training.

We add l_2 penalty for weights with coefficient 10^{-5}, and dropout of embeddings with rate 0.5. We applied AdaDelta for optimization (Zeiler, 2012), where gradients are computed with an adaptive learning rate.

3.3 Results

Table 1 compares our BRCNN model with other state-of-the-art methods. The first entry in the table presents the highest performance achieved by traditional feature-based methods. Rink and Harabagiu. (2010) fed a variety of handcrafted features to the SVM classifier and achieve an F_1-score of 82.2%.

Recent performance improvements on this dataset are mostly achieved with the help of neural networks. Socher et al. (2012) built a recursive neural network on the constituency tree and achieved a comparable performance with Rink and Harabagiu. (2010). Further, they extended their recursive network with matrix-vector interaction and elevated the F_1 to 82.4%. Xu et al. (2015b) first introduced a type of gated recurrent neural network (LSTM) into this task and raised the F_1-score to 83.7%.

From the perspective of convolution, Zeng et al. (2014) constructed a CNN on the word sequence; they also integrated word position embeddings, which helped a lot on the CNN architecture. dos Santos et al. (2015) proposed a similar CNN model, named CR-CNN, by replacing the common $softmax$ cost function with a ranking-based cost function. By diminishing the impact of the Other class, they have achieved an F_1-score of 84.1%. Along the line of CNNs, Xu et al. (2015a) designed a simple negative sampling method, which introduced additional samples from other corpora like the NYT dataset. Doing so greatly improved the performance to a high F_1-score of 85.6%. Liu et al. (2015) proposed a convolutional neural network with a recursive neural network designed to model the subtrees, and achieve an F_1-score of 83.6%.

Without the use of neural networks, Yu et al. (2014) proposed a Feature-based Compositional Embedding Model (FCM), which combined unlexicalized linguistic contexts and word embeddings. They achieved an F_1-score of 83.0%.

We make use of three types of information to improve the performance of BRCNN: POS tags, NER features and WordNet hypernyms. Our proposed BRCNN model yields an F_1-score of 86.3%, outperforming existing competing approaches. Without using any human-designed features, our model still achieve an F_1-score of 85.4%, while the best performance of state-of-the-art methods is 84.1% (dos Santos et al., 2015).

3.4 Analysis

Table 2 compares our RCNN model with CNNs and RNNs.

Model	F_1
CNN	81.8
LSTM	76.6
Two-channel LSTM	81.5
RCNN	**82.4**

Table 2: Comparing RCNN with CNNs and RNNS.

For a fair comparison, hyperparameters are set according to the performance on validation dataset as BRCNN . CNN with embeddings of words, positions and dependency relations as input achieves an F_1-score of 81.8%. LSTM with word embeddings as input only achieves an F_1-score of 76.6%, which proves that dependency relations in SDPs play an important role in relation classification. Two-channel LSTM concatenates the pooling layers of words and dependency relations along the shortest dependency path, achieves an F_1-score of 81.5% which is still lower than CNN. RCNN captures features from dependency units by combining the advantages of CNN and RNN, and achieves an F_1-score of 82.4%.

Model	**Input**	F_1
RCNN	$\overrightarrow{S}$ of all relations	82.4
Bi-RCNN	$\overrightarrow{S}$ and $\overleftarrow{S}$ of all relations	81.2
Bi-RCNN	$\overrightarrow{S}$ and $\overleftarrow{S}$ of directed relations , $\overrightarrow{S}$ of Other	84.9
BRCNN	$\overrightarrow{S}$ and $\overleftarrow{S}$ of directed relations, $\overrightarrow{S}$ of Other	**85.4**

Table 3: Comparing different variants of our model.

Bi-RCNN is a variant of BRCNN, which doesn't have the coarse-grained classifier. $\overrightarrow{S}$ and $\overleftarrow{S}$ are shortest dependency paths described in section 2.4. As shown in Table 3, if we inverted the SDP of all relations as input, we observe a performance degradation of 1.2% compared with RCNN. As mentioned in section 3.1, the SemEval-2010 task 8 dataset contains an undirected class Other in addition to 9 directed relations(18 classes). For bidirectional model, it is natural that the inversed Other relation is also in

the Other class itself. However, the class Other is used to indicate that relation between two nominals dose not belong to any of the 9 directed classes. Therefore, the class Other is very noisy since it groups many different types of relations with different directions.

On the basis of the analysis above, we only inverse the SDP of directed relations. A significant improvement is observed and Bi-RCNN achieves an F_1-score of 84.9%. This proves bidirectional representations provide more useful information to classify directed relations. We can see that our model still benefits from the coarse-grained classification, which can help our model learn inherent correlation between directed relations with opposite directions. Compared with Bi-RCNN classifying $\overrightarrow{S}$ and $\overleftarrow{S}$ into 19 classes separately, BRCNN also conducts a 10 classes (9 directed relations and Other) classification and improves 0.5% in F_1-score. Beyond the relation classification task, we believe that our bidirectional method is general technique, which is not restricted in a specific dataset and has the potential to benefit other NLP tasks.

4 Related Work

Relation classification is an important topic in NLP. Traditional Methods for relation classification mainly fall into three classes: feature-based, kernel-based and neural network-based.

In feature-based approaches, different types of features are extracted and fed into a classifier. Generally, three types of features are often used. Lexical features concentrate on the entities of interest, e.g., POS. Syntactic features include chunking, parse trees, etc. Semantic features are exemplified by the concept hierarchy, entity class. Kambhatla (2004) used a maximum entropy model for feature combination. Rink and Harabagiu (2010) collected various features, including lexical, syntactic as well as semantic features.

In kernel based methods, similarity between two data samples is measured without explicit feature representation. Bunescu and Mooney (2005) designed a kernel along the shortest dependency path between two entities by observing that the relation strongly relies on SDPs. Wang (2008) provided a systematic analysis of several kernels and showed that relation extraction can benefit from combining convolution kernel and syntactic features. Plank and Moschitti (2013) combined structural information and semantic information in a tree kernel. One potential difficulty of kernel methods is that all data information is completely summarized by the kernel function, and thus designing an effective kernel becomes crucial.

Recently, deep neural networks are playing an important role in this task. Socher et al. (2012) introduced a recursive neural network model that assigns a matrix-vector representation to every node in a parse tree, in order to learn compositional vector representations for sentences of arbitrary syntactic type and length.

Convolutional neural works are widely used in relation classification. Zeng et al. (2014) proposed an approach for relation classification where sentence-level features are learned through a CNN, which has word embedding and position features as its input. In parallel, lexical features were extracted according to given nouns. dos Santos et al. (2015) tackled the relation classification task using a convolutional neural network and proposed a new pairwise ranking loss function, which achieved the state-of-the-art result in SemEval-2010 Task 8.

Yu et al. (2014) proposed a Factor-based Compositional Embedding Model (FCM) by deriving sentence-level and substructure embeddings from word embeddings, utilizing dependency trees and named entities. It achieved slightly higher accuracy on the same dataset than Zeng et al. (2014), but only when syntactic information is used.

Nowadays, many works concentrate on extracting features from the SDP based on neural networks. Xu et al. (2015a) learned robust relation representations from SDP through a CNN, and proposed a straightforward negative sampling strategy to improve the assignment of subjects and objects. Liu et al. (2015) proposed a recursive neural network designed to model the subtrees, and CNN to capture the most important features on the shortest dependency path. Xu et al. (2015b) picked up heterogeneous information along the left and right sub-path of the SDP respectively, leveraging recurrent neural networks with long short term memory units. We propose BRCNN to model the SDP, which can pick up bidirectional information with a combination of LSTM and CNN.

5 Conclusion

In this paper, we proposed a novel bidirectional neural network BRCNN, to improve the performance of relation classification. The BRCNN model, consisting of two RCNNs, learns features along SDP and inversely at the same time. Information of words and dependency relations are used utilizing a two-channel recurrent neural network with LSTM units. The features of dependency units in SDP are extracted by a convolution layer.

We demonstrate the effectiveness of our model by evaluating the model on SemEval-2010 relation classification task. RCNN achieves a better performance at learning features along the shortest dependency path, compared with some common neural networks. A significant improvement is observed when BRCNN is used, outperforming state-of-the-art methods.

Abstract

A major challenge of semantic parsing is the vocabulary mismatch problem between natural language and target ontology. In this paper, we propose a sentence rewriting based semantic parsing method, which can effectively resolve the mismatch problem by rewriting a sentence into a new form which has the same structure with its target logical form. Specifically, we propose two sentence-rewriting methods for two common types of mismatch: a dictionary-based method for 1-N mismatch and a template-based method for N-1 mismatch. We evaluate our sentence rewriting based semantic parser on the benchmark semantic parsing dataset – WEBQUESTIONS. Experimental results show that our system outperforms the base system with a 3.4% gain in F1, and generates logical forms more accurately and parses sentences more robustly.

1 Introduction

Semantic parsing is the task of mapping natural language sentences into logical forms which can be executed on a knowledge base (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Kate and Mooney, 2006; Wong and Mooney, 2007; Lu et al., 2008; Kwiatkowksi et al., 2010). Figure 1 shows an example of semantic parsing. Semantic parsing is a fundamental technique of natural language understanding, and has been used in many applications, such as question answering (Liang et al., 2011; He et al., 2014; Zhang et al., 2016) and information extraction (Krishnamurthy and Mitchell, 2012; Choi et al., 2015; Parikh et al., 2015).

Semantic parsing, however, is a challenging task. Due to the variety of natural language expressions, the same meaning can be expressed using different sentences. Furthermore, because logical forms depend on the vocabulary of target-ontology, a sentence will be parsed into different logical forms when using different ontologies. For example, in below the two sentences s_1 and s_2 express the same meaning, and they both can be parsed into the two different logical forms lf_1 and lf_2 using different ontologies.

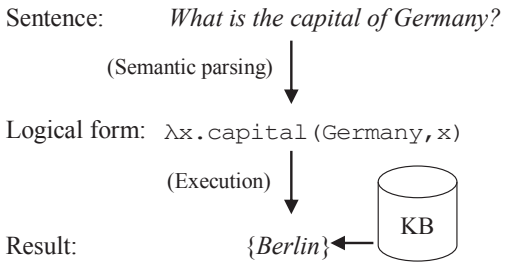

Figure 1: An example of semantic parsing.

s_1	*What is the population of Berlin?*
s_2	*How many people live in Berlin?*
lf_1	λx.population(Berlin,x)
lf_2	count(λx.person(x)∧live(x,Berlin))

Based on the above observations, one major challenge of semantic parsing is the structural mismatch between a natural language sentence and its target logical form, which are mainly raised by the vocabulary mismatch between natural language and ontologies. Intuitively, if a sentence has the same structure with its target logical form, it is easy to get the correct parse, e.g., a semantic parser can easily parse s_1 into lf_1 and s_2 into lf_2. On the contrary, it is difficult to parse a sentence into its logic form when they have different structures, e.g., $s_1 \rightarrow lf_2$ or $s_2 \rightarrow lf_1$.

To resolve the vocabulary mismatch problem,

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 766–777,
Berlin, Germany, August 7-12, 2016.

(a) An example using traditional method

s_0 : *What is the name of Sonia Gandhis daughter?*
l_0 : λ`x.child(S.G.,x)`
r_0 : {*Rahul Gandhi (Wrong answer), Priyanka Vadra*}

(b) An example using our method

s_0 : *What is the name of Sonia Gandhis daughter?*
s_1 : *What is the name of Sonia Gandhis female child?*
l_1 : λ`x.child(S.G.,x)`$\wedge$`gender(x,female)`
r_1 : {*Priyanka Vadra*}

Table 1: Examples of (a) sentences s_0, possible logical form l_0 from traditional semantic parser, result r_0 for the logical form l_0; (b) possible sentence s_1 from rewriting for the original sentence s_0, possible logical form l_1 for sentence s_1, result r_1 for l_1. *Rahul Gandhi* is a wrong answer, as he is the son of *Sonia Gandhi*.

this paper proposes a sentence rewriting approach for semantic parsing, which can rewrite a sentence into a form which will have the same structure with its target logical form. Table 1 gives an example of our rewriting-based semantic parsing method. In this example, instead of parsing the sentence "*What is the name of Sonia Gandhis daughter?*" into its structurally different logical form `childOf.S.G.`$\wedge$`gender.female` directly, our method will first rewrite the sentence into the form "*What is the name of Sonia Gandhis female child?*", which has the same structure with its logical form, then our method will get the logical form by parsing this new form. In this way, the semantic parser can get the correct parse more easily. For example, the parse obtained through traditional method will result in the wrong answer "*Rahul Gandhi*", because it cannot identify the vocabulary mismatch between "*daughter*" and `child`$\wedge$`female`[1]. By contrast, by rewriting "*daughter*" into "*female child*", our method can resolve this vocabulary mismatch.

Specifically, we identify two common types of vocabulary mismatch in semantic parsing:

1. 1-N mismatch: a simple word may correspond to a compound formula. For example, the word "*daughter*" may correspond to the compound formula `child`$\wedge$`female`.

2. N-1 mismatch: a logical constant may correspond to a complicated natural language expression, e.g., the formula `population` can be expressed using many phrases such as "*how many people*" and "*live in*".

[1] In this paper, we may simplify logical forms for readability, e.g., `female` for `gender.female`.

To resolve the above two vocabulary mismatch problems, this paper proposes two sentence rewriting algorithms: One is a dictionary-based sentence rewriting algorithm, which can resolve the 1-N mismatch problem by rewriting a word using its explanation in a dictionary. The other is a template-based sentence rewriting algorithm, which can resolve the N-1 mismatch problem by rewriting complicated expressions using paraphrase template pairs.

Given the generated rewritings of a sentence, we propose a ranking function to jointly choose the optimal rewriting and the correct logical form, by taking both the rewriting features and the semantic parsing features into consideration.

We conduct experiments on the benchmark WEBQUESTIONS dataset (Berant et al., 2013). Experimental results show that our method can effectively resolve the vocabulary mismatch problem and achieve accurate and robust performance.

The rest of this paper is organized as follows. Section 2 reviews related work. Section 3 describes our sentence rewriting method for semantic parsing. Section 4 presents the scoring function which can jointly ranks rewritings and logical forms. Section 5 discusses experimental results. Section 6 concludes this paper.

2 Related Work

Semantic parsing has attracted considerable research attention in recent years. Generally, semantic parsing methods can be categorized into synchronous context free grammars (SCFG) based methods (Wong and Mooney, 2007; Arthur et al., 2015; Li et al., 2015), syntactic structure based methods (Ge and Mooney, 2009; Reddy et al., 2014; Reddy et al., 2016), combinatory categorical grammars (CCG) based methods (Zettlemoyer and Collins, 2007; Kwiatkowksi et al., 2010; Kwiatkowski et al., 2011; Krishnamurthy and Mitchell, 2014; Wang et al., 2014; Artzi et al., 2015), and dependency-based compositional semantics (DCS) based methods (Liang et al., 2011; Berant et al., 2013; Berant and Liang, 2014; Berant and Liang, 2015; Pasupat and Liang, 2015; Wang et al., 2015).

One major challenge of semantic parsing is how to scale to open-domain situation like Freebase and Web. A possible solution is to learn lexicons from large amount of web text and a knowledge base using a distant supervised method (Krishna-

murthy and Mitchell, 2012; Cai and Yates, 2013a; Berant et al., 2013). Another challenge is how to alleviate the burden of annotation. A possible solution is to employ distant-supervised techniques (Clarke et al., 2010; Liang et al., 2011; Cai and Yates, 2013b; Artzi and Zettlemoyer, 2013), or unsupervised techniques (Poon and Domingos, 2009; Goldwasser et al., 2011; Poon, 2013).

There were also several approaches focused on the mismatch problem. Kwiatkowski et al. (2013) addressed the ontology mismatch problem (i.e., two ontologies using different vocabularies) by first parsing a sentence into a domain-independent underspecified logical form, and then using an ontology matching model to transform this underspecified logical form to the target ontology. However, their method is still hard to deal with the 1-N and the N-1 mismatch problems between natural language and target ontologies. Berant and Liang (2014) addressed the structure mismatch problem between natural language and ontology by generating a set of canonical utterances for each candidate logical form, and then using a paraphrasing model to rerank the candidate logical forms. Their method addresses mismatch problem in the reranking stage, cannot resolve the mismatch problem when constructing candidate logical forms. Compared with these two methods, we approach the mismatch problem in the parsing stage, which can greatly reduce the difficulty of constructing the correct logical form, through rewriting sentences into the forms which will be structurally consistent with their target logic forms.

Sentence rewriting (or paraphrase generation) is the task of generating new sentences that have the same meaning as the original one. Sentence rewriting has been used in many different tasks, e.g., used in statistical machine translation to resolve the word order mismatch problem (Collins et al., 2005; He et al., 2015). To our best knowledge, this paper is the first work to apply sentence rewriting for vocabulary mismatch problem in semantic parsing.

3 Sentence Rewriting for Semantic Parsing

As discussed before, the vocabulary mismatch between natural language and target ontology is a big challenge in semantic parsing. In this section, we describe our sentence rewriting algorithm for solving the mismatch problem. Specifically, we solve the 1-N mismatch problem by dictionary-based rewriting and solve the N-1 mismatch problem by template-based rewriting. The details are as follows.

Word	Logical Form	Wiktionary Explanation
son	`child⋀male`	*male child*
actress	`actor⋀female`	*female actor*
father	`parent⋀male`	*male parent*
grandaprent	`parent⋀parent`	*parent of one's parent*
brother	`sibling⋀male`	*male sibling*

Table 2: Several examples of words, their logical forms and their explanations in Wiktionary.

3.1 Dictionary-based Rewriting

In the 1-N mismatch case, a word will correspond to a compound formula, e.g., the target logical form of the word "*daughter*" is `child⋀female` (Table 2 has more examples).

To resolve the 1-N mismatch problem, we rewrite the original word ("*daughter*") into an expression ("*female child*") which will have the same structure with its target logical form (`child⋀female`). In this paper, we rewrite words using their explanations in a dictionary. This is because each word in a dictionary will be defined by a detailed explanation using simple words, which often will have the same structure with its target formula. Table 2 shows how the vocabulary mismatch between a word and its logical form can be resolved using its dictionary explanation. For instance, the word "*daughter*" is explained as "*female child*" in Wiktionary, which has the same structure as `child⋀female`.

In most cases, only common nouns will result in the 1-N mismatch problem. Therefore, in order to control the size of rewritings, this paper only rewrite the common nouns in a sentence by replacing them with their dictionary explanations. Because a sentence usually will not contain too many common nouns, the size of candidate rewritings is thus controllable. Given the generated rewritings of a sentence, we propose a sentence selection model to choose the best rewriting using multiple features (See details in Section 4).

Table 3 shows an example of the dictionary-based rewriting. In Table 3, the example sentence s contains two common nouns ("*name*" and "*daughter*"), therefore we will generate three rewritings r_1, r_2 and r_3. Among these rewritings,

s : *What is the name of Sonia Gandhis daughter?*
r_1: *What is the reputation of Sonia Gandhis daughter?*
r_2: *What is the name of Sonia Gandhis female child?*
r_3: *What is the reputation of Sonia Gandhis female child?*

Table 3: An example of the dictionary-based sentence rewriting.

the candidate rewriting r_2 is what we expected, as it has the same structure with the target logical form and doesn't bring extra noise (i.e., replacing "*name*" with its explanation "*reputation*").

For the dictionary used in rewriting, this paper uses Wiktionary. Specifically, given a word, we use its "Translations" part in the Wiktionary as its explanation. Because most of the 1-N mismatch are caused by common nouns, we only collect the explanations of common nouns. Furthermore, for polysomic words which have several explanations, we only use their most common explanations. Besides, we ignore explanations whose length are longer than 5.

3.2 Template-based Rewriting

In the N-1 mismatch case, a complicated natural language expression will be mapped to a single logical constant. For example, considering the following mapping from the natural language sentence s to its logical form lf based on Freebase ontology:

s: *How many people live in Berlin?*
lf: λx.population(Berlin,x)

where the three words: "*how many*" (count), "*people*" (people) and "*live in*" (live) will map to the predicate population together. Table 4 shows more N-1 examples.

Expression	Logical constant
how many, people, live in	population
how many, people, visit, annually	annual-visit
what money, use	currency
what school, go to	education
what language, speak, officially	official-language

Table 4: Several N-1 mismatch examples.

To resolve the N-1 mismatch problem, we propose a template rewriting algorithm, which can rewrite a complicated expression into its simpler form. Specifically, we rewrite sentences based on a set of paraphrase template pairs $P = \{(t_{i1}, t_{i2})|i = 1, 2, ..., n\}$, where each template t is a sentence with an argument slot \$y, and t_{i1} and t_{i2} are paraphrases. In this paper, we only consider single-slot templates. Table 5 shows several paraphrase template pairs.

Template 1	Template 2
How many people live in \$y	*What is the population of \$y*
What money in \$y is used	*What is the currency of \$y*
What school did \$y go to	*What is the education of \$y*
What language does \$y speak officially	*What is the official language of \$y*

Table 5: Several examples of paraphrase template pairs.

Given the template pair database and a sentence, our template-based rewriting algorithm works as follows:

1. Firstly, we generate a set of candidate templates $ST = \{st_1, st_2, ..., st_n\}$ of the sentence by replacing each named entity within it by "\$y". For example, we will generate template "*How many people live in \$y*" from the sentence "*How many people live in Berlin*".

2. Secondly, using the paraphrase template pair database, we retrieve all possible rewriting template pairs (t_1, t_2) with $t_1 \in ST$, e.g., we can retrieve template pair ("*How many people live there in \$y*", "*What is the population of \$y*" for t_2) using the above ST.

3. Finally, we get the rewritings by replacing the argument slot "\$y" in template t_2 with the corresponding named entity. For example, we get a new candidate sentence "*What is the population of Berlin*" by replacing "\$y" in t_2 with Berlin. In this way we can get the rewriting we expected, since this rewriting will match its target logical form population(Berlin).

To control the size and measure the quality of rewritings using a specific template pair, we also define several features and the similarity between template pairs (See Section 4 for details).

To build the paraphrase template pair database, we employ the method described in Fader et al. (2014) to automatically collect paraphrase template pairs. Specifically, we use the WikiAnswers paraphrase corpus (Fader et al., 2013), which contains 23 million question-clusters, and all ques-

How many people live in chembakolli?
How many people is in chembakolli?
How many people live in chembakolli india?
How many people live there chembakolli?
How many people live there in chembakolli?
What is the population of Chembakolli india?
What currency is used on St Lucia?
What is st lucia money?
What is the money used in st lucia?
What kind of money did st lucia have?
What money do st Lucia use?
Which money is used in St Lucia?

Table 6: Two paraphrase clusters from the WikiAnswers corpus.

tions in the same cluster express the same meaning. Table 6 shows two paraphrase clusters from the WikiAnswers corpus. To build paraphrase template pairs, we first replace the shared noun words in each cluster with the placeholder "$y", then each two templates in a cluster will form a paraphrase template pair. To filter out noisy template pairs, we only retain salient paraphrase template pairs whose co-occurrence count is larger than 3.

4 Sentence Rewriting based Semantic Parsing

In this section we describe our semantic rewriting based semantic parsing system. Figure 2 presents the framework of our system. Given a sentence, we first rewrite it into a set of new sentences, then we generate candidate logical forms for each new sentence using a base semantic parser, finally we score all logical forms using a scoring function and output the best logical form as the final result. In following, we first introduce the used base semantic parser, then we describe the proposed scoring function.

4.1 Base Semantic Parser

In this paper, we produce logical forms for each sentence rewritings using an agenda-based semantic parser (Berant and Liang, 2015), which is based on the lambda-DCS proposed by Liang (2013). For parsing, we use the lexicons and the grammars released by Berant et al. (2013), where lexicons are used to trigger unary and binary predicates, and grammars are used to conduct logical forms. The only difference is that we also use the composition rule to make the parser can handle complicated questions involving two binary predicates, e.g., `child.obama⊓gender.female`.

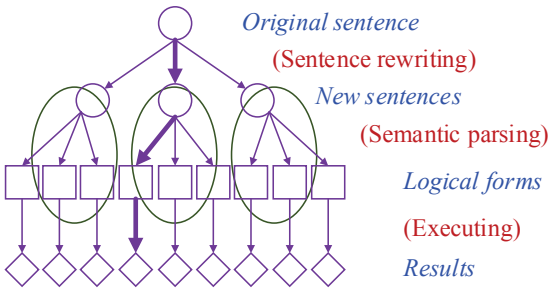

Figure 2: The framework of our sentence rewriting based semantic parsing.

For model learning and sentence parsing, the base semantic parser learned a scoring function by modeling the policy as a log-linear distribution over (partial) agenda derivations Q:

$$p_\theta(a|s) = \frac{\exp\{\phi(a)^T\theta)\}}{\sum_{a' \in A} \exp\{\phi(a')^T\theta)\}} \quad (1)$$

The policy parameters are updated as follows:

$$\theta \leftarrow \theta + \eta R(h_{target}) \sum_{t=1}^{T} \delta(h_{target}) \quad (2)$$

$$\begin{aligned} \delta_t(h) &= \nabla_\theta \log p_\theta(a_t|s_t) \\ &= \phi(a_t) - E_{p_\theta(a'_t|s_t)}[\phi(a'_t)] \end{aligned} \quad (3)$$

The reward function $R(h)$ measures the compatibility of the resulting derivation, and η is the learning rate which is set using the AdaGrad algorithm (Duchi et al., 2011). The target history h_{target} is generated from the root derivation d^* with highest reward out of the K (beam size) root derivations, using local reweighting and history compression.

4.2 Scoring Function

To select the best semantic parse, we propose a scoring function which can take both sentence rewriting features and semantic parsing features into consideration. Given a sentence x, a generated rewriting x' and the derivation d of x', we score them using follow function:

$$\begin{aligned} score(x, x', d) &= \theta \cdot \phi(x, x', d) \\ &= \theta_1 \cdot \phi(x, x') + \theta_2 \cdot \phi(x', d) \end{aligned}$$

This scoring function is decomposed into two parts: one for sentence rewriting – $\theta_1 \cdot \phi(x, x')$ and the other for semantic parsing – $\theta_2 \cdot \phi(x', d)$. Following Berant and Liang (2015), we update the parameters θ_2 of semantic parsing features as the

Input: Q/A pairs $\{(x_i, y_i) : i = 1...n\}$; Knowledge base $\mathcal{K}$; Number of sentences N; Number of iterations T.

Definitions: The function $REWRITING(x_i)$ returns a set of candidate sentences by applying sentence rewriting on sentence x; $PARSE(p_\theta, x)$ parses the sentence x based on current parameters θ, using agenda-based parsing; $CHOOSEORACLE(h_0)$ chooses the derivation with highest reward from the root of h_0; $CHOOSEORACLE(H_{target})$ chooses the derivation with highest reward from a set of derivations. $CHOOSEORACLE(h^*_{target})$ chooses the new sentence that results in derivation with highest reward.

Algorithm:

$\theta_1 \leftarrow \mathbf{0}, \theta_2 \leftarrow \mathbf{0}$
for $t = 1...T, i = 1...N$:
  $X = REWRITING(x_i)$
  for each $x'_i \in X$:
    $h_0 \leftarrow PARSE(p_\theta, x'_i)$
    $d^* \leftarrow CHOOSEORACLE(h_0)$
    $h_{target} \leftarrow PARSE(p_\theta^{+cw}, x'_i)$
  $h^*_{target} \leftarrow CHOOSEORACLE(H_{target})$
  $x'^*_i \leftarrow CHOOSEORACLE(h^*_{target})$
  $\theta_2 \leftarrow \theta_2 + \eta R(h^*_{target}) \sum_{t=1}^{T} \delta(h^*_{target})$
  $\theta_1 \leftarrow \theta_1 + \eta R(h^*_{target}) \delta(x_i, x'^*_i)$

Output: Estimated parameters θ_1 and θ_2.

Table 7: Our learning algorithm for parameter estimation from question-answer pairs.

same as (2). Similarly, the parameters θ_1 of sentence rewriting features are updated as follows:

$$\theta_1 \leftarrow \theta_1 + \eta R(h^*_{target}) \delta(x, x'^*)$$

$$\begin{aligned}\delta(x, x'^*) &= \nabla \log p_{\theta_1}(x'^* | x) \\ &= \phi(x, x'^*) - E_{p_{\theta_1}(x'|x)}[\phi(x, x')]\end{aligned}$$

where the learning rate η is set using the same algorithm in Formula (2).

4.3 Parameter Learning Algorithm

To estimate the parameters θ_1 and θ_2, our learning algorithm uses a set of question-answer pairs (x_i, y_i). Following Berant and Liang (2015), our updates for θ_1 and θ_2 do not maximize reward nor the log-likelihood. However, the reward provides a way to modulate the magnitude of the updates. Specifically, after each update, our model results in making the derivation, which has the highest reward, to get a bigger score. Table 7 presents our learning algorithm.

4.4 Features

As described in Section 4.3, our model uses two kinds of features. One for the semantic parsing module which are simply the same features described in Berant and Liang (2015). One for the sentence rewriting module these features are defined over the original sentence, the generated sentence rewritings and the final derivations:

Features for dictionary-based rewriting. Given a sentence s_0, when the new sentence s_1 is generated by replacing a word to its explanation $w \rightarrow ex$, we will generate four features: The first feature indicates the word replaced. The second feature indicates the replacement $w \rightarrow ex$ we used. The final two features are the POS tags of the left word and the right word of w in s_0.

Features for template-based rewriting. Given a sentence s_0, when the new sentence s_1 is generated through a template based rewriting $t_1 \rightarrow t_2$, we generate four features: The first feature indicates the template pair (t_1, t_2) we used. The second feature is the similarity between the sentence s_0 and the template t_1, which is calculated using the word overlap between s_0 and t_1. The third feature is the compatibility of the template pair, which is the pointwise mutual information (PMI) between t_1 and t_2 in the WikiAnswers corpus. The final feature is triggered when the target logical form only contains an atomic formula (or predicate), and this feature indicates the mapping from template t_2 to the predicate p.

5 Experiments

In this section, we assess our method and compare it with other methods.

5.1 Experimental Settings

Dataset: We evaluate all systems on the benchmark WEBQUESTIONS dataset (Berant et al., 2013), which contains 5,810 question-answer pairs. All questions are collected by crawling the Google Suggest API, and their answers are obtained using Amazon Mechanical Turk. This dataset covers several popular topics and its questions are commonly asked on the web. According to Yao (2015), 85% of questions can be answered by predicting a single binary relation. In our experiments, we use the standard train-test split (Berant et al., 2013), i.e., 3,778 questions (65%) for training and 2,032 questions (35%) for testing, and divide the training set into 3 random 80%-20% splits for development.

Furthermore, to verify the effectiveness of our method on solving the vocabulary mismatch problem, we manually select 50 mismatch test examples from the WEBQUESTIONS dataset, where

all sentences have different structure with their target logical forms, e.g., "*Who is keyshia cole dad?*" and "*What countries have german as the official language?*".

System Settings: In our experiments, we use the Freebase Search API for entity lookup. We load Freebase using Virtuoso, and execute logical forms by converting them to SPARQL and querying using Virtuoso. We learn the parameters of our system by making three passes over the training dataset, with the beam size $K = 200$, the dictionary rewriting size $K_D = 100$, and the template rewriting size $K_T = 100$.

Baselines: We compare our method with several traditional systems, including semantic parsing based systems (Berant et al., 2013; Berant and Liang, 2014; Berant and Liang, 2015; Yih et al., 2015), information extraction based systems (Yao and Van Durme, 2014; Yao, 2015), machine translation based systems (Bao et al., 2014), embedding based systems (Bordes et al., 2014; Yang et al., 2014), and QA based system (Bast and Haussmann, 2015).

Evaluation: Following previous work (Berant et al., 2013), we evaluate different systems using the fraction of correctly answered questions. Because golden answers may have multiple values, we use the average F1 score as the main evaluation metric.

5.2 Experimental Results

Table 8 provides the performance of all base-lines and our method. We can see that:

1. Our method achieved competitive performance: Our system outperforms all baselines and get the best F1-measure of 53.1 on WEBQUESTIONS dataset.

2. Sentence rewriting is a promising technique for semantic parsing: By employing sentence rewriting, our system gains a 3.4% F1 improvement over the base system we used (Berant and Liang, 2015).

3. Compared to all baselines, our system gets the highest precision. This result indicates that our parser can generate more-accurate logical forms by sentence rewriting. Our system also achieves the second highest recall, which is a competitive performance. Interestingly, both the two systems with the highest recall (Bast and Haussmann, 2015; Yih et al., 2015) rely on extra-techniques such as entity linking and relation matching.

System	Prec.	Rec.	F1 (avg)
Berant et al., 2013	48.0	41.3	35.7
Yao and Van-Durme, 2014	51.7	45.8	33.0
Berant and Liang, 2014	40.5	46.6	39.9
Bao et al., 2014	–	–	37.5
Bordes et al., 2014a	–	–	39.2
Yang et al., 2014	–	–	41.3
Bast and Haussmann, 2015	49.8	60.4	49.4
Yao, 2015	52.6	54.5	44.3
Berant and Liang, 2015	50.5	55.7	49.7
Yih et al., 2015	52.8	**60.7**	52.5
Our approach	**53.7**	60.0	**53.1**

Table 8: The results of our system and recently published systems. The results of other systems are from either original papers or the standard evaluation web.

The effectiveness on mismatch problem. To analyze the commonness of mismatch problem in semantic parsing, we randomly sample 500 questions from the training data and do manually analysis, we found that 12.2% out of the sampled questions have mismatch problems: 3.8% out of them have 1-N mismatch problem and 8.4% out of them have N-1 mismatch problem.

To verify the effectiveness of our method on solving the mismatch problem, we conduct experiments on the 50 mismatch test examples and Table 9 shows the performance. We can see that our system can effectively resolve the mismatch between natural language and target ontology: compared to the base system, our system achieves a significant 54.5% F1 im-provement.

System	Prec.	Rec.	F1 (avg)
Base system	31.4	43.9	29.4
Our system	**83.3**	**92.3**	**83.9**

Table 9: The results on the 50 mismatch test dataset.

When scaling a semantic parser to open-domain situation or web situation, the mismatch problem will be more common as the ontology and language complexity increases (Kwiatkowski et al., 2013). Therefore we believe the sentence rewriting method proposed in this paper is an important technique for the scalability of semantic parser.

The effect of different rewriting algorithms. To analyze the contribution of different rewriting methods, we perform experiments using different sentence rewriting methods and the results are presented in Table 10. We can see that:

Method	Prec.	Rec.	F1 (avg)
base	49.8	55.3	49.1
+ dictionary SR (only)	51.6	57.5	50.9
+ template SR (only)	52.9	59.0	52.3
+ both	**53.7**	**60.0**	**53.1**

Table 10: The results of the base system and our systems on the 2032 test questions.

1. Both sentence rewriting methods improved the parsing performance, they resulted in 1.8% and 3.2% F1 improvements respectively[2].

2. Compared with the dictionary-based rewriting method, the template-based rewriting method can achieve higher performance improvement. We believe this is because N-1 mismatch problem is more common in the WEBQUESTIONS dataset.

3. The two rewriting methods are good complementary of each other. The semantic parser can achieve a higher performance improvement when using these two rewriting methods together.

The effect on improving robustness. We found that the template-based rewriting method can greatly improve the robustness of the base semantic parser. Specially, the template-based method can rewrite similar sentences into a uniform template, and the (template, predicate) feature can provide additional information to reduce the uncertainty during parsing. For example, using only the uncertain alignments from the words "*people*" and "*speak*" to the two predicates `official_language` and `language_spoken`, the base parser will parse the sentence "*What does jamaican people speak?*" into the incorrect logical form `official_language.jamaican` in our experiments, rather than into the correct form `language_spoken.jamaican` (See the final example in Table 11). By exploiting the alignment from the template "*what language does $y people speak*" to the predicate , our system can parse the above sentence correctly.

The effect on OOV problem. We found that the sentence rewriting method can also provide extra profit for solving the OOV problem. Traditionally, if a sentence contains a word which is not covered by the lexicon, it will cannot be correctly parsed. However, with the help of sentence rewriting, we may rewrite the OOV words into the words which are covered by our lexicons. For example, in Table 11 the 3rd question "*What are some of the traditions of islam?*" cannot be correctly parsed as the lexicons dont cover the word "*tradition*". Through sentence rewriting, we can generate a new sentence "*What is of the religion of islam?*", where all words are covered by the lexicons, in this way the sentence can be correctly parsed.

[2]Our base system yields a slight drop in accuracy compared to the original system (Berant and Liang, 2015), as we parallelize the learning algorithm, and the order of the data for updating the parameter is different to theirs.

O	*Who is willow smith mom name?*
R	*Who is willow smith female parent name?*
LF	`parentOf.willow_smith⊓gender.female`
O	*Who was king henry viii son?*
R	*Who was king henry viii male child?*
LF	`childOf.king_henry⊓gender.male`
O	*What are some of the traditions of islam?*
R	*What is of the religion of islam?*
LF	`religionOf.islam`
O	*What does jamaican people speak?*
R	*What language does jamaican people speak?*
LF	`language_spoken.jamaica`

Table 11: Examples which our system generates more accurate logical form than the base semantic parser. **O** is the original sentence; **R** is the generated sentence from sentence rewriting (with the highest score for the model, including rewriting part and parsing part); **LF** is the target logical form.

5.3 Error Analysis

To better understand our system, we conduct error analysis on the parse results. Specifically, we randomly choose 100 questions which are not correctly answered by our system. We found that the errors are mainly raised by following four reasons (See Table 12 for detail):

Reason	#(Ratio)	Sample Example
Label issue	38	*What band was george clinton in?*
N-ary predicate($n > 2$)	31	*What year did the seahawks win the superbowl?*
Temporal clause	15	*Who was the leader of the us during wwii?*
Superlative	8	*Who was the first governor of colonial south carolina?*
Others	8	*What is arkansas state capitol?*

Table 12: The main reasons of parsing errors, the ratio and an example for each reason are also provided.

The first reason is the label issue. The main label issue is incompleteness, i.e., the answers of a question may not be labeled completely. For example, for the question "*Who does nolan ryan play for?*", our system returns 4 correct teams but the golden answer only contain 2 teams. One another label issue is the error labels. For example, the gold answer of the question "*What state is barack obama from?*" is labeled as "*Illinois*", however, the correct answer is "*Hawaii*".

The second reason is the n-ary predicate problem ($n > 2$). Currently, it is hard for a parser to conduct the correct logical form of n-ary predicates. For example, the question "*What year did the seahawks win the superbowl?*" describes an n-ary championship event, which gives the championship and the champion of the event, and expects the season. We believe that more research attentions should be given on complicated cases, such as the n-ary predicates parsing.

The third reason is temporal clause. For example, the question "*Who did nasri play for before arsenal?*" contains a temporal clause "*before*". We found temporal clause is complicated and makes it strenuous for the parser to understand the sentence.

The fourth reason is superlative case, which is a hard problem in semantic parsing. For example, to answer "*What was the name of henry viii first wife?*", we should choose the first one from a list ordering by time. Unfortunately, it is difficult for the current parser to decide what to be ordered and how to order.

There are also many other miscellaneous error cases, such as spelling error in the question, e.g., "*capitol*" for "*capital*", "*mary*" for "*marry*".

6 Conclusions

In this paper, we present a novel semantic parsing method, which can effectively deal with the mismatch between natural language and target ontology using sentence rewriting. We resolve two common types of mismatch (i) one word in natural language sentence vs one compound formula in target ontology (1-N), (ii) one complicated expression in natural language sentence vs one formula in target ontology (N-1). Then we present two sentence rewriting methods, dictionary-based method for 1-N mismatch and template-based method for N-1 mismatch. The resulting system significantly outperforms the base system on the WEBQUESTIONS dataset.

Currently, our approach only leverages simple sentence rewriting methods. In future work, we will explore more advanced sentence rewriting methods. Furthermore, we also want to employ sentence rewriting techniques for other challenges in semantic parsing, such as the spontaneous, unedited natural language input, etc.

Chinese Zero Pronoun Resolution with Deep Neural Networks

Chen Chen and **Vincent Ng**

Abstract

While unsupervised anaphoric zero pronoun (AZP) resolvers have recently been shown to rival their supervised counterparts in performance, it is relatively difficult to scale them up to reach the next level of performance due to the large amount of feature engineering efforts involved and their ineffectiveness in exploiting lexical features. To address these weaknesses, we propose a supervised approach to AZP resolution based on deep neural networks, taking advantage of their ability to learn useful task-specific representations and effectively exploit lexical features via word embeddings. Our approach achieves state-of-the-art performance when resolving the Chinese AZPs in the OntoNotes corpus.

1 Introduction

A zero pronoun (ZP) is a gap in a sentence that is found when a phonetically null form is used to refer to a real-world entity. An anaphoric zero pronoun (AZP) is a ZP that corefers with one or more preceding mentions in the associated text. Below is an example taken from the Chinese Treebank (CTB), where the ZP (denoted as *pro*) refers to 俄罗斯 (Russia).

[俄罗斯] 作为米洛舍夫维奇一贯的支持者，*pro* 曾经提出调停这场政治危机。

([Russia] is a consistent supporter of Milošević, *pro* has proposed to mediate the political crisis.)

As we can see, ZPs lack grammatical attributes that are useful for overt pronoun resolution such as number and gender. This makes ZP resolution more challenging than overt pronoun resolution.

Automatic ZP resolution is typically composed of two steps. The first step, AZP identification, involves extracting ZPs that are anaphoric. The second step, AZP resolution, aims to identify an antecedent of an AZP. State-of-the-art ZP resolvers have tackled both of these steps in a supervised manner, training one classifier for AZP identification and another for AZP resolution (e.g., Zhao and Ng (2007), Kong and Zhou (2010)).

More recently, Chen and Ng (2014b; 2015) have proposed unsupervised probabilistic AZP resolution models (henceforth the CN14 model and the CN15 model, respectively) that rival their supervised counterparts in performance. An appealing aspect of these unsupervised models is that their language-independent generative process enables them to be applied to languages where data annotated with ZP links are not readily available. Though achieving state-of-the-art performance, these models have several weaknesses.

First, a lot of manual efforts need to be spent on engineering the features for generative probabilistic models, as these models are sensitive to the choice of features. For instance, having features that are (partially) dependent on each other could harm model performance. Second, in the absence of labeled data, it is difficult, though not impossible, for these models to profitably employ lexical features (e.g., word pairs, syntactic patterns involving words), as determining which lexical features are useful and how to combine the potentially large number of lexical features in an unsupervised manner is a very challenging task. In fact, the unsupervised models proposed by Chen and Ng (2014b; 2015) are unlexicalized, presumably owing to the aforementioned reasons. Unfortunately, as shown in previous work (e.g, Zhao and Ng (2007), Chen and Ng (2013)), the use of lexical features contributed significantly to the performance of state-of-the-art supervised AZP resolvers. Finally, owing to the lack of labeled data, the model parameters are learned to maximize data

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 778–788,
Berlin, Germany, August 7-12, 2016.

likelihood, which may not correlate well with the desired evaluation measure (i.e., F-score). Hence, while unsupervised resolvers have achieved state-of-the-art performance, these weaknesses together suggest that it is very challenging to scale these models up so that they can achieve the next level of performance.

Our goal in this paper is to improve the state of the art in AZP resolution. Motivated by the aforementioned weaknesses, we propose a novel approach to AZP resolution using deep neural networks, which we believe has three key advantages over competing unsupervised counterparts.

First, deep neural networks are particularly good at discovering hidden structures from the input data and learning task-specific representations via successive transformations of the input vectors, where different layers of a network correspond to different levels of abstractions that are useful for the target task. For the task of AZP resolution, this is desirable. Traditionally, it is difficult to correctly resolve an AZP if its context is lexically different from its antecedent's context. This is especially the case for unsupervised resolvers. In contrast, a deep network can handle difficult cases like this via learning representations that make lexically different contexts look similar.

Second, we train our deep network in a supervised manner.[1] In particular, motivated by recent successes of applying the mention-ranking model (Denis and Baldridge, 2008) to entity coreference resolution (e.g., Chang et al. (2013), Durrett and Klein (2013), Clark and Manning (2015), Martschat and Strube (2015), Wiseman et al. (2015)), we propose to employ a ranking-based deep network, which is trained to assign the highest probability to the correct antecedent of an AZP given a set of candidate antecedents. This contrasts with existing supervised AZP resolvers, all of which are classification-based. Optimizing this objective function is better than maximizing data likelihood, as the former is more tightly coupled with the desired evaluation metric (F-score) than the latter.

Finally, given that our network is trained in a supervised manner, we can extensively employ lexical features and use them in combination with other types of features that have been shown to be useful for AZP resolution. However, rather than employing words directly as features, we employ word embeddings trained in an unsupervised manner. The goal of the deep network will then be to take these task-independent word embeddings as input and convert them into embeddings that would work best for AZP resolution via supervised learning. We call our approach an *embedding matching* approach because the underlying deep network attempts to compare the embedding learned for an AZP with the embedding learned for each of its antecedents.

To our knowledge, this is the first approach to AZP resolution based on deep networks. When evaluated on the Chinese portion of the OntoNotes 5.0 corpus, our embedding matching approach to AZP resolution outperforms the CN15 model, achieving state-of-the-art results.

The rest of the paper is organized as follows. Section 2 overviews related work on zero pronoun resolution for Chinese and other languages. Section 3 describes our embedding matching approach, specifically the network architecture and the way we train and apply the network. We present our evaluation results in Section 4 and our conclusions in Section 5.

2 Related Work

Chinese ZP resolution. Early approaches to Chinese ZP resolution are *rule-based*. Converse (2006) applied Hobbs' algorithm (Hobbs, 1978) to resolve the ZPs in the CTB documents. Yeh and Chen (2007) hand-engineered a set of rules for ZP resolution based on Centering Theory (Grosz et al., 1995).

In contrast, virtually all recent approaches to this task are *learning-based*. Zhao and Ng (2007) are the first to employ a supervised learning approach to Chinese ZP resolution. They trained an AZP resolver by employing syntactic and positional features in combination with a decision tree learner. Unlike Zhao and Ng, Kong and Zhou (2010) employed context-sensitive convolution tree kernels (Zhou et al., 2008) in their resolver to model syntactic information. Chen and Ng (2013) extended Zhao and Ng's feature set with novel features that encode the context surrounding a ZP and its candidate antecedents, and exploited the coreference links between ZPs as bridges to

[1] Note that deep neural networks do *not* necessarily have to be trained in a supervised manner. In fact, in early research on extending semantic modeling using auto-encoders (Salakhutdinov and Hinton, 2007), the networks were trained in an unsupervised manner, where the model parameters were optimized for the reconstruction of the input vectors.

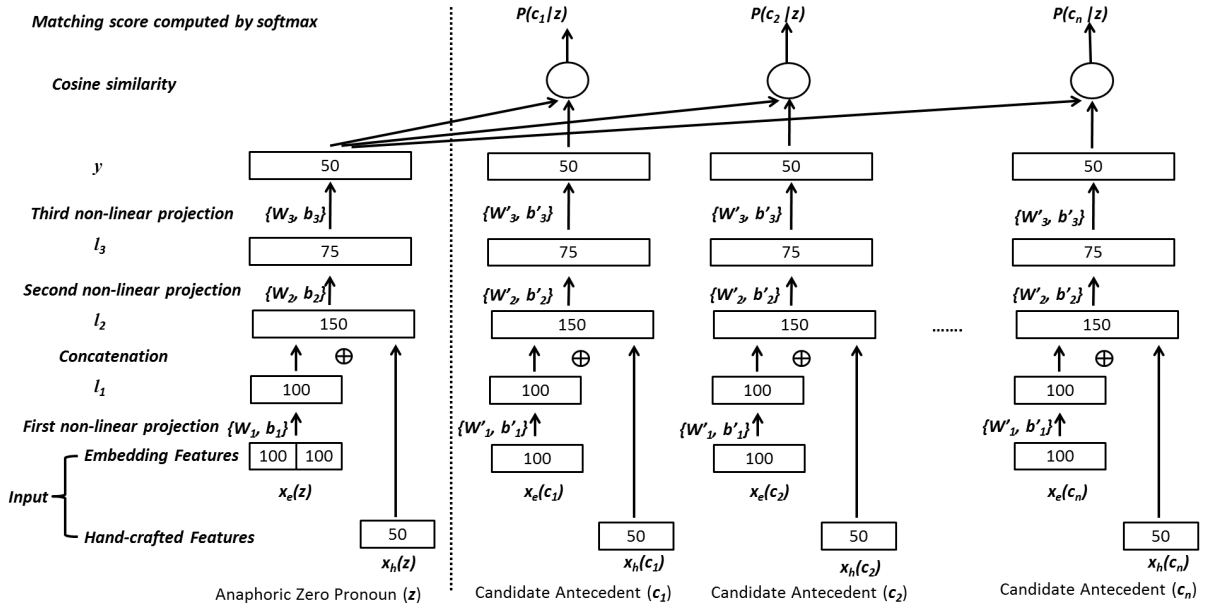

Figure 1: The architecture of our embedding matching model. The number in each box indicates the size of the corresponding vector.

find textually distant antecedents for ZPs. As mentioned above, there have been attempts to perform unsupervised AZP resolution. For instance, using only data containing manually resolved *overt* pronouns, Chen and Ng (2014a) trained a supervised overt pronoun resolver and applied it to resolve AZPs. More recently, Chen and Ng (2014b; 2015) have proposed unsupervised probabilistic AZP resolution models that rivaled their supervised counterparts in performance. While we aim to resolve *anaphoric* ZPs, Rao et al. (2015) resolved *deictic non-anaphoric* ZPs, which "refer to salient entities in the environment such as the speaker, hearer or pragmatically accessible referent without requiring any introduction in the preceding text".

ZP resolution for other languages. There have been rule-based and supervised machine learning approaches for resolving ZPs in other languages. For example, to resolve ZPs in Spanish texts, Ferrández and Peral (2000) proposed a set of hand-crafted rules that encode preferences for candidate antecedents. In addition, supervised approaches have been extensively employed to resolve ZPs in Korean (e.g., Han (2006)), Japanese (e.g., Seki et al. (2002), Isozaki and Hirao (2003), Iida et al. (2006; 2007), Sasano et al. (2008), Taira et al. (2008), Imamura et al. (2009), Sasano et al. (2009), Watanabe et al. (2010), Hayashibe et al. (2011), Iida and Poesio (2011), Sasano and Kurohashi (2011), Yoshikawa et al. (2011), Hangyo et al. (2013), Yoshino et al. (2013), Iida et al. (2015)), and Italian (e.g., Iida and Poesio (2011)).

3 Model

In this section, we first introduce our network architecture (Section 3.1), and then describe how we train it (Section 3.2) and apply it (Section 3.3).

3.1 Network Architecture

The network architecture is shown in Figure 1. Since we employ a ranking model to rank the candidate antecedents of an AZP z, the inputs to the network are (1) a feature vector representing the AZP, and (2) n feature vectors representing its n candidate antecedents, c_1, c_2, ..., c_n. As will be explained in detail in Section 3.2.2, the features in each feature vector can be divided into two types: word embedding features and hand-crafted features. Each input feature vector will then be passed through three hidden layers in the network, which will successively map it into a low-dimensional feature space. The resulting vector can be viewed as the low-dimensional semantic embedding of the corresponding input vector. Finally, the model computes a *matching* score between z and each of its candidate antecedents based on their low-dimensional representations. These scores are then normalized into probabilities using a softmax.

More formally, let $x_e(z)$ and $x_h(z)$ be the vec-

tors of embedding and hand-crafted features representing AZP z respectively, and let $x_e(c_i)$ and $x_h(c_i)$ be the vectors of embedding and hand-crafted features representing candidate antecedent c_i respectively. In addition, let $y(z)$ and $y(c_i)$ be the (low-dimensional) output vectors for z and c_i respectively, l_1, l_2, and l_3 be the intermediate hidden layers, W_i and W_i' be the weight matrices associated with z and the c_i's in hidden layer i, b_i and b_i' be the bias terms associated with z and the c_i's.[2] We then have:

$$\begin{aligned} l_1(z) &= f(W_1 x_e(z) + b_1) \\ l_2(z) &= l_1(z) \oplus x_h(z) \\ l_3(z) &= f(W_2 l_2(z) + b_2) \\ y(z) &= f(W_3 l_3(z) + b_3) \end{aligned} \quad (1)$$

$$\begin{aligned} l_1(c_i) &= f(W_1' x_e(c_i) + b_1') \\ l_2(c_i) &= l_1(c_i) \oplus x_h(c_i) \\ l_3(c_i) &= f(W_2' l_2(c_i) + b_2') \\ y(c_i) &= f(W_3' l_3(z) + b_3') \end{aligned} \quad (2)$$

where f is the activation function at output layer y and hidden layers l_1 and l_3. In this network, we employ tanh as the activation function. Hence,

$$f(x) = \tanh(x) = \frac{1 - e^{-2x}}{1 + e^{-2x}} \quad (3)$$

The matching score between an AZP z and a candidate antecedent c_i is then measured as:

$$R(z, c_i) = \cos(y(z), y(c_i)) = \frac{y(z)^T y(c_i)}{||y(z)||||y(c_i)||} \quad (4)$$

3.2 Training

3.2.1 Training Instance Creation

We create one training instance from each AZP in each training document. Since our model is ranking-based, each training instance corresponds to an AZP z and all of its candidate antecedents C_i. In principle, we can follow previous work and assume that the set of candidate antecedents C contains all and only those maximal or modifier noun phrases (NPs) that precede z in the associated text and are at most two sentences away from it. However, to improve *training* efficiency, we select exactly four candidate antecedents for each AZP z as follows. First, we take the closest correct antecedent z to be one of the four candidate antecedents. Next, we compute a salience score for each of its *non-coreferent* candidate antecedents and select the three with the highest salience scores as the remaining three candidate antecedents.

We compute salience as follows. For each AZP z, we compute the salience score for each (partial) entity preceding z.[3] To reduce the size of the list of preceding entities, we only consider a partial entity *active* if at least one of its mentions appears within two sentences of the active AZP z. We compute the salience score of each active entity w.r.t. z using the following equation:

$$\sum_{m \in E} g(m) * decay(m) \quad (5)$$

where m is a mention belonging to active entity E, $g(m)$ is a grammatical score which is set to 4, 2, or 1 depending on whether m's grammatical role is SUBJECT, OBJECT, or OTHER respectively, and $decay(m)$ is a decay factor that is set to 0.5^{dis} (where dis is the sentence distance between m and z).

Finally, we assign the correct label (i.e., the *matching score*) to each candidate antecedent. The score is 1 for the correct antecedent and 0 otherwise.

3.2.2 Features

As we can see from Figure 1, each input feature vector, regardless of whether it is representing an AZP or one of its candidate antecedents, is composed of two types of features, embedding features and hand-crafted features, as described below.

Embedding features. To encode the lexical contexts of the AZP and its candidate antecedents, one could employ one-hot vectors. However, the resulting lexical features may suffer from sparsity. To see the reason, assuming that the vocabulary size is V and the number of neurons in the first hidden layer l_1 is L_1, the size of the weight matrices W_1 and W_1' is $V * L_1$, which in our dataset is around two million while the number of training examples is much smaller.

Therefore, instead of using one-hot vectors, we employ embedding features. Specifically, we employ the pre-trained word embeddings (of size 100)

[2] Note that the target AZP and its candidate antecedents use different weight matrices and biases within each layer. This is needed because the features of the AZP and those of the candidate antecedents come from two different feature spaces.

[3] We compute the list of preceding entities automatically using SinoCoreferencer (Chen and Ng, 2014c), a Chinese entity coreference resolver downloadable from `http://www.hlt.utdallas.edu/~yzcchen/coreference/`.

Syntactic features (13)	whether z is the first gap in an IP clause; whether z is the first gap in a subject-less IP clause, and if so, POS(w_1); whether POS(w_1) is NT; whether w_1 is a verb that appears in a NP or VP; whether P_l is a NP node; whether P_r is a VP node; the phrasal label of the parent of the node containing POS(w_1); whether V has a NP, VP or CP ancestor; whether C is a VP node; whether there is a VP node whose parent is an IP node in the path from w_1 to C.
Other features (6)	whether z is the first gap in a sentence; whether z is in the headline of the text; the type of the clause in which z appears; the grammatical role of z (SUBJECT, OBJECT, or OTHER); whether w_{-1} is a punctuation; whether w_{-1} is a comma.

Table 1: Hand-crafted features associated with an AZP. z is a zero pronoun. V is the VP node following z. w_i is the ith word to the right of z (if i is positive) or the ith word to the left of z (if i is negative). C is lowest common ancestor of w_{-1} and w_1. P_l and P_r are the child nodes of C that are the ancestors of w_{-1} and w_1 respectively.

Syntactic features (12)	whether c has an ancestor NP, and if so, whether this NP is a descendent of c's lowest ancestor IP; whether c has an ancestor VP, and if so, whether this VP is a descendent of c's lowest ancestor IP; whether c has an ancestor CP; the grammatical role of c (SUBJECT, OBJECT, or OTHER); the clause type in which c appears; whether c is an adverbial NP, a temporal NP, a pronoun or a named entity.
Distance features (4)	the sentence distance between c and z; the segment distance between c and z, where segments are separated by punctuations; whether c is the closest NP to z; whether c and z are siblings in the associated parse tree.
Other features (2)	whether c is in the headline of the text; whether c is a subject whose governing verb is lexically identical to the verb governing of z.

Table 2: Hand-crafted features associated with a candidate antecedent. z is a zero pronoun. c is a candidate antecedent of z. V is the VP node following z in the parse tree.

obtained by training *word2vec*[4] on the Chinese portion of the training data from the OntoNotes 5.0 corpus. For an AZP z, we first find the word preceding it and its governing verb, and then concatenate the embeddings of these two words to form the AZP's embedding features. (If z happens to begin a sentence, we use a special embedding to represent the word preceding it.) For a candidate antecedent, we employ the word embedding of its head word as its embedding features.

Hand-crafted features. The hand-crafted features are (low-dimensional) features that capture the syntactic, positional and other relationships between an AZP and its candidate antecedents. These features are similar to the ones employed in previous work on AZP resolution (e.g., Zhao and Ng (2007), Kong and Zhou (2010), Chen and Ng (2013)).

We split these hand-crafted features into two disjoint sets: those associated with an AZP and those associated with a candidate antecedent. If a feature is computed based on the AZP, then we regard it as a feature associated with the AZP; otherwise, we put it in the other feature set. A brief description of the hand-crafted features associated with an AZP and those associated with a candidate antecedent are shown in Table 1 and Table 2 respectively. Note that we convert each multi-valued feature into a corresponding set of binary-valued features (i.e., if a feature has N different values, we will create N binary indicators to represent it). To ensure that the number of hand-crafted features representing an AZP is equal to the number of hand-crafted features representing a candidate antecedent[5], we append to the end of a feature vector as many dummy zeroes as needed.[6]

[4] `https://code.google.com/p/word2vec/`

3.2.3 Parameter Estimation

We employ online learning to train the network, with one training example in a mini-batch. In other words, we update the weights after processing each training example based on the *correct* matching scores of the training example (which is 1 for the correct antecedent and 0 otherwise) and the network's *predicted* matching scores.

To compute the predicted matching score between AZP z and one of its candidate antecedents c_i, we apply the following softmax function:

$$P(c_i|z,\Lambda) = \frac{exp(\gamma R(z,c_i))}{\sum_{c' \in \mathcal{C}} exp(\gamma R(z,c'))} \quad (6)$$

where (1) γ is a smoothing factor that is empirically set on a held-out data set, (2) $R(z,c_i)$ is the cosine similarity between vector $y(z)$ and vector $y(c_i)$ (see Section 3.1), (3) $\mathcal{C}$ denotes the set of candidate antecedents of z, and (4) Λ denotes the set of parameters of our neural network:

[5] As seen in Figure 1, we set the length of the vector to 50.

[6] Appending dummy 0s is solely for the convenience of the network implementation: doing so does not have any effect on any computation.

$$\Lambda = \{W_1, W_2, W_3, b_1, b_2, b_3, W_1', W_2', W_3', b_1', b_2', b_3'\} \quad (7)$$

To maximize the matching score of the correct antecedent, we estimate the model parameters to minimize the following loss function:

$$\mathcal{J}_z(\Lambda) = -\sum_{c_i \in \mathcal{C}} \delta(z, c_i) P(c_i|z, \Lambda) \quad (8)$$

where $\delta(z, c_i)$ is an indicator function indicating whether AZP z and candidate antecedent c_i are coreferent:

$$\delta(z, c_i) = \begin{cases} 1, & \text{if } z \text{ and } c_i \text{ are coreferent} \\ 0, & \text{otherwise} \end{cases} \quad (9)$$

Since $\mathcal{J}_z(\Lambda)$ is differentiable w.r.t. to Λ, we train the model using stochastic gradient descent. Specifically, the model parameters Λ are updated according to the following update rule:

$$\Lambda_t = \Lambda_{t-1} - \alpha \frac{\partial \mathcal{J}(\Lambda_{t-1})}{\partial \Lambda_{t-1}} \quad (10)$$

where α is the learning rate, and Λ_t and Λ_{t-1} are model parameters at the tth iteration and the $(t-1)$th iteration respectively. To avoid overfitting, we determine the hyperparameters of the network using a held-out development set.

3.3 Inference

After training, we can apply the resulting network to find an antecedent for each AZP. Each test instance corresponds to an AZP z and four of its candidate antecedents. Specifically, the four candidate antecedents with the highest salience scores will be chosen. Importantly, unlike in training, where we guarantee that the correct antecedents is among the set of candidate antecedents, in testing, we *don't*. We use the network to rank the candidate antecedents by computing the posterior probability of each of them being a correct antecedent of z, and select the one with the highest probability to be its antecedent.

The aforementioned resolution procedure can be improved, however. The improvement is motivated by a problem we observed previously (Chen and Ng, 2013): an AZP and its closest antecedent can sometimes be far away from each other, thus making it difficult to correctly resolve the AZP. To address this problem, we employ the following resolution procedure in our experiments. Given a test document, we process its AZPs in a left-to-right manner. As soon as we resolve an AZP to a preceding NP c, we fill the corresponding AZP's gap with c. Hence, when we process an AZP z, all of its preceding AZPs in the associated text have been resolved, with their gaps filled by the NPs they are resolved to. To resolve z, we create test instances between z and its four most salient candidate antecedents in the same way as described before. The only difference is that the set of candidate antecedents of z may now include those NPs that are used to fill the gaps of the AZPs resolved so far. Some of these additional candidate antecedents are closer to z than the original candidate antecedents, thereby facilitating the resolution of z. If the model resolves z to the additional candidate antecedent that fills the gap left behind by, say, AZP z', we postprocess the output by resolving z to the NP that z' is resolved to.[7]

	Training	Test

Table 3: Statistics on the training and test sets.

4 Evaluation

4.1 Experimental Setup

Datasets. We employ the Chinese portion of the OntoNotes 5.0 corpus that was used in the official CoNLL-2012 shared task (Pradhan et al., 2012). In the CoNLL-2012 data, the training set and the development set contain ZP coreference annotations, but the test set does not. Therefore, we train our models on the training set and perform evaluation on the development set. Statistics on the datasets are shown in Table 3. The documents in these datasets come from six sources, namely Broadcast News (BN), Newswire (NW), Broadcast Conversation (BC), Telephone Conversation (TC), Web Blog (WB) and Magazine (MZ).

Evaluation measures. Following previous work on AZP resolution (e.g., Zhao and Ng (2007), Chen and Ng (2013)), we express the results of AZP resolution in terms of recall (R), precision (P) and F-score (F). We report the scores for each source in addition to the overall score.

[7] This postprocessing step is needed because the additional candidate antecedents are only gap fillers.

Number of embedding features for a word	100
Number of hand-crafted features	50
Number of neurons in l_1	100
Number of neurons in l_3	75
Number of neurons in y	50
Number of epochs over the training data	100
Smoothing factor γ	20
Learning rate α	0.01

Table 4: Hyperparameter values.

Hyperparameter tuning. We reserve 20% of the training set for tuning hyperparameters. The tuned hyperparameter values are shown in Table 4.

Evaluation settings. Following Chen and Ng (2013), we evaluate our model in three settings. In Setting 1, we assume the availability of gold syntactic parse trees and gold AZPs. In Setting 2, we employ gold syntactic parse trees and system (i.e., automatically identified) AZPs. Finally, in Setting 3, we employ system syntactic parse trees and system AZPs. The gold and system syntactic parse trees, as well as the gold AZPs, are obtained from the CoNLL-2012 shared task dataset, while the system AZPs are identified by a learning-based AZP identifier described in the Appendix.

Baseline system. As our baseline, we employ Chen and Ng's (2015) system, which has achieved the best result on our test set.

4.2 Results and Discussion

Results of the baseline system and our model on entire test set are shown in row 1 of Table 5. The three major columns in the table show the results obtained in the three settings. As we can see, our model outperforms the baseline significantly by 2.0%, 1.8%, and 1.1% in F-score under Settings 1, 2, and 3, respectively.[8]

Rows 2−7 of Table 5 show the resolution results on each of the six sources. As we can see, in Setting 1, our model beats the baseline on all six sources in F-score: by 2.4% (NW), 2.5% (MZ), 4.5% (WB), 1.6% (BN), 1.4% (BC), and 0.4% (TC). All the improvements are significant except for TC. These results suggest that our approach works well across different sources. In Setting 2, our model outperforms the baseline on all sources except NW and BC, where the F-scores drop insignificantly by 0.1% for both sources. Finally, in Setting 3, our model outperforms the baseline on all sources except NW and TC, where F-scores drop significantly by 0.7% for NW and 1.1% for TC.

Given the challenges in applying supervised learning (in particular, the difficulty and time involved in training the deep neural network as well as the time and effort involved in manually annotating the data needed to train the network), one may wonder whether the small though statistically significant improvements in these results provide sufficient justification for going back to supervised learning from the previous state-of-the-art unsupervised model. We believe that this is the beginning, not the end, of applying deep neural networks for AZP resolution. In particular, there is a lot of room for improvements, which may involve incorporating more sophisticated features and improving the design of the network (e.g., the dimensionality of the intermediate representations, the number of hidden layers, the objective function), for instance.

4.3 Ablation Results

Recall that the input of our model is composed of two groups of features, embedding features and hand-crafted features. To investigate the contribution of each of these two feature groups, we conduct ablation experiments. Specifically, in each ablation experiment, we retrain the network using only one group of features.

Ablation results under the three settings are shown in Table 6. In Setting 1, when the hand-crafted features are ablated, F-score drops significantly by 12.2%. We attribute the drop to the fact that the syntactic, positional, and other relationships encoded in the hand-crafted features play an important role in resolving AZPs. When the embedding features are ablated, F-score drops significantly by 3.7%. This result suggest the effectiveness of the embedding features.

Similar trends can be observed w.r.t. the other two settings: in Setting 2, F-score drops significantly by 6.8% and 2.2% when the hand-crafted features and the embedding features are ablated respectively, while in Setting 3, F-score drops significantly by 4.6% and 1.1% when the hand-crafted features and the embedding features are ablated.

4.4 Learning Curve

We show in Figure 2 the learning curve of the our model obtained under Setting 1. As we can see, after the first epoch, the F-score on the entire test set is around 46%, and it gradually increases to

[8] All significance tests are paired t-tests, with $p < 0.05$.

52% in the 80th epoch when performance starts to plateau. These results provide suggestive evidence for our earlier hypothesis that our objective function (Equation (8)) is tightly coupled with the desired evaluation metric (F-score).

4.5 Analysis of Results

To gain additional insights into our approach, we examine the outputs of our model obtained under Setting 1.

We first analyze the cases where the AZP was correctly resolved by our model but incorrectly resolved by the baseline. Consider the following representative example with the corresponding English translation.

[陈水扁] 在登机前发表简短谈话时表示，[台湾] 要站起来走出去。... ∗*pro*∗ 也希望此行能把国际友谊带回来。
[Chen Shui-bian] delivered a short speech before boarding, saying that [Taiwan] should stand up and go out. ... ∗*pro*∗ also hopes that this trip can bring back international friendship.

In this example, the correct antecedent of the AZP is 陈水扁 (Chen Shui-bian). However, the baseline incorrectly resolves it to 台湾 (Taiwan). The baseline's mistake can be attributed to the facts that (1) 台湾 is the most salient candidate antecedent in the discourse, and (2) 台湾 is closer to the AZP than the correct antecedent 陈水扁. Nevertheless, our model still correctly identifies 陈水扁 as the AZP's antecedent because of the embedding features. A closer inspection of the training data reveals that although the word 陈水扁 never appeared as the antecedent of an AZP whose governing verb is 希望 (hope) in the training data, many AZPs that are governed by 希望 are coreferent with other person names. Because the word 陈水扁 has a similar word embedding as those person names, our approach successfully generalizes such lexical context and makes the right resolution decision.

Next, we examine the errors made by our model and find that the majority of the mistakes result from insufficient lexical contexts. Currently, to encode the lexical contexts, we only consider the word preceding the AZP and its governing verb, as well as the head word of the candidate antecedent. However, this encoding ignored a lot of potentially useful context information, such as the clause following the AZP, the modifier of the candidate antecedent and the clause containing the candidate antecedent. Consider the following example:

[我] 前一会精神上太紧张。...∗pro∗ 现在比较平静了。
[I] was too nervous a while ago. ... ∗pro∗ am now calmer.

To resolve the AZP to its correct antecedent 我 (I), one needs to compare the two clauses containing the AZP and 我. However, since our model does not encode a candidate antecedent's context, it does not resolve the AZP correctly. One way to address this problem would be to employ *sentence embeddings* to represent the clauses containing the AZP and its candidate antecedents, and then perform sentence embedding matching to resolve the AZP. The primary challenge concerns how to train the model to match two clauses with probably no overlapping words and with a limited number of training examples.

5 Conclusions

We proposed an embedding matching approach to zero pronoun resolution based on deep networks. To our knowledge, this is the first neural network-based approach to zero pronoun resolution. When evaluated on the Chinese portion of the OntoNotes corpus, our approach achieved state-of-the-art results.

Appendix: Anaphoric Zero Pronoun Identification

Recall that Settings 2 and 3 in our evaluation involve the use of system AZPs. Our supervised AZP identification procedure is composed of two steps. First, in the *extraction* step, we heuristically extract ZPs. Then, in the *classification* step, we train a classifier to determine which of the ZPs extracted in the first step are AZPs.

To implement the extraction step, we use Zhao and Ng's (2007) observation: ZPs can only occur before a VP node in a syntactic parse tree. However, according to Kong and Zhou (2010), ZPs do not need to be extracted from every VP: if a VP node occurs in a coordinate structure or is modified by an adverbial node, then only its parent VP node needs to be considered. We extract ZPs from all VPs that satisfy the above constraints.

To implement the classification step, we train a binary classifier using SVM^{light} (Joachims, 1999) on the CoNLL-2012 training set to distinguish AZPs from non-AZPs. Each instance corresponds to a ZP extracted in the first step and is represented by 32 features, 13 of which were proposed by Zhao and Ng (2007) and 19 of which were proposed by Yang and Xue (2010). A brief description of these features can be found in Table 7.

Syntactic features (13)	whether z is the first gap in an IP clause; whether z is the first gap in a subject-less IP clause, and if so, POS(w_1); whether POS(w_1) is NT; whether t_1 is a verb that appears in a NP or VP; whether P_l is a NP, QP, IP or ICP node; whether P_r is a VP node; the phrasal label of the parent of the node containing POS(t_1); whether V has a NP, VP, QP or CP ancestor; whether C is a VP node; whether the parent of V is an IP node; whether V's lowest IP ancestor has (1) a VP node as its parent and (2) a VV node as its left sibling; whether there is a VP node whose parent is an IP node in the path from t_1 to C.
Lexical features (13)	the words surrounding z and/or their POS tags, including w_1, w_{-1}, POS(w_1), POS(w_{-1}) + POS(w_1), POS(w_1) + POS(w_2), POS(w_{-2}) + POS(w_{-1}), POS(w_1) + POS(w_2) + POS(w_3), POS(w_{-1}) + w_1, and w_{-1} + POS(w_1); whether w_1 is a transitive verb, an intransitive verb or a preposition; whether w_{-1} is a transitive verb without an object.
Other features (6)	whether z is the first gap in a sentence; whether z is in the headline of the text; the type of the clause in which z appears; the grammatical role of z; whether w_{-1} is a punctuation; whether w_{-1} is a comma.

Table 7: Features for AZP identification. z is a zero pronoun. V is the VP node following z. w_i is the ith word to the right of z (if i is positive) or the ith word to the left of z (if i is negative). C is lowest common ancestor of w_{-1} and w_1. P_l and P_r are the child nodes of C that are the ancestors of w_{-1} and w_1 respectively.

When gold parse trees are employed, the recall, precision and F-score of the AZP identifier on our test set are 75.1%, 50.1% and 60.1% respectively. Using automatic parse trees, the performance of the AZP identifier drops to 43.7% (R), 30.7% (P) and 36.1% (F).

Constrained Multi-Task Learning for Automated Essay Scoring

Abstract

Supervised machine learning models for automated essay scoring (AES) usually require substantial task-specific training data in order to make accurate predictions for a particular writing task. This limitation hinders their utility, and consequently their deployment in real-world settings. In this paper, we overcome this shortcoming using a constrained multi-task pairwise-preference learning approach that enables the data from multiple tasks to be combined effectively.

Furthermore, contrary to some recent research, we show that high performance AES systems can be built with little or no task-specific training data. We perform a detailed study of our approach on a publicly available dataset in scenarios where we have varying amounts of task-specific training data and in scenarios where the number of tasks increases.

1 Introduction

Automated essay scoring (AES) involves the prediction of a score (or scores) relating to the *quality* of an extended piece of written text (Page, 1966). With the burden involved in manually grading student texts and the increase in the number of ESL (English as a second language) learners worldwide, research into AES is increasingly seen as playing a viable role in assessment. Automating the assessment process is not only useful for educators but also for learners, as it can provide instant feedback and encourage iterative refinement of their writing.

The AES task has usually been addressed using machine learning. Given a set of texts and associated gold scores, machine learning approaches aim to build models that can generalise to unseen instances. Regression (Page, 1994; Persing and Ng, 2014; Phandi et al., 2015), classification (Larkey, 1998; Rudner and Liang, 2002), and preference-ranking[1] approaches (Yannakoudakis et al., 2011) have all been applied to the task. In general, machine learning models only perform well when the training and test instances are from similar distributions. However, it is usually the case that essays are written in response to prompts which are carefully designed to elicit answers according to a number of dimensions (e.g. register, topic, and genre). For example, Table 1 shows extracts from two prompts from a publicly available dataset[2] that aim to elicit different genres of persuasive/argumentative responses on different topics.

Most previous work on AES has either ignored the differences between essays written in response to different prompts (Yannakoudakis et al., 2011) with the aim of building general AES systems, or has built prompt-specific models for each prompt independently (Chen and He, 2013; Persing and Ng, 2014). One of the problems hindering the wide-scale adoption and deployment of AES systems is the dependence on prompt-specific training data, i.e. substantial model retraining is often needed when a new prompt is released. Therefore, systems that can adapt to new writing tasks (i.e. prompts) with relatively few new task-specific training examples are particularly appealing. For example, a system that is trained using only responses from prompt #1 in Table 1 may not generalise well to essays written in response to prompt #2, and vice versa. Even more complications arise when the scoring scale, marking criteria, and/or grade level (i.e. educational stage) vary from task

to task. If essays written in response to different tasks are marked on different scoring scales, then the actual scores assigned to essays across tasks are not directly comparable. This effect becomes even more pronounced when prompts are aimed at students in different educational stages.

In this paper, we address this problem of prompt adaptation using multi-task learning. In particular, we treat each prompt as a different task and introduce a constrained preference-ranking approach that can learn from multiple tasks even when the scoring scale and marking criteria are different across tasks. Our constrained preference-ranking approach significantly increases performance over a strong baseline system when there is limited prompt-specific training data available. Furthermore, we perform a detailed study using varying amounts of task-specific training data and varying numbers of tasks. First, we review some related work.

2 Related Work

A number of commercially available systems for AES, have been developed using machine learning techniques. These include PEG (Project Essay Grade) (Page, 2003), e-Rater (Attali and Burstein, 2006), and Intelligent Essay Assessor (IEA) (Landauer et al., 1998). Beyond commercial systems, there has been much research into varying aspects involved in automated assessment, including coherence (Higgins et al., 2004; Yannakoudakis and Briscoe, 2012), prompt-relevance (Persing and Ng, 2014; Higgins et al., 2006), argumentation (Labeke et al., 2013; Somasundaran et al., 2014; Persing and Ng, 2015), grammatical error detection and correction (Rozovskaya and Roth, 2011; Felice et al., 2014), and the development of publicly available resources (Yannakoudakis et al., 2011; Dahlmeier et al., 2013; Persing and Ng, 2014; Ng et al., 2014).

While most of the early commercially available systems use linear-regression models to map essay features to a score, a number of more sophisticated approaches have been developed. Preference-ranking (or pairwise learning-to-rank) has been shown to outperform regression for the AES problem (Yannakoudakis et al., 2011). However, they did not study prompt-specific models, as their models used training data originating from different prompts. We also adopt a preference-ranking approach but explicitly model prompt effects during learning. Algorithms that aim to directly maximise an evaluation metric have also been attempted. A listwise learning-to-rank approach (Chen and He, 2013) that directly optimises quadratic-weighted Kappa, a commonly used evaluation measure in AES, has also shown promising results.

Using training data from natural language tasks to boost performance of related tasks, for which there is limited training data, has received much attention of late (Collobert and Weston, 2008; Duh et al., 2010; Cheng et al., 2015). However, there have been relatively few attempts to apply transfer learning to automated assessment tasks. Notwithstanding, Napoles and Callison-Burch (2015) use a multi-task approach to model differences in assessors, while Heilman and Madnani (2013) specifically focus on domain-adaptation for short answer scoring over common scales. Most relevant is the work of Phandi et al. (2015), who applied domain-adaptation to the AES task using EasyAdapt (EA) (Daume III, 2007). They showed that supplementing a Bayesian linear ridge regression model (BLRR) with data from one other source domain is beneficial when there is limited target domain data. However, it was shown that simply using the source domain data as extra training data outperformed the EA domain adaptation approach in three out of four cases. One major limitation to their approach was that in many instances the source domain and target domain pairs were from different grade levels. This means that any attempt to resolve scores to a common scale is undermined by the fact that the gold scores are not comparable across domains, as the essays were written by students of different educational levels. A further limitation is that multi-domain adapta-

tion (whereby one has access to multiple source domains) was not considered.

The main difference between our work and previous work is that our model incorporates *multiple* source tasks and introduces a learning mechanism that enables us to combine these tasks even when the scores across tasks are not directly comparable. This has not been achieved before. This is non-trivial as it is difficult to see how this can be accomplished using a standard linear-regression approach. Furthermore, we perform the first comprehensive study of multi-task learning for AES using different training set sizes for a number of different learning scenarios.

3 Preference Ranking Model

In this section, we describe our baseline AES model which is somewhat similar to that developed by Yannakoudakis et al. (2011).

3.1 Perceptron Ranking (TAP$_{rank}$)

We use a preference-ranking model based on a binary margin-based linear classifier (the Timed Aggregate Perceptron or TAP) (Briscoe et al., 2010). In its simplest form this Perceptron uses batch learning to learn a decision boundary for classifying an input vector $\boldsymbol{x_i}$ as belonging to one of two categories. A timing-variable τ (set to 1.0 by default) controls both the learning rate and the number of epochs during training. A preference-ranking model is then built by learning to classify pairwise *difference vectors*, i.e. learning a weight vector $\boldsymbol{w}$ such that $\boldsymbol{w}(\boldsymbol{x_i} - \boldsymbol{x_j}) > \delta$, when essay i has a higher gold score than essay j, where δ is the one-sided margin[3] (Joachims, 2002; Chapelle and Keerthi, 2010). Therefore, instead of directly learning to predict the gold score of an essay vector, the model learns a weight vector $\boldsymbol{w}$ that minimizes the misclassification of *difference vectors*. Given that the number of pairwise difference vectors in a moderately sized dataset can be extremely large, the training set is reduced by randomly sampling difference vectors according to a user-defined probability (Briscoe et al., 2010). In all experiments in our paper we choose this probability such that $5n$ difference vectors are sampled, where n is the number of training instances (essays) used. We did not tune any of the hyper-parameters of the model.

[3]This margin is set to $\delta = 2.0$ by default.

3.2 From Rankings to Predicted Scores

As the weight vector $\boldsymbol{w}$ is optimized for pairwise ranking, a further step is needed to use the ranking model for predicting a score. In particular, for each of the n vectors in our training set, a real-scalar value is assigned according to the dot-product of the weight vector and the training instance (i.e. $\boldsymbol{w} \cdot \boldsymbol{x_i}$), essentially giving its distance (or margin) from the zero vector. Then using the training data, we train a one-dimensional linear regression model $\beta + \epsilon$ to map these assignments to the gold score of each instance.

Finally, to make a prediction $\hat{y}$ for a test vector, we first calculate its distance from the zero vector using $\boldsymbol{w} \cdot \boldsymbol{x_i}$ and map it to the scoring scale using the linear regression model $\hat{y} = \beta(\boldsymbol{w} \cdot \boldsymbol{x_i}) + \epsilon$. For brevity we denote this entire approach (a ranking and a linear regression step) to predicting the final score as **TAP**.

3.3 Features

The set of features used for our ranking model is similar to those identified in previous work (Yannakoudakis et al., 2011; Phandi et al., 2015) and is as follows:

1. word unigrams, bigrams, and trigrams
2. POS (part-of-speech) counts
3. essay length (as the number of unique words)
4. GRs (grammatical relations)
5. max-word length and min-sentence length
6. the presence of cohesive devices
7. an estimated error rate

Each essay is processed by the RASP system (Briscoe et al., 2006) with the standard tokenisation and sentence boundary detection modules. All n-grams are extracted from the tokenised sentences. The grammatical relations (GRs) are extracted from the top parse of each sentence in the essay. The presence of cohesive devices are used as features. In particular, we use four categories (i.e. addition, comparison, contrast and conclusion) which are hypothesised to measure the cohesion of a text.

The error rate is estimated based on a language model using ukWaC (Ferraresi et al., 2008) which contains more than 2 billion English tokens. A trigram in an essay will be treated as an error if it

Details						System Performance (QW-κ)		
Task	**# essays**	**Grade Level**	**Original Scale**	**Mean Score Resolved (0-60)**	**Human Agreement**	**BLRR Phandi**	**SVM Phandi**	**TAP**

Table 2: Details of ASAP dataset and a preliminary evaluation of the performance of our **TAP** baseline against previous work (Phandi et al., 2015). All models used only task-specific data and 5-fold cross-validation. Best result is in **bold**.

is not found in the language model. Spelling errors are detected using a dictionary lookup, while a rule-based error module (Andersen et al., 2013) with rules generated from the Cambridge Learner Corpus (CLC) (Nicholls, 2003) is used to detect further errors. Finally, the unigrams, bigrams and trigrams are weighted by *tf-idf* (Sparck Jones, 1972), while all other features are weighted by their actual frequency in the essay.

4 Data and Preliminary Evaluation

In order to compare our baseline with previous work, we use the ASAP (Automated Student Assessment Prize) public dataset. Some details of the essays for the eight tasks in the dataset are described in the Table 2. The prompts elicit responses of different genres and of different lengths. In particular, it is important to note that the prompts have different scoring scales and are associated with different grade levels (7-10). Furthermore, the gold scores are distributed differently even if resolved to a common 0-60 scale. In order to benchmark our baseline system against previously developed approaches (BLRR and SVM regression (Phandi et al., 2015)) which use this data, we learned task-specific models using 5-fold cross-validation within each of the eight ASAP sets and aim to predict the unresolved *original* score as per previous work. We present the quadratic weighted kappa (QW-κ) of the systems in Table 2.[4] Our baseline preference-ranking model (TAP) outperforms previous approaches on task-specific data. It is worth noting that we did not tune either of the hyperparameters of TAP.

[4]The results for BLRR and SVM regression are taken directly from the original work and it is unlikely that we have used the exact same fold split. Regardless, the consistent increases mean that TAP represents a strong baseline system upon which we develop our constrained multi-task approach.

5 Multi-Task Learning

For multi-task learning we use EA encoding (Daume III, 2007) extended over k tasks $\mathcal{T}_{j=1..k}$ where each essay x_i is associated with one task $x_i \in \mathcal{T}_j$. The transfer-learning algorithm takes a set of input vectors associated with the essays, and for each vector $\boldsymbol{x}_i \in \mathbb{R}^F$ maps it via $\Phi(\boldsymbol{x}_i)$ to a higher dimensional space $\Phi(\boldsymbol{x}_i) \in \mathbb{R}^{(1+k)\cdot F}$. The encoding function $\Phi(\boldsymbol{x}_i)$ is as follows:

$$\Phi(\boldsymbol{x}) = \bigoplus_{j=0}^{k} f(\boldsymbol{x}, j) \tag{1}$$

where $\bigoplus$ is vector concatenation and $f(\boldsymbol{x}, j)$ is as follows:

$$f(\boldsymbol{x}, j) = \begin{cases} \boldsymbol{x}, & \text{if } j = 0 \\ \boldsymbol{x}, & \text{if } x \in \mathcal{T}_j \\ \mathbf{0}^F, & \text{otherwise} \end{cases} \tag{2}$$

Essentially, the encoding makes a task-specific copy of the original feature space of dimensionality F to ensure that there is one shared-representation and one task-specific representation for each input vector (with a zero vector for all other tasks). This approach can be seen as a re-encoding of the input vectors and can be used with any vector-based learning algorithm. Fig. 1 (left) shows an example of the extended feature vectors for three tasks $\mathcal{T}_j$ on different scoring scales. Using only the shared-representation (in blue) as input vectors to a learning algorithm results in a standard approach which does not learn task-specific characteristics. However, using the full representation allows the learning algorithm to capture both general and task-specific characteristics jointly. This simple encoding technique is easy to implement and has been shown to be useful for a number of NLP tasks (Daume III, 2007).

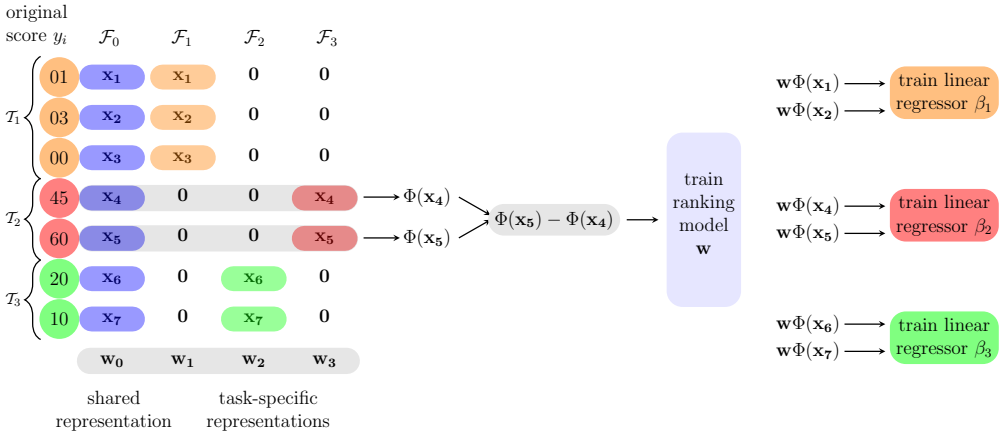

Figure 1: Example of the constrained multi-task learning approach for three tasks where the shared representation is in blue and the task-specific representations are in orange, red, and green. The original gold scores for each task $\mathcal{T}_j$ are on different scoring scales. The preference-ranking weight vector $\boldsymbol{w}$ to be learned is shown at the bottom. A one-dimensional linear regression model is learned for each task.

5.1 Constrained Preference-Ranking

Given essays from multiple tasks, it is often the case that the gold scores have different distributions, are not on the same scale, and have been marked using different criteria. Therefore, we introduce a modification to TAP (called cTAP$_{rank}$) that constrains the creation of pairwise difference vectors when training the weight vector $\boldsymbol{w}$. In particular, during training we ensure that pairwise difference vectors are not created from pairs of essays originating from different tasks.[5] We ensure that the same number of difference vectors are sampled during training for both TAP$_{rank}$ and our constrained version (i.e. both models use the same number of training instances). Figure 1 shows an example of the creation of a valid pairwise-difference vector in the multi-task framework.

Furthermore, for cTAP$_{rank}$ we train a final linear regression step on each of the task-specific training data separately. Therefore, we predict a score y for essay $\boldsymbol{x_i}$ for task $\mathcal{T}_j$ as $\hat{y} = \beta_j(\boldsymbol{w} \cdot \boldsymbol{x_i}) + \epsilon_j$. This is because for cTAP$_{rank}$ we assume that scores across tasks are not necessarily comparable. Therefore, although we utilise information originating from different tasks, the approach *never* mixes or directly compares instances originating from different tasks. This approach to predicting the final score is denoted **cTAP**.

[5]The same effect can be achieved in SVM^{rank} by encoding the prompt/task using the query id (*qid*). This constraint is analogous to the way SVM^{rank} is used in information retrieval where document relevance scores returned from different queries are not comparable.

6 Experimental Set-up

In this section, we outline the different learning scenarios, data folds, and evaluation metrics used in our main experiments.

6.1 Learning Approaches

We use the same features outlined in Section 3.3 to encode feature vectors for our learning approaches. In particular we study three learning approaches denoted and summarised as follows:

TAP: which uses the TAP$_{rank}$ algorithm with input vectors $\boldsymbol{x_i}$ of dimensionality F.

MTL-TAP: which uses the TAP$_{rank}$ algorithm with MTL extended input vectors $\Phi(\boldsymbol{x}_i)$.

MTL-cTAP: which uses the cTAP$_{rank}$ algorithm with MTL extended input vectors $\Phi(\boldsymbol{x}_i)$.[6]

For TAP and MTL-TAP, we attempt to resolve the essay score to a common scale (0-60) and subsequently train and test using this resolved scale. We then convert the score back to the original prompt-specific scale for evaluation. This is the approach used by the work most similar to ours (Phandi et al., 2015). It is worth noting that the resolution of scores to a common scale prior to training is *necessary* for both TAP and MTL-TAP when using data from multiple ASAP prompts. However, this step is *not* required for MTL-cTAP as this algorithm learns a ranking function $\boldsymbol{w}$ without directly comparing essays from different sets during training. Furthermore, the final regres-

[6]In the standard learning scenario when only target task data is available, MTL-TAP and MTL-cTAP are identical.

System	Target Task/Prompts 1	2	3	4	5	6	7	8

Table 3: Average Spearman ρ of systems over two-folds on the ASAP dataset. The best approach per prompt is in **bold**. ‡ (†) means that ρ is statistically greater than **Src-TAP** (top half) and **All-TAP** (bottom half) using the Steiger test at the 0.05 level (‡ means significant for both folds, † means for one of the folds), while $^{\star}_{\star}$ means statistically greater than **All-MTL-TAP** on both folds ($_{\star}$ for one fold).

System	Target Tasks/Prompts 1	2	3	4	5	6	7	8
Tgt-TAP	0.813	0.667	0.626	0.779	0.789	0.763	0.758	0.665
All-TAP	0.803	0.598	0.583	0.648	0.747	0.741	0.674	0.462
All-MTL-TAP	**0.825**‡	0.658‡	0.643‡	0.702‡	0.784‡	0.759‡	0.778‡	0.692‡
All-MTL-cTAP	0.816‡	**0.667**‡$_{\star}$	**0.654**$^{\star}_{\star}$‡	**0.783**$^{\star}_{\star}$‡	**0.801**$^{\star}_{\star}$‡	**0.778**$^{\star}_{\star}$‡	**0.787**‡$_{\star}$	**0.692**‡

Table 4: Average QW-κ of systems over two-folds on the ASAP dataset. The best approach per prompt is in **bold**. ‡ (†) means that κ is statistically ($p < 0.05$) greater than **All-TAP** using an approximate randomisation test (Yeh, 2000) using 50,000 samples. $^{\star}_{\star}$ means statistically greater than **All-MTL-TAP** on both folds ($_{\star}$ for one fold).

sion step in cTAP only uses original target task scores and therefore predicts scores on the correct scoring scale for the task. We study the three different learning approaches, TAP, MTL-TAP, and MTL-cTAP, in the following scenarios:

All: where the approach uses data from both the target task and the available source tasks.

Tgt: where the approach uses data from the target task only.

Src: where the approach uses data from only the available source tasks.

6.2 Data Folds

For our main experiments we divide the essays associated with each of the eight tasks into two folds. For *all* subsequent experiments, we train using data in one fold (often associated with multiple tasks) and test on data in the remaining fold of the specific target task. We report results for each task separately. These splits allow us to perform studies of all three learning approaches (TAP, MTL-TAP, and MTL-cTAP) using varying amounts of source and target task training data.

6.3 Evaluation Metrics

We use both Spearman's ρ correlation and Quadratic-weighted κ (QW-κ) to evaluate the performance of all approaches. Spearman's ρ measures the quality of the ranking of predicted scores produced by the system (i.e. the output from the ranking-preference model). We calculate Spearman's ρ using the ordinal gold score and the real-valued prediction on the original prompt-specific scoring scale of each prompt. Statistical significant differences between two correlations sharing one dependent variable (i.e. the gold scores) can be determined using Steiger's (1980) test.

QW-κ measures the chance corrected agreement between the predicted scores and the gold scores. QW-κ can be viewed as a measure of accuracy as it is lower when the predicted scores are further away from the gold scores. This metric measures both the quality of the ranking of scores and the quality of the linear regression step of our approach. These metrics are complementary as they measure different aspects of performance. We calculate QW-κ using the ordinal gold score and the real-valued prediction rounded to the nearest score on the original prompt-specific scale (see Table 2).

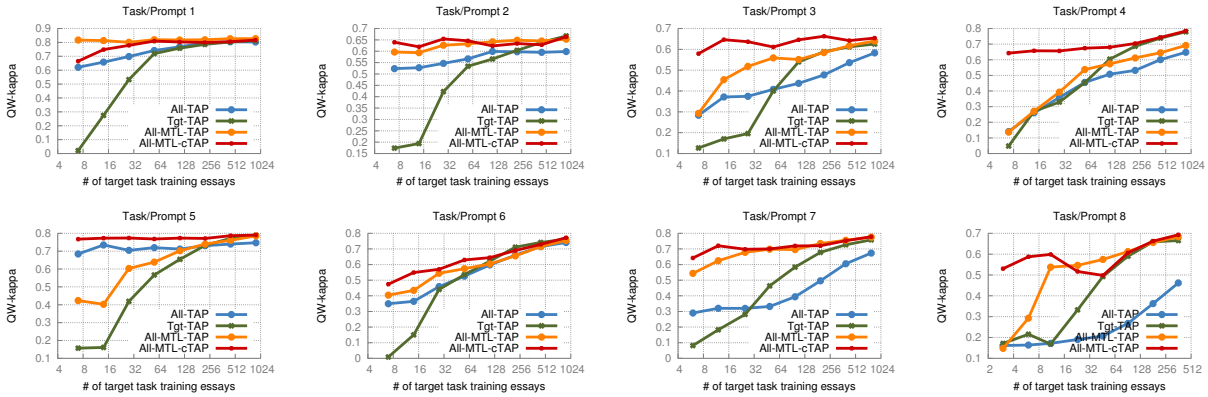

Figure 2: Average QW-κ over two folds for all tasks as size of target task training data increases

7 Results and Discussion

Table 3 and Table 4 show the performance of a number of models for both ρ and κ respectively. In general, we see that the **MTL** versions nearly always outperform the baseline TAP when using the same training data. This shows that multi-task learning is superior to simply using the source tasks as extra training data for the AES task. Interestingly this has not been shown before. Furthermore, the MTL-cTAP approach tends to be significantly better than the other for many prompts under varying scenarios for both Spearman's ρ and QW-κ. This shows that models that attempt to directly compare essays scores across certain writing-tasks lead to poorer performance.

When looking at Spearman's ρ in Table 3 we see that the models that do not use any target task data during training (Src) can achieve a performance which is close to the baseline that only uses all of the available target data (Tgt-TAP). This indicates that our system can *rank* essays well without any target task data. However, it is worth noting that *without* any target task training data and lacking any prior information as to the distribution of gold scores for the target task, achieving a consistently high accuracy (i.e. QW-κ) is extremely difficult (if not impossible). Therefore, Table 4 only shows results for models that make use of target task data.

For the models trained with data from all eight tasks, we can see that All-MTL-cTAP outperforms both All-TAP and All-MTL-TAP on most of the tasks for both evaluation metrics (ρ and κ). Interestingly, All-MTL-cTAP also outperforms Tgt-TAP on most of the prompts for both evaluation metrics. This indicates that All-MTL-cTAP manages to successfully incorporate useful information from the source tasks even when there is ample target-task data. We next look at scenarios when target-task training data is lacking.

7.1 Study of Target-Task Training Size

In real-world scenarios, it is often the case that we lack training data for a new writing task. We now report the results of an experiment that uses varying amounts of target-task training data. In particular, we use all source tasks and initially a small sample of task-specific data for each task (every 128^{th} target essay) and measure the performance of Tgt-TAP and the **All-*** models. We then double the amount of target-task training data used (by using every 64^{th} essay) and again measure performance, repeating this process until all target-task data is used. Figure 2 shows the performance of Tgt-TAP and the **All-*** models as target-task data increases.

In particular, Figure 2 shows that All-MTL-cTAP consistently outperforms all approaches in terms of agreement (QW-κ) and is particularly superior when there is very little target-task training data. It is worth remembering that All-MTL-cTAP only uses the target-task training instances for the final linear regression step. These results indicate that because the preference-ranking model performs so well, only a few target-task training instances are needed for the linear-regression step of All-MTL-cTAP. On the other hand, All-MTL-TAP uses all of the training instances in its final linear regression step, and performs significantly worse on a number of prompts. Again this shows the strengths of the constrained multi-task approach.

7.2 Study of Number of Source-tasks

All previous experiments that used source task data used the entire seven additional tasks. We

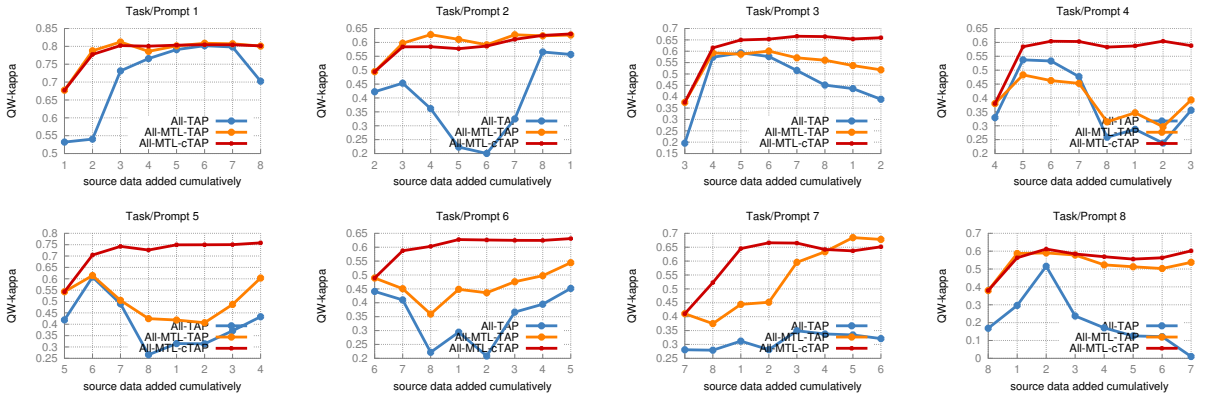

Figure 3: Average QW-κ over two folds as number of source tasks increases (using 25 target task instances)

now study the performance of the approaches as the number of source tasks changes. In particular, we limit the number of target task training instances to 25 and cumulatively add entire source task data in the order in which they occur in Table 2, starting with the source task appearing directly after the target task. We then measure performance at each stage. At the end of the process, each approach has access to all source tasks and the limited target task data.

Figure 3 shows the QW-κ for each prompt as the number of source tasks increases. We can see that All-TAP is the worst performing approach and often decreases as certain tasks are added as training data. All-MTL-cTAP is the best performing approach for nearly all prompts. Furthermore, All-MTL-cTAP is more robust than other approaches, as it rarely decreases in performance as the number of tasks increases.

8 Qualitative Analysis

As an indication of the type of interpretable information contained in the task-specific representations of the All-MTL-cTAP model, we examined the shared representation and two task-specific representations that relate to the example tasks outlined in Table 1. Table 5 shows the top weighted lexical features (i.e. unigrams, bigrams, or trigrams) (and their respective weights) in different parts of the All-MTL-cTAP model.

In general, we can see that the task-specific lexical components of the model capture topical aspects of the tasks and enable domain adaptation to occur. For example, we can see that *books*, *materials*, and *censorship* are highly discriminative lexical features for ranking essays written in response to task #2. The shared representation contains highly weighted lexical features across all tasks and captures vocabulary items useful for ranking in general. While this analysis gives us some insight into our model, it is more difficult to interpret the weights of other feature types (e.g. POS, GRs) across different parts of the model. We leave further analysis of our approach to future work.

9 Discussion and Conclusion

Unlike previous work (Phandi et al., 2015) we have shown, for the first time, that MTL outperforms an approach of simply using source task data as extra training data. This is because our approach uses information from multiple tasks without directly relying on the comparability of gold scores across tasks. Furthermore, it was concluded in previous work that at least some target-task training data is necessary to build high performing AES systems. However, as seen in Table 3, high performance rankers (ρ) can be built *without any* target-task data. Nevertheless, it is worth noting that without any target-data, accurately predicting the actual score (high κ) is extremely difficult. Therefore, although some extra information (i.e. the expected distribution of gold scores) would need to be used to produce accurate scores with a high quality ranker, the ranking is still useful for assessment in a number of scenarios (e.g. grading on a curve where the distribution of student scores is predefined).

The main approach adopted in this paper is quite similar to using SVM^{rank} (Joachims, 2002) while encoding the prompt id as the qid. When combined with a multi-task learning technique this allows the preference-ranking algorithm to learn

Shared		Task #1		Task #2

Table 5: Highest weighted lexical features (i.e. unigrams, bigrams, or trigrams) and their weights in both shared and task-specific representations of the **All-MTL-cTAP** model (associated with results in Table 4) for the two example tasks referred to in Table 1.

both task-specific and shared-representations in a theoretically sound manner (i.e. without making any speculative assumptions about the relative orderings of essays that were graded on different scales using different marking criteria), and is general enough to be used in many situations.

Ultimately these complementary techniques (multi-task learning and constrained pairwise preference-ranking) allow essay scoring data from *any* source to be included during training. As shown in Section 7.2, our approach is robust to increases in the number of tasks, meaning that one can freely add extra data when available and expect the approach to use this data appropriately. This constrained multi-task preference-ranking approach is likely to be useful for many applications of multi-task learning, when the gold-scores across tasks are not directly comparable.

Future work will aim to study different dimensions of the prompt (e.g. genre, topic) using multi-task learning at a finer level. We also aim to further study the characteristics of the multi-task model in order to determine which features transfer well across tasks. Another avenue of potential research is to use multi-task learning to predict scores for different aspects of text quality (e.g. coherence, grammaticality, topicality).

CFO: Conditional Focused Neural Question Answering with Large-scale Knowledge Bases

Zihang Dai* Carnegie Mellon University dzihang@andrew.cmu.edu

Lei Li* Toutiao.com lileicc@gmail.com

Wei Xu Baidu Research xuwei06@baidu.com

Abstract

How can we enable computers to automatically answer questions like "*Who created the character Harry Potter*"? Carefully built knowledge bases provide rich sources of facts. However, it remains a challenge to answer factoid questions raised in natural language due to numerous expressions of one question. In particular, we focus on the most common questions — ones that can be answered with a single fact in the knowledge base. We propose CFO, a **C**onditional **Fo**cused neural-network-based approach to answering factoid questions with knowledge bases. Our approach first zooms in a question to find more probable candidate subject mentions, and infers the final answers with a unified conditional probabilistic framework. Powered by deep recurrent neural networks and neural embeddings, our proposed CFO achieves an accuracy of 75.7% on a dataset of 108k questions – the largest public one to date. It outperforms the current state of the art by an absolute margin of 11.8%.

1 Introduction

Community-driven question answering (QA) websites such as Quora, Yahoo-Answers, and Answers.com are accumulating millions of users and hundreds of millions of questions. A large portion of the questions are about facts or trivia. It has been a long pursuit to enable machines to answer such questions automatically.

In recent years, several efforts have been made on utilizing open-domain knowledge bases to answer factoid questions. A knowledge base (KB) consists of structured representation of facts in the form of subject-relation-object triples. Lately, several large-scale general-purpose KBs have been constructed, including YAGO (Suchanek et al., 2007), Freebase (Bollacker et al., 2008), NELL (Carlson et al., 2010), and DBpedia (Lehmann et al., 2014). Typically, structured queries with predefined semantics (e.g. SPARQL) can be issued to retrieve specified facts from such KBs. Thus, answering factoid questions will be straightforward once they are converted into the corresponding structured form. However, due to complexity of language, converting natural language questions to structure forms remains an open challenge.

Among all sorts of questions, there is one category that only requires a single fact (triple) in KB as the supporting evidence. As a typical example, the question "*Who created the character Harry Potter*" can be answered with the single fact `(HarryPotter, CharacterCreatedBy, J.K.Rowling)`. In this work, we refer to such questions as *single-fact questions*. Previously, it has been observed that *single-fact questions* constitute the majority of factoid questions in community QA sites (Fader et al., 2013). Despite the simplicity, automatically answering such questions remains far from solved — the latest best result on a dataset of 108k single-fact questions is only 63.9% in terms of accuracy (Bordes et al., 2015).

To find the answer to a single-fact question, it suffices to identify the subject entity and relation (implicitly) mentioned by the question, and then forms a corresponding structured query. The problem can be formulated into a probabilistic form. Given a single-fact question q, finding the subject-relation pair $\hat{s}, \hat{r}$ from the KB $\mathcal{K}$ which maximizes the conditional probability $p(s, r|q)$, i.e.

$$\hat{s}, \hat{r} = \arg\max_{s,r \in \mathcal{K}} p(s, r|q) \quad (1)$$

*Part of the work was done while at Baidu.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 800–810, Berlin, Germany, August 7-12, 2016.

Based on the formulation (1), the central problem is to estimate the conditional distribution $p(s, r|q)$. It is very challenging because of *a*) the vast amount of facts — a large-scale KB such as Freebase contains billions of triples, *b*) the huge variety of language — there are multiple aliases for an entity, and numerous ways to compose a question, *c*) the severe sparsity of supervision — most combinations of s, r, q are not expressed in training data. Faced with these challenges, existing methods have exploited to incorporate prior knowledge into semantic parsers, to design models and representations with better generalization property, to utilize large-margin ranking objective to estimate the model parameters, and to prune the search space during inference. Noticeably, models based on neural networks and distributed representations have largely contributed to the recent progress (see section 2).

In this paper, we propose CFO, a novel method to answer *single-fact questions* with large-scale knowledge bases. The contributions of this paper are,

- we employ a fully probabilistic treatment of the problem with a novel conditional parameterization using neural networks,
- we propose the focused pruning method to reduce the search space during inference, and
- we investigate two variations to improve the generalization of representations for millions of entities under highly sparse supervision.

In experiments, CFO achieves 75.7% in terms of top-1 accuracy on the largest dataset to date, outperforming the current best record by an absolute margin of 11.8%.

2 Related Work

The research of KB supported QA has evolved from earlier domain-specific QA (Zelle and Mooney, 1996; Tang and Mooney, 2001; Liang et al., 2013) to open-domain QA based on large-scale KBs. An important line of research has been trying to tackle the problem by semantic parsing, which directly parses natural language questions into structured queries (Liang et al., 2011; Cai and Yates, 2013; Kwiatkowski et al., 2013; Yao and Van Durme, 2014). Recent progresses include designing KB specific logical representation and parsing grammar (Berant et al., 2013), using distant supervision (Berant et al., 2013), utilizing paraphrase information (Fader et al., 2013; Berant and Liang, 2014), requiring little question-answer pairs (Reddy et al., 2014), and exploiting ideas from agenda-based parsing (Berant and Liang, 2015).

In contrast, another line of research tackles the problem by deep learning powered similarity matching. The core idea is to learn semantic representations of both the question and the knowledge from observed data, such that the correct supporting evidence will be the nearest neighbor of the question in the learned vector space. Thus, a main difference among several approaches lies in the neural networks proposed to represent questions and KB elements. While (Bordes et al., 2014b; Bordes et al., 2014a; Bordes et al., 2015; Yang et al., 2014) use relatively shallow embedding models to represent the question and knowledge, (Yih et al., 2014; Yih et al., 2015) employ a convolutional neural network (CNN) to produce the representation. In the latter case, both the question and the relation are treated as a sequence of letter-trigram patterns, and fed into two parameter shared CNNs to get their embeddings. What's more, instead of measuring the similarity between a question and an evidence triple with a single model as in (Bordes et al., 2015), (Yih et al., 2014; Yih et al., 2015) adopt a multi-stage approach. In each stage, one element of the triple is compared with the question to produce a partial similarity score by a dedicated model. Then, these partial scores are combined to generate the overall measurement.

Our proposed method is closely related to the second line of research, since neural models are employed to learn semantic representations. As in (Bordes et al., 2015; Yih et al., 2014), we focus on *single-fact questions*. However, we propose to use recurrent neural networks (RNN) to produce the question representation. More importantly, our method follows a probabilistic formulation, and our parameterization relies on factors other than similarity measurement.

Besides KB-based QA, our work is also loosely related to work using deep learning systems in QA tasks with free text evidences. For example, (Iyyer et al., 2014) focuses questions from the quiz bowl competition with recursive neural network. New architectures including memory networks (Weston et al., 2015), dynamic memory networks (Kumar et al., 2015), and more (Peng et al., 2015; Lee et al., 2015) have been explored under the `bAbI` syn-

thetic QA task (Weston et al., 2016). In addition, (Hermann et al., 2015) seeks to answer Cloze style questions based on news articles.

3 Overview

In this section, we formally formulate the problem of *single-fact question answering* with knowledge bases. A knowledge base $\mathcal{K}$ contains three components: a set of entities $\mathcal{E}$, a set of relations $\mathcal{R}$, and a set of facts $\mathcal{F} = \{\langle s, r, o\rangle\} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$, where $s, o \in \mathcal{E}$ are the subject and object entities, and $r \in \mathcal{R}$ is a binary relation. $\mathrm{E}(r), \mathrm{E}(s)$ are the vector representations of a relation and an entity, respectively. $s \rightarrow r$ indicates that there exists some entity o such that $\langle s, r, o\rangle \in \mathcal{F}$. For single-fact questions, a common assumption is that the answer entity o and some triple $\langle s_i, r_k, o\rangle \in \mathcal{F}$ reside in the given knowledge base. The goal of our model is to find such subject s_i and relation r_k mentioned or implied in the question. Once found, a structured query (e.g. in SPARQL) can be constructed to retrieve the result entity.

3.1 Conditional Factoid Factorization

Given a question q, the joint conditional probability of subject-relation pairs $p(s, r|q)$ can be used to retrieve the answer using the exact inference defined by Eq. (1). However, since there can be millions of entities and thousands of relations in a knowledge base, it is less effective to model $p(s, r|q)$ directly. Instead, we propose a conditional factoid factorization,

$$p(s, r|q) = p(r|q) \cdot p(s|q, r) \tag{2}$$

and utilize two neural networks to parameterize each component, $p(r|q)$ and $p(s|q, r)$, respectively. Hence, our proposed method contains two phases: inferring the implied relation r from the question q, and inferring the mentioned subject entity s given the relation r and the question q.

There is an alternative factorization $p(s, r|q) = p(s|q) \cdot p(r|s, q)$. However, it is rather challenging to estimate $p(s|q)$ directly due to the vast amount of entities ($> 10^6$) in a KB. In comparison, our proposed factorization takes advantage of the relatively limited number of relations (on the order of thousands). What's more, by exploiting additional information from the candidate relation r, it's more feasible to model $p(s|q, r)$ than $p(s|q)$, leading to more robust estimation.

A key difference from prior multi-step approach is that our method do not assume any independence between the target subject and relation given a question, as does in the prior method (Yih et al., 2014). It proves effective in our experiments.

3.2 Inference via Focused Pruning

As defined by the Eq. (1), a solution needs to consider all available subject-relation pairs in the KB as candidates. With a large-scale KB, the number of candidates can be notoriously large, resulting in a extremely noisy candidate pool. We propose a method to prune the candidate space. The pruning is equivalent to a function that takes a KB $\mathcal{K}$ and a question q as input, and outputs a much limited set $\mathcal{C}$ of candidate subject-relation pairs.

$$\mathcal{H}(\mathcal{K}, q) \rightarrow \mathcal{C} \tag{3}$$

$\mathcal{C}_s$ and $\mathcal{C}_r$ are used to represent the subject and relation candidates, respectively.

The fundamental intuition for pruning is that the subject entity must be mentioned by some textual substring (*subject mention*) in the question. Thus, the candidate space can be restricted to entities whose name/alias matches an n-gram of the question, as in (Yih et al., 2014; Yih et al., 2015; Bordes et al., 2015). We refer to this straight-forward method as *N-Gram pruning*. By considering all n-grams, this approach usually achieves a high recall rate. However, the candidate pool is still noisy due to many non-subject-mention n-grams.

Our key idea is to reduce the noise by guiding the pruning method's attention to more probable parts of a question. An observation is that certain parts of a sentence are more likely to be the subject mention than others. For example, "*Harry Potter*" in "*Who created the character Harry Potter*" is more likely than "*the character*", "*character Harry*", etc. Specifically, our method employs a deep network to identify such focus segments in a question. This way, the candidate pool can be not only more compact, but also significantly less noisy.

Finally, combing the ideas of Eq.(2) and (3), we propose an approximate solution to the problem defined by Eq. (1)

$$\hat{s}, \hat{r} \approx \arg\max_{s,r \in \mathcal{C}} p(s|q, r)p(r|q) \tag{4}$$

4 Proposed CFO

In this section, we first review the gated recurrent unit (GRU), an RNN variant extensively used in

this work. Then, we describe the model parameterization of $p(r|q)$ and $p(s|q,r)$, and the focused pruning method in inference.

4.1 Review: Gated Recurrent Units

In this work we employ GRU (Cho et al., 2014) as the RNN structure. At time step t, a GRU computes its hidden state h_t using the following compound functions

$$z = \text{sigmoid}\left(W_{xz}x_t + W_{hz}h_{t-1} + b_z\right) \quad (5)$$

$$r = \text{sigmoid}\left(W_{xr}x_t + W_{hr}h_{t-1} + b_r\right) \quad (6)$$

$$\tilde{h} = \tanh\left(W_{xh}x_t + r \otimes W_{hh}h_{t-1} + b_h\right) \quad (7)$$

$$h_t = z \otimes h_{t-1} + (1 - z) \otimes \tilde{h} \quad (8)$$

where $W_{\{.\}}$, and $b_{\{.\}}$ are all trainable parameters. To better capture the context information on both sides, two GRUs with opposite directions can be combined to form a bidirectional GRU (BiGRU).

4.2 Model Parameterization

Relation network In this work, the probability of relations given a question, $p(r|q)$, is modeled by the following network

$$p_{\theta_r}(r|q) = \frac{\exp\big(v(r,q)\big)}{\sum_{r'}\exp\big(v(r',q)\big)} \quad (9)$$

where the *relation scoring function* $v(r,q)$ measures the similarity between the question and the relation

$$v(r,q) = f(q)^\top \mathrm{E}(r) \quad (10)$$

$\mathrm{E}(r)$ is the trainable embedding of the relation (randomly initialized in this work) and $f(q)$ computes the semantic question embedding. Specifically, the question q is represented as a sequence of tokens (potentially with unknown ones). Then, the question embedding model f consists of a word embedding layer to transform tokens into distributed representations, a two-layer BiGRU to capture the question semantics, and a linear layer to project the final hidden states of the BiGRU into the same vector space as $\mathrm{E}(r)$.

Subject network As introduced in section 3, the factor $p(s|q,r)$ models the fitness of a subject s appearing in the question q, given the main topic is about the relation r. Thus, two forces *a*) the raw context expressed by q, and *b*) the candidate topic described by r, jointly impact the fitness of the subject s. For simplicity, we use two additive terms to model the joint effect

$$p_{\theta s}(s|q,r) = \frac{\exp\big(u(s,r,q)\big)}{\sum_{s'}\exp\big(u(s',r,q)\big)} \quad (11)$$

where $u(s,r,q)$ is the *subject scoring function*,

$$u(s,r,q) = g(q)^\top \mathrm{E}(s) + \alpha h(r,s) \quad (12)$$

$g(q)$ is another semantic question embedding, $\mathrm{E}(s)$ is a vector representation of a subject, $h(r,s)$ is the subject-relation score, and α is the weight parameter used to trade off the two sources.

Firstly, the *context score* $g(q)^\top \mathrm{E}(s)$ models the intrinsic plausibility that the subject s appears in the question q using vector space similarity. As $g(q)^\top \mathrm{E}(s)$ has the same form as equation (10), we let g adpot the same model structure as f. However, initializing $\mathrm{E}(s)$ randomly and training it with supervised signal, just like training $\mathrm{E}(r)$, is insufficient in practice — while a large-scale KB has millions of subjects, only thousands of question-triple pairs are available for training. To alleviate the problem, we seek two potential solutions: *a) pretrained* embeddings, and *b) type vector* representation.

The pretrained embedding approach utilizes unsupervised method to train entity embedings. In particular, we employ the `TransE` (Bordes et al., 2013), which trains the embedings of entities and relations by enforcing $\mathrm{E}(s) + \mathrm{E}(r) = \mathrm{E}(o)$ for every observed triple $(s,r,o) \in \mathcal{K}$. As there exists other improved variants (Gu et al., 2015), `TransE` scales the best when KB size grows.

Alternatively, type vector is a fixed (not trainable) vector representation of entities using type information. Since each entity in the KB has one or more predefined types, we can encode the entity as a vector (bag) of types. Each dimension of a type vector is either 1 or 0, indicating whether the entity is associated with a specific type or not. Thus, the dimensionality of a type vector is equal to the number of types in KB. Under this setting, with $\mathrm{E}(s)$ being a binary vector, let $g(q)$ be a continuous vector with arbitrary value range can be problematic. Therefore, when type vector is used as $\mathrm{E}(s)$, we add a sigmoid layer upon the final linear projection of g, squashing each element of $g(q)$ to the range $[0,1]$.

Compared to the first solution, type vector is fully based on the type profile of an entity, and requires no training. As a benefit, considerably

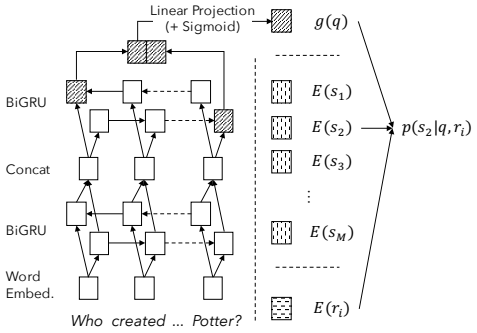

Figure 1: Overall structure of the subject network. Sigmoid layer is added only when type vector is used as $\mathrm{E}(s)$.

fewer parameters are needed. Also, given the type information is discriminative enough, using type vector will lead to easier generalization. However, containing only type information can be very restrictive.

In addition to the context score, we use the *subject-relation score* $h(r, s)$ to capture the compatibility that s and r show up together. Intuitively, for an entity to appear in a topic characterized by a relation, a necessary condition will be that the entity has the relation connected to it. Inspired by this structural regularity, in the simplest manner, we instantiate the idea with an indicator function,

$$h(r, s) = \mathbb{1}(s \rightarrow r) \tag{13}$$

As there exists other more sophisticated statistical parameterizations, the proposed approach is able to capture the core idea of the structural regularity without any parameter. Finally, putting two scores together, Fig.1 summarizes the overall structure of the subject network.

4.3 Focused Pruning

As discussed in section 3.2, N-Gram pruning is still subject to large amount of noise in inference due to many non-subject-mention n-grams. Motivated by this problem, we propose to reduce such noise by focusing on more probable candidates using a special-purpose sequence labeling network. Basically, a sequence labeling model is trained to tag some consecutive tokens as the subject mention. Following this idea, during inference, only the most probable n-gram predicted by the model will be retained, and then used as the subject mention to generate the candidate pool $\mathcal{C}$. Hence, we refer to this method as *focused pruning*. Formally, let $\mathcal{W}(q)$ be all the n-grams of the question q, $p(w|q)$ be the probability that the n-gram w is the subject mention of q, the focused pruning function $\mathcal{H}_s$ is defined as

$$\begin{aligned} \hat{w} &= \arg\max_{w \in \mathcal{W}(q)} p_\kappa(w|q) \\ \mathcal{C} &= \{(s, r) : \mathcal{M}(s, \hat{w}), s \rightarrow r\} \end{aligned} \tag{14}$$

where $\mathcal{M}(s, \hat{w})$ represents some predefined match between the subject s and the predicted subject mention $\hat{w}$. Intuitively, this pruning method resembles the human behavior of first identifying the subject mention with the help of context, and then using it as the key word to search the KB.

To illustrate the effectiveness of this idea, we parameterize $p_\kappa(w|q)$ with a general-purpose neural labeling model, which consists of a word embedding layer, two layers of BiGRU, and a linear-chain conditional random field (CRF). Thus, given a question q of length T, the score of a sequence label configuration $y \in \mathbb{R}^T$ is

$$s(y, q) = \sum_{t=1}^{T} \mathbf{H}(q)_{t,y_t} + \sum_{t=2}^{T} \mathbf{A}_{y_{t-1},y_t}$$

where $\mathbf{H}(q)$ is the hidden output of the top-layer BiGRU, $\mathbf{A}$ is the transition matrix possesed by the CRF, and $[\cdot]_{i,j}$ indicates the matrix element on row i collum j.

Finally, the match function $\mathcal{M}(s, \hat{w})$ is simply defined as either strict match between an alias of s and $\hat{w}$, or approximate match provided by the Freebase entity suggest API [1]. Note that more elaborative match function can further boost the performance, but we leave it for future work.

5 Parameter Estimation

In this section, we discuss the parameter estimation for the neural models presented in section 4.

With standard parameterization, the focused labeling model $p_\kappa(w|q)$ can be directly trained by maximum likelihood estimation (MLE) and back-propagation. Thus, we omit the discussion here, and refer readers to (Huang et al., 2015) for details. Also, we leave the problem of how to obtain the training data to section 6.

5.1 Decomposable Log-Likelihood

To estimate the parameters of $p_{\theta_r}(r|q)$ and $p_{\theta_s}(s|r, q)$, MLE can be utilized to maximize the empirical (log-)likelihood of subject-relation pairs

[1] The approximate match is used only when there is no strict match. The suggest API takes a string as input, and returns no more than 20 potentially matched entities.

given the associated question. Following this idea, let $\{s^{(i)}, r^{(i)}, q^{(i)}\}_{i=1}^{N}$ be the training dataset, the MLE solution takes the form

$$\theta^{\text{MLE}} = \arg\max_{\theta_r, \theta_s} \sum_{i=1}^{N} \Big(\log p_{\theta_r}(r^{(i)}|q^{(i)}) + \log p_{\theta_s}(s^{(i)}|r^{(i)}, q^{(i)}) \Big) \tag{15}$$

Note that there is no shared parameter between $p_{\theta_s}(s|q,r)$ and $p_{\theta_r}(r|q)$. [2] Therefore, the same solution can be reached by separately optimizing the two log terms, i.e.

$$\begin{aligned} \theta_r^{\text{MLE}} &= \arg\max_{\theta_r} \sum_{i=1}^{N} \log p_{\theta_r}(r^{(i)}|q^{(i)}) \\ \theta_s^{\text{MLE}} &= \arg\max_{\theta_s} \sum_{i=1}^{N} \log p_{\theta_s}(s^{(i)}|r^{(i)}, q^{(i)}) \end{aligned} \tag{16}$$

It is important to point out that the decomposability does not always hold. For example, when the parametric form of $h(s,r)$ depends on the embedding of r, the two terms will be coupled and joint optimization must be performed. From this perspective, the simple form of $h(s,r)$ also eases the training by inducing the decomposability.

5.2 Approximation with Negative Samples

As the two problems defined by equation (16) take the standard form of classification, theoretically, cross entropy can used as the training objective. However, computing the partition function is often intractable, especially for $p_{\theta_s}(s|r,q)$, since there can be millions of entities in the KB. Faced with this problem, classic solutions include contrastive estimation (Smith and Eisner, 2005), importance sampling approximation (Bengio et al., 2003), and hinge loss with negative samples (Collobert and Weston, 2008).

In this work, we utilize the hinge loss with negative samples as the training objective. Specifically, the loss function w.r.t θ_r has the form

$$\mathcal{L}(\theta_r) = \sum_{i=1}^{N} \sum_{j=1}^{M_r} \max\big[0, \gamma_r - v(r^{(i)}, q^{(i)}) + v(r^{(j)}, q^{(i)})\big] \tag{17}$$

where $r^{(j)}$ is one of the M_r negative samples (i.e. $s^{(i)} \not\rightarrow r^{(j)}$) randomly sampled from $\mathcal{R}$, and γ_r is the predefined margin. Similarly, the loss function w.r.t θ_s takes the form

$$\mathcal{L}(\theta_s) = \sum_{i=1}^{N} \sum_{j=1}^{M_s} \max\big[0, \gamma_s - u(s^{(i)}, r^{(i)}, q^{(i)}) + u(s^{(j)}, r^{(i)}, q^{(i)})\big] \tag{18}$$

Despite the negative sample based approximation, there is another practical difficulty when type vector is used as the subject representation. Specifically, computing the value of $u(s^{(j)}, r^{(i)}, q^{(i)})$ requires to query the KB for all types of each negative sample $s^{(j)}$. So, when M_s is large, the training can be extremely slow due to the limited bandwidth of KB query. Consequently, under the setting of type vector, we instead resort to the following type-wise binary cross-entropy loss

$$\tilde{\mathcal{L}}(\theta_s) = -\sum_{i=1}^{N} \sum_{k=1}^{K} \Big(\text{E}(s^{(i)})_k \log g(q^{(i)})_k + \big[1 - \text{E}(s^{(i)})_k\big] \log \big[1 - g(q^{(i)})_k\big] \Big) \tag{19}$$

where K is the total number of types, $g(q)_k$ and $\text{E}(s^{(i)})_k$ are the k-th element of $g(q)$ and $\text{E}(s^{(i)})$ respectively. Intuitively, with sigmoid squashed output, $g(q)$ can be regarded as K binary classifiers, one for each type. Hence, $g(q)_k$ reprents the predicted probability that the subject is associated with the k-th type.

6 Experiments

In this section, we conduct experiments to evaluate the proposed system empirically.

6.1 Dataset and Knowledge Base

We train and evaluate our method on the SIMPLEQUESTIONS dataset[3] — the largest question-triple dataset. It consists of 108,442 questions written in English by human annotators. Each question is paired with a subject-relation-object triple from Freebase. We follow the same splitting for training (70%), validation (10%) and testing (20%) as (Bordes et al., 2015). We use the same subset of Freebase (`FB5M`) as our knowledge base so that the results are directly comparable. It includes 4,904,397 entities, 7,523 relations, and 22,441,880 facts.

There are alternative datasets available, such as WebQuestions (Berant et al., 2013) and

[2] Word embeddings are not shared across models.

[3] `https://research.facebook.com/researchers/1543934539189348`

Free917 (Cai and Yates, 2013). However, these datasets are quite restricted in sample size — the former includes 5,810 samples (train + test) and the latter includes 917 ones. They are fewer than the number of relations in Freebase.

To train the focused labeling model, the information about whether a word is part of the subject mention is needed. We obtain such information by reverse linking from the ground-truth subject to its mention in the question. Given a question q corresponding to subject s, we match the name and aliases of s to all n-grams that can be generated from q. Once a match is found, we label the matched n-gram as the subject mention. In the case of multiple matches, only the longest matched n-gram is used as the correct one.

6.2 Evaluation and Baselines

For evaluation, we consider the same metric introduced in (Bordes et al., 2015), which takes the prediction as correct if both the subject and relation are correctly retrieved. Based on this metric, we compare CFO with a few baseline systems, which include both the Memory Network QA system (Bordes et al., 2015), and systems with alternative components and parameterizations from existing work (Yih et al., 2014; Yih et al., 2015). We did not compare with alternative subject networks because the only existing method (Yih et al., 2014) relies on unique textual name of each entity, which does not generally hold in knowledge bases (except in REVERB). Alternative approaches for pruning method, relation network, and entity representation are described below.

Pruning methods We consider two baseline methods previously used to prune the search space. The first baseline is the N-Gram pruning method introduced in Section 3, as it has been successfully used in previous work (Yih et al., 2014; Yih et al., 2015). Basically, it establishes the candidate pool by retaining subject-relation pairs whose subject can be linked to one of the n-grams generated from the question. The second one is N-Gram+, a revised version of the N-Gram pruning with additional heuristics (Bordes et al., 2015). Instead of considering all n-grams that can be linked to entities in KB, heuristics related to overlapping n-grams, stop words, interrogative pronouns, and so on are exploited to further shrink the n-gram pool. Accordingly, the search space is restricted to subject-relation pairs whose subject can be linked to one of the remaining n-grams after applying the heuristic filtering.

Relation scoring network We compare our proposed method with two previously used models. The first baseline is the embedding average model (Embed-AVG) used in (Bordes et al., 2014a; Bordes et al., 2014b; Bordes et al., 2015). Basically, it takes the element-wise average of the word embeddings of the question to be the question representation. The second one is the letter-tri-gram CNN (LTG-CNN) used in (Yih et al., 2014; Yih et al., 2015), where the question and relation are separately embedded into the vector space by two parameter shared LTG-CNNs. [4] In addition, (Yih et al., 2014; Yih et al., 2015) observed better performance of the LTG-CNN when substituting the subject mention with a special symbol. Naturally, this can be combined with the proposed focused labeling, since the latter is able to identify the potential subject mention in the question. So, we train another LTG-CNN with symbolized questions, which is denoted as LTG-CNN+. Note that this model is only tested when the focused labeling pruning is used.

Entity representation In section 4.2, we describe two possible ways to improve the vector representation of the subject, `TransE` pretrained embedding and type vectors. To evaluate their effectiveness, we also include this variation in the experiment, and compare their performance with randomly initialized entity embeddings.

6.3 Experiment Setting

During training, all word embeddings are initialized using the pretrained GloVe (Pennington et al., 2014), and then fine tuned in subsequent training. The word embedding dimension is set to 300, and the BiGRU hidden size 256. For pretraining the entity embeddings using `TransE` (see section 4.2), only triples included in `FB5M` are used. All other parameters are randomly initialized uniformly from $[-0.08, 0.08]$, following (Graves, 2013). Both hinge loss margins γ_s and γ_r are set to 0.1. Negative sampling sizes M_s and M_r are both 1024.

For optimization, parameters are trained using mini-batch AdaGrad (Duchi et al., 2011) with Momentum (Pham et al., 2015). Learning rates are

[4] In Freebase, each predefined relation has a *single* human-recognizable reference form, usually a sequence of words.

Pruning Method	Relation Network	Entity Representation		
		Random	Pretrain	Type Vec
Memory Network		62.9	63.9*	
N-Gram	Embed-AVG	39.4	42.2	50.9
	LTG-CNN	32.8	36.8	45.6
	BiGRU	43.7	46.7	55.7
N-Gram+	Embed-AVG	53.8	57.0	58.7
	LTG-CNN	46.3	50.9	56.0
	BiGRU	58.3	61.6	62.6
Focused Pruning	Embed-AVG	71.4	71.7	72.1
	LTG-CNN	67.6	67.9	68.6
	LTG-CNN+	70.2	70.4	71.1
	BiGRU	75.2	75.5	**75.7**

Table 1: Accuracy on SIMPLEQUESTIONS testing set. * indicates using ensembles. N-Gram+ uses additional heuristics. The proposed CFO (focused pruning + BiGRU + type vector) achieves the top accuracy.

tuned to be 0.001 for question embedding with type vector, 0.03 for LTG-CNN methods, and 0.02 for rest of the models. Momentum rate is set to 0.9 for all models, and the mini-batch size is 256. In addition, vertical dropout (Pham et al., 2014; Zaremba et al., 2014) is used to regularize all BiGRUs in our experiment. [5]

6.4 Results

Trained on 75,910 questions, our proposed model and baseline methods are evaluated on the testing set with 21,687 questions. Table 1 presents the accuracy of those methods. We evaluated all combinations of pruning methods, relation networks and entity representation schemes, as well as the result from memory network, as described in Section 6.1. CFO (focused pruning + BiGRU + type vector) achieves the best performance, outperforming all other methods by substantial margins.

By inspecting vertically within each cell in Table 1, for the same pruning methods and entity representation scheme, BiGRU based relation scoring network boosts the accuracy by 3.5 % to 4.8% compared to the second best alternative. This evidence suggests the superiority of RNN in capturing semantics of question utterances. Surprisingly, it turns out that Embed-AVG achieves better performance than the more complex LTG-CNN.

By inspecting Table 1 horizontally, type vector based representation constantly leads to better performance, especially when N-Gram pruning is used. It suggests that under sparse supervision, training high-quality distributed knowledge representations remains a challenging problem. That said, pretraining entity embeddings with `TransE` indeed gives better performance compared to random initialization, indicating the future potential of unsupervised methods in improving continuous knowledge representation.

In addition, all systems using our proposed focused pruning method outperform their counterparts with alternative pruning methods. Without using ensembles, CFO is already better than the memory network ensembles by 11.8%. It substantiates the general effectiveness of the focused pruning with subject labeling method regardless of other sub-modules.

6.5 Effectiveness of Pruning

According to the results in section 6.4, the focused pruning plays a critical role in achieving the best performance. To get a deeper understanding of its effectiveness, we analyze how the pruning methods affect the accuracy of the system. Due to space limit, we focus on systems with BiGRU as the relation scoring function and type vector as the entity representation.

Table 2 summarizes the recall — the percentage of pruned subject-relation candidates containing the answer — and the resulting accuracy. The single-subject case refers to the scenario that there is only one candidate entity in $\mathcal{C}_s$ (possibly with multiple relations), and the multi-subject case means there are multiple entities in $\mathcal{C}_s$. As the table shows, focused pruning achieves comparable recall rate to N-Gram pruning.[6] Given the state-of-the-art performance of sequence labeling systems, this result should not be surprising. Thus, the difference in performances entirely comes from their resulting accuracy. Notice that there exists a huge accuracy gap between the two cases. Essentially, in the single-candidate case, the system only need to identify the relation based on the more robust model $p_{\theta_r}(r|q)$. In contrast, under the multi-candidate case, the system also relies on $p_{\theta_s}(s|q,r)$, which has significantly more parameters to estimate, and thus is less robust. Consequently, by only focusing on the most probable sub-string, the proposed focused pruning produces much more single-candidate situations, leading to a better overall accuracy.

[5] For more details, source code is available at `http://zihangdai.github.io/cfo` for reference.

[6] Less than 3% of the recalled candidates rely on approximate matching in the focused pruning.

Pruning method	Pruning recall	Inference accuracy within the recalled		Overall accuracy
		Single-subject case	Multi-subject case	
N-Gram	94.8%	18 / 21 = 85.7%	12051 / 20533 = 58.7%	55.7%
N-Gram+	92.9%	126 / 138 = 91.3%	13460 / 20017 = 67.2%	62.6%
Focused pruning	94.9%	9925 / 10705 = 92.7%	6482 / 9876 = 65.6%	**75.7%**

Table 2: Comparison of different space pruning methods. N-Gram+ uses additional heuristics. Single- and multi-subject refers to the number of distinct subjects in candidates. The proposed focused pruning achieves best scores.

6.6 Additional Analysis

In the aforementioned experiments, we have kept the focused labeling model and the subject scoring network fixed. To further understand the importance and sensitivity of this specific model design, we investigate some variants of these two models.

Alternative focus with CRF RNN-CRF based models have achieved the state-of-the-art performance on various sequence labeling tasks (Huang et al., 2015; Lu et al., 2015). However, the labeling task we consider here is relatively unsophisticated in the sense that there are only two categories of labels - part of subject string (`SUB`) or not (`O`). Thus, it's worth investigating whether RNN (BiGRU in our case) is still a critical component when the task gets simple. Hence, we establish a CRF baseline which uses traditional features as input. Specifically, the model is trained with `Stanford CRF-NER` toolkit [7] on the same reversely linked labeling data (section 6.1). For evaluation, we directly compare the sentence level accuracy of these two models on the test portion of the labeling data. A sentence labeling is considered correct only when all tokens are correctly labeled. [8] It turns out the RNN-CRF achieves an accuracy of 95.5% while the accuracy of feature based CRF is only 91.2%. Based on the result, we conclude that BiGRU plays a crucial role in our focused pruning module.

Subject scoring with average embedding As discussed in section 4.2, the subject network g is chosen to be the same as f, mainly relying on a two-layer BiGRU to produce the semantic question embeding. Although it is a natural choice, it remains unclear whether the final performance is sensitive to this design. Motivated by this question, we substitute the BiGRU with an Embed-AVG model, and evalute the system performance.

[7] `http://nlp.stanford.edu/software/CRF-NER.shtml`

[8] As F-1 score is usually used as the metric for sequence labeling, sentence level accuracy is more informative here.

Relation Network	**Subject Network**	
	Embed-AVG	BiGRU
Embed-AVG	71.6	72.1
LTG-CNN	68.0	68.6
LTG-CNN+	70.4	71.1
BiGRU	75.4	75.7

Table 3: System performance with different subject network structures.

For this experiment, we always use focused pruning and type vector, but vary the structure of the relation scoring network to allow high-order interaction across models. The result is summarized in Table 3. Insepcting the table horizontally, when BiGRU is employed as the subject network, the accuracy is consistently higher regardless of relation network structures. However, the margin is quite narrow, especially compared to the effect of varying the relation network structure the same way. We suspect this difference reflects the fact that modeling $p(s|r, q)$ is intrinsically more challenging than modeling $p(r|q)$. It also suggests that learning smooth entity representations with good discriminative power remains an open problem.

7 Conclusion

In this paper, we propose CFO, a novel approach to single-fact question answering. We employ a conditional factoid factorization by inferring the target relation first and then the target subject associated with the candidate relations. To resolve the representation for millions of entities, we proposed type-vector scheme which requires no training. Our focused pruning largely reduces the candidate space without loss of recall rate, leading to significant improvement of overall accuracy. Compared with multiple baselines across three aspects, our method achieves the state-of-the-art accuracy on a 108k question dataset, the largest publicly available one. Future work could be extending the proposed method to handle more complex questions.

Verbs Taking Clausal and Non-Finite Arguments as Signals of Modality – Revisiting the Issue of Meaning Grounded in Syntax

Judith Eckle-Kohler
Research Training Group AIPHES and UKP Lab
Computer Science Department, Technische Universität Darmstadt
www.aiphes.tu-darmstadt.de, www.ukp.tu-darmstadt.de

Abstract

We revisit Levin's theory about the correspondence of verb meaning and syntax and infer semantic classes from a large syntactic classification of more than 600 German verbs taking clausal and non-finite arguments. Grasping the meaning components of Levin-classes is known to be hard. We address this challenge by setting up a multi-perspective semantic characterization of the inferred classes. To this end, we link the inferred classes and their English translation to independently constructed semantic classes in three different lexicons – the German wordnet GermaNet, VerbNet and FrameNet – and perform a detailed analysis and evaluation of the resulting German–English classification (available at www.ukp.tu-darmstadt.de/modality-verbclasses/).

1 Introduction

Verbs taking clausal and non-finite arguments add a further meaning component to their embedded argument. For example, the embedded argument is realized as *that*-clause in (1) and (2), but *understand* in (1) marks it as factual and *hope* in (2) as uncertain. The verb *pretend* in (3) realizes its embedded argument as non-finite construction and marks it as non-factual.

(1) *He understands* ***that his computer has a hardware problem***.

(2) *She hopes* ***that her experience will help others***.

(3) *He pretends* ***to take notes on his laptop****, but really is updating his Facebook profile.*

The entities expressed by embedded clausal and non-finite arguments are also called "abstract object" (AO) in the rest of this paper (following Asher (1993)); we will use the linguistic term "modality" (Hacquard, 2011) to subsume the meanings (such as factuality, non-factuality and uncertainty) denoted by AO-selecting verbs.

As AO-selecting verbs can change the meaning of a text in important ways, text understanding systems should be sensitive to them. In particular, classifications of AO-selecting verbs according to semantic criteria are important knowledge sources for a wide range of NLP applications, such as event tagging (Saurí et al., 2005), commited belief tagging (Prabhakaran et al., 2010), reported speech tagging (Krestel et al., 2008), the detection of uncertainty (Szarvas et al., 2012) and future-oriented content (Eckle-Kohler et al., 2008), textual entailment (Saurí and Pustejovsky, 2007; Lotan et al., 2013), or determining the degree of factuality of a given text (Saurí and Pustejovsky, 2012; de Marneffe et al., 2012). Accordingly, various semantic classifications of AO-selecting verbs have been developed, e.g., (Kiparsky and Kiparsky, 1970; Karttunen, 1971; Karttunen, 2012), some of them explicitly in the context of NLP (Nairn et al., 2006; Saurí, 2008).

However, these classifications are constructed manually and often quite limited in coverage. Consequently, extending or adapting them to specific domains or other languages is a major issue.

We propose to address this issue by exploiting the relationship between the syntactic behavior of verbs and their meaning following Levin's theory (Levin, 1993). This has not been done yet for verbs signaling modality, as far as we are aware. For the particular category of AO-selecting verbs, Levin's theory allows constructing verb classifications in a purely syntax-driven way, i.e. inducing semantic classes from syntactically defined

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 811–822,
Berlin, Germany, August 7-12, 2016.

classes, and thus possibly also extending given classes using large corpora.[1]

While the appeal of Levin's hypotheses is clear, we are aware of a major difficulty, making our approach a challenging research problem: it is very hard to grasp the precise meaning components which are to be associated with a syntactic "Levin" class. At the same time, it is vital to have a good semantic characterization of the meaning components in order to apply such classes to NLP tasks in an informed way.

We address these issues and make the following contributions: (i) We consider a purely syntactic classification of more than 600 German AO-selecting verbs and induce semantic classes based on findings from formal semantics about correspondences between verb syntax and meaning. This yields an initial description of the meaning components associated with the classes, along with a tentative class name. (ii) In a second step, we refine and extend the semantic characterization of the verb classes by translating it to English and linking it to existing semantic classes in lexical resources at the word sense level: we consider the coarse semantic fields in the German wordnet GermaNet (Kunze and Lemnitzer, 2002), the verb classes in the English lexicon VerbNet (Kipper et al., 2008), and the semantic frames in the English lexicon FrameNet (Baker et al., 1998). As a result, we obtain a detailed semantic characterization of the verb classes, as well as insights into the validity of Levin's theory across the related languages German and English. (iii) We also perform a task-oriented evaluation of the verb classes in textual entailment recognition, making use of insights from the previous two steps. The results suggest that the verb classes might be a promising resource for this task, for German and for English.

2 Related Work

This section summarizes related work about the correspondence between verb meaning and syntax and discusses related work on modality in NLP.

Syntactic Reflections of Verb Meaning Semantic verb classifications that are grounded in lexical-syntactic properties of verbs are particularly appealing, because they can automatically be recovered in corpora based on syntactic features. The most well known verb classification based on correspondences between verb syntax and verb meaning is Levin's classification (Levin, 1993). According to Levin (2015a), verbs that share common syntactic argument alternation patterns also have particular meaning components in common, thus they can be grouped into a semantic verb class. For example, verbs participating in the dative alternation[2] can be grouped into a semantic class of verbs sharing the particular meaning component "change of possession", thus this shared meaning component characterizes the semantic class. Recent work on verb semantics provides additional evidence for this correspondence of verb syntax and meaning: Hartshorne et al. (2014) report that the syntactic behavior of some verbs can be predicted based on their meaning.

VerbNet is a broad-coverage verb lexicon organized in verb classes based on Levin-style syntactic alternations: verbs with common subcategorization frames and syntactic alternation behavior that also share common semantic roles are grouped into VerbNet classes. VerbNet not only includes the verbs from the original verb classification by Levin, but also more than 50 additional verb classes (Kipper et al., 2006) automatically acquired from corpora (Korhonen and Briscoe, 2004). These classes contain many AO-selecting verbs that were not covered by Levin's classification. However, VerbNet does not provide information about the modal meaning of AO-selecting verbs and does not reflect fine-grained distinctions between various kinds of modality.

There is also some criticism in previous work regarding the validity of Levin's approach. Baker and Ruppenhofer (2002) and Schnorbusch (2004) both discuss various issues with Levin's original classification, in particular the difficulty to grasp the meaning components, which are to be associated with a Levin class.

While approaches to exploit the syntactic behavior of verbs for the automatic acquisition of semantic verb classes from corpora have been developed in the past, they were used to recover only small verb classifications: Schulte im Walde (2006)'s work considered a semantically balanced set of 168 German verbs, Merlo and Stevenson (2001) used 60 English verbs from three particular semantic classes.

In contrast to previous work, we consider a large

[1] Abstract objects already characterize the possible semantic roles to a certain extent.

[2] These verbs can realize an argument syntactically either as noun phrase or as prepositional phrase with *to*.

set of more than 600 German AO-selecting verbs and focus on their modal meaning (i.e., expressing factuality or uncertainty).

Related Work on Modality in NLP Previous work in NLP on the automatic (and manual) annotation of modality has often tailored the concept of modality to particular applications. Szarvas et al. (2012) introduce a taxonomy of different kinds of modality expressing uncertainty, such as deontic, bouletic, abilitative modality, and use it for detecting uncertainty in an Information Extraction setting. Their uncertainty cues also include verbs.

Saurí and Pustejovsky (2012) use discrete values in a modality continuum ranging from uncertain to absolutely certain in order to automatically determine the factuality of events mentioned in text. Their automatic approach is based on the FactBank corpus (Saurí and Pustejovsky, 2009), a corpus of newswire data with manually annotated event mentions. For the factuality annotation of the event mentions, the human annotators were instructed to primarily base their decision on lexical cues. For example, they used verbs of belief and opinion, perception verbs, or verbs expressing proof.

Nissim et al. (2013) introduce an annotation scheme for the cross-linguistic annotation of modality in corpora. Their annotation scheme defines two dimensions which are to be annotated (called layers): factuality (characterizing the embedded proposition or concept) and speaker's attitude (characterizing the embedding predicate). Their annotation scheme starts from a fixed set of modal meanings and aims at finding previously unknown triggers of modality. However, some modal meanings are not distinguished, in particular those involving future-orientation. A classification approach grounded in syntax – as in our work – can be considered as complementary: it starts from the syntactic analysis of a large set of trigger words, and induces a broad range of modal meanings based on correspondences between verbs syntax and meaning.

Our semantic classification for AO-selecting verbs covers a *wide range* of different kinds of modality in text, thus considerably extending previous work.

3 Inferring Semantic Verb Classes

In this section, we infer semantic verb classes from the syntactic alternation behavior of a large dataset of German AO-selecting verbs. The research hypotheses underlying our method can be summarized as follows: There are correspondences between verb syntax and meaning: certain syntactic alternations correspond to particular meaning components (Levin, 2015a).

3.1 German Subcategorization Lexicon

We consider a set of 637 AO-selecting verbs given in (Eckle-Kohler, 1999). These verbs are a subset of a subcategorization lexicon (i.e., pairs of lemma and subcategorization frame) that has automatically been extracted from large newspaper corpora using a shallow regular expression grammar covering more than 240 subcategorization frames (short: subcat frames). All the subcat frames extracted for a given verb were manually checked and only the correct ones were included in the final lexicon, because high quality lexical information was crucial in the target application Lexical Functional Grammar parsing.[3]

Eckle-Kohler (1999) specified the alternation behavior of each AO-selecting verb regarding different types of clausal and non-finite arguments, yielding a *syntactic signature* for each verb (e.g., 111101 for the verb *einsehen (realize)* using the encoding in Table 1, top to bottom corresponding to left to right).[4] For this, each verb was inspected regarding its ability to take any of the considered clausal and non-finite constructions as argument – either on the basis of the automatically acquired subcat frames or by making use of linguistic introspection. Linguistic introspection is necessary to reliably identify non-possible argument types, since missing subcat frames that were not extracted automatically are not sufficient as evidence.

Although there are 64 possible syntactic signatures according to basic combinatorics, in the data only 46 signatures were found, which group the verbs into 46 classes. While Eckle-Kohler (1999) points out a few semantic characteristics of these classes, most of them lack a semantic characterization. Our goal is to address this gap and to infer shared meaning components for all the classes.

[3]Today, this lexicon is part of the larger resource "IMSLex German Lexicon" (Fitschen, 2004).

[4]The automatically extracted subcategorization lexicon also contains adjectives and nouns taking clausal or infinitival arguments. However, many of the 1191 nouns and 666 adjectives are derived from verbs, which makes them the central word class.

Argument Type	Y/N	Example
daß(that)-clause	1/0	*sehen (see)*
zu(to)-infinitive, present	1/0	*versuchen (try)*
zu(to)-infinitive, past	1/0	*bereuen (regret)*
wh-clause	1/0	*einsehen (realize)*
ob(whether/if)-clause	1/0	*fragen (ask)*
declarative clause	1/0	*schreien (shout)*

Table 1: Clausal and infinitival arguments distinguished in the syntactic classification; possibility of each type is encoded as 1 (possible) or 0 (not possible).

For this, we use linguistic research findings as described in the next section.

3.2 Findings from Formal Semantics

We employ the following findings on correspondences between verb meaning and syntax in order to infer semantic classes from the syntactic signatures. This gives also rise to tentative names (labels) for the corresponding meaning components.

Factuals: the *that-wh* and the *that-wh/if* alternation. Verbs that are able to alternatively take *that* and *wh*-clauses coerce the embedded interrogative and declarative clauses into factual AOs, corresponding to a particular fact (Ginzburg, 1996). Among the verbs showing the *that-wh* alternation are the well-known factive verbs (Kiparsky and Kiparsky, 1970) (e.g., *She proves that she exists.* vs. *She proves who she is.* vs. *He proves whether he can mine gold.*).

There is a further distinction among these verbs regarding the ability to take an embedded *if/whether*-question: Schwabe and Fittler (2009) show that the *that-wh/if* alternation is connected to objective verbs entailing the existence of an independent witness, whereas the *that-wh* alternation (i.e., an *if/whether*-question is not possible) occurs with non-objective verbs (e.g., *He regrets whom he ended up with.* vs. ⋆*He regrets whether he ended up playing this game.*).

"Aspectuals": the inability to take *that*-clauses and *to*-infinitives in the past tense. Recently, linguistic research has increasingly addressed particular semantic aspects of *to*-infinitives. Kush (2011) has investigated AOs that can neither be realized as *that*-clause nor as *to*-infinitive in the past tense (e.g., *She hesitates to answer.* vs. ⋆*She hesitates to have answered.*[7] vs. ⋆*She hesitates that ...*) These AOs are selected by control verbs[8] and can be characterized as mental actions. Kush (2011) points out that the verbs selecting those AOs have an aspectual meaning in common.

Future orientation: *to*-infinitives in the present tense and the inability to take *to*-infinitives in the past tense. Laca (2013) has investigated verbs across English and Spanish that embed future-oriented AOs. Only future-oriented AOs can be used with future-oriented adverbials, such as *tomorrow*, and these AOs are often realized as non-finite constructions, e.g., *to*-infinitives. She points out that not only control verbs take future-oriented AOs, but also verbs expressing attitudes of preference. This finding implies that such future-oriented AOs are typically incompatible with past-oriented adverbials (e.g., *yesterday*) and verb forms in the past tense (e.g., ⋆*She plans having finished the assignment yesterday.*).

3.3 Mapping to Meaning Components

We automatically infer semantic classes based on a manually constructed mapping between the syntactic signatures from Eckle-Kohler (1999) and the meaning components grounded in syntax summarized in Section 3.2.[9]

We constructed this mapping in two steps: In a first step, the signatures are aligned to the meaning components from Section 3.2 based on substrings of the signatures: future-orientation matches the 110 prefix, aspectual the 010 prefix, and factuality matches 1's in fourth or fifth position. It is important to point out that future-orientation can be combined with factuality: this corresponds to an independent matching of the 110 prefix and the factuality substring. While this combination may seem contradictory, it reflects the lexical data and shows that also weak forms of factuality ("it will most likely be factual at some point in the future") are expressed in language.

In a second step, the pre-aligned signatures are merged, if the remaining slots of the signature are either 1 or 0 (i.e. the respective argument types can or can not occur); in the resulting merged sig-

[7] This is the literal translation of the German equivalent to English. In English, the ing-form in the past would be more typical instead of a *to*-infinitive in the past tense.

[8] "Control" refers to the co-reference between the implicit subject of the infinitival argument and syntactic arguments in the main clause, either the subject (subject control) or direct object (object control).

[9] We did not consider verbs can be used with all kinds of clausal and infinitival arguments, such as the majority of communication verbs (e.g., *comment, whisper*).

signature	#verbs – examples	meaning components	semantic characterization (#linked verbs)
010 ---	36 (6%) – *wagen (dare), zögern (hesitate), weigern (refuse)*	**aspectual**: verbs expressing the ability of doing an action	**VN** (2): consider-29.9, wish-62; **FN** (2): purpose, cogitation

Table 2: The 632 verbs in 8 semantic classes (5 verbs show idiosyncratic behavior). Signature substrings in bold correspond to meaning components, which (along with tentative class names) are based on Sec. 3.2. The cross-lingual semantic characterization shows aligned VerbNet (VN) classes covering 265 (42%) verbs and aligned FrameNet (FN) frames covering 126 (20%) verbs, see Sec. 4.1.[6]

nature, these slots are left underspecified. Merging the signatures in this way yields 8 partially underspecified signatures which correspond to the final semantic classes. This procedure covers more than 99% of the 637 verbs under investigation: only 5 verbs showed idiosyncratic syntactic behavior, 4 of those are verbs that can take an AO as subject (e.g., *bedeuten (mean)*). As a consequence of the automatic part of this procedure, every verb is assigned to exactly one class – a simplification which we plan to resolve as part of future work.

Table 2 provides an overview and a characterization of these classes, also showing the final signatures and their substrings which correspond to the meaning components. The non-factual class is derived from the wh-factual class: the only difference is the inability to take a *wh*-clause (e.g. ⋆ *He hopes, <u>when</u> he will succeed.*).

While the descriptions of the meaning components and the class names are inspired from research in linguistics (typically a very deep analysis of only few verbs), transferring them to our verb resource – which is of much larger scale – inevitably leads to outlier verbs in the classes, e.g., verbs that do not strictly match the class label. Examples include verbs such as *überlegen (consider)* in the *wh/if-factual* class (not covering the future-oriented meaning component) or *schaden (harm)* as *non-factual rather* than as *wh-factual*. For this reason, and also because of the assignment of highly polysemous verbs to only one class, the definitions of meaning components and the class names should rather be considered as loose, providing a first tentative semantic characterization of the modality classes.

In sum, this section presented an inventory

of modal meaning components that we primarily synthesized from research in linguistics. The classification work is strictly grounded in syntactic properties of the verbs and was not targeted a priori at modal meanings.

4 Evaluation

4.1 Linking to Semantic Classes

Our first set of experiments aims at refining the initial semantic characterization of the classes by linking them to independently constructed semantic classifications *at the word sense level*. Specifically, we consider three different semantic classifications from computational lexicons, which have been created by linguistic experts: (i) the so-called semantic fields in GermaNet, grouping verb senses into 15 coarse classes, such as *perception, emotion*, (ii) the verb classes given in VerbNet, and (iii) the Frame-semantic frames in FrameNet. As the GermaNet and FrameNet classes are based on different lexicographic and linguistic theories, we expect an additional semantic characterization from the linking. The VerbNet classes, which also follow Levin's hypotheses, however, are used to investigate if the syntax-semantics correspondence is maintained across the related languages German and English.

For this linking experiment, we used the UBY framework (Gurevych et al., 2012)[10], containing standardized versions of the above lexicons, as well as a linking between VerbNet and FrameNet on the word sense level.

Approach In order to link our classes to verb senses in GermaNet and VerbNet, we developed an automatic linking method based on subcat frame similarity. Recognizing subcat frame similarity requires a common standardized format for the otherwise incomparable frames. UBY provides such a standardized format which has been presented in detail by Eckle-Kohler and Gurevych (2012). It represents subcat frames uniformly across German and English, and at a fine-grained level of individual syntactic arguments. Our linking approach is based on the following hypothesis: Two verb senses with equivalent lemmas are equivalent, if they have similar subcat frames.[11] Our method interprets the pairs of verb and subcat frame listed in our classification[12] as senses. While we do not claim that this hypothesis is sufficient in general, i.e., for all verb senses, we found that it is valid for the subset of senses belonging to the class of AO-selecting verbs.

The cross-lingual linking of our classes to VerbNet senses requires an additional translation step, which we describe first.

Manual Translation While UBY also provides translations between German and English verb senses, e.g., as part of the Interlingual Index from EuroWordnet (ILI), we found that many of the translations were not present in our target lexicon VerbNet. Therefore, the main author of this paper, a native speaker of German with a good proficiency in English, translated the AO-compatible verbs (i.e., word senses) manually using Linguee[13] and dictionaries. This took about 7 hours.

For 23 German verbs, we could not find any equivalent lexicalized translation, because these verbs express very fine-grained semantic nuances. For example, we did not find an equivalent English verb for a few verbs in the aspectual class but only a translation consisting of an adjective in combination with *to be*. Examples include *be easy (leichtfallen)*, *be willing (sich bereitfinden)*, *be capable (vermögen)*, which have German equivalents that are lexicalized as verbs. As a result, we arrived at translations for 614 out of 637 German verbs. These 614 German verbs are translated to 413 English verbs, indicating that the English translation has a more general meaning in many cases.

Automatic Verb Sense Linking Our algorithm links a German verb sense (or its English translation) with a GermaNet (or VerbNet) sense, if the subcat frames of both verb senses have the same number of arguments and if the arguments have certain features in common.[14] For example, to create a link to GermaNet, features such as the complementizer of clausal arguments and the case of noun phrase arguments have to agree. In a similar way, the linking to VerbNet is based on a comparison of German subcat frames and English subcat

[10] `http://www.ukp.tu-darmstadt.de/uby/`

[11] This approach is applicable for GermaNet, because GermaNet contains fine-grained syntactic subcat frames.

[12] We consider only verb senses that are compatible with AOs, as indicated by subcat frames with clausal or non-finite arguments.

[13] Linguee (`http://www.linguee.de/`) is a translation tool combining an editorial dictionary and a search engine processing bilingual texts. In particular, it provides a large variety of contextual translation examples.

[14] We do not link the subcat frames, but we do compare them across the related languages German and English to determine their similarity in the context of linking.

frames – which are represented uniformly across German and English. In Section A.2, we provide more details about the algorithm.

Results According to a manual evaluation of a random sample of 200 sense pairs, the automatic verb sense linking yielded an accuracy of 89.95% for the linking to GermaNet, and 87.54% for the linking to VerbNet (κ agreement on the sample annotated by two annotators was 0.7 and 0.8, respectively). The main types of errors in the linking to GermaNet and VerbNet are due to specific syntactic features of the subcat frames which diverge and are not considered in the automatic linking. The differences regarding these specific features are due to cross-lingual differences (VerbNet, e.g., verb phrase arguments with ing-form) and diverging linguistic analyses of particular constructions (GermaNet, e.g., constructions with *es (it)*), see also Eckle-Kohler and Gurevych (2012).

By linking the verbs in our classification to semantic classes in GermaNet, VerbNet and FrameNet, we obtain a three-way semantic characterization of our classes. The linking to the GermaNet semantic fields covers 270 (43%) of the source verbs. Of these, 219 (81%) are linked to the three semantic fields *cognition*, *communication* and *social*. Fewer verbs (32 (12%)) are linked to the semantic fields *emotion, perception, change*. Semantic fields not among the target classes are *consumption, competition, contact, body* and *weather*.

Table 2 summarizes the linking to VerbNet and FrameNet and shows how many verbs from each source class could be linked to any of the classes in VerbNet or FrameNet.[15] As the class distribution of the verb subsets covered by our linking-based evaluation is similar as for the original classes, we consider our evaluation as valid, although less than 50% of all verbs could be evaluated this way.

The target classes in VerbNet and FrameNet reveal meaning components that are on the one hand unique for individual classes, and on the other hand shared across several German classes.

The *future-oriented* class contains object control verbs (e.g., force-59, forbid-67 in VerbNet, and *request, preventing* in FrameNet). The *wh/if-factual* class is unique regarding the *cognition and perception* verbs (e.g., discover-84, see-30.1-1, and *perception-experience*). The *future-directed wh/if-factual* class also contains *objective assessment* verbs, as shown by the estimate-34.2 class. The verbs in the two *wh-factual* classes share meaning components as well, as shown by the *opinion verb* classes admire-31.2 and defend-85 in VerbNet or *judgment, tolerating* in FrameNet.

While there are also other VerbNet and FrameNet classes shared across several classes, they turned out to be very general and underspecified regarding their meaning, thus not contributing to a more fine-grained semantic characterization. For example, the conjecture-29.5 class assembles quite diverse conjecture verbs, e.g. verbs expressing opinion (*feel, trust*) and factuality (*observe, discover*). A similar observation holds for the *statement* frame in FrameNet.

Verb class	Wiki	Web	News	News Eng.
all	25.85	50.58	33.91	25.31
aspectual	0.90	0.80	1.44	1.96
future-oriented	9.45	23.04	13.65	12.58
interrogative	0.01	0.05	0.05	0.65
wh-factual	4.26	17.89	4.99	3.48
fo. wh-factual	0.29	0.28	0.85	1.14
wh/if -factual	3.02	2.54	3.53	5.20
fo. wh/if-factual	2.36	1.77	3.14	5.75
non-factual	4.29	3.36	4.84	3.57

Table 3: Percentage of classes in corpora: German Wikipedia (Wiki), SDeWaC (Web), Tiger (News); English Reuters corpus (News Eng.).

4.2 Analysis of Frequency and Polysemy

In order to assess the usefulness of the verb resource for NLP tasks, we determined the lemma frequency of all verbs in the 8 classes in SDeWaC (Faaß and Eckart, 2013), a cleaned version of the German DeWaC corpus (Baroni and Kilgarriff, 2006). A ranking of the verbs according to their lemma frequency showed that 89% of the verbs occur more than 50 times in SDeWaC.[16]

We also analyzed the frequency distribution of the 8 verb classes in two other German corpora belonging to different genres, and also for English, see Table 3:[17] encyclopedic text (the German Wikipedia[18]), German newspaper text (the Tiger corpus (Brants et al., 2004)), and the English

[15] Based on the percentage of source class members linked to any of the target classes, we only display target classes with an overlap of at least 1.8% due to space constraints.

[16] In the verb resource we provide for download, we included this frequency information in order to enable frequency-based filtering.

[17] Details of the computation of the verb lemma frequency lists are given in the appendix A.1.

[18] `www.wikipedia.de`, dump of 2009-06-18

Reuters-21578 corpus.[19] Table 3 shows that the large verb classes constitute a substantial proportion of verb occurrences across different genres. This suggests that the verb classes might be useful features for various text classification tasks.

We performed a further analysis of the polysemy of the German and English verbs in our classes relative to several fine and coarse word sense inventories. Regarding GermaNet, there are 2.28 senses per verb (1.53 for all GermaNet verbs), whereas WordNet lists 5.11 senses per verb (2.17 for all WordNet verbs). In VerbNet, we find 1.74 senses per verb (1.42 for all VerbNet verbs), and in FrameNet 1.96 (1.52 for all FrameNet verbs). This analysis shows that the task of automatic sense linking is particularly hard for the category of AO-selecting verbs we consider. Whether the polysemy is an issue for any application where the verb classes are used as features is not a priori clear and depends on the task at hand.

4.3 Textual Entailment Experiment

For an extrinsic evaluation, we investigated the usefulness of the German *and* the English verb classes as features in recognizing textual entailment (RTE). In RTE, the task is to determine whether for a pair of text fragments – the text T and the hypothesis H – the meaning of H is entailed by T (Dagan et al., 2006); for non-entailing pairs, sometimes a further category "unknown" is used as a label.

We employed a simple classification-based approach to RTE and trained and evaluated a Naive Bayes classifier on the test sets of three RTE benchmarks, using 10-fold cross validation: the English RTE-3 data (Giampiccolo et al., 2009) and their German translation[20] (the development sets and the test sets each consist of 800 pairs), and an expanded version of the English RTE-3 data from the Sagan Textual Entailment Test Suite (Castillo, 2010) consisting of 2974 pairs. While the German dataset provides a two-way classification of the T-H pairs, the two English datasets provide a three-way classification, also using the "unknown" label. We used the DKPro TC framework (Daxenberger et al., 2014) for classification and applied POS tagging and lemmatization as preprocessing.

As a baseline feature, we use the word overlap measure between two T-H pairs (no stopword filtering, no lemmatization, no normalization of overlap score), which is quite competitive on the RTE-3 data, because this dataset shows a high difference in word overlap between positive (entailment) and negative (no entailment) pairs (Bentivogli et al., 2009).

An analysis of the development set of the German RTE-3 data showed that 62% of the pairs contain at least one occurrence of any of the verbs from the classification in either T or H. However, T and H fragments display no statistically significant differences[21] regarding the occurrences of any of the verb classes.

A detailed analysis revealed that pairs without entailment are often characterized by a mismatch between T and H regarding the presence of factuality markers. For example, the presence of verbs indicating uncertainty (all classes apart from wh-factual and wh/if-factual) in T and an absence of such verbs in H might indicate non-entailment as in the following not entailing pair from the English RTE3 development set where "long" signals non-factuality, but "researching" signals factuality:

> T: *The BBC's Americas editor Will Grant says many Mexicans are tired of conflict and long for a return to normality.*
> H: *Will Grant is researching a conflict with Mexicans.*

Thus, an insufficient overlap of modality markers in T and H might actually indicate non-entailment, but lead to an incorrect classification as entailment when considering only word overlap.

Accordingly, we implemented a factuality-mismatch feature both for German and for English, based on our new German and English classes. This feature is similar to the word overlap feature but with lemmatization and normalization of overlap score. Verb class counts are based on verb lemma counts of the member verbs; for English verbs that are members of more than one class, we included all verb classes in our factuality-mismatch feature.[22] Table 4 shows the results. While the differences

[19] Reuters-21578, Distribution 1.0, see http://kdd.ics.uci.edu/databases/reuters21578/reuters21578.html.

[20] http://www.dfki.de/~neumann/resources/RTE3_DE_V1.2_2013-12-02.zip

[21] All significance scores in this paper are based on Fisher's exact test at significance level $p<0.05$.

[22] In the German part, every verb is assigned to one class, while the translation to English resulted in 22% of the English verbs being members in more than one class. However, only 11% of the multiple class assignments involve a combination of factual and uncertainty classes.

for RTE-3 DE and RTE-3 EN are not statistically significant, the factuality-mismatch feature yielded a small but significant improvement on the expanded RTE-3 EN dataset. This is due to the different nature of the expanded RTE dataset, which was created using a paraphrasing technique. As a result, the number of occurrences of verbs from our classes increased, and the factuality-mismatch became a discriminative feature for distinguishing between CONTRADICTION and UNKNOWN/ENTAILMENT.

Considering the fact that we employed only simple overlap features that do not rely on dependency parsing and did not perform any word sense disambiguation, these results suggest that the verb classes might be promising features for RTE, both for German *and* English. As factuality can be expressed by a variety of further linguistic means, including modal verbs, negation, tense and certain adverbs, investigating the combination of our verb classes with other modality signals might be especially promising as part of future work.

	RTE-3 DE	**RTE-3 EN**	**RTE-3 EN exp.**
WO	59.87	54.75	54.98
WO+FM	59.25	54.62	**58.81**

Table 4: Accuracy of a Naive Bayes classifier (10-fold cross validation on the test sets) with word overlap (WO) and additional factuality-mismatch (WO+FM) features.

5 Results and Discussion

Our construction of semantic classes from the syntactic behavior of AO-selecting verbs results in an inventory of modal meanings that emerged from a large lexical resource. The main result of the linking based evaluation is a detailed semantic characterization of the inferred classes – a prerequisite for using them in NLP tasks in an informed way. The semantic classes seem to be particular suited for tasks related to opinion analysis, textual inference, or argumentation mining. In this context, the relationship between our large resource of lexical verbs and the closed class of modal verbs might be an interesting question for future research.

Most of all, the linking to GermaNet and FrameNet shows that it is indeed possible to narrow down meaning components for Levin classes. Moreover, the results of the linking to VerbNet also provide support for Levin's hypothesis that the correspondences between verb syntax and meaning described for English largely apply to the related language German as well (Levin, 2015b).

The English version of the semantic classes which we created by means of translation has the same semantic properties as the German classes. However, the syntactic properties of the English classes are not fully specified, because English has additional kinds of non-finite arguments, such as ing-forms or bare infinitives. Therefore, it might be interesting to address this question in the future and to build a similar semantic classification for English from scratch, in particular in the context of extracting modality classes from corpora. This would require an adaptation of the syntactic signatures, considering the various kinds of non-finite arguments particular to English. Based on large subcategorization lexicons available for English (e.g. COMLEX (Grishman et al., 1994) or VerbNet), it should be feasible to derive such signatures and to construct a mapping of signatures to modality aspects in a similar way as for German.

The question whether the syntactic signatures can be recovered in large corpora is particularly interesting, because this would allow extending the existing classes and to also acquire AO-selecting adjectives and nouns. We plan to investigate this question as part of future work.

6 Conclusion

We inferred semantic classes from a large syntactic classification of German AO-selecting verbs based on findings from formal semantics about correspondences between verb syntax and meaning. Our thorough evaluation and analysis yields detailed insights into the semantic characteristics of the inferred classes, and we hope that this allows an informed use of the resulting resource in various semantic NLP tasks.

A Supplemental Material

A.1 Verb Lemma Frequency List

In order to count the occurrences of verb lemmas in the German corpus SDeWaC, we used a reader and pre-processing components (i.e., the LanguageTool segmenter and the TreeTagger for POS tagging and lemmatization) from the DKPro Core collection (Eckart de Castilho and Gurevych, 2014). From DKPro Core, we also used a component that detects separated particles of German particle verbs and replaces the lemma of the verb base form annotated by the TreeTagger by the true lemma of the particle verb. Our verb lemma counting pipeline is available at `github.com/UKPLab/acl2016-modality-verbclasses`.

Sense linking based on subcategorization frames

get lexical entry le_s of source verb v_s
get equivalent verb v_t in target lexicon
get lexical entry le_t of target verb v_t
forall frame f_i in le_s
  get listOfArguments l_i of f_i
  forall frame f_j in le_t
    get sense s_j of frame f_j
    get listOfArguments l_j of f_j
    if $size(l_i) = size(l_j)$
    AND $features(l_i) = features(l_j)$
      link (v_s, f_i) and s_j
    end if
  end for
end for

Abstract

Most of the existing Neural Machine Translation (NMT) models focus on the conversion of sequential data and do not directly use syntactic information. We propose a novel end-to-end syntactic NMT model, extending a sequence-to-sequence model with the source-side phrase structure. Our model has an attention mechanism that enables the decoder to generate a translated word while softly aligning it with phrases as well as words of the source sentence. Experimental results on the WAT'15 English-to-Japanese dataset demonstrate that our proposed model considerably outperforms sequence-to-sequence attentional NMT models and compares favorably with the state-of-the-art tree-to-string SMT system.

1 Introduction

Machine Translation (MT) has traditionally been one of the most complex language processing problems, but recent advances of Neural Machine Translation (NMT) make it possible to perform translation using a simple end-to-end architecture. In the Encoder-Decoder model (Cho et al., 2014b; Sutskever et al., 2014), a Recurrent Neural Network (RNN) called the *encoder* reads the whole sequence of source words to produce a fixed-length vector, and then another RNN called the *decoder* generates the target words from the vector. The Encoder-Decoder model has been extended with an *attention* mechanism (Bahdanau et al., 2015; Luong et al., 2015a), which allows the model to jointly learn the soft alignment between the source language and the target language. NMT models have achieved state-of-the-art results in English-to-French and English-to-German translation tasks (Luong et al., 2015b; Luong et al., 2015a). However, it is yet to be seen whether NMT is competitive with traditional Statistical Machine Translation (SMT) approaches in translation tasks for structurally distant language pairs such as English-to-Japanese.

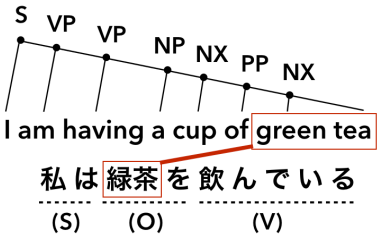

Figure 1: Alignment between an English phrase and a Japanese word.

Figure 1 shows a pair of parallel sentences in English and Japanese. English and Japanese are linguistically distant in many respects; they have different syntactic constructions, and words and phrases are defined in different lexical units. In this example, the Japanese word "緑茶" is aligned with the English words "green" and "tea", and the English word sequence "a cup of" is aligned with a special symbol "*null*", which is not explicitly translated into any Japanese words. One way to solve this mismatch problem is to consider the phrase structure of the English sentence and align the phrase "a cup of green tea" with "緑茶". In SMT, it is known that incorporating syntactic constituents of the source language into the models improves word alignment (Yamada and Knight, 2001) and translation accuracy (Liu et al., 2006; Neubig and Duh, 2014). However, the existing NMT models do not allow us to perform this kind of alignment.

In this paper, we propose a novel attentional NMT model to take advantage of syntactic infor-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 823–833,
Berlin, Germany, August 7-12, 2016.

mation. Following the phrase structure of a source sentence, we encode the sentence recursively in a bottom-up fashion to produce a vector representation of the sentence and decode it while aligning the input phrases and words with the output. Our experimental results on the WAT'15 English-to-Japanese translation task show that our proposed model achieves state-of-the-art translation accuracy.

2 Neural Machine Translation

2.1 Encoder-Decoder Model

NMT is an end-to-end approach to data-driven machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015). In other words, the NMT models directly estimate the conditional probability $p(\boldsymbol{y}|\boldsymbol{x})$ given a large collection of source and target sentence pairs $(\boldsymbol{x}, \boldsymbol{y})$. An NMT model consists of an encoder process and a decoder process, and hence they are often called *Encoder-Decoder* models. In the Encoder-Decoder models, a sentence is treated as a sequence of words. In the encoder process, the encoder embeds each of the source words $\boldsymbol{x} = (x_1, x_2, \cdots, x_n)$ into a d-dimensional vector space. The decoder then outputs a word sequence $\boldsymbol{y} = (y_1, y_2, \cdots, y_m)$ in the target language given the information on the source sentence provided by the encoder. Here, n and m are the lengths of the source and target sentences, respectively. RNNs allow one to effectively embed sequential data into the vector space.

In the RNN encoder, the i-th hidden unit $\boldsymbol{h}_i \in \mathbb{R}^{d\times 1}$ is calculated given the i-th input x_i and the previous hidden unit $\boldsymbol{h}_{i-1} \in \mathbb{R}^{d\times 1}$,

$$\boldsymbol{h}_i \;=\; f_{enc}(x_i, \boldsymbol{h}_{i-1}), \tag{1}$$

where f_{enc} is a non-linear function, and the initial hidden unit $\boldsymbol{h}_0$ is usually set to zeros. The encoding function f_{enc} is recursively applied until the n-th hidden unit $\boldsymbol{h}_n$ is obtained. The RNN Encoder-Decoder models assume that $\boldsymbol{h}_n$ represents a vector of the meaning of the input sequence up to the n-th word.

After encoding the whole input sentence into the vector space, we decode it in a similar way. The initial decoder unit $\boldsymbol{s}_1$ is initialized with the input sentence vector ($\boldsymbol{s}_1 = \boldsymbol{h}_n$). Given the previous target word and the j-th hidden unit of the decoder, the conditional probability that the j-th target word is generated is calculated as follows:

$$p(y_j|\boldsymbol{y}_{<j}, \boldsymbol{x}) \;=\; g(\boldsymbol{s}_j), \tag{2}$$

where g is a non-linear function. The j-th hidden unit of the decoder is calculated by using another non-linear function f_{dec} as follows:

$$\boldsymbol{s}_j \;=\; f_{dec}(y_{j-1}, \boldsymbol{s}_{j-1}). \tag{3}$$

We employ Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997; Gers et al., 2000) in place of vanilla RNN units. The t-th LSTM unit consists of several *gates* and two different types of states: a hidden unit $\boldsymbol{h}_t \in \mathbb{R}^{d\times 1}$ and a memory cell $\boldsymbol{c}_t \in \mathbb{R}^{d\times 1}$,

$$\begin{aligned}
\boldsymbol{i}_t &= \sigma(\boldsymbol{W}^{(i)}\boldsymbol{x}_t + \boldsymbol{U}^{(i)}\boldsymbol{h}_{t-1} + \boldsymbol{b}^{(i)}),\\
\boldsymbol{f}_t &= \sigma(\boldsymbol{W}^{(f)}\boldsymbol{x}_t + \boldsymbol{U}^{(f)}\boldsymbol{h}_{t-1} + \boldsymbol{b}^{(f)}),\\
\boldsymbol{o}_t &= \sigma(\boldsymbol{W}^{(o)}\boldsymbol{x}_t + \boldsymbol{U}^{(o)}\boldsymbol{h}_{t-1} + \boldsymbol{b}^{(o)}),\\
\tilde{\boldsymbol{c}}_t &= \tanh(\boldsymbol{W}^{(\tilde{c})}\boldsymbol{x}_t + \boldsymbol{U}^{(\tilde{c})}\boldsymbol{h}_{t-1} + \boldsymbol{b}^{(\tilde{c})}),\\
\boldsymbol{c}_t &= \boldsymbol{i}_t \odot \tilde{\boldsymbol{c}}_t + \boldsymbol{f}_t \odot \boldsymbol{c}_{t-1},\\
\boldsymbol{h}_t &= \boldsymbol{o}_t \odot \tanh(\boldsymbol{c}_t),
\end{aligned} \tag{4}$$

where each of $\boldsymbol{i}_t$, $\boldsymbol{f}_t$, $\boldsymbol{o}_t$ and $\tilde{\boldsymbol{c}}_t \in \mathbb{R}^{d\times 1}$ denotes an input gate, a forget gate, an output gate, and a state for updating the memory cell, respectively. $\boldsymbol{W}^{(\cdot)} \in \mathbb{R}^{d\times d}$ and $\boldsymbol{U}^{(\cdot)} \in \mathbb{R}^{d\times d}$ are weight matrices, $\boldsymbol{b}^{(\cdot)} \in \mathbb{R}^{d\times 1}$ is a bias vector, and $\boldsymbol{x}_t \in \mathbb{R}^{d\times 1}$ is the word embedding of the t-th input word. $\sigma(\cdot)$ is the logistic function, and the operator $\odot$ denotes element-wise multiplication between vectors.

2.2 Attentional Encoder-Decoder Model

The NMT models with an attention mechanism (Bahdanau et al., 2015; Luong et al., 2015a) have been proposed to softly align each decoder state with the encoder states. The attention mechanism allows the NMT models to explicitly quantify how much each encoder state contributes to the word prediction at each time step.

In the attentional NMT model in Luong et al. (2015a), at the j-th step of the decoder process, the attention score $\boldsymbol{\alpha}_j(i)$ between the i-th source hidden unit $\boldsymbol{h}_i$ and the j-th target hidden unit $\boldsymbol{s}_j$ is calculated as follows:

$$\boldsymbol{\alpha}_j(i) \;=\; \frac{\exp(\boldsymbol{h}_i \cdot \boldsymbol{s}_j)}{\sum_{k=1}^{n}\exp(\boldsymbol{h}_k \cdot \boldsymbol{s}_j)}, \tag{5}$$

where $\boldsymbol{h}_i \cdot \boldsymbol{s}_j$ is the inner product of $\boldsymbol{h}_i$ and $\boldsymbol{s}_j$, which is used to directly calculate the similarity score between $\boldsymbol{h}_i$ and $\boldsymbol{s}_j$. The j-th context vector

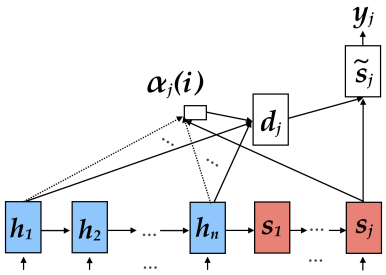

Figure 2: Attentional Encoder-Decoder model.

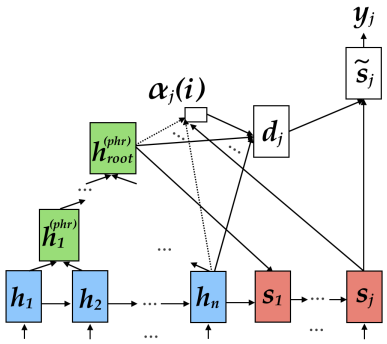

Figure 3: Proposed model: Tree-to-sequence attentional NMT model.

$\boldsymbol{d}_j$ is calculated as the summation vector weighted by $\boldsymbol{\alpha}_j(i)$:

$$\boldsymbol{d}_j = \sum_{i=1}^{n} \boldsymbol{\alpha}_j(i)\boldsymbol{h}_i. \quad (6)$$

To incorporate the attention mechanism into the decoding process, the context vector is used for the the j-th word prediction by putting an additional hidden layer $\tilde{\boldsymbol{s}}_j$:

$$\tilde{\boldsymbol{s}}_j = \tanh(\boldsymbol{W}_d[\boldsymbol{s}_j;\ \boldsymbol{d}_j] + \boldsymbol{b}_d), \quad (7)$$

where $[\boldsymbol{s}_j; \boldsymbol{d}_j] \in \mathbb{R}^{2d\times 1}$ is the concatenation of $\boldsymbol{s}_j$ and $\boldsymbol{d}_j$, and $\boldsymbol{W}_d \in \mathbb{R}^{d\times 2d}$ and $\boldsymbol{b}_d \in \mathbb{R}^{d\times 1}$ are a weight matrix and a bias vector, respectively. The model predicts the j-th word by using the softmax function:

$$p(y_j|\boldsymbol{y}_{<j}, \boldsymbol{x}) = \text{softmax}(\boldsymbol{W}_s\tilde{\boldsymbol{s}}_j + \boldsymbol{b}_s), \quad (8)$$

where $\boldsymbol{W}_s \in \mathbb{R}^{|V|\times d}$ and $\boldsymbol{b}_s \in \mathbb{R}^{|V|\times 1}$ are a weight matrix and a bias vector, respectively. $|V|$ stands for the size of the vocabulary of the target language. Figure 2 shows an example of the NMT model with the attention mechanism.

2.3 Objective Function of NMT Models

The objective function to train the NMT models is the sum of the log-likelihoods of the translation pairs in the training data:

$$J(\boldsymbol{\theta}) = \frac{1}{|\mathcal{D}|}\sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{D}} \log p(\boldsymbol{y}|\boldsymbol{x}), \quad (9)$$

where $\mathcal{D}$ denotes a set of parallel sentence pairs. The model parameters $\boldsymbol{\theta}$ are learned through Stochastic Gradient Descent (SGD).

3 Attentional Tree-to-Sequence Model

3.1 Tree-based Encoder + Sequential Encoder

The exsiting NMT models treat a sentence as a sequence of words and neglect the structure of a sentence inherent in language. We propose a novel tree-based encoder in order to explicitly take the syntactic structure into consideration in the NMT model. We focus on the phrase structure of a sentence and construct a sentence vector from phrase vectors in a bottom-up fashion. The sentence vector in the tree-based encoder is therefore composed of the structural information rather than the sequential data. Figure 3 shows our proposed model, which we call a *tree-to-sequence attentional NMT model*.

In Head-driven Phrase Structure Grammar (HPSG) (Sag et al., 2003), a sentence is composed of multiple phrase units and represented as a binary tree as shown in Figure 1. Following the structure of the sentence, we construct a tree-based encoder on top of the standard sequential encoder. The k-th parent hidden unit $\boldsymbol{h}_k^{(phr)}$ for the k-th phrase is calculated using the left and right child hidden units $\boldsymbol{h}_k^l$ and $\boldsymbol{h}_k^r$ as follows:

$$\boldsymbol{h}_k^{(phr)} = f_{tree}(\boldsymbol{h}_k^l, \boldsymbol{h}_k^r), \quad (10)$$

where f_{tree} is a non-linear function.

We construct a tree-based encoder with LSTM units, where each node in the binary tree is represented with an LSTM unit. When initializing the leaf units of the tree-based encoder, we employ the sequential LSTM units described in Section 2.1. Each non-leaf node is also represented with an LSTM unit, and we employ Tree-LSTM (Tai et al., 2015) to calculate the LSTM unit of the parent node which has two child LSTM units. The hidden unit $\boldsymbol{h}_k^{(phr)} \in \mathbb{R}^{d\times 1}$ and the memory cell $\boldsymbol{c}_k^{(phr)} \in \mathbb{R}^{d\times 1}$ for the k-th parent node are calcu-

lated as follows:

$$\begin{aligned}
\boldsymbol{i}_k &= \sigma(\boldsymbol{U}_l^{(i)}\boldsymbol{h}_k^l + \boldsymbol{U}_r^{(i)}\boldsymbol{h}_k^r + \boldsymbol{b}^{(i)}),\\
\boldsymbol{f}_k^l &= \sigma(\boldsymbol{U}_l^{(f_l)}\boldsymbol{h}_k^l + \boldsymbol{U}_r^{(f_l)}\boldsymbol{h}_k^r + \boldsymbol{b}^{(f_l)}),\\
\boldsymbol{f}_k^r &= \sigma(\boldsymbol{U}_l^{(f_r)}\boldsymbol{h}_k^l + \boldsymbol{U}_r^{(f_r)}\boldsymbol{h}_k^r + \boldsymbol{b}^{(f_r)}),\\
\boldsymbol{o}_k &= \sigma(\boldsymbol{U}_l^{(o)}\boldsymbol{h}_k^l + \boldsymbol{U}_r^{(o)}\boldsymbol{h}_k^r + \boldsymbol{b}^{(o)}),\\
\tilde{\boldsymbol{c}}_k &= \tanh(\boldsymbol{U}_l^{(\tilde{c})}\boldsymbol{h}_k^l + \boldsymbol{U}_r^{(\tilde{c})}\boldsymbol{h}_k^r + \boldsymbol{b}^{(\tilde{c})}),\\
\boldsymbol{c}_k^{(phr)} &= \boldsymbol{i}_k \odot \tilde{\boldsymbol{c}}_k + \boldsymbol{f}_k^l \odot \boldsymbol{c}_k^l + \boldsymbol{f}_k^r \odot \boldsymbol{c}_k^r,\\
\boldsymbol{h}_k^{(phr)} &= \boldsymbol{o}_k \odot \tanh(\boldsymbol{c}_k^{(phr)}), \qquad (11)
\end{aligned}$$

where $\boldsymbol{i}_k$, $\boldsymbol{f}_k^l$, $\boldsymbol{f}_k^r$, $\boldsymbol{o}_j$, $\tilde{\boldsymbol{c}}_j \in \mathbb{R}^{d\times 1}$ are an input gate, the forget gates for left and right child units, an output gate, and a state for updating the memory cell, respectively. $\boldsymbol{c}_k^l$ and $\boldsymbol{c}_k^r$ are the memory cells for the left and right child units, respectively. $\boldsymbol{U}^{(\cdot)} \in \mathbb{R}^{d\times d}$ denotes a weight matrix, and $\boldsymbol{b}^{(\cdot)} \in \mathbb{R}^{d\times 1}$ represents a bias vector.

Our proposed tree-based encoder is a natural extension of the conventional sequential encoder, since Tree-LSTM is a generalization of chain-structured LSTM (Tai et al., 2015). Our encoder differs from the original Tree-LSTM in the calculation of the LSTM units for the leaf nodes. The motivation is to construct the phrase nodes in a context-sensitive way, which, for example, allows the model to compute different representations for multiple occurrences of the same word in a sentence because the sequential LSTMs are calculated in the context of the previous units. This ability contrasts with the original Tree-LSTM, in which the leaves are composed only of the word embeddings without any contextual information.

3.2 Initial Decoder Setting

We now have two different sentence vectors: one is from the sequence encoder and the other from the tree-based encoder. As shown in Figure 3, we provide another Tree-LSTM unit which has the final sequential encoder unit ($\boldsymbol{h}_n$) and the tree-based encoder unit ($\boldsymbol{h}_{root}^{(phr)}$) as two child units and set it as the initial decoder $\boldsymbol{s}_1$ as follows:

$$\boldsymbol{s}_1 = g_{tree}(\boldsymbol{h}_n, \boldsymbol{h}_{root}^{(phr)}), \qquad (12)$$

where g_{tree} is the same function as f_{tree} with another set of Tree-LSTM parameters. This initialization allows the decoder to capture information from both the sequential data and phrase structures. Zoph and Knight (2016) proposed a similar method using a Tree-LSTM for initializing the decoder, with which they translate multiple source languages to one target language. When the syntactic parser fails to output a parse tree for a sentence, we encode the sentence with the sequential encoder by setting $\boldsymbol{h}_{root}^{(phr)} = \boldsymbol{0}$. Our proposed tree-based encoder therefore works with any sentences.

3.3 Attention Mechanism in Our Model

We adopt the attention mechanism into our tree-to-sequence model in a novel way. Our model gives attention not only to sequential hidden units but also to phrase hidden units. This attention mechanism tells us which words or phrases in the source sentence are important when the model decodes a target word. The j-th context vector $\boldsymbol{d}_j$ is composed of the sequential and phrase vectors weighted by the attention score $\boldsymbol{\alpha}_j(i)$:

$$\boldsymbol{d}_j = \sum_{i=1}^{n} \boldsymbol{\alpha}_j(i)\boldsymbol{h}_i + \sum_{i=n+1}^{2n-1} \boldsymbol{\alpha}_j(i)\boldsymbol{h}_i^{(phr)}. \qquad (13)$$

Note that a binary tree has $n-1$ phrase nodes if the tree has n leaves. We set a final decoder $\tilde{\boldsymbol{s}}_j$ in the same way as Equation (7).

In addition, we adopt the *input-feeding* method (Luong et al., 2015a) in our model, which is a method for feeding $\tilde{\boldsymbol{s}}_{j-1}$, the previous unit to predict the word y_{j-1}, into the current target hidden unit $\boldsymbol{s}_j$,

$$\boldsymbol{s}_j = f_{dec}(y_{j-1}, [\boldsymbol{s}_{j-1};\ \tilde{\boldsymbol{s}}_{j-1}]), \qquad (14)$$

where $[\boldsymbol{s}_{j-1};\ \tilde{\boldsymbol{s}}_{j-1}]$ is the concatenation of $\boldsymbol{s}_{j-1}$ and $\tilde{\boldsymbol{s}}_{j-1}$. The input-feeding approach contributes to the enrichment in the calculation of the decoder, because $\tilde{\boldsymbol{s}}_{j-1}$ is an informative unit which can be used to predict the output word as well as to be compacted with attentional context vectors. Luong et al. (2015a) showed that the input-feeding approach improves BLEU scores. We also observed the same improvement in our preliminary experiments.

3.4 Sampling-Based Approximation to the NMT Models

The biggest computational bottleneck of training the NMT models is in the calculation of the softmax layer described in Equation (8), because its computational cost increases linearly with the size of the vocabulary. The speedup technique with GPUs has proven useful for sequence-based NMT models (Sutskever et al., 2014; Luong et al.,

2015a) but it is not easily applicable when dealing with tree-structured data. In order to reduce the training cost of the NMT models at the softmax layer, we employ *BlackOut* (Ji et al., 2016), a sampling-based approximation method. BlackOut has been shown to be effective in RNN Language Models (RNNLMs) and allows a model to run reasonably fast even with a million word vocabulary with CPUs.

At each word prediction step in the training, BlackOut estimates the conditional probability in Equation (2) for the target word and K negative samples using a weighted softmax function. The negative samples are drawn from the unigram distribution raised to the power $\beta \in [0, 1]$ (Mikolov et al., 2013). The unigram distribution is estimated using the training data and β is a hyperparameter. BlackOut is closely related to Noise Contrastive Estimation (NCE) (Gutmann and Hyvärinen, 2012) and achieves better perplexity than the original softmax and NCE in RNNLMs. The advantages of Blackout over the other methods are discussed in Ji et al. (2016). Note that BlackOut can be used as the original softmax once the training is finished.

4 Experiments

4.1 Training Data

We applied the proposed model to the English-to-Japanese translation dataset of the ASPEC corpus given in WAT'15.[1] Following Zhu (2015), we extracted the first 1.5 million translation pairs from the training data. To obtain the phrase structures of the source sentences, i.e., English, we used the probabilistic HPSG parser *Enju* (Miyao and Tsujii, 2008). We used Enju only to obtain a binary phrase structure for each sentence and did not use any HPSG specific information. For the target language, i.e., Japanese, we used KyTea (Neubig et al., 2011), a Japanese segmentation tool, and performed the pre-processing steps recommended in WAT'15.[2] We then filtered out the translation pairs whose sentence lengths are longer than 50 and whose source sentences are not parsed successfully. Table 1 shows the details of the datasets used in our experiments. We carried out two experiments on a small training dataset to investigate the effectiveness of our proposed model and on a large training dataset to compare our proposed methods with the other systems.

	Sentences	Parsed successfully
Train	1,346,946	1,346,946
Development	1,790	1,789
Test	1,812	1,811

Table 1: Dataset in ASPEC corpus.

	Train (small)	Train (large)
sentence pairs	100,000	1,346,946
$\|V\|$ in English	25,478	87,796
$\|V\|$ in Japanese	23,532	65,680

Table 2: Training dataset and the vocabulary sizes.

The vocabulary consists of words observed in the training data more than or equal to N times. We set $N = 2$ for the small training dataset and $N = 5$ for the large training dataset. The out-of-vocabulary words are mapped to the special token "*unk*". We added another special symbol "*eos*" for both languages and inserted it at the end of all the sentences. Table 2 shows the details of each training dataset and its corresponding vocabulary size.

4.2 Training Details

The biases, softmax weights, and BlackOut weights are initialized with zeros. The hyperparameter β of BlackOut is set to 0.4 as recommended by Ji et al. (2016). Following Józefowicz et al. (2015), we initialize the forget gate biases of LSTM and Tree-LSTM with 1.0. The remaining model parameters in the NMT models in our experiments are uniformly initialized in $[-0.1, 0.1]$. The model parameters are optimized by plain SGD with the mini-batch size of 128. The initial learning rate of SGD is 1.0. We halve the learning rate when the development loss becomes worse. Gradient norms are clipped to 3.0 to avoid exploding gradient problems (Pascanu et al., 2012).

Small Training Dataset We conduct experiments with our proposed model and the sequential attentional NMT model with the input-feeding approach. Each model has 256-dimensional hidden units and word embeddings. The number of negative samples K of BlackOut is set to 500 or 2000.

[1] http://orchid.kuee.kyoto-u.ac.jp/WAT/WAT2015/index.html

[2] http://orchid.kuee.kyoto-u.ac.jp/WAT/WAT2015/baseline/dataPreparationJE.html

Large Training Dataset Our proposed model has 512-dimensional word embeddings and d-dimensional hidden units ($d \in \{512, 768, 1024\}$). K is set to 2500.

Our code[3] is implemented in C++ using the Eigen library,[4] a template library for linear algebra, and we run all of the experiments on multi-core CPUs.[5] It takes about a week to train a model on the large training dataset with $d = 512$.

4.3 Decoding process

We use beam search to decode a target sentence for an input sentence $\boldsymbol{x}$ and calculate the sum of the log-likelihoods of the target sentence $\boldsymbol{y} = (y_1, \cdots, y_m)$ as the beam score:

$$score(\boldsymbol{x}, \boldsymbol{y}) = \sum_{j=1}^{m} \log p(y_j | \boldsymbol{y}_{<j}, \boldsymbol{x}). \quad (15)$$

Decoding in the NMT models is a generative process and depends on the target language model given a source sentence. The score becomes smaller as the target sentence becomes longer, and thus the simple beam search does not work well when decoding a long sentence (Cho et al., 2014a; Pouget-Abadie et al., 2014). In our preliminary experiments, the beam search with the length normalization in Cho et al. (2014a) was not effective in English-to-Japanese translation. The method in Pouget-Abadie et al. (2014) needs to estimate the conditional probability $p(\boldsymbol{x}|\boldsymbol{y})$ using another NMT model and thus is not suitable for our work.

In this paper, we use statistics on sentence lengths in beam search. Assuming that the length of a target sentence correlates with the length of a source sentence, we redefine the score of each candidate as follows:

$$score(\boldsymbol{x}, \boldsymbol{y}) = L_{\boldsymbol{x},\boldsymbol{y}} + \sum_{j=1}^{m} \log p(y_j | \boldsymbol{y}_{<j}, \boldsymbol{x}), \quad (16)$$

$$L_{\boldsymbol{x},\boldsymbol{y}} = \log p(len(\boldsymbol{y}) | len(\boldsymbol{x})), \quad (17)$$

where $L_{\boldsymbol{x},\boldsymbol{y}}$ is the penalty for the conditional probability of the target sentence length $len(\boldsymbol{y})$ given the source sentence length $len(\boldsymbol{x})$. It allows the model to decode a sentence by considering the length of the target sentence. In our experiments, we computed the conditional probability $p(len(\boldsymbol{y})|len(\boldsymbol{x}))$ in advance following the statistics collected in the first one million pairs of the training dataset. We allow the decoder to generate up to 100 words.

4.4 Evaluation

We evaluated the models by two automatic evaluation metrics, RIBES (Isozaki et al., 2010) and BLEU (Papineni et al., 2002) following WAT'15. We used the KyTea-based evaluation script for the translation results.[6] The RIBES score is a metric based on rank correlation coefficients with word precision, and the BLEU score is based on n-gram word precision and a Brevity Penalty (BP) for outputs shorter than the references. RIBES is known to have stronger correlation with human judgements than BLEU in translation between English and Japanese as discussed in Isozaki et al. (2010).

5 Results and Discussion

5.1 Small Training Dataset

Table 3 shows the perplexity, BLEU, RIBES, and the training time on the development data with the Attentional NMT (ANMT) models trained on the small dataset. We conducted the experiments with our proposed method using BlackOut and softmax. We decoded a translation by our proposed beam search with a beam size of 20.

As shown in Table 3, the results of our proposed model with BlackOut improve as the number of negative samples K increases. Although the result of softmax is better than those of BlackOut ($K = 500, 2000$), the training time of softmax per epoch is about three times longer than that of BlackOut even with the small dataset.

As to the results of the ANMT model, reversing the word order in the input sentence decreases the scores in English-to-Japanese translation, which contrasts with the results of other language pairs reported in previous work (Sutskever et al., 2014; Luong et al., 2015a). By taking syntactic information into consideration, our proposed model improves the scores, compared to the sequential attention-based approach.

We found that better perplexity does not always lead to better translation scores with BlackOut as shown in Table 3. One of the possible reasons is that BlackOut distorts the target word distribution

	RIBES	BLEU
Without sequential LSTMs	69.4	19.5
With sequential LSTMs	**72.3**	**20.0**

Table 5: Effects of the sequential LSTMs in our proposed tree-based encoder on the development data.

by the modified unigram-based negative sampling where frequent words can be treated as the negative samples multiple times at each training step.

Effects of the proposed beam search Table 4 shows the results on the development data of proposed method with BlackOut ($K = 2000$) by the simple beam search and our proposed beam search. The beam size is set to 6 or 20 in the simple beam search, and to 20 in our proposed search. We can see that our proposed search outperforms the simple beam search in both scores. Unlike RIBES, the BLEU score is sensitive to the beam size and becomes lower as the beam size increases. We found that the BP had a relatively large impact on the BLEU score in the simple beam search as the beam size increased. Our search method works better than the simple beam search by keeping long sentences in the candidates with a large beam size.

Effects of the sequential LSTM units We also investigated the effects of the sequential LSTMs at the leaf nodes in our proposed tree-based encoder. Table 5 shows the result on the development data of our proposed encoder and that of an attentional tree-based encoder without sequential LSTMs with BlackOut ($K = 2000$).[7] The results show that our proposed encoder considerably outperforms the encoder without sequential LSTMs, suggesting that the sequential LSTMs at the leaf nodes contribute to the context-aware construction of the phrase representations in the tree.

5.2 Large Training Dataset

Table 6 shows the experimental results of RIBES and BLEU scores achieved by the trained models on the large dataset. We decoded the target sentences by our proposed beam search with the beam size of 20.[8] The results of the other systems are the ones reported in Nakazawa et al. (2015).

All of our proposed models show similar performance regardless of the value of d. Our ensemble model is composed of the three models with $d = 512, 768$, and 1024, and it shows the best RIBES score among all systems.[9]

As for the time required for training, our implementation needs about one day to perform one epoch on the large training dataset with $d = 512$. It would take about 11 days without using the BlackOut sampling.

Comparison with the NMT models The model of Zhu (2015) is an ANMT model (Bahdanau et al., 2015) with a bi-directional LSTM encoder, and uses 1024-dimensional hidden units and 1000-

[7] For this evaluation, we used the 1,789 sentences that were successfully parsed by Enju because the encoder without sequential LSTMs always requires a parse tree.

[8] We found two sentences which ends without *eos* with $d = 512$, and then we decoded it again with the beam size of 1000 following Zhu (2015).

[9] Our ensemble model yields a METEOR (Denkowski and Lavie, 2014) score of 53.6 with language option "-l other".

Model	RIBES	BLEU
Proposed model ($d = 512$)	81.46	34.36
Proposed model ($d = 768$)	81.89	34.78
Proposed model ($d = 1024$)	81.58	34.87
Ensemble of the above three models	**82.45**	36.95
ANMT with LSTMs (Zhu, 2015)	79.70	32.19
+ Ensemble, *unk* replacement	80.27	34.19
+ System combination, 3 pre-reordered ensembles	80.91	36.21
ANMT with GRUs (Lee et al., 2015) + character-based decoding, Begin/Inside representation	81.15	35.75
PB baseline	69.19	29.80
HPB baseline	74.70	32.56
T2S baseline	75.80	33.44
T2S model (Neubig and Duh, 2014)	79.65	36.58
+ ANMT Rerank (Neubig et al., 2015)	81.38	38.17

Table 6: Evaluation results on the test data.

dimensional word embeddings. The model of Lee et al. (2015) is also an ANMT model with a bi-directional Gated Recurrent Unit (GRU) encoder, and uses 1000-dimensional hidden units and 200-dimensional word embeddings. Both models are sequential ANMT models. Our single proposed model with $d = 512$ outperforms the best result of Zhu (2015)'s end-to-end NMT model with ensemble and unknown replacement by $+1.19$ RIBES and by $+0.17$ BLEU scores. Our ensemble model shows better performance, in both RIBES and BLEU scores, than that of Zhu (2015)'s best system which is a hybrid of the ANMT and SMT models by $+1.54$ RIBES and by $+0.74$ BLEU scores and Lee et al. (2015)'s ANMT system with special character-based decoding by $+1.30$ RIBES and $+1.20$ BLEU scores.

Comparison with the SMT models PB, HPB and T2S are the baseline SMT systems in WAT'15: a phrase-based model, a hierarchical phrase-based model, and a tree-to-string model, respectively (Nakazawa et al., 2015). The best model in WAT'15 is Neubig et al. (2015)'s tree-to-string SMT model enhanced with reranking by ANMT using a bi-directional LSTM encoder. Our proposed end-to-end NMT model compares favorably with Neubig et al. (2015).

5.3 Qualitative Analysis

We illustrate the translations of test data by our model with $d = 512$ and several attentional relations when decoding a sentence. In Figures 4 and 5, an English sentence represented as a binary tree is translated into Japanese, and several attentional relations between English words or phrases and

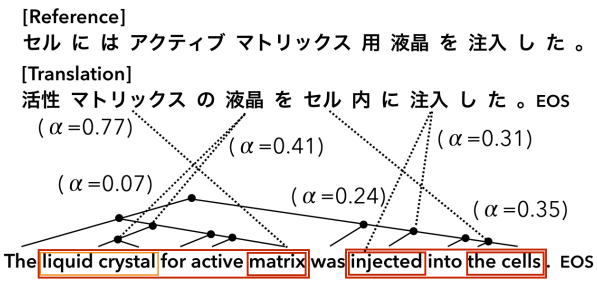

Figure 4: Translation example of a short sentence and the attentional relations by our proposed model.

Japanese word are shown with the highest attention score α. The additional attentional relations are also illustrated for comparison. We can see the target words softly aligned with source words and phrases.

In Figure 4, the Japanese word "液晶" means "liquid crystal", and it has a high attention score ($\alpha = 0.41$) with the English phrase "liquid crystal for active matrix". This is because the j-th target hidden unit $\boldsymbol{s}_j$ has the contextual information about the previous words $\boldsymbol{y}_{<j}$ including "活性 マトリックス の" ("for active matrix" in English). The Japanese word "セル" is softly aligned with the phrase "the cells" with the highest attention score ($\alpha = 0.35$). In Japanese, there is no definite article like "the" in English, and it is usually aligned with *null* described as Section 1.

In Figure 5, in the case of the Japanese word "示" ("showed" in English), the attention score with the English phrase "showed excellent performance" ($\alpha = 0.25$) is higher than that with the English word "showed" ($\alpha = 0.01$). The Japanese word "の" ("of" in English) is softly aligned with the phrase "of Si dot MOS capacitor" with the highest attention score ($\alpha = 0.30$). It is because our attention mechanism takes each previous context of the Japanese phrases "優れ た 性能" ("excellent performance" in English) and "Ｓｉ ドット ＭＯＳ コンデンサ" ("Si dot MOS capacitor" in English) into account and softly aligned the target words with the whole phrase when translating the English verb "showed" and the preposition "of". Our proposed model can thus flexibly learn the attentional relations between English and Japanese.

We observed that our model translated the word "active" into "活性", a synonym of the reference word "アクティブ". We also found similar examples in other sentences, where our model outputs

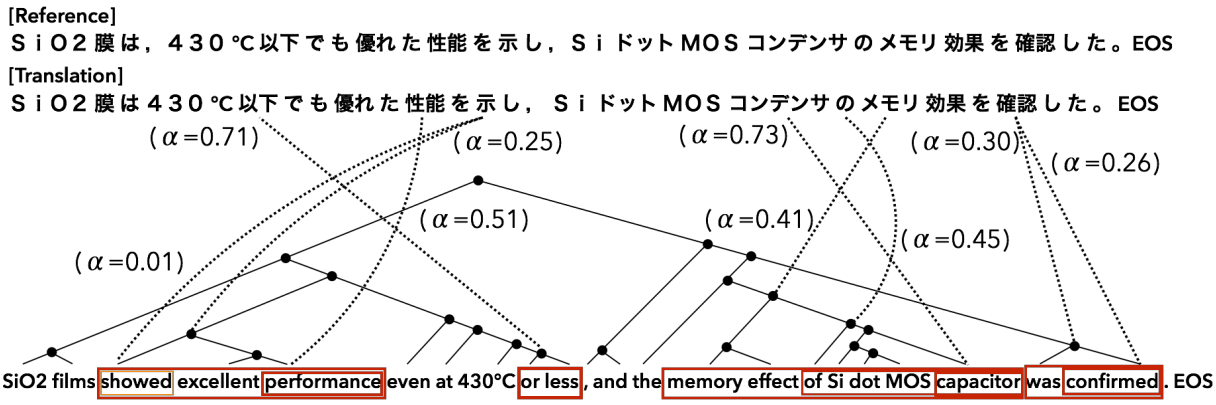

Figure 5: Translation example of a long sentence and the attentional relations by our proposed model.

synonyms of the reference words, e.g. “女” and “女性” (“female” in English) and “NASA” and “航空宇宙局” (“National Aeronautics and Space Administration” in English). These translations are penalized in terms of BLEU scores, but they do not necessarily mean that the translations were wrong. This point may be supported by the fact that the NMT models were highly evaluated in WAT’15 by crowd sourcing (Nakazawa et al., 2015).

6 Related Work

Kalchbrenner and Blunsom (2013) were the first to propose an end-to-end NMT model using Convolutional Neural Networks (CNNs) as the source encoder and using RNNs as the target decoder. The Encoder-Decoder model can be seen as an extension of their model, and it replaces the CNNs with RNNs using GRUs (Cho et al., 2014b) or LSTMs (Sutskever et al., 2014).

Sutskever et al. (2014) have shown that making the input sequences reversed is effective in a French-to-English translation task, and the technique has also proven effective in translation tasks between other European language pairs (Luong et al., 2015a). All of the NMT models mentioned above are based on sequential encoders. To incorporate structural information into the NMT models, Cho et al. (2014a) proposed to jointly learn structures inherent in source-side languages but did not report improvement of translation performance. These studies motivated us to investigate the role of syntactic structures explicitly given by existing syntactic parsers in the NMT models.

The attention mechanism (Bahdanau et al., 2015) has promoted NMT onto the next stage. It enables the NMT models to translate while aligning the target with the source. Luong et al. (2015a) refined the attention model so that it can dynamically focus on local windows rather than the entire sentence. They also proposed a more effective attentional path in the calculation of ANMT models. Subsequently, several ANMT models have been proposed (Cheng et al., 2016; Cohn et al., 2016); however, each model is based on the existing sequential attentional models and does not focus on a syntactic structure of languages.

7 Conclusion

In this paper, we propose a novel syntactic approach that extends attentional NMT models. We focus on the phrase structure of the input sentence and build a tree-based encoder following the parsed tree. Our proposed tree-based encoder is a natural extension of the sequential encoder model, where the leaf units of the tree-LSTM in the encoder can work together with the original sequential LSTM encoder. Moreover, the attention mechanism allows the tree-based encoder to align not only the input words but also input phrases with the output words. Experimental results on the WAT’15 English-to-Japanese translation dataset demonstrate that our proposed model achieves the best RIBES score and outperforms the sequential attentional NMT model.

Abstract

Coordination is an important and common syntactic construction which is not handled well by state of the art parsers. Coordinations in the Penn Treebank are missing internal structure in many cases, do not include explicit marking of the conjuncts and contain various errors and inconsistencies. In this work, we initiated manual annotation process for solving these issues. We identify the different elements in a coordination phrase and label each element with its function. We add phrase boundaries when these are missing, unify inconsistencies, and fix errors. The outcome is an extension of the PTB that includes consistent and detailed structures for coordinations. We make the coordination annotation publicly available, in hope that they will facilitate further research into coordination disambiguation. [1]

1 Introduction

The Penn Treebank (PTB) (Marcus et al., 1993) is perhaps the most commonly used resource for training and evaluating syntax-based natural language processing systems. Despite its widespread adoption and undisputed usefulness, some of the annotations in PTB are not optimal, and could be improved. The work of Vadas and Curran (2007) identified and addressed one such annotation deficiency – the lack of internal structure in base NPs. In this work we focus on the annotation of coordinating conjunctions.

Coordinating conjunctions (e.g. *"John **and** Mary"*, *"to be **or** not to be"*) are a very common syntactic construction, appearing in 38.8% of the sentences in the PTB. As noted by Hogan (2007), coordination annotation in the PTB are not consistent, include errors, and lack internal structure in many cases (Hara et al., 2009; Hogan, 2007; Shimbo and Hara, 2007). Another issue is that PTB does not mark whether a punctuation is part of the coordination or not. This was resolved by Maier et al. (2012) which annotated punctuation in the PTB .

These errors, inconsistencies, and in particular the lack of internal structural annotation turned researchers that were interested specifically in coordination disambiguation away from the PTB and towards much smaller, domain specific efforts such as the Genia Treebank (Kim et al., 2003) of biomedical texts (Hara et al., 2009; Shimbo and Hara, 2007).

In addition, we also find that the PTB annotation make it hard, and often impossible, to correctly identify the elements that are being coordinated, and tell them apart from other elements that may appear in a coordination construction. While most of the coordination phrases are simple and include only conjuncts and a coordinator, many cases include additional elements with other syntactic functions , such as markers (e.g. *"**Both** Alice and Bob"*), connectives (e.g. *"Fast and **thus** useful"*) and shared elements (e.g. *"**Bob's** principles and opinions"*) (Huddleston et al., 2002). The PTB annotations do not differentiate between these elements. For example, consider the following coordination phrases which begin with a PP:

(a) *"[in the open market]$_{PP}$, [in private transactions] or [otherwise]."*
(b) *"[According to Fred Demler]$_{PP}$, [Highland Valley has already started operating] and [Cananea is expected to do so soon]."*

Even though the first element is a conjunct only in (a), both phrases are represented with the

[1] The data is available in:
https://github.com/Jess1ca/CoordinationExtPTB

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 834–842,
Berlin, Germany, August 7-12, 2016.

marked elements as siblings.

Our goal in this work is to fix these deficiencies. We aim for an annotation in which:

- All coordination phrases are explicitly marked and are differentiated from non-coordination structures.
- Each element in the coordination structure is explicitly marked with its role within the coordination structure.
- Similar structures are assigned a consistent annotation.

We also aim to fix existing errors involving coordination, so that the resulting corpus includes as few errors as possible. On top of these objectives, we also like to stay as close as possible to the original PTB structures.

We identify the different elements that can participate in a coordination phrase, and enrich the PTB by labeling each element with its function. We add phrase boundaries when these are missing, unify inconsistencies, and fix errors. This is done based on a combination of automatic processing and manual annotation. The result is an extension of the PTB trees that include consistent and more detailed coordination structures. We release our annotation as a diff over the PTB.

The extended coordination annotation fills an important gap in wide-scale syntactic annotation of English syntax, and is a necessary first step towards research on improving coordination disambiguation.

2 Background

Coordination is a very common syntactic structure in which two or more elements are linked. An example for a coordination structure is *"Alice and Bob traveled to Mars"*. The elements (*Alice* and *Bob*) are called the *conjuncts* and *and* is called the *coordinator*. Other coordinator words include *or*, *nor* and *but*. Any grammatical function can be coordinated. For examples: *"[relatively active]$_{ADJP}$ but [unfocused]$_{ADJP}$"* ; *"[in]$_{IN}$ and [out]$_{IN}$ the market"*. While it is common for the conjuncts to be of the same syntactic category, coordination of elements with different syntactic categories are also possible (e.g. *"Alice will visit Earth [tomorrow]$_{NP}$ or [in the next decade]$_{PP}$"*).

Less common coordinations are those with non-constituent elements. These are cases such as *"equal to or higher than"*, and coordinations from the type of Argument-Cluster (e.g. *"Alice has visited 4 planets in 2014 and 3 more since then"*) and Gapping (e.g. *"Bob lives in Earth and Alice in Saturn"*) (Dowty, 1988).

2.1 Elements of Coordination Structure

While the canonical coordination cases involve conjuncts linked with a coordinator, other elements may also take part in the coordination structure: markers, connective adjectives, parentheticals, and shared arguments and modifiers. These elements are often part of the same syntactic phrase as the conjuncts, and should be taken into account in coordination structure annotation. We elaborate on the possible elements in a coordination phrase:

Shared modifiers Modifiers that are related to each of the conjuncts in the phrase. For instance, in *"Venus's density and mean temperature are very high"*, *Venus's* is a shared modifier of the conjuncts *"density"* and *"mean temperature"* [2].

Shared arguments Phrases that function as arguments for each of the conjuncts. For instance, in *"Bob cleaned and refueled the spaceship."*, *"the spaceship"* and *"Bob"* are arguments of the conjuncts *cleaned* and *refuel* [3].

Markers Determiners such as *both* and *either* that may appear at the beginning of the coordination phrase (Huddleston et al., 2002). As for example in *"Both Alice and Bob are Aliens"* and *"Either Alice or Bob will drive the spaceship"*. In addition to the cases documented by Huddleston et al, our annotation of the Penn Treebank data reveals additional markers. For examples: *"between 15 million and 20 million* ; *"first and second respectively*".

Connective adjectives Adverbs such as *so*, *yet*, *however*, *then*, etc. that commonly appear right after the coordinator (Huddleston et al., 2002). For instance *"We plan to meet in the middle of the way and then continue together"*.

Parenthetical Parenthetical remarks that may appear between the conjuncts. For examples:

[2] Here, the NP containing the coordination ("Venus's density and mean temperature") is itself an argument of "are very high".

[3] While both are shared arguments, standard syntactic analyses consider the subject (Bob) to be outside the VP containing the coordination, and the direct object (the spaceship) as a part of the VP.

"The vacation packages include hotel accommodations and, in some cases, tours"; *"Some shows just don't impress, he says, and this is one of them"*.

Consider the coordinated PP phrase in *"Alice traveled [both inside and outside the galaxy]$_{PP}$."* Here, *inside* and *outside* are the conjuncts, *both* is a marker, and *"the galaxy"* is a shared argument. A good representation of the coordination structure would allow us to identify the different elements and their associated functions. As we show below, it is often not possible to reliably extract such information from the existing PTB annotation scheme.

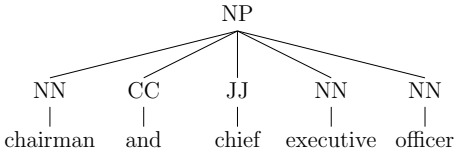
3 Coordinations in the Penn Tree Bank

We now turn to describe how coordination is handled in the PTB, focusing on the parts where we find the annotation scheme to be deficient.

There is no explicit annotation for coordination phrases Some coordinators do not introduce a coordination structure. For example, the coordinator *"and"* can be a discourse marker connecting two sentences (e.g. *"And they will even serve it themselves"*), or introduce a parenthetical (e.g. *"The Wall Street Journal is an excellent publication that I enjoy reading (and must read) daily"*). These are not explicitly differentiate in the PTB from the case where *"and"* connects between at least two elements (e.g. *"loyalty and trust"*).

NPs without internal structure The PTB guidelines (Bies et al., 1995) avoid giving any structure to NPs with nominal modifiers. Following this, 4759 NPs that include coordination were left flat, i.e. all the words in the phrase are at the same level. For example *(NP (NNP chairman) (CC and) (NP chief executive officer))* which is annotated in the PTB as:

[1]



It is impossible to reliably extract conjunct boundaries from such structures. Although work has been done for giving internal structures for flat NPs (Vadas and Curran, 2007), only 48% of the flat NP coordinators that include more than two nouns were given an internal structure, leaving 1744 cases of flat NPs with ambiguous conjunct boundaries.

Coordination parts are not categorized Coordination phrases may include markers, shared modifiers, shared arguments, connective adjectives and parentheticals. Such elements are annotated on the same level as the conjuncts[4]. This is true not only in the case of flat NPs but also in cases where the coordination phrase elements do have internal structures. For examples:

- The *Both* marker in *(NP (DT both) (NP the self) (CC and) (NP the audience))*
- The parenthetical *maybe* in *(NP (NP predictive tests) (CC and) (PRN , maybe ,) (NP new therapies))*
- The shared-modifier "the economy's" in *(NP (NP the economy's) (NNS ups) (CC and) (NNS downs))*

Automatic categorization of the phrases elements is not trivial. Consider the coordination phrase *"a phone, a job, and even into a school"*, which is annotated in the PTB where the NPs *"a phone"* and *"a job"*, the ADVP *"even"* and the PP *"into a school"* are siblings. A human reader can easily deduce that the conjuncts are *"a phone"*, *"a job"* and *"into a school"*, while *"even"* is a connective. However, for an automatic analyzer, this structure is ambiguous: NPs can be conjoined with ADVPs as well as PPs, and a coordination phrase of the form NP NP CC ADVP PP has at least two possible interpretations: (1) Coord Coord CC Conn Coord (2) Coord Coord CC Coord Shared.

Inconsistency in shared elements and markers level The PTB guidelines allows inconsistency in the case of shared ADVP pre-modifiers of VPs (e.g. *"deliberately chewed and winked"*). The pre-modifier may be annotated in the same level of the VP *((ADVP deliberately) (VP chewed and winked))* or inside it *(VP (ADVP deliberately) chewed and winked)*). In addition to this documented inconsistency, we also found markers that are inconsistently annotated in and outside the coordination phrase, such as *respectively* which is

[4] shared arguments may appear in the PTB outside the coordination phrase. For example *He* is an argument for *bought* and for *sold* in *((He) ((bought) (and) (sold) (stocks)))*.

tagged as sibling to the conjuncts in *(NP (NP Feb. 1 1990) (CC and) (NP May. 3 1990), (ADVP respectively))* and as sibling to the conjuncts parent in *(VP (VBD were) (NP 7.37% and 7.42%), (ADVP respectively))*.

Inconsistency in comparative quantity coordination Quantity phrases with a second conjunct of *more*, *less*, *so*, *two* and *up* are inconsistently tagged. Consider the following sentences: *"[50] [or] [so] projects are locked up"*, *"Street estimates of [$ 1] [or so] are low"*. The coordination phrase is similar in both the sentences but is annotated differently.

Various errors The PTB coordination structures include errors. Some are related to flat coordinations (Hogan, 2007). In addition, we found cases where a conjunct is not annotated as a complete phrase, but with two sequenced phrases. For instance, the conjuncts in the sentence *"But less than two years later, the LDP started to crumble, and dissent rose to unprecedented heights"* are *"the LDP started to crumble"* and *"dissent rose to unprecedented heights"*. In the PTB, this sentence is annotated where the first conjunct is splitted into two phrases: *"[the LDP] [started to crumble], and [dissent rose to unprecedented heights]"*.

4 Extended Coordination Annotation

The PTB annotation of coordinations makes it difficult to identify phrases containing coordination and to distinguish the conjuncts from the other parts of a coordination phrase. In addition it contains various errors, inconsistencies and coordination phrases with no internal structure. We propose an improved representation which aims to solve these problems, while keeping the deviation from the original PTB trees to a minimum.

4.1 Explicit Function Marking

We add function labels to non-terminal symbols of nodes participating in coordination structures. The function labels are indicated by appending a -XXX suffix to the non-terminal symbol, where the XXX mark the function of the node. Phrases containing a coordination are marked with a CCP label. Nodes directly dominated by a CCP node are assigned one of the following labels according to their function: *CC* for coordinators, *CONJ* for conjuncts, *MARK* for markers[5], *CONN* for connectives and parentheticals, and *SHARED* for shared modifiers/arguments. For shared elements, we deal only with those that are inside the coordination phrase. We do not assign function labels to punctuation symbols and empty elements. For example, our annotation for the sentence *"... he observed among his fellow students and, more important, among his officers and instructors ..."* is:

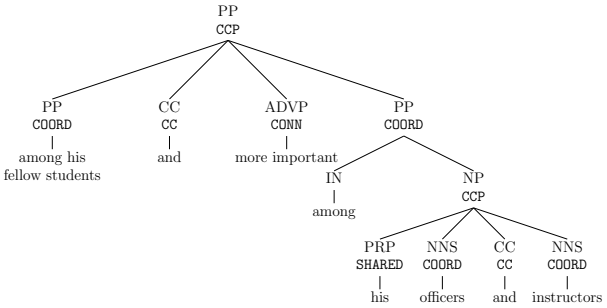


Table 1 summarizes the number of labels for each type in the enhanced version of the Penn Treebank.

Function label	#
CC	24,572
CCP	24,450
COORD	52,512
SHARED	3372
CONN	526
MARK	522

Table 1: The number of labels that were added to the Penn Treebank by type.

4.2 Changes in Tree Structure

As a guiding principle, we try not to change the structure of the original PTB trees. The exceptions to this rule are cases where the structure is changed to provide internal structure when it is missing, as well as when fixing systematic inconsistencies and occasional errors.

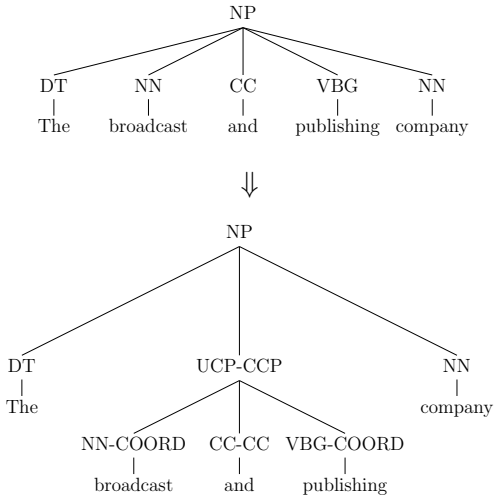
1. In flat coordination structures which include elements with more than one word, we add brackets to delimit the element spans. For instance, in the flat NP in [1] we add brackets to delimit the conjunct *"chief executive officer"*. The full phrase

[5] *both*, *either*, *between*, *first*, *neither*, *not*, *not only*, *respectively* and *together*

structure is: *(NP-CCP (NN-COORD chairman) (CC-CC and) (NP-COORD chief executive officer))*.

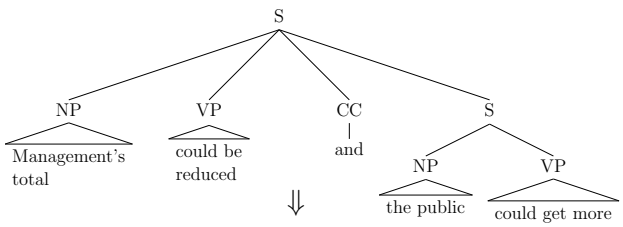
2. Comparative quantity phrases (*"5 dollars or less"*) are inconsistently analyzed in the PTB. When needed, we add an extra bracket with a QP label so they are consistently analyzed as *"5 dollars [or less]$_{QP}$"*. Note that we do not consider these cases as coordination phrases.

3. We add brackets to delimit the coordination phrase in flat cases that include coordination between modifiers while the head is annotated in the same phrase:



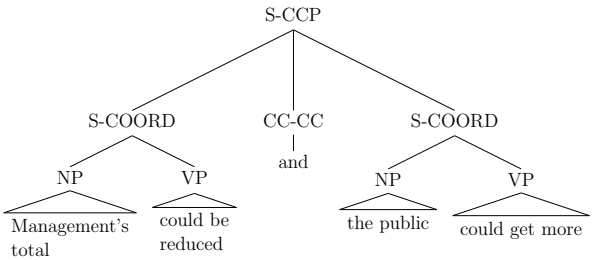
company, which is the head of the phrase, is originally annotated at the same level as the conjuncts *broadcast* and *publishing*, and the determiner *the*. In such cases, the determiner and modifiers are related to the head which is not part of the coordination phrase, requiring the extra bracketing level to delimit the coordination. This is in contrast to the case of coordination between verbs (e.g *"Bob (VP cleaned and refueled the spaceship)"*), where the non coordinated elements (*"the spaceship"*) are shared.

4. When a conjunct is split into two phrases or more due to an error, we add extra brackets to delimit the conjunct as a complete phrase:



Type	#
(1) Flat structures	1872
(2) Comparative quantity phrases	52
(3) Coordination between modifiers	1264
(4) Coordination with errors	213
(5) ADVP inconsistency	206

Table 2: The number of subtrees in the Penn Treebank that were changed in our annotation by type.



5. We consolidate cases where markers and ADVP pre-modifiers are annotated outside the coordination phrase, so they are consistently annotated inside the coordination phrase.

Table 2 summarizes the numbers and types of subtrees that receive a new tree structure in the enhanced version of the Penn Treebank.

5 The Annotation Process

Some of the changes can be done automatically, while other require human judgment. Our annotation procedure combines automatic rules and manual annotation that was performed by a dedicated annotator that was trained for this purpose.

5.1 Explicit marking of coordination phrases

We automatically annotate coordination phrases with a CCP function label. We consider a phrase as coordination phrase if it includes a coordinator and at least one phrase on each side of the coordinator, unlike coordinators that function as discourse markers or introduce parentheticals, which appear as the first element in the phrase.

5.2 Assigning internal structure to flat coordinations

Flat coordinations that include only a coordinator and two conjuncts (e.g. *(NP (NNP Poland) (CC and) (NNP Hungary))*) are trivial and are left with the same structure. For the rest of the flat coordinations (3498 cases), we manually annotated the elements spans. For example, given the flat

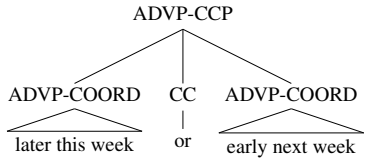
NP: *"[General]$_{NNP}$ [Electric]$_{NNP}$ [Co.]$_{NNP}$ [executives]$_{NNS}$ [and]$_{CC}$ [lawyers]$_{NNS}$"*. The annotator is expected to provide the analysis: *"[General Electric Co.] [executives] [and] [lawyers]"*. We then add brackets around multi-token elements (e.g. *"General Electric Co."*), and set the label according the syntactic structure. The annotation was done while ignoring inner structures that were given in the NP-Bracketing extension of Vadas and Curran (2007). We compare agreement with their annotations in the next section.

To handle cases such as in 4.2(3), where the coordination is between modifiers of a head which is annotated in the PTB on the same level of the conjuncts, we first identify potential candidate phrases of this type by looking for coordination phrases where the last element was not tagged by the annotator as a conjunct. Out of this set, we remove cases where we can reliably identify the non-conjunct element as a marker. For the rest of the cases, we distinguish between NP phrases and non-NP phrases. For NP phrases, we automatically add extra brackets to delimit the coordination phrase span so that it includes only the coordinated modifiers. For the rest of the phrases we found that an such automatic procedure was not feasible (consider the ADVP phrases: *(ADVP (RBR farther) (CC and) (RBR farther) (RB apart))* ; *(ADVP (RB up) (CC and) (RB down) (NP (NNP Florida)))*. The first phrase head is *apart* while in the second phrase, *Florida* is a complement). We manually annotated the coordination phrase boundary in these cases.

When adding an extra tree level in this cases, we set its syntactic label to UCP when the conjuncts are from different types and same as the conjuncts label when the conjuncts are from the same type.[6]

5.3 Annotating roles within coordination phrases

Cases where there are only a coordinator and two siblings in the coordinated phrase are trivial to automatically annotate, marking both siblings as conjuncts:



To categorize the phrase elements for the rest of the coordination phrases, we first manually marked the conjuncts in the sentence (for flat structures, the conjuncts were already annotated in the internal structure annotation phase). The annotator was given a sentence where the coordinator and the coordination phrase boundaries are marked. For example "`Coke has been able to improve (bottlers' efficiency and production, {and} in some cases, marketing)`". The annotation task was to mark the conjuncts.[7] We automatically concluded the types of the other elements according to their relative position – elements before or after the conjuncts are categorized as markers/shared, while an element between conjuncts is a connective or the coordinator itself.

Mismatches with the PTB phrase boundaries In 5% of the cases of coordination with inner structure, a conjunct span as it was annotated by our annotator was not consistent with the elements spans in the PTB. For example, the annotator provided the following annotation: "`(The [economic loss], [jobs lost], [anguish],[frustration] {and} [humiliation]) are beyond measure`", treating the determiner "The" as a shared modifier. In contrast, the PTB analysis considers "The" as part of the first conjunct ("`[The economic loss]`").

The vast majority of the mismatches were on the point of a specific word such as *the* (as demonstrated in the above example), *to*, *a* and punctuation symbols. In a small number of cases the mismatch was because of an ambiguity. For example, in "`The declaration immediately made the counties eligible for (temporary housing, grants {and} low-cost loans to cover uninsured property losses)`" the annotator marked *"temporary housing"*, *"grants"*, and *"low-cost loans"* as conjuncts (leaving *"to cover uninsured property loss"* as a shared

[6]When the conjuncts are in POS level, a corresponding syntactic label is set. For example: ***(NP-CCP (NN-COORD head) (CC-CC and) (NNS-COORD shoulders))***

[7]The coordination phrase boundaries were taken from the PTB annotations and were used to focus the annotators attention, rather than to restrict the annotation. The annotators were allowed to override them if they thought they were erronous. We did not encounter such cases.

modifier, while the PTB annotation considers *"to cover..."* as part of the last conjunct. Following our desiderata of minimizing changes to existing tree structures, in a case of a mismatch we extend the conjunct spans to be consistent with the PTB phrasing (each such case was manually verified).

5.4 Handling inconsistencies and errors

We automatically recognize ADVPs that appear right before a VP coordination phrase and markers that are adjunct to a coordination phrase. We change the structure such that such ADVPs and markers appear inside the coordination phrase.

Quantity phrases that includes two conjuncts with a second conjunct of *more, less, so, two* and *up* are automatically recognized and consolidated by adding an extra level.

Errors in conjuncts span are found during the manual annotation that is done for the categorization. When the manual annotation includes a conjunct that is originally a combination of two siblings phrases, we add extra brackets and name the new level according to the syntactic structure.

6 Annotator Agreement

We evaluate the resulting corpus with inter-annotators agreement for coordination phrases with inner structure as well as agreement with the flat conjuncts that were annotated in the NP bracketing annotation effort of Vadas and Curran (2007).

6.1 Inter-annotator agreement

To test the inter-annotator agreement, we were assisted with an additional linguist who annotated 1000 out of 7823 coordination phrases with inner structure. We measured the number of coordination phrases where the spans are inconsistent at least in one conjunct. The annotators originally agreed in 92.8% of the sentences. After revision, the agreement increased to 98.1%. The disagreements occurred in semantically ambiguous cases. For instance, *"potato salad, baked beans and pudding, plus coffee or iced tea"* was tagged differently by the 2 annotators. One considered *"pudding"* as the last conjunct and the other marked *"pudding, plus coffee or iced tea"*.

6.2 Agreement with NP Bracketing for flat coordinations

The NP Bracketing extension of Vadas and Curran (2007) includes inner structures for flat NP phrases in the PTB, that are given an internal structure using the NML tag. For instance, in *(NP (NNP Air) (NNP Force) (NN contract))*, *"Air Force"* is considered as an independent entity and thus is delimited with the NML tag: *(NP (NML (NNP Air) (NNP Force)) (NN contract))*.

As mentioned, 48% (1655 sentences) of the NP flat coordination were disambiguated in this effort.[8] For these, the agreement on the conjuncts spans with the way they were marked by our annotators is 88%. The disagreements were in cases where a modifier is ambiguous. For examples consider *"luxury"* in *"The luxury airline and casino company"*, *"scientific"* in *"scientific institutions or researchers"* and *"Japanese"* in *"some Japanese government officials and businessmen"*. In cases of disagreement we followed our annotators decisions.[9]

	R	P	F1

PTB + NPB + CCP	90.83	91.18	91.01

Table 3: The parser results on section 22.

7 Experiments

We evaluate the impact of the new annotation on the PTB parsing accuracy. We use the state-of-the-art Berkeley parser (Petrov et al., 2006), and compare the original PTB annotations (including Vadas and Curran's base-NP bracketing – **PTB+NPB**) to the coordination annotations in this work (**PTB+NPB+CCP**). We use sections 2-21 for training, and report accuracies on the traditional dev set (section 22). The parse trees are scored using EVALB (Sekine and Collins, 1997).

Structural Changes We start by considering how the changes in tree structures affect the parser performance. We compared the parsing performance when trained and tested on PTB+NPB, to the parsing performance when trained and tested on PTB+NPB+CCP. The new function labels were ignored in both training and testing. The results

[8] We consider a flat NP coordination as disambiguated if it includes a coordinator and two other elements, i.e.: *(NML (NML (NN eye) (NN care)) (CC and) (NML (NN skin) (NN care)))* ; *(NML (NN buy) (CC or) (NN sell))*.

[9] A by-product of this process is a list of ambiguous modifier attachment cases, which can be used for future research on coordination disambiguation, for example in designing error metrics that take such annotator disagreements into account.

Gold \ Pred	CC	CCP	COORD	MARK	SHARED	CONN	None	Err
CC	849					1	5	
CCP		552	1				91	205
COORD		3	1405		2		184	200
MARK				9			2	1
SHARED	1				29		85	3
CONN						1	4	2
None	4	124	113	4	26	14		

Table 4: Confusion-matrix over the predicted function labels. **None** indicate no function label (a constituent which is not directly inside a CCP phrase). **Err** indicate cases in which the gold span was not predicted by the parser.

are presented in Table 3. Parsing accuracy on the coordination-enhanced corpus is higher than on the original trees. However, the numbers are not strictly comparable, as the test sets contain trees with somewhat different number of constituents. To get a fairer comparison, we also evaluate the parsers on the subset of trees in section 22 whose structures did not change. We check two conditions: trees that include coordination, and trees that do not include coordination. Here, we see a small drop in parsing accuracy when using the new annotation. When trained and tested on PTB+NPB+CCP, the parser results are slightly decreased compared to PTB+NPB – from 89.89% F1 to 89.4% F1 for trees with coordination and from 91.78% F1 to 91.75% F1 for trees without coordination. However, the drop is small and it is clear that the changes did not make the corpus substantially harder to parse. We also note that the parsing results for trees including coordinations are lower than those for trees without coordination, highlighting the challenge in parsing coordination structures.

Function Labels How good is the parser in predicting the function labels, distinguishing between conjuncts, markers, connectives and shared modifiers? When we train and test the parser on trees that include the function labels, we see a rather large drop in accuracy: from 89.89% F1 (for trees that include a coordination) to 85.27% F1. A closer look reveals that a large part of this drop is superficial: taking function labels into account cause errors in coordination scope to be punished multiple times.[10] When we train the parser with function labels but ignore them at evaluation time, the results climb back up to 87.45% F1. Furthermore, looking at coordination phrases whose structure was perfectly predicted (65.09% of the cases), the parser assigned the correct function label for all the coordination parts in 98.91% of the cases. The combined results suggest that while the parser is reasonably effective at assigning the correct function labels, there is still work to be done on this form of disambiguation.

The availability of function labels annotation allows us to take a finer-grained look at the parsing behavior on coordination. Table 4 lists the parser assigned labels against the gold labels. Common cases of error are (1) conjuncts identification – where 200 out of 1794 gold conjuncts were assigned an incorrect span and 113 non-conjunct spans were predicted as participating as conjuncts in a coordination phrase; and (2) Shared elements identification, where 74.57% of the gold shared elements were analyzed as either out of the coordination phrase or as part of the last coordinates. These numbers suggest possible areas of future research with respect to coordination disambiguation which are likely to provide high gains.

8 Conclusions

Coordination is a frequent and important syntactic phenomena, that pose a great challenge to automatic syntactic annotation. Unfortunately, the current state of coordination annotation in the PTB is lacking. We present a version of the PTB with improved annotation for coordination structure. The

[10] Consider the gold structure (NP (NP-CCP (DT-MARK a) (NP-COORD b) (CC and) (NP-COORD c) (PP-SHARED d))) and the incorrect prediction (NP (DT a) (NP-CCP (NP-COORD b) (CC and) (NP-COORD c)) (PP d)). When taking only the syntactic labels into account there is only the mistake of the coordination span. When taking the coordination roles into account, there are two additional mistakes – the missing labels for a and d.

new annotation adds structure to the previously flat NPs, unifies inconsistencies, fix errors, and marks the role of different participants in the coordination structure with respect to the coordination. We make our annotation available to the NLP community. This resource is a necessary first step towards better disambiguation of coordination structures in syntactic parsers.

Abstract

User traits disclosed through written text, such as age and gender, can be used to personalize applications such as recommender systems or conversational agents. However, human perception of these traits is not perfectly aligned with reality. In this paper, we conduct a large-scale crowdsourcing experiment on guessing age and gender from tweets. We systematically analyze the quality and possible biases of these predictions. We identify the textual cues which lead to miss-assessments of traits or make annotators more or less confident in their choice. Our study demonstrates that differences between real and perceived traits are noteworthy and elucidates inaccurately used stereotypes in human perception.

1 Introduction

There are notable differences between actual user traits and their perception by others (John and Robins, 1994; Kobrynowicz and Branscombe, 1997). Assessments of the perceived traits are dependent, for example, on the interpretation skills of a judge (Kenny and Albright, 1987) and the ability of users to deliberately adjust their behavior to the way they intend to be perceived e.g., for following a social goal (Kanellakos, 2002). People typically use stereotypes – a set of beliefs, generalizations, and associations about a social group – to make judgements about others. The discrepancy between stereotypes and actual group differences is an important topic in psychological research (Eagly, 1995; Dovidio et al., 1996; John and Robins, 1994; Kobrynowicz and Branscombe, 1997). Such differences are likely reflected through one's writing.

With the Internet a substantial part of daily life, users leave enough footprints which allow algorithms to learn a range of individual traits, some with even higher accuracy than the users' own family (Youyou et al., 2015). With an increase in readily available user generated content, prediction of user attributes has become more popular than ever. Researchers built learning models to infer different user traits from text, such as age (Rao et al., 2010), gender (Burger et al., 2011; Flekova and Gurevych, 2013), location (Eisenstein et al., 2010), political orientation (Volkova et al., 2014), income (Preoţiuc-Pietro et al., 2015c), socio-economic status (Lampos et al., 2016), popularity (Lampos et al., 2014), personality (Schwartz et al., 2013) or mental illnesses (De Choudhury et al., 2013; Coppersmith et al., 2014; Preoţiuc-Pietro et al., 2015a).

Prediction models are trained on large data sets with labels extracted either from user self-reports (Preoţiuc-Pietro et al., 2015b) or perceived from annotations (Volkova et al., 2015; Volkova and Bachrach, 2015). The former is useful in obtaining accurate prediction models for unknown users while the latter is more suitable in applications that interact with humans. Previous studies showed the implications of perceived individual traits to the believability and likability of autonomous agents (Bates, 1994; Loyall and Bates, 1997; Baylor and Kim, 2004).

This study aims to emphasize the differences between real user traits and how these are perceived by humans from Twitter posts. In this context, we address the following research questions:

[*] Project carried out during a research stay at the University of Pennsylvania

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 843–854,
Berlin, Germany, August 7-12, 2016.

- How accurate are people at judging traits of other users?
- Are there systematic biases humans are subject to?
- What are the implications of using human perception as a proxy for truth?
- Which textual cues lead to a false perception of the truth?
- Which textual cues make people more or less confident in their ratings?

We use age and gender as target traits for our analysis, as these are considered basic categories in person assessment (Quinn and Macrae, 2005) and are highly studied by previous research. Using a large-scale crowdsourcing experiment, we demonstrate that human annotators are generally accurate in assessing the traits of others. However, they make systematically different types of errors compared to a prediction model trained using the bag-of-words assumption. This hints at the fact that annotators over-emphasize some linguistic features based on their stereotypes. We show how this phenomenon can be leveraged to improve prediction performance and demonstrate that by replacing self-reports with perceived annotations we introduce systematic biases into our models.

In our analysis section, we directly test the accuracy of these stereotypes, as the human predictions must rely on these theories of relative differences between groups if no explicit cues are mentioned. We uncover remarkable differences between actual and perceived traits by using multiple lexical features: unigrams, clusters of words built from word embeddings and emotions expressed through posts. In our analysis of features that lead to wrong assessments we uncover that humans mostly rely on accurate stereotypes from textual cues, but sometimes over-emphasize them. For example, annotators assume that males post more than they do about sports and business, females show more joy, older users more interest in politics and younger users use more slang and are more self-referential. Similarly, we highlight the textual features which lead to higher self-reported confidence in guesses, such as the mentions of family and beauty products for gender or college and school related topics for age.

2 Related Work

Studying gender differences has been a popular psychological interest over the past decades (Gleser et al., 1959; McMillan et al., 1977). Traditional studies worked on small data sets, which sometimes led to contradictory results – (Mulac et al., 1990) cf. (Pennebaker et al., 2003). Over the past years, researchers discovered a wide range of gender differences using large collections of data from social media or books combined with more sophisticated techniques. For example, Schler et al. (2006) apply machine learning techniques to a corpus of 37,478 blogs from the Blogger platform and find differences in the topics males and females discuss. Newman et al. (2008) showed that female authors are more likely to include pronouns, verbs, references to home, family, friends and to various emotions. Male authors use longer words, more articles, prepositions and numbers. Topical differences include males writing more about current concerns (e.g., money, leisure or sports). More recent author profiling experiments (Rangel et al., 2014; Rangel et al., 2015) revealed that gender can be well predicted from a large spectrum of textual features, ranging from paraphrase choice (Preoţiuc-Pietro et al., 2016), emotions (Volkova and Bachrach, 2016), part-of-speech (Johannsen et al., 2015) and abbreviation usage to social network metadata, web traffic (Culotta et al., 2015), apps installed (Seneviratne et al., 2015) or Facebook likes (Kosinski et al., 2013). Bamman et al. (2014) also examine individuals whose language does not match their automatically predicted gender. Most of these experiments were based on self-reported gender in social media profiles.

The relationship between age and language has also been extensively studied by both psychologists and computational linguists. Schler et al. (2006) automatically classified blogposts into three age groups based on self-reported age using features from the Linguistic Inquiry and Word Count Framework (Pennebaker et al., 2001), online slang and part-of-speech information. Rosenthal and McKeown (2011) analyzed how both stylistic and lexical cues relate to gender on blogs. On Twitter, Nguyen et al. (2013) analyzed the relationship between language use and age, modelled as a continuous variable. They found similar language usage trends for both genders, with increasing word and tweet length with age, and an increasing tendency to write more grammatically correct, standardized

text. Flekova et al. (2016) identified age specific differences in writing style and analyzed their impact beyond income. Recently, Nguyen et al. (2014) showed that age prediction is more difficult as age increases, specifically over 30 years. Hovy and Søgaard (2015) showed that the author age is a factor influencing training part-of-speech taggers.

Recent results on social media data report a performance of over 90% for gender classification and a correlation of $r \sim 0.85$ for age prediction (Sap et al., 2014). However, authors can introduce their biases in text (Recasens et al., 2013). Accurate prediction of the true user traits is important for applications such as recommender systems (Braunhofer et al., 2015) or medical diagnoses (Chattopadhyay et al., 2011). Influencing perceived traits, on the other hand, enables a whole different range of applications - for example, researchers demonstrated that the perceived demographics influence student attitude towards a tutor (Baylor and Kim, 2004; Rosenberg-Kima et al., 2008). Perception alterations do not only strive for likeability - people intentionally use linguistic nuances to express social power (Kanellakos, 2002), which can be recognized by computational means (Bramsen et al., 2011). McConnell and Fazio (1996) show how gender-marked language colors the perception of target personality characteristics – enhanced accessibility of masculine and feminine attributes brought about by frequent exposure to occupation title suffixes influences the inferences drawn about the target person.

3 Data

In this study, we focus on analyzing human perception of two user traits: gender and age. For judging, we build data sets using publicly available Twitter posts from users with known self-reported age and gender. To study gender, we use the users from Burger et al. (2011), which are mapped to their self-identified gender as mentioned in other user public profiles linked to their Twitter account. This data set consists of 67,337 users, from which we subsample 2,607 users for human assessment. The age data set consists of 826 users that self-reported their year of birth and Twitter handle as part of an online survey.

We use the Twitter API to download up to 3200 tweets from these users. These are filtered for English language using an automatic method (Lui and Baldwin, 2012) and duplicate tweets are eliminated (i.e., having the same first 6 tokens) as these are usually generated automatically by apps. Tweet URLs and @-mentions are anonymized as they may contain sensitive information or cues external to language use. For human assessment, we randomly select 100 tweets posted in the same 6 month time interval from the users where gender is known. For the users of known age we randomly select 100 tweets posted during the year 2015.

4 Experimental Setup

We use Amazon Mechanical Turk to create crowdsourcing tasks for predicting age and gender from tweets. Each HIT consists of 20 tweets randomly sampled from the pool of 100 tweets of a single user. Each user was assessed independently by 9 different annotators. Using only these tweets as cues, the annotators were asked to predict either age (integer value) or gender (forced choice binary male/female) and self-rate the confidence of their guess on a scale from 1 (not at all confident) to 5 (very confident).

Participants received a small compensation (.02$) for each rating and could repeat the task as many times as they wished, but never for the same author. They were also presented with an initial bonus (.25$) and a similar one upon completing a number of guesses. For quality control, we used a set of HITs where the user's age or gender was explicitly stated within the top 10 tweets displayed in the task. The control HIT appeared 10% of the time and all annotators missing the correct answer twice were excluded from annotation and all their HITs invalidated. A total of 28 annotators were banned from the study. Further, we limited annotator location to the US and they had to spend at least 10 seconds on each HIT before they were allowed to submit their guess.

5 Crowdsourcing Results

We first analyze the annotator performance on the gender and age prediction tasks from text. For gender, individual ratings have an overall accuracy of 75.7% (78.3% for females and 72.8% for males). The pairwise inter-annotator agreement for 9 annotators is 70.0%, Fleiss' Kappa 39.6% and Krippendorf's Alpha 39.6%, while keeping in mind that the annotators are not the same for all Twitter users. In terms of confidence, average self-rated confidence for correct guesses is $\mu = 3.47$, while average confidence for wrong guesses is $\mu = 2.84$. In total,

1083 individual annotators performed an average of $\mu = 22.3$ ratings with the standard deviation $\sigma = 32.76$ and the median of 12.

We use the majority vote as the method of label aggregation for gender prediction. The majority vote accuracy on predicting the gender of Twitter users is 85.8% with the majority class baseline being 51.9% female, a result comparable to a previous study (Nguyen et al., 2014). Table 1a presents the gender confusion matrix. Female users were more often classified into a correct class (88.3% recall for females cf. 83.5% for males). The majority of errors was caused by male users mislabeled as female. This results in higher precision on classifying male users (86.9% cf. 85.3% for females). In terms of overall self-reported confidence of the annotators, decisions on actual female users were on average more confidently rated ($\mu = 3.60$) compared to males ($\mu = 3.31$), which is in consensus with higher accuracy for females. Figure 2 shows the relationship between annotation accuracy and average confidence per Twitter users. The relationship is non-linear, with the average confidence in the 1–3 range for gender having little impact on the prediction accuracy.

For the age annotations, the correlation between predicted and real age for individual ratings is $r = 0.416$. The mean absolute error (MAE) is 7.31, while the baseline MAE obtained if predicted the sample mean real age is 8.61. The intraclass correlation coefficient between the 9 ratings is 0.367 and taking into account the fact that the annotators were different across users (Shrout and Fleiss, 1979), while the average standard deviation of the 9 user guesses for a single Twitter user is $\sigma = 5.60$. Individual rating confidence and the Mean Absolute Error (MAE) are anti-correlated with $r = -0.112$, matching the expectation that higher self-reported confidence leads to lower errors. The 691 different annotators performed on average $\mu = 10.68$ ratings with standard deviation $\sigma = 21.95$ and a median of only 4 ratings. Based on feedback, this was due to the difficulty of the age task.

In the rest of the age experiments, we consider the predicted age of a user as a mean of the 9 human guesses. Overall, the correlation between average predicted age and real age is $r = 0.631$. The MAE of the average predicted age is 6.05. MAE and average self-rated confidence by user are negatively correlated with $r = -0.21$. Figure 3 plots annotation confidence on a Twitter user level and MAE of

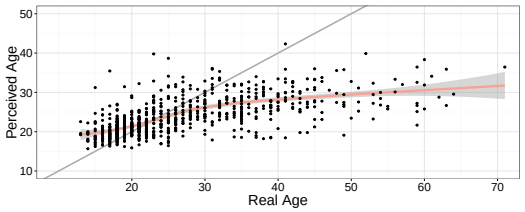

Figure 1: Real age predictions compared to average predicted age. The line shows a LOESS fit.

age guesses. Again, the relationship between confidence and MAE is non-linear, with confidences of 1–2 having similar average MAE, with the error decreasing as the average of the confidence ratings per author is higher. Figure 1 shows a scatter plot comparing real and predicted age together with a non-linear fit of the data. From this figure, we observe that annotators under-predict age, especially for older users. The correlation of MAE with real age is very high ($r = 0.824$) and the residuals are not normally distributed.

Figures 4 and 5 show the accuracy if only a subsample of the ratings is used and the labels are aggregated using majority vote for gender and using average ratings for age. For gender, we notice that accuracy abruptly increases from 1 to 3 votes and to a lesser extent from 3 to 5 votes, but the differences between 5, 7 and 9 votes are very small. Similarly, for age, MAE decreases up until using 4 guesses, where it reaches a plateau. These experiments suggest that a human perception accuracy can be sufficiently approximated using up to 5 ratings - additional annotations after this point have negligible contribution.

Finally, the individual annotator accuracy is independent on the number of users rated. For gender, the Pearson correlation between accuracy and number of ratings performed is $r = .009$ ($p = .75$) and for age the Pearson correlation between MAE and the number of ratings performed by a user is $r = -.013$ ($p = .71$). This holds even when excluding users who performed few ratings.

6 Uncovering Systematic Biases

In this section, we use the extended gender data set in order to investigate if human guesses contain systematic biases by comparing these guesses to those from a bag-of-words prediction model. We then test what is the impact of using human guesses as labels and if human ratings offer additional in-

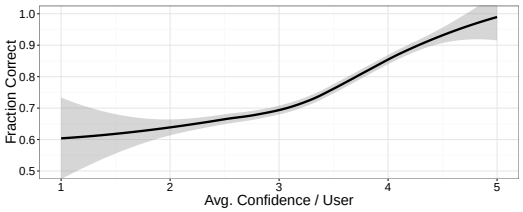

Figure 2: Gender – Fraction of correct guesses as a function of average confidence per rated Twitter user. Black line shows a LOESS fit.

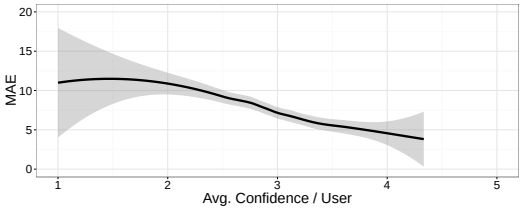

Figure 3: Age – Mean Absolute Error as a function of average confidence per rated Twitter user. Black line shows a LOESS fit.

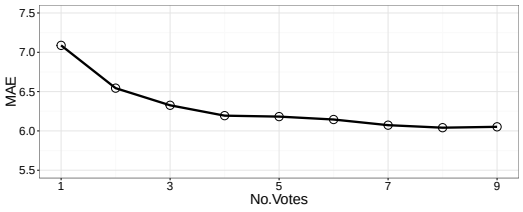

Figure 5: Age – Average Mean Absolute Error based on number of annotator guesses aggregated.

formation to predictive models.[1]

6.1 Comparison to Bag-of-Words Predictions

First, we test the hypothesis that annotators emphasize certain stereotypical words to make their guesses. To study their impact, we compare human guesses with those from a statistical model using the bag-of-words assumption for systematic differences. The automatic prediction method using bag-of-words text features offers a generalisation of individual word usage patterns shielded from biases.

We use Support Vector Machines (SVM) with a linear kernel and ℓ_1 regularization (Tibshirani, 1996), similarly to the state-of-the-art method in predicting user age and gender (Sap et al., 2014). The features for these models are unigram frequency distributions computed over the aggregate set of messages from each user. Due to the sparse and large vocabulary of social media data, we limit the unigrams to those used by at least 1% of users.

We train a classifier on a balanced set of 11,196 Twitter users from our extended data set. We test on the 2,607 users rated by the annotators using only the 100 tweets the humans had access when making their predictions. Table 1b shows the system performance reaching an accuracy of 82.9%, with the human performance on the same data at 85.88%. In contrast to the human prediction, the precision is higher for classifying females (84.9% cf. 80.9% for males) and the recall is higher for males (85.4% cf. 80.4% for female). This is caused by both higher classifier accuracy for males and by a switch in rank between the type I and type II errors.

In Table 1c we directly compare the human and automatic predictions, highlighting that 13.6% of the labels are different. Moreover, there is an asymmetry between the tendency of humans to mislabel males with females and the classifier. This leads to the conclusion that humans are sensitive to biases which we will qualitatively investigate in the following sections.

6.2 Human Predictions as Labels

Previously, we have shown that perceived annotated traits are different in many aspects to actual traits. To quantify their impact, we use these labels for training two classifiers and compare them on predicting the true gender for unseen users.

Both systems are trained on the 260,700 messages from 2,607 users and only differ in the labels assigned to users: majority annotator vote or self-reports. Results on the held-out set of 11,196 users (of which 6,851 males and 7,596 females) are presented in Table 2. The system trained on real labels outperforms that trained on perceived ones (accuracy of 85.32% cf. 83.40%). Furthermore, in the system trained on perceived labels, the same type of error as for the human annotation is more prevalent and is overemphasized compared to our

[1]Experiments for age could not be replicated due to insufficient labeled users.

(a) Majority annotator vote.

Real		Pred.H Male	Pred.H Female
	Male	40.1%	7.9%
	Female	6.1%	45.8%

(b) Classifier.

Real		Pred.C Male	Pred.C Female
	Male	42.2%	7.2%
	Female	9.9%	40.7%

(c) Classifier compared to majority annotator vote.

Pred.C		Pred.H Male	Pred.H Female
	Male	40.3%	8.0%
	Female	5.6%	46.1%

Table 1: Normalized confusion matrices of human annotations (**Pred.H**) to ground truth (**Real**), classifier performance (**Pred.C**) to ground truth (**Real**), and human annotations (**Pred.H**) to classifier performance (**Pred.C**) on the same data set.

previous results – males are predicted with high precision (85%) but low recall (79%) and many of them are misclassified as women. In the system trained on ground truth, both types of errors are more balanced with more males classified correctly – similar precision (84%) but higher recall (86%).

6.3 Combining Human and Automatic Predictions

We have shown that human perceived labels and automatic methods capture different information. This information may be leveraged to obtain better overall predicting performance. We test this by using a linear model that combines two features: the human guesses – measured as the proportion of guesses for female – and classifier prediction – binary value. Even this simple method of label combination obtains a classification accuracy of 87.7%, significantly above majority vote of human guesses (85.8%) and automatic prediction (82.9%) individually. This demonstrates that both methods can complement each other if an increase in accuracy is needed.

(a) Trained on perceived gender. Accuracy = 83.4%

Real		Pred. Male	Pred. Female
	Male	37.5%	9.9%
	Female	6.6%	45.9%

(b) Trained on actual gender. Accuracy = 85.3%

Real		Pred. Male	Pred. Female
	Male	40.5%	6.9%
	Female	7.8%	44.7%

Table 2: Normalized confusion matrices for system comparison when using perceived or ground truth labels.

7 Textual Differences between Perceived and Actual Traits

We have so far demonstrated that differences exist between the human perception of traits and real traits. Further, human errors differ systematically from a statistical model which generalizes word occurrence patterns. In this section, we directly identify the textual cues that bias humans and cause them to mislabel users.

In addition to unigram analysis, in order to aid interpretability of the feature analysis, we group words into clusters of semantically similar words or *topics* using a method from (Preoţiuc-Pietro et al., 2015b). We first obtain word representations using the popular skip-gram model with negative sampling introduced by Mikolov et al. (2013) and implemented in the Gensim package (layer size 50, context window 5). We train this model on a **separate** reference corpus containing ~ 400 million tweets. After computing the word vectors, we create a word $\times$ word semantic similarity matrix using cosine similarity between the vectors and group the words into clusters using spectral clustering (Shi and Malik, 2000). Each word is only assigned to one cluster. We choose a number of 1,000 topics based on preliminary experiments. Further, we use the NRC Emotion Lexicon (Mohammad and Turney, 2013) to measure eight *emotions* (anger, fear, anticipation, trust, surprise, sadness, joy and disgust) and two *sentiments* (negative and positive). A user's score in each of these 10 dimensions is represented as a weighted sum of its words multiplied by their lexicon score.

7.1 Gender Perception

To study gender perception, we first define a measure of *perceived gender expression*, calculated as the fraction of female guesses out of the 9 guesses for each Twitter user. We then compute univariate correlations the text-derived features and the user

Perceived – Female				**Perceived – Male**

Table 6: Textual features highlighting high and low confidence in human perception of age. Table shows correlation to average self-reported confidence (**Conf**), to ground truth (**Real**) and with self-reported confidence controlled for ground truth (**Cont**). Correlation values of age unigrams, topics and emotions statistically significant at $p < .001$ (t-test) unless in brackets.

labels. Table 3 displays the features with significant correlation to perceived gender expression when controlled for real gender using partial correlation, as well as the standalone correlations with the real gender label and perceived gender expression. Note that all correlations with both males and females have the same sign for both perceived gender and real gender. This highlights that humans are *not* wrong in using these features to make gender assessments. Rather, these stereotypical associates are overestimated by humans.

By analyzing the topics that are still correlated with perception after controlling for ground truth correlation, we see that topics related to sports, politics, business and technology are considered by annotators to be stronger cues for predicting males than they really are. Female perception is dominated by topics and words relating to feelings,

shopping, dreaming, housework and beauty. For emotions, joy is perceived to be more associated to females than the data shows, while users expressing more anger and fear are significantly more likely to be perceived as males than the data supports.

Our crowdsourcing experiment allowed annotators to self-report their confidence in each choice. This gives us the opportunity to measure which textual features lead to higher self-reported confidence in predicting user traits. Table 4 shows the textual features most correlated with self-reported confidence of the annotators when controlled for ground truth, in order to account for the effect that overall confidence is on average higher for groups of users that are easier to predict (i.e., females in case of gender, younger people in case of age).

Annotations are most confident when family relationships or other people are mentioned, which aid them to easily assign a label to a user (e.g., 'husband'). Other topics leading to high confidence are related to apparel or beauty. Also the presence of joy leads to higher confidence (for predicting females based on the previous result). Low confidence is associated with work related topics or astrology as well as to clusters of general adverbs and verbs and tentatively, to a more formal vocabulary e.g., 'specified', 'negotiable', 'exploratory'. Intriguingly, low confidence in predicting gender is also related to unigrams like 'emotions', 'relationship', 'emotional'.

7.2 Age Perception

Table 5 displays the features most correlated with perceived age – the average of the 9 annotator guesses – when controlled for real age, and the individual correlations to perceived and real age.

Again, annotators relied on correct stereotypes, but relied on them more heavily than warranted by data. The results show that the perception of users as being older compared to their biological age, is driven by topics including politics, business and news events. Vocabulary contains somewhat longer words (e.g., 'regarding', 'upcoming', 'original'). Additionally, annotators perceived older users to express more positive emotions, trust and anticipation. This is in accordance with psychology research, which showed that both positive emotion (Mather and Carstensen, 2005) and trust (Poulin and Haase, 2015) increase as people get older.

The perception of users being younger than their biological age is highly correlated with the use of short and colloquial words, and self-references, such as the personal pronoun 'I'. Remarkably, the negative sentiment is perceived as more specific of younger users, as well as the negative emotions of disgust, sadness and anger, the later of which is actually uncorrelated to age.

Table 6 displays the features with the highest correlation to annotation confidence in predicting age when controlling for the true age, as well as separate correlations to real and perceived age. Annotators appear to be more confident in their guess when the posts display more joy, positive emotion, trust and anticipation words. In terms of topics mentioned, these are more informal, self-referential or related to school or college. Topics leading to lower confidence are either about sports or online contests or are frequently retweets.

8 Conclusions

This is the first study to systematically analyze differences between real user traits and traits as perceived from text, here Twitter posts. Overall, participants were generally accurate in guessing a person's traits supporting earlier research that stereotypical associations are frequently accurate (McCauley, 1995). However, we have demonstrated that humans use stereotypes which lead to systematic biases by comparing their guesses to predictions from statistical models using the bag-of-words assumption. While qualitatively different, these predictions were shown to offer complimentary information in case of gender, boosting overall accuracy when used jointly.

Our experimental design allowed us to directly test which textual cues lead to inaccurate assessments. Correlation analysis showed that aspects of stereotypes associated with errors tended not to be completely wrong but rather poorly applied. Annotators generally exaggerated the diagnostic utility of behaviors that they correctly associated with one group or another. Further, we used the same methodology to analyze self-reported confidence.

Follow-up studies can analyze the perception of other user traits such as education level, race or political orientation. Another avenue of future research can look at the annotators' own traits and how these relate to perception (Flekova et al., 2015). This would allow to uncover demographic or psychological traits that influence the ability to make more accurate judgements. This is particularly useful in offering task requesters a prior over which annotators are expected to perform tasks better.

Acknowledgments

Modeling Social Norms Evolution for Personalized Sentiment Classification

Abstract

Motivated by the findings in social science that people's opinions are diverse and variable while together they are shaped by evolving social norms, we perform personalized sentiment classification via *shared model adaptation* over time. In our proposed solution, a global sentiment model is constantly updated to capture the homogeneity in which users express opinions, while personalized models are simultaneously adapted from the global model to recognize the heterogeneity of opinions from individuals. Global model sharing alleviates data sparsity issue, and individualized model adaptation enables efficient online model learning. Extensive experimentations are performed on two large review collections from Amazon and Yelp, and encouraging performance gain is achieved against several state-of-the-art transfer learning and multi-task learning based sentiment classification solutions.

1 Introduction

Sentiment is personal; the same sentiment can be expressed in various ways and the same expression might carry distinct polarities across different individuals (Wiebe et al., 2005). Current mainstream solutions of sentiment analysis overlook this fact by focusing on population-level models (Liu, 2012; Pang and Lee, 2008). But the idiosyncratic and variable ways in which individuals communicate their opinions make a global sentiment classifier incompetent and consequently lead to suboptimal opinion mining results. For instance, a shared statistical classifier can hardly recognize that in restaurant reviews, the word "expensive" may indicate some users' satisfaction with a restaurant's quality, although it is generally associated with negative attitudes. Hence, a personalized sentiment classification solution is required to achieve fine-grained understanding of individuals' distinctive and dynamic opinions and benefit downstream opinion mining applications.

Sparse observations of individuals' opinionated data (Max, 2014) prevent straightforward solutions from building personalized sentiment classification models, such as estimating supervised classifiers on a per-user basis. Semi-supervised methods are developed to address the data sparsity issue. For example, leveraging auxiliary information from user-user and user-document relations in transductive learning (Hu et al., 2013; Tan et al., 2011). However, only one global model is estimated there, and the details of how individual users express diverse opinions cannot be captured. More importantly, existing solutions build static sentiment models on historic data; but the means in which a user expresses his/her opinion is changing over time. To capture temporal dynamics in a user's opinions with existing solutions, repeated model reconstruction is unavoidable, albeit it is prohibitively expensive. As a result, personalized sentiment analysis requires effective exploitation of users' own opinionated data and efficient execution of model updates across all users.

To address these challenges, we propose to build personalized sentiment classification models via *shared model adaptation*. Our solution roots in the social psychology theories about humans' dispositional tendencies (Briley et al., 2000). Humans' behaviors are shaped by social norms, a set of socially shared "feelings" and "display rules" about how one should feel and express opinions (Barsäde and Gibson, 1998; Sherif, 1936). In the context of content-based sentiment classification, we interpret social norms as global model sharing and adaptation across users. Formally, we assume a global sentiment model serves as the basis to capture self-enforcing sentimental regulari-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 855–865,
Berlin, Germany, August 7-12, 2016.

ties across users, and each individual user tailors the shared model to realize his/her personal preference. In addition, social norms also evolve over time (Ehrlich and Levin, 2005), which leads to shifts in individuals' behaviors. This can again be interpreted as model adaptation: a new global model is adapted from an existing one to reflect the newly adopted sentimental norms. The temporal changes in individuals' opinions can be efficiently captured via online model adaptation at the levels of both global and personalized models.

Our proposed solution can also be understood from the perspective of multi-task learning (Evgeniou and Pontil, 2004; Jacob et al., 2009). Intuitively, personalized model adaptations can be considered as a set of related tasks in individual users, which contribute to a shared global model adaptation. In particular, we assume the distinct ways in which users express their opinions can be characterized by a linear classifier's parameters, i.e., the weights of textual features. Personalized models are thus achieved via a series of linear transformations over a globally shared classifier's parameters (Wang et al., 2013), e.g., shifting and scaling the weight vector. This globally shared classifier itself is obtained via another set of linear transformations over a given base classifier, which can be estimated from an isolated collection beforehand and serves as a prior for shared sentiment classification. The shared global model adaptation makes personalized model estimation no longer independent, such that regularity is formed across individualized learning tasks.

We empirically evaluated the proposed solution on two large collections of reviews, i.e., Amazon and Yelp reviews. Extensive experiment results confirm its effectiveness: the proposed method outperformed user-independent classification methods, several state-of-the-art model adaption methods, and multi-task learning algorithms.

2 Related Work

Text-based sentiment classification forms the foundation of sentiment analysis (Liu, 2012; Pang and Lee, 2008). There are two typical types of studies in sentiment classification. The first is classifying input text units (such as documents, sentences and phrases) into predefined categories, e.g., positive v.s., negative (Pang et al., 2002; Gao et al., 2014) and multiple classes (Pang and Lee, 2005). Both lexicon-based and learning-based solutions have been explored. The second is identifying topical aspects and corresponding opinions, e.g., developing topic models to predict fine-grained aspect ratings (Titov and McDonald, 2008; Wang et al., 2011). However, all those works emphasize population-level analysis, which applies a global model on all users and therefore fails to recognize the heterogeneity in which different users express their diverse opinions.

Our proposed solution is closely related to multi-task learning, which exploits the relatedness among multiple learning tasks to benefit each single task. Tasks can be related in various ways. A typical assumption is that all learnt models are close to each other in some matrix norms (Evgeniou and Pontil, 2004; Jacob et al., 2009). This has been empirically proved to be effective for capturing preferences of individual users (Evgeniou et al., 2007). Task relatedness has also been imposed via constructing a common underlying representation across different tasks (Argyriou et al., 2008; Evgeniou and Pontil, 2007). Our solution postulates task relatedness via a two-level model adaptation procedure. The global model adaptation accounts for the homogeneity and shared dynamics in users' opinions; and personalized model adaptation realizes heterogeneity in individual users.

The idea of model adaptation has been extensively explored in the context of transfer learning (Pan and Yang, 2010), which focuses on applying knowledge gained while solving one problem to different but related problems. In opinion mining community, transfer learning is mostly exploited for domain adaptation, e.g., adapting sentiment classifiers trained on book reviews to DVD reviews (Blitzer et al., 2006; Pan et al., 2010). Personalized model adaptation has also been studied in literature. The idea of linear transformation based model adaptation is introduced in (Wang et al., 2013) for personalized web search. Al Boni et al. applied a similar idea to achieve personalized sentiment classification (Al Boni et al., 2015). (Li et al., 2010) developed an online learning algorithm to continue training personalized classifiers based on a given global model. However, all of these aforementioned solutions perform model adaptation from a fixed global model, such that the learning of personalized models is independent from each other. Data sparsity again is the major bottleneck for such solutions. Our solution associates individual model adaptation via a shared global model adaptation, which leverages observations across users and thus reduces preference learning complexity.

3 Methodology

We propose to build personalized sentiment classifiers via shared model adaptation for both a global sentiment model and individualized models. Our solution roots in the social psychology theories about humans' dispositional tendencies, e.g., social norms and the evolution of social norms over time. In the following discussions, we will first briefly discuss the social theories that motivate our research, and then carefully describe the model assumptions and technical details about the proposed personalized model adaptation solution.

3.1 The Evolution of Social Norms

Social norms create pressures to establish socialization of affective experience and expression (Shott, 1979). Within the limit set by social norms and internal stimuli, individuals construct their sentiment, which is not automatic, physiological consequences but complex consequences of learning, interpretation, and social influence. This motivates us to build a global sentiment classification model to capture the shared basis on which users express their opinions. For example, the phrase "a waste of money" generally represents negative opinions across all users; and it is very unlikely that anybody would use it in a positive sense. On the other hand, members of some segments of a social structure tend to feel certain emotions more often or more intensely than members of other segments (Hochschild, 1975). Personalized model adaptation from the shared global model becomes necessary to capture the variability in affective expressions across users. For example, the word "expensive" may indicate some users' satisfaction with their received service.

Studies in social psychology also suggest that social norms shift and spread through infectious transfer mediated by webs of contact and influence over time (Ostrom, 2014; Ehrlich and Levin, 2005). Members inside a social structure influence the other members; confirmation of shifted beliefs leads to the development and evolution of social norms, which in turn regulate the shared social behaviors as a whole over time. The evolving nature of social norms urges us to take a dynamic view of the shared global sentiment model: instead of treating it as fixed, we further assume this model is also adapted from a predefined one, which serves as prior for sentiment classification. All individual users are coupled and contribute to this shared global model adaptation. This two-level model adaptation assumption leads us to the proposed multi-task learning solution, which will be carefully discussed in the next section.

3.2 Shared Linear Model Adaptation

In this paper, we focus on linear models for personalized sentiment classification due to their empirically superior performance in text-based sentiment analysis (Pang et al., 2002; Pang and Lee, 2005). We assume the diverse ways in which users express their opinions can be characterized by different settings of a linear model's parameters, i.e., the weights of textual features.

Formally, we denote a given set of opinionated text documents from user u as $D^u = \{(x_d^u, y_d^u)\}_{d=1}^{|D^u|}$, where each document x_d^u is represented by a V-dimensional vector of textual features and y_d^u is the corresponding sentiment label. The task of personalized sentiment classification is to estimate a personalized model $y = f^u(x)$ for user u, such that $f^u(x)$ best captures u's opinions in his/her generated text content. Instead of assuming $f^u(x)$ is solely estimated from user u's own opinionated data, which is prone to overfitting, we assume it is derived from a globally shared sentiment model $f^s(x)$ via model adaptation (Al Boni et al., 2015; Wang et al., 2013), i.e., shifting and scaling $f^s(x)$'s parameters for each individual user. To simplify the following discussions, we will focus on binary classification, i.e., $y_d \in \{0, 1\}$, and use the logistic regression as our reference model. But the developed techniques are general and can be easily extended to multi-class classification and generalized linear models.

We only consider scaling and shifting operations, given rotation requires to estimate much more free parameters (i.e., $O(V^2)$ v.s., $O(V)$) but contributes less in final classification performance (Al Boni et al., 2015). We further assume the adaptations can be performed in a group-wise manner (Wang et al., 2013): features in the same group will be updated synchronously by enforcing the same shifting and scaling operations. This enables the observations from seen features to be propagated to unseen features in the same group during adaptation. Various feature grouping methods have been explored in (Wang et al., 2013).

Specifically, we define $g(i) \rightarrow j$ as a feature grouping method, which maps feature i in $\{1, 2, \ldots, V\}$ to feature group j in $\{1, 2, \ldots, K\}$. A personalized model adaptation matrix can then be represented as a $2K$-dimensional vector $A^u = (a_1^u, a_2^u, \ldots, a_K^u, b_1^u, b_2^u, \ldots, b_K^u)$, where a_k^u and b_k^u

represent the scaling and shifting operations in feature group k for user u accordingly. Plugging this group-wise model adaptation into the logistic function, we can get a personalized logistic regression model $P^u(y_d = 1|x_d)$ for user u as follows,

$$P^u(y_d = 1|x_d) = \frac{1}{1 + e^{-\sum_{k=1}^{K} \sum_{g(i)=k} (a_k^u w_i^s + b_k^u) x_i}} \quad (1)$$

where w^s is the feature weight vector in the global model $f^s(x)$. As a result, personalized model adaptation boils down to identifying the optimal model transformation operation A^u for each user based on w^s and D^u.

In (Al Boni et al., 2015; Wang et al., 2013), $f^s(x)$ is assumed to be given and fixed. It leads to isolated estimation of personalized models. Based on the social norms evolution theory, $f^s(x)$ should also be dynamic and ever-changing to reflect shifted social norms. Hence, we impose another layer of model adaptation on top of the shared global sentiment model $f^s(x)$, by assuming itself is also adapted from a predefined base sentiment model. Denote this base classifier as $f^0(x)$, which is parameterized by a feature weight vector w^0 and serves as a prior for sentiment classification. Then w^s can be derived via the same aforementioned model adaptation procedure: $w^s = A^s \tilde{w}^0$, where $\tilde{w}^0$ is an augmented vector of w^0, i.e., $\tilde{w}^0 = (w^0, 1)$, to facilitate shifting operations, and A^s is the adaptation matrix for the shared global model. We should note A^s can take a different configuration (i.e., feature groupings) from individual users' adaptation matrices.

Putting these two levels of model adaptation together, a personalized sentiment classifier is achieved via,

$$w^u = A^u A^s \tilde{w}^0 \quad (2)$$

which can then be plugged into Eq (1) for personalized sentiment classification.

We name this resulting algorithm as Mutli-Task Linear Model Adaptation, or *MT-LinAdapt* in short. The benefits of shared model adaptation defined in Eq (2) are three folds. First, the homogeneity in which users express their diverse opinions are captured in the jointly estimated sentiment model $f^s(x)$ across users. Second, the learnt individual models are coupled together to reduce preference learning complexity, i.e., they collaboratively serve to reduce the models' overall prediction error. Third, non-linearity is achieved via the two-level model adaptation, which introduces more flexibility in capturing heterogeneity in different users' opinions. In-depth discussions of those unique benefits will be provided when we introduce the detailed model estimation methods.

3.3 Joint Model Estimation

The ideal personalized model adaptation should be able to adjust the individualized classifier $f^u(x)$ to minimize misclassification rate on each user's historical data in D^u. In the meanwhile, the shared sentiment model $f^s(x)$ should serve as the basis for each individual user to reduce the prediction error, i.e., capture the homogeneity. These two related objectives can be unified under a joint optimization problem.

In logistic regression, the optimal adaptation matrix A^u for an individual user u, together with A^s can be retrieved by a maximum likelihood estimator (i.e., minimizing logistic loss on a user's own opinionated data). The log-likelihood function in each individual user is defined as,

$$L(A^u, A^s) = \sum_{d=1}^{|D^u|} \Big[y_d \log P^u(y_d = 1|x_d) + (1 - y_d) \log P^u(y_d = 0|x_d) \Big] \quad (3)$$

To avoid overfitting, we penalize the transformations which increase the discrepancy between the adapted model and its source model (i.e., between w^u and w^s, and between w^s and w^0) via a L2 regularization term,

$$R(A) = \frac{\eta_1}{2} ||\boldsymbol{a} - 1||_2 + \frac{\eta_2}{2} ||\boldsymbol{b}||_2 \quad (4)$$

and it enforces scaling to be close to one and shifting to be close to zero.

By defining a new model adaptation matrix $\mathring{A} = \{A^{u_1}, A^{u_2}, \ldots, A^{u_N}, A^s\}$ to include all unknown model adaptation parameters for individual users and shared global model, we can formalize the joint optimization problem in MT-LinAdapt as,

$$\max L(\mathring{A}) = \sum_{i=1}^{N} \Big[L(A^{u_i}) - R(A^{u_i}) \Big] - R(A^s) \quad (5)$$

which can be efficiently solved by a gradient-based optimizer, such as quasi-Newton method (Zhu et al., 1997).

Direct optimization over $\mathring{A}$ requires synchronization among all the users. But in practice, users will generate their opinionated data with different paces, such that we have to postpone model adaptation until all the users have at least one observation to update their own adaptation matrix.

This delayed model update is at high risk of missing track of active users' recent opinion changes, but timely prediction of users' sentiment is always preferred. To monitor users' sentiment in realtime, we can also estimate MT-LinAdapt in an asynchronized manner: whenever there is a new observation available, we update the corresponding user's personalized model together with the shared global model immediately. i.e., online optimization of MT-LinAdapt.

This asychronized estimation of MT-LinAdapt reveals the insight of our two-level model adaptation solution: the immediate observations in user u will not only be used to update his/her own adaptation parameters in A^u, but also be utilized to update the shared global model, thus to influence the other users, who do not have adaptation data yet. Two types of competing force drive the adaptation among all the users: $w_s = A^s \tilde{w}_0$ requires timely update of global model across users; and $w_u = A^u w_s$ enforces the individual user to conform to the newly updated global model. This effect can be better understood with the actual gradients used in this asychronized update. We illustrate the decomposed gradients for scaling operation in A^u and A^s from the log-likelihood part in Eq (5) on a specific adaptation instance (x_d^u, y_d^u):

$$\frac{\partial L(A^u,A^s)}{\partial a_k^u} = \Delta_d^u \sum_{g^u(i)=k} \left(a^s_{g^s(i)} w_i^0 + b^s_{g^s(i)} \right) x^u_{di} \quad (6)$$

$$\frac{\partial L(A^u,A^s)}{\partial a_l^s} = \Delta_d^u \sum_{g^s(i)=l} a^u_{g^u(i)} w_i^0 x^u_{di} \quad (7)$$

where $\Delta_d^u = y_d^u - P^u(y_d^u = 1|x_d^u)$, and $g^u(\cdot)$ and $g^s(\cdot)$ are feature grouping functions in individual user u and shared global model $f^s(x)$.

As stated in Eq (6) and (7), the update of scaling operation in the shared global model and individual users depends on each other; the gradient with respect to global model adaptation will be accumulated among all the users. As a result, all users are coupled together via the global model adaptation in MT-LinAdapt, such that model update is propagated through users to alleviate data sparsity issue in each single user. This achieves the effect of multi-task learning. The same conclusion also applies to the shifting operations.

It is meaningful for us to compare our proposed MT-LinAdapt algorithm with those discussed in the related work section. Different from the model adaptation based personalized sentiment classification solution proposed in (Al Boni et al., 2015), which treats the global model as fixed, MT-LinAdapt adapts the global model to capture the evolving nature of social norms. As a result, in (Al Boni et al., 2015) the individualized model adaptations are independent from each other; but in MT-LinAdapt, the individual learning tasks are coupled together to enable observation sharing across tasks, i.e., multi-task learning. Additionally, as illustrated in Eq (6) and (7), nonlinear model adaptation is achieved in MT-LinAdapt because of the different feature groupings in individual users and global model. This enables observations sharing across different feature groups, while in (Al Boni et al., 2015) observations can only be shared within the same feature group, i.e., linear model adaptation. Multi-task SVM introduced in (Evgeniou and Pontil, 2004) can be considered as a special case of MT-LinAdapt. In Multi-task SVM, only shifting operation is considered in individual users and the global model is simply estimated from the pooled observations across users. Therefore, only linear model adaptation is achieved in Multi-task SVM and it cannot leverage prior knowledge conveyed in a predefined sentiment model.

4 Experiments

In this section, we perform empirical evaluations of the proposed MT-LinAdapt model. We verified the effectiveness of different feature groupings in individual users' and shared global model adaptation by comparing our solution with several state-of-the-art transfer learning and multi-task learning solutions for personalized sentiment classification, together with some qualitative studies to demonstrate how our model recognizes users' distinct expressions of sentiment.

4.1 Experiment Setup

• **Datesets.** We evaluated the proposed model on two large collections of review documents, i.e., Amazon product reviews (McAuley et al., 2015) and Yelp restaurant reviews (Yelp, 2016). Each review document contains a set of attributes such as author ID, review ID, timestamp, textual content, and an opinion rating in discrete five-star range. We applied the following pre-processing steps on both datasets: 1) filtered duplicated reviews; 2) labeled reviews with overall rating above 3 stars as positive, below 3 stars as negative, and removed the rest; 3) removed reviewers who posted more than 1,000 reviews and those whose positive review ratio is more than 90% or less than 10%

(little variance in their opinions and thus easy to classify). Since such users can be easily captured by the base model, the removal emphasizes comparisons on adapted models; 4) sorted each user's reviews in chronological order. Then, we performed feature selection by taking the union of top unigrams and bigrams ranked by Chi-square and information gain metrics (Yang and Pedersen, 1997), after removing a standard list of stopwords and porter stemming. The final controlled vocabulary consists of 5,000 and 3,071 textual features for Amazon and Yelp datasets respectively; and we adopted TF-IDF as the feature weighting scheme. From the resulting data sets, we randomly sampled 9,760 Amazon reviewers and 11,733 Yelp reviewers for testing purpose. There are 105,472 positive reviews and 37,674 negative reviews in the selected Amazon dataset; 108,105 positive reviews and 32,352 negative reviews in the selected Yelp dataset.

• **Baselines.** We compared the performance of MT-LinAdapt against seven different baselines, ranging from user-independent classifiers to several state-of-the-art model adaption methods and multi-task learning algorithms. Due to space limit, we will briefly discuss the baseline models below.

Our solution requires a user-independent classifier as base sentiment model for adaptation. We estimated logistic regression models from a separated collection of reviewers outside the preserved testing data on Amazon and Yelp datasets accordingly. We also included these isolated base models in our comparison and name them as *Base*. In order to verify the necessity of personalized sentiment models, we trained a global SVM based on the pooled adaptation data from all testing reviewers, and name it as *Global SVM*. We also estimated an independent SVM model for each single user only based on his/her adaptation reviews, and name it as *Individual SVM*. We included an instance-based transfer learning method (Brighton and Mellish, 2002), which considers the k-nearest neighbors of each testing review document from the isolated training set for personalized model training. As a result, for each testing case, we estimated an independent classification model, which is denoted as *ReTrain*. (Geng et al., 2012) used L2 regularization to enforce the adapted models to be close to the global model. We applied this method to get personalized logistic regression models and refer to it as *RegLR*. *LinAdapt* developed in (Al Boni et al., 2015) also performs group-wise linear model adaptation to build personalization classifiers. But it isolates model adaptation in individual users. *MT-SVM* is a multi-task learning method, which encodes task relatedness via a shared linear kernel (Evgeniou and Pontil, 2004).

• **Evaluation Settings.** We evaluated all the models with both synchronized (batch) and asynchronized (online) model update. We should note MT-SVM can only be tested in batch mode, because it is prohibitively expensive to retrain SVM repeatedly. In batch evaluation, we split each user's reviews into two sets: the first 50% for adaptation and the rest 50% for testing. In online evaluation, once we get a new testing instance, we first evaluate the up-to-date personalized classifier against the ground-truth; then use the instance to update the personalized model. To simulate the real-world situation where user reviews arrive sequentially and asynchronously, we ordered all reviews chronologically and accessed them one at a time for online model update. In particular, we utilized stochastic gradient descent for this online optimization (Kiwiel, 2001). Because of the biased class distribution in both datasets, we computed F1 measure for both positive and negative class in each user, and took macro average among users to compare the different models' performance.

4.2 Effect of Feature Grouping

In MT-LinAdapt, different feature groupings can be postulated in individual users' and shared global model adaptation. Nonlinearity is introduced when different grouping functions are used in these two levels of model adaptation. Therefore, we first investigated the effect of feature grouping in MT-LinAdapt.

We adopted the feature grouping method named "*cross*" in (Wang et al., 2013) to cluster features into different groups. More specifically, we evenly spilt the training collection into N non-overlapping folds, and train a single SVM model on each fold. Then, we create a $V \times N$ matrix by putting the learned weights from N folds together, on which k-means clustering is applied to extract K feature groups. We compared the batch evaluation performance of varied combinations of feature groups in MT-LinAdapt. The experiment results are demonstrated in Table 1; and for comparison purpose, we also included the base classifier's performance in the table.

In Table 1, the two numbers in the first column denote the feature group sizes in personalized models and global model respectively. And *all* indicates one feature per group (i.e., no fea-

Table 1: Effect of different feature groupings in MT-LinAdapt.

Method	Amazon		Yelp	
	Pos F1	Neg F1	Pos F1	Neg F1

800-1600	0.8386	0.5250	0.8302	0.4962
800-all	0.8443	**0.5426**	**0.8361**	**0.5122**
1600-all	**0.8445**	0.5424	0.8357	0.5106
all-all	0.8438	0.5416	0.8361	0.5100

ture grouping). The adapted models in MT-LinAdapt achieved promising performance improvement against the base sentiment classifier, especially on the Yelp data set. As we increased the feature group size for global model, MT-LinAdapt's performance kept improving; while with the same feature grouping in the shared global model, a moderate size of feature groups in individual users is more advantageous.

These observations are expected. Because the global model is shared across users, all their adaptation reviews can be leveraged to adapt the global model so that sparsity is no longer an issue. Since more feature groups in the global model can be afforded, more accurate estimation of adaptation parameters can be achieved. But at the individual user level, data sparsity is still the bottleneck for accurate adaptation estimation, and trade-off between observation sharing and estimation accuracy has to be made. Based on this analysis, we selected **800** and **all** feature groups for individual models and global model respectively in the following experiments.

4.3 Personalized Sentiment Classification

• **Synchronized model update.** Table 2 demonstrated the classification performance of MT-LinAdapt against all baselines on both Amazon and Yelp datasets, where binomial tests on win-loss comparison over individual users were performed between the best algorithm and runner-up to verify the significance of performance improvement. We can clearly notice that MT-LinAdapt significantly outperformed all baselines in negative class, and it was only slightly worse than MT-SVM on positive class. More specifically, per-user classifier estimation clearly failed to obtain a usable classifier, due to the sparse observations in single users. Model-adaptation based baselines, i.e., RegLR and LinAdapt, slightly improved over the base model. But because the adaptations across users are isolated and the base model is fixed, their improvement is very limited. As for negative class, MT-LinAdapt outperformed Global SVM significantly on both datesets. Since negative class suffers more from the biased prior distribution, the considerable performance improvement indicates effectiveness of our proposed personalized sentiment classification solution. As for positive class, the performance difference is not significant between MT-LinAdapt and MT-SVM on Amazon data set nor between MT-LinAdapt and Global SVM on Yelp data set. By looking into detailed results, we found that MT-LinAdapt outperformed MT-SVM on users with fewer adaptation reviews. Furthermore, though MT-SVM benefits from multi-task learning, it cannot leverage information from the given base classifier. Considering the biased class prior in these two data sets (2.8:1 on Amazon and 3.3:1 on Yelp), the improved classification performance on negative class from MT-LinAdapt is more encouraging.

Table 2: Classification results in batch mode.

Method	Amazon		Yelp	
	Pos F1	Neg F1	Pos F1	Neg F1
Base	0.8092	0.4871	0.7048	0.3495
Global SVM	0.8352	0.5403	**0.8411**	0.5007
Individual SVM	0.5582	0.2418	0.3515	0.3547
ReTrain	0.7843	0.4263	0.7807	0.3729

MT-LinAdapt	0.8441	**0.5422***	0.8358	**0.5119***

$*$ indicates p-value$<$0.05 with Binomial test.

• **Asynchronized model update.** In online model estimation, classifiers can benefit from immediate update, which provides a feasible solution for timely sentiment analysis in large datasets. In this setting, only two baseline models are applicable without model reconstruction, i.e., RegLR and LinAdapt. To demonstrate the utility of online update in personalized sentiment models, we illustrate the relative performance gain of these models over the base sentiment model in Figure 1. The x-axis indicates the number of adaptation instances consumed in online update from all users, i.e., the 1st review means after collecting the first review of each user.

MT-LinAdapt converged to satisfactory performance with only a handful of observations in each user. LinAdapt also quickly converged, but its performance was very close to the base model, since no observation is shared across users. RegLR needs the most observations to estimate satisfac-

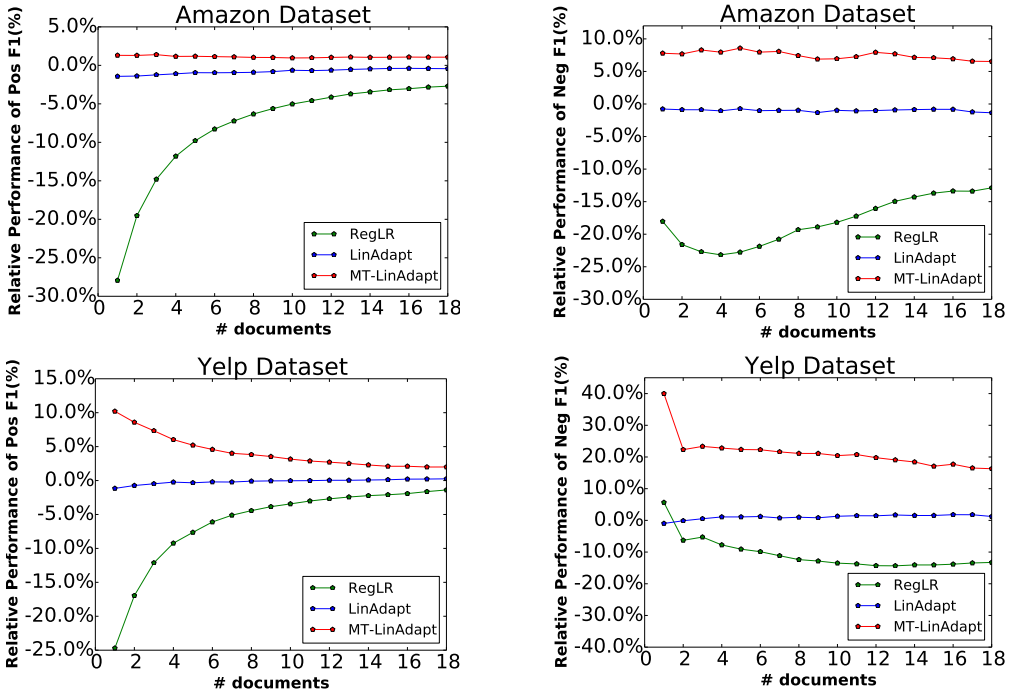

Figure 1: Relative performance gain between MT-LinAdapt and baselines on Amazon and Yelp datasets.

tory personalized models. The improvement in MT-LinAdapt demonstrates the benefit of shared model adaptation, which is vital when the individuals' adaptation data are not immediately available but timely sentiment classification is required.

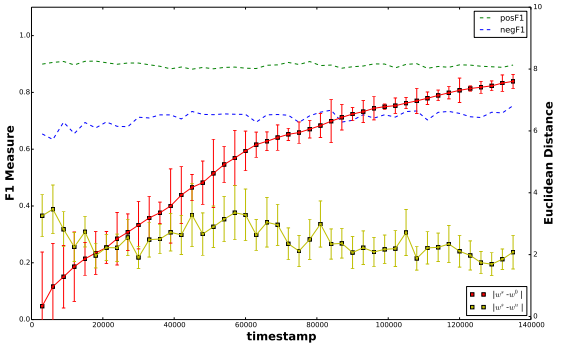

Figure 2: Online model update trace on Amazon.

It is meaningful to investigate how the shared global model and personalized models are updated during online learning. The shift in the shared global model reflects changes in social norms, and the discrepancy between the shared global model and personalized models indicates the variances of individuals' opinions. In particular, we calculated Euclidean distance between global model w^s and base model w^0 and that between individualized model w^u and shared global model w^s during online model updating. To visualize the results, we computed and plotted the average Euclidean distances in every 3000 observations during online learning, together with the corresponding variance. To illustrate a comprehensive picture of online model update, we also plotted the corresponding average F1 performance for both positive and negative class. Because the Euclidean distance between w^s and w^0 is much larger than that between w^s and w^u, we scaled $||w^s - w^0||$ by 0.02 on Amazon dataset in Figure 2. Similar results were observed on Yelp data as well; but due to space limit, we do not include them.

As we can clearly observe that the difference between the base model and newly adapted global model kept increasing during online update. At the earlier stage, it is increasing much faster than the later stage, and the corresponding classification performance improves more rapidly (especially in negative class). The considerably large variance between w^0 and w^s at the beginning indicates the divergence between old and new social norms across users. Later on, variance decreased and converged with more observations, which can be understood as the formation of the new social norms among users. On the other hand, the distance between personalized models and shared global model fluctuated a lot at the beginning; with more observations, it became stable later on. This is also reflected in the range of variance: the variance is much smaller in later stage than earlier stage, which indicates users comply to the newly established social norms.

Table 3: Shared model adaptation for cold start on Amazon and Yelp.

4.4 Shared Adaptation Against Cold Start

Cold start refers to the challenge that a statistic model cannot draw any inference for users before sufficient observations are gathered (Schein et al., 2002). The shared model adaptation in MT-LinAdapt helps alleviate cold start in personalized sentiment analysis, while individualized model adaptation method, such as RegLR and LinAdapt, cannot achieve so. To verify this aspect, we separated both Amazon and Yelp reviewers into two sets: we randomly selected 1,000 reviewers from the isolated training set and exhausted all their reviews to estimate a shared SVM model, MT-LinAdapt and MT-SVM. Then those models were directly applied onto the testing reviewers for evaluation. Again, because it is time consuming to retrain a SVM model repeatedly, only MT-LinAdapt performed online model update in this evaluation. We report the performance on the first three observations from all testing users accordingly in Table 3.

MT-LinAdapt achieved promising performance on the first testing cases, especially on the negative class. This indicates its estimated global model is more accurate on the new testing users. Because MT-SVM cannot be updated during this online test, only its previously estimated global model from the 1,000 training users can be applied here. As we can notice, its performance is very similar to the shared SVM model (especially on Amazon dataset). MT-LinAdapt adapts to this new collection of users very quickly, so that improved performance against the static models at later stage is achieved.

4.5 Vocabulary Stability

One derivative motivation for personalized sentiment analysis is to study the diverse use of vocabulary across individual users. We analyzed the variance of words' sentiment polarities estimated in the personalized models against the base model. Table 4 shows the most and the least variable features on both datasets. It is interesting to find that words with strong sentiment polarities tend to be more stable across users, such as "disgust," "regret," and "excel." This demonstrates the sign of conformation to social norms. There are also words exhibiting high variances in sentiment polarity, such as "was-yummi," "lazi," and "cheat," which indicates the heterogeneity of users' opinionated expressions.

Table 4: Top six words with the highest and lowest variances of learned polarities by MT-LinAdapt.

Amazon	Highest	cheat astound	healthi the-wrong	enjoy-read the-amaz
	Lowest	mistak regret	favor perfect-for	excel great
Yelp	Highest	total-worth advis	lazi impress	was-yummi so-friend
	Lowest	omg frustrat	veri-good disgust	hungri a-must

5 Conclusions

In this work, we proposed to perform personalized sentiment classification based on the notion of shared model adaptation, which is motivated by the social theories that humans' opinions are diverse but shaped by the ever-changing social norms. In the proposed MT-LinAdapt algorithm, global model sharing alleviates data sparsity issue, and individualized model adaptation captures the heterogeneity in humans' sentiments and enables efficient online model learning. Extensive experiments on two large review collections from Amazon and Yelp confirmed the effectiveness of our proposed solution.

The idea of shared model adaptation is general and can be further extended. We currently used a two-level model adaptation scheme. The adaptation can be performed at the user group level, i.e., three-level model adaptation. The user groups can be automatically identified to maximize the effectiveness of shared model adaptation. In addition, this method can also be applied to domain adaptation, where a domain taxonomy enables a hierarchically shared model adaptation.

Abstract

Our goal is to generate reading lists for students that help them optimally learn technical material. Existing retrieval algorithms return items directly relevant to a query but do not return results to help users read about the concepts supporting their query. This is because the dependency structure of concepts that must be understood before reading material pertaining to a given query is never considered. Here we formulate an information-theoretic view of concept dependency and present methods to construct a "concept graph" automatically from a text corpus. We perform the first human evaluation of concept dependency edges (to be published as open data), and the results verify the feasibility of automatic approaches for inferring concepts and their dependency relations. This result can support search capabilities that may be tuned to help users learn a subject rather than retrieve documents based on a single query.

1 Introduction

Corpora of technical documents, such as the ACL Anthology, are valuable for learners, but it can be difficult to find the most appropriate documents to read in order to learn about a concept. This problem is made more complicated by the need to trace the ideas back to those that need to be learned first (e.g., before you can learn about Markov logic networks, you should understand first-order logic and probability). That is, a crucial question when learning a new subject is "What do I need to know before I start reading about this?"

To answer this question, learners typically rely on the guidance of domain experts, who can devise pedagogically valuable reading lists that order documents to progress from prerequisite to target concepts. Thus, it is desirable to have a model where each concept is linked to the prerequisite concepts it depends upon – a *concept graph*. A manually constructed concept graph excerpt related to automatic speech recognition is shown in Figure 1. The dependency relation between two concepts is interpreted as whether understanding one concept would help a learner understand the other.

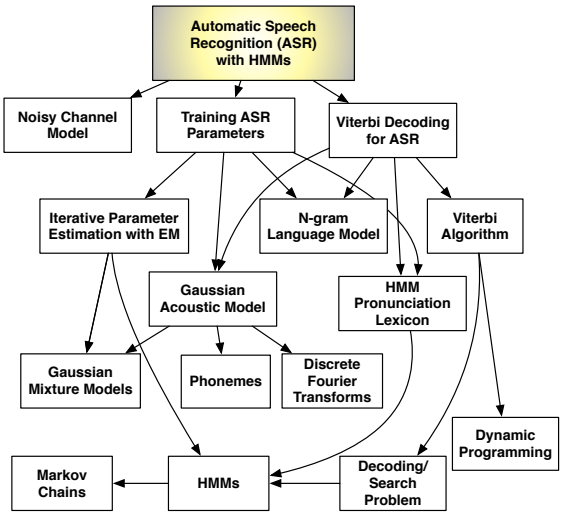

Figure 1: A human-authored concept graph excerpt, showing possible concepts related to automatic speech recognition and their concept dependencies.

Representing a scientific corpus in this way can improve tasks such as curriculum planning (Yang et al., 2015), automatic reading list generation (Jardine, 2014), and improving education quality (Rouly et al., 2015). Motivated by the importance of representing the content of a scientific corpus as a concept graph, the challenge we address in this work is to automatically infer the concepts and their dependency relations.

Towards this end, we first instantiate each concept as a topic from statistical topic modeling (Blei et al., 2003). To link concepts with directed depen-

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 866–875,
Berlin, Germany, August 7-12, 2016.

dency edges, we propose the use of information-theoretic measures, which we compare against baseline methods of computing word similarity, hierarchical clustering, and citation prediction. We then gather human annotations of concept graph nodes and edges learned from the ACL Anthology, which we use to evaluate these methods.

The main contributions of this paper are:

1 We introduce the concept graph representation for modeling the technical concepts in a corpus and their relations.
2 We present information-theoretic approaches to infer concept dependence relations.
3 We perform the first human annotation of concept dependence for a technical corpus.
4 We release the human annotation data for use in future research.

In the following section, we contrast this problem with previous work. We then describe the concept graph framework (Section 3) and present automatic approaches for inferring concept graphs (Section 4). The details of human evaluation are presented in Section 5. We discuss some interesting open questions related to this work in Section 6 before concluding this work.

2 Related Work

There is a long history of work on identifying structure in the contents of a text corpus. Our approach is to link documents to concepts and to model relations among these concepts rather than to identify the specific claims (Schäfer et al., 2011) or empirical results (Choi et al., 2016) in each document. In this section, we first provide an overview of different relations between concepts, followed by discussion of some representative methods for inferring them. We briefly discuss the differences between these relations and the concept dependency relation we are interested in.

Similarity Concepts are similar to the extent that they share content. Grefenstette (1994) applied the Jaccard similarity measure to relate concepts to each other. White and Jose (2004) empirically studied 10 similarity metrics on a small sample of 10 pairs of topics, and the results suggested that correlation-based measures best match general subject perceptions of search topic similarity.

Hierarchy Previous work on linking concepts has usually been concerned with forming subsumption hierarchies from text (Woods, 1997; Sanderson and Croft, 1999; Cimiano et al., 2005) – e.g., *Machine translation* is part of *Natural language processing* – and more recent work does so for statistical topic models. Jonyer et al. (2002) applied graph-based hierarchical clustering to learn hierarchies from both structured and unstructured data. Ho et al. (2012) learn a topic taxonomy from the ACL Anthology and from Wikipedia with a method that scales linearly with the number of topics and the tree depth.

Other relations Every pair of concepts is statistically correlated with each other based on word co-occurrence (Blei and Lafferty, 2006) providing a simple baseline metric for comparison. For a topic modeling approach performed over document citation links rather than over words or n-grams, Wang et al. (2013) gave a topic A's dependence on another topic B as the probability of a document in A citing a document in B.

Our approach to studying *concept dependence* differs from the relations derived from similarity, hierarchy, correlation and citation mentioned above, but intuitively they are related. We thus adapt one representative method for the similarity (Grefenstette, 1994), hierarchy (Jonyer et al., 2002), and citation likelihood (Wang et al., 2013) relations as baselines for computing concept dependency relations in Section 4.2.3.

Concept dependence is also related to curriculum planning. Yang et al. (2015) and Talukdar and Cohen (2012) studied prerequisite relationships between course material documents based on external information from Wikipedia. They assumed that hyperlinks between Wikipedia pages and course material indicate a prerequisite relationship. With this assumption, Talukdar and Cohen (2012) use crowdsourcing approaches to obtain a subset of the prerequisite structure and train a maximum entropy–based classifier to identify the prerequisite structure. Yang et al. (2015) applied both classification and learning to rank approaches in order to classify or rank prerequisite structure.

3 Concept Graph Representation of a Text Corpus

We represent the scientific literature as a labeled graph, where nodes represent both documents and concepts – and, optionally, metadata (such as author, title, conference, year) and features (such as

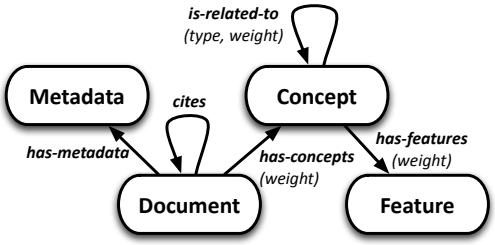

Figure 2: The Concept Graph Data Schema. Each node is a class and edges are named relations between classes (with associated attributes).

words, or n-grams) – and labeled edges represent the relations between nodes. Figure 2 shows an example schema for a concept graph representation for a scientific corpus.

Concepts are abstract and require a concrete representation. In this work, we use statistical topic modeling, where each topic – a multinomial distribution over a vocabulary of words – is taken as a single concept. Documents are linked to concepts by weighted edges, which can be derived from the topic model's document–topic composition distributions. Other approaches to identifying concepts are considered in Section 6.

Concepts exhibit various relations to other concepts, such as *hierarchy*, connecting more general and more specific concepts; *similarity*; and *correlation*. We model each concept as a node and concept-to-concept relations as directed, weighted, labeled edges. The label of an edge denotes the type of relation, such as "is similar to", "depends on", and "relates to", and the weights represent the strength of different relations.

In this work, we focus on *concept dependency*, which is the least studied of these relations and, intuitively, the most important for learners. We consider there to be a dependency relation between two concepts if understanding one concept would help you to understand the other. This notion forms the core of our human-annotated data set which demonstrates that this idea is meaningful and robust for expert annotators when asked to judge if there exists a dependency relation between two concepts defined by LDA topics (see Section 5.2).

4 Learning the Concept Graph

4.1 Identifying Concepts

The representation of concepts using topics is very general, and any effective topic modeling approach can be applied. These include probabilistic latent semantic indexing (PLSI) (Hofmann, 1999), latent Dirichlet allocation (LDA) (Blei et al., 2003), and non-negative matrix factorization (NMF) (Arora et al., 2012). In our experiments, we use the open-source tool Mallet (McCallum, 2002), which provides a highly scalable implementation of LDA; see Section 5.1 for more details.

4.2 Discovering Concept Dependency Relations

Identifying concept dependency relations between topics is the key step for building a useful concept graph. These relations add semantic structure to the contents of the text corpus, and they facilitate search and ordering in information retrieval. In this section, as a proof-of-concept, we propose two information-theoretic approaches to learn concept dependency relations: an approach based on cross entropy and another based on information flow.

4.2.1 Cross-entropy Approach

The intuition of the cross-entropy approach is simple: Given concepts c_i and c_j, if most of the instances of c_i can be explained by the occurrences of c_j, but not vice versa, it is likely that c_i depends on c_j. For example, if c_i is *Markov logic networks* (*MLNs*) and c_j is *Probability*, we might say that observing *MLNs* depends on seeing *Probability* since most of the times that we see *MLNs*, we also see *Probability*, but the opposite does not hold.

Given concepts c_i and c_j, the cross-entropy approach predicts that c_i depends on c_j if they satisfy these conditions:

1 The distribution of c_i is better approximated by that of c_j than the distribution of c_j is approximated by that of c_i.
2 The co-occurrence frequency of instances of c_i and c_j is relatively higher than that of a non-dependency pair.

Therefore, to predict the concept dependency relation, we need to examine whether the distribution of c_i could well approximate the distribution of c_j and the joint distribution of c_i and c_j. For this, we use cross entropy and joint entropy:

Cross entropy measures the difference between two distributions. Specifically, the cross entropy for the distributions X and Y over a given set is defined as:

$$H(X;Y) = H(X) + D_{KL}(X||Y) \qquad (1)$$

where $H(X)$ is the entropy of X, and $D_{KL}(X||Y)$ is the Kullback–Leibler divergence of an estimated distribution Y from true distribution X. Therefore, $H(X;Y)$ examines how well the distribution of Y approximates that of X.

Joint entropy measures the information we obtained when we observe both X and Y. The joint Shannon entropy of two variables X and Y is defined as:

$$H(X,Y) = \sum_X \sum_Y P(X,Y) \log_2 P(X,Y) \quad (2)$$

where $P(X,Y)$ is the joint probability of these values occurring together.

Based on the conditions listed above and these definitions, we say that c_i depends on c_j if and only if they satisfy the following constraints:

$$\begin{aligned} H(c_i;c_j) &> H(c_j;c_i) \\ H(c_i,c_j) &\leq \theta \end{aligned} \quad (3)$$

with θ as a threshold value, which can be interpreted as "the average joint entropy of any non-dependence concepts". The weight of the dependency is defined as:

$$D_{\mathrm{CE}}(c_i,c_j) = H(c_i;c_j)$$

The cross-entropy method is general and can be applied to different distributions used to model concepts, such as distributions of relevant words, of relevant documents, or of the documents that are cited by relevant documents.

4.2.2 Information-flow Approach

Now we consider predicting concept dependency relations from the perspective of navigating information. Imagine that we already have a perfect concept dependency graph. When we are at a concept node (e.g., reading a document about it), the navigation is more likely to continue to a concept it depends on than to other concepts that it doesn't depend on. To give a concrete example, if we are navigating from the concept *Page rank*, it is more likely for us to jump to *Eigenvalue* than to *Language model*. Therefore, if concept c_i depends on concept c_j, then c_j generally receives more navigation hits than c_i and has higher "information flow".

Based on this intuition, we can predict concept dependency relations using information flow: Given concepts c_i and c_j, c_i depends on c_j if they satisfy these conditions:

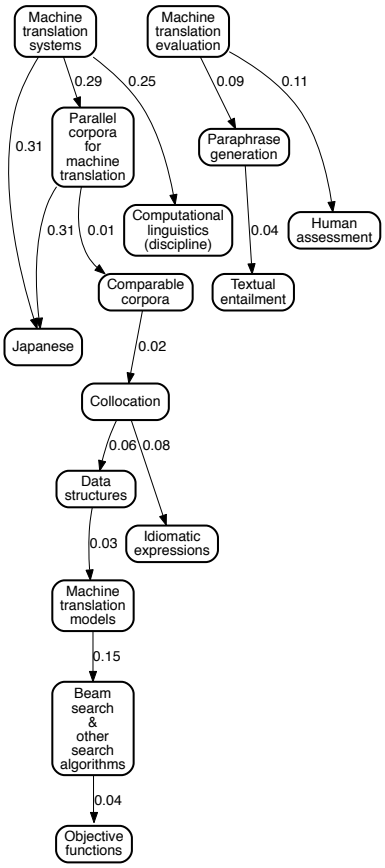

Figure 3: A concept graph excerpt related to machine translation, where concepts are linked based on cross entropy. Concepts are represented by manually chosen names, and links to documents are omitted.

1 The concept c_i receives relatively lower navigation hits than c_j.
2 The number of navigation traces from concept c_i to c_j is much stronger than that to another non-dependent concept c_k.

While we do not have data for human navigation between concepts, a natural way to simulate this is through information flow. As proposed by Rosvall and Bergstrom (2008), we use the probability flow of random walks on a network as a proxy for information flow in the real system. Given any observed graph G, the information score $I(v)$ of a node v, is defined as its steady state visit frequency. The information flow $I(u,v)$ from node u to node v, is consequently defined as the transition probability (or "exit probability") from u to v.

To this end, we construct a graph connecting concepts by their co-occurrences in documents, and we can use either Map Equation (Rosvall and

Bergstrom, 2008) or Content Map Equation (Smith et al., 2014) to compute the information flow network and the information score for each concept node. The details are outlined as follows:

1 Construct a concept graph G^{co} based on co-occurrence observations. We define weighted, undirected edges within the concept graph based on the number of documents in which the concepts co-occur. Formally, given concepts c_i and c_j and a threshold $0 \leq \tau \leq 1$, the weighted edge is calculated as:

$$w^{co}(c_i, c_j) = \begin{cases} \sum_d p(c_i|d)p(c_j|d) & \text{if } p(c|d) > \tau \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

2 Given the graph G^{co}, we compute the information score $I(c)$ for each concept node c and information flow $I(c_i, c_j)$ between a pair of nodes c_i and c_j. For the details of calculating $I(c)$ and $I(c_i, c_j)$, refer to Map Equation (Rosvall and Bergstrom, 2008) and Content Map Equation (Smith et al., 2014).

3 Given two concepts c_i and c_j, we link c_i to c_j with a directed edge if $I(c_i) > I(c_j)$ with weight:

$$D_{\text{IF}}(c_i, c_j) = I(c_i, c_j)$$

The information flow approach for inferring dependency can be further improved with a few true human navigation traces. As introduced earlier, the concept graph representation facilitates applications such as reading list generation, and document retrieval. Those applications enable the collection of human navigation traces, which can provide a better approximation of dependency relation.

4.2.3 Baseline Approaches

Similarity Relations Intuitively, concepts that are more similar (e.g., *Machine translation* and *Machine translation evaluation*) are more likely to be connected by concept dependency relations than less similar concepts are. As a baseline, we compute the Jaccard similarity coefficient based on the top 20 words or n-grams in the concept's topic word distributions.

Hierarchical Relations Previous work has looked at learning hierarchies that connect broader topics (acting as equivalent proxies for concepts in our work) to more specific subtopics (Cimiano et al., 2005; Sanderson and Croft, 1999). We compare against a method for doing so to see how close identifying hierarchical relations comes to our goal of identifying concept dependency relations. Specifically, we perform agglomerative clustering over the topic–topic co-occurrence graph G^{co} with weights defined in Eq. 4, in order to obtain the hierarchical representation for concepts.

Citation-based Given concepts c_i and c_j, if the documents that are highly related to c_j are cited by most of the instances of c_i, c_i may depend on c_j. Wang et al. (2013) used this approach in the context of CitationLDA topic modeling, where topics are learned from citation links rather than text. We adapt this for regular LDA so that the concept c_i depends on c_j with weight

$$\text{D}_{\text{Cite}}(c_i, c_j) = \sum_{d_1 \in D} \sum_{d_2 \in C_{d_1}} T_{1,i} T_{2,j} \quad (5)$$

where D is the set of all documents, C_d are the documents cited by d, and $T_{x,y}$ is the distribution of documents d_x composed of concepts c_y. For this method, we return a score of 0 if the concepts do not co-occur in at least three documents.

5 Evaluation of Concept Graphs

There are two main approaches to evaluating a concept graph: We can directly evaluate the graph, using human judgments to measure the quality of the concepts and the reliability of the links between them. Alternatively, we can evaluate the application of a concept graph to a task, such as ordering documents for a reading list or recommending documents to cite when writing a paper.

Our motivation to build a concept graph from a technical corpus is to improve performance at the task of reading list generation. However, an applied evaluation makes it harder to judge the quality of the concept graph itself. Each document contains a combination of concepts, which have different ordering restrictions, and other factors also affect the quality of a reading list, such as the classification of document difficulty and type (e.g., survey, tutorial, or experimental results). As such, we focus on a direct human evaluation of our proposed methods for building a concept graph and leave the measure of applied performance to future work.

5.1 Corpus and its Evaluation Concept Graphs

For this evaluation, the scientific corpus we use is the ACL Anthology. This consists of articles published in a variety of journals, conferences,

and workshops related to computational linguistics. Specifically, we use a modified copy of the plain text distributed for the ACL Anthology Network (AAN), release 2013 (Radev et al., 2013), which includes 23,261 documents from 1965 to 2013. The AAN includes plain text for documents, with OCR performed using PDFBox. We manually substituted OmniPage OCR output from the ACL Anthology Reference Corpus, version 1 (Bird et al., 2008) for documents where it was observed to be of higher quality. The text was processed to join words that were split across lines with hyphens. We manually removed documents that were not written in English or where text extraction failed, leaving 20,264 documents, though this filtering was not exhaustive.

The topic model we used was built using the Mallet (McCallum, 2002) implementation of LDA. It is composed of bigrams, filtered of typical English stop words before the generation of bigrams, so that, e.g., "word to word" yields the bigram "word word". We generated topic models consisting of between 20 and 400 topics and selected a 300-topic model based on manual inspection. Documents were linked to concepts based on the document's LDA topic composition. The concept nodes for each topic were linked in concept dependency relations using each of the methods described in Section 4, producing five concept graphs to evaluate. We applied the general cross-entropy method to the distribution of top-k bigrams for each concept. For all methods, the results we report are for $k = 20$. Changing this value shifts the precision–recall trade-off, but in our experiments, the relative performance of the methods are generally consistent for different values of k.

Since it is impractical to manually annotate all pairs of concept nodes from a 300-node graph, we selected a subset of edges for evaluation. Intuitively, the evaluation set should satisfy the following sampling criteria: (1) The evaluation set should cover the top weighted edges for a precision evaluation. (2) The evaluation set should cover the bottom-weighted edges for a recall evaluation. (3) The evaluation set should provide low-biased sampling. With respect to these requirements, we generated an evaluation edge set as the union of the following three sets:

1 Top-20 edges for each approach (including baseline approaches)
2 A random shuffle selection from the union of the top-50 and bottom-50 edges in terms of the baseline word similarity.[1]
3 A random shuffle section from the union of top-100 edges in terms of the proposed approaches.

Judges	All	Coherent	Related	Dependent
Non-NLP	0.407	0.446	0.305	0.329
NLP	0.526	0.610	0.448	0.395
All	0.467	0.529	0.354	0.357

Table 1: Inter-annotator agreement measured as Pearson correlation.

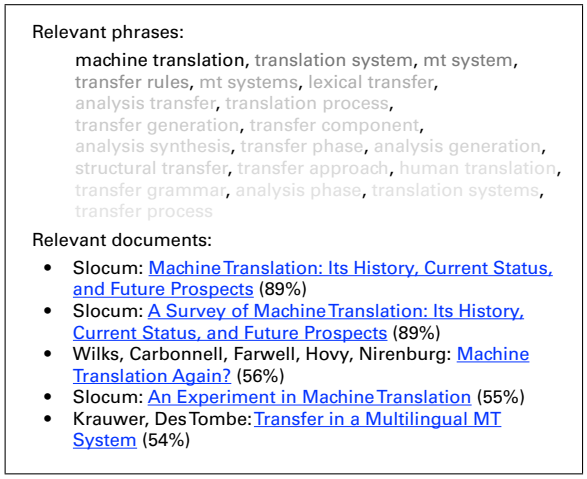

Figure 4: An example of the presentation of a topic for human evaluation.

5.2 Human Annotation

For annotation, we present pairs of topics followed by questions. Each topic is presented to a judge as a list of the most relevant bigrams in descending order of their topic-specific "collapsed" probabilities. These are presented in greyscale so that the most relevant items appear black, fading through grey to white as the strength of that item's association with the topic decreases. The evaluation interface also lists the documents that are most relevant to the topic, linked to the original PDFs. These documents can be used to clarify the occurrence of unfamiliar terms, such as author names or common examples that may show up in the topic representation. An example topic is shown in Figure 4.

For each topic, judges were asked:

1 How clear and coherent is Topic 1?
2 How clear and coherent is Topic 2?

[1] We observe that usually if the edge strength in terms of one of the information-theoretic methods is zero, the word similarity is zero as well, but if the word similarity is zero, the edge strength in terms of the proposed methods may be non-zero.

Edges	Top 20	Top 150			All scores > 0		
	Prec.	Prec.	Rec.	f_1	Prec.	Rec.	f_1
Cross entropy (D_{CE})	**0.851**	0.765	0.358	0.487	0.693	0.670	0.681
Information flow (D_{IF})	0.793	0.696	0.311	0.429	0.693	0.323	0.441
Word similarity (D_{Sim})	0.808	**0.768**	0.382	**0.511**	**0.768**	0.382	0.511
Hierarchy (D_{Hier})	0.680	0.692	0.297	0.416	0.686	0.638	0.661

Table 2: Precision, recall, and f-scores (with different thresholds for which edges are included) for the methods of predicting dependency relations between concepts described in Section 4.2.

If both topics are at least somewhat clear:

3 How related are these topics?
4 Would understanding Topic 1 help you to understand Topic 2?
5 Would understanding Topic 2 help you to understand Topic 1?

For each question, they could answer "I don't know" or select from an ordinal scale:

1 Not at all
2 Somewhat
3 Very much

The evaluation was completed by eight judges with varying levels of familiarity with the technical domain. Four judges are NLP researchers: Three PhD students working in the area and one of the authors. Four judges are familiar with NLP but have less experience with NLP research: two MS students, an AI PhD student, and one of the authors. The full evaluation was divided into 10 sets taking a total of around 6–8 hours per person to annotate. Their overall inter-annotator agreement and the agreement for each question type is given in Table 1. Agreement is higher when we consider only judgments from NLP researchers, but in all cases is moderate, indicating the difficulty of interpreting statistical topics as concepts and judging the strength (if any) of the concept dependency relation between them.

The topic coherence judgments that were collected served to make each human judge consider how well she understood each topic before judging their dependence. The topic relatedness questions provided an opportunity to indicate that if the annotator recognized a relation between the topics without needing to say that their was a dependence.

5.3 Evaluation of Automatic Methods

To measure the quality of the concept dependency edges in our graphs, we compute the average precision for the strongest edges in each concept graph, up to three thresholds: the top 20 edges, the top 150, and all edges with strength > 0. These precision scores are in Table 2 as well as the corresponding recall, and f_1 scores for the larger thresholds. Despite the difference in inter-annotator agreement reported in Table 1, the ordering of methods by precision is the same whether we consider only the judgments of NLP experts, non-NLP judges, or everyone, so we only report the average across all annotators.

When we examine the results of precision at 20 – the strongest edges predicted by each method – we see that the cross-entropy method performs best. For comparison, we report the accuracy of a baseline of random numbers between 0 and 1. While all methods have better than chance precision, the random baseline has higher recall since it predicts a dependency relation of non-zero strength for all pairs. As we consider edges predicted with lower confidence, the word similarity approach shows the highest precision. A limitation of the word similarity baseline is that it is symmetric while concept dependence relations can be asymmetric.

Annotators marked many pairs of concepts as being at least somewhat co-dependent. E.g., understanding *Speech recognition* strongly helps you understand *Natural language processing*, but being familiar with this broader topic also somewhat helps you understand the narrower one. The precision scores we report count both annotations of concept dependence ("Somewhat" and "Very much") as positive predictions, but other evaluation metrics might show a greater benefit for methods like D_{CE} that can predict dependency with asymmetric strengths.

6 Discussion

Another natural evaluation of an automatically generated concept graph would be to compare it to a

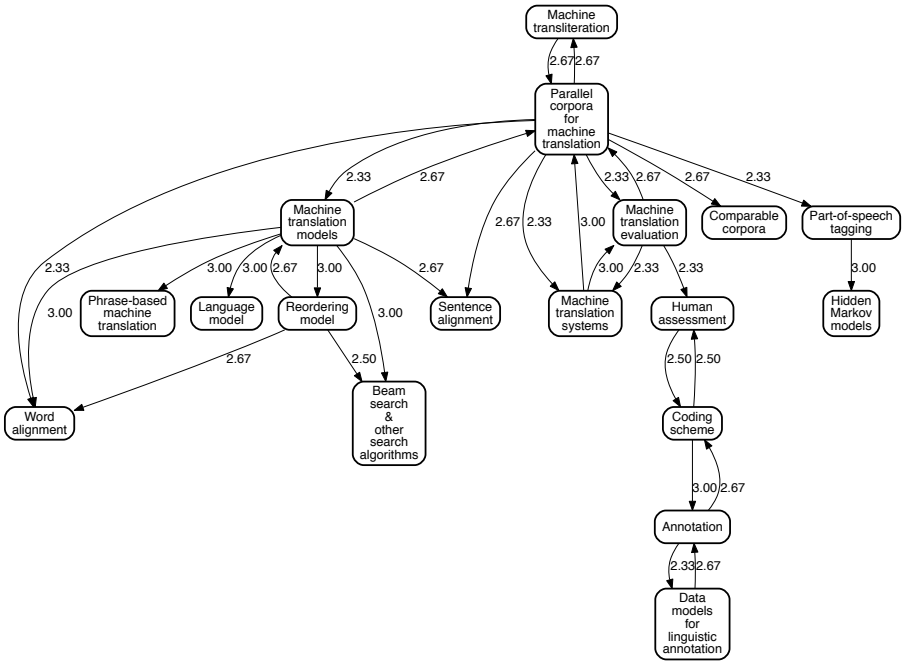

Figure 5: A concept graph excerpt related to machine translation, where concepts are joined based on the judgments of human annotators. Concepts are represented by manually chosen names, and links to documents are omitted.

human-generated gold standard, where an expert has created concept nodes at the optimal level of generality and linked these by her understanding of the conceptual dependencies among concepts in the domain. However, there are several difficulties with this approach: (1) It is quite labor-intensive to manually generate a concept graph; (2) we expect only moderate agreement between graphs produced by different experts, who have different ideas of what concepts are important and distinct and which concepts are important to understanding others; and (3) the concept graphs we learn from a collection of documents will differ significantly from those we imagine, without these differences necessarily being better or worse.

In this work, we assume that a topic model provides a reasonable proxy for the concepts a person might identify in a technical corpus. However, topic modeling approaches are better at finding general areas of research than at identifying fine-grained concepts like those shown in Figure 1. The concept graph formalism can be extended with the use of discrete entities, identified by a small set of names, e.g., (*First-order logic*, *FOL*). We have performed initial work on two approaches to extract entities:

1 We can use an external reference, Wikipedia, to help entity extraction. We count the occurrences of each article title in the scientific corpus, and we keep the high-frequency titles as entities. For example, in the ACL Anthology corpus, we obtain 56 thousand entities (page titles) that occurred at least once and 1,123 entities that occur at least 100 times.

2 We cannot assume that the important entities in every scientific or technical corpus will be well-represented on Wikipedia. In the absence of a suitable external reference source, we can use the open-source tool SKIMMR (Nováček and Burns, 2014) or the method proposed by Jardine (2014) to extract important noun phrases to use as entities. The importance of a potential entity can be computed based on the occurrence frequency and the sentence-level co-occurrence frequency with other phrases.

Another limitation of using a topic model like LDA as a proxy for concepts is that the topics are static, while a corpus may span decades of research. Studying how latent models might evolve or "drift" over time within a textual corpus describing a technical discipline is an important research question, and our approach could be extended to add or remove topics in a central model over time.

Despite its limitations, a topic model is useful for automatically discovering concepts in a corpus even if the concept is not explicitly mentioned in a document (e.g., the words "axiom" or "predi-

cate" might indicate discussion of logic) or has no canonical name. The concept graph representation allows for the introduction of additional or alternative features for concepts, making it suitable for new methods of identifying and linking concepts.

7 Conclusions

Problems such as reading list generation require a representation of the structure of the content of a scientific corpus. We have proposed the concept graph framework, which gives weighted links from documents to the concepts they discuss and links concepts to one another. The most important link in the graph is the concept dependency relation, which indicates that one concept helps a learner to understand another, e.g., *Markov logic networks* depends on *Probability*.

We have presented four approaches to predicting these relations. We propose information-theoretic measures based on cross entropy and on information flow. We also present baselines that compute the similarity of the word distributions associated with each concept, the likelihood of a citation connecting the concepts, and a hierarchical clustering approach. While word similarity proves a strong baseline, the strongest edges predicted by the cross-entropy approach are more precise. We are releasing human annotations of concept nodes and possible dependency edges learned from the ACL Anthology as well as implementations of the methods described in this paper to enable future research on modeling scientific corpora.[2]

Normalized Log-Linear Interpolation of Backoff Language Models is Efficient

Abstract

We prove that log-linearly interpolated backoff language models can be efficiently and exactly collapsed into a single normalized backoff model, contradicting Hsu (2007). While prior work reported that log-linear interpolation yields lower perplexity than linear interpolation, normalizing at query time was impractical. We normalize the model offline in advance, which is efficient due to a recurrence relationship between the normalizing factors. To tune interpolation weights, we apply Newton's method to this convex problem and show that the derivatives can be computed efficiently in a batch process. These findings are combined in new open-source interpolation tool, which is distributed with KenLM. With 21 out-of-domain corpora, log-linear interpolation yields 72.58 perplexity on TED talks, compared to 75.91 for linear interpolation.

1 Introduction

Log-linearly interpolated backoff language models yielded better perplexity than linearly interpolated models (Klakow, 1998; Gutkin, 2000), but experiments and adoption were limited due the impractically high cost of querying. This cost is due to normalizing to form a probability distribution by brute-force summing over the entire vocabulary for each query. Instead, we prove that the log-linearly interpolated model can be normalized offline in advance and exactly expressed as an ordinary backoff language model. This contradicts Hsu (2007), who claimed that log-linearly interpolated models "cannot be efficiently represented as a backoff n–gram model."

We show that offline normalization is efficient due to a recurrence relationship between the normalizing factors (Whittaker and Klakow, 2002). This forms the basis for our open-source implementation, which is part of KenLM: `https://kheafield.com/code/kenlm/`.

Linear interpolation (Jelinek and Mercer, 1980), combines several language models p_i into a single model p_{L}

$$p_{\text{L}}(w_n \mid w_1^{n-1}) = \sum_i \lambda_i p_i(w_n \mid w_1^{n-1})$$

where λ_i are weights and w_1^n are words. Because each component model p_i is a probability distribution and the non-negative weights λ_i sum to 1, the interpolated model p_{L} is also a probability distribution. This presumes that the models have the same vocabulary, an issue we discuss in §3.1.

A log-linearly interpolated model p_{LL} uses the weights λ_i as powers (Klakow, 1998).

$$p_{\text{LL}}(w_n \mid w_1^{n-1}) \propto \prod_i p_i(w_n \mid w_1^{n-1})^{\lambda_i}$$

The weights λ_i are unconstrained real numbers, allowing parameters to soften or sharpen distributions. Negative weights can be used to divide a mixed-domain model by an out-of-domain model. To form a probability distribution, the product is normalized

$$p_{\text{LL}}(w_n \mid w_1^{n-1}) = \frac{\prod_i p_i(w_n \mid w_1^{n-1})^{\lambda_i}}{Z(w_1^{n-1})}$$

where normalizing factor Z is given by

$$Z(w_1^{n-1}) = \sum_x \prod_i p_i(x \mid w_1^{n-1})^{\lambda_i}$$

The sum is taken over all words x in the combined vocabulary of the underlying models, which can number in the millions or even billions. Computing Z efficiently is a key contribution in this work.

Our proofs assume the component models p_i are backoff language models (Katz, 1987) that memorize probability for seen n–grams and charge a

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 876–886, Berlin, Germany, August 7-12, 2016.

backoff penalty b_i for unseen n–grams.

$$p_i(w_n \mid w_1^{n-1}) = \begin{cases} p_i(w_n \mid w_1^{n-1}) \text{ if } w_1^n \text{ is seen} \\ p_i(w_n \mid w_2^{n-1}) b_i(w_1^{n-1}) \text{ o.w.} \end{cases}$$

While linearly or log-linearly interpolated models can be queried online by querying the component models (Stolcke, 2002; Federico et al., 2008), doing so costs RAM to store duplicated n–grams and CPU time to perform lookups. Log-linear interpolation is particularly slow due to normalizing over the entire vocabulary. Instead, it is preferable to combine the models offline into a single backoff model containing the union of n–grams. Doing so is impossible for linear interpolation (§3.2); SRILM (Stolcke, 2002) and MITLM (Hsu and Glass, 2008) implement an approximation. In contrast, we prove that offline log-linear interpolation requires no such approximation.

2 Related Work

Instead of building separate models then weighting, Zhang and Chiang (2014) show how to train Kneser-Ney models (Kneser and Ney, 1995) on weighted data. Their work relied on prescriptive weights from domain adaptation techniques rather than tuning weights, as we do here.

Our exact normalization approach relies on the backoff structure of component models. Several approximations support general models: ignoring normalization (Chen et al., 1998), noise-contrastive estimation (Vaswani et al., 2013), and self-normalization (Andreas and Klein, 2015). In future work, we plan to exploit the structure of other features in high-quality unnormalized log-linear language models (Sethy et al., 2014).

Ignoring normalization is particularly common in speech recognition and machine translation. This is one of our baselines. Unnormalized models can also be compiled into a single model by multiplying the weighted probabilities and backoffs.[1] Many use unnormalized models because weights can be jointly tuned along with other feature weights. However, Haddow (2013) showed that linear interpolation weights can be jointly tuned by pairwise ranked optimization (Hopkins and May, 2011). In theory, normalized log-linear interpolation weights can be jointly tuned in the same way.

[1]Missing probabilities are found from the backoff algorithm and missing backoffs are implicitly one.

Dynamic interpolation weights (Weintraub et al., 1996) give more weight to models familiar with a given query. Typically the weights are a function of the contexts that appear in the combined language model, which is compatible with our approach. However, normalizing factors would need to be calculated in each context.

3 Linear Interpolation

To motivate log-linear interpolation, we examine two issues with linear interpolation: normalization when component models have different vocabularies and offline interpolation.

3.1 Vocabulary Differences

Language models are normalized with respect to their vocabulary, including the unknown word.

$$\sum_{x \in \text{vocab}(p_1)} p_1(x) = 1$$

If two models have different vocabularies, then the combined vocabulary is larger and the sum is taken over more words. Component models assign their unknown word probability to these new words, leading to an interpolated model that sums to more than one. An example is shown in Table 1.

	p_1	p_2	p_{L}	Zero
<unk>	0.4	0.2	0.3	0.3
A	0.6		0.4	0.3
B		0.8	0.6	0.4
Sum	1	1	1.3	1

Table 1: Linearly interpolating two models p_1 and p_2 with equal weight yields an unnormalized model p_{L}. If gaps are filled with zeros instead, the model is normalized.

To work around this problem, SRILM (Stolcke, 2002) uses zero probability instead of the unknown word probability for new words. This produces a model that sums to one, but differs from what users might expect.

IRSTLM (Federico et al., 2008) asks the user to specify a common large vocabulary size. The unknown word probability is downweighted so that all models sum to one over the large vocabulary.

A component model can also be renormalized with respect to a larger vocabulary. For unigrams, the extra mass is the number of new words times the unknown word probability. For longer contexts, if we assume the typical case where the

unknown word appears only as a unigram, then queries for new words will back off to unigrams. The total mass in context w_1^{n-1} is

$$1 + |new| p(\text{<unk>}) \prod_{i=1}^{n-1} b(w_i^{n-1})$$

where new is the set of new words. This is efficient to compute online or offline. While there are tools to renormalize models, we are not aware of a tool that does this for linear interpolation.

Log-linear interpolation is normalized by construction. Nonetheless, in our experiments we extend IRSTLM's approach by training models with a common vocabulary size, rather than retrofitting it at query time.

3.2 Offline Linear Interpolation

Given an interpolated model, offline interpolation seeks a combined model meeting three criteria: (i) encoding the same probability distribution, (ii) being a backoff model, and (iii) containing the union of n–grams from component models.

Theorem 1. *The three offline criteria cannot be satisfied for general linearly interpolated backoff models.*

Proof. By counterexample. Consider the models given in Table 2 interpolated with equal weight.

	p_1	p_2	p_L
$p(\text{A})$	0.4	0.2	0.3
$p(\text{B})$	0.3	0.3	0.3
$p(\text{C})$	0.3	0.5	0.4
$p(\text{C} \mid \text{A})$	0.4	0.8	0.6
b(A)	$\frac{6}{7} \approx 0.857$	0.4	$\frac{2}{3} \approx 0.667$

Table 2: Counterexample models.

The probabilities shown for p_L result from encoding the same distribution. Taking the union of n–grams implies that p_L only has entries for A, B, C, and A C. Since the models have the same vocabulary, they are all normalized to one.

$$p(\text{A} \mid \text{A}) + p(\text{B} \mid \text{A}) + p(\text{C} \mid \text{A}) = 1$$

Since all models have backoff structure,

$$p(\text{A})b(\text{A}) + p(\text{B})b(\text{A}) + p(\text{C} \mid \text{A}) = 1$$

which when solved for backoff $b(\text{A})$ gives the values shown in Table 2. We then query $p_\text{L}(\text{B} \mid \text{A})$ online and offline. Online interpolation yields

$$\begin{aligned} p_\text{L}(\text{B} \mid \text{A}) &= \frac{1}{2} p_1(\text{B} \mid \text{A}) + \frac{1}{2} p_2(\text{B} \mid \text{A}) \\ &= \frac{1}{2} p_1(\text{B}) b_1(\text{A}) + \frac{1}{2} p_2(\text{B}) b_2(\text{A}) = \frac{33}{175} \end{aligned}$$

Offline interpolation yields

$$p_\text{L}(\text{B} \mid \text{A}) = p_\text{L}(\text{B}) b_\text{L}(\text{A}) = 0.2 \neq \frac{33}{175} \approx 0.189$$

□

The same problem happens with real language models. To understand why, we attempt to solve for the backoff $b_\text{L}(w_1^{n-1})$. Supposing w_1^n is not in either model, we query $p_\text{L}(w_n \mid w_1^{n-1})$ offline

$$\begin{aligned} & p_\text{L}(w_n | w_1^{n-1}) \\ =& p_\text{L}(w_n | w_2^{n-1}) b_\text{L}(w_1^{n-1}) \\ =& (\lambda_1 p_1(w_n | w_2^{n-1}) + \lambda_2 p_2(w_n | w_2^{n-1})) b_\text{L}(w_1^{n-1}) \end{aligned}$$

while online interpolation yields

$$\begin{aligned} & p_\text{L}(w_n | w_1^{n-1}) \\ =& \lambda_1 p_1(w_n | w_1^{n-1}) + \lambda_2 p_2(w_n | w_1^{n-1}) \\ =& \lambda_1 p_1(w_n | w_2^{n-1}) b_1(w_1^{n-1}) + \lambda_1 p_2(w_n | w_2^{n-1}) b_2(w_1^{n-1}) \end{aligned}$$

Solving for $b_\text{L}(w_1^{n-1})$ we obtain

$$\frac{\lambda_1 p_1(w_n | w_2^{n-1}) b_1(w_1^{n-1}) + \lambda_2 p_2(w_n | w_2^{n-1}) b_2(w_1^{n-1})}{\lambda_1 p_1(w_n | w_2^{n-1}) + \lambda_2 p_2(w_n | w_2^{n-1})}$$

which is a weighted average of the backoff weights $b_1(w_1^{n-1})$ and $b_2(w_1^{n-1})$. The weights depend on w_n, so b_L is no longer a function of w_1^{n-1}.

In the SRILM approximation (Stolcke, 2002), probabilities for n–grams that exist in the model are computed exactly. The backoff weights are chosen to produce a model that sums to one. However, newer versions of SRILM (Stolcke et al., 2011) interpolate by ingesting one component model at a time. For example, the first two models are approximately interpolated before adding a third model. An n–gram appearing only in the third model will have an approximate probability. Therefore, the output depends on the order in which users specify models. Moreover, weights were optimized for correct linear interpolation, not the approximation.

Stolcke (2002) find that the approximation actually decreases perplexity, which we also see in the experiments (§6). However, approximation only happens when the model backs off, which is less likely to happen in fluent sentences used for perplexity scoring.

4 Offline Log-Linear Interpolation

Log-linearly interpolated backoff models p_i can be collapsed into a single offline model p_{LL}. The combined model takes the union of n–grams in component models.[2] For those n–grams, it memorizes correct probability p_{LL}.

$$p_{\text{LL}}(w_n \mid w_1^{n-1}) = \frac{\prod_i p_i(w_n \mid w_1^{n-1})^{\lambda_i}}{Z(w_1^{n-1})} \quad (1)$$

When w_1^n does not appear, the backoff $b_{\text{LL}}(w_1^{n-1})$ modifies $p_{\text{LL}}(w_n \mid w_2^{n-1})$ to make an appropriately normalized probability. To do so, it cancels out the shorter query's normalization term $Z(w_2^{n-1})$ then applies the correct term $Z(w_1^{n-1})$. It also applies the component backoff terms.

$$b_{\text{LL}}(w_1^{n-1}) = \frac{Z(w_2^{n-1})}{Z(w_1^{n-1})} \prod_i b_i(w_1^{n-1})^{\lambda_i} \quad (2)$$

Almost by construction, the model satisfies two of our criteria (§3.2): being a backoff model and containing the union of n–grams. However, backoff models require that the backoff weight of an unseen n–gram be implicitly 1.

Lemma 1. *If w_1^{n-1} is unseen in the combined model, then the backoff weight $b_{LL}(w_1^{n-1}) = 1$.*

Proof. Because we have taken the union of entries, w_1^{n-1} is unseen in component models. These components are backoff models, so implicitly $b_i(w_1^{n-1}) = 1 \; \forall i$. Focusing on the normalization term $Z(w_1^{n-1})$,

$$\begin{aligned} Z(w_1^{n-1}) &= \sum_x \prod_i p_i(x \mid w_1^{n-1})^{\lambda_i} \\ &= \sum_x \prod_i p_i(x \mid w_2^{n-1})^{\lambda_i} b_i(w_1^{n-1})^{\lambda_i} \\ &= \sum_x \prod_i p_i(x \mid w_2^{n-1})^{\lambda_i} \\ &= Z(w_2^{n-1}) \end{aligned}$$

All of the models back off because $w_1^{n-1}x$ is unseen, being a superstring of w_1^{n-1}. Relevant backoff weights $b_i(w_1^{n-1}) = 1$ as noted earlier. Recalling the definition of $b_{\text{LL}}(w_1^{n-1})$,

$$\frac{Z(w_2^{n-1})}{Z(w_1^{n-1})} \prod_i b_i(w_1^{n-1})^{\lambda_i} = \frac{Z(w_2^{n-1})}{Z(w_1^{n-1})} = 1 \quad \square$$

[2] We further assume that every substring of a seen n–gram is also seen. This follows from estimating on text, except in the case of adjusted count pruning by SRILM. In such cases, we add the missing entries to component models, with no additional memory cost in trie data structures.

We now have a backoff model containing the union of n–grams. It remains to show that the offline model produces correct probabilities.

Theorem 2. *The proposed offline model agrees with online log-linear interpolation.*

Proof. By induction on the number of words backed off in offline interpolation. To disambiguate, we will use p_{on} to refer to online interpolation and p_{off} to refer to offline interpolation.
Base case: the queried n–gram is in the offline model and we have memorized the online probability by construction.
Inductive case: Let $p_{\text{off}}(w_n \mid w_1^{n-1})$ be a query that backs off. In online interpolation,

$$p_{\text{on}}(w_n \mid w_1^{n-1}) = \frac{\prod_i p_i(w_n \mid w_1^{n-1})^{\lambda_i}}{Z(w_1^{n-1})}$$

Because w_1^n is unseen in the offline model and we took the union, it is unseen in every model p_i.

$$\begin{aligned} &= \frac{\prod_i p_i(w_n \mid w_2^{n-1})^{\lambda_i} b_i(w_1^{n-1})^{\lambda_i}}{Z(w_1^{n-1})} \\ &= \frac{\left(\prod_i p_i(w_n \mid w_2^{n-1})^{\lambda_i}\right) \prod_i b_i(w_1^{n-1})^{\lambda_i}}{Z(w_1^{n-1})} \end{aligned}$$

Recognizing the unnormalized probability $Z(w_2^{n-1})p_{\text{on}}(w_n \mid w_2^{n-1})$,

$$\begin{aligned} &= \frac{Z(w_2^{n-1})p_{\text{on}}(w_n \mid w_2^{n-1}) \prod_i b_i(w_1^{n-1})^{\lambda_i}}{Z(w_1^{n-1})} \\ &= p_{\text{on}}(w_n \mid w_2^{n-1}) \frac{Z(w_2^{n-1})}{Z(w_1^{n-1})} \prod_i b_i(w_1^{n-1})^{\lambda_i} \\ &= p_{\text{on}}(w_n \mid w_2^{n-1}) b_{\text{off}}(w_1^{n-1}) \end{aligned}$$

The last equality follows from the definition of b_{off} and Lemma 1, which extended the domain of b_{off} to any w_1^{n-1}. By the inductive hypothesis, $p_{\text{on}}(w_n \mid w_2^{n-1}) = p_{\text{off}}(w_n \mid w_2^{n-1})$ because it backs off one less time.

$$= p_{\text{off}}(w_n \mid w_2^{n-1}) b_{\text{off}}(w_1^{n-1}) = p_{\text{off}}(w_n \mid w_1^{n-1})$$

The offline model $p_{\text{off}}(w_n \mid w_1^{n-1})$ backs off because that is the case we are considering. Combining our chain of equalities,

$$p_{\text{on}}(w_n \mid w_1^{n-1}) = p_{\text{off}}(w_n \mid w_1^{n-1})$$

By induction, the claim holds for all w_1^n. $\square$

4.1 Normalizing Efficiently

In order to build the offline model, the normalization factor Z needs to be computed in every seen context. To do so, we extend the tree-structure method of Whittaker and Klakow (2002), which they used to compute and cache normalization factors on the fly. It exploits the sparsity of language models: when summing over the vocabulary, most queries will back off. Formally, we define $s(w_1^n)$ to be the set of words x where $p_i(x \mid w_1^n)$ does not back off in some model.

$$s(w_1^n) = \{x : w_1^n x \text{ is seen in any model}\}$$

To exploit this, we use the normalizing factor $Z(w_2^n)$ from a lower order and patch it up by summing over $s(w_1^n)$.

Theorem 3. *The normalization factors Z obey a recurrence relationship:*

$$Z(w_1^n) = \sum_{x \in s(w_1^n)} \prod_i p_i(x \mid w_1^n)^{\lambda_i} + \left(Z(w_2^n) - \sum_{x \in s(w_1^n)} \prod_i p_i(x \mid w_2^n)^{\lambda_i} \right) \prod_i b_i(w_1^n)^{\lambda_i}$$

Proof. The first term handles seen n–grams while the second term handles unseen n–grams. The definition of Z

$$Z(w_1^n) = \sum_{x \in \text{vocab}} \prod_i p_i(x \mid w_1^n)^{\lambda_i}$$

can be partitioned by cases.

$$\sum_{x \in s(w_1^n)} \prod_i p_i(x \mid w_1^n)^{\lambda_i} + \sum_{x \notin s(w_1^n)} \prod_i p_i(x \mid w_1^n)^{\lambda_i}$$

The first term agrees with the claim, so we focus on the case where $x \notin s(w_1^n)$. By definition of s, all models back off.

$$\begin{aligned}
&\sum_{x \notin s(w_1^n)} \prod_i p_i(x \mid w_1^n)^{\lambda_i} \\
&= \sum_{x \notin s(w_1^n)} \prod_i p_i(x \mid w_2^n)^{\lambda_i} b_i(w_1^n)^{\lambda_i} \\
&= \left(\sum_{x \notin s(w_1^n)} \prod_i p_i(x \mid w_2^n)^{\lambda_i} \right) \prod_i b_i(w_1^n)^{\lambda_i} \\
&= \left(Z(w_2^n) - \sum_{x \in s(w_1^n)} \prod_i p_i(x \mid w_2^n)^{\lambda_i} \right) \prod_i b_i(w_1^n)^{\lambda_i}
\end{aligned}$$

This is the second term of the claim. □

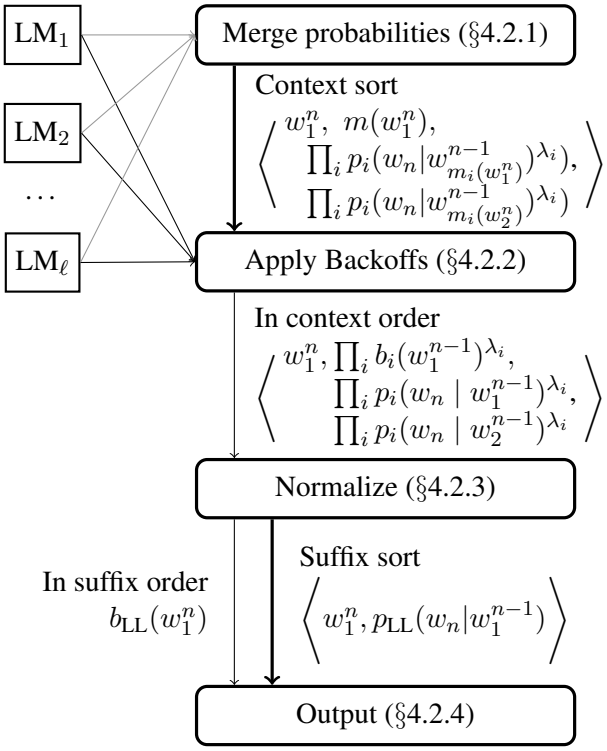

Figure 1: Multi-stage streaming pipeline for offline log-linear interpolation. Bold arrows indicate sorting is performed.

The recurrence structure of the normalization factors suggests a computational strategy: compute $Z(\epsilon)$ by summing over the unigrams, $Z(w_n)$ by summing over bigrams $w_n x$, $Z(w_{n-1}^n)$ by summing over trigrams $w_{n-1}^n x$, and so on.

4.2 Streaming Computation

Part of the point of offline interpolation is that there may not be enough RAM to fit all the component models. Moreover, with compression techniques that rely on immutable models (Whittaker and Raj, 2001; Talbot and Osborne, 2007), a mutable version of the combined model may not fit in RAM. Instead, we construct the offline model with disk-based streaming algorithms, using the framework we designed for language model estimation (Heafield et al., 2013). Our pipeline (Figure 1) has four conceptual steps: merge probabilities, apply backoffs, normalize, and output. Applying backoffs and normalization are performed in the same pass, so there are three total passes.

4.2.1 Merge Probabilities

This step takes the union of n–grams and multiplies probabilities from component models. We

assume that the component models are sorted in suffix order (Figure 4), which is true of models produced by `lmplz` (Heafield et al., 2013) or stored in a reverse trie. Moreover, despite having different word indices, the models are consistently sorted using the string word, or a hash thereof.

3	**2**	**1**
		A
	A	A
A	A	A
B	A	A
		B

Table 3: Merging probabilities processes n–grams in lexicographic order by suffix. Column headings indicate precedence.

The algorithm processes n–grams in lexicographic (depth-first) order by suffix (Table 3). In this way, the algorithm processes $p_i(A)$ before it might be used as a backoff point for $p_i(A \mid B)$ in one of the models. It jointly streams through all models, so that $p_1(A \mid B)$ and $p_2(A \mid B)$ are available at the same time. Ideally, we would compute unnormalized probabilities.

$$\prod_i p_i(w_n \mid w_1^{n-1})^{\lambda_i}$$

However, these queries back off when models contain different n–grams. The appropriate backoff weights $b_i(w_1^{n-1})$ are not available in a streaming fashion. Instead, we proceed without charging backoffs

$$\prod_i p_i(w_n \mid w_{m_i(w_1^n)}^{n-1})^{\lambda_i}$$

where $m_i(w_1^n)$ records what backoffs should be charged later.

The normalization step (§4.2.3) also uses lower-order probabilities

$$\prod_i p_i(w_n \mid w_2^{n-1})^{\lambda_i}$$

and needs to access them in a streaming fashion, so we also output

$$\prod_i p_i(w_n \mid w_{m_i(w_2^n)}^{n-1})^{\lambda_i}$$

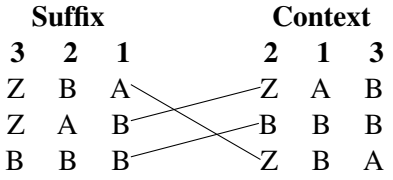

Table 4: Sorting orders (Heafield et al., 2013). In suffix order, the last word is primary. In context order, the penultimate word is primary. Column headings indicate precedence.

Each output tuple has the form

$$\left\langle w_1^n, m(w_1^n), \prod_i p_i(w_n|w_{m_i(w_1^n)}^{n-1})^{\lambda_i}, \prod_i p_i(w_n|w_{m_i(w_2^n)}^{n-1})^{\lambda_i} \right\rangle$$

where $m(w_1^n)$ is a vector of backoff requests, from which $m(w_2^n)$ can be computed.

4.2.2 Apply Backoffs

This step fulfills the backoff requests from merging probabilities. The merged probabilities are sorted in context order (Table 4) so that n–grams w_1^n sharing the same context w_1^{n-1} are consecutive. Moreover, contexts w_1^{n-1} appear in suffix order. We use this property to stream through the component models again in their native suffix order, this time reading backoff weights $b_i(w_1^{n-1}), b_i(w_2^{n-1}), \ldots, b_i(w_{n-1})$. Multiplying the appropriate backoff weights by $\prod_i p_i(w_n|w_{m_i(w_1^n)}^{n-1})^{\lambda_i}$ yields unnormalized probability

$$\prod_i p_i(w_n|w_1^{n-1})^{\lambda_i}$$

The same applies to the lower order.

$$\prod_i p_i(w_n|w_2^{n-1})^{\lambda_i}$$

This step also merges backoffs from component models, with output still in context order.

$$\left\langle w_1^n, \prod_i b_i(w_1^{n-1})^{\lambda_i}, \prod_i p_i(w_n|w_1^{n-1})^{\lambda_i} \prod_i p_i(w_n|w_2^{n-1})^{\lambda_i} \right\rangle$$

The implementation is combined with normalization, so the tuple is only conceptual.

4.2.3 Normalize

This step computes normalization factor Z for all contexts, which it applies to produce p_{LL} and b_{LL}. Recalling §4.1, $Z(w_1^{n-1})$ is efficient to compute in a batch process by processing suffixes $Z(\epsilon), Z(w_n), \ldots Z(w_2^{n-1})$ first. In order to minimize memory consumption, we chose to evaluate the contexts in depth-first order by suffix, so that $Z(\text{A})$ is computed immediately before it is needed to compute $Z(\text{A A})$ and forgotten at $Z(\text{B})$.

Computing $Z(w_1^{n-1})$ by applying Theorem 3 requires the sum

$$\sum_{x \in s(w_1^{n-1})} \prod_i p_i(x \mid w_1^{n-1})^{\lambda_i}$$

where $s(w_1^{n-1})$ restricts to seen n–grams. For this, we stream through the output of the apply backoffs step in context order, which makes the various values of x consecutive. Theorem 3 also requires a sum over the lower-order unnormalized probabilities

$$\sum_{x \in s(w_1^{n-1})} \prod_i p_i(x \mid w_2^{n-1})^{\lambda_i}$$

We placed these terms in the input tuple for $w_1^{n-1}x$. Otherwise, it would be hard to access these values while streaming in context order.

While we have shown how to compute $Z(w_1^{n-1})$, we still need to normalize the probabilities. Unfortunately, $Z(w_1^{n-1})$ is only known after streaming through all records of the form $w_1^{n-1}x$, which are the very same records to normalize. We therefore buffer up to the vocabulary size for each order in memory to allow rewinding. Processing context w_1^{n-1} thus yields normalized probabilities $p_{\text{LL}}(x \mid w_1^{n-1})$ for all seen $w_1^{n-1}x$.

$$\left\langle w_1^n, p_{\text{LL}}(x \mid w_1^{n-1}) \right\rangle$$

These records are generated in context order, the same order as the input.

The normalization step also computes backoffs.

$$b_{\text{LL}}(w_1^{n-1}) = \frac{Z(w_2^{n-1})}{Z(w_1^{n-1})} \prod_i b_i(w_1^{n-1})^{\lambda_i}$$

Normalization $Z(w_1^{n-1})$ is computed by this step, numerator $Z(w_2^{n-1})$ is available due to depth-first search, and the backoff terms $\prod_i b_i(w_1^{n-1})^{\lambda_i}$ are present in the input. The backoffs b_{LL} are generated in suffix order, since each context produces a backoff value. These are written to a sidechannel stream as bare values without keys.

4.2.4 Output

Language model toolkits store probability $p_{\text{LL}}(w_n \mid w_1^{n-1})$ and backoff $b_{\text{LL}}(w_1^n)$ together as values for the key w_1^n. To reunify them, we sort $\langle w_1^n, p_{\text{LL}}(w_n \mid w_1^{n-1}) \rangle$ in suffix order and merge with the backoff sidechannel from normalization, which is already in suffix order. Suffix order is also preferable because toolkits can easily build a reverse trie data structure.

5 Tuning

Weights are tuned to maximize the log probability of held-out data. This is a convex optimization problem (Klakow, 1998). Iterations are expensive due to the need to normalize over the vocabulary at least once. However, the number of weights is small, which makes the Hessian matrix cheap to store and invert. We therefore selected Newton's method.[3]

The log probability of tuning data w is

$$\log \prod_n p_{\text{LL}}(w_n \mid w_1^{n-1})$$

which expands according to the definition of p_{LL}

$$\sum_n \left(\sum_i \lambda_i \log p_i(w_n \mid w_1^{n-1}) \right) - \log Z(w_1^{n-1})$$

The gradient with respect to λ_i has a compact form

$$\sum_n \log p_i(w_n \mid w_1^{n-1}) + \text{CH}(p_{\text{LL}}, p_i \mid w_1^{n-1})$$

where CH is cross entropy. However, computing the cross entropy directly would entail a sum over the vocabulary for every word in the tuning data. Instead, we apply Theorem 3 to express $Z(w_1^{n-1})$ in terms of $Z(w_2^{n-1})$ before taking the derivative. This allows us to perform the same depth-first computation as before (§4.2.3), only this time $\frac{\partial}{\partial \lambda_i} Z(w_1^{n-1})$ is computed in terms of $\frac{\partial}{\partial \lambda_i} Z(w_2^{n-1})$.

The same argument applies when taking the Hessian with respect to λ_i and λ_j. Rather than compute it directly in the form

$$\sum_n -\sum_x p_{\text{LL}}(x|w_1^{n-1}) \log p_i(x|w_1^{n-1}) \log p_j(x|w_1^{n-1}) + \text{CH}(p_{\text{LL}}, p_i \mid w_1^{n-1})\text{CH}(p_{\text{LL}}, p_j \mid w_1^{n-1})$$

we apply Theorem 3 to compute the Hessian for w_1^n in terms of the Hessian for w_2^n.

[3] We also considered minibatches, though grouping tuning data to reduce normalization cost would introduce bias.

6 Experiments

We perform experiments for perplexity, query speed, memory consumption, and effectiveness in a machine translation system.

Individual language models were trained on English corpora from the WMT 2016 news translation shared task (Bojar et al., 2016). This includes the seven newswires (afp, apw, cna, ltw, nyt, wpb, xin) from English Gigaword Fifth Edition (Parker et al., 2011); the 2007–2015 news crawls;[4] News discussion; News commmentary v11; English from Europarl v8 (Koehn, 2005); the English side of the French-English parallel corpus (Bojar et al., 2013); and the English side of SETIMES2 (Tiedemann, 2009). We additionally built one language model trained on the concatenation of all of the above corpora. All corpora were preprocessed using the standard Moses (Koehn et al., 2007) scripts to perform normalization, tokenization, and truecasing. To prevent SRILM from running out of RAM, we excluded the large monolingual CommonCrawl data, but included English from the parallel CommonCrawl data.

All language models are 5-gram backoff language models trained with modified Kneser-Ney smoothing (Chen and Goodman, 1998) using `lmplz` (Heafield et al., 2013). Also to prevent SRILM from running out of RAM, we pruned singleton trigrams and above.

For linear interpolation, we tuned weights using IRSTLM. To work around SRILM's limitation of ten models, we interpolated the first ten then carried the combined model and added nine more component models, repeating this last step as necessary. Weights were normalized within batches to achieve the correct final weighting. This simply extends the way SRILM internally carries a combined model and adds one model at a time.

6.1 Perplexity experiments

We experiment with two domains: TED talks, which is out of domain, and news, which is in-domain for some corpora. For TED, we tuned on the IWSLT 2010 English dev set and test on the 2010 test set. For news, we tuned on the English side of the WMT 2015 Russian–English evaluation set and test on the WMT 2014 Russian–English evaluation set. To measure generalization, we also evaluated news on models tuned for TED and vice-versa. Results are shown in Table 5.

[4]For News Crawl 2014, we used version 2.

	Component Models	
Component	**TED test**	**News test**
Gigaword afp	163.48	221.57
Gigaword apw	140.65	206.85
Gigaword cna	299.93	448.56
Gigaword ltw	106.28	243.35

News commentary v11	236.23	495.27
Europarl v8	268.41	574.74
CommonCrawl fr-en.en	149.10	343.20
SETIMES2 ro-en.en	331.37	521.19
All concatenated	80.69	96.15

	TED weights	
Interpolation	**TED test**	**News test**
Offline linear	75.91	100.43
Online linear	76.93	152.37
Log-linear	72.58	112.31

	News weights	
Interpolation	**TED test**	**News test**
Offline linear	83.34	107.69
Online linear	83.94	110.95
Log-linear	89.62	124.63

Table 5: Test set perplexities. In the middle table, weights are optimized for TED and include a model trained on all concatenated text. In the bottom table, weights are optimized for news and exclude the model trained on all concatenated text.

LM	Tuning		Compiling		Querying	
All concatenated	N/A	N/A	N/A	N/A	0.186μs	46.7G
Offline linear	0.876m	60.2G	641m	123G	0.186μs	46.8G
Online linear	0.876m	60.2G	N/A	N/A	5.67μs	89.1G
Log-linear	600m	63.9G	89.8m	63.9G	0.186μs	46.8G

Table 6: Speed and memory consumption of LM combination methods. Interpolated models include the concatenated model. Tuning and compiling times are in minutes, memory consumption in gigabytes, and query time in microseconds per query (on 1G of held-out Common Crawl monolingual data).

Log-linear interpolation performs better on TED (72.58 perplexity versus 75.91 for offline linear interpolation). However, it performs worse on news. In future work, we plan to investigate whether log-linear wins when all corpora are out-of-domain since it favors agreement by all models.

Table 6 compares the speed and memory performance of the competing methods. While the log-linear tuning is much slower, its compilation is faster compared to the offline linear model's long run time. Since the model formats are the same for the concatenation and log-linear, they share the fastest query speeds. Query speed was measured using KenLM's (Heafield, 2011) faster probing data structure.[5]

6.2 MT experiments

We trained a statistical phrase-based machine translation system for Romanian-English on the Romanian-English parallel corpora released as part of the 2016 WMT news translation shared task. We trained three variants of this MT system. The first used a single language model trained on the concatenation of the 21 individual LM training corpora. The second used 22 language models, with each LM presented to Moses as a separate feature. The third used a single language model which is an interpolation of all 22 models. This variant was run with offline linear, online linear, and log-linear interpolation. All MT system variants were optimized using IWSLT 2011 Romanian-English TED test as the development set, and were evaluated using the IWSLT 2012 Romanian-English TED test set.

As shown in Table 7, no significant difference in MT quality as measured by BLEU was observed; the best BLEU score came from separate features at 18.40 while log-linear scored 18.15. We leave jointly tuned normalized log-linear interpolation to future work.

[5]KenLM does not natively implement online linear interpolation, so we wrote a custom wrapper, which is faster than querying IRSTLM.

LM	BLEU	BLEU-c
22 separate LMs	18.40	17.91
All concatenated	18.02	17.55
Offline linear	18.00	17.53
Online linear	18.27	17.82
Log-linear	18.15	17.70

Table 7: Machine translation performance comparison in an end-to-end system.

7 Conclusion

Normalized log-linear interpolation is now a tractable alternative to linear interpolation for backoff language models. Contrary to Hsu (2007), we proved that these models can be exactly collapsed into a single backoff language model. This solves the query speed problem. Empirically, compiling the log-linear model is faster than SRILM can collapse its approximate offline linear model. In future work, we plan to improve performace of feature weight tuning and investigate more general features.

Abstract

Recently a few systems for automatically solving math word problems have reported promising results. However, the datasets used for evaluation have limitations in both scale and diversity. In this paper, we build a large-scale dataset which is more than 9 times the size of previous ones, and contains many more problem types. Problems in the dataset are semi-automatically obtained from community question-answering (CQA) web pages. A ranking SVM model is trained to automatically extract problem answers from the answer text provided by CQA users, which significantly reduces human annotation cost. Experiments conducted on the new dataset lead to interesting and surprising results.

1 Introduction

Designing computer systems for automatically solving math word problems is a challenging research topic that dates back to the 1960s (Bobrow, 1964a; Briars and Larkin, 1984; Fletcher, 1985). As early proposals seldom report empirical evaluation results, it is unclear how well they perform. Recently, promising results have been reported on both statistical learning approaches (Kushman et al., 2014; Hosseini et al., 2014; Koncel-Kedziorski et al., 2015; Zhou et al., 2015; Roy and Roth, 2015) and semantic parsing methods (Shi et al., 2015). However, we observe two limitations on the datasets used by these previous works. First, the datasets are small. The most frequently used dataset (referred to as Alg514 hereafter) only contains 514 algebra problems. The Dolphin1878 dataset (Shi et al., 2015), the largest collection among them, contains 1878 problems. Second, the diversity of problems in the datasets is low. The Alg514 collection contains linear algebra problems of 28 types (determined by 28 unique equation systems), with each problem type corresponding to at least 6 problems. Although the Dolphin1878 collection has over 1,000 problem types, only number word problems (i.e., math word problems about the operations and relationship of numbers) are contained in the collection.

Due to the above two limitations, observations and conclusions based on existing datasets may not be representative. Therefore it is hard to give a convincing answer to the following question: How well do state-of-the-art computer algorithms perform in solving math word problems?

To answer this question, we need to re-evaluate state-of-the-art approaches on a larger and more diverse data set. It is not hard to collect a large set of problems from the web. The real challenge comes from attaching annotations to the problems. Important annotation types include equation systems (required by most statistical learning methods for model training) and gold answers (for testing algorithm performance). Manually adding equation systems and gold answers is extremely time-consuming[1].

In this paper, we build a large-scale and diverse dataset called Dolphin18K [2], which contains over 18,000 annotated math word problems. It is constructed by semi-automatically extracting problems, equation systems and answers from community question-answering (CQA) web pages. The source data we leverage are the (question, answer text) pairs in the math category of Yahoo! An-

*Work done while this author was an intern at Microsoft Research.

[1] According to our experience, the speed is about 10-15 problems per hour for a person with good math skills.

Berlin, Germany, August 7-12, 2016.

swers[3]. Please note that the answer text provided by CQA users cannot be used directly in evaluation as gold answers, because answer numbers and other numbers are often mixed together in answer text (refer to Figure 1 of Section 3). We train a ranking SVM model to identify (structured) problem answers from unstructured answer text.

We then conduct experiments to test the performance of some recent math problem solving systems on the dataset. We make the following main observations,

1. All systems evaluated on the Dolphin18K dataset perform much worse than on their original small and less diverse datasets.

2. On the large dataset, a simple similarity-based method performs as well as more sophisticated statistical learning approaches.

3. System performance improves sub-linearly as more training data is used. This suggests that we need to develop algorithms which can utilize data more effectively.

Our experiments indicate that the problem of automatic math word problem solving is still far from being solved. Good results obtained on small datasets may not be good indicators of high performance on larger and diverse datasets. For current methods, simply adding more training data is not an effective way to improve performance. New methodologies are required for this topic.

2 Related Work

2.1 Math Word Problem Solving

Previous work on automatic math word problem solving falls into two categories: symbolic approaches and statistical learning methods. In symbolic approaches (Bobrow, 1964a; Bobrow, 1964b; Charniak, 1968; Charniak, 1969; Bakman, 2007; Liguda and Pfeiffer, 2012; Shi et al., 2015), math problem sentences are transformed to certain structures (usually trees) by pattern matching, verb categorization, or semantic parsing. Math equations are then derived from the structured representation. Addition/subtraction problems are studied most in early research (Briars and Larkin, 1984; Fletcher, 1985; Dellarosa, 1986; Bakman, 2007; Yuhui et al., 2010). Please refer to Mukherjee and Garain (2008) for a review of symbolic approaches before 2008.

[3]https://answers.yahoo.com/

Statistical machine learning methods have been proposed to solve math word problems since 2014. Hosseini et al. (2014) solve single step or multi-step homogeneous addition and subtraction problems by learning verb categories from the training data. Kushman et al. (2014) and Zhou et al. (2015) solve a wide range of algebra word problems, given that systems of linear equations are attached to problems in the training set. Seo et al. (2015) focuses on SAT geometry questions with text and diagram provided. Koncel-Kedziorski et al. (2015) and Roy and Roth (2015) target math problems that can be solved by one single linear equation.

No empirical evaluation results are reported in most early publications on this topic. Although promising empirical results are reported in recent work, the datasets employed in their evaluation are small and lack diversity. For example, the Alg514 dataset used in Kushman et al. (2014) and Zhou et al. (2015) only contains 514 problems of 28 types. Please refer to Section 3.4 for more details about the datasets.

Recently, a framework was presented in Koncel-Kedziorsk et al. (2016) for building an online repository of math word problems. The framework is initialized by including previous public available datasets. The largest dataset among them contains 1,155 problems.

2.2 Answer Extraction in CQA

Our work on automatic answer and equation extraction is related to the recent CQA extraction work (Agichtein et al., 2008; Cong et al., 2008; Ding et al., 2008). Most of them aim to discover high-quality (question, answer text) pairs from CQA posts. We are different because we extract structured data (i.e., numbers and equation systems) *inside* the pieces of answer text.

3 Dataset Construction

Our goal is to construct a large and diverse problem collection of elementary mathematics (i.e., math topics frequently taught at the primary or secondary school levels). We build our dataset by automatically extracting problems and their annotations from the mathematics category of the Yahoo! Answers web site. A math problem post on Yahoo! Answers consists of the raw problem text and one or multiple pieces of answer text provided by its answerers (refer to Figure 1).

Please note that posts cannot be used directly as our dataset entries. For example, for training statistical models, we have to extract equation systems from the unstructured text of user answers. We also need to extract numbers (56,000 and 21,000 in Figure 1) from the raw answer text as gold answers. We perform the following actions to the posts,

- Removing the posts that do not contain a math problem of our scope (Section 3.1)
- Cleaning problem text (Section 3.1)
- Extracting gold answers (Section 3.2)
- Extracting equation systems (Section 3.3)

In Section 3.4, we report some statistics of our dataset and compare them with previous ones.

3.1 Preprocessing

We crawl over one million posts from the mathematics categories of Yahoo! Answers. They are part of the posts submitted and answered by users since year 2008. By examining some examples, we soon find that many of them do not contain math problems of our scope. We discard or ignore the posts with the following types:

1. Containing a general math-related question but not a typical math problem. For example, "*Can anyone teach me how to set up two equations for one problem, and then how to solve it after?*".
2. College-level math
3. Containing multiple math problems in a single post. They are discarded for simplifying our answer and equation system extraction process.

As the size of a set of one million problems is large for human annotation and many of them belong to the above three types, we need a way to automatically filter out undesired problems. We manually annotate 6,000 posts with the speed of about 150 posts per hour per person. Then a logistic regression classifier of posts is trained with a precision of 80% and a recall of 70%. The post collection after classification is reduced to 120,000 posts.

Then we randomly sample 46,000 posts from the reduced post collection to perform two actions manually: post classification and problem text cleaning. Please note that, since the precision of the automatic classifier is only 80%, we rely on manual classification to remove the remaining 20% undesired posts. Problem text cleaning is for removing sentences like "please help" and "Son's 6th grade math" (refer to Figure 1). The problem text after cleaning is just like that appearing in a formal math test in an elementary or secondary school.

Question part:
Son's 6th grade math? The number of cans produced in one day by two companies A and B were in ratio 8:3 and their difference was 35,000. How many cans did each company produce that day?

Answer part:
Answer 1: Let can produced by 1 company be 8x and the other 3x. so 8x - 3x = 35000. 5x = 35000. x = 7000. So the first company produced 8 x 7000 = 56,000 cans, and the other produced 3 x 7000 = 21,000 cans.
Answer 2: From the ratio: 3A=8B or A=(8/3)B. From the difference: A-B=35000. By substituting for A, we get (8/3)B-B=35000 and further to B = 21000. From the difference: A = 21000+35000=56000.
Answer 3: It's 56000 and 21000.
Answer 4: what the hell thats not 6th grade math!!!

Figure 1: An example post from Yahoo! answers

Eight annotators participated in the manual post classification and problem text cleaning, at an average speed of about 80 posts per hour per person.

3.2 Automatic Answer Extraction

Compared to post classification and problem text cleaning, it is much more time consuming to manually assign gold answers and equation systems to a problem (10-15 problems per hour per person vs. 80 posts per hour per person). In addition, the latter has higher requirements of the math skills of annotators. Since manually annotating all problems exceeds our budget, we choose to train a high precision model to automatically extract numbers as gold answers from the answer part of a post.

In our dataset, the gold answer to a problem is one or a set of numbers acting as the solution to the problem. We define *answer dimension* as the

count of numbers required in the gold answer. For example, the gold answer to the problem in Figure 1 is $\{56000, 21000\}$, with dimension 2.

Extracting gold answers from the answer part of a post is nontrivial. We tried an intuitive approach called last-number-majority-voting, where the last number in each answer of the post is chosen as a candidate and then majority voting is performed among all the candidates. We got a low accuracy of 47% on our annotated data. Thus, we turn to a machine learning model for better utilizing more features in the posts.

Notations: Let χ denote the set of training problems. For each problem x_i in χ, $N_{ij} = \{n_{ij}^1, n_{ij}^2, \ldots, n_{ij}^m\}$ denote the set of all unique numbers given the *j*th answer, where *m* represents the size of N_{ij}. For each N_{ij}, we generate possible subsets of numbers as candidate answers to the problems. Please pay attention that the gold answer to a problem may contain multiple numbers (in the case that the answer dimension is larger than 1). We use Y_i to denote all the candidate answers in problem x_i.

Model: We define the conditional probability of $y_{ik} \in Y_i$ given x_i:

$$p(y_{ik}|x_i;\nu) = \frac{\exp(\nu \cdot f(x_i, y_{ik}))}{\sum_{y'_{ik} \in Y_i} \exp(\nu \cdot f(x_i, y'_{ik}))}$$

where ν is a parameter vector of the model and $f(x_i, y_{ik})$ is the feature vector. We apply the Ranking SVM (Herbrich et al., 2000) to maximize the margin between the correct instances and the negative ones. Constructing the SVM model is equivalent to solving the following Quadratic Optimization problem:

$$\min_{\nu} M(\nu) = \frac{1}{2}\|\nu\|^2 + C\sum_i \xi_i$$

$$\textit{s.t. } \xi_i \geq 0, \nu \cdot \langle f(x_i, y_{ik})^+ - f(x_i, y_{il})^- \rangle \geq 1 - \xi_i$$

where subscript "+" indicates the correct instance and "-" indicates the false ones.

Features: Features are extracted from the answer part of each post for model training. We design features based on the following observations. In Yahoo! answers, users tend to write down correct answers at the beginning of the answer text, or at the end after providing the solving procedure. Surrounding words also give hints for finding correct solutions. For example, numbers that are close to the word *"answer"* are more likely to be in the gold answer. Given a post, numbers appearing in the answer text of more users are more likely to be the correct solution. Some words in the question sentence help determine answer dimension. For example, *"How far does Tom run?"* requires a one-dimension answer while *"How much do they each earn?"* indicates multiple dimensions. Main features are listed in table 1.

Table 1: Features for automatic answer extraction

Local context features
Relative position in the procedure
On right side of the symbol "="?
On left side of the symbol "="?
Close to *"ans", "answer", "result", or "therefore"*
Global features
Is in the text of the first answer (the first answer is often marked as the best answer in Yahoo! answers)?
Is in problem text?
Frequency in the text of all answers for this problem
Frequency in the first position of all answers
Frequency in the last position of all answers
Number value features
Is positive?
Is an integer?
Its value is between 0 to 1?
Equals to the predicted solution in automatic equation extraction?
Number set features
Are numbers at same line of answer text?
Are numbers at consecutive lines of answer text?
Frequency of the numbers at same line in all answers
Frequency of the numbers at consecutive lines in all answers
Dimension features
Has singular verb in question?
Has plural noun in question?
Has special words (e.g., *and, both, each, all*) in question?

Inference: After we train the model to get parameter vector ν, the predicated gold answer is selected from the candidate number subsets by maximizing $\nu \cdot f(x_i, y_{ik})$. Formally, the predicated gold

answer is,

$$\arg\max_{y_{ik} \in Y_i} \nu \cdot f(x_i, y_{ik})$$

About 3,000 problems are manually annotated with answers and equations by the human annotators we hire. Then we train and evaluate our model using 5-fold cross validation. The extractor's performance is shown in Figure 2. To preserve an accuracy rate of 90%, we use score = 3 as the threshold and only keep problems with predicted confidence score >= 3.

Please note that precision is more important than recall in our scenario. We need to guarantee that most extracted answers are correct. Lower recall can be tackled by processing more posts.

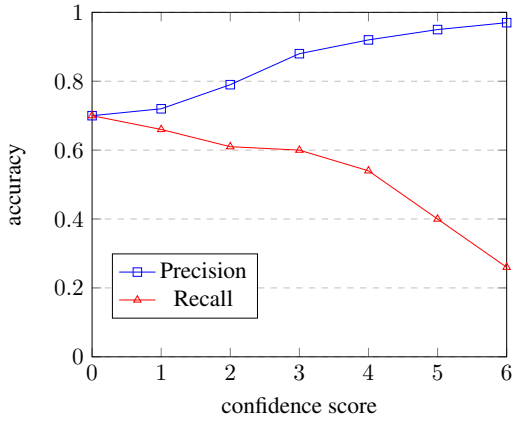

Figure 2: Accuracy of answer extraction

3.3 Automatic Equation Annotation

Now we illustrate how to extract equation systems automatically from the unstructured answer text of a post. The input is the answer text of n answers:

$$T = \{T_1, T_2, \ldots, T_n\}$$

For example in Figure 1, there are four answers, each corresponding to a piece of answer text T_i.

The task is not easy, because variables and equations may not be in standard formats in answer text. In addition, equations may be duplicate (like those in Answer 1 of Figure 1). Our algorithm is a two-phase procedure:

Candidate extraction: We extract an equation system from each piece of answer text T_i. In processing T_i, we first extract a list of equations by regular expression matching. Then the equations are added to the equation system by the order of their occurrences in the text. Before adding an equation, we check whether it can be induced by the already-added equations. If so, we skip it. Duplicate equations are effectively reduced in this way.

Voting by solution: We solve each equation system obtained from the first phase and build a (equation system, solution) bipartite graph. We then choose the equation system that has the maximum degree as our output. For example, if three equation systems return the solution $\{24\}$ and the fourth returns $\{-1\}$, we will choose one from the first three equation systems. To improve precision, we do not return any equation system if the maximal degree is less than 2.

We evaluate our equation extractor on 3,000 manually annotated problems [4]. For an equation system extracted for a problem, we say it is correct if the annotated gold answer is a subset of the solutions to the equation system. For example, if the gold answer is $\{16, 34\}$ and the solution to the equation system is $\{16, 34, 100\}$, then the equation system is considered correct. Evaluation results show a precision of **91.4%** and a recall of **64.7%**.

3.4 Datasets Summary

Below are a list of previous benchmark datasets for math word problem solving.

Alg514 is introduced in Kushman et al. (2014) and also used in Zhou et al. (2015) for evaluation. It consists of 514 algebra word problems from algebra.com[5], with each problem annotated with linear equations. The *template* (explained later) of each problem has to appear at least six times in the whole set.

Verb395 (Hosseini et al., 2014): A collection of addition/subtraction problems.

Dolphin1878: A collection built by Shi et al. (2015), containing 1,878 number word problems obtained from algebra.com and Yahoo! answers.

DRAW (Upadhyay and Chang, 2015): Containing 1,000 algebra word problems from algebra.com, each annotated with linear equations.

SingleEQ: By Koncel-Kedziorski et al. (2015), containing 508 problems, each of which corresponds to one single equation.

Before comparing the datasets, let's first introduce the concept of *equation system templates*, which are first introduced in Kushman et al. (2014)

[4] the same set of problems as we used in training and evaluating answer extraction

[5] http://www.algebra.com

Table 2: Comparison of different datasets

Dataset	# Problems	# Templates	# Sentences	# Words	Problems types
Verb395	395	3	1.13k	12.4k	homogeneous addition or subtraction problems
Alg514	514	28	1.62k	19.3k	algebra, linear
Dolphin1878	1,878	1,183	3.30k	41.4k	number word problems
DRAW	1,000	232	2.67k	35.3k	algebra, linear
SingleEQ	508	31	1.38k	13.8k	single equation, linear
Dolphin18K	18,460	5,871	49.9k	604k	linear + nonlinear

for math word problem solving. A *template* is a unique form of equation system. For example, the following is a template of two equations:

$$n_1 \cdot x_1 + x_2 = n_2$$
$$x_1 + n_3 \cdot x_2 = n_4$$

The following equation system corresponds to the above template,

$$3 \cdot x_1 + x_2 = 5$$
$$x_1 + 7 \cdot x_2 = 15$$

Table 2 shows some statistical information of our dataset and previous ones. It can be seen that our dataset has a much larger scale (about 10 times the size of the Dolphin1878 collection and more than 17 times larger than the others) and higher diversity (in terms of both problem types and the number of templates contained).

We split our dataset into a development set and an evaluation set. The development set is used for algorithm design and debugging, while the evaluation set is for training and testing. Any problem in the evaluation set should be invisible to the people who design an automatic math problem solving system. Statistics on our dataset are shown in Table 3, where *dev* and *eval* represent the development set and the evaluation set respectively. Most problems are assigned with both equation systems and gold answers. Some of them are annotated with answers only, either because annotators feel it is hard to do so, or because our equation extraction algorithm returns empty results.

As most previous systems only handle linear equation systems, we summarize, in Table 4, the distribution of linear problems in the evaluation set by template size. In the table, the size of a template is defined as the number of problems corresponding to this template. Between the two numbers in each cell, the first one is the number of problems, and the second number (or the one in parentheses) is the number of templates in this category. For example, in the automatically annotated evaluation set, 166 templates have size 6 or larger. They correspond to 4,826 problems.

Table 3: Annotation statistics for our dataset

		Equations + answer	Answer only	Sum
dev	Manual	909	67	976
	Auto	2,245	507	2,752
	All	3,154	574	3,728
eval	Manual	3,605	321	3,926
	Auto	8,754	2,052	10,806
	All	12,359	2,373	14,732

4 Experiments

4.1 Systems for evaluation

We report the performance of several state-of-the-art systems on our new dataset.

KAZB: A template-based statistical learning method introduced in Kushman et al. (2014). It maps a problem to one equation template defined in the training set by reasoning across problem sentences. KAZB reports an accuracy of 68.7% on the Alg514 dataset.

ZDC: Proposed in Zhou et al. (2015) as an improved version of KAZB. It reduces the search space by not modeling alignment between noun phrases and variables. It achieves an accuracy of 79.7% on Alg514.

SIM is a simple similarity-based method implemented by us. To solve a problem, it calculates the lexical similarity between the problem and each problem in the training set. Then the equation system of the most similar problem is ap-

Table 4: Problem distribution by template size (for linear problems only)

Template size	Manual	Auto	All
(all linear templates)	2,675 (876)	7,969 (2,609)	10,644 (3,158)
>=2	2,036 (237)	5,956 (596)	8,229 (743)
>=5	1,678 (98)	4,979 (196)	7,081 (254)
>=6	1,578 (78)	4,826 (166)	6,827 (216)
>=10	1,337 (43)	4,329 (96)	6,216 (130)
>=20	1,039 (22)	3,673 (48)	5,392 (68)
>=50	634 7	2,684 18	4,281 30

plied to the new problem. In a little more details, a test problem P_T is solved in two steps: template selection, and template slot filling. In the first step, each problem is modeled as a vector of word TF-IDF scores. The similarity between two problems is calculated by the weighted Jaccard similarity between their corresponding vectors. We choose, from the training data, problem P_1 that has the maximal similarity with P_T and use the equation template T of P_1 as the template of problem P_T. In the second step, the numbers appearing in problem P_T are mapped to the number slots of template T (which has been identified in the first step). The mapping is implemented by selecting one problem P_2 from all the training problems corresponding to template T so that it has the minimum word-level edit-distance to P_T. Then the number mapping of P_2 is borrowed as the number mapping of P_T. For example, for the following test problem,

An overnight mail service charges $3.60 for the first six ounces and $0.45 for each additional ounce or fraction of an ounce. Find the number of ounces in a package that cost $7.65 to deliver.

Assuming that a problem P_1 has maximum Jaccard similarity with the above problem and its corresponding equation template is as follows, this template will be identified in the first step,

$$n_1 + n_2 * (x - n_3) = n_4$$

Assume that P_2 has the minimum edit-distance to P_T among all the training problems corresponding to template T. Suppose the numbers in P_2 are (by their order in the problem text),

$$3.5, 5, 0.5, 6.5$$

Also suppose P_2 is annotated with the following equation system,

$$3.5 + 0.5 * (x - 5) = 6.5$$

Then we will choose P_2 and borrow its number mapping. So the mapping from numbers in the above test problem to template slots will be,

$$3.60/n_1; 6/n_3; 0.45/n_2; 7.65/n_4$$

In implementing SIM, we do not use any POS tagging or syntactic parsing features for similarity calculation. This method gets an accuracy of 71.2% on Alg514 and 49.0% on SingleEQ.

Systems not included for evaluation: Although the system of Shi et al. (2015) achieves very high performance on number word problems, we do not include it in our evaluation because it is unknown how to extend it to other problem types. The system of Hosseini et al. (2014) is not included in our evaluation because it only handles homogeneous addition/subtraction problems. The systems of Koncel-Kedziorski et al. (2015) and Roy and Roth (2015) are also not included because so far they only supports problems with one single linear equation.

4.2 Overall Evaluation Results

Table 5 shows the accuracy of various systems on different subsets of our dataset. In the table, Manual.Linear contains all the manually annotated problems with linear equation systems. It contains 2,675 problems and 876 templates (as shown in Table 4). Auto.LinearT6 (containing 4,826 problems) is the set of all the automatically annotated problems with a template size larger than or equal to 6. Similarly, LinearT2 means the subset of problems with template size ≥ 2. For each system on each subset, experiments are conducted using 5-fold cross-validation with 80% problems randomly selected as training data and the remaining 20% for test.

In the table, "-" means that the system does not complete running on the dataset in three days. Since KAZB and ZDC only handle linear equation systems, they are not applicable to the datasets

	Systems		
Dataset	KAZB	ZDC	SIM
Manual.Linear	10.7%	11.1%	13.3%
Manual.LinearT2	12.8%	13.9%	17.3%
Manual.LinearT6	17.6%	17.1%	18.8%
Auto.Linear	-	17.2%	17.4%
Auto.LinearT2	-	20.1%	19.2%
Auto.LinearT6	-	19.2%	18.4%
All.Linear	-	17.9%	18.4%
All.LinearT2	-	20.6%	20.3%
All.LinearT6	-	21.7%	20.2%
All (Dolphin18K)	n/a	n/a	16.7%
Alg514	68.7%	79.7%	71.2%

Table 5: Overall evaluation results

containing nonlinear problems. An "n/a" is filled in the corresponding cell in this case.

The results show that all three systems (KAZB, ZDC, and SIM) have extremely low performance on our new datasets. Surprisingly, no system achieves an accuracy rate of over 25%. Such results indicate that automatic math word problem solving is still a very challenging task.

Another surprising observation is that KAZB and ZDC do not perform better than SIM, a simple similarity-based method which runs much faster than the two statistical learning systems.

By comparing the results obtained from the manual version of the datasets with their corresponding auto version (for example, Manuall.Linear vs. Auto.Linear), we can see larger accuracy scores on the auto versions [6]. This demonstrates the usefulness of the automatically annotated data. Considering the huge cost of manually assigning equation systems and gold answers, automatic annotation has good potential in constructing larger datasets.

4.3 Why Different from Previous Results

The last line of Table 5 displays the results on Alg514. All three systems perform well on Alg514 but poorly on Dolphin18K. To study the reason of such a large gap, we derive two small datasets from All.Linear by referring to the equation templates in Alg514.

Small.01: The set of all problems in All.Linear that correspond to one of the 28 templates in Alg514. The dataset contains 2,021 problems.

[6]Please note that the auto versions are more than 2 times larger.

Small.02: A subset of Small.01, constructed by randomly removing problems from Small.01 so that each template contains similar number of problems as in Alg514. In other words, Small.02 and Alg514 have similar problem distribution among templates.

	Small.01	Small.02
KAZB	29.9%	50.0%
ZDC	30.1%	52.7%
SIM	33.7%	43.0%

Table 6: The case of fewer number of templates

We still use 5-fold cross validation to test and compare system performance on the two small datasets. Evaluation results are displayed in Table 6. We now obtain higher accuracy scores for each system, but there is a big difference between the results on Small.01 and Small.02. As mentioned in (Upadhyay and Chang, 2015), Alg514 has a skewed problem distribution, with a few templates covering almost 50% problems. This may be the main reason why all three systems achieve high accuracy on this dataset and on Small.02. From all of the above results, we see at least two factors which affect system performance: number of templates in the dataset, and the distribution of problems among the templates. For a small dataset, the distribution of problems among templates have a huge impact on evaluation results.

4.4 Effect of Training Data Size

Now we investigate the performance change of various systems when the size of training data changes. The goal is to check whether the accuracy increases quickly when more training data are added. This is important: If it is the case, we can tackle this task by simply adding more training data, either manually or automatically. Otherwise, we have to discover new approaches.

We conduct experiments in two settings: fixed-test-set, and increasing-test-set. In the first setting, we randomly choose 1/2 of the problems from the Manual.Linear subset to form a fixed test-set (with size 1330). Then the other problems in All.Linear forms a candidate training collection (containing 9314 elements). We construct training sets of different scales by doing random sampling from the candidate training collection.

In the second setting (i.e., increasing-test-set), we construct datasets (training set plus test set) of

Training data source	All.LinearT6					All.Linear				
Training data size	138	434	1024	2940	5771	500	1000	2000	5000	9000
Test set size	1330	1330	1330	1330	1330	1330	1330	1330	1330	1330
KAZB accuracy (%)	6.7	7.2	-	-	-	7.1	8.3	-	-	-
ZDC accuracy (%)	6.1	7.5	8.6	11.4	12.6	5.5	9.2	10.5	12.5	13.1
SIM accuracy (%)	5.5	8.7	11.0	13.7	15.9	6.5	10.8	12.2	14.9	18.4

Table 7: System performance with different training data size (setting: fixed-test-set)

Training data size	400	800	1600	4000	8516
Test set size	100	200	400	1000	2128
KAZB	5.4%	6.7%	11.7%	-	-
ZDC	5.8%	7.6%	12.9%	17.0%	17.9%
SIM	7.4%	10.0%	13.3%	16.9%	18.4%

Table 8: System performance with different training data size (setting: increasing-test-set)

different scales by doing random sampling from All.Linear, and then conduct 5-fold cross validation on each dataset. In each fold, 80% problems are chosen at random for training, and the other 20% for testing.

The results in the two settings are reported in Tables 7 and 8 respectively. Both tables show that the accuracy of all the three systems improves steadily but slowly along with the increasing of training data size. So it is not very effective to improve accuracy by simply adding more training data.

4.5 Results Summary

In summary, the following observations are made from the experiments on our new dataset. First, all systems evaluated on the Dolphin18K dataset perform much worse than on the small and less diverse datasets. Second, the two statistical learning methods do not perform better than a simple similarity-based method. Third, it seems not promising for the current methods to achieve much better results by simply adding more training data. Automatic math word problem solving is still a very challenging task so far.

5 Conclusion

We have constructed Dolphin18K, a large dataset for training and evaluating automatic math word problem solving systems. The new dataset is almost one order of magnitude larger than most of previous ones, and has a much higher level of diversity in term of problem types. We reduce human annotation cost by automatically extracting gold answers and equation systems from the unstructured answer text of CQA posts.

We have also conducted experiments on our dataset to evaluate state-of-the-art systems. Interesting and surprising observations are made from the experimental results.

Acknowledgments

We would like to thank the annotators for their efforts in annotating the math problems in our dataset. Thanks to the anonymous reviewers for their helpful comments and suggestions.

Abstract

Recent years have seen a dramatic growth in the popularity of word embeddings mainly owing to their ability to capture semantic information from massive amounts of textual content. As a result, many tasks in Natural Language Processing have tried to take advantage of the potential of these distributional models. In this work, we study how word embeddings can be used in Word Sense Disambiguation, one of the oldest tasks in Natural Language Processing and Artificial Intelligence. We propose different methods through which word embeddings can be leveraged in a state-of-the-art supervised WSD system architecture, and perform a deep analysis of how different parameters affect performance. We show how a WSD system that makes use of word embeddings alone, if designed properly, can provide significant performance improvement over a state-of-the-art WSD system that incorporates several standard WSD features.

1 Introduction

Embeddings represent words, or concepts in a low-dimensional continuous space. These vectors capture useful syntactic and semantic information, such as regularities in language, where relationships are characterized by a relation-specific vector offset. The ability of embeddings to capture knowledge has been exploited in several tasks, such as Machine Translation (Mikolov et al., 2013, MT), Sentiment Analysis (Socher et al., 2013), Word Sense Disambiguation (Chen et al., 2014, WSD) and Language Understanding (Mesnil et al., 2013). Supervised WSD is based on the hypothesis that contextual information provides a good approximation to word meaning, as suggested by Miller and Charles (1991): semantically similar words tend to have similar contextual distributions.

Recently, there have been efforts on leveraging embeddings for improving supervised WSD systems. Taghipour and Ng (2015) showed that the performance of conventional supervised WSD systems can be increased by taking advantage of embeddings as new features. In the same direction, Rothe and Schütze (2015) trained embeddings by mixing words, lexemes and synsets, and introducing a set of features based on calculations on the resulting representations. However, none of these techniques takes full advantage of the semantic information contained in embeddings. As a result, they generally fail in providing substantial improvements in WSD performance.

In this paper, we provide for the first time a study of different techniques for taking advantage of the combination of embeddings with standard WSD features. We also propose an effective approach for leveraging embeddings in WSD, and show that this can provide significant improvement on multiple standard benchmarks.

2 Word Embeddings

An embedding is a representation of a topological object, such as a manifold, graph, or field, in a certain space in such a way that its connectivity or algebraic properties are preserved (Insall et al., 2015). Presented originally by Bengio et al. (2003), word embeddings aim at representing, i.e., embedding, the ideal semantic space of words in a real-valued continuous vector space. In contrast to traditional distributional techniques, such as Latent Semantic Analysis (Landauer and Dutnais, 1997, LSA) and Latent Dirichlet Allocation (Blei et al., 2003, LDA), Bengio et al. (2003) designed a

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 897–907,
Berlin, Germany, August 7-12, 2016.

feed-forward neural network capable of predicting a word given the words preceding (i.e., leading up to) that word. Collobert and Weston (2008) presented a much deeper model consisting of several layers for feature extraction, with the objective of building a general architecture for NLP tasks. A major breakthrough occurred when Mikolov et al. (2013) put forward an efficient algorithm for training embeddings, known as Word2vec. A similar model to Word2vec was presented by Pennington et al. (2014, GloVe), but instead of using latent features for representing words, it makes an explicit representation produced from statistical calculation on word countings.

Numerous efforts have been made to improve different aspects of word embeddings. One way to enhance embeddings is to represent more fine-grained semantic items, such as word senses or concepts, given that conventional embeddings conflate different meanings of a word into a single representation. Several research studies have investigated the representation of word senses, instead of words (Reisinger and Mooney, 2010; Huang et al., 2012; Camacho-Collados et al., 2015b; Iacobacci et al., 2015; Rothe and Schütze, 2015). Another path of research is aimed at refining word embeddings on the basis of additional information from other knowledge resources (Faruqui et al., 2015; Yu and Dredze, 2014). A good example of this latter approach is that proposed by Faruqui et al. (2015), which improves pre-trained word embeddings by exploiting the semantic knowledge from resources such as PPDB[1] (Ganitkevitch et al., 2013), WordNet (Miller, 1995) and FrameNet (Baker et al., 1998). In the following section we discuss how embeddings can be integrated into an important lexical semantic task, i.e., Word Sense Disambiguation.

3 Word Sense Disambiguation

Natural language is inherently ambiguous. Most commonly-used words have several meanings. In order to identify the intended meaning of a word one has to analyze the context in which it appears by directly exploiting information from raw texts. The task of automatically assigning predefined meanings to words in contexts, known as Word Sense Disambiguation, is a fundamental task in computational lexical semantics (Navigli, 2009). There are four conventional approaches to WSD which we briefly explain in the following.

3.1 Supervised methods

These methods make use of manually sense-annotated data, which are curated by human experts. They are based on the assumption that a word's context can provide enough evidence for its disambiguation. Since manual sense annotation is a difficult and time-consuming process, something known as the "knowledge acquisition bottleneck" (Pilehvar and Navigli, 2014), supervised methods are not scalable and they require repetition of a comparable effort for each new language. Currently, the best performing WSD systems are those based on supervised learning. It Makes Sense (Zhong and Ng, 2010, IMS) and the system of Shen et al. (2013) are good representatives for this category of systems. We provide more information on IMS in Section 4.1.

3.2 Unsupervised methods

These methods create their own annotated corpus. The underlying assumption is that similar senses occur in similar contexts, therefore it is possible to group word usages according to their shared meaning and induce senses. These methods lead to the difficulty of mapping their induced senses into a sense inventory and they still require manual intervention in order to perform such mapping. Examples of this approach were studied by Agirre et al. (2006), Brody and Lapata (2009), Manandhar et al. (2010), Van de Cruys and Apidianaki (2011) and Di Marco and Navigli (2013).

3.3 Semi-supervised methods

Other methods, called semi-supervised, take a middle-ground approach. Here, a small manually-annotated corpus is usually used as a seed for bootstrapping a larger annotated corpus. Examples of these approaches were presented by Mihalcea and Faruque (2004). A second option is to use a word-aligned bilingual corpus approach, based on the assumption that an ambiguous word in one language could be unambiguous in the context of a second language, hence helping to annotate the sense in the first language (Ng and Lee, 1996).

3.4 Knowledge-based methods

These methods are based on existing lexical resources, such as knowledge bases, semantic networks, dictionaries and thesauri. Their main feature is their coverage, since they function indepen-

[1] www.paraphrase.org/#/download

dently of annotated data and can exploit the graph structure of semantic networks to identify the most suitable meanings. These methods are able to obtain wide coverage and good performance using structured knowledge, rivaling supervised methods (Patwardhan and Pedersen, 2006; Mohammad and Hirst, 2006; Agirre et al., 2010; Guo and Diab, 2010; Ponzetto and Navigli, 2010; Miller et al., 2012; Agirre et al., 2014; Moro et al., 2014; Chen et al., 2014; Camacho-Collados et al., 2015a).

3.5 Standard WSD features

As was analyzed by Lee and Ng (2002), conventional WSD systems usually make use of a fixed set of features to model the context of a word. The first feature is based on the words in the surroundings of the target word. The feature usually represents the local context as a binary array, where each position represents the occurrence of a particular word. Part-of-speech (POS) tags of the neighboring words have also been used extensively as a WSD feature. Local collocations represent another standard feature that captures the ordered sequences of words which tend to appear around the target word (Firth, 1957). Though not very popular, syntactic relations have also been studied as a possible feature (Stetina et al., 1998) in WSD.

More sophisticated features have also been studied. Examples are distributional semantic models, such as Latent Semantic Analysis (Van de Cruys and Apidianaki, 2011) and Latent Dirichlet Allocation (Cai et al., 2007). Inasmuch as they are the dominant distributional semantic model, word embeddings have also been applied as features to WSD systems. In this paper we study different methods through which word embeddings can be used as WSD features.

3.6 Word Embeddings as WSD features

Word embeddings have become a prominent technique in distributional semantics. These methods leverage neural networks in order to model the contexts in which a word is expected to appear. Thanks to their ability in efficiently learning the semantics of words, word embeddings have been applied to a wide range of NLP applications. Several studies have also investigated their integration into the Word Sense Disambiguation setting. These include the works of Zhong and Ng (2010), Taghipour and Ng (2015), Rothe and Schütze (2015), and Chen et al. (2014), which leverage embeddings for supervised (the former three) and knowledge-based (the latter) WSD. However, to our knowledge, no previous work has investigated methods for integrating word embeddings in WSD and the role that different training parameters can play. In this paper, we put forward a framework for a comprehensive evaluation of different methods of leveraging word embeddings as WSD features in a supervised WSD system. We provide an analysis of the impact of different parameters in the training of embeddings on the WSD performance. We consider four different strategies for integrating a pre-trained word embedding in a supervised WSD system, discussed in what follows.

3.6.1 Concatenation

Concatenation is our first strategy, which is inspired by the model of Bengio et al. (2003). This method consists of concatenating the vectors of the words surrounding a target word into a larger vector that has a size equal to the aggregated dimensions of all the individual embeddings. Let w_{ij} be the weight associated with the i^{th} dimension of the vector of the j^{th} word in the sentence, let D be the dimensionality of this vector, and W be the window size which is defined as the number of words on a single side. We are interested in representing the context of the I^{th} word in the sentence. The i^{th} dimension of the concatenation feature vector, which has a size of $2WD$, is computed as follows:

$$e_i = \begin{cases} w_{i \bmod D,\, I-W+\lfloor \frac{i}{D} \rfloor} & \text{if } \lfloor \frac{i}{D} \rfloor < W \\ w_{i \bmod D,\, I-W+1+\lfloor \frac{i}{D} \rfloor} & \text{otherwise} \end{cases}$$

where *mod* is the modulo operation, i.e., the remainder after division.

3.6.2 Average

As its name indicates, the average strategy computes the centroid of the embeddings of all the surrounding words. The formula divides each dimension by $2W$ since the number of context words is twice the window size:

$$e_i = \sum_{\substack{j=I-W \\ j \neq I}}^{I+W} \frac{w_{ij}}{2W}$$

3.6.3 Fractional decay

Our third strategy for constructing a feature vector on the basis of the context word embeddings is inspired by the way Word2vec combines the words in the context. Here, the importance of a word

for our representation is assumed to be inversely proportional to its distance from the target word. Hence, surrounding words are weighted based on their distance from the target word:

$$e_i = \sum_{\substack{j=I-W \\ j \neq I}}^{I+W} w_{ij} \frac{W - |I - j|}{W}$$

3.6.4 Exponential decay

Exponential decay functions similarly to the fractional decay, which gives more importance to the close context, but in this case the weighting in the former is performed exponentially:

$$e_i = \sum_{\substack{j=I-W \\ j \neq I}}^{I+W} w_{ij} (1 - \alpha)^{|I-j|-1}$$

where $\alpha = 1 - 0.1^{(W-1)^{-1}}$ is the decay parameter. We choose the parameter in such a way that the immediate surrounding words contribute 10 times more than the last words on both sides of the window.

4 Framework

Our goal was to experiment with a state-of-the-art conventional supervised WSD system and a varied set of word embedding techniques. In this section we discuss the WSD system as well as the word embeddings used in our experiments.

4.1 WSD System

We selected It Makes Sense (Zhong and Ng, 2010, IMS) as our underlying framework for supervised WSD. IMS provides an extensible and flexible platform for supervised WSD by allowing the verification of different WSD features and classification techniques. By default, IMS makes use of three sets of features: (1) POS tags of the surrounding words, with a window of three words on each side, restricted by the sentence boundary, (2) the set of words that appear in the context of the target word after stopword removal, and (3) local collocations which consist of 11 features around the target word. IMS uses a linear support vector machine (SVM) as its classifier.

4.2 Embedding Features

We take the real-valued word embeddings as new features of IMS and introduce them into the system without performing any further modifications. We carried out experiments with three different embeddings:

- **Word2vec** (Mikolov et al., 2013): We used the Word2vec toolkit[2] to learn 400 dimensional vectors on the September-2014 dump of the English Wikipedia which comprises around three billion tokens. We chose the Skip-gram architecture with the negative sampling set to 10. The sub-sampling of frequent words was set to 10^{-3} and the window size to 10 words.

- **C&W** (Collobert and Weston, 2008): These 50 dimensional embeddings were learnt using a neural network model, consisting of several layers for feature extraction. The vectors were trained on a subset of the English Wikipedia.[3]

- **Retrofitting**: Finally, we used the approach of Faruqui et al. (2015) to retrofit our Word2vec vectors. We used the Paraphrase Database (Ganitkevitch et al., 2013, PPDB) as external knowledge base for retrofitting and set the number of iterations to 10.

5 Experiments

We evaluated the performance of our embedding-based WSD system on two standard WSD tasks: lexical sample and all-words. In all the experiments in this section we used the exponential decay strategy (cf. Section 3.6) and a window size of ten words on each side of the target word.

5.1 Lexical Sample WSD Experiment

The lexical sample WSD tasks provide training datasets in which different occurrences of a small set of words are sense annotated. The goal is for a WSD system to analyze the contexts of the individual senses of these words and to capture clues that can be used for distinguishing different senses of a word from each other at the test phase.

Datasets. As our benchmark for the lexical sample WSD, we chose the Senseval-2 (Edmonds and Cotton, 2001), Senseval-3 (Mihalcea et al., 2004), and SemEval-2007 (Pradhan et al., 2007) English Lexical Sample WSD tasks. The former two cover nouns, verbs and adjectives in their datasets whereas the latter task focuses on nouns and verbs

IMS + Retrofitting	65.9	72.8	88.3
C&W feature only	55.0	61.6	83.4
Word2vec feature only	65.6	69.4	87.0
Retrofitting feature only	67.2	72.7	88.0

Table 2: F1 performance on the three English lexical sample datasets. IMS + X denotes the improved IMS system when the X set of word representations were used as additional features. We also show in the last three rows the results for the IMS system when word representations were used as the only features.

only. Table 1 shows the number of sentences per part of speech for the training and test datasets of each of these tasks.

Comparison systems. In addition to the vanilla IMS system in its default setting we compared our system against two recent approaches that also modify the IMS system so that it can benefit from the additional knowledge derived from word embeddings for improved WSD performance: (1) the system of Taghipour and Ng (2015), which combines word embeddings of Collobert and Weston (2008) using the concatenation strategy (cf. Section 3.6) and introduces the combined embeddings as a new feature in addition to the standard WSD features in IMS; and (2) AutoExtend (Rothe and Schütze, 2015), which constructs a whole new set of features based on vectors made from words, senses and synsets of WordNet and incorporates them in IMS.

5.1.1 Lexical sample WSD results

Table 2 shows the F1 performance of the different systems on the three lexical sample datasets. As can be seen, the IMS + Word2vec system improves over all comparison systems including those that combine standard WSD and embedding features (i.e., the system of Taghipour and Ng (2015) and AutoExtend) across all the datasets. This shows that our proposed strategy for introducing word embeddings into the IMS system on the basis of exponential decay was beneficial. In the last three rows of the table, we also report the performance of the WSD systems that leverage only word embeddings as their features and do not incorporate any standard WSD feature. It can be seen that word embeddings, in isolation, provide competitive performance, which proves their capability in obtaining the information captured by standard WSD features. Among different embeddings, the retrofitted vectors provide the best performance when used in isolation.

5.2 All-Words WSD Experiments

The goal in this task is to disambiguate all the content words in a given text. In order to learn models for disambiguating a large set of content words, a high-coverage sense-annotated corpus is required. Since all-words tasks do not usually provide any training data, the challenge here is not only to learn accurate disambiguation models from the training data, as is the case in the lexical sample task, but also to gather high-coverage training data and to learn disambiguation models for as many words as possible.

Training corpus. As our training corpus we opted for two available resources: SemCor and OMSTI. SemCor (Miller et al., 1994) is a manually sense-tagged corpus created by the WordNet project team at Princeton University. The dataset is a subset of the English Brown Corpus and comprises around 360,000 words, providing annotations for more than 200K content words.[4] OM-

[4]We used automatic mappings to WordNet 3.0 provided in `web.eecs.umich.edu/~mihalcea/downloads.html`.

STI[5] (One Million Sense-Tagged for Word Sense Disambiguation and Induction) was constructed based on the DSO corpus (Ng and Lee, 1996) and provides annotations for around 42K different nouns, verbs, adjectives, and adverbs.

Datasets. As benchmark for this experiment, we considered the Senseval-2 (Edmonds and Cotton, 2001), Senseval-3 (Snyder and Palmer, 2004), and SemEval-2007 (Pradhan et al., 2007) English all-words tasks. There are 2474, 2041, and 465 words for which at least one of the occurrences has been sense annotated in the Senseval-2, Senseval-3 and SemEval-2007 datasets, respectively.

Experimental setup. Similarly to the lexical sample experiment, in the all-words setting we used the exponential decay strategy (cf. Section. 4.2) in order to incorporate word embeddings as new features in IMS. For this experiment, we only report the results for the best-performing word embeddings in the lexical sample experiment, i.e., Word2vec (see Table 2).

Comparison systems. We benchmarked the performance of our system against five other systems. Similarly to our lexical sample experiment, we compared against the vanilla IMS system and the work of Taghipour and Ng (2015). In addition, we performed experiments on the nouns subsets of the datasets in order to be able to provide comparisons against two other WSD approaches: Babelfy (Moro et al., 2014) and Muffin (Camacho-Collados et al., 2015a). Babelfy is a multilingual knowledge-based WSD and Entity Linking algorithm based on the semantic network of BabelNet. Muffin is a multilingual sense representation technique that combines the structural knowledge derived from semantic networks with the distributional statistics obtained from text corpora. The system uses sense-based representations for performing WSD. Camacho-Collados et al. (2015a) also proposed a hybrid system that averages the disambiguation scores of IMS with theirs (shown as "Muffin + IMS" in our tables). We also report the results for UKB w2w (Agirre and Soroa, 2009), another knowledge-based WSD approach based on Personalized PageRank (Haveliwala, 2002). Finally, we also carried out experiments with the pre-trained models[6] that are provided with the IMS toolkit, as well as IMS trained on our two training corpora, i.e., SemCor and OMSTI.

5.2.1 All-words WSD results

Tables 3 and 4 list the performance of different systems on, respectively, the whole and the noun-subset datasets of the three all-words WSD tasks. Similarly to our lexical sample experiment, the IMS + Word2vec system provided the best performance across datasets and benchmarks. The coupling of Word2vec embeddings to the IMS system proved to be consistently helpful. Among the two training corpora, as expected, OMSTI provided a better performance owing to its considerably larger size and higher coverage. Another point to be noted here is the difference between results of the IMS with the pre-trained models and those trained on the OMSTI corpus. Since we used the same system configuration across the two runs, we conclude that the OMSTI corpus is either substantially smaller or less representative than the corpus used by Zhong and Ng (2010) for building

the pre-trained models of IMS. Despite this fact, the IMS + Word2vec system can consistently improve the performance of IMS (pre-trained models) across the three datasets. This shows that a proper introduction of word embeddings into a supervised WSD system can compensate the negative effect of using lower quality training data.

6 Analysis

We carried out a series of experiments in order to check the impact of different system parameters on the final WSD performance. We were particularly interested in observing the role that various training parameters of embeddings as well as WSD features have in the WSD performance. We used the Senseval-2 English Lexical Sample task as our benchmark for this analysis.

6.1 The effect of different parameters

Table 5 shows F1 performance of different configurations of our system on the task's dataset. We studied five different parameters: the type (i.e., w2v or Retrofitting) and dimensionality (200, 400, or 800) of the embeddings, combination strategy (concatenation, average, fractional or exponential decay), window size (5, 10, 20 and words), and WSD features (collocations, POS tags, surrounding words, all of these or none). All the embeddings in this experiment were trained on the same training data and, unless specified, with the same configuration as described in Section 4.2. As baseline we show in the table the performance of the vanilla WSD system, i.e., IMS. For better readability, we report the differences between the performances of our system and the baseline.

We observe that the addition of Word2vec word embeddings to IMS (+w2v in the table) was beneficial in all settings. Among combination strategies, concatenation and average produced the smallest gain and did not benefit from embeddings of higher dimensionality. However, the other two strategies, i.e., fractional and exponential decay, showed improved performance with the increase in the size of the employed embeddings, irrespective of the WSD features. The window size showed a peak of performance when 10 words were taken in the case of standard word embeddings. For retrofitting, a larger window seems to have been beneficial, except when no standard WSD features were taken. Another point to note here is that, among the three WSD features, POS proved to be the most effective one while due to the nature of the embeddings, the exclusion of the Surroundings features in addition to the inclusion of the embeddings was largely beneficial in all the configurations. Furthermore, we found that the best configurations for this task were the ones that excluded Surroundings, and included w2v embeddings with a window of 10 and 800 dimensions with exponential decay strategy (70.2% of F1 performance) as well as the configuration used in our experiments, with all the standard features, and w2v embeddings with 400 dimensions, a window of 10 and exponential decay strategy (69.9% of F1 performance).

The retrofitted embeddings provided lower performance improvement when added on top of standard WSD features. However, when they were used in isolation (shown in the right-most column), the retrofitted embeddings interestingly provided the best performance, improving the vanilla WSD system with standard features by 2.8 percentage points (window size 5, dimensionality 800). In fact, the standard features had a destructive role in this setting as the overall performance was reduced when they were combined with the retrofitted embeddings. Finally, we point out the missing values in the configuration with 800 dimensions and a window size of 20. Due to the nature of the concatenation strategy, this configuration greatly increased the number of features from embeddings only, reaching 32000 (800 x 2 x 20) features. Not only was the concatenation strategy unable to take advantage of the increased dimensionality, but also it was not able to scale.

These results show that a state-of-the-art supervised WSD system can be constructed without incorporating any of the conventional WSD features, which in turn demonstrates the potential of retrofitted word embeddings for WSD. This finding is interesting, because it provides the basis for further studies on how synonymy-based semantic knowledge introduced by retrofitting might play a role in effective WSD, and how retrofitting might be optimized for improved WSD. Indeed, such studies may provide the basis for re-designing the standard WSD features.

6.2 Comparison of embedding types

We were also interested in comparing different types of embeddings in our WSD framework. We tested for seven sets of embeddings with dif-

Table 6: F1 percentage performance on the Senseval-2 English Lexical Sample dataset with different word representations models, vector dimensionalities (Dim.) and combination strategies.

ing the semantics than CBOW and GloVe. Additionally, the use of embeddings with decay fares well, independently of the type of embedding. The only exception is the C&W embeddings, for which the average strategy works best. We attribute this behavior to the nature of these embeddings, rather than to their dimensionality. This is shown in our comparison against the 50-dimensional Skip-gram embeddings trained on the Wikipedia corpus (bottom of Table 6), which performs well with both decay strategies, outperforming C&W embeddings.

7 Conclusions

In this paper we studied different ways of integrating the semantic knowledge of word embeddings in the framework of WSD. We carried out a deep analysis of different parameters and strategies across several WSD tasks. We draw three main findings. First, word embeddings can be used as new features to improve a state-of-the-art supervised WSD that only uses standard features. Second, integrating embeddings on the basis of an exponential decay strategy proves to be more consistent in producing high performance than the other conventional strategies, such as vector concatenation and centroid. Third, the retrofitted embeddings that take advantage of the knowledge derived from semi-structured resources, when used as the only feature for WSD can outperform state-of-the-art supervised models which use standard WSD features. However, the best performance is obtained when standard WSD features are augmented with the additional knowledge from Word2vec vectors on the basis of a decay function strategy. Our hope is that this work will serve as the first step for further studies on re-designing standard WSD features. We release at `https://github.com/iiacobac/ims_wsd_emb` all the codes and resources used in our experiments in order to provide a framework for research on the evaluation of new VSM models in the WSD framework. As future work, we plan to investigate the possibility of designing word representations that best suit the WSD framework.

Abstract

Several large cloze-style context-question-answer datasets have been introduced recently: the CNN and Daily Mail news data and the Children's Book Test. Thanks to the size of these datasets, the associated text comprehension task is well suited for deep-learning techniques that currently seem to outperform all alternative approaches. We present a new, simple model that uses attention to directly pick the answer from the context as opposed to computing the answer using a blended representation of words in the document as is usual in similar models. This makes the model particularly suitable for question-answering problems where the answer is a single word from the document. Ensemble of our models sets new state of the art on all evaluated datasets.

1 Introduction

Most of the information humanity has gathered up to this point is stored in the form of plain text. Hence the task of teaching machines how to understand this data is of utmost importance in the field of Artificial Intelligence. One way of testing the level of text understanding is simply to ask the system questions for which the answer can be inferred from the text. A well-known example of a system that could make use of a huge collection of unstructured documents to answer questions is for instance IBM's Watson system used for the Jeopardy challenge (Ferrucci et al., 2010).

Cloze style questions (Taylor, 1953), i.e. questions formed by removing a phrase from a sentence, are an appealing form of such questions (for example see Figure 1). While the task is easy to evaluate, one can vary the context, the question sentence or the specific phrase missing in the question to dramatically change the task structure and difficulty.

Document: What was supposed to be a fantasy sports car ride at Walt Disney World Speedway turned deadly when a Lamborghini crashed into a guardrail. The crash took place Sunday at the Exotic Driving Experience, which bills itself as a chance to drive your dream car on a racetrack. The Lamborghini's passenger, 36-year-old Gary Terry of Davenport, Florida, died at the scene, Florida Highway Patrol said. The driver of the Lamborghini, 24-year-old Tavon Watson of Kissimmee, Florida, lost control of the vehicle, the Highway Patrol said. (...)
Question: Officials say the driver, 24-year-old Tavon Watson, lost control of a _____
Answer candidates: Tavon Watson, Walt Disney World Speedway, Highway Patrol, Lamborghini, Florida, (...)
Answer: Lamborghini

Figure 1: Each example consists of a context document, question, answer cadidates and, in the training data, the correct answer. This example was taken from the CNN dataset (Hermann et al., 2015). Anonymization of this example that makes the task harder is shown in Table 3.

One way of altering the task difficulty is to vary the word type being replaced, as in (Hill et al., 2015). The complexity of such variation comes from the fact that the level of context understanding needed in order to correctly predict different types of words varies greatly. While predicting prepositions can easily be done using relatively simple models with very little context knowledge, predicting named entities requires a deeper understanding of the context.

Also, as opposed to selecting a random sentence from a text (as done in (Hill et al., 2015)), the questions can be formed from a specific part of a document, such as a short summary or a list of

tags. Since such sentences often paraphrase in a condensed form what was said in the text, they are particularly suitable for testing text comprehension (Hermann et al., 2015).

An important property of cloze style questions is that a large amount of such questions can be automatically generated from real world documents. This opens the task to data-hungry techniques such as deep learning. This is an advantage compared to smaller machine understanding datasets like MCTest (Richardson et al., 2013) that have only hundreds of training examples and therefore the best performing systems usually rely on handcrafted features (Sachan et al., 2015; Narasimhan and Barzilay, 2015).

In the first part of this article we introduce the task at hand and the main aspects of the relevant datasets. Then we present our own model to tackle the problem. Subsequently we compare the model to previously proposed architectures and finally describe the experimental results on the performance of our model.

2 Task and datasets

In this section we introduce the task that we are seeking to solve and relevant large-scale datasets that have recently been introduced for this task.

2.1 Formal Task Description

The task consists of answering a cloze style question, the answer to which is dependent on the understanding of a context document provided with the question. The model is also provided with a set of possible answers from which the correct one is to be selected. This can be formalized as follows:

The training data consist of tuples $(\mathbf{q}, \mathbf{d}, a, A)$, where $\mathbf{q}$ is a question, $\mathbf{d}$ is a document that contains the answer to question $\mathbf{q}$, A is a set of possible answers and $a \in A$ is the ground truth answer. Both $\mathbf{q}$ and $\mathbf{d}$ are sequences of words from vocabulary V. We also assume that all possible answers are words from the vocabulary, that is $A \subseteq V$, and that the ground truth answer a appears in the document, that is $a \in \mathbf{d}$.

2.2 Datasets

We will now briefly summarize important features of the datasets.

2.2.1 News Articles — CNN and Daily Mail

The first two datasets[1] (Hermann et al., 2015) were constructed from a large number of news articles from the CNN and Daily Mail websites. The main body of each article forms a context, while the cloze style question is formed from one of short highlight sentences, appearing at the top of each article page. Specifically, the question is created by replacing a named entity from the summary sentence (*e.g. "Producer X will not press charges against Jeremy Clarkson, his lawyer says."*).

Furthermore the named entities in the whole dataset were replaced by anonymous tokens which were further shuffled for each example so that the model cannot build up any world knowledge about the entities and hence has to genuinely rely on the context document to search for an answer to the question.

Qualitative analysis of reasoning patterns needed to answer questions in the CNN dataset together with human performance on this task are provided in (Chen et al., 2016).

[1]The CNN and Daily Mail datasets are available at `https://github.com/deepmind/rc-data`

2.2.2 Children's Book Test

The third dataset[2], the Children's Book Test (CBT) (Hill et al., 2015), is built from books that are freely available thanks to Project Gutenberg[3]. Each context document is formed by 20 consecutive sentences taken from a children's book story. Due to the lack of summary, the cloze style question is then constructed from the subsequent (21^{st}) sentence.

One can also see how the task complexity varies with the type of the omitted word (named entity, common noun, verb, preposition). (Hill et al., 2015) have shown that while standard LSTM language models have human level performance on predicting verbs and prepositions, they lack behind on named entities and common nouns. In this article we therefore focus only on predicting the first two word types.

Basic statistics about the CNN, Daily Mail and CBT datasets are summarized in Table 1.

3 Our Model — Attention Sum Reader

Our model called the *Attention Sum Reader (AS Reader)*[4] is tailor-made to leverage the fact that the answer is a word from the context document. This is a double-edged sword. While it achieves state-of-the-art results on all of the mentioned datasets (where this assumption holds true), it cannot produce an answer which is not contained in the document. Intuitively, our model is structured as follows:

1. We compute a vector embedding of the query.
2. We compute a vector embedding of each individual word in the context of the whole document (*contextual embedding*).
3. Using a dot product between the question embedding and the contextual embedding of each occurrence of a candidate answer in the document, we select the most likely answer.

3.1 Formal Description

Our model uses one word embedding function and two encoder functions. The word embedding function e translates words into vector representations. The first encoder function is a document encoder f that encodes every word from the document $\mathbf{d}$ in the context of the whole document. We call this the *contextual embedding*. For convenience we will denote the contextual embedding of the i-th word in $\mathbf{d}$ as $f_i(\mathbf{d})$. The second encoder g is used to translate the query $\mathbf{q}$ into a fixed length representation of the same dimensionality as each $f_i(\mathbf{d})$. Both encoders use word embeddings computed by e as their input. Then we compute a weight for every word in the document as the dot product of its contextual embedding and the query embedding. This weight might be viewed as an attention over the document $\mathbf{d}$.

To form a proper probability distribution over the words in the document, we normalize the weights using the *softmax* function. This way we model probability s_i that the answer to query $\mathbf{q}$ appears at position i in the document $\mathbf{d}$. In a functional form this is:

$$s_i \propto \exp\left(f_i(\mathbf{d}) \cdot g(\mathbf{q})\right) \tag{1}$$

Finally we compute the probability that word w is a correct answer as:

$$P(w|\mathbf{q},\mathbf{d}) \propto \sum_{i \in I(w,\mathbf{d})} s_i \tag{2}$$

where $I(w,\mathbf{d})$ is a set of positions where w appears in the document $\mathbf{d}$. We call this mechanism *pointer sum attention* since we use attention as a pointer over discrete tokens in the context document and then we directly sum the word's attention across all the occurrences. This differs from the usual use of attention in sequence-to-sequence models (Bahdanau et al., 2015) where attention is used to blend representations of words into a new embedding vector. Our use of attention was inspired by Pointer Networks (Ptr-Nets) (Vinyals et al., 2015).

A high level structure of our model is shown in Figure 2.

3.2 Model instance details

In our model the document encoder f is implemented as a bidirectional Gated Recurrent Unit (GRU) network (Cho et al., 2014; Chung et al., 2014) whose hidden states form the contextual word embeddings, that is $f_i(\mathbf{d}) = \overrightarrow{f_i}(\mathbf{d}) \mid\mid \overleftarrow{f_i}(\mathbf{d})$, where $\mid\mid$ denotes vector concatenation and $\overrightarrow{f_i}$ and

Figure 4: Attention over an example where our system failed to select the correct answer (entity43). The system was probably mislead by the co-occurring word 'film'. Namely, entity11 occurs 7 times in the whole document and 6 times it is together with the word 'film'. On the other hand, the correct answer occurs only 3 times in total and only once together with 'film'.

$\overleftarrow{f_i}$ denote forward and backward contextual embeddings from the respective recurrent networks. The query encoder g is implemented by another bidirectional GRU network. This time the last hidden state of the forward network is concatenated with the last hidden state of the backward network to form the query embedding, that is $g(\mathbf{q}) = \overrightarrow{g_{|\mathbf{q}|}}(\mathbf{q}) \mid\mid \overleftarrow{g_1}(\mathbf{q})$. The word embedding function e is implemented in a usual way as a look-up table $\mathbf{V}$. $\mathbf{V}$ is a matrix whose rows can be indexed by words from the vocabulary, that is $e(w) = V_w, w \in V$. Therefore, each row of $\mathbf{V}$ contains embedding of one word from the vocabulary. During training we jointly optimize parameters of f, g and e.

4 Related Work

Several recent deep neural network architectures (Hermann et al., 2015; Hill et al., 2015; Chen et al., 2016; Kobayashi et al., 2016) were applied to the task of text comprehension. The last two architectures were developed independently at the same time as our work. All of these architectures use an attention mechanism that allows them to highlight places in the document that might be relevant to answering the question. We will now briefly describe these architectures and compare

them to our approach.

4.1 Attentive and Impatient Readers

Attentive and *Impatient Readers* were proposed in (Hermann et al., 2015). The simpler Attentive Reader is very similar to our architecture. It also uses bidirectional document and query encoders to compute an attention in a similar way we do. The more complex Impatient Reader computes attention over the document after reading every word of the query. However, empirical evaluation has shown that both models perform almost identically on the CNN and Daily Mail datasets.

The key difference between the Attentive Reader and our model is that the Attentive Reader uses attention to compute a fixed length representation r of the document $\mathbf{d}$ that is equal to a weighted sum of contextual embeddings of words in $\mathbf{d}$, that is $r = \sum_i s_i f_i(\mathbf{d})$. A joint query and document embedding m is then a non-linear function of r and the query embedding $g(\mathbf{q})$. This joint embedding m is in the end compared against all candidate answers $a' \in A$ using the dot product $e(a') \cdot m$, in the end the scores are normalized by softmax. That is: $P(a'|\mathbf{q}, \mathbf{d}) \propto \exp(e(a') \cdot m)$.

In contrast to the Attentive Reader, we select the answer from the context directly using the computed attention rather than using such attention for a weighted sum of the individual representations (see Eq. 2). The motivation for such simplification is the following.

Consider a context "*A UFO was observed above our city in January and again in March.*" and question "*An observer has spotted a UFO in ___ .*"

Since both January and March are equally good candidates, the attention mechanism might put the same attention on both these candidates in the context. The blending mechanism described above would compute a vector between the representations of these two words and propose the closest word as the answer - this may well happen to be February (it is indeed the case for Word2Vec trained on Google News). By contrast, our model would correctly propose January or March.

4.2 Chen et al. 2016

A model presented in (Chen et al., 2016) is inspired by the Attentive Reader. One difference is that the attention weights are computed with a bilinear term instead of simple dot-product, that is: $s_i \propto \exp(f_i(\mathbf{d})^\intercal W\, g(\mathbf{q}))$. The document embedding r is computed using a weighted sum as in the Attentive Reader: $r = \sum_i s_i f_i(\mathbf{d})$. In the end $P(a'|\mathbf{q}, \mathbf{d}) \propto \exp(e'(a') \cdot r)$, where e' is a new embedding function.

Even though it is a simplification of the Attentive Reader this model performs significantly better than the original.

4.3 Memory Networks

MemNNs (Weston et al., 2014) were applied to the task of text comprehension in (Hill et al., 2015).

The best performing memory networks model setup - window memory - uses windows of fixed length (8) centered around the candidate words as memory cells. Due to this limited context window, the model is unable to capture dependencies out of scope of this window. Furthermore, the representation within such window is computed simply as the sum of embeddings of words in that window. By contrast, in our model the representation of each individual word is computed using a recurrent network, which not only allows it to capture context from the entire document but also the embedding computation is much more flexible than a simple sum.

To improve on the initial accuracy, a heuristic approach called *self supervision* is used in (Hill et al., 2015) to help the network to select the right supporting "memories" using an attention mechanism showing similarities to the ours. Plain MemNNs without this heuristic are not competitive on these machine reading tasks. Our model does not need any similar heuristics.

4.4 Dynamic Entity Representation

The Dynamic Entity Representation model (Kobayashi et al., 2016) has a complex architecture also based on the weighted attention mechanism and max pooling over contextual embeddings of vectors for each named entity.

4.5 Pointer Networks

Our model architecture was inspired by Ptr-Nets (Vinyals et al., 2015) in using an attention mechanism to select the answer in the context rather than to blend words from the context into an answer representation. While a Ptr-Net consists of an encoder as well as a decoder, which uses the attention to select the output at each step, our model outputs the answer in a single step. Furthermore,

the pointer networks assume that no input in the sequence appears more than once, which is not the case in our settings.

4.6 Summary

Our model combines the best features of the architectures mentioned above. We use recurrent networks to "read" the document and the query as done in (Hermann et al., 2015; Chen et al., 2016; Kobayashi et al., 2016) and we use attention in a way similar to Ptr-Nets. We also use summation of attention weights in a way similar to MemNNs (Hill et al., 2015).

From a high level perspective we simplify all the discussed text comprehension models by removing all transformations past the attention step. Instead we use the attention directly to compute the answer probability.

5 Evaluation

In this section we evaluate our model on the CNN, Daily Mail and CBT datasets. We show that despite the model's simplicity its ensembles achieve state-of-the-art performance on each of these datasets.

5.1 Training Details

To train the model we used stochastic gradient descent with the ADAM update rule (Kingma and Ba, 2015) and learning rate of 0.001 or 0.0005. During training we minimized the following negative log-likelihood with respect to θ:

$$-logP_\theta(a|\mathbf{q},\mathbf{d}) \tag{3}$$

where a is the correct answer for query $\mathbf{q}$ and document $\mathbf{d}$, and θ represents parameters of the encoder functions f and g and of the word embedding function e. The optimized probability distribution $P(a|\mathbf{q},\mathbf{d})$ is defined in Eq. 2.

The initial weights in the word embedding matrix were drawn randomly uniformly from the interval $[-0.1, 0.1]$. Weights in the GRU networks were initialized by random orthogonal matrices (Saxe et al., 2014) and biases were initialized to zero. We also used a gradient clipping (Pascanu et al., 2012) threshold of 10 and batches of size 32.

During training we randomly shuffled all examples in each epoch. To speedup training, we always pre-fetched 10 batches worth of examples and sorted them according to document length. Hence each batch contained documents of roughly the same length.

For each batch of the CNN and Daily Mail datasets we randomly reshuffled the assignment of named entities to the corresponding word embedding vectors to match the procedure proposed in (Hermann et al., 2015). This guaranteed that word embeddings of named entities were used only as semantically meaningless labels not encoding any intrinsic features of the represented entities. This forced the model to truly deduce the answer from the single context document associated with the question. We also do not use pre-trained word embeddings to make our training procedure comparable to (Hermann et al., 2015).

We did not perform any text pre-processing since the original datasets were already tokenized.

We do not use any regularization since in our experience it leads to longer training times of single models, however, performance of a model ensemble is usually the same. This way we can train the whole ensemble faster when using multiple GPUs for parallel training.

For Additional details about the training procedure see Appendix A.

5.2 Evaluation Method

We evaluated the proposed model both as a single model and using ensemble averaging. Although the model computes attention for every word in the document we restrict the model to select an answer from a list of candidate answers associated with each question-document pair.

For single models we are reporting results for the best model as well as the average of accuracies for the best 20% of models with best performance on validation data since single models display considerable variation of results due to random weight initialization[5], even for identical hyperparameter values. Single model performance may consequently prove difficult to reproduce.

What concerns ensembles, we used simple averaging of the answer probabilities predicted by ensemble members. For ensembling we used 14, 16, 84 and 53 models for CNN, Daily Mail and CBT CN and NE respectively. The ensemble models were chosen either as the top 70% of all trained models, we call this *avg ensemble*. Alternatively we use the following algorithm: We started with

[5]The standard deviation for models with the same hyperparameters was between 0.6-2.5% in absolute test accuracy.

the best performing model according to validation performance. Then in each step we tried adding the best performing model that had not been previously tried. We kept it in the ensemble if it did improve its validation performance and discarded it otherwise. This way we gradually tried each model once. We call the resulting model a *greedy ensemble*.

5.3 Results

Performance of our models on the CNN and Daily Mail datasets is summarized in Table 2, Table 3 shows results on the CBT dataset. The tables also list performance of other published models that were evaluated on these datasets. Ensembles of our models set the new state-of-the-art results on all evaluated datasets.

Table 4 then measures accuracy as the proportion of test cases where the ground truth was among the top k answers proposed by the greedy ensemble model for $k = 1, 2, 5$.

CNN and Daily Mail. The CNN dataset is the most widely used dataset for evaluation of text comprehension systems published so far. Perfor-

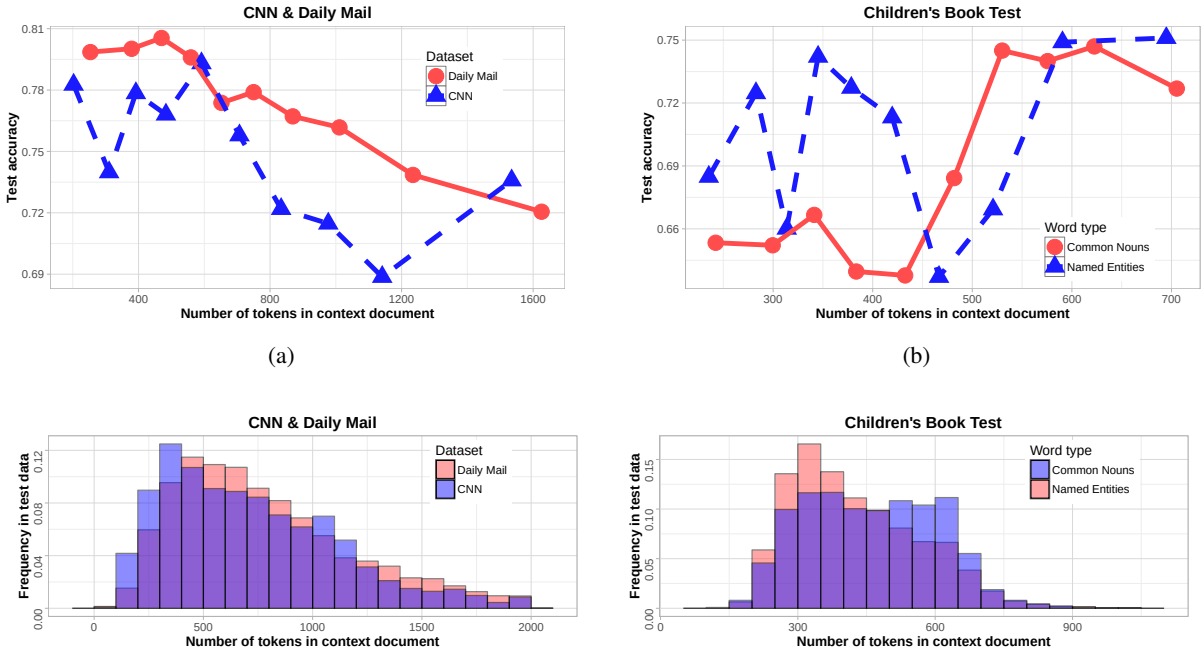

Figure 5: Sub-figures (a) and (b) plot the test accuracy against the length of the context document. The examples were split into ten buckets of equal size by their context length. Averages for each bucket are plotted on each axis. Sub-figures (c) and (d) show distributions of context lengths in the four datasets.

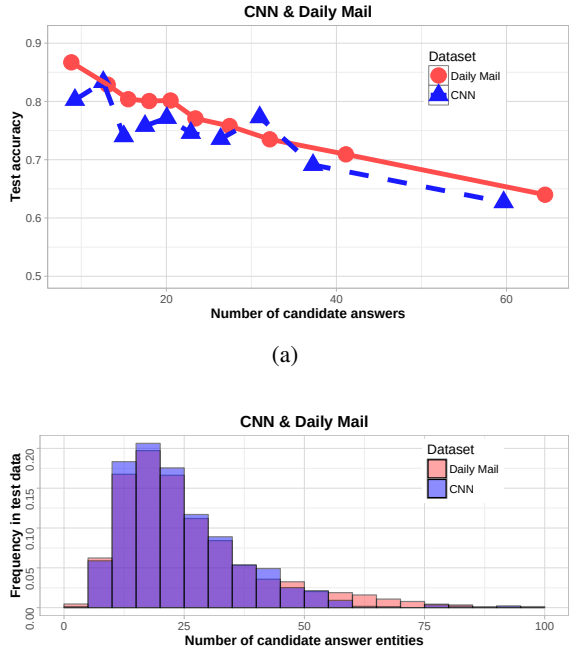

Figure 6: Subfigure (a) illustrates how the model accuracy decreases with an increasing number of candidate named entities. Subfigure (b) shows the overall distribution of the number of candidate answers in the news datasets.

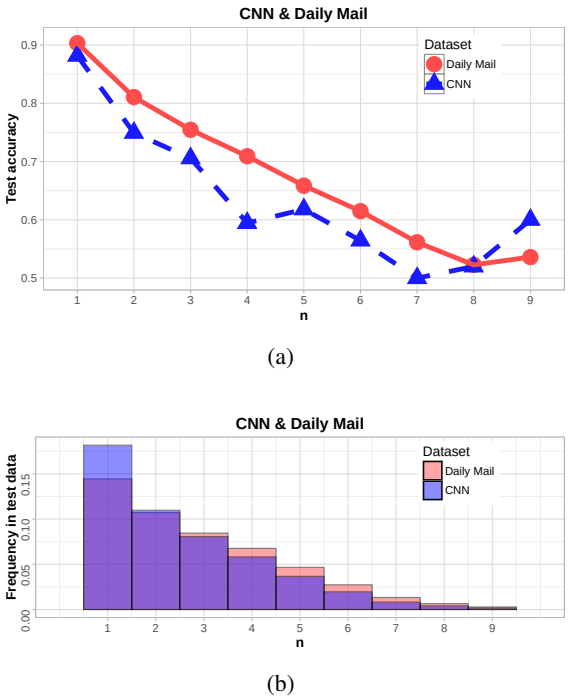

Figure 7: Subfigure (a) shows the model accuracy when the correct answer is the n^{th} most frequent named entity for $n \in [1, 10]$. Subfigure (b) shows the number of test examples for which the correct answer was the n–th most frequent entity. The plots for CBT look almost identical (see Appendix B).

mance of our single model is a little bit worse than performance of simultaneously published models (Chen et al., 2016; Kobayashi et al., 2016). Compared to our work these models were trained with Dropout regularization (Srivastava et al., 2014) which might improve single model performance. However, ensemble of our models outperforms these models even though they use pre-trained word embeddings.

On the CNN dataset our single model with best validation accuracy achieves a test accuracy of 69.5%. The average performance of the top 20% models according to validation accuracy is 69.9% which is even 0.5% better than the single best-validation model. This shows that there were many models that performed better on test set than the best-validation model. Fusing multiple models then gives a significant further increase in accuracy on both CNN and Daily Mail datasets..

CBT. In named entity prediction our best single model with accuracy of 68.6% performs 2% absolute better than the MemNN with self supervision, the averaging ensemble performs 4% absolute better than the best previous result. In common noun prediction our single models is 0.4% absolute better than MemNN however the ensemble improves the performance to 69% which is 6% absolute better than MemNN.

Dataset	$k = 1$	$k = 2$	$k = 5$

CBT NE	71.0	86.9	96.8
CBT CN	67.5	82.5	95.4

Table 4: Proportion of test examples for which the top k answers proposed by the greedy ensemble included the correct answer.

6 Analysis

To further analyze the properties of our model, we examined the dependence of accuracy on the length of the context document (Figure 5), the number of candidate answers (Figure 6) and the frequency of the correct answer in the context (Figure 7).

On the CNN and Daily Mail datasets, the accuracy decreases with increasing document length (Figure 5a). We hypothesize this may be due to multiple factors. Firstly long documents may make the task more complex. Secondly such cases are quite rare in the training data (Figure 5b) which motivates the model to specialize on shorter contexts. Finally the context length is correlated with the number of named entities, i.e. the number of possible answers which is itself negatively correlated with accuracy (see Figure 6).

On the CBT dataset this negative trend seems to disappear (Fig. 5c). This supports the later two explanations since the distribution of document lengths is somewhat more uniform (Figure 5d) and the number of candidate answers is constant (10) for all examples in this dataset.

The effect of increasing number of candidate answers on the model's accuracy can be seen in Figure 6a. We can clearly see that as the number of candidate answers increases, the accuracy drops. On the other hand, the amount of examples with large number of candidate answers is quite small (Figure 6b).

Finally, since the summation of attention in our model inherently favours frequently occurring tokens, we also visualize how the accuracy depends on the frequency of the correct answer in the document. Figure 7a shows that the accuracy significantly drops as the correct answer gets less and less frequent in the document compared to other candidate answers. On the other hand, the correct answer is likely to occur frequently (Fig. 7a).

7 Conclusion

In this article we presented a new neural network architecture for natural language text comprehension. While our model is simpler than previously published models, it gives a new state-of-the-art accuracy on all the evaluated datasets.

An analysis by (Chen et al., 2016) suggests that on CNN and Daily Mail datasets a significant proportion of questions is ambiguous or too difficult to answer even for humans (partly due to entity anonymization) so the ensemble of our models may be very near to the maximal accuracy achievable on these datasets.

Acknowledgments

We would also like to thank Tim Klinger for providing us with masked softmax code that we used in our implementation.

Appendix A Training Details

During training we evaluated the model performance after each epoch and stopped the training when the error on the validation set started increasing.

The models usually converged after two epochs of training. Time needed to complete a single epoch of training on each dataset on an Nvidia K40 GPU is shown in Table 5.

Dataset	Time per epoch
CNN	10h 22min
Daily Mail	25h 42min
CBT Named Entity	1h 5min
CBT Common Noun	0h 56min

Table 5: Average duration of one epoch of training on the four datasets.

The hyperparameters, namely the recurrent hidden layer dimension and the source embedding dimension, were chosen by grid search. We started with a range of 128 to 384 for both parameters and subsequently kept increasing the upper bound by 128 until we started observing a consistent decrease in validation accuracy. The region of the parameter space that we explored together with the parameters of the model with best validation accuracy are summarized in Table 6.

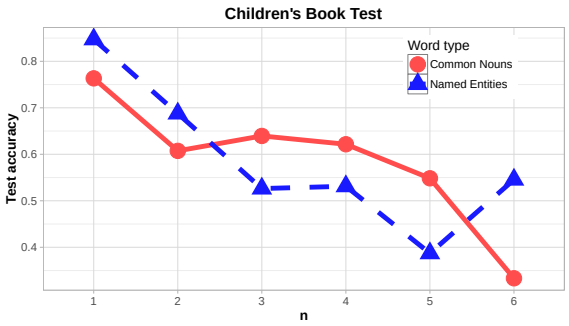
	Rec. Hid. Layer			Embedding		
Dataset	min	max	best	min	max	best
CNN	128	512	384	128	512	128
Daily Mail	128	1024	512	128	512	384
CBT NE	128	512	384	128	512	384
CBT CN	128	1536	256	128	512	384

Table 6: Dimension of the recurrent hidden layer and of the source embedding for the best model and the range of values that we tested. We report number of hidden units of the unidirectional GRU; the bidirectional GRU has twice as many hidden units.

Our model was implemented using Theano (Bastien et al., 2012) and Blocks (van Merrienboer et al., 2015).

Appendix B Dependence of accuracy on the frequency of the correct answer

In Section 6 we analysed how the test accuracy depends on how frequent the correct answer is compared to other answer candidates for the news datasets. The plots for the Children's Book Test looks very similar, however we are adding it here for completeness.



(a)

(b)

Figure 8: Subfigure (a) shows the model accuracy when the correct answer is among n most frequent named entities for $n \in [1, 10]$. Subfigure (b) shows the number of test examples for which the correct answer was the n–th most frequent entity.

Investigating LSTMs for Joint Extraction of Opinion Entities and Relations

arzoo, cardie@cs.cornell.edu

Abstract

We investigate the use of deep bi-directional LSTMs for joint extraction of opinion entities and the IS-FROM and IS-ABOUT relations that connect them — the first such attempt using a deep learning approach. Perhaps surprisingly, we find that standard LSTMs are not competitive with a state-of-the-art CRF+ILP joint inference approach (Yang and Cardie, 2013) to opinion entities extraction, performing below even the standalone sequence-tagging CRF. Incorporating sentence-level and a novel relation-level optimization, however, allows the LSTM to identify opinion relations and to perform within 1–3% of the state-of-the-art joint model for opinion entities and the IS-FROM relation; and to perform as well as the state-of-the-art for the IS-ABOUT relation — all without access to opinion lexicons, parsers and other preprocessing components required for the feature-rich CRF+ILP approach.

1 Introduction

There has been much research in recent years in the area of fine-grained opinion analysis where the goal is to identify subjective expressions in text along with their associated sources and targets. More specifically, fine-grained opinion analysis aims to identify three types of *opinion entities*:

- **opinion expressions**, O, which are direct subjective expressions (i.e., explicit mentions of otherwise private states or speech events expressing private states (Wiebe and Cardie, 2005));
- **opinion targets**, T, which are the entities or topics that the opinion is about; and
- **opinion holders**, H, which are the entities expressing the opinion.

In addition, the task involves identifying the IS-FROM and IS-ABOUT relations between an opinion expression and its holder and target, respectively. In the sample sentences, numerical subscripts indicate an IS-FROM or IS-ABOUT relation.

S1 [The sale]$_{T_1}$ [infuriated]$_{O_1}$ [Beijing]$_{H_{1,2}}$ which [regards]$_{O_2}$ [Taiwan]$_{T_2}$ an integral part of its territory awaiting reunification, by force if necessary.

S2 "[Our agency]$_{T_1,H_2}$ [seriously needs]$_{O_2}$ [equipment for detecting drugs]$_{T_2}$," [he]$_{H_1}$ [said]$_{O_1}$.

In S1, for example, "infuriated" indicates that there is an (negative) opinion from "Beijing" regarding "the sale."[1]

Traditionally, the task of extracting opinion entities and opinion relations was handled in a pipelined manner, i.e., extracting the opinion expressions first and then extracting opinion targets and opinion holders based on their syntactic and semantic associations with the opinion expressions (Kim and Hovy, 2006; Kobayashi et al., 2007). More recently, methods that *jointly* infer the opinion entity and relation extraction tasks (e.g., using Integer Linear Programming (ILP)) have been introduced (Choi et al., 2006; Yang and Cardie, 2013) and show that the existence of opinion relations provides clues for the identification of opinion entities and vice-versa, and thus results in better performance than a pipelined approach. However, the success of these methods depends critically on the availability of opinion lexicons, dependency parsers, named-entity taggers, etc.

[1] This paper does not attempt to determine the sentiment, i.e., the positive or negative polarity, of an opinion.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 919–929,
Berlin, Germany, August 7-12, 2016.

Alternatively, neural network-based methods have been employed. In these approaches, the required latent features are automatically learned as dense vectors of the hidden layers. Liu et al. (2015), for example, compare several variations of recurrent neural network methods and find that long short-term memory networks (LSTMs) perform the best in identifying opinion expressions and opinion targets for the specific case of product/service reviews.

Motivated by the recent success of LSTMs on this and other problems in NLP, we investigate here the use of deep bi-directional LSTMs for joint extraction of opinion expressions, holders, targets and the relations that connect them. This is the first attempt to handle the full opinion entity and relation extraction task using a deep learning approach.

In experiments on the MPQA dataset for opinion entities (Wiebe and Cardie, 2005; Wilson, 2008), we find that standard LSTMs are not competitive with the state-of-the-art CRF+ILP joint inference approach of Yang and Cardie (2013), performing below even the standalone sequence-tagging CRF. Inspired by Huang et al. (2015), we show that incorporating sentence-level, and our newly proposed relation-level optimization, allows the LSTM to perform within 1–3% of the ILP joint model for all three opinion entity types and to do so without access to opinion lexicons, parsers or other preprocessing components.

For the primary task of identifying opinion entities together with their IS-FROM and IS-ABOUT relations, we show that the LSTM with sentence- and relation-level optimizations outperforms an LSTM baseline that does not employ joint inference. When compared to the CRF+ILP-based joint inference approach, the optimized LSTM performs slightly better for the IS-ABOUT[2] relation and within 3% for the IS-FROM relation.

In the sections that follow, we describe: related work (Section 2) and the multi-layer bi-directional LSTM (Section 3); the LSTM extensions (Section 4); the experiments on the MPQA corpus (Sections 5 and 6) and error analysis (Section 7).

[2]Target and IS-ABOUT relation identification is one important aspect of opinion analysis that hasn't been much addressed in previous work and has proven to be difficult for existing methods.

2 Related Work

LSTM-RNNs (Hochreiter and Schmidhuber, 1997) have recently been applied to many sequential modeling and prediction tasks, such as machine translation (Bahdanau et al., 2014; Sutskever et al., 2014), speech recognition (Graves et al., 2013), NER (Hammerton, 2003). The bi-directional variant of RNNs has been found to perform better as it incorporates information from both the past and the future (Schuster and Paliwal, 1997; Graves et al., 2013). Deep RNNs (stacked RNNs) (Schmidhuber, 1992; Hihi and Bengio, 1996) capture more abstract and higher-level representation in different layers and benefit sequence modeling tasks (İrsoy and Cardie, 2014). Collobert et al. (2011) found that adding dependencies between the tags in the output layer improves the performance of Semantic Role Labeling task. Later, Huang et al. (2015) also found that adding a CRF layer on top of bi-directional LSTMs to capture these dependencies can produce state-of-the-art performance on part-of-speech (POS), chunking and NER.

For fine-grained opinion extraction, earlier work (Wilson et al., 2005; Breck et al., 2007; Yang and Cardie, 2012) focused on extracting subjective phrases using a CRF-based approach from open-domain text such as news articles. Choi et al. (2005) extended the task to jointly extract opinion holders and these subjective expressions. Yang and Cardie (2013) proposed a ILP-based joint-inference model to jointly extract the opinion entities and opinion relations, which performed better than the pipelined based approaches (Kim and Hovy, 2006).

In the neural network domain, İrsoy and Cardie (2014) proposed a deep bi-directional recurrent neural network for identifying subjective expressions, outperforming the previous CRF-based models. Irsoy and Cardie (2013) additionally proposed a bi-directional recursive neural network over a binary parse tree to jointly identify opinion entities, but performed significantly worse than the feature-rich CRF+ILP approach of Yang and Cardie (2013). Liu et al. (2015) used several variants of recurrent neural networks for joint opinion expression and aspect/target identification on customer reviews for restaurants and laptops, outperforming the feature-rich CRF based baseline. In the product reviews domain, however, the opinion holder is generally the reviewer and the task

does not involve identification of relations between opinion entities. Hence, standard LSTMs are applicable in this domain. None of the above neural network based models can jointly model opinion entities and opinion relations.

In the relation extraction domain, several neural networks have been proposed for relation classification, such as RNN-based models (Socher et al., 2012) and LSTM-based models (Xu et al., 2015). These models depend on constituent or dependency tree structures for relation classification, and also do not model entities jointly. Recently, Miwa and Bansal (2016) proposed a model to jointly represent both entities and relations with shared parameters, but it is not a joint-inference framework.

3 Methodology

For our task, we propose the use of multi-layer bi-directional LSTMs, a type of recurrent neural network. Recurrent neural networks have recently been used for modeling sequential tasks. They are capable of modeling sequences of arbitrary length by repetitive application of a recurrent unit along the tokens in the sequence. However, recurrent neural networks are known to have several disadvantages like the problem of vanishing and exploding gradients. Because of these problems, it has been found that recurrent neural networks are not sufficient for modeling long term dependencies. Hochreiter and Schmidhuber (1997), thus proposed long short term memory (LSTMs), a variant of recurrent neural networks.

3.1 Long Short Term Memory (LSTM)

Long short term memory networks are capable of learning long-term dependencies. The recurrent unit is replaced by a memory block. The memory block contains two cell states – memory cell C_t and hidden state h_t; and three multiplicative gates – input gate i_t, forget gate f_t and output gate o_t. These gates regulate the addition or removal of information to the cell state thus overcoming vanishing and exploding gradients.

$$f_t = \sigma(W_f x_t + U_f h_{t-1} + b_f)$$
$$i_t = \sigma(W_i x_t + U_i h_{t-1} + b_i)$$

The forget gate f_t and input gate i_t above decides what part of the information we are going to throw away from the cell state and what new information we are going to store in the cell state. The sigmoid outputs a number between 0 and 1 where 0 implies that the information is completely lost and 1 means that the information is completely retained.

$$\widetilde{C}_t = \tanh(W_c x_t + U_c h_{t-1} + b_c)$$
$$C_t = i_t * \widetilde{C}_t + f_t * C_{t-1}$$

Thus, the intermediate cell state $\widetilde{C}_t$ and previous cell state C_{t-1} are used to update the new cell state C_t.

$$o_t = \sigma(W_o x_t + U_o h_{t-1} + V_o C_t + b_o)$$
$$h_t = o_t * \tanh(C_t)$$

Next, we update the hidden state h_t based on the output gate o_t and the cell state C_t. We pass both the cell state C_t and the hidden state h_t to the next time step.

3.2 Multi-layer Bi-directional LSTM

In sequence tagging problems, it has been found that only using past information for computing the hidden state h_t may not be sufficient. Hence, previous works (Graves et al., 2013; İrsoy and Cardie, 2014) proposed the use of bi-directional recurrent neural networks for speech and NLP tasks, respectively. The idea is to also process the sequence in the backward direction. Hence, we can compute the hidden state $\overrightarrow{h_t}$ in the forward direction and $\overleftarrow{h_t}$ in the backward direction for every token.

Also, in more traditional feed-forward networks, deep networks have been found to learn abstract and hierarchical representations of the input in different layers (Bengio, 2009). The multi-layer LSTMs have been proposed (Hermans and Schrauwen, 2013) to capture long-term dependencies of the input sequences in different layers.

For the first hidden layer, the computation proceeds similar to that described in Section 3.1. However, for higher hidden layers i the input to the memory block is the hidden state and memory cell from the previous layer $i-1$ instead of the input vector representation.

For this paper, we only use the hidden state from the last layer L to compute the output state y_t.

$$z_t = \overrightarrow{V}\overrightarrow{h_t}^{(L)} + \overleftarrow{V}\overleftarrow{h_t}^{(L)} + c$$
$$y_t = g(z_t)$$

4 Network Training

For our problem, we wish to predict a label y from a discrete set of classes Y for every word in a sentence. As is the norm, we train the network by

maximizing the log-likelihood

$$\sum_{(x,y)\in \mathrm{T}} \log p(y|x,\theta)$$

over the training data T, with respect to the parameters θ, where x is the input sentence and y is the corresponding tag sequence. We propose three alternatives for the log-likelihood computation.

4.1 Word-Level Log-Likelihood (WLL)

We first formulate a word-level log-likelihood (WLL) (adapted from Collobert et al. (2011)) that considers all words in a sentence independently. We interpret the score z_t corresponding to the i^{th} tag $[z_t]_i$ as a conditional tag probability $\log p(i|x,\theta)$ by applying a softmax operation.

$$\begin{aligned} p(i|x,\theta) &= softmax(z_t^i) \\ &= \frac{e^{z_t^i}}{\sum_j e^{z_t^j}} \end{aligned}$$

For the tag sequence y given the input sentence x the log-likelihood is :

$$\log p(y|x,\theta) = z^y - \operatorname*{logadd}_j z^j$$

4.2 Sentence-Level Log-Likelihood (SLL)

In the word-level approach above, we discard the dependencies between the tags in a tag sequence. In our sentence-level log-likelihood (SLL) formulation (also adapted from Collobert et al. (2011)) we incorporate these dependencies: we introduce a transition score $[A]_{i,j}$ for jumping from tag i to tag j of adjacent words in the tag sequence to the set of parameters $\widetilde{\theta}$. These transition scores are going to be trained.

We use both the transition scores $[A]$ and the output scores z to compute the sentence score $s(x|_{t=1}^T, y|_{t=1}^T, \widetilde{\theta})$.

$$s(x,y,\widetilde{\theta}) = \sum_{t=1}^{T} \left([A]_{y_{t-1},y_t} + z_t^{y_t} \right)$$

We normalize this sentence score over all possible paths of tag sequences $\widetilde{y}$ to get the log conditional probability as below :

$$\log p_{sent}(y|x,\widetilde{\theta}) = s(x,y,\widetilde{\theta}) - \operatorname*{logadd}_{\widetilde{y}} s(x,\widetilde{y},\widetilde{\theta})$$

Even though the number of tag sequences grows exponentially with the length of the sentence, we can compute the normalization factor in linear time (Collobert et al., 2011).

At inference time, we find the best tag sequence

$$\operatorname*{argmax}_{\widetilde{y}} s(x,\widetilde{y},\widetilde{\theta})$$

for an input sentence x using Viterbi decoding. In this case, we basically maximize the same likelihood as in a CRF except that a CRF is a linear model.

The above sentence-level log-likelihood is useful for sequential tagging, but it cannot be directly used for modeling relations between non-adjacent words in the sentence. In the next subsection, we extend the above idea to also model relations between non-adjacent words.

4.3 Relation-Level Log-Likelihood (RLL)

For every word x_t in the sentence x, we output the tag y_t and a distance d_t. If a word at position t is related to a word at position k and $k < t$, then $d_t = (t-k)$. If word t is not related to any other word to its left, then $d_t = 0$. Let D_{Left} be the maximum distance we model for such *left*-relations [3].

$$z_t = \overrightarrow{V_r}\overrightarrow{h_t}^{(L)} + \overleftarrow{V_r}\overleftarrow{h_t}^{(L)} + c_r$$

We let $\overrightarrow{V_r} \in \mathbb{R}^{(D_{Left}+1)\times Y \times d_h}$ (where d_h is the dimensionality of hidden units) such that the output state $z_t \in \mathbb{R}^{(D_{Left}+1)\times Y}$ as compared to $z_t \in \mathbb{R}^{(1)\times Y}$ in case of sentence-level log-likelihood.

In order to add dependencies between tags and relations, we introduce a transition score $[A]_{i,j,d',d"}$ for jumping from tag i and relation distance $d^{'}$ to tag j and relation distance $d^{"}$ of adjacent words in the tag sequence, to the set of parameters $\theta^{'}$. These transition scores are also going to be trained similar to the transition scores in sentence-level log-likelihood.

The sentence score $s(x|_{t=1}^T, y|_{t=1}^T, d|_{t=1}^T, \theta^{'})$ is:

$$s(x,y,d,\theta^{'}) = \sum_{t=1}^{T} \left([A]_{y_{t-1},y_t,d_{t-1},d_t} + z_t^{y_t,d_t} \right)$$

We normalize this sentence score over all possible paths of tag $\widetilde{y}$ and relation sequences $\widetilde{d}$ to get the log conditional probability as below :

$$\begin{aligned} \log p_{rel,Left}(y,d|x,\widetilde{\theta}) =& s(x,y,d,\theta^{'}) \\ & - \operatorname*{logadd}_{\widetilde{y},\widetilde{d}} s(x,\widetilde{y},\widetilde{d},\theta^{'}) \end{aligned}$$

[3] Later in this section, we will also add a similar likelihood in the objective function for *right*-relations, i.e., for each word the related words are in its right context.

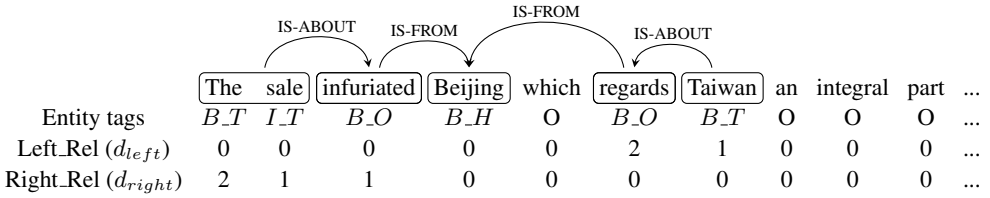

Figure 1: Gold standard annotation for an example sentence from MPQA dataset. O represents the 'Other' tag in the BIO scheme.

We can still compute the normalization factor in linear time similar to sentence-level log-likelihood.

At inference time, we jointly find the best tag and relation sequence

$$\underset{\widetilde{y},\widetilde{d}}{\operatorname{argmax}}\, s(x, \widetilde{y}, \widetilde{d}, \theta^{'})$$

for an input sentence x using Viterbi decoding.

For our task of joint extraction of opinion entities and relations, we train our model to predict tag y and relation distance d for every word in the sentence by maximizing the log-likelihood (**SLL+RLL**) below using Adadelta (Zeiler, 2012).

$$\sum_{(x,y)\in \mathrm{T}} \log p_{sent}(y|x,\theta^{'}) + \log p_{rel,Left}(y,d|x,\theta^{'}) + \log p_{rel,Right}(y,d|x,\theta^{'})$$

5 Experiments

5.1 Data

We use the MPQA 2.0 corpus (Wiebe and Cardie, 2005; Wilson, 2008). It contains news articles and editorials from a wide variety of news sources. There are a total of 482 documents in our dataset containing 9471 sentences with phrase-level annotations. We set aside 132 documents as a development set and use the remaining 350 documents as the evaluation set. We report the results using 10-fold cross validation at the document level to mimic the methodology of Yang and Cardie (2013).

The dataset contains gold-standard annotations for opinion entities — expressions, targets, holders. We use only the direct subjective/opinion expressions. There are also annotations for opinion relations – IS-FROM between opinion holders and opinion expressions; and IS-ABOUT between opinion targets and opinion expressions. These relations can overlap but we discard all relations that contain sub-relations similar to Yang and Cardie (2013). We also leave identification of overlapping relations for future work.

Figure 1 gives an example of an annotated sentence from the dataset: boxes denote opinion entities and opinion relations are shown by arcs. We interpret these relations arcs as directed — from an opinion expression towards an opinion holder, and from an opinion target towards an opinion expression.

In order to use the RLL formulation as defined in Section 4.3, we pre-process these relation arcs to obtain the left-relation distances (d_{left}) and right-relation distances (d_{right}) as shown in Figure 1. For each word in an entity, we find its distance to the nearest word in the related entity. These distances become our relation tags. The entity tags are interpreted using the BIO scheme, also shown in the figure. Our RLL model jointly models the entity tags and relation tags. At inference time, these entity tags and relation tags are used together to determine IS-FROM and IS-ABOUT relations. We use a simple majority vote to determine the final entity tag from SLL+RLL model.

5.2 Evaluation Metrics

We use precision, recall and F-measure (as in Yang and Cardie (2013)) as evaluation metrics. Since the identification of exact boundaries for opinion entities is hard even for humans (Wiebe and Cardie, 2005), soft evaluation methods such as Binary Overlap and Proportional Overlap are reported. Binary Overlap counts every overlapping predicted and gold entity as correct, while Proportional Overlap assigns a partial score proportional to the ratio of overlap span and the correct span (Recall) or the ratio of overlap span and the predicted span (Precision).

For the case of opinion relations, we report precision, recall and F-measure according to the Binary Overlap. It considers a relation correct if there is an overlap between the predicted opin-

ion expression and the gold opinion expression as well as an overlap between the predicted entity (holder/target) and the gold entity (holder/target).

5.3 Baselines

CRF+ILP. We use the ILP-based joint inference model (Yang and Cardie, 2013) as baseline for both the entity and relation extraction tasks. It represents the state-of-the-art for fine-grained opinion extraction. Their method first identifies opinion entities using **CRF**s (an additional baseline) with a variety of features such as words, POS tags, and lexicon features (the subjectivity strength of the word in the Subjectivity Lexicon). They also train a relation classifier (logistic regression) by over-generating candidates from the CRFs (50-best paths) using local features such as word, POS tags, subjectivity lexicons as well as semantic and syntactic features such as semantic frames, dependency paths, WordNet hypernyms, etc. Finally, they use ILP for joint-inference to find the optimal prediction for both opinion entity and opinion relation extraction.

LSTM+SLL+Softmax. As an additional baseline for relation extraction, we train a softmax classifier on top of our SLL framework. We jointly learn the relation classifier and SLL model. For every entity pair $[x]_i^j$, $[x]_k^l$, we first sum the start and end word output representation $[z_t]$ and then concatenate them to learn softmax weight W' where $W' \in \mathbb{R}^{3 \times 2d_h}$.

$$y_{rel} = softmax(W' \begin{bmatrix} [z_t]_i + [z_t]_j \\ [z_t]_k + [z_t]_l \end{bmatrix})$$

The inference is pipelined in this case. At the time of inference, we first predict the entity spans and then use these spans for relation classification.

5.4 Hyperparameter and Training Details

We use multi-layer bi-directional LSTMs for all the experiments such that the number of hidden layers is 3 and the dimensionality of hidden units (d_h) is 50. We use Adadelta for training. We initialize our word representation using publicly available word2vec (Mikolov et al., 2013) trained on Google News dataset and keep them fixed during training. For RLL, we keep D_{Left} and D_{Right} as 15. All the weights in the network are initialized from small random uniform noise. We train all our models for 200 epochs. We do not pretrain our network. We regularize our network using dropout (Srivastava et al., 2014) with the dropout rate tuned using the development set. We select the final model based on development-set performance (average of Proportional Overlap for entities and Binary Overlap for relations).

6 Results

6.1 Opinion Entities

Table 1 shows the performance of opinion entity identification using the Binary Overlap and Proportional Overlap evaluation metrics. We discuss specific results in the paragraphs below.

WLL vs. SLL. SLL performs better than WLL on all entity types, particularly with respect to Proportional Overlap on opinion holder and target entities. A similar trend can be seen for the example sentences in Table 3. In S1, SLL extracts "has been in doubt" as the opinion expression whereas WLL only identifies "has". Similarly in S2, WLL annotates "Saudi Arabia's request on a case-by-case" as the target while SLL correctly includes "basis" in its annotation. Thus, we find that modeling the transitions between adjacent tags enables

Table 2: Performance on opinion relation extraction using Binary Overlap on the opinion entities. Superscripts designate one standard deviation.

SLL to find entire opinion entity phrases better than WLL, leading to better Proportional Overlap scores.

SLL vs. SLL+RLL. From Table 1, we see that the joint-extraction model (SLL+RLL) performs better than SLL as expected. More specifically, SLL+RLL model has better recall for all opinion entity types. The example sentences from Table 3 corroborate these results. In S1, SLL+RLL identifies "announced" as an opinion expression, which was missing in both WLL and SLL. In S3, neither the WLL nor the SLL model can annotate opinion holder (H_1) or the target (T_1), but SLL+RLL correctly identifies the opinion entities because of modeling the relations between the opinion expression "will decide" and the holder/target entities.

CRF vs. LSTM-based Models. From the analysis of the performance in Table 1, we find that our WLL and SLL models perform worse while our best SLL+RLL model can only match the performance of the CRF baseline on opinion expressions. Even though the recall of all our LSTM-based models is higher than the recall of the CRF-baseline for opinion expressions, we cannot match the precision of CRF baseline. We suspect that the reason for such high precision on the part of the CRF is its access to carefully prepared subjectivity-lexicons[4]. Our LSTM-based models do not rely on such features except via the word-vectors. With respect to holders and targets, we find that our SLL model performs similar to the CRF baseline. However, the SLL+RLL model outperforms CRF baseline.

CRF+ILP vs. SLL+RLL. Even though we find that our LSTM-based joint-model (SLL+RLL) outperforms our LSTM-based only-entity extraction model (SLL), the performance is still below the ILP-based joint-model (CRF+ILP). However, we perform comparably with respect to target entities (Binary Overlap). Also, our recall on targets is much better than all other models whereas the recall on holders is very similar to CRF+ILP. Our SLL+RLL model can identify targets such as "Australia's involvement in Kyoto" which the ILP-based model cannot, as observed for S1 in Table 3. In S3, the ILP-based model also erroneously divides the target "consider Saudi Arabia's request on a case-by-case basis" into a holder "Saudi Arabia's" and opinion expression "request", while SLL+RLL model can correctly identify it. We will compare the two models in detail in Section 7.

[4]http://mpqa.cs.pitt.edu/lexicons/ subj_lexicon/

6.2 Opinion Relations

The extraction of opinion relations is our primary task. Table 2[5] shows the performance on opinion relation extraction task using Binary Overlap.

SLL+Softmax vs. SLL+RLL. The opinion entities and relations are jointly modeled in both the models, but we see a significant improvement in performance by adding relation level dependencies to the model vs. learning a classifier on top of sentence-level dependencies to learn the relation between entities. LSTM+SLL+RLL performs much better in terms of both precision and recall on both IS-FROM and IS-ABOUT relations.

CRF+ILP vs. SLL+RLL. We find that our SLL+RLL model performs comparably and even slightly better on IS-ABOUT relations. Such performance is encouraging because our LSTM-based model does not rely on features such as dependency paths, semantic frames or subjectivity lexicons for our model. Our sequential LSTM model is able to learn these relations thus validating that LSTMs can model long-term dependencies. However, for IS-FROM relations, we find that our recall is lower than the ILP-based joint model.

[5]Yang and Cardie (2013) omitted a subset of targets and IS-ABOUT relations. We fixed this and re-ran their models on the updated dataset, obtaining the lower F-score 54.39 for IS-ABOUT relations.

S1 :	[Australia's involvement in Kyoto]$_{\mathbf{T_1}}$ [has been in doubt]$_{\mathbf{O_1}}$ ever since [the US President, George Bush]$_{\mathbf{H_2}}$, [announced]$_{\mathbf{O_2}}$ last year that [ratifying the protocol]$_{\mathbf{T_2}}$ would hurt the US economy.

7 Discussion

In this section, we discuss the various advantages and disadvantages of the LSTM-based SLL+RLL model as compared to the joint-inference (CRF+ILP) model. We provide examples from the dataset in Table 4.

From Table 2, we find that SLL+RLL model performs worse with respect to the opinion expression entities and opinion holder entities. On careful analysis of the output, we found cases such as S1 in Table 4. For such sentences SLL+RLL model prefers to annotate the opinion target (T_3) "US requests for more oil exports", whereas the ILP model annotates the embedded opinion holder (H_4) "US" and opinion expression (T_4) "requests". Both models are valid with respect to the gold-standard. In order to simplify our problem, we discard these embedded relations during training similar to Yang and Cardie (2013). However, for future work we would like to model these overlapping relations which could potentially improve our performance on opinion holders and opinion expressions.

We also found several cases such as S2, where the SLL+RLL model fails to annotate "said" as an opinion expression. The gold standard opinion expressions include speech events like "said" or "a statement", but not all occurrences of these speech events are opinion expressions, some are merely objective events. In S2, "was martyred" is an indication of an opinion being expressed, so "said" is annotated as an opinion expression. From our observation, the ILP model is more relaxed in annotating most of these speech events as opinion expressions and thus likely to identify corresponding

S1 :	However, [Chavez]$_{\mathbf{T_1}}$ who [is known for]$_{\mathbf{O_1}}$ [his]$_{\mathbf{H_2}}$ [ala Fidel Castro left-leaning anti-American philosophy]$_{O_2}$ had on a number of occasions [rebuffed]$_{O_3}$ [[US]$_{\mathbf{H_4}}$ [requests]$_{\mathbf{O_4}}$ for [more oil exports]$_{\mathbf{T_4}}$]$_{\mathbf{T_3}}$.
CRF+ILP	However, [Chavez]$_{\mathbf{H_1}}$ who [is known]$_{\mathbf{O}}$ for [his ala Fidel Castro]$_{\mathbf{H_2}}$ [left-leaning anti-American philosophy]$_{\mathbf{O_2}}$ had on a number of occasions [rebuffed]$_{\mathbf{O_1}}$ [US]$_{\mathbf{H_3}}$ [requests]$_{\mathbf{O_3}}$ for more oil exports.
SLL+RLL	However, Chavez who [is known]$_{\mathbf{O}}$ for his ala Fidel Castro left-leaning anti-American [philosophy]$_{\mathbf{O}}$ had on a number of occasions [rebuffed]$_{\mathbf{O_1}}$ [US requests for more oil exports]$_{\mathbf{T_1}}$.
S2 :	A short while ago, [our correspondent in Bethlehem]$_{\mathbf{H_1}}$ [said]$_{\mathbf{O_1}}$ that [Ra'fat al-Bajjali]$_{\mathbf{T_1}}$ **was martyred** of wounds sustained in the explosion.
CRF+ILP	A short while ago, [our correspondent]$_{\mathbf{H_1}}$ in Bethlehem [said]$_{\mathbf{O_1}}$ that [Ra'fat al-Bajjali]$_{T_1}$ was martyred of wounds sustained in the explosion.
SLL+RLL	A short while ago, our correspondent in Bethlehem said that Ra'fat al-Bajjali was martyred of wounds sustained in the explosion.
S3 :	This is no criticism, and is widely known and appreciated.
CRF+ILP	This is no criticism, and is widely known and appreciated.
SLL+RLL	[This]$_{\mathbf{T_1}}$ [is no criticism]$_{\mathbf{O_1}}$, and is widely [known and appreciated]$_{\mathbf{O}}$.
S4 :	From the fact that mothers care for their young, we can not deduce that they ought to do so, Hume argued.
CRF+ILP	From the fact that [mothers]$_{\mathbf{H_1}}$ [care]$_{\mathbf{O_1}}$ for their young, we can not deduce that they ought to do so, [Hume]$_{\mathbf{H_2}}$ [argued]$_{\mathbf{O_2}}$.
SLL+RLL	From the fact that mothers care for their young, [we]$_{\mathbf{H_1}}$ [can not deduce]$_{\mathbf{O_1}}$ that [they]$_{\mathbf{T_1}}$ ought to do so, [Hume]$_{\mathbf{H_2}}$ [argued]$_{\mathbf{O_2}}$.

Table 4: Examples from the dataset with label annotations from CRF+ILP and SLL+RLL models for comparison. The first row for each example is the gold standard.

opinion holders and opinion targets as compared to SLL+RLL model.

There were also instances such as S3 and S4 in Table 4 for which the gold standard does not have an annotation but the SLL+RLL output looks reasonable with respect to our task. In S3, SLL+RLL identifies "is no criticism" as an opinion expression for the target "This". However, it fails to identify the relation-link between "known and appreciated" and the target "This". Similarly, SLL+RLL also identifies reasonable opinion entities in S4, whereas the ILP model erroneously annotates "mothers" as the opinion holder and "care" as the opinion expression.

We handle the task of joint-extraction of opinion entities and opinion relations as a sequence labeling task in this paper and report the performance of the 1-best path at the time of Viterbi inference. However, there are approaches such as discriminative reranking (Collins and Koo, 2005) to rerank the output of an existing system that offer a means for further improving the performance of our SLL+RLL model. In particular, the oracle performance using the top-10 Viterbi paths from our SLL+RLL model has an F-score of 82.11 for opinion expressions, 76.77 for targets and 78.10 for holders. Similarly, IS-ABOUT relations have an F-score of 65.99 and IS-FROM relations, an F-score of 70.80. These scores are on average 10 points better than the performance of the current SLL+RLL model, indicating that substantial gains might be attained via reranking.

8 Conclusion

In this paper, we explored LSTM-based models for the joint extraction of opinion entities and relations. Experimentally, we found that adding sentence-level and relation-level dependencies on the output layer improves the performance on opinion entity extraction, obtaining results within 1-3% of the ILP-based joint model on opinion entities, within 3% for IS-FROM relation and comparable for IS-ABOUT relation.

In future work, we plan to explore the effects of pre-training (Bengio et al., 2009) and scheduled sampling (Bengio et al., 2015) for training our LSTM network. We would also like to explore re-ranking methods for our problem. With respect to the fine-grained opinion mining task, a potential future direction to be able to model overlapping and embedded entities and relations and also to extend this model to handle cross-sentential relations.

Abstract

This paper proposes a left-corner parser which can identify nonlocal dependencies. Our parser integrates nonlocal dependency identification into a transition-based system. We use a structured perceptron which enables our parser to utilize global features captured by nonlocal dependencies. An experimental result demonstrates that our parser achieves a good balance between constituent parsing and nonlocal dependency identification.

1 Introduction

Many constituent parsers based on the Penn Treebank (Marcus et al., 1993) are available, but most of them do not deal with nonlocal dependencies. Nonlocal dependencies represent syntactic phenomenon such as wh-movement, A-movement in passives, topicalization, raising, control, right node raising and so on. Nonlocal dependencies play an important role on semantic interpretation. In the Penn Treebank, a nonlocal dependency is represented as a pair of an empty element and a filler.

Several methods of identifying nonlocal dependencies have been proposed so far. These methods can be divided into three approaches: pre-processing approach (Dienes and Dubey, 2003b), in-processing approach (Dienes and Dubey, 2003a; Schmid, 2006; Cai et al., 2011; Kato and Matsubara, 2015) and post-processing approach (Johnson, 2002; Levy and Manning, 2004; Campbell, 2004; Xue and Yang, 2013; Xiang et al., 2013; Takeno et al., 2015).[1] In pre-processing approach, a tagger called "trace tagger" detects empty elements. The trace tagger uses only surface word information. In-processing approach integrates nonlocal dependency identification into a parser. The parser uses a probabilistic context-free grammar to rank candidate parse trees. Post-processing approach recovers nonlocal dependencies from a parser output which does not include nonlocal dependencies.

The parsing models of the previous methods cannot use global features captured by nonlocal dependencies. Pre- or in-processing approach uses a probabilistic context-free grammar, which makes it difficult to use global features. Post-processing approach performs constituent parsing and nonlocal dependency identification separately. This means that the constituent parser cannot use any kind of information about nonlocal dependencies.

This paper proposes a parser which integrates nonlocal dependency identification into constituent parsing. Our method adopts an in-processing approach, but does not use a probabilistic context-free grammar. Our parser is based on a transition system with structured perceptron (Collins, 2002), which can easily introduce global features to its parsing model. We adopt a left-corner strategy in order to use the syntactic relation *c-command*, which plays an important role on nonlocal dependency identification. Previous work on transition-based constituent parsing adopts a shift-reduce strategy with a tree binarization (Sagae and Lavie, 2005; Sagae and Lavie, 2006; Zhang and Clark, 2009; Zhu et al., 2013; Wang and Xue, 2014; Mi and Huang, 2015; Thang et al., 2015; Watanabe and Sumita, 2015), or convert constituent trees to "spinal trees", which are similar to dependency trees (Ballesteros and Carreras, 2015). These conversions make it difficult for their parsers to capture c-command relations in the parsing process. On the other hand, our parser does not require such kind of conversion.

[1]The methods of (Cai et al., 2011; Xue and Yang, 2013; Xiang et al., 2013; Takeno et al., 2015) only detect empty elements.

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 930–940,
Berlin, Germany, August 7-12, 2016.

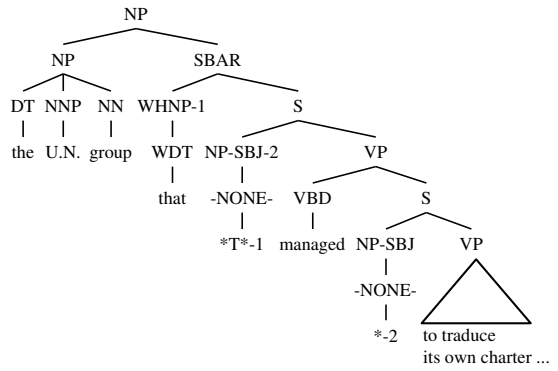

Figure 1: A parse tree in the Penn Treebank.

Our contribution can be summarized as follows:

1. We introduce empty element detection into transition-based left-corner constituent parsing.
2. We extend c-command relation to deal with nodes in *parse tree stack* in the transition system, and develop heuristic rules which coindex empty elements with their fillers on the basis of the extended version of c-command.
3. We introduce new features about nonlocal dependency to our parsing model.

This paper is organized as follows: Section 2 explains how to represent nonlocal dependencies in the Penn Treebank. Section 3 describes our transition-based left-corner parser. Section 4 introduces nonlocal dependency identification into our parser. Section 5 describes structured perceptron and features. Section 6 reports an experimental result, which demonstrated that our parser achieved a good balance between constituent parsing and nonlocal dependency identification. Section 7 concludes this paper.

2 Nonlocal Dependency

This section describes nonlocal dependencies in the Penn Treebank (Marcus et al., 1993). A nonlocal dependency is represented as a pair of an *empty element* and a *filler*. Figure 1 shows an example of (partial) parse tree in the Penn Treebank. The parse tree includes several nonlocal dependencies. The nodes labeled with -NONE- are empty elements. The terminal symbols such as $*$ and $*$T$*$ represent the type of nonlocal dependency: $*$ represents an unexpressed subject of to-infinitive. $*$T$*$ represents a trace of wh-movement. When a terminal symbol of empty element is indexed, its filler exists in the parse tree. The filler has the same number. For example, $*$T$*$-1 means that the node WHNP-1 is the corresponding filler. Table 1 gives a brief description of empty elements quoted from the annotation guideline (Bies et al., 1995). For more details, see the guideline.

3 Transition-Based Left-Corner Parsing

This section describes our transition-based left-corner parser.

As with previous work (Sagae and Lavie, 2005; Sagae and Lavie, 2006; Zhang and Clark, 2009; Zhu et al., 2013; Wang and Xue, 2014; Mi and Huang, 2015; Thang et al., 2015; Watanabe and Sumita, 2015), our transition-based parsing system consists of a set of parser states and a finite set of transition actions, each of which maps a state into a new one. A parser state consists of a stack of parse tree nodes and a buffer of input words. A state is represented as a tuple (σ, i), where σ is the stack and i is the next input word position in the buffer. The initial state is $(\langle\rangle, 0)$. The final states are in the form of $(\langle[\cdots]_{\texttt{TOP}}\rangle, n)$, where TOP is a special symbol for the root of the parse tree and n is the length of the input sentence. The transition actions for our parser are as follows:

- SHIFT(X): pop up the first word from the buffer, assign a POS tag X to the word and push it onto the stack.

The SHIFT action assigns a POS tag to the shifted word to perform POS tagging and constituent parsing simultaneously. This is in the same way as Wang and Xue (2014).

- LEFTCORNER-$\{$H/$\emptyset\}(X)$: pop up the first node from the stack, attach a new node labeled with X to the node as the parent and push it back onto the stack. H and $\emptyset$ indicate whether or not the popped node is the head child of the new node.
- ATTACH-$\{$H/$\emptyset\}$: pop up the top two nodes from the stack, attach the first one to the second one as the rightmost child and push it back onto the stack. H and $\emptyset$ indicate whether or not the first node is the head child of the second one.

We introduce new actions LEFTCORNER and ATTACH. ATTACH action is similar to REDUCE action standardly used in the previous transition-based parsers. However, there is an important

SHIFT(X)	$(\langle s_m, \ldots, s_0 \rangle, i) \Rightarrow (\langle s_m, \ldots, s_0, [w_i]_X \rangle, i+1)$
LEFTCORNER-{H/∅}(X)	$(\langle s_m, \ldots, s_1, s_0 \rangle, i) \Rightarrow (\langle s_m, \ldots, s_1, [s_0]_X \rangle, i)$
ATTACH-{H/∅}	$(\langle s_m, \ldots, s_2, [\sigma_1]_X, s_0 \rangle, i) \Rightarrow (\langle s_m, \ldots, s_2, [\sigma_1 s_0]_X \rangle, i)$

Figure 2: Transition actions for left-corner parsing.

difference between ATTACH and REDUCE. The REDUCE action cannot deal with any node with more than two children. For this reason, the previous work converts parse trees into binarized ones. The conversion makes it difficult to capture the hierarchical structure of the parse trees. On the other hand, ATTACH action can handle more than two children. Therefore, our parser does not require such kind of tree binarization. These transition actions are similar to the ones described in (Henderson, 2003), although his parser uses right-binarized trees and does not identify head-children. Figure 2 summarizes the transition actions for our parser.

To guarantee that every non-terminal node has exactly one head child, our parser uses the following constraints:

- LEFTCORNER and ATTACH are not allowed when s_0 has no head child.
- ATTACH-H is not allowed when s_1 has a head child.

Table 2 shows the first several transition actions which derive the parse tree shown in Figure 1. Head children are indicated by the superscript *.

Previous transition-based constituent parsing does not handle nonlocal dependencies. One exception is the work of Maier (2015), who proposes shift-reduce constituent parsing with swap action. The parser can handle nonlocal dependencies represented as discontinuous constituents. In this framework, discontinuities are directly annotated by allowing crossing branches. Since the annotation style is quite different from the PTB annotation, the parser is not suitable for identifying the PTB style nonlocal dependencies.[2]

4 Nonlocal Dependency Identification

Nonlocal dependency identification consists of two subtasks:

- empty element detection.
- empty element resolution, which coindexes empty elements with their fillers.

Our parser can insert empty elements at an arbitrary position to realize empty element detection. This is in a similar manner as the in-processing approach. Our method coindexes empty elements with their fillers using simple heuristic rules, which are developed for our transition system.

4.1 Empty Element Detection

We introduce the following action to deal with empty elements:

$$\text{E-SHIFT}(E, t):$$
$$(\langle s_m, \ldots, s_0 \rangle, i) \Rightarrow (\langle s_m, \ldots, s_0, [t]_E \rangle, i)$$

This action simply inserts an empty element at an arbitrary position and pops up no element from the buffer (see the transition from #11 to #12 shown in Table 2 as an example).

4.2 Annotations

For empty element resolution, we augment the Penn Treebank. For nonlocal dependency types

[2]In (Evang and Kallmeyer, 2011), the PTB-style annotation of types *EXP, *ICH*, *RNR* and *T* is transformed into an annotation with crossing branches.

action	#	state

Table 2: An example of transition action sequence.

EXP, *ICH*, *RNR* and *T*, we assign the following information to each filler and each empty element:

- The nonlocal dependency type (only for filler).
- The nonlocal dependency category, which is defined as the category of the parent of the empty element.
- The relative position of the filler, which take a value from $\{\texttt{A}, \texttt{L}, \texttt{R}\}$. "A" means that the filler is an ancestor of the empty element. "L" ("R") means that the filler occurs to the left (right) of the empty element. Table 1 summarizes which value each empty element can take.

The information is utilized for coindexing empty elements with fillers. Below, we write $\texttt{n-type}(x)$, $\texttt{n-cat}(x)$ and $\texttt{n-posi}(x)$ for the information of a node x, respectively.

If an empty element of type $*$ is indexed, we annotate the empty element in the same way.[3] Furthermore, we assign a tag OBJCTRL to every empty element if its coindexed constituent does not have the function tag SBJ.[4] This enables our parser to distinguish between subject control and object control.

Figure 3 shows the augmented version of the parse tree of Figure 1.

4.3 Empty Element Resolution

Nonlocal dependency annotation in the Penn Treebank is based on Chomsky's GB-theory (Chomsky, 1981). This means that there exist c-command relations between empty elements and

[3]We omit its nonlocal dependency category, since it is always NP.

[4]In the Penn Treebank, every subject has the tag SBJ.

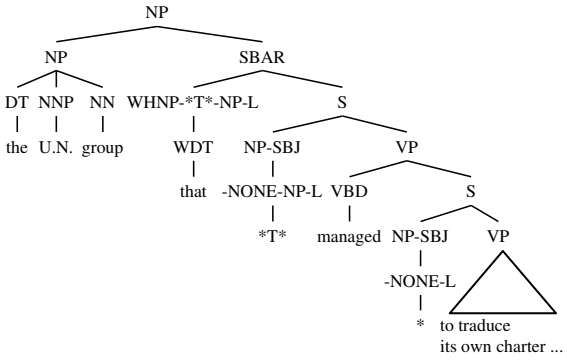

Figure 3: An augmented parse tree.

fillers in many cases. For example, all the empty elements in Figure 1 are c-commanded by their fillers. Our method coindexes empty elements with their fillers by simple heuristic rules based on the c-command relation.

4.3.1 C-command Relation

Here, we define c-command relation in a parse tree as follows:

- A node x *c-commands* a node y if and only if there exists some node z such that z is a sibling of $x (x \neq z)$ and y is a descendant of z.

It is difficult for previous transition-based shift-reduce constituent parsers to recognize c-command relations between nodes, since parse trees are binarized. On the other hand, our left-corner parser needs not to binarize parse trees and can easily recognize c-command relations. Furthermore, we extend c-command relation to handle nodes in a stack of our transition system. For two nodes x and y in a stack, the following statement necessarily holds:

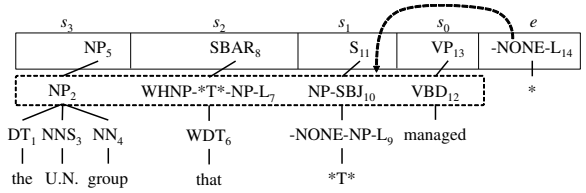

Figure 4: An example of resolution of $[*]$-NONE-L.

- Let $S = (\langle s_m, \ldots, s_0 \rangle, i)$ be a parser state. Let y be a descendant of s_j and x be a child of some node $s_k (j < k \leq m)$, respectively. Then, x c-commands y in any final state derived from the state S.

Below, we say that x c-commands y, even when the nodes x and y satisfy the above statement.

As an example, let us consider the state shown in Figure 4. The subscripts of nodes indicate the order in which the nodes are instantiated. The nodes in dotted box c-command the shifted node -NONE-L$_{14}$ in terms of the above statement. In the parse tree shown in Figure 3, which is derived from this state, these nodes c-commands -NONE-L$_{14}$ by the original definition.

4.3.2 Resolution Rules

Our parser coindexes an empty element with its filler, when E-SHIFT or ATTACH is executed. E-SHIFT action coindexes the shifted empty element e such that $\texttt{n-posi}(e) = \texttt{L}$ with its filler. ATTACH action coindexes the attached filler s_0 such that $\texttt{n-posi}(s_0) = \texttt{R}$ with its corresponding empty element. Resolution rules consist of three parts: PRECONDITION, CONSTRAINT and SELECT. Empty element resolution rule is applied to a state when the state satisfies PRECONDITION of the rule. CONSTRAINT represents the conditions which coindexed element must satisfy. SELECT can take two values ALL and RIGHTMOST. When there exist several elements satisfying the CONSTRAINT, SELECT determines how to select coindexed elements. ALL means that all the elements satisfying the CONSTRAINT are coindexed. RIGHTMOST selects the rightmost element satisfying the CONSTRAINT.

The most frequent type of nonlocal dependency in the Penn Treebank is $*$. Figure 5 shows the resolution rules for type $*$. Here, $\texttt{ch}(s)$ designates the set of the children of s. $\texttt{sbj}(x)$ means that x has a function tag SBJ. $\texttt{par}(x)$ designates the parent of x. $\texttt{cat}(x)$ represents the constituent category of x. $\texttt{des}(s)$ designates the set of the proper descendants of s. $\texttt{free}(x, \sigma)$ means that x is not coindexed with a node included in σ.

Rule: $*$-L
- PRECONDITION
  - ACTION=E-SHIFT(-NONE-L, $*$)
- CONSTRAINT for coindexed element x
  - $x \in \bigcup_{j=0}^{m} \texttt{ch}(s_j)$ # x c-commands e
  - $\texttt{sbj}(x)$
- SELECT: RIGHTMOST

Rule: $*$-L-OBJCTRL
- PRECONDITION
  - ACTION=E-SHIFT(-NONE-L-OBJCTRL, $*$)
- CONSTRAINT for coindexed element x
  - $x \in \bigcup_{j=0}^{m} \texttt{ch}(s_j)$ # x c-commands e
  - $\texttt{cat}(x) = \texttt{NP} \vee \texttt{cat}(x) = \texttt{PP}$
  - $\texttt{cat}(\texttt{par}(x)) = \texttt{VP}$
- SELECT: RIGHTMOST

Rule: $*$-R
- PRECONDITION
  - ACTION=ATTACH
  - $\texttt{sbj}(s_0)$
- CONSTRAINT for coindexed element x
  - $x \in \texttt{des}(s_1)$ # s_0 c-commands x
  - $x = [*]$-NONE-R
  - $\texttt{free}(x, \langle s_m, \ldots, s_0 \rangle)$
- SELECT: ALL

Figure 5: Resolution rules for type $*$.

The first rule $*$-L is applied to a state when E-SHIFT action inserts an empty element $e = [*]$-NONE-L. This rule seeks a subject which c-commands the shifted empty element. The first constraint means that the node x c-commands the empty element e, since the resulting state of E-SHIFT action is $(\langle s_m, \ldots, s_0, e \rangle, i)$, and x and e satisfy the statement in section 4.3.1. For example, the node NP-SBJ$_{10}$ shown in Figure 4 satisfies these constraints (the dotted box represents the first constraint). Therefore, our parser coindexes NP-SBJ$_{10}$ with -NONE-L$_{14}$.

The second rule $*$-L-OBJCTRL seeks an object instead of a subject. The second and third constraints identify whether or not x is an argument. If x is a prepositional phrase, our parser coindexes e with x's child noun phrase instead of x itself, in order to keep the PTB-style annotation.

The third rule $*$-R is for null subject of participial clause. Figure 6 shows an example of applying the rule $*$-R to a state. This rule is applied to a state when the transition action is ATTACH and s_0 is a subject. By definition, the first constraint means that s_0 c-commands x.

The second most frequent type is $*$T$*$. Figure 7 shows the rule for $*$T$*$. This rule is ap-

plied to a state when E-SHIFT action inserts an empty element of type $*\mathtt{T}*$. Here, $\mathtt{match}(x, y)$ checks the consistency between x and y, that is, $\mathtt{match}(x, y)$ holds if and only if $\mathtt{n\text{-}type}(x) = \mathtt{n\text{-}type}(y)$, $\mathtt{n\text{-}cat}(x) = \mathtt{n\text{-}cat}(y)$, $\mathtt{n\text{-}posi}(x) = \mathtt{n\text{-}posi}(y)$, $\mathtt{cat}(x) \neq$ -NONE- and $\mathtt{cat}(y) =$ -NONE-. $\mathtt{removeCRD}(\langle s_m, \ldots, s_0 \rangle)$ is a stack which is obtained by removing $s_j (0 \leq j \leq m)$ which is annotated with a tag CRD.[5] The tag CRD

[5]We assign a tag CRD to a node, when it matches the pattern $[\cdots[\cdots]_X \cdots [\cdots]_{(\mathtt{CC|CONJP}|,|:)} \cdots [\cdots]_X \cdots]_X$.

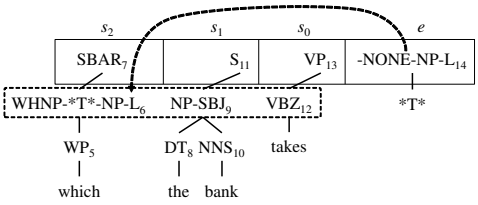

Figure 8: An example of resolution of $[*\mathtt{T}*]_{\mathtt{-NONE-NP-L}}$.

means that the node is coordinate structure. In general, each filler of type $*\mathtt{T}*$ is coindexed with only one empty element. However, a filler of type $*\mathtt{T}*$ can be coindexed with several empty elements if the empty elements are included in coordinate structure. This is the reason why our parser uses removeCRD. Figure 8 and 9 give examples of resolution for type $*\mathtt{T}*$.

The empty elements $[*\mathtt{T}*]_{\mathtt{-NONE-A}}$ are handled by an exceptional process. When ATTACH action is applied to a state $(\langle s_m, \ldots, s_0 \rangle, i)$ such that $\mathtt{cat}(s_0) = \mathtt{PRN}$, the parser coindexes the empty element $x = [*\mathtt{T}*]_{\mathtt{-NONE-A}}$ included in s_0 with s_1. More precisely, the coindexation is executed if the following conditions hold:

- $x \in \mathtt{des}(s_0)$
- $\mathtt{match}(s_1, x)$
- $\mathtt{free}(x, \langle s_m, \ldots, s_0 \rangle)$

For the other types of nonlocal dependencies, that is, $*\mathtt{EXP}*$, $*\mathtt{ICH}*$ and $*\mathtt{RNR}*$, we use a simi-

Figure 10: Resolution rule for ∗EXP∗, ∗ICH∗ and ∗RNR∗.

lar idea to design the resolution rules. Figure 10 shows the resolution rules.

These heuristic resolution rules are similar to the previous work (Campbell, 2004; Kato and Matsubara, 2015), which also utilizes c-command relation. An important difference is that we design heuristic rules not for fully-connected parse tree but for stack of parse trees derived by left-corner parsing. That is, the extend version of c-command relation plays an important role on our heuristic rules.

5 Parsing Strategy

We use a beam-search decoding with the structured perceptron (Collins, 2002). A transition action a for a state S has a score defined as follows:

$$score(S, a) = \mathbf{w} \cdot \mathbf{f}(S, a)$$

where $\mathbf{f}(S, a)$ is the feature vector for the state-action pair (S, a), and $\mathbf{w}$ is a weight vector. The

input: sentence $w_1 \cdots w_n$, beam size k
$H \leftarrow \{S_0\}$ # S_0 is the initial state for $w_1 \cdots w_0$
repeat N times **do**
  $C \leftarrow \{\}$
  for each $S \in H$ **do**
    for each possible action a **do**
      $S' \leftarrow$ apply a to S
      push S' to C
  $H \leftarrow k$ best states of C
return best final state in C

Figure 11: Beam-search parsing.

score of a state S' which is obtained by applying an action a to a state S is defined as follows:

$$score(S') = score(S) + score(S, a)$$

For the initial state S_0, $score(S_0) = 0$.

We learn the weight vector $\mathbf{w}$ by max-violation method (Huang et al., 2012) and average the weight vector to avoid overfitting the training data (Collins, 2002).

In our method, action sequences for the same sentence have different number of actions because of E-SHIFT action. To absorb the difference, we use an IDLE action, which are proposed in (Zhu et al., 2013):

$$\text{IDLE} : (\langle [\cdots]_{\texttt{TOP}} \rangle, n) \Rightarrow (\langle [\cdots]_{\texttt{TOP}} \rangle, n)$$

Figure 11 shows details of our beam-search parsing. The algorithm is the same as the previous transition-based parsing with structured perceptron. One point to be noted here is how to determine the maximum length of action sequence ($= N$) which the parser allows. Since it is impossible to know in advance how many empty elements a parse tree has, we need to set this parameter as a sufficiently larger value.

5.1 Features

A feature is defined as the concatenation of a transition action and a state feature which is extracted using a feature template. Table 3 shows our baseline feature templates. The feature templates are similar to the ones of (Zhang and Clark, 2009), which are standardly used as baseline templates for transition-based constituent parsing. Here, b_i and s_i stand for the i-th element of buffer and stack, respectively. $x.\texttt{c}$ represents x's augmented label. $x.\texttt{l}$, $x.\texttt{r}$ and $x.\texttt{h}$ represent x's leftmost, rightmost and head children. $x.\texttt{t}$ and $x.\texttt{w}$ represents x's head POS tag and head word, respectively. $x.\texttt{i}$ indicates whether or not the initial letter of x is capitalized. When a non-terminal node

type	feature templates
unigram	s_0.c $\circ$ s_0.t, s_0.c $\circ$ s_0.w,

does not yet have a head child, the head-based atomic features are set to a special symbol nil. To extract the features, we need to identify head children in parse trees. We use the head rules described in (Surdeanu et al., 2008).

In addition to these features, we introduce a new feature which is related to empty element resolution. When a transition action invokes empty element resolution described in section 4.3.2, we use as a feature, whether or not the procedure coindexes empty elements with a filler. Such a feature is difficult for a PCFG to capture. This feature enables our parsing model to learn the resolution rule preferences implicitly, while the training process is performed only with oracle action sequences.

In addition, we use features about free empty elements and fillers. Table 4 summarizes such feature templates. Here, x.n$_i$ stands for the i-th rightmost free element included in x, and $rest_i$ stands for the stack $\langle s_m, \ldots, s_i \rangle$.

6 Experiment

We conducted an experiment to evaluate the performance of our parser using the Penn Treebank. We used a standard setting, that is, section 02-21 is for the training data, section 22 is for the development data and section 23 is for the test data.

In training, we set the beam size k to 16 to achieve a good efficiency. We determined the optimal iteration number of perceptron training, and the beam size (k was set to 16, 32 and 64) for decoding on the development data. The maximum length of action sequences ($= N$) was set to $7n$, where n is the length of input sentence. This maximum length was determined to deal with the sentences in the training data.

Table 5: Comparison for constituent parsing.

Table 5 presents the constituent parsing performances of our system and previous systems. We used the labeled bracketing metric PARSEVAL (Black et al., 1991). Here, "CF" is the parser which was learned from the training data where nonlocal dependencies are removed. This result demonstrates that our nonlocal dependency identification does not have a bad influence on constituent parsing. From the viewpoint of transition-based constituent parsing, our left-corner parser is somewhat inferior to other perceptron-based shift-reduce parsers. On the other hand, our parser outperforms the parsers which identify nonlocal dependency based on in-processing approach.

We use the metric proposed by Johnson (2002) to evaluate the accuracy of nonlocal dependency identification. Johnson's metric represents a nonlocal dependency as a tuple which consists of the type of the empty element, the category of the empty element, the position of the empty element, the category of the filler and the position of the filler. For example, the nonlocal dependency of the type $*$T$*$ in Figure 1 is represented as $(*\texttt{T}*, \texttt{NP}, [4, 4], \texttt{WHNP}, [3, 4])$. The precision and the recall are measured using these tuples. For more details, see (Johnson, 2002).

Table 6 shows the nonlocal dependency identification performances of our method and previous methods. Previous in-processing approach

achieved the state-of-the-art performance of nonlocal dependency identification, while it was inferior in terms of constituent parsing accuracy. Our nonlocal dependency identification is competitive with previous in-processing approach, and its accuracy of constituent parsing is higher than previous in-processing approach. As a whole, our parser achieves a good balance between constituent parsing and nonlocal dependency identification. Table 7 summarizes the accuracy of nonlocal dependency identification for each type of nonlocal dependency.

7 Conclusion

This paper proposed a transition-based parser which identifies nonlocal dependencies. Our parser achieves a good balance between constituent parsing and nonlocal dependency identification. In the experiment reported in this paper, we used simple features which are captured by nonlocal dependencies. In future work, we will develop lexical features which are captured by nonlocal dependencies.

Siamese CBOW: Optimizing Word Embeddings for Sentence Representations

Tom Kenter[1] tom.kenter@uva.nl

[2] Yandex, Moscow

Abstract

We present the *Siamese Continuous Bag of Words* (Siamese CBOW) model, a neural network for efficient estimation of high-quality sentence embeddings. Averaging the embeddings of words in a sentence has proven to be a surprisingly successful and efficient way of obtaining sentence embeddings. However, word embeddings trained with the methods currently available are not optimized for the task of sentence representation, and, thus, likely to be suboptimal. Siamese CBOW handles this problem by training word embeddings directly for the purpose of being averaged. The underlying neural network learns word embeddings by predicting, from a sentence representation, its surrounding sentences. We show the robustness of the Siamese CBOW model by evaluating it on 20 datasets stemming from a wide variety of sources.

1 Introduction

Word embeddings have proven to be beneficial in a variety of tasks in NLP such as machine translation (Zou et al., 2013), parsing (Chen and Manning, 2014), semantic search (Reinanda et al., 2015; Voskarides et al., 2015), and tracking the meaning of words and concepts over time (Kim et al., 2014; Kenter et al., 2015). It is not evident, however, how word embeddings should be combined to represent larger pieces of text, like sentences, paragraphs or documents. Surprisingly, simply averaging word embeddings of all words in a text has proven to be a strong baseline or feature across a multitude of tasks (Faruqui et al., 2014; Yu et al., 2014; Gershman and Tenenbaum, 2015; Kenter and de Rijke, 2015).

Word embeddings, however, are not optimized specifically for representing sentences. In this paper we present a model for obtaining word embeddings that are tailored specifically for the task of averaging them. We do this by directly including a comparison of sentence embeddings—the averaged embeddings of the words they contain—in the cost function of our network.

Word embeddings are typically trained in a fast and scalable way from unlabeled training data. As the training data is unlabeled, word embeddings are usually not task-specific. Rather, word embeddings trained on a large training corpus, like the ones from (Collobert and Weston, 2008; Mikolov et al., 2013b) are employed across different tasks (Socher et al., 2012; Kenter and de Rijke, 2015; Hu et al., 2014). These two qualities— (i) being trainable from large quantities of unlabeled data in a reasonable amount of time, and (ii) robust performance across different tasks—are highly desirable and allow word embeddings to be used in many large-scale applications. In this work we aim to optimize word embeddings for sentence representations in the same manner. We want to produce general purpose sentence embeddings that should score robustly across multiple test sets, and we want to leverage large amounts of unlabeled training material.

In the word2vec algorithm, Mikolov et al. (2013a) construe a supervised training criterion for obtaining word embeddings from unsupervised data, by predicting, for every word, its surrounding words. We apply this strategy at the sentence level, where we aim to predict a sentence from its adjacent sentences (Kiros et al., 2015; Hill et al., 2016). This allows us to use unlabeled training data, which is easy to obtain; the only restriction is that documents need to be split into sentences and that the order between sentences is preserved.

The main research question we address is

Proceedings of the 54th Annual Meeting of the Association for Computational Linguistics, pages 941–951,
Berlin, Germany, August 7-12, 2016.

whether directly optimizing word embeddings for the task of being averaged to produce sentence embeddings leads to word embeddings that are better suited for this task than word2vec does. Therefore, we test the embeddings in an unsupervised learning scenario. We use 20 evaluation sets that stem from a wide variety of sources (newswire, video descriptions, dictionary descriptions, microblog posts). Furthermore, we analyze the time complexity of our method and compare it to our baselines methods.

Summarizing, our main contributions are:

- We present Siamese CBOW, an efficient neural network architecture for obtaining high-quality word embeddings, directly optimized for sentence representations;
- We evaluate the embeddings produced by Siamese CBOW on 20 datasets, originating from a range of sources (newswire, tweets, video descriptions), and demonstrate the robustness of embeddings across different settings.

2 Siamese CBOW

We present the *Siamese Continuous Bag of Words* (CBOW) model, a neural network for efficient estimation of high-quality sentence embeddings. Quality should manifest itself in embeddings of semantically close sentences being similar to one another, and embeddings of semantically different sentences being dissimilar. An efficient and surprisingly successful way of computing a sentence embedding is to average the embeddings of its constituent words. Recent work uses pre-trained word embeddings (such as word2vec and GloVe) for this task, which are not optimized for sentence representations. Following these approaches, we compute sentence embeddings by averaging word embeddings, but we optimize word embeddings directly for the purpose of being averaged.

2.1 Training objective

We construct a supervised training criterion by having our network predict sentences occurring next to each other in the training data. Specifically, for a pair of sentences (s_i, s_j), we define a probability $p(s_i, s_j)$ that reflects how likely it is for the sentences to be adjacent to one another in the training data. We compute the probability $p(s_i, s_j)$ using a softmax function:

$$p_\theta(s_i, s_j) = \frac{e^{\cos(\mathbf{s_i^\theta}, \mathbf{s_j^\theta})}}{\sum_{s_{\prime} \in S} e^{\cos(\mathbf{s_i^\theta}, \mathbf{s_{\prime}^\theta})}}, \qquad (1)$$

where $\mathbf{s}_x^\theta$ denotes the embedding of sentence s_x, based on the model parameters θ. In theory, the summation in the denominator of Equation 1 should range over all possible sentences S, which is not feasible in practice. Therefore, we replace the set S with the union of the set S^+ of sentences that occur next to the sentence s_i in the training data, and S^-, a set of n randomly chosen sentences that are not observed next to the sentence s_i in the training data. The loss function of the network is categorical cross-entropy:

$$L = - \sum_{s_j \in \{S^+ \cup S^-\}} p(s_i, s_j) \cdot \log(p_\theta(s_i, s_j)),$$

where $p(\cdot)$ is the target probability the network should produce, and $p_\theta(\cdot)$ is the prediction it estimates based on parameters θ, using Equation 1. The target distribution simply is:

$$p(s_i, s_j) = \begin{cases} \frac{1}{|S^+|}, & \text{if } s_j \in S^+ \\ 0, & \text{if } s_j \in S^-. \end{cases}$$

I.e., if there are 2 positive examples (the sentences preceding and following the input sentence) and 2 negative examples, the target distribution is (0.5, 0.5, 0, 0).

2.2 Network architecture

Figure 1 shows the architecture of the proposed Siamese CBOW network. The input is a projection layer that selects embeddings from a word embedding matrix W (that is shared across inputs) for a given input sentence. The word embeddings are averaged in the next layer, which yields a sentence representation with the same dimensionality as the input word embeddings (the boxes labeled $average_i$ in Figure 1). The cosine similarities between the sentence representation for $sentence_i$ and the other sentences are calculated in the penultimate layer and a softmax is applied in the last layer to produce the final probability distribution.

2.3 Training

The weights in the word embedding matrix are the only trainable parameters in the Siamese CBOW network. They are updated using stochastic gradient descent. The initial learning rate is monotonically decreased proportionally to the number of training batches.

3 Experimental Setup

To test the efficacy of our siamese network for producing sentence embeddings we use multiple

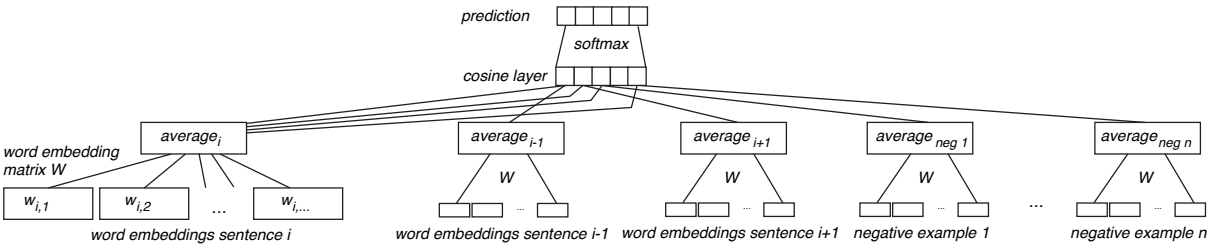

Figure 1: Siamese CBOW network architecture. (Input projection layer omitted.)

test sets. We use Siamese CBOW to learn word embeddings from an unlabeled corpus. For every sentence pair in the test sets, we compute two sentence representations by averaging the word embeddings of each sentence. Words that are missing from the vocabulary and, hence, have no word embedding, are omitted. The cosine similarity between the two sentence vectors is produced as a final semantic similarity score.

As we want a clean way to directly evaluate the embeddings on multiple sets we train our model and the models we compare with on exactly the same training data. We do not compute extra features, perform extra preprocessing steps or incorporate the embeddings in supervised training schemes. Additional steps like these are very likely to improve evaluation scores, but they would obscure our main evaluation purpose in this paper, which is to directly test the embeddings.

3.1 Data

We use the Toronto Book Corpus[1] to train word embeddings. This corpus contains 74,004,228 already pre-processed sentences in total, which are made up of 1,057,070,918 tokens, originating from 7,087 unique books. In our experiments, we consider tokens appearing 5 times or more, which leads to a vocabulary of 315,643 words.

3.2 Baselines

We employ two baselines for producing sentence embeddings in our experiments. We obtain similarity scores between sentence pairs from the baselines in the same way as the ones produced by Siamese CBOW, i.e., we calculate the cosine similarity between the sentence embeddings they produce.

Word2vec We average word embeddings trained with word2vec.[2] We use both architectures, Skipgram and CBOW, and apply default settings: minimum word frequency 5, word embedding size 300, context window 5, sample threshold 10^{-5}, no hierarchical softmax, 5 negative examples.

Skip-thought As a second baseline we use the sentence representations produced by the skip-thought architecture (Kiros et al., 2015).[3] Skip-thought is a recently proposed method that learns sentence representations in a different way from ours, by using recurrent neural networks. This allows it to take word order into account. As it trains sentence embeddings from unlabeled data, like we do, it is a natural baseline to consider.

Both methods are trained on the Toronto Book Corpus, the same corpus used to train Siamese CBOW. We should note that as we use skip-thought vectors as trained by Kiros et al. (2015), skip-thought has an advantage over both word2vec and Siamese CBOW as the vocabulary used for encoding sentences contains 930,913 words, three times the size of the vocabulary that we use.

3.3 Evaluation

We use 20 SemEval datasets from the SemEval semantic textual similarity task in 2012, 2013, 2014 and 2015 (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015), which consist of sentence pairs from a wide array of sources (e.g., newswire, tweets, video descriptions) that have been manually annotated by multiple human assessors on a 5 point scale (1: semantically unrelated, 5: semantically similar). In the ground truth, the final similarity score for every sentence pair is

[1]The corpus can be downloaded from `http://www.cs.toronto.edu/~mbweb/`; cf. (Zhu et al., 2015).

[2]The code is available from `https://code.google.com/archive/p/word2vec/`.

[3]The code and the trained models can be downloaded from `https://github.com/ryankiros/skip-thoughts/`.

Table 1: Results on SemEval datasets in terms of Pearson's r (Spearman's r). Highest scores, in terms of Pearson's r, are displayed in bold. Siamese CBOW runs statistically significantly different from the word2vec CBOW baseline runs are marked with a †. See §3.3 for a discussion of the statistical test used.

the mean of the annotator judgements, and as such can be a floating point number like 2.685.

The evaluation metric used by SemEval, and hence by us, is Pearson's r. As Spearman's r is often reported as well, we do so too.

Statistical significance To see whether Siamese CBOW yields significantly different scores for the same input sentence pairs from word2vec CBOW—the method it is theoretically most similar to—we compute Wilcoxon signed-rank test statistics between all runs on all evaluation sets. Runs are considered statistically significantly different for p-values < 0.0001.

3.4 Network

To comply with results reported in other research (Mikolov et al., 2013b; Kusner et al., 2015) we fix the embedding size to 300 and only consider words appearing 5 times or more in the training corpus. We use 2 negative examples (see §4.2.2 for an analysis of different settings). The embeddings are initialized randomly, by drawing from a normal distribution with $\mu = 0.0$ and $\sigma = 0.01$. The batch size is 100. The initial learning rate α is 0.0001, which we obtain by observing the loss on the training data. Training consists of one epoch.

We use Theano (Theano Development Team, 2016) to implement our network.[4] We ran our experiments on GPUs in the DAS5 cluster (Bal et al., 2016).

[4]The code for Siamese CBOW is available under an open-source license at `https://bitbucket.org/TomKenter/siamese-cbow`.

4 Results

In this section we present the results of our experiments, and analyze the stability of Siamese CBOW with respect to its (hyper)parameters.

4.1 Main experiments

In Table 1, the results of Siamese CBOW on 20 SemEval datasets are displayed, together with the results of the baseline systems. As we can see from the table, Siamese CBOW outperforms the baselines in the majority of cases (14 out of 20). The very low scores of skip-thought on MSRpar appear to be a glitch, which we will ignore.

It is interesting to see that for the set with the highest average sentence length (2013 SMT, with 24.7 words per sentence on average) Siamese CBOW is very close to skip-thought, the best performing baseline. In terms of lexical term overlap, unsurprisingly, all methods have trouble with the sets with little overlap (2013 FNWN, 2015 answers-forums, which both have 7% lexical overlap). It is interesting to see, however, that for the next two sets (2015 belief and 2012 MSRpar, 11% and 14% overlap respectively) Siamese CBOW manages to get the best performance. The highest performance on all sets is 0.7315 Pearson's r of Siamese CBOW on the 2014 tweet-news set. This figure is not very far from the best performing SemEval run that year which has 0.792 Pearson's r. This is remarkable as Siamese CBOW is completely unsupervised, while the NTNU system which scored best on this set (Lynum et al., 2014) was optimized using multiple training sets.

In recent work, Hill et al. (2016) present FastSent, a model similar to ours (see §5 for a more elaborate discussion); results are not reported for all evaluation sets we use, and hence, we compare the results of FastSent and Siamese CBOW separately, in Table 2.

FastSent and Siamese CBOW each outperform the other on half of the evaluation sets, which clearly suggests that the differences between the two methods are complementary.[5]

4.2 Analysis

Next, we investigate the stability of Siamese CBOW with respect to its hyper-parameters. In particular, we look into stability across iterations, different numbers of negative examples, and the dimensionality of the embeddings. Other parameter settings are set as reported in §3.4.

Table 2: Results on SemEval 2014 datasets in terms of Pearson's r (Spearman's r). Highest scores (in Pearson's r) are displayed in bold. FastSent results are reprinted from (Hill et al., 2016) where they are reported in two-digit precision.

Dataset	FastSent	Siamese CBOW
OnWN	**.74** (.70)	.6073 (.6554)
deft-forum	**.41** (.36)	.4082 (.4188)
deft-news	.58 (.59)	**.5913** (.5754)
headlines	.57 (.59)	**.6364** (.6260)
images	**.74** (.78)	.6497 (.6484)
tweet-news	.63 (.66)	**.7315** (.7128)

4.2.1 Performance across iterations

Ideally, the optimization criterion of a learning algorithm ranges over the full domain of its loss function. As discussed in §2, our loss function only observes a sample. As such, convergence is not guaranteed. Regardless, an ideal learning system should not fluctuate in terms of performance relative to the amount of training data it observes, provided this amount is substantial: as training proceeds the performance should stabilize.

To see whether the performance of Siamese CBOW fluctuates during training we monitor it during 5 epochs; at every 10,000,000 examples, and at the end of every epoch. Figure 2 displays the results for all 20 datasets. We observe that on the majority of datasets the performance shows very little variation. There are three exceptions. The performance on the 2014 deft-news dataset steadily decreases while the performance on 2013 OnWN steadily increases, though both seem to stabilize at the end of epoch 5. The most notable exception, however, is 2012 MSRvid, where the score, after an initial increase, drops consistently. This effect might be explained by the fact that this evaluation set primarily consists of very short sentences—it has the lowest average sentence length of all set: 6.63 with a standard deviation of 1.812. Therefore, a 300-dimensional representation appears too large for this dataset; this hypothesis is supported by the fact that 200-dimensional embeddings work slightly better for this dataset (see Figure 4).

[5]The comparison is to be interpreted with caution as it is not evident what vocabulary was used for the experiments in (Hill et al., 2016); hence, the differences observed here might simply be due to differences in vocabulary coverage.

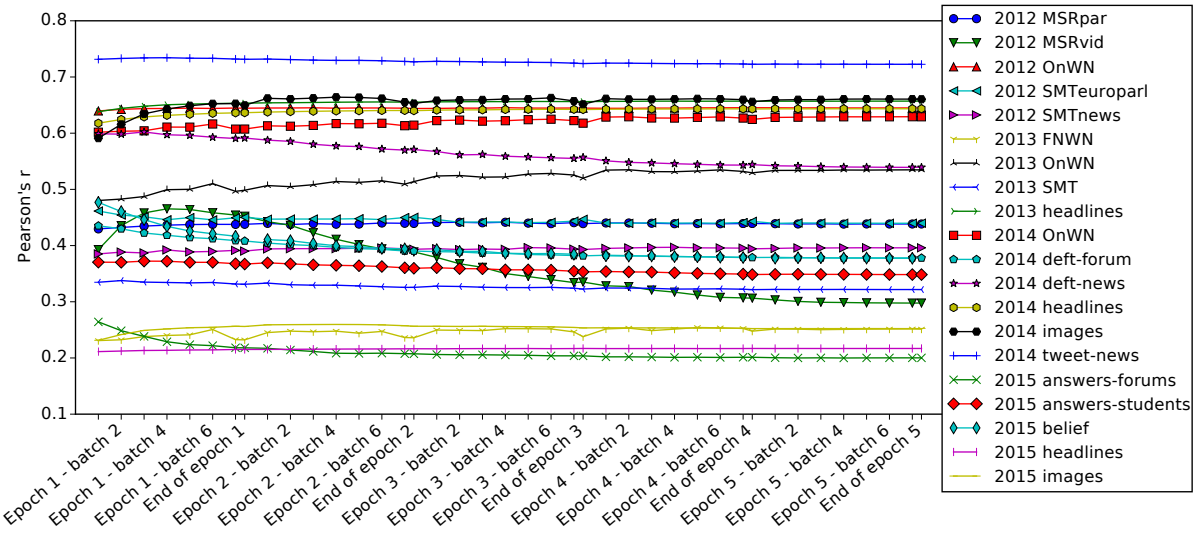

Figure 2: Performance of Siamese CBOW across 5 iterations.

4.2.2 Number of negative examples

In Figure 3, the results of Siamese CBOW in terms of Pearson's r are plotted for different numbers of negative examples. We observe that on most sets, the number of negative examples has limited effect on the performance of Siamese CBOW. Choosing a higher number, like 10, occasionally leads to slightly better performance, e.g., on the 2013 FNWN set. However, a small number like 1 or 2 typically suffices, and is sometimes markedly better, e.g., in the case of the 2015 belief set. As a high number of negative examples comes at a substantial computational cost, we conclude from the findings presented here that, although Siamese CBOW is robust against different settings of this parameter, setting the number of negative examples to 1 or 2 should be the default choice.

4.2.3 Number of dimensions

Figure 4 plots the results of Siamese CBOW for different numbers of vector dimensions. We observe from the figure that for some sets (most notably 2014 deft-forum, 2015 answ-forums and 2015 belief) increasing the number of embedding dimensions consistently yields higher performance. A dimensionality that is too low (50 or 100) invariably leads to inferior results. As, similar to a higher number of negative examples, a higher embedding dimension leads to higher computational costs, we conclude from these findings

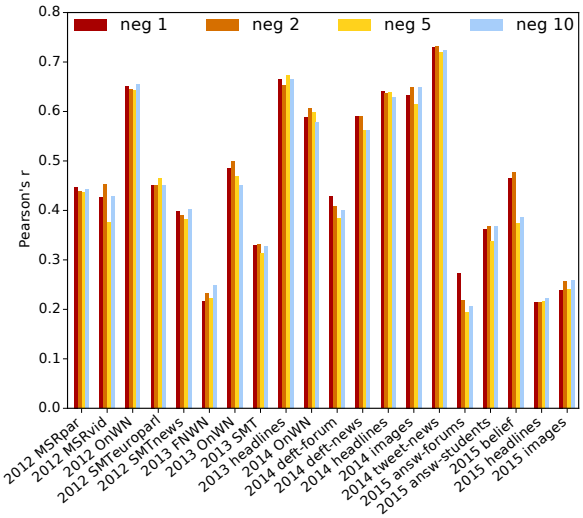

Figure 3: Performance of Siamese CBOW with different numbers of negative examples.

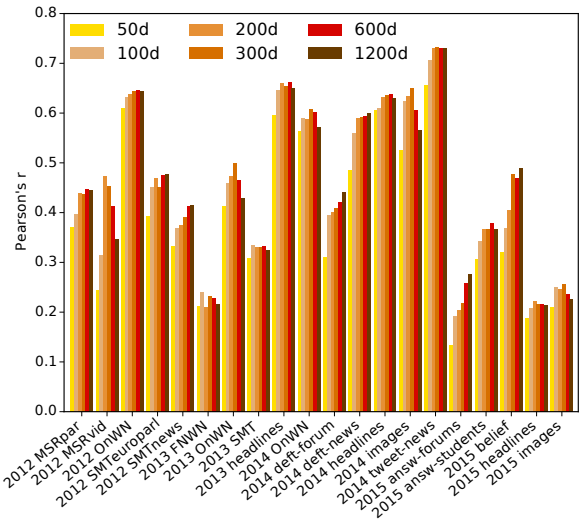

Figure 4: Performance of Siamese CBOW across number of embedding dimensions.

that a moderate number of dimensions (200 or 300) is to be preferred.

4.3 Time complexity

For learning systems, time complexity comes into play in the training phase and in the prediction phase. For an end system employing sentence embeddings, the complexity at prediction time is the most crucial factor, which is why we omit an analysis of training complexity. We focus on comparing the time complexity for generating sentence embeddings for Siamese CBOW, and compare it to the baselines we use.

The complexity of all algorithms we consider is $\mathcal{O}(n)$, i.e., linear in the number of input terms. As in practice the number of arithmetic operations is the critical factor in determining computing time, we will now focus on these.

Both word2vec and the Siamese CBOW compute embeddings of a text $T = t_1, \ldots, t_{|T|}$ by averaging the term embeddings. This requires $|T|-1$ vector additions, and 1 multiplication by a scalar value (namely, $1/|T|$). The skip-thought model is a recurrent neural network with GRU cells, which computes a set of equations for every term t in T, which we reprint for reference (Kiros et al., 2015):

$$\begin{aligned}
\mathbf{r}^t &= \sigma(\mathbf{W}_r\mathbf{x}^t + \mathbf{U}_r\mathbf{h}^{t-1}) \\
\mathbf{z}^t &= \sigma(\mathbf{W}_z\mathbf{x}^t + \mathbf{U}_z\mathbf{h}^{t-1}) \\
\overline{\mathbf{h}}^t &= \tanh(\mathbf{W}\mathbf{x}^t + \mathbf{U}(\mathbf{r}^t \odot \mathbf{h}^{t-1})) \\
\mathbf{h}^t &= (1 - \mathbf{z}^t) \odot \mathbf{h}^{t-1} + \mathbf{z}^t \odot \overline{\mathbf{h}}^t
\end{aligned}$$

As we can see from the formulas, there are $5|T|$ vector additions (+/-), $4|T|$ element-wise multiplications by a vector, $3|T|$ element-wise operations and $6|T|$ matrix multiplications, of which the latter, the matrix multiplications, are most expensive.

This considerable difference in numbers of arithmetic operations is also observed in practice. We run tests on a single CPU, using identical code for extracting sentences from the evaluation sets, for every method. The sentence pairs are presented one by one to the models. We disregard the time it takes to load models. Speedups might of course be gained for all methods by presenting the sentences in batches to the models, by computing sentence representations in parallel and by running code on a GPU. However, as we are interested in the differences between the systems, we run the most simple and straightforward scenario. Table 3 lists the number of seconds each method takes to generate and compare sentence embeddings for an input sentence pair. The difference between word2vec and Siamese CBOW is because of a different implementation of word lookup.

Table 3: Time spent per method on all 20 SemEval datasets, 17,608 sentence pairs, and the average time spent on a single sentence pair (time in seconds unless indicated otherwise).

	20 sets	1 pair
Siamese CBOW (300d)	7.7	0.0004
word2vec (300d)	7.0	0.0004
skip-thought (1200d)	98,804.0	5.6

We conclude from the observations presented here, together with the results in §4.1, that in a setting where speed at prediction time is pivotal, simple averaging methods like word2vec or Siamese CBOW are to be preferred over more involved methods like skip-thought.

4.4 Qualitative analysis
