We extend objective 1 so that it assigns value not just to the bigrams that appear in the summary, but also to the choices made in the creation of the summary. In our complete model, which jointly extracts and compresses sentences, we choose whether or not to cut individual subtrees in the constituency parses

[1] See Text Analysis Conference results in 2008 and 2009.

of each sentence. This is in contrast to the extractive case where choices are made on full sentences.

$$\max_{\mathbf{y} \in Y(x)} \sum_{b \in B(\mathbf{y})} v_b + \sum_{c \in C(\mathbf{y})} v_c \quad (2)$$

$C(\mathbf{y})$ is the set of cut choices made in $\mathbf{y}$, and v_c assigns value to each.

Next, we present details of our representation of compressive summaries. Assume a constituency parse t_s for every sentence s. We represent a compressive summary as a vector $\mathbf{y} = (y_n : n \in t_s, s \in x)$ of indicators, one for each non-terminal node in each parse tree of the sentences in the document set x. A word is present in the output summary if and only if its parent parse tree node n has $y_n = 1$ (see Figure 1b). In addition to the length constraint on the members of $Y(x)$, we require that each node n may have $y_n = 1$ only if its parent $\pi(n)$ has $y_{\pi(n)} = 1$. This ensures that only subtrees may be deleted. While we use constituency parses rather than dependency parses, this model has similarities with the vine-growth model of Daumé III (2006).

For the compressive model we define the set of cut choices $C(\mathbf{y})$ for a summary $\mathbf{y}$ to be the set of edges in each parse that are broken in order to delete a subtree (see Figure 1b). We require that each subtree has a non-terminal node for a root, and say that an edge $(n, \pi(n))$ between a node and its parent is broken if the parent has $y_{\pi(n)} = 1$ but the child has $y_n = 0$. Notice that breaking a single edge deletes an entire subtree.

2.1 Parameterization

Before learning weights in Section 3, we parameterize objectives 1 and 2 using features. This entails to parameterizing each bigram score v_b and each subtree deletion score v_c. For weights $\mathbf{w} \in \mathbb{R}^d$ and feature functions $\mathbf{g}(b, x) \in \mathbb{R}^d$ and $\mathbf{h}(c, x) \in \mathbb{R}^d$ we let:

$$v_b = \mathbf{w}^{\mathrm{T}} \mathbf{g}(b, x)$$
$$v_c = \mathbf{w}^{\mathrm{T}} \mathbf{h}(c, x)$$

For example, $\mathbf{g}(b, x)$ might include a feature the counts the number of documents in x that b appears in, and $\mathbf{h}(c, x)$ might include a feature that indicates whether the deleted subtree is an SBAR modifying a noun.

This parameterization allows us to cast summarization as structured prediction. We can define a feature function $f(\mathbf{y}, x) \in \mathbb{R}^d$ which factors over summaries $\mathbf{y}$ through $B(\mathbf{y})$ and $C(\mathbf{y})$:

$$\mathbf{f}(\mathbf{y}, x) = \sum_{b \in B(\mathbf{y})} \mathbf{g}(b, x) + \sum_{c \in C(\mathbf{y})} \mathbf{h}(c, x)$$

Using this characterization of summaries as feature vectors we can define a linear predictor for summarization:

$$\begin{aligned} d(x; \mathbf{w}) &= \arg\max_{\mathbf{y} \in Y(x)} \mathbf{w}^{\mathrm{T}} f(\mathbf{y}, x) \quad (3) \\ &= \arg\max_{\mathbf{y} \in Y(x)} \sum_{b \in B(\mathbf{y})} v_b + \sum_{c \in C(\mathbf{y})} v_c \end{aligned}$$

The arg max in Equation 3 optimizes Objective 2.

Learning weights for Objective 1 where $Y(x)$ is the set of *extractive* summaries gives our LEARNED EXTRACTIVE system. Learning weights for Objective 2 where $Y(x)$ is the set of *compressive* summaries, and $C(\mathbf{y})$ the set of broken edges that produce subtree deletions, gives our LEARNED COMPRESSIVE system, which is our joint model of extraction and compression.

3 Structured Learning

Discriminative training attempts to minimize the loss incurred during prediction by optimizing an objective on the training set. We will perform discriminative training using a loss function that directly measures end-to-end summarization quality.

In Section 4 we show that finding summaries that optimize Objective 2, Viterbi prediction, is efficient. Online learning algorithms like perceptron or the margin-infused relaxed algorithm (MIRA) (Crammer and Singer, 2003) are frequently used for structured problems where Viterbi inference is available. However, we find that such methods are unstable on our problem. We instead turn to an approach that optimizes a batch objective which is sensitive to all constraints on all instances, but is efficient by adding these constraints incrementally.

3.1 Max-margin objective

For our problem the data set consists of pairs of document sets and label summaries, $D = \{(x_i, \mathbf{y}_i^*) : i \in 1, \ldots, N\}$. Note that the label summaries

can be expressed as vectors $\mathbf{y}^*$ because our training summaries are variously extractive or extractive and compressive (see Section 5). We use a soft-margin support vector machine (SVM) (Vapnik, 1998) objective over the full structured output space (Taskar et al., 2003; Tsochantaridis et al., 2004) of extractive and compressive summaries:

$$\min_{\mathbf{w}} \ \frac{1}{2}\|\mathbf{w}\|^2 + \frac{C}{N}\sum_{i=1}^{N}\xi_i \quad (4)$$

$$s.t. \ \forall i, \forall \mathbf{y} \in Y(x_i) \quad (5)$$

$$\mathbf{w}^{\mathrm{T}}\Big(f(\mathbf{y}_i^*, x_i) - f(\mathbf{y}, x_i)\Big) \geq \ell(\mathbf{y}, \mathbf{y}_i^*) - \xi_i$$

The constraints in Equation 5 require that the difference in model score between each possible summary $\mathbf{y}$ and the gold summary $\mathbf{y}_i^*$ be no smaller than the loss $\ell(\mathbf{y}, \mathbf{y}_i^*)$, padded by a per-instance slack of ξ_i. We use bigram recall as our loss function (see Section 3.3). C is the regularization constant. When the output space $Y(x_i)$ is small these constraints can be explicitly enumerated. In this case it is standard to solve the dual, which is a quadratic program. Unfortunately, the size of the output space of extractive summaries is exponential in the number of sentences in the input document set.

3.2 Cutting-plane algorithm

The cutting-plane algorithm deals with the exponential number of constraints in Equation 5 by performing constraint induction (Tsochantaridis et al., 2004). It alternates between solving Objective 4 with a reduced set of currently active constraints, and adding newly active constraints to the set. In our application, this approach efficiently solves the structured SVM training problem up to some specified tolerance ϵ.

Suppose $\hat{\mathbf{w}}$ and $\hat{\boldsymbol{\xi}}$ optimize Objective 4 under the currently active constraints on a given iteration. Notice that the $\hat{\mathbf{y}}_i$ satisfying

$$\hat{\mathbf{y}}_i = \arg\max_{\mathbf{y} \in Y(x_i)} \left[\hat{\mathbf{w}}^{\mathrm{T}}\mathbf{f}(\mathbf{y}, x_i) + \ell(\mathbf{y}, \mathbf{y}_i^*)\right] \quad (6)$$

corresponds to the constraint in the fully constrained problem, for training instance $(x_i, \mathbf{y}_i^*)$, most violated by $\hat{\mathbf{w}}$ and $\hat{\boldsymbol{\xi}}$. On each round of constraint induction the cutting-plane algorithm computes the arg max in Equation 6 for a training instance, which is referred to as loss-augmented prediction, and adds the corresponding constraint to the active set.

The constraints from Equation (5) are equivalent to: $\forall i \ \ \mathbf{w}^{\mathrm{T}}\mathbf{f}(\mathbf{y}_i^*, x_i) \geq \max_{\mathbf{y} \in Y(x_i)} \left[\mathbf{w}^{\mathrm{T}}\mathbf{f}(\mathbf{y}, x_i) + \ell(\mathbf{y}, \mathbf{y}_i^*)\right] - \xi_i$. Thus, if loss-augmented prediction turns up no new constraints on a given iteration, the current solution to the reduced problem, $\hat{\mathbf{w}}$ and $\hat{\boldsymbol{\xi}}$, is the solution to the full SVM training problem. In practice, constraints are only added if the right hand side of Equation (5) exceeds the left hand side by at least ϵ. Tsochantaridis et al. (2004) prove that only $O(\frac{N}{\epsilon})$ constraints are added before constraint induction finds a $C\epsilon$-optimal solution.

Loss-augmented prediction is not always tractable. Luckily, our choice of loss function, bigram recall, factors over bigrams. Thus, we can easily perform loss-augmented prediction using the same procedure we use to perform Viterbi prediction (described in Section 4). We simply modify each bigram value v_b to include bigram b's contribution to the total loss. We solve the intermediate partially-constrained max-margin problems using the factored sequential minimal optimization (SMO) algorithm (Platt, 1999; Taskar et al., 2004). In practice, for $\epsilon = 10^{-4}$, the cutting-plane algorithm converges after only three passes through the training set when applied to our summarization task.

3.3 Loss function

In the simplest case, 0-1 loss, the system only receives credit for exactly identifying the label summary. Since there are many reasonable summaries we are less interested in exactly matching any specific training instance, and more interested in the degree to which a predicted summary deviates from a label.

The standard method for automatically evaluating a summary against a reference is ROUGE, which we simplify slightly to *bigram recall*. With an extractive reference denoted by $\mathbf{y}^*$, our loss function is:

$$\ell(\mathbf{y}, \mathbf{y}^*) = \frac{|B(\mathbf{y}) \bigcap B(\mathbf{y}^*)|}{|B(\mathbf{y}^*)|}$$

We verified that bigram recall correlates well with ROUGE and with manual metrics.

4 Efficient Prediction

We show how to perform prediction with the extractive and compressive models by solving ILPs. For many instances, a generic ILP solver can find exact solutions to the prediction problems in a matter of seconds. For difficult instances, we present a fast approximate algorithm.

4.1 ILP for extraction

Gillick and Favre (2009) express the optimization of Objective 1 for extractive summarization as an ILP. We begin here with their algorithm. Let each input sentence s have length l_s. Let the presence of each bigram b in $B(\mathbf{y})$ be indicated by the binary variable z_b. Let Q_{sb} be an indicator of the presence of bigram b in sentence s. They specify the following ILP over binary variables $\mathbf{y}$ and $\mathbf{z}$:

$$\max_{\mathbf{y},\mathbf{z}} \sum_b v_b z_b$$

$$s.t. \sum_s l_s y_s \leq L_{\text{max}}$$

$$\forall b \quad \sum_s Q_{sb} \leq z_b \tag{7}$$

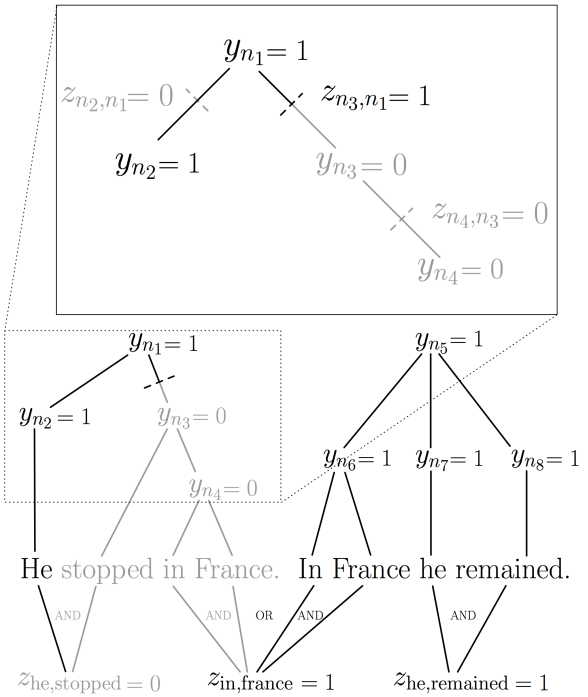
$$\forall s, b \quad y_s Q_{sb} \geq z_b \tag{8}$$

Constraints 7 and 8 ensure consistency between sentences and bigrams. Notice that the Constraint 7 requires that selecting a sentence entails selecting all its bigrams, and Constraint 8 requires that selecting a bigram entails selecting at least one sentence that contains it. Solving the ILP is fast in practice. Using the GNU Linear Programming Kit (GLPK) on a 3.2GHz Intel machine, decoding took less than a second on most instances.

4.2 ILP for joint compression and extraction

We can extend the ILP formulation of extraction to solve the compressive problem. Let l_n be the number of words node n has as children. With this notation we can write the length restriction as $\sum_n l_n y_n \leq L_{\text{max}}$. Let the presence of each cut c in $C(\mathbf{y})$ be indicated by the binary variable z_c, which is active if and only if $y_n = 0$ but $y_{\pi(n)} = 1$, where node $\pi(n)$ is the parent of node n. The constraints on z_c are diagrammed in Figure 2.

While it is possible to let $B(\mathbf{y})$ contain all bigrams present in the compressive summary, the reduction of $B(\mathbf{y})$ makes the ILP formulation efficient. We omit from $B(\mathbf{y})$ bigrams that are the result of deleted intermediate words. As a result the required number of variables z_b is linear in the length of a sentence. The constraints on z_b are given in Figure 2. They can be expressed in terms of the variables y_n.



$B(\mathbf{y}) = \{(\text{in, france}), (\text{france, he}), (\text{he, remained})\}$
$C(\mathbf{y}) = \{(n_3, n_1)\}$

Figure 2: Diagram of ILP for joint extraction and compression. Variables z_b indicate the presence of bigrams in the summary. Variables z_c indicate edges in the parse tree that have been cut in order to remove subtrees. The figure suppresses bigram variables $z_{\text{stopped,in}}$ and $z_{\text{france,he}}$ to reduce clutter. Note that the edit shown is intentionally bad. It demonstrates a loss of bigram coverage.

By solving the following ILP we can compute the arg max required for prediction in the joint model:

$$\max_{\mathbf{y},\mathbf{z}} \sum_b v_b z_b + \sum_c v_c z_c$$

$$s.t. \sum_n l_n y_n \leq L_{\text{max}}$$

$$\forall n \;\; y_n \leq y_{\pi(n)} \tag{9}$$

$$\forall b \;\; z_b = \mathbb{1}\big[b \in B(\mathbf{y})\big] \tag{10}$$

$$\forall c \;\; z_c = \mathbb{1}\big[c \in C(\mathbf{y})\big] \tag{11}$$

Constraint 9 encodes the requirement that only full subtrees may be deleted. For simplicity, we have written Constraints 10 and 11 in implicit form. These constraints can be encoded explicitly using $O(N)$ linear constraints, where N is the number of words in the document set x. The reduction of $B(\mathbf{y})$ to include only bigrams not resulting from deleted intermediate words avoids $O(N^2)$ required constraints.

In practice, solving this ILP for joint extraction and compression is, on average, an order of magnitude slower than solving the ILP for pure extraction, and for certain instances finding the exact solution is prohibitively slow.

4.3 Fast approximate prediction

One common way to quickly approximate an ILP is to solve its LP relaxation (and round the results). We found that, while very fast, the LP relaxation of the joint ILP gave poor results, finding unacceptably suboptimal solutions. This appears possibly to have been problematic for Martins and Smith (2009) as well. We developed an alternative fast approximate joint extractive and compressive solver that gives better results in terms of both objective value and bigram recall of resulting solutions.

The approximate joint solver first extracts a subset of the sentences in the document set that total no more than M words. In a second step, we apply the exact joint extractive and compressive summarizer (see Section 4.2) to the resulting extraction. The objective we maximize in performing the initial extraction is different from the one used in extractive summarization. Specifically, we pick an extraction that maximizes $\sum_{s \in \mathbf{y}} \sum_{b \in s} v_b$. This objective rewards redundant bigrams, and thus is likely to give the joint solver multiple options for including the same piece of relevant content.

M is a parameter that trades-off between approximation quality and problem difficulty. When M is the size of the document set x, the approximate solver solves the exact joint problem. In Figure 3 we plot the trade-off between approximation quality and computation time, comparing to the exact joint solver, an exact solver that is limited to extractive solutions, and the LP relaxation solver. The results show that the approximate joint solver yields substantial improvements over the LP relaxation, and can achieve results comparable to those produced by the exact solver with a 5-fold reduction in computation time. On particularly difficult instances the parameter M can be decreased, ensuring that all instances are solved in a reasonable time period.

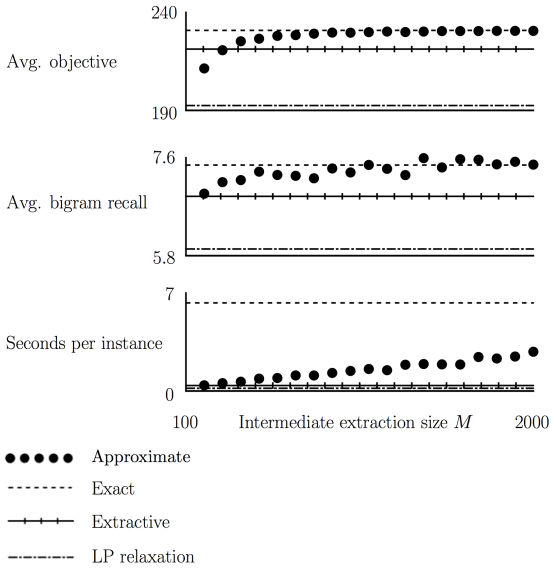


Figure 3: Plot of objective value, bigram recall, and elapsed time for the approximate joint extractive and compressive solver against size of intermediate extraction set. Also shown are values for an LP relaxation approximate solver, a solver that is restricted to extractive solutions, and finally the exact compressive solver. These solvers do not use an intermediate extraction. Results are for 44 document sets, averaging about 5000 words per document set.

5 Data

We use the data from the Text Analysis Conference (TAC) evaluations from 2008 and 2009, a total of 92 multi-document summarization problems. Each problem asks for a 100-word-limited summary of 10 related input documents and provides a set of four abstracts written by experts. These are the non-update portions of the TAC 2008 and 2009 tasks.

To train the extractive system described in Section 2, we use as our labels $\mathbf{y}^*$ the extractions with the largest bigram recall values relative to the sets of references. While these extractions are inferior to the abstracts, they are attainable by our model, a quality found to be advantageous in discriminative training for machine translation (Liang et al., 2006;

COUNT:	$\mathbb{1}(\text{docCount}(b) = \cdot)$ where $\text{docCount}(b)$ is the number of documents containing b.
STOP:	$\mathbb{1}(\text{isStop}(b_1) = \cdot, \text{isStop}(b_2) = \cdot)$ where $\text{isStop}(w)$ indicates a stop word.
POSITION:	$\mathbb{1}(\text{docPosition}(b) = \cdot)$ where $\text{docPosition}(b)$ is the earliest position in a document of any sentence containing b, buckets earliest positions ≥ 4.
CONJ:	All two- and three-way conjunctions of COUNT, STOP, and POSITION features.
BIAS:	Bias feature, active on all bigrams.

Table 1: **Bigram features**: component feature functions in $\mathbf{g}(b, x)$ that we use to characterize the bigram b in both the extractive and compressive models.

Chiang et al., 2008).

Previous work has referred to the lack of extracted, compressed data sets as an obstacle to joint learning for summarizaiton (Daumé III, 2006; Martins and Smith, 2009). We collected joint data via a Mechanical Turk task. To make the joint annotation task more feasible, we adopted an approximate approach that closely matches our fast approximate prediction procedure. Annotators were shown a 150-word maximum bigram recall extractions from the full document set and instructed to form a compressed summary by deleting words until 100 or fewer words remained. Each task was performed by two annotators. We chose the summary we judged to be of highest quality from each pair to add to our corpus. This gave one gold compressive summary $\mathbf{y}^*$ for each of the 44 problems in the TAC 2009 set. We used these labels to train our joint extractive and compressive system described in Section 2. Of the 288 total sentences presented to annotators, 38 were unedited, 45 were deleted, and 205 were compressed by an average of 7.5 words.

6 Features

Here we describe the features used to parameterize our model. Relative to some NLP tasks, our feature sets are small: roughly two hundred features on bigrams and thirteen features on subtree deletions. This is because our data set is small; with only 48 training documents we do not have the statistical support to learn weights for more features. For larger training sets one could imagine lexicalized versions of the features we describe.

COORD:	Indicates phrase involved in coordination. Four versions of this feature: NP, VP, S, SBAR.
S-ADJUNCT:	Indicates a child of an S, adjunct to and left of the matrix verb. Four version of this feature: CC, PP, ADVP, SBAR.
REL-C:	Indicates a relative clause, SBAR modifying a noun.
ATTR-C:	Indicates a sentence-final attribution clause, e.g. 'the senator announced Friday.'
ATTR-PP:	Indicates a PP attribution, e.g. 'according to the senator.'
TEMP-PP:	Indicates a temporal PP, e.g. 'on Friday.'
TEMP-NP:	Indicates a temporal NP, e.g. 'Friday.'
BIAS:	Bias feature, active on all subtree deletions.

Table 2: **Subtree deletion features**: component feature functions in $\mathbf{h}(c, x)$ that we use to characterize the subtree deleted by cutting edge $c = (n, \pi(n))$ in the joint extractive and compressive model.

6.1 Bigram features

Our bigram features include document counts, the earliest position in a document of a sentence that contains the bigram, and membership of each word in a standard set of stopwords. We also include all possible two- and three-way conjuctions of these features. Table 1 describes the features in detail. We use stemmed bigrams and prune bigrams that appear in fewer than three input documents.

6.2 Subtree deletion features

Table 2 gives a description of our subtree tree deletion features. Of course, by training to optimize a metric like ROUGE, the system benefits from restrictions on the syntactic variety of edits; the learning is therefore more about deciding when an edit is worth the coverage trade-offs rather than fine-grained decisions about grammaticality.

We constrain the model to only allow subtree deletions where one of the features in Table 2 (aside from BIAS) is active. The root, and thus the entire sentence, may always be cut. We choose this particular set of allowed deletions by looking at human annotated data and taking note of the most common types of edits. Edits which are made rarely by humans should be avoided in most scenarios, and we simply don't have enough data to learn when to do them safely.

System	BR	R-2	R-SU4	Pyr	LQ
LAST DOCUMENT	4.00	5.85	9.39	23.5	**7.2**
EXT. BASELINE	6.85	10.05	13.00	35.0	6.2

Table 4: Summary statistics for the summaries generated by each system: Average number of sentences per summary, average number of words per summary sentence, and average number of non-stopword word types per summary.

7 Experiments

7.1 Experimental setup

We set aside the TAC 2008 data set (48 problems) for testing and use the TAC 2009 data set (44 problems) for training, with hyper-parameters set to maximize six-fold cross-validation bigram recall on the training set. We run the factored SMO algorithm until convergence, and run the cutting-plane algorithm until convergence for $\epsilon = 10^{-4}$. We used GLPK to solve all ILPs. We solved extractive ILPs exactly, and joint extractive and compressive ILPs approximately using an intermediate extraction size of 1000. Constituency parses were produced using the Berkeley parser (Petrov and Klein, 2007). We show results for three systems, EXTRACTIVE BASELINE, LEARNED EXTRACTIVE, LEARNED COMPRESSIVE, and the standard baseline that extracts the first 100 words in the the most recent document, LAST DOCUMENT.

7.2 Results

Our evaluation results are shown in Table 3. ROUGE-2 (based on bigrams) and ROUGE-SU4 (based on both unigrams and skip-bigrams, separated by up to four words) are given by the official ROUGE toolkit with the standard options (Lin, 2004).

Pyramid (Nenkova and Passonneau, 2004) is a manually evaluated measure of recall on facts or *Semantic Content Units* appearing in the reference summaries. It is designed to help annotators distinguish information content from linguistic quality. Two annotators performed the entire evaluation without overlap by splitting the set of problems in half.

To evaluate linguistic quality, we sent all the summaries to Mechanical Turk (with two times redundancy), using the template and instructions designed by Gillick and Liu (2010). They report that Turkers can faithfully reproduce experts' rankings of average system linguistic quality (though their judgements of content are poorer). The table shows average linguistic quality.

All the content-based metrics show substantial improvement for learned systems over unlearned ones, and we see an extremely large improvement for the learned joint extractive and compressive system over the previous state-of-the-art EXTRACTIVE BASELINE. The ROUGE scores for the learned joint system, LEARNED COMPRESSIVE, are, to our knowledge, the highest reported on this task. We cannot compare Pyramid scores to other reported scores because of annotator difference. As expected, the LAST DOCUMENT baseline outperforms other systems in terms of linguistic quality. But, importantly, the gains achieved by the joint extractive and compressive system in content-based metrics do not come at the cost of linguistic quality when compared to purely extractive systems.

Table 4 shows statistics on the outputs of the systems we evaluated. The joint extractive and compressive system fits more word types into a summary than the extractive systems, but also produces longer sentences on average. Reading the output summaries more carefully suggests that by learning to extract and compress jointly, our joint system has the flexibility to use or create reasonable, medium-length sentences, whereas the extractive systems are stuck with a few valuable long sentences, but several less productive shorter sentences. Example summaries produced by the joint system are given in Figure 4 along with reference summaries produced by humans.

LEARNED COMPRESSIVE: The country's work safety authority will release the list of the first batch of coal mines to be closed down said Wang Xianzheng, deputy director of the National Bureau of Production Safety Supervision and Administration. With its coal mining safety a hot issue, attracting wide attention from both home and overseas, China is seeking solutions from the world to improve its coal mining safety system. Despite government promises to stem the carnage the death toll in China's disaster-plagued coal mine industry is rising according to the latest statistics released by the government Friday. Fatal coal mine accidents in China rose 8.5 percent in the first eight months of this year with thousands dying despite stepped-up efforts to make the industry safer state media said Wednesday.

REFERENCE: China's accident-plagued coal mines cause thousands of deaths and injuries annually. 2004 saw over 6,000 mine deaths. January through August 2005, deaths rose 8.5% over the same period in 2004. Most accidents are gas explosions, but fires, floods, and cave-ins also occur. Ignored safety procedures, outdated equipment, and corrupted officials exacerbate the problem. Official responses include shutting down thousands of ill-managed and illegally-run mines, punishing errant owners, issuing new safety regulations and measures, and outlawing local officials from investing in mines. China also sought solutions at the Conference on South African Coal Mining Safety Technology and Equipment held in Beijing.

LEARNED COMPRESSIVE: Karl Rove the White House deputy chief of staff told President George W. Bush and others that he never engaged in an effort to disclose a CIA operative's identity to discredit her husband's criticism of the administration's Iraq policy according to people with knowledge of Rove's account in the investigation. In a potentially damaging sign for the Bush administration special counsel Patrick Fitzgerald said that although his investigation is nearly complete it's not over. Lewis Scooter Libby Vice President Dick Cheney's chief of staff and a key architect of the Iraq war was indicted Friday on felony charges of perjury making false statements to FBI agents and obstruction of justice for impeding the federal grand jury investigating the CIA leak case.

REFERENCE: Special Prosecutor Patrick Fitzgerald is investigating who leaked to the press that Valerie Plame, wife of former Ambassador Joseph Wilson, was an undercover CIA agent. Wilson was a critic of the Bush administration. Administration staffers Karl Rove and I. Lewis Libby are the focus of the investigation. NY Times correspondent Judith Miller was jailed for 85 days for refusing to testify about Libby. Libby was eventually indicted on five counts: 2 false statements, 1 obstruction of justice, 2 perjury. Libby resigned immediately. He faces 30 years in prison and a fine of $1.25 million if convicted. Libby pleaded not guilty.

Figure 4: Example summaries produced by our learned joint model of extraction and compression. These are each 100-word-limited summaries of a collection of ten documents from the TAC 2008 data set. Constituents that have been removed via subtree deletion are grayed out. References summaries produced by humans are provided for comparison.

8 Conclusion

Jointly learning to extract and compress within a unified model outperforms learning pure extraction, which in turn outperforms a state-of-the-art extractive baseline. Our system gives substantial increases in both automatic and manual content metrics, while maintaining high linguistic quality scores.

Abstract

Extractive methods for multi-document summarization are mainly governed by information overlap, coherence, and content constraints. We present an unsupervised probabilistic approach to model the hidden abstract concepts across documents as well as the correlation between these concepts, to generate topically coherent and non-redundant summaries. Based on human evaluations our models generate summaries with higher linguistic quality in terms of coherence, readability, and redundancy compared to benchmark systems. Although our system is unsupervised and optimized for topical coherence, we achieve a 44.1 ROUGE on the DUC-07 test set, roughly in the range of state-of-the-art supervised models.

1 Introduction

A query-focused multi-document summarization model produces a short-summary text of a set of documents, which are retrieved based on a user's query. An ideal generated summary text should contain the shared relevant content among set of documents *only once*, plus other unique information from individual documents that are directly related to the user's query addressing different levels of *detail*. Recent approaches to the summarization task has somewhat focused on the *redundancy* and *coherence* issues. In this paper, we introduce a series of new generative models for multiple-documents, based on a discovery of hierarchical topics and their correlations to extract topically coherent sentences.

Prior research has demonstrated the usefulness of sentence extraction for generating summary text taking advantage of surface level features such as word repetition, position in text, cue phrases, etc, (Radev, 2004; Nenkova and Vanderwende, 2005a; Wan and Yang, 2006; Nenkova et al., 2006). Because documents have pre-defined structures (e.g., sections, paragraphs, sentences) for different levels of concepts in a hierarchy, most recent summarization work has focused on structured probabilistic models to represent the corpus concepts (Barzilay et al., 1999; Daumé-III and Marcu, 2006; Eisenstein and Barzilay, 2008; Tang et al., 2009; Chen et al., 2000; Wang et al., 2009). In particular (Haghighi and Vanderwende, 2009; Celikyilmaz and Hakkani-Tur, 2010) build hierarchical topic models to identify salient sentences that contain abstract concepts rather than specific concepts. Nonetheless, all these systems crucially rely on extracting various levels of generality from documents, focusing little on redundancy and coherence issues in model building. A model than can focus on both issues is deemed to be more beneficial for a summarization task.

Topical coherence in text involves identifying key concepts, the relationships between these concepts, and linking these relationships into a hierarchy. In this paper, we present a novel, fully generative Bayesian model of document corpus, which can discover topically coherent sentences that contain key shared information with as little detail and redundancy as possible. Our model can discover hierarchical latent structure of multi-documents, in which some words are governed by low-level topics (T) and others by high-level topics (H). The main contributions of this work are:

− construction of a novel bayesian framework to

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 491–499,
Portland, Oregon, June 19-24, 2011.

capture higher level topics (concepts) related to summary text discussed in §3,
– representation of a linguistic system as a sequence of increasingly enriched models, which use posterior topic correlation probabilities in sentences to design a novel sentence ranking method in §4 and 5,
– application of the new hierarchical learning method for generation of less redundant summaries discussed in §6. Our models achieve comparable qualitative results on summarization of multiple newswire documents. Human evaluations of generated summaries confirm that our model can generate non-redundant and topically coherent summaries.

2 Multi-Document Summarization Models

Prior research has demonstrated the usefulness of sentence extraction for summarization based on lexical, semantic, and discourse constraints. Such models often rely on different approaches including: identifying important keywords (Nenkova et al., 2006); topic signatures based on user queries (Lin and Hovy, 2002; Conroy et al., 2006; Harabagiu et al., 2007); high frequency content word feature based learning (Nenkova and Vanderwende, 2005a; Nenkova and Vanderwende, 2005b), to name a few.

Recent research focusing on the extraction of latent concepts from document clusters are close in spirit to our work (Barzilay and Lee, 2004; Daumé-III and Marcu, 2006; Eisenstein and Barzilay, 2008; Tang et al., 2009; Wang et al., 2009). Some of these work (Haghighi and Vanderwende, 2009; Celikyilmaz and Hakkani-Tur, 2010) focus on the discovery of hierarchical concepts from documents (from abstract to specific) using extensions of hierarchal topic models (Blei et al., 2004) and reflect this hierarchy on the sentences. Hierarchical concept learning models help to discover, for instance, that "baseball" and "football" are both contained in a general class "sports", so that the summaries reference terms related to more abstract concepts like "sports".

Although successful, the issue with concept learning methods for summarization is that the extracted sentences usually contain correlated concepts. We need a model that can identify salient sentences referring to general concepts of documents and there should be minimum correlation between them.

Our approach differs from the early work, in that, we utilize the advantages of previous topic models and build an unsupervised generative model that can associate each word in each document with three random variables: a sentence $\boldsymbol{S}$, a higher-level topic $\boldsymbol{H}$, and a lower-level topic $\boldsymbol{T}$, in an analogical way to PAM models (Li and McCallum, 2006), i.e., a directed acyclic graph (DAG) representing mixtures of hierarchical structure, where super-topics are multinomials over sub-topics at lower levels in the DAG. We define a tiered-topic clustering in which the upper nodes in the DAG are *higher-level topics* $\boldsymbol{H}$, representing common co-occurence patterns (correlations) between lower-level topics $\boldsymbol{T}$ in documents. This has not been the focus in prior work on generative approaches for summarization task. Mainly, our model can discover correlated topics to eliminate redundant sentences in summary text.

Rather than representing sentences as a layer in hierarchical models, e.g., (Haghighi and Vanderwende, 2009; Celikyilmaz and Hakkani-Tur, 2010), we model sentences as *meta-variables*. This is similar to author-topic models (Rosen-Zvi et al., 2004), in which words are generated by first selecting an author uniformly from an observed author list and then selecting a topic from a distribution over topics that is specific to that author. In our model, words are generated from different topics of documents by first selecting a sentence containing the word and then topics that are specific to that sentence. This way we can directly extract from documents the summary related sentences that contain high-level topics. In addition in (Celikyilmaz and Hakkani-Tur, 2010), the sentences can only share topics if the sentences are represented on the same path of captured topic hierarchy, restricting topic sharing across sentences on different paths. Our DAG identifies tiered topics distributed over document clusters that can be shared by each sentence.

3 Topic Coherence for Summarization

In this section we discuss the main contribution, our two hierarchical mixture models, which improve summary generation performance through the use of tiered topic models. Our models can identify lower-level topics T (concepts) defined as distributions over words or higher-level topics H, which represent correlations between these lower level topics given

sentences. We present our synthetic experiment for model development to evaluate extracted summaries on redundancy measure. In §6, we demonstrate the performance of our models on coherence and informativeness of generated summaries by qualitative and intrinsic evaluations.

For model development we use the DUC 2005 dataset[1], which consists of 45 document clusters, each of which include 1-4 set of human generated summaries (10-15 sentences each). Each document cluster consists $\sim$ 25 documents (25-30 sentences/document) retrieved based on a user query. We consider each document cluster as a corpus and build 45 separate models.

For the synthetic experiments, we include the provided human generated summaries of each corpus as additional documents. The sentences in human summaries include general concepts mentioned in the corpus, the salient sentences of documents. Contrary to usual qualitative evaluations of summarization tasks, our aim during development is to measure the percentage of sentences in a human summary that our model can identify as salient among all other document cluster sentences. Because human produced summaries generally contain non-redundant sentences, we use total number of top-ranked human summary sentences as a qualitative redundancy measure in our synthetic experiments.

In each model, a document d is a vector of N_d words $\mathbf{w}_d$, where each w_{id} is chosen from a vocabulary of size V, and a vector of sentences $\mathbf{S}$, representing all sentences in a corpus of size S_D. We identify sentences as meta-variables of document clusters, which the generative process models both sentences and documents using *tiered* topics. A sentence's relatedness to summary text is tied to the document cluster's user query. The idea is that a lexical word present or related to a query should increase its sentence's probability of relatedness.

4 Two-Tiered Topic Model - TTM

Our base model, the two-tiered topic model (TTM), is inspired by the hierarchical topic model, PAM, proposed by Li and McCallum (2006). PAM structures documents to represent and learn arbitrary, nested, and possibly sparse topic correlations using a directed acyclic graph. Our goals are not so different: we aim to discover concepts from documents that would attribute for the general topics related to a user query, however, we want to relate this information to sentences. We represent sentences $\boldsymbol{S}$ by discovery of general (more general) to specific topics (Fig.1). Similarly, we represent summary unrelated (document specific) sentences as corpus specific distributions θ over background words $\mathbf{w_B}$, (functional words like prepositions, etc.).

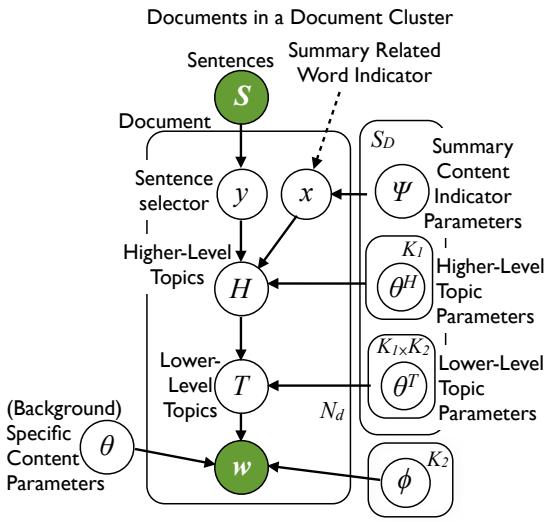

Figure 1: Graphical model depiction of two-tiered topic model (TTM) described in section §4. $\mathbf{S}$ are sentences $s_{i=1..S_D}$ in document clusters. The high-level topics ($H_{k_1=1...K_1}$), representing topic correlations, are modeled as distributions over low-level-topics ($T_{k_2=1...K_2}$). Shaded nodes indicate observed variables. Hyper-parameters for ϕ, θ^H, θ^T, θ are omitted.

Our two-tiered topic model for salient sentence discovery can be generated for each word in the document (Algorithm 1) as follows: For a word w_{id} in document d, a random variable x_{id} is drawn, which determines if w_{id} is query related, i.e., w_{id} either exists in the query or is related to the query[2]. Otherwise, w_{id} is unrelated to the user query. Then sentence s_i is chosen uniformly at random ($y_{s_i} \sim Uniform(s_i)$) from sentences in the document containing w_{id} (deterministic if there is only one sentence containing w_{id}). We assume that if a word is related to a query, it is likely to be summary-related

[1] www-nlpir.nist.gov/projects/duc/data.html

[2] We measure relatedness to a query if a word exists in the query or it is synonymous based on information extracted from WordNet (Miller, 1995).

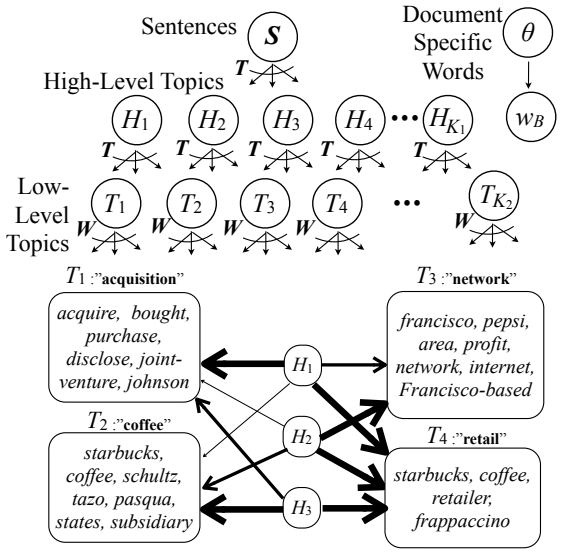

Figure 2: Depiction of TTM given the query *"D0718D: Starbucks Coffee :* ***How has Starbucks Coffee attempted to expand and diversify through joint ventures, acquisitions, or subsidiaries?"***. If a word is query/summary related sentence S, first a sentence then a high-level (H) and a low-level (T) topic is sampled. ($\overset{C}{\curlywedge}$ represents that a random variable is a parent of all C random variables.) The bolded links from $H-T$ represent correlated low-level topics.

    - Draw a discrete $x \sim Binomial(\Psi_{w_{id}})^{\star}$
    - If $x = 1$, w_{id} is summary related;
      · conditioned on S draw a sentence
        $y_{s_i} \sim Uniform(s_i)$ containing w_i,
      · sample a high-level topic $H_{k_1} \sim \theta^H_{k_1}(\alpha^H)$,
        and a low-level topic $T_{k_2} \sim \theta^T_{k_2}(\alpha^T)$,
      · sample a word $w_{ik_1k_2} \sim \phi_{H_{k_1}T_{k_2}}(\alpha)$,
    - If $x = 0$, the word is unrelated **
      sample a word $w_B \sim \theta(\alpha)$,
      corpus specific distribution.
  end for
end for

$\star$ if w_{id} exists or related to the the query then $x = 1$ deterministic, otherwise it is stochastically assigned $x \sim Bin(\Psi)$.
$\star\star$ w_{id} is a background word.

(so as the sampled sentence s_i). We keep track of the frequency of s_i's in a vector, $DS \in Z^{S_D}$. Every time an s_i is sampled for a query related w_{id}, we increment its count, a degree of sentence saliency.

Given that w_{id} is related to a query, it is associated with two-tiered multinomial distributions: high-level *H* topics and low-level *T* topics. A high-level topic H_{k_i} is chosen first from a distribution over low-level topics *T* specific to that s_i and one low-level topic T_{k_j} is chosen from a distribution over words, and w_{id} is generated from the sampled low-level topic. If w_{id} is *not* query-related, it is generated as a background word w_B.

The resulting tiered model is shown as a graph and plate diagrams in Fig.1 & 2. A sentence sampled from a query related word is associated with a distribution over K_1 number of high-level topics H_{k_i}, each of which are also associated with K_2 number of low-level topics T_{k_j}, a multinomial over lexical words of a corpus. In Fig.2 the most confident words of four low-level topics is shown. The bolded links between H_{k_i} and T_{k_j} represent the strength of correlation between T_{k_j}'s, e.g., the topic *"acquisition"* is found to be more correlated with *"retail"* than the "network" topic given H_1. This information is used to rank sentences based on the correlated topics.

4.1 Learning and Inference for TTM

Our learning procedure involves finding parameters, which likely integrates out model's posterior distribution $P(\mathbf{H}, \mathbf{T}|\mathbf{W_d}, \mathbf{S})$, $d \in D$. EM algorithms might face problems with local maxima in topic models (Blei et al., 2003) suggesting implementation of approximate methods in which some of the parameters, e.g., θ^H, θ^T, ψ, and θ, can be integrated out, resulting in standard Dirichlet-multinomial as well as binomial distributions. We use Gibbs sampling which allows a combination of estimates from several local maxima of the posterior distribution.

For each word, x_{id} is sampled from a sentence specific binomial ψ which in turn has a smoothing prior η to determine if the sampled word w_{id} is (query) summary-related or document-specific. Depending on x_{id}, we either sample a sentence along with a high/low-level topic pair or just sample background words w_B. The probability distribution over sentence assignments, $P(y_{s_i} = s|\mathbf{S})$ $s_i \in \mathbf{S}$, is assumed to be uniform over the elements of **S**, and deterministic if there is only one sentence in the docu-

ment containing the corresponding word. The optimum hyper-parameters are set based on the training dataset model performance via cross-validation [3].

For each word we sample a high-level H_{k_i} and a low-level T_{k_j} topic if the word is query related ($x_{id} = 1$). The sampling distribution for TTM for a word given the remaining topics and hyper-parameters $\alpha^H, \alpha^T, \alpha, \beta, \eta$ is:

$$p_{\texttt{TTM}}(H_{k_1}, T_{k_2}, x = 1 | \mathbf{w}, \mathbf{H}_{-k_1}, \mathbf{T}_{-k_2}) \propto \frac{\alpha^H + n_d^{k_1}}{\sum_{H\prime} \alpha^{H\prime} + n_d} * \frac{\alpha^T + n_d^{k_1 k_2}}{\sum_{T\prime} \alpha^{T\prime} + n_d{}^H} * \frac{\eta + n_x^{k_1 k_2}}{2\eta + n_{k_1 k_2}} * \frac{\beta_w + n^w_{k_1 k_2 x}}{\sum_{w\prime} \beta_{w\prime} + n_{k_1 k_2 x}}$$

and when $x = 0$ (a corpus specific word),

$$p_{\texttt{TTM}}(x = 0 | \mathbf{w}, \mathbf{z}_{H-k}, \mathbf{z}_{t-k}) \propto \frac{\eta + n^x_{k_1 k_2}}{2\eta + n_{k_1 k_2}} * \frac{\alpha_w + n^w}{\sum_{w\prime} \alpha_{w\prime} + n}$$

The $n_d^{k_1}$ is the number of occurrences of high-level topic k_1 in document d, and $n_d^{k_1 k_2}$ is the number of times the low-level topic k_2 is sampled together with high-level topic k_1 in d, $n^w_{k_1 k_2 x}$ is the number of occurrences of word w sampled from path H-T given that the word is query related. Note that the number of tiered topics in the model is fixed to K_1 and K_2, which is optimized with validation experiments. It is also possible to construct extended models of TTM using non-parametric priors, e.g., hierarchal Dirichlet processes (Li et al., 2007) (left for future work).

4.2 Summary Generation with TTM

We can observe the frequency of draws of every sentence in a document cluster **S**, given it's words are related, through $DS \in \mathbb{Z}^{S_D}$. We obtain DS during Gibbs sampling (in §4.1), which indicates a saliency score of each sentence $s_j \in \mathbf{S}$, $j = 1..S_D$:

$$score^{\texttt{TTM}}(s_j) \propto \#\left[w_{id} \in s_j, x_{id} = 1\right] / nw_j \quad (1)$$

where w_{id} indicates a word in a document d that exists in s_j and is sampled as summary related based on random indicator variable x_{id}. nw_j is the number of words in s_j and normalizes the score favoring sentences with many related words. We rank sentences based on (1). We compare TTM results on synthetic experiments against PAM (Li and McCallum, 2006) a similar topic model that clusters topics in a hierarchical structure, where super-topics are distributions over sub-topics. We obtain sentence scores for PAM models by calculating the sub-topic significance (TS) based on super-topic correlations, and discover topic correlations over the entire document space (corpus wide). Hence; we calculate the TS of a given sub-topic, $k = 1, .., K_2$ by:

$$TS(z_k) = \frac{1}{D} \sum_{d \in D} \frac{1}{K_1} \sum_{k_1}^{K_1} p(z^k_{sub} | z^{k_1}_{sup}) \quad (2)$$

where z^k_{sub} is a sub-topic $k = 1..K_2$ and $z^{k_1}_{sup}$ is a super-topic k_1. The conditional probability of a sub-topic k given a super-topic k_1, $p(z^k_{sub}|z^{k_1}_{sup})$, explains the variation of that sub-topic in relation to other sub-topics. The higher the variation over the entire corpus, the better it represents the general theme of the documents. So, sentences including such topics will have higher saliency scores, which we quantify by imposing topic's significance on vocabulary:

$$score^{\texttt{PAM}}(s_i) = \frac{1}{K_2} \sum_{k}^{K_2} \prod_{w \in s_i} p(w | z^k_{sub}) * TS(z_k) \quad (3)$$

Fig. 4 illustrates the average salience sentence selection performance of TTM and PAM models (for 45 models). The x-axis represents the percentage of sentences selected by the model among all sentences in the DUC2005 corpus. 100% means all sentences in the corpus included in the summary text. The y-axis is the % of selected human sentences over all sentences. The higher the human summary sentences are ranked, the better the model is in selecting the salient sentences. Hence, the system which peaks sooner indicates a better model.

In Fig.4 TTM is significantly better in identifying human sentences as salient in comparison to PAM. The statistical significance is measured based on the area under the curve averaged over 45 models.

5 Enriched Two-Tiered Topic Model

Our model can discover words that are related to summary text using posteriors $\hat{P}(\theta^H)$ and $\hat{P}(\theta^T)$,

[3] An alternative way would be to use Dirichlet priors (Blei et al., 2003) which we opted for due to computational reasons but will be investigated as future research.

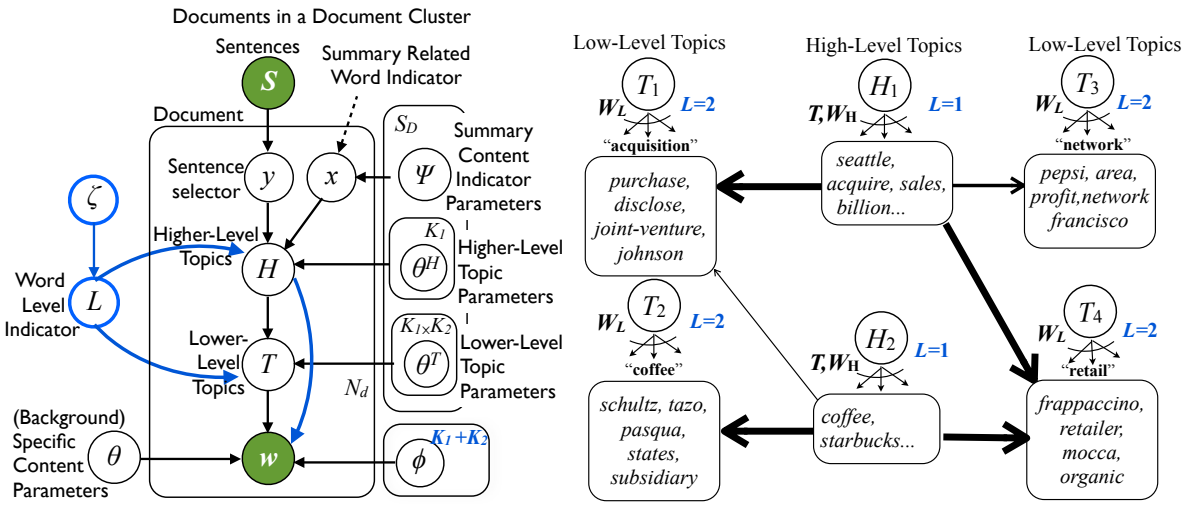

Figure 3: Graphical model depiction of sentence level enriched two-tiered model (ETTM) described in section §5. Each path defined by **H/T** pair $k_1 k_2$, has a multinomial ζ over which level of the path outputs a given word. **L** indicates which level, i.e, high or low, the word is sampled from. On the right is the high-level topic-word and low-level topic-word distributions characterized by ETTM. Each $\mathbf{H_{k_1}}$ also represented as distributions over general words $\mathbf{W_H}$ as well as indicates the degree of correlation between low-level topics denoted by boldness of the arrows.

as well as words w_B specific to documents (via $\hat{P}(\theta)$) (Fig.1). TTM can discover topic correlations, but cannot differentiate if a word in a sentence is more general or specific given a query. Sentences with general words would be more suitable to include in summary text compared to sentences containing specific words. For instance for a given sentence: *"Starbucks Coffee has attempted to expand and diversify through joint ventures, and acquisitions."*, *"starbucks"* and *"coffee"* are more general words given the document clusters compared to *"joint"* and *"ventures"* (see Fig.2), because they appear more frequently in document clusters. However, TTM has no way of knowing that *"starbucks"* and *"coffee"* are common terms given the context. We would like to associate general words with high-level topics, and context specific words with low-level topics. Sentence containing words that are sampled from high-level topics would be a better candidate for summary text. Thus; we present enriched TTM (ETTM) generative process (Fig.3), which samples words not only from low-level topics but also from high-level topics as well.

ETTM discovers three separate distributions over words: (*i*) high-level topics *H* as distributions over corpus general words $\mathbf{W_H}$, (*ii*) low-level topics *T* as distributions over corpus specific words $\mathbf{W_L}$, and

Level Generation for Enriched TTM

Fetch $\zeta_k \sim Beta(\gamma)$; $k = 1...K_1 \times K_2$.
For w_{id}, $i = 1, ..., N_d$, $d = 1, ..D$:
  If $x = 1$, sentence s_i is summary related;
    - sample H_{k_1} and T_{k_2}
    - sample a level L from $Bin(\zeta_{k_1 k_2})$
    - If $L = 1$ (general word); $w_{id} \sim \phi_{H_{k_i}}$
    - else if $L = 2$ (context specific); $w_{id} \sim \phi_{H_{k_1} T_{k_2}}$
  else if $x = 0$, do Step 14-16 in Alg. 1.

(*iii*) background word distributions, i.e,. document specific $\mathbf{W_B}$ (less confidence for summary text). Similar to TTM's generative process, if w_{id} is related to a given query, then $x = 1$ is deterministic, otherwise $x \in \{0, 1\}$ is stochastically determined if w_{id} should be sampled as a background word (w_B) or through hierarchical path, i.e., *H-T* pairs. We first sample a sentence s_i for w_{id} uniformly at random from the sentences containing the word $y_{s_i} \sim Uniform(s_i)$). At this stage we sample a *level* $\mathbf{L}_{w_{id}} \in \{1, 2\}$ for w_{id} to determine if it is a high-level word, e.g., more general to context like *"starbucks"* or *"coffee"* or more specific to related context such as *"subsidiary"*, *"frappucino"*. Each path through the DAG, defined by a H-T pair (total of $K_1 K_2$ pairs), has a binomial $\zeta_{K_1 K_2}$ over which

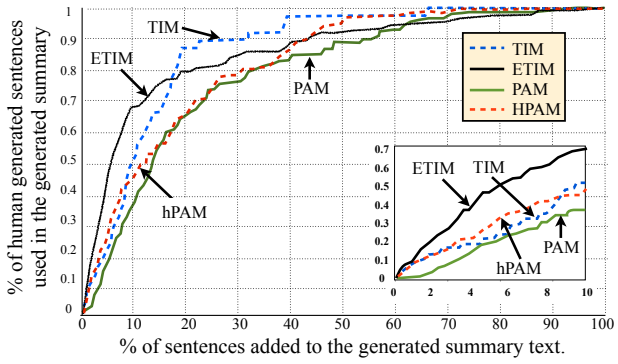

Figure 4: Average saliency performance of four systems over 45 different DUC models. The area under each curve is shown in legend. Inseam is the magnified view of top-ranked 10% of sentences in corpus.

level of the path outputs sampled word. If the word is a specific type, $x = 0$, then it is sampled from the background word distribution θ, a document specific multinomial. Once the level and conditional path is drawn (see level generation for ETTM above) the rest of the generative model is same as TTM.

5.1 Learning and Inference for ETTM

For each word, x is sampled from a sentence specific binomial ψ, just like TTM. If the word is related to the query $x = 1$, we sample a high and low-level topic pair $H - T$ as well as an additional level $\boldsymbol{L}$ is sampled to determine which level of topics the word should be sampled from. L is a corpus specific binomial one for all $H - T$ pairs. If $L = 1$, the word is one of corpus general words and sampled from the high-level topic, otherwise ($L = 2$) the word is corpus specific and sampled from a the low-level topic. The optimum hyper-parameters are set based on training performance via cross validation.

The conditional probabilities are similar to TTM, but with additional random variables, which determine the level of generality of words as follows:

$$p_{\text{ETTM}}(T_{k_1}, T_{k_2}, L|\mathbf{w}, \mathbf{T}_{-k_1}, \mathbf{T}_{-k_2}, L_{)} \propto$$
$$p_{\text{TTM}}(T_{k_1}, T_{k_2}, x = 1|.) * \frac{\gamma + N^L_{k_1 k_2}}{2\gamma + n_{k_1 k_2}}$$

5.2 Summary Generation with ETTM

For ETTM models, we extend the TTM sentence score to be able to include the effect of the general words in sentences (as word sequences in language models) using probabilities of K_1 high-level topic distributions, $\phi^w_{H_{k=1..K_1}}$, as:

$$score^{\text{ETTM}}(s_i) \propto \#\left[w_{id} \in s_j, x_{id} = 1\right] / nw_j * \frac{1}{K_1} \sum_{k=1..K_1} \prod_{w \in s_i} p(w|T_k)$$

where $p(w|T_k)$ is the probability of a word in s_i being generated from high-level topic H^k. Using this score, we re-rank the sentences in documents of the synthetic experiment. We compare the results of ETTM to a structurally similar probabilistic model, entitled hierarchical PAM (Mimno et al., 2007), which is designed to capture topics on a hierarchy of two layers, i.e., super topics and subtopics, where super-topics are distributions over abstract words. In Fig. 4 out of 45 models ETTM has the best performance in ranking the human generated sentences at the top, better than the TTM model. Thus; ETTM is capable of capturing focused sentences with general words related to the main concepts of the documents and much less redundant sentences containing concepts specific to user query.

6 Final Experiments

In this section, we qualitatively compare our models against state-of-the art models and later apply an intrinsic evaluation of generated summaries on topical coherence and informativeness.

For a qualitative comparison with the previous state-of-the models, we use the standard summarization datasets on this task. We train our models on the datasets provided by DUC2005 task and validate the results on DUC 2006 task, which consist of a total of 100 document clusters. We evaluate the performance of our models on DUC2007 datasets, which comprise of 45 document clusters, each containing 25 news articles. The task is to create max. 250 word long summary for each document cluster.

6.1. ROUGE Evaluations: We train each document cluster as a separate corpus to find the optimum parameters of each model and evaluate on test document clusters. ROUGE is a commonly used measure, a standard DUC evaluation metric, which computes recall over various n-grams statistics from a model generated summary against a set of human generated summaries. We report results in R-1 (recall against unigrams), R-2 (recall against bigrams), and R-SU4

ROUGE	w/o stop words			w/ stop words		
	R-1	R-2	R-4	R-1	R-2	R-4
PYTHY	**35.7**	8.9	**12.1**	42.6	**11.9**	**16.8**
HIERSUM	33.8	**9.3**	11.6	42.4	11.8	16.7
HybHSum	35.1	8.3	11.8	**45.6**	11.4	**17.2**
PAM	32.1	7.1	11.0	41.7	9.1	15.3
hPAM	31.9	7.0	11.1	41.2	8.9	15.2
TTM*	**34.0**	8.7	11.5	**44.7**	10.7	16.5
ETTM*	32.4	8.3	11.2	**44.1**	10.4	16.4

Table 1: ROUGE results of the best systems on DUC2007 dataset (best results are **bolded**.) * indicate our models.

(recall against skip-4 bigrams) ROUGE scores w/ and w/o stop words included.

For our models, we ran Gibbs samplers for 2000 iterations for each configuration throwing out first 500 samples as burn-in. We iterated different values for hyperparameters and measured the performance on validation dataset to capture the optimum values.

The following models are used as benchmark: (***i***) PYTHY (Toutanova et al., 2007): Utilizes human generated summaries to train a sentence ranking system using a classifier model; (***ii***) HIERSUM (Haghighi and Vanderwende, 2009): Based on hierarchical topic models. Using an approximation for inference, sentences are greedily added to a summary so long as they decrease KL-divergence of the generated summary concept distributions from document word-frequency distributions. (***iii***) HybHSum (Celikyilmaz and Hakkani-Tur, 2010): A semi-supervised model, which builds a hierarchial LDA to probabilistically score sentences in training dataset as summary or non-summary sentences. Using these probabilities as output variables, it learns a discriminative classifier model to infer the scores of new sentences in testing dataset. (***iv***) PAM (Li and McCallum, 2006) and hPAM (Mimno et al., 2007): Two hierarchical topic models to discover high and low-level concepts from documents, baselines for synthetic experiments in §4 & §5.

Results of our experiments are illustrated in Table 6. Our unsupervised TTM and ETTM systems yield a 44.1 R-1 (w/ stop-words) outperforming the rest of the models, except HybHSum. Because HybHSum uses the human generated summaries as supervision during model development and our systems do not, our performance is quite promising considering the generation is completely unsupervised without seeing any human generated summaries during training. However, the R-2 evaluation (as well as R-4) w/ stop-words does not outperform other models. This is because R-2 is a measure of bi-gram recall and neither of our models represent bi-grams whereas, for instance, PHTHY includes several bi-gram and higher order n-gram statistics. For topic models bi-grams tend to degenerate due to generating inconsistent bag of bi-grams (Wallach, 2006).

6.2. Manual Evaluations: A common DUC task is to manually evaluate models on the quality of generated summaries. We compare our best model ETTM to the results of PAM, our benchmark model in synthetic experiments, as well as hybrid hierarchical summarization model, hLDA (Celikyilmaz and Hakkani-Tur, 2010). Human annotators are given two sets of summary text for each document set, generated from either one of the two approaches: best ETTM and PAM or best ETTM and HybHSum models. The annotators are asked to mark the better summary according to five criteria: *non-redundancy* (which summary is less redundant), *coherence* (which summary is more coherent), *focus and readability* (content and no unnecessary details), *responsiveness* and *overall* performance.

We asked 3 annotators to rate DUC2007 predicted summaries (45 summary pairs per annotator). A total of 42 pairs are judged for ETTM vs. PAM models and 49 pairs for ETTM vs. HybHSum models. The evaluation results in frequencies are shown in Table 6. The participants rated ETTM generated summaries more coherent and focused compared to PAM, where the results are statistically significant (based on t-test on 95% confidence level) indicating that ETTM summaries are rated significantly better. The results of ETTM are slightly better than HybHSum. We consider our results promising because, being unsupervised, ETTM does not utilize human summaries for model development.

7 Conclusion

We introduce two new models for extracting topically coherent sentences from documents, an important property in extractive multi-document summarization systems. Our models combine approaches from the hierarchical topic models. We empha-

	PAM	ETTM	Tie	HybHSum	ETTM	Tie
Non-Redundancy	13	**26**	3	12	**18**	19
Coherence	13	**26**	3	15	**18**	16
Focus	14	**24**	4	14	**17**	18
Responsiveness	15	**24**	3	**19**	12	18
Overall	15	**25**	2	17	**22**	10

Table 2: Frequency results of manual evaluations. Tie indicates evaluations where two summaries are rated equal.

size capturing correlated semantic concepts in documents as well as characterizing general and specific words, in order to identify topically coherent sentences in documents. We showed empirically that a fully unsupervised model for extracting general sentences performs well at summarization task using datasets that were originally used in building automatic summarization system challenges. The success of our model can be traced to its capability of directly capturing coherent topics in documents, which makes it able to identify salient sentences.

Acknowledgments

The authors would like to thank Dr. Zhaleh Feizollahi for her useful comments and suggestions.

Abstract

In citation-based summarization, text written by several researchers is leveraged to identify the important aspects of a target paper. Previous work on this problem focused almost exclusively on its extraction aspect (i.e. selecting a representative set of citation sentences that highlight the contribution of the target paper). Meanwhile, the fluency of the produced summaries has been mostly ignored. For example, diversity, readability, cohesion, and ordering of the sentences included in the summary have not been thoroughly considered. This resulted in noisy and confusing summaries. In this work, we present an approach for producing readable and cohesive citation-based summaries. Our experiments show that the proposed approach outperforms several baselines in terms of both extraction quality and fluency.

1 Introduction

Scientific research is a cumulative activity. The work of downstream researchers depends on access to upstream discoveries. The footnotes, end notes, or reference lists within research articles make this accumulation possible. When a reference appears in a scientific paper, it is often accompanied by a span of text describing the work being cited.

We name the sentence that contains an explicit reference to another paper *citation sentence*. Citation sentences usually highlight the most important aspects of the cited paper such as the research problem it addresses, the method it proposes, the good results it reports, and even its drawbacks and limitations.

By aggregating all the citation sentences that cite a paper, we have a rich source of information about it. This information is valuable because human experts have put their efforts to read the paper and summarize its important contributions.

One way to make use of these sentences is creating a summary of the target paper. This summary is different from the abstract or a summary generated from the paper itself. While the abstract represents the author's point of view, the citation summary is the summation of multiple scholars' viewpoints. The task of summarizing a scientific paper using its set of citation sentences is called citation-based summarization.

There has been previous work done on citation-based summarization (Nanba et al., 2000; Elkiss et al., 2008; Qazvinian and Radev, 2008; Mei and Zhai, 2008; Mohammad et al., 2009). Previous work focused on the extraction aspect; i.e. analyzing the collection of citation sentences and selecting a representative subset that covers the main aspects of the paper. The cohesion and the readability of the produced summaries have been mostly ignored. This resulted in noisy and confusing summaries.

In this work, we focus on the coherence and readability aspects of the problem. Our approach produces citation-based summaries in three stages: preprocessing, extraction, and postprocessing. Our experiments show that our approach produces better summaries than several baseline summarization systems.

The rest of this paper is organized as follows. After we examine previous work in Section 2, we outline the motivation of our approach in Section 3. Section 4 describes the three stages of our summarization system. The evaluation and the results are presented in Section 5. Section 6 concludes the paper.

Portland, Oregon, June 19-24, 2011.

2 Related Work

The idea of analyzing and utilizing citation information is far from new. The motivation for using information latent in citations has been explored tens of years back (Garfield et al., 1984; Hodges, 1972). Since then, there has been a large body of research done on citations.

Nanba and Okumura (2000) analyzed citation sentences and automatically categorized citations into three groups using 160 pre-defined phrase-based rules. They also used citation categorization to support a system for writing surveys (Nanba and Okumura, 1999). Newman (2001) analyzed the structure of the citation networks. Teufel et al. (2006) addressed the problem of classifying citations based on their function.

Siddharthan and Teufel (2007) proposed a method for determining the scientific attribution of an article by analyzing citation sentences. Teufel (2007) described a rhetorical classification task, in which sentences are labeled as one of Own, Other, Background, Textual, Aim, Basis, or Contrast according to their role in the authors argument. In parts of our approach, we were inspired by this work.

Elkiss et al. (2008) performed a study on citation summaries and their importance. They concluded that citation summaries are more focused and contain more information than abstracts. Mohammad et al. (2009) suggested using citation information to generate surveys of scientific paradigms.

Qazvinian and Radev (2008) proposed a method for summarizing scientific articles by building a similarity network of the citation sentences that cite the target paper, and then applying network analysis techniques to find a set of sentences that covers as much of the summarized paper facts as possible. We use this method as one of the baselines when we evaluate our approach. Qazvinian et al. (2010) proposed a citation-based summarization method that first extracts a number of important keyphrases from the set of citation sentences, and then finds the best subset of sentences that covers as many keyphrases as possible. Qazvinian and Radev (2010) addressed the problem of identifying the non-explicit citing sentences to aid citation-based summarization.

3 Motivation

The coherence and readability of citation-based summaries are impeded by several factors. First, many citation sentences cite multiple papers besides the target. For example, the following is a citation sentence that appeared in the NLP literature and talked about Resnik's (1999) work.

(1) Grefenstette and Nioche (2000) and Jones and Ghani (2000) use the web to generate corpora for languages where electronic resources are scarce, while ***Resnik (1999)*** *describes a method for mining the web for bilingual texts.*

The first fragment of this sentence describes different work other than Resnik's. The contribution of Resnik is mentioned in the underlined fragment. Including the irrelevant fragments in the summary causes several problems. First, the aim of the summarization task is to summarize the contribution of the target paper using minimal text. These fragments take space in the summary while being irrelevant and less important. Second, including these fragments in the summary breaks the context and, hence, degrades the readability and confuses the reader. Third, the existence of irrelevant fragments in a sentence makes the ranking algorithm assign a low weight to it although the relevant fragment may cover an aspect of the paper that no other sentence covers.

A second factor has to do with the ordering of the sentences included in the summary. For example, the following are two other citation sentences for Resnik (1999).

*(2) Mining the Web for bilingual text (****Resnik, 1999****) is not likely to provide sufficient quantities of high quality data.*

(3) ***Resnik (1999)*** *addressed the issue of language identification for finding Web pages in the languages of interest.*

If these two sentences are to be included in the summary, the reasonable ordering would be to put the second sentence first.

Thirdly, in some instances of citation sentences, the reference is not a syntactic constituent in the sen-

tence. It is added just to indicate the existence of citation. For example, in sentence (2) above, the reference could be safely removed from the sentence without hurting its grammaticality.

In other instances (e.g. sentence (3) above), the reference is a syntactic constituent of the sentence and removing it makes the sentence ungrammatical. However, in certain cases, the reference could be replaced with a suitable pronoun (i.e. he, she or they). This helps avoid the redundancy that results from repeating the author name(s) in every sentence.

Finally, a significant number of citation sentences are not suitable for summarization (Teufel et al., 2006) and should be filtered out. The following sentences are two examples.

(4) The two algorithms we employed in our dependency parsing model are the Eisner parsing ***(Eisner, 1996)*** *and Chu-Lius algorithm (Chu and Liu, 1965).*

(5) This type of model has been used by, among others, ***Eisner (1996)****.*

Sentence (4) appeared in a paper by Nguyen et al (2007). It does not describe any aspect of Eisner's work, rather it informs the reader that Nguyen et al. used Eisner's algorithm in their model. There is no value in adding this sentence to the summary of Eisner's paper. Teufel (2007) reported that a significant number of citation sentences (67% of the sentences in her dataset) were of this type.

Likewise, the comprehension of sentence (5) depends on knowing its context (i.e. its surrounding sentences). This sentence alone does not provide any valuable information about Eisner's paper and should not be added to the summary unless its context is extracted and included in the summary as well.

In our approach, we address these issues to achieve the goal of improving the coherence and the readability of citation-based summaries.

4 Approach

In this section we describe a system that takes a scientific paper and a set of citation sentences that cite it as input, and outputs a citation summary of the paper. Our system produces the summaries in three stages. In the first stage, the citation sentences are preprocessed to rule out the unsuitable sentences and the irrelevant fragments of sentences. In the second stage, a number of citation sentences that cover the various aspects of the paper are selected. In the last stage, the selected sentences are post-processed to enhance the readability of the summary. We describe the stages in the following three subsections.

4.1 Preprocessing

The aim of this stage is to determine which pieces of text (sentences or fragments of sentences) should be considered for selection in the next stage and which ones should be excluded. This stage involves three tasks: reference tagging, reference scope identification, and sentence filtering.

4.1.1 Reference Tagging

A citation sentence contains one or more references. At least one of these references corresponds to the target paper. When writing scientific articles, authors usually use standard patterns to include pointers to their references within the text. We use pattern matching to tag such references. The reference to the target is given a different tag than the references to other papers.

The following example shows a citation sentence with all the references tagged and the target reference given a different tag.

*In <**TREF**>**Resnik (1999)**</**TREF**>, <REF>Nie, Simard, and Foster (2001)</REF>, <REF>Ma and Liberman (1999)</REF>, and <REF>Resnik and Smith (2002)</REF>, the Web is harvested in search of pages that are available in two languages.*

4.1.2 Identifying the Reference Scope

In the previous section, we showed the importance of identifying the scope of the target reference; i.e. the fragment of the citation sentence that corresponds to the target paper. We define the scope of a reference as the shortest fragment of the citation sentence that contains the reference and could form a grammatical sentence if the rest of the sentence was removed.

To find such a fragment, we use a simple yet adequate heuristic. We start by parsing the sentence using the link grammar parser (Sleator and Temperley,

1991). Since the parser is not trained on citation sentences, we replace the references with placeholders before passing the sentence to the parser. Figure 1 shows a portion of the parse tree for Sentence (1) (from Section 1).

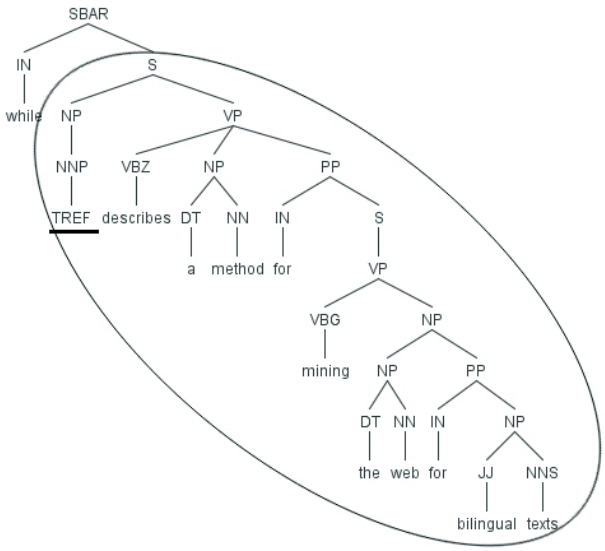

Figure 1: An example showing the scope of a target reference

We extract the scope of the reference from the parse tree as follows. We find the smallest subtree rooted at an S node (sentence clause node) and contains the target reference node. We extract the text that corresponds to this subtree if it is grammatical. Otherwise, we find the second smallest subtree rooted at an S node and so on. For example, the parse tree shown in Figure 1 suggests that the scope of the reference is:

Resnik (1999) *describes a method for mining the web for bilingual texts.*

4.1.3 Sentence Filtering

The task in this step is to detect and filter out unsuitable sentences; i.e., sentences that depend on their context (e.g. Sentence (5) above) or describe the own work of their authors, not the contribution of the target paper (e.g Sentence (4) above). Formally, we classify the citation sentences into two classes: suitable and unsuitable sentences. We use a machine learning technique for this purpose. We extract a number of features from each sentence and train a classification model using these features. The trained model is then used to classify the sentences. We use Support Vector Machines (SVM) with linear kernel as our classifier. The features that we use in this step and their descriptions are shown in Table 1.

4.2 Extraction

In the first stage, the sentences and sentence fragments that are not useful for our summarization task are ruled out. The input to this stage is a set of citation sentences that are believed to be suitable for the summary. From these sentences, we need to select a representative subset. The sentences are selected based on these three main properties:

First, they should cover diverse aspects of the paper. Second, the sentences that cover the same aspect should not contain redundant information. For example, if two sentences talk about the drawbacks of the target paper, one sentence can mention the computation inefficiency, while the other criticize the assumptions the paper makes. Third, the sentences should cover as many important facts about the target paper as possible using minimal text.

In this stage, the summary sentences are selected in three steps. In the first step, the sentences are classified into five functional categories: *Background, Problem Statement, Method, Results*, and *Limitations*. In the second step, we cluster the sentences within each category into clusters of similar sentences. In the third step, we compute the LexRank (Erkan and Radev, 2004) values for the sentences within each cluster. The summary sentences are selected based on the classification, the clustering, and the LexRank values.

4.2.1 Functional Category Classification

We classify the citation sentences into the five categories mentioned above using a machine learning technique. A classification model is trained on a number of features (Table 2) extracted from a labeled set of citation sentences. We use SVM with linear kernel as our classifier.

4.2.2 Sentence Clustering

In the previous step we determined the category of each citation sentence. It is very likely that sentences from the same category contain similar or overlapping information. For example, Sentences (6), (7), and (8) below appear in the set of citation

Feature	Description
Similarity to the target paper	The value of the cosine similarity (using TF-IDF vectors) between the citation sentence and the target paper.
Headlines	The section in which the citation sentence appeared in the citing paper. We recognize 10 section types such as *Introduction, Related Work, Approach, etc*.
Relative position	The relative position of the sentence in the section and the paragraph in which it appears
First person pronouns	This feature takes a value of 1 if the sentence contains a first person pronoun (I, we, our, us, etc.), and 0 otherwise.
Tense of the first verb	A sentence that contains a past tense verb near its beginning is more likely to be describing previous work.
Determiners	Demonstrative Determiners (this, that, these, those, and which) and Alternative Determiners (another, other). The value of this feature is the relative position of the first determiner (if one exists) in the sentence.

Table 1: The features used for sentence filtering

Feature	Description
Similarity to the sections of the target paper	The sections of the target paper are categorized into five categories: 1) *Introduction, Motivation, Problem Statement*. 2) *Background, Prior Work, Previous Work,* and *Related Work*. 3) *Experiments, Results,* and *Evaluation*. 4) *Discussion, Conclusion,* and *Future work*. 5) All other headlines. The value of this feature is the cosine similarity (using TF-IDF vectors) between the sentence and the text of the sections of each of the five section categories.
Headlines	This is the same feature that we used for sentence filtering in Section 4.1.3.
Number of references in the sentence	Sentences that contain multiple references are more likely to be *Background* sentences.
Verbs	We use all the verbs that their lemmatized form appears in at least three sentences that belong to the same category in the training set. Auxiliary verbs are excluded. In our annotated dataset, for example, the verb *propose* appeared in 67 sentences from the *Methodology* category, while the verbs *outperform* and *achieve* appeared in 33 *Result* sentences.

Table 2: The features used for sentence classification

sentences that cite Goldwater and Griffiths' (2007). These sentences belong to the same category (i.e *Method*). Both Sentences (6) and (7) convey the same information about Goldwater and Griffiths (2007) contribution. Sentence (8), however, describes a different aspect of the paper methodology.

(6) ***Goldwater and Griffiths (2007)*** *proposed an information-theoretic measure known as the Variation of Information (VI)*

(7) ***Goldwater and Griffiths (2007)*** *propose using the Variation of Information (VI) metric*

(8) A fully-Bayesian approach to unsupervised POS tagging has been developed by ***Goldwater and Griffiths (2007)*** *as a viable alternative to the traditional maximum likelihood-based HMM approach.*

Clustering divides the sentences of each category into groups of similar sentences. Following Qazvinian and Radev (2008), we build a cosine similarity graph out of the sentences of each category. This is an undirected graph in which nodes are sentences and edges represent similarity relations. Each edge is weighted by the value of the cosine similarity (using TF-IDF vectors) between the two sentences the edge connects. Once we have the similarity network constructed, we partition it into clusters using a community finding technique. We use the Clauset algorithm (Clauset et al., 2004), a hierarchical agglomerative community finding algorithm that runs in linear time.

4.2.3 Ranking

Although the sentences that belong to the same cluster are similar, they are not necessarily equally important. We rank the sentences within each cluster by computing their LexRank (Erkan and Radev, 2004). Sentences with higher rank are more important.

4.2.4 Sentence Selection

At this point we have determined (Figure 2), for each sentence, its category, its cluster, and its relative importance. Sentences are added to the summary in order based on their category, the size of their clusters, then their LexRank values. The categories are

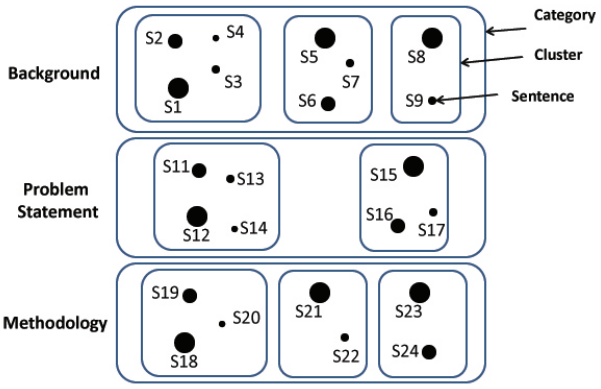

Figure 2: Example illustrating sentence selection

ordered as *Background, Problem, Method, Results*, then *Limitations*. Clusters within each category are ordered by the number of sentences in them whereas the sentences of each cluster are ordered by their LexRank values.

In the example shown in Figure 2, we have three categories. Each category contains several clusters. Each cluster contains several sentences with different LexRank values (illustrated by the sizes of the dots in the figure.) If the desired length of the summary is 3 sentences, the selected sentences will be in order S1, S12, then S18. If the desired length is 5, the selected sentences will be S1, S5, S12, S15, then S18.

4.3 Postprocessing

In this stage, we refine the sentences that we extracted in the previous stage. Each citation sentence will have the target reference (the author's names and the publication year) mentioned at least once. The reference could be either syntactically and semantically part of the sentence (e.g. Sentence (3) above) or not (e.g. Sentence (2)). The aim of this refinement step is to avoid repeating the author's names and the publication year in every sentence. We keep the author's names and the publication year only in the first sentence of the summary. In the following sentences, we either replace the reference with a suitable personal pronoun or remove it. The reference is replaced with a pronoun if it is part of the sentence and this replacement does not make the sentence ungrammatical. The reference is removed if it is not part of the sentence. If the sentence contains references for other papers, they are removed if this doesn't hurt the grammaticality of the sentence.

To determine whether a reference is part of the sentence or not, we again use a machine learning approach. We train a model on a set of labeled sentences. The features used in this step are listed in Table 3. The trained model is then used to classify the references that appear in a sentence into three classes: *keep*, *remove*, *replace*. If a reference is to be replaced, and the paper has one author, we use "*he/she*" (we do not know if the author is male or female). If the paper has two or more authors, we use "*they*".

5 Evaluation

We provide three levels of evaluation. First, we evaluate each of the components in our system separately. Then we evaluate the summaries that our system generate in terms of extraction quality. Finally, we evaluate the coherence and readability of the summaries.

5.1 Data

We use the ACL Anthology Network (AAN) (Radev et al., 2009) in our evaluation. AAN is a collection of more than 16000 papers from the Computational Linguistics journal, and the proceedings of the ACL conferences and workshops. AAN provides all citation information from within the network including the citation network, the citation sentences, and the citation context for each paper.

We used 55 papers from AAN as our data. The papers have a variable number of citation sentences, ranging from 15 to 348. The total number of citation sentences in the dataset is 4,335. We split the data randomly into two different sets; one for evaluating the components of the system, and the other for evaluating the extraction quality and the readability of the generated summaries. The first set (*dataset1*, henceforth) contained 2,284 sentences coming from 25 papers. We asked humans with good background in NLP (the area of the annotated papers) to provide two annotations for each sentence in this set: 1) label the sentence as *Background, Problem, Method, Result, Limitation,* or *Unsuitable*, 2) for each reference in the sentence, determine whether it could be *replaced* with a pronoun, *removed*, or should be *kept*.

Feature	Description
Part-of-speech (POS) tag	We consider the POS tags of the reference, the word before, and the word after. Before passing the sentence to the POS tagger, all the references in the sentence are replaced by placeholders.
Style of the reference	It is common practice in writing scientific papers to put the whole citation between parenthesis when the authors are not a constitutive part of the enclosing sentence, and to enclose just the year between parenthesis when the author's name is a syntactic constituent in the sentence.
Relative position of the reference	This feature takes one of three values: *first*, *last*, and *inside*.
Grammaticality	Grammaticality of the sentence if the reference is removed/replaced. Again, we use the Link Grammar parser (Sleator and Temperley, 1991) to check the grammaticality

Table 3: The features used for author name replacement

Each sentence was given to 3 different annotators. We used the majority vote labels.

We use Kappa coefficient (Krippendorff, 2003) to measure the inter-annotator agreement. Kappa coefficient is defined as:

$$Kappa = \frac{P(A) - P(E)}{1 - P(E)} \quad (1)$$

where $P(A)$ is the relative observed agreement among raters and $P(E)$ is the hypothetical probability of chance agreement.

The agreement among the three annotators on distinguishing the *unsuitable* sentences from the other five categories is 0.85. On Landis and Kochs(1977) scale, this value indicates an *almost perfect* agreement. The agreement on classifying the sentences into the five functional categories is 0.68. On the same scale this value indicates *substantial agreement*.

The second set (*dataset2*, henceforth) contained 30 papers (2051 sentences). We asked humans with a good background in NLP (the papers topic) to generate a readable, coherent summary for each paper in the set using its citation sentences as the source text. We asked them to fix the length of the summaries to 5 sentences. Each paper was assigned to two humans to summarize.

5.2 Component Evaluation

Reference Tagging and Reference Scope Identification Evaluation: We ran our reference tagging and scope identification components on the 2,284 sentences in *dataset1*. Then, we went through the tagged sentences and the extracted scopes, and counted the number of correctly/incorrectly tagged (extracted)/missed references (scopes). Our tagging component achieved 98.2% precision and 94.4% recall. The reference to the target paper was tagged correctly in all the sentences.

-	Bkgrnd	Prob	Method	Results	Limit.
Precision	64.62%	60.01%	88.66%	76.05%	33.53%
Recall	72.47%	59.30%	75.03%	82.29%	59.36%
F1	68.32%	59.65%	81.27%	79.04%	42.85%

Table 4: Precision and recall results achieved by our citation sentence classifier

Our scope identification component extracted the scope of target references with good precision (86.4%) but low recall (35.2%). In fact, extracting a useful scope for a reference requires more than just finding a grammatical substring. In future work, we plan to employ text regeneration techniques to improve the recall by generating grammatical sentences from ungrammatical fragments.

Sentence Filtering Evaluation: We used Support Vector Machines (SVM) with linear kernel as our classifier. We performed 10-fold cross validation on the labeled sentences (*unsuitable* vs *all other categories*) in *dataset1*. Our classifier achieved 80.3% accuracy.

Sentence Classification Evaluation: We used SVM in this step as well. We also performed 10-fold cross validation on the labeled sentences (the five functional categories). This classifier achieved 70.1% accuracy. The precision and recall for each category are given in Table 4

Author Name Replacement Evaluation: The classifier used in this task is also SVM. We performed 10-fold cross validation on the labeled sentences of *dataset1*. Our classifier achieved 77.41% accuracy.

Produced using our system
There has been a large number of studies in tagging and morphological disambiguation using various techniques such as statistical techniques, e.g. constraint-based techniques and transformation-based techniques. A thorough removal of ambiguity requires a syntactic process. A rule-based tagger described in Voutilainen (1995) was equipped with a set of guessing rules that had been hand-crafted using knowledge of English morphology and intuitions. The precision of rule-based taggers may exceed that of the probabilistic ones. The construction of a linguistic rule-based tagger, however, has been considered a difficult and time-consuming task.
Produced using Qazvinian and Radev (2008) system
Another approach is the rule-based or constraint-based approach, recently most prominently exemplified by the Constraint Grammar work (Karlsson et al. , 1995; Voutilainen, 1995b; Voutilainen et al. , 1992; Voutilainen and Tapanainen, 1993), where a large number of hand-crafted linguistic constraints are used to eliminate impossible tags or morphological parses for a given word in a given context. Some systems even perform the POS tagging as part of a syntactic analysis process (Voutilainen, 1995). A rule-based tagger described in (Voutilainen, 1995) is equipped with a set of guessing rules which has been hand-crafted using knowledge of English morphology and intuition. Older versions of EngCG (using about 1,150 constraints) are reported (butilainen et al. 1992; Voutilainen and HeikkiUi 1994; Tapanainen and Voutilainen 1994; Voutilainen 1995) to assign a correct analysis to about 99.7% of all words while each word in the output retains 1.04-1.09 alternative analyses on an average, i.e. some of the ambiguities remait unresolved. We evaluate the resulting disambiguated text by a number of metrics defined as follows (Voutilainen, 1995a).

Table 5: Sample Output

5.3 Extraction Evaluation

To evaluate the extraction quality, we use *dataset2* (that has never been used for training or tuning any of the system components). We use our system to generate summaries for each of the 30 papers in *dataset2*. We also generate summaries for the papers using a number of baseline systems (described in Section 5.3.1). All the generated summaries were 5 sentences long. We use the Recall-Oriented Understudy for Gisting Evaluation (ROUGE) based on the longest common substrings (ROUGE-L) as our evaluation metric.

5.3.1 Baselines

We evaluate the extraction quality of our system (FL) against 7 different baselines. In the first baseline, the sentences are selected randomly from the set of citation sentences and added to the summary. The second baseline is the MEAD summarizer (Radev et al., 2004) with all its settings set to default. The third baseline is LexRank (Erkan and Radev, 2004) run on the entire set of citation sentences of the target paper. The forth baseline is Qazvinian and Radev (2008) citation-based summarizer (QR08) in which the citation sentences are first clustered then the sentences within each cluster are ranked using LexRank. The remaining baselines are variations of our system produced by removing one component from the pipeline at a time. In one variation (FL-1), we remove the *sentence filtering* component. In another variation (FL-2), we remove the *sentence classification* component; so, all the sentences are assumed to come from one category in the subsequent components. In a third variation (FL-3), the clustering component is removed. To make the comparison of the extraction quality to those baselines fair, we remove the *author name replacement* component from our system and all its variations.

5.3.2 Results

Table 6 shows the average ROUGE-L scores (with 95% confidence interval) for the summaries of the 30 papers in *dataset2* generated using our system and the different baselines. The two human summaries were used as models for comparison. The *Human* score reported in the table is the result of comparing the two human summaries to each others. Statistical significance was tested using a 2-tailed paired t-test. The results are statistically significant at the 0.05 level.

The results show that our approach outperforms all the baseline techniques. It achieves higher ROUGE-L score for most of the papers in our testing set. Comparing the score of FL-1 to the score of FL shows that sentence filtering has a significant impact on the results. It also shows that the classification and clustering components both improve the extraction quality.

5.4 Coherence and Readability Evaluation

We asked human judges (not including the authors) to rate the coherence and readability of a number of summaries for each of *dataset2* papers. For each paper we evaluated 3 summaries. The sum-

-	**Human**	**Random**	**MEAD**	**LexRank**	**QR08**
ROUGE-L	0.733	0.398	0.410	0.408	0.435
-	**FL-1**	**FL-2**	**FL-3**	**FL**	-
ROUGE-L	0.475	0.511	0.525	**0.539**	-

Table 6: Extraction Evaluation

Average Coherence Rating	Number of summaries		
	Human	FL	QV08
1≤ coherence <2	0	9	17
2≤ coherence <3	3	11	12
3≤ coherence <4	16	9	1
4≤ coherence ≤5	11	1	0

Table 7: Coherence Evaluation

mary that our system produced, the human summary, and a summary produced by Qazvinian and Radev (2008) summarizer (the best baseline - after our system and its variations - in terms of extraction quality as shown in the previous subsection.) The summaries were randomized and given to the judges without telling them how each summary was produced. The judges were not given access to the source text. They were asked to use a five point-scale to rate how coherent and readable the summaries are, where 1 means that the summary is totally incoherent and needs significant modifications to improve its readability, and 5 means that the summary is coherent and no modifications are needed to improve its readability. We gave each summary to 5 different judges and took the average of their ratings for each summary. We used Weighted Kappa with linear weights (Cohen, 1968) to measure the inter-rater agreement. The Weighted Kappa measure between the five groups of ratings was 0.72.

Table 7 shows the number of summaries in each rating range. The results show that our approach significantly improves the coherence of citation-based summarization. Table 5 shows two sample summaries (each 5 sentences long) for the Voutilainen (1995) paper. One summary was produced using our system and the other was produced using Qazvinian and Radev (2008) system.

6 Conclusions

In this paper, we presented a new approach for citation-based summarization of scientific papers that produces readable summaries. Our approach involves three stages. The first stage preprocesses the set of citation sentences to filter out the irrelevant sentences or fragments of sentences. In the second stage, a representative set of sentences are extracted and added to the summary in a reasonable order. In the last stage, the summary sentences are refined to improve their readability. The results of our experiments confirmed that our system outperforms several baseline systems.

Abstract

We design a class of submodular functions meant for document summarization tasks. These functions each combine two terms, one which encourages the summary to be representative of the corpus, and the other which positively rewards diversity. Critically, our functions are monotone nondecreasing and submodular, which means that an efficient scalable greedy optimization scheme has a constant factor guarantee of optimality. When evaluated on DUC 2004-2007 corpora, we obtain better than existing state-of-art results in both generic and query-focused document summarization. Lastly, we show that several well-established methods for document summarization correspond, in fact, to submodular function optimization, adding further evidence that submodular functions are a natural fit for document summarization.

1 Introduction

In this paper, we address the problem of generic and query-based extractive summarization from collections of related documents, a task commonly known as *multi-document summarization*. We treat this task as monotone submodular function maximization (to be defined in Section 2). This has a number of critical benefits. On the one hand, there exists a simple greedy algorithm for monotone submodular function maximization where the summary solution obtained (say $\hat{S}$) is guaranteed to be almost as good as the best possible solution (say S_{opt}) according to an objective $\mathcal{F}$. More precisely, the greedy algorithm is a constant factor approximation to the cardinality constrained version of the problem, so that $\mathcal{F}(\hat{S}) \geq (1 - 1/e)\mathcal{F}(S_{\text{opt}}) \approx 0.632\mathcal{F}(S_{\text{opt}})$. This is particularly attractive since the quality of the solution does not depend on the size of the problem, so even very large size problems do well. It is also important to note that this is a worst case bound, and in most cases the quality of the solution obtained will be much better than this bound suggests.

Of course, none of this is useful if the objective function $\mathcal{F}$ is inappropriate for the summarization task. In this paper, we argue that monotone nondecreasing submodular functions $\mathcal{F}$ are an ideal class of functions to investigate for document summarization. We show, in fact, that many well-established methods for summarization (Carbonell and Goldstein, 1998; Filatova and Hatzivassiloglou, 2004; Takamura and Okumura, 2009; Riedhammer et al., 2010; Shen and Li, 2010) correspond to submodular function optimization, a property not explicitly mentioned in these publications. We take this fact, however, as testament to the value of submodular functions for summarization: if summarization algorithms are repeatedly developed that, by chance, happen to be an instance of a submodular function optimization, this suggests that submodular functions are a natural fit. On the other hand, other authors have started realizing explicitly the value of submodular functions for summarization (Lin and Bilmes, 2010; Qazvinian et al., 2010).

Submodular functions share many properties in common with convex functions, one of which is that they are closed under a number of common combination operations (summation, certain compositions, restrictions, and so on). These operations give us the tools necessary to design a powerful submodular objective for submodular document summarization that extends beyond any previous work. We demonstrate this by carefully crafting a class of submodular func-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 510–520,
Portland, Oregon, June 19-24, 2011.

tions we feel are ideal for extractive summarization tasks, both generic and query-focused. In doing so, we demonstrate better than existing state-of-the-art performance on a number of standard summarization evaluation tasks, namely DUC-04 through to DUC-07. We believe our work, moreover, might act as a springboard for researchers in summarization to consider the problem of "how to design a submodular function" for the summarization task.

In Section 2, we provide a brief background on submodular functions and their optimization. Section 3 describes how the task of extractive summarization can be viewed as a problem of submodular function maximization. We also in this section show that many standard methods for summarization are, in fact, already performing submodular function optimization. In Section 4, we present our own submodular functions. Section 5 presents results on both generic and query-focused summarization tasks, showing as far as we know the best known ROUGE results for DUC-04 through DUC-06, and the best known precision results for DUC-07, and the best recall DUC-07 results among those that do not use a web search engine. Section 6 discusses implications for future work.

2 Background on Submodularity

We are given a set of objects $V = \{v_1, \ldots, v_n\}$ and a function $\mathcal{F} : 2^V \rightarrow \mathbb{R}$ that returns a real value for any subset $S \subseteq V$. We are interested in finding the subset of bounded size $|S| \leq k$ that maximizes the function, e.g., $\operatorname{argmax}_{S \subseteq V} \mathcal{F}(S)$. In general, this operation is hopelessly intractable, an unfortunate fact since the optimization coincides with many important applications. For example, $\mathcal{F}$ might correspond to the value or coverage of a set of sensor locations in an environment, and the goal is to find the best locations for a fixed number of sensors (Krause et al., 2008).

If the function $\mathcal{F}$ is monotone submodular then the maximization is still NP complete, but it was shown in (Nemhauser et al., 1978) that a greedy algorithm finds an approximate solution guaranteed to be within $\frac{e-1}{e} \sim 0.63$ of the optimal solution, as mentioned in Section 1. A version of this algorithm (Minoux, 1978), moreover, scales to very large data sets. Submodular functions are those that satisfy the property of *diminishing returns*: for any $A \subseteq B \subseteq V \backslash v$, a *submodular* function $\mathcal{F}$ must satisfy $\mathcal{F}(A+v) - \mathcal{F}(A) \geq \mathcal{F}(B+v) - \mathcal{F}(B)$. That is, the incremental "value" of v decreases as the context in which v is considered grows from A to B. An equivalent definition, useful mathematically, is that for any $A, B \subseteq V$, we must have that $\mathcal{F}(A) + \mathcal{F}(B) \geq \mathcal{F}(A \cup B) + \mathcal{F}(A \cap B)$. If this is satisfied everywhere with equality, then the function $\mathcal{F}$ is called *modular*, and in such case $\mathcal{F}(A) = c + \sum_{a \in A} \vec{f}_a$ for a sized $|V|$ vector $\vec{f}$ of real values and constant c. A set function $\mathcal{F}$ is *monotone nondecreasing* if $\forall A \subseteq B$, $\mathcal{F}(A) \leq \mathcal{F}(B)$. As shorthand, in this paper, monotone nondecreasing submodular functions will simply be referred to as *monotone submodular*.

Historically, submodular functions have their roots in economics, game theory, combinatorial optimization, and operations research. More recently, submodular functions have started receiving attention in the machine learning and computer vision community (Kempe et al., 2003; Narasimhan and Bilmes, 2005; Krause and Guestrin, 2005; Narasimhan and Bilmes, 2007; Krause et al., 2008; Kolmogorov and Zabin, 2004) and have recently been introduced to natural language processing for the tasks of document summarization (Lin and Bilmes, 2010) and word alignment (Lin and Bilmes, 2011).

Submodular functions share a number of properties in common with convex and concave functions (Lovász, 1983), including their wide applicability, their generality, their multiple options for their representation, and their closure under a number of common operators (including mixtures, truncation, complementation, and certain convolutions). For example, if a collection of functions $\{\mathcal{F}_i\}_i$ is submodular, then so is their weighted sum $\mathcal{F} = \sum_i \alpha_i \mathcal{F}_i$ where α_i are nonnegative weights. It is not hard to show that submodular functions also have the following composition property with concave functions:

Theorem 1. *Given functions $\mathcal{F} : 2^V \rightarrow \mathbb{R}$ and $f : \mathbb{R} \rightarrow \mathbb{R}$, the composition $\mathcal{F}' = f \circ \mathcal{F} : 2^V \rightarrow \mathbb{R}$ (i.e., $\mathcal{F}'(S) = f(\mathcal{F}(S))$) is nondecreasing submodular, if f is non-decreasing concave and $\mathcal{F}$ is nondecreasing submodular.*

This property will be quite useful when defining submodular functions for document summarization.

3 Submodularity in Summarization

3.1 Summarization with knapsack constraint

Let the *ground set* V represents all the sentences (or other linguistic units) in a document (or document collection, in the multi-document summarization case). The task of extractive document summarization is to select a subset $S \subseteq V$ to represent the entirety (ground set V). There are typically constraints on S, however. Obviously, we should have $|S| < |V| = N$ as it is a summary and should be small. In standard summarization tasks (e.g., DUC evaluations), the summary is usually required to be length-limited. Therefore, constraints on S can naturally be modeled as *knapsack constraints*: $\sum_{i \in S} c_i \leq b$, where c_i is the non-negative cost of selecting unit i (e.g., the number of words in the sentence) and b is our *budget*. If we use a set function $\mathcal{F} : 2^V \rightarrow \mathbb{R}$ to measure the quality of the summary set S, the summarization problem can then be formalized as the following combinatorial optimization problem:

Problem 1. *Find*

$$S^* \in \operatorname*{argmax}_{S \subseteq V} \mathcal{F}(S) \textit{ subject to: } \sum_{i \in S} c_i \leq b.$$

Since this is a generalization of the cardinality constraint (where $c_i = 1, \forall i$), this also constitutes a (well-known) NP-hard problem. In this case as well, however, a modified greedy algorithm with partial enumeration can solve Problem 1 near-optimally with $(1-1/e)$-approximation factor if $\mathcal{F}$ is monotone submodular (Sviridenko, 2004). The partial enumeration, however, is too computationally expensive for real world applications. In (Lin and Bilmes, 2010), we generalize the work by Khuller et al. (1999) on the budgeted maximum cover problem to the general submodular framework, and show a practical greedy algorithm with a $(1 - 1/\sqrt{e})$-approximation factor, where each greedy step adds the unit with the largest ratio of objective function gain to scaled cost, while not violating the budget constraint (see (Lin and Bilmes, 2010) for details). Note that in all cases, submodularity and monotonicity are two necessary ingredients to guarantee that the greedy algorithm gives near-optimal solutions.

In fact, greedy-like algorithms have been widely used in summarization. One of the more popular approaches is *maximum marginal relevance* (MMR) (Carbonell and Goldstein, 1998), where a greedy algorithm selects the most relevant sentences, and at the same time avoids redundancy by removing sentences that are too similar to ones already selected. Interestingly, the gain function defined in the original MMR paper (Carbonell and Goldstein, 1998) satisfies diminishing returns, a fact apparently unnoticed until now. In particular, Carbonell and Goldstein (1998) define an objective function gain of adding element k to set S ($k \notin S$) as:

$$\lambda Sim_1(s_k, q) - (1 - \lambda) \max_{i \in S} Sim_2(s_i, s_k), \quad (1)$$

where $Sim_1(s_k, q)$ measures the similarity between unit s_k to a query q, $Sim_2(s_i, s_k)$ measures the similarity between unit s_i and unit s_k, and $0 \leq \lambda \leq 1$ is a trade-off coefficient. We have:

Theorem 2. *Given an expression for $\mathcal{F}_{MMR}$ such that $\mathcal{F}_{MMR}(S \cup \{k\}) - \mathcal{F}_{MMR}(S)$ is equal to Eq. 1, $\mathcal{F}_{MMR}$ is non-monotone submodular.*

Obviously, diminishing-returns hold since

$$\max_{i \in S} Sim_2(s_i, s_k) \leq \max_{i \in R} Sim_2(s_i, s_k)$$

for all $S \subseteq R$, and therefore $\mathcal{F}_{\text{MMR}}$ is submodular. On the other hand, $\mathcal{F}_{\text{MMR}}$, would not be monotone, so the greedy algorithm's constant-factor approximation guarantee does not apply in this case.

When scoring a summary at the sub-sentence level, submodularity naturally arises. Concept-based summarization (Filatova and Hatzivassiloglou, 2004; Takamura and Okumura, 2009; Riedhammer et al., 2010; Qazvinian et al., 2010) usually maximizes the weighted credit of concepts covered by the summary. Although the authors may not have noticed, their objective functions are also submodular, adding more evidence suggesting that submodularity is natural for summarization tasks. Indeed, let S be a subset of sentences in the document and denote $\Gamma(S)$ as the set of concepts contained in S. The total credit of the concepts covered by S is then

$$\mathcal{F}_{\text{concept}}(S) \triangleq \sum_{i \in \Gamma(S)} c_i,$$

where c_i is the credit of concept i. This function is known to be submodular (Narayanan, 1997).

Similar to the MMR approach, in (Lin and Bilmes, 2010), a submodular graph based objective function is proposed where a graph cut function, measuring the similarity of the summary to the rest of document, is combined with a subtracted redundancy penalty function. The objective function is submodular but again, non-monotone. We theoretically justify that the performance guarantee of the greedy algorithm holds for this objective function with high probability (Lin and Bilmes, 2010). Our justification, however, is shown to be applicable only to certain particular non-monotone submodular functions, under certain reasonable assumptions about the probability distribution over weights of the graph.

3.2 Summarization with covering constraint

Another perspective is to treat the summarization problem as finding a low-cost subset of the document under the constraint that a summary should cover all (or a sufficient amount of) the information in the document. Formally, this can be expressed as

Problem 2. *Find*

$$S^* \in \operatorname*{argmin}_{S \subseteq V} \sum_{i \in S} c_i \textit{ subject to: } \mathcal{F}(S) \geq \alpha,$$

where c_i are the element costs, and set function $\mathcal{F}(S)$ measure the information covered by S. When $\mathcal{F}$ is submodular, the constraint $\mathcal{F}(S) \geq \alpha$ is called a *submodular cover* constraint. When $\mathcal{F}$ is monotone submodular, a greedy algorithm that iteratively selects k with minimum $c_k/(\mathcal{F}(S \cup \{k\}) - \mathcal{F}(S))$ has approximation guarantees (Wolsey, 1982). Recent work (Shen and Li, 2010) proposes to model document summarization as finding a minimum dominating set and a greedy algorithm is used to solve the problem. The dominating set constraint is also a submodular cover constraint. Define $\delta(S)$ be the set of elements that is either in S or is adjacent to some element in S. Then S is a dominating set if $|\delta(S)| = |V|$. Note that

$$\mathcal{F}_{\text{dom}}(S) \triangleq |\delta(S)|$$

is monotone submodular. The dominating set constraint is then also a submodular cover constraint, and therefore the approaches in (Shen and Li, 2010) are special cases of Problem 2. The solutions found in this framework, however, do not necessarily satisfy a summary's budget constraint. Consequently, a subset of the solution found by solving Problem 2 has to be constructed as the final summary, and the near-optimality is no longer guaranteed. Therefore, solving Problem 1 for document summarization appears to be a better framework regarding global optimality. In the present paper, our framework is that of Problem 1.

3.3 Automatic summarization evaluation

Automatic evaluation of summary quality is important for the research of document summarization as it avoids the labor-intensive and potentially inconsistent human evaluation. ROUGE (Lin, 2004) is widely used for summarization evaluation and it has been shown that ROUGE-N scores are highly correlated with human evaluation (Lin, 2004). Interestingly, ROUGE-N is monotone submodular, adding further evidence that monotone submodular functions are natural for document summarization.

Theorem 3. *ROUGE-N is monotone submodular.*

Proof. By definition (Lin, 2004), ROUGE-N is the n-gram recall between a candidate summary and a set of reference summaries. Precisely, let S be the candidate summary (a set of sentences extracted from the ground set V), $c_e : 2^V \rightarrow \mathbb{Z}_+$ be the number of times n-gram e occurs in summary S, and R_i be the set of n-grams contained in the reference summary i (suppose we have K reference summaries, i.e., $i = 1, \cdots, K$). Then ROUGE-N can be written as the following set function:

$$\mathcal{F}_{\text{ROUGE-N}}(S) \triangleq \frac{\sum_{i=1}^{K} \sum_{e \in R_i} \min(c_e(S), r_{e,i})}{\sum_{i=1}^{K} \sum_{e \in R_i} r_{e,i}},$$

where $r_{e,i}$ is the number of times n-gram e occurs in reference summary i. Since $c_e(S)$ is monotone modular and $\min(x, a)$ is a concave non-decreasing function of x, $\min(c_e(S), r_{e,i})$ is monotone submodular by Theorem 1. Since summation preserves submodularity, and the denominator is constant, we see that $\mathcal{F}_{\text{ROUGE-N}}$ is monotone submodular. □

Since the reference summaries are unknown, it is of course impossible to optimize $\mathcal{F}_{\text{ROUGE-N}}$ directly. Therefore, some approaches (Filatova and Hatzivassiloglou, 2004; Takamura and Okumura, 2009; Riedhammer et al., 2010) instead define "concepts". Alter-

natively, we herein propose a class of monotone submodular functions that naturally models the quality of a summary while not depending on an explicit notion of concepts, as we will see in the following section.

4 Monotone Submodular Objectives

Two properties of a good summary are *relevance* and *non-redundancy*. Objective functions for extractive summarization usually measure these two separately and then mix them together trading off encouraging relevance and penalizing redundancy. The redundancy penalty usually violates the monotonicity of the objective functions (Carbonell and Goldstein, 1998; Lin and Bilmes, 2010). We therefore propose to positively *reward diversity* instead of negatively penalizing redundancy. In particular, we model the summary quality as

$$\mathcal{F}(S) = \mathcal{L}(S) + \lambda \mathcal{R}(S), \tag{2}$$

where $\mathcal{L}(S)$ measures the coverage, or "fidelity", of summary set S to the document, $\mathcal{R}(S)$ rewards diversity in S, and $\lambda \geq 0$ is a trade-off coefficient. Note that the above is analogous to the objectives widely used in machine learning, where a loss function that measures the training set error (we measure the coverage of summary to a document), is combined with a regularization term encouraging certain desirable (e.g., sparsity) properties (in our case, we "regularize" the solution to be more diverse). In the following, we discuss how both $\mathcal{L}(S)$ and $\mathcal{R}(S)$ are naturally monotone submodular.

4.1 Coverage function

$\mathcal{L}(S)$ can be interpreted either as a set function that measures the similarity of summary set S to the document to be summarized, or as a function representing some form of "coverage" of V by S. Most naturally, $\mathcal{L}(S)$ should be monotone, as coverage improves with a larger summary. $\mathcal{L}(S)$ should also be submodular: consider adding a new sentence into two summary sets, one a subset of the other. Intuitively, the increment when adding a new sentence to the small summary set should be larger than the increment when adding it to the larger set, as the information carried by the new sentence might have already been covered by those sentences that are in the larger summary but not in the smaller summary. This is exactly the property of diminishing returns. Indeed, Shannon entropy, as the measurement of information, is another well-known monotone submodular function.

There are several ways to define $\mathcal{L}(S)$ in our context. For instance, we could use $\mathcal{L}(S) = \sum_{i \in V, j \in S} w_{i,j}$ where $w_{i,j}$ represents the similarity between i and j. $\mathcal{L}(S)$ could also be facility location objective, i.e., $\mathcal{L}(S) = \sum_{i \in V} \max_{j \in S} w_{i,j}$, as used in (Lin et al., 2009). We could also use $\mathcal{L}(S) = \sum_{i \in \Gamma(S)} c_i$ as used in concept-based summarization, where the definition of "concept" and the mechanism to extract these concepts become important. All of these are monotone submodular.

Alternatively, in this paper we propose the following objective that does not reply on concepts. Let

$$\mathcal{L}(S) = \sum_{i \in V} \min \left\{ \mathcal{C}_i(S), \alpha\, \mathcal{C}_i(V) \right\}, \tag{3}$$

where $\mathcal{C}_i : 2^V \rightarrow \mathbb{R}$ is a monotone submodular function and $0 \leq \alpha \leq 1$ is a threshold co-efficient. Firstly, $\mathcal{L}(S)$ as defined in Eqn. 3 is a monotone submodular function. The monotonicity is immediate. To see that $\mathcal{L}(S)$ is submodular, consider the fact that $f(x) = \min(x, a)$ where $a \geq 0$ is a concave non-decreasing function, and by Theorem 1, each summand in Eqn. 3 is a submodular function, and as summation preserves submodularity, $\mathcal{L}(S)$ is submodular.

Next, we explain the intuition behind Eqn. 3. Basically, $\mathcal{C}_i(S)$ measures how similar S is to element i, or how much of i is "covered" by S. Then $\mathcal{C}_i(V)$ is just the largest value that $\mathcal{C}_i(S)$ can achieve. We call i "saturated" by S when $\min\{\mathcal{C}_i(S), \alpha\mathcal{C}_i(V)\} = \alpha\mathcal{C}_i(V)$. When i is already saturated in this way, any new sentence j can not further improve the coverage of i even if it is very similar to i (i.e., $\mathcal{C}_i(S \cup \{j\}) - \mathcal{C}_i(S)$ is large). This will give other sentences that are not yet saturated a higher chance of being better covered, and therefore the resulting summary tends to better cover the entire document.

One simple way to define $\mathcal{C}_i(S)$ is just to use

$$\mathcal{C}_i(S) = \sum_{j \in S} w_{i,j} \tag{4}$$

where $w_{i,j} \geq 0$ measures the similarity between i and j. In this case, when $\alpha = 1$, Eqn. 3 reduces to the case where $\mathcal{L}(S) = \sum_{i \in V, j \in S} w_{i,j}$. As we will see in Section 5, having an α that is less than

1 significantly improves the performance compared to the case when $\alpha = 1$, which coincides with our intuition that using a truncation threshold improves the final summary's coverage.

4.2 Diversity reward function

Instead of penalizing redundancy by subtracting from the objective, we propose to reward diversity by adding the following to the objective:

$$\mathcal{R}(S) = \sum_{i=1}^{K} \sqrt{\sum_{j \in P_i \cap S} r_j}. \quad (5)$$

where $P_i, i = 1, \cdots K$ is a partition of the ground set V (i.e., $\bigcup_i P_i = V$ and the P_is are disjoint) into separate clusters, and $r_i \geq 0$ indicates the *singleton reward* of i (i.e., the reward of adding i into the empty set). The value r_i estimates the importance of i to the summary. The function $\mathcal{R}(S)$ rewards diversity in that there is usually more benefit to selecting a sentence from a cluster not yet having one of its elements already chosen. As soon as an element is selected from a cluster, other elements from the same cluster start having diminishing gain, thanks to the square root function. For instance, consider the case where $k_1, k_2 \in P_1$, $k_3 \in P_2$, and $r_{k_1} = 4$, $r_{k_2} = 9$, and $r_{k_3} = 4$. Assume k_1 is already in the summary set S. Greedily selecting the next element will choose k_3 rather than k_2 since $\sqrt{13} < 2 + 2$. In other words, adding k_3 achieves a greater reward as it increases the diversity of the summary (by choosing from a different cluster). Note, $\mathcal{R}(S)$ is distinct from $\mathcal{L}(S)$ in that $\mathcal{R}(S)$ might wish to include certain outlier material that $\mathcal{L}(S)$ could ignore.

It is easy to show that $\mathcal{R}(S)$ is submodular by using the composition rule from Theorem 1. The square root is non-decreasing concave function. Inside each square root lies a modular function with non-negative weights (and thus is monotone). Applying the square root to such a monotone submodular function yields a submodular function, and summing them all together retains submodularity, as mentioned in Section 2. The monotonicity of $\mathcal{R}(S)$ is straightforward. Note, the form of Eqn. 5 is similar to structured group norms (e.g., (Zhao et al., 2009)), recently shown to be related to submodularity (Bach, 2010; Jegelka and Bilmes, 2011).

Several extensions to Eqn. 5 are discussed next: First, instead of using a ground set partition, intersecting clusters can be used. Second, the square root function in Eqn. 5 can be replaced with any other non-decreasing concave functions (e.g., $f(x) = log(1 + x)$) while preserving the desired property of $\mathcal{R}(S)$, and the curvature of the concave function then determines the rate that the reward diminishes. Last, multi-resolution clustering (or partitions) with different sizes (K) can be used, i.e., we can use a mixture of components, each of which has the structure of Eqn. 5. A mixture can better represent the core structure of the ground set (e.g., the hierarchical structure in the documents (Celikyilmaz and Hakkani-tür, 2010)). All such extensions preserve both monotonicity and submodularity.

5 Experiments

The document understanding conference (DUC) (`http://duc.nist.org`) was the main forum providing benchmarks for researchers working on document summarization. The tasks in DUC evolved from single-document summarization to multi-document summarization, and from generic summarization (2001–2004) to query-focused summarization (2005–2007). As ROUGE (Lin, 2004) has been officially adopted for DUC evaluations since 2004, we also take it as our main evaluation criterion. We evaluated our approaches on DUC data 2003-2007, and demonstrate results on both generic and query-focused summarization. In all experiments, the modified greedy algorithm (Lin and Bilmes, 2010) was used for summary generation.

5.1 Generic summarization

Summarization tasks in DUC-03 and DUC-04 are multi-document summarization on English news articles. In each task, 50 document clusters are given, each of which consists of 10 documents. For each document cluster, the system generated summary may not be longer than 665 bytes including spaces and punctuation. We used DUC-03 as our development set, and tested on DUC-04 data. We show ROUGE-1 scores[1] as it was the main evaluation criterion for DUC-03, 04 evaluations.

[1]ROUGE version 1.5.5 with options: -a -c 95 -b 665 -m -n 4 -w 1.2

Documents were pre-processed by segmenting sentences and stemming words using the Porter Stemmer. Each sentence was represented using a bag-of-terms vector, where we used context terms up to bi-grams. Similarity between sentence i and sentence j, i.e., $w_{i,j}$, was computed using cosine similarity:

$$w_{i,j} = \frac{\sum_{w \in s_i} \text{tf}_{w,i} \times \text{tf}_{w,j} \times \text{idf}_w^2}{\sqrt{\sum_{w \in s_i} \text{tf}_{w,s_i}^2 \text{idf}_w^2} \sqrt{\sum_{w \in s_j} \text{tf}_{w,j}^2 \text{idf}_w^2}},$$

where $\text{tf}_{w,i}$ and $\text{tf}_{w,j}$ are the numbers of times that w appears in s_i and sentence s_j respectively, and idf_w is the inverse document frequency (IDF) of term w (up to bigram), which was calculated as the logarithm of the ratio of the number of articles that w appears over the total number of all articles in the document cluster.

Table 1: ROUGE-1 recall (R) and F-measure (F) results (%) on DUC-04. DUC-03 was used as development set.

DUC-04	R	F
$\sum_{i \in V} \sum_{j \in S} w_{i,j}$	33.59	32.44
$\mathcal{L}_1(S)$	39.03	38.65
$\mathcal{R}_1(S)$	38.23	37.81
$\mathcal{L}_1(S) + \lambda \mathcal{R}_1(S)$	**39.35**	**38.90**
Takamura and Okumura (2009)	38.50	-
Wang et al. (2009)	39.07	-
Lin and Bilmes (2010)	-	38.39
Best system in DUC-04 (peer 65)	38.28	37.94

We first tested our coverage and diversity reward objectives separately. For coverage, we use a modular $\mathcal{C}_i(S) = \sum_{j \in S} w_{i,j}$ for each sentence i, i.e.,

$$\mathcal{L}_1(S) = \sum_{i \in V} \min \left\{ \sum_{j \in S} w_{i,j}, \alpha \sum_{k \in V} w_{i,k} \right\}. \quad (6)$$

When $\alpha = 1$, $\mathcal{L}_1(S)$ reduces to $\sum_{i \in V, j \in S} w_{i,j}$, which measures the overall similarity of summary set S to ground set V. As mentioned in Section 4.1, using such similarity measurement could possibly over-concentrate on a small portion of the document and result in a poor coverage of the whole document. As shown in Table 1, optimizing this objective function gives a ROUGE-1 F-measure score 32.44%. On the other hand, when using $\mathcal{L}_1(S)$ with an $\alpha < 1$ (the value of α was determined on DUC-03 using a grid search), a ROUGE-1 F-measure score 38.65% is achieved, which is already better than the best performing system in DUC-04.

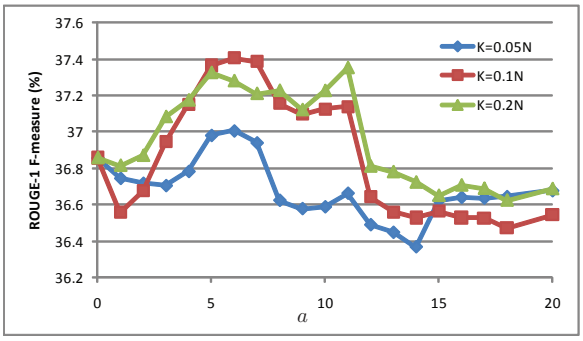

Figure 1: ROUGE-1 F-measure scores on DUC-03 when α and K vary in objective function $\mathcal{L}_1(S) + \lambda \mathcal{R}_1(S)$, where $\lambda = 6$ and $\alpha = \frac{a}{N}$.

As for the diversity reward objective, we define the singleton reward as $r_i = \frac{1}{N} \sum_j w_{i,j}$, which is the average similarity of sentence i to the rest of the document. It basically states that the more similar to the whole document a sentence is, the more reward there will be by adding this sentence to an empty summary set. By using this singleton reward, we have the following diversity reward function:

$$\mathcal{R}_1(S) = \sum_{k=1}^{K} \sqrt{\sum_{j \in S \cap P_k} \frac{1}{N} \sum_{i \in V} w_{i,j}}. \quad (7)$$

In order to generate $P_k, k = 1, \cdots K$, we used CLUTO[2] to cluster the sentences, where the IDF-weighted term vector was used as feature vector, and a direct K-mean clustering algorithm was used. In this experiment, we set $K = 0.2N$. In other words, there are 5 sentences in each cluster on average. And as we can see in Table 1, optimizing the diversity reward function alone achieves comparable performance to the DUC-04 best system.

Combining $\mathcal{L}_1(S)$ and $\mathcal{R}_1(S)$, our system outperforms the best system in DUC-04 significantly, and it also outperforms several recent systems, including a concept-based summarization approach (Takamura and Okumura, 2009), a sentence topic model based system (Wang et al., 2009), and our MMR-styled submodular system (Lin and Bilmes, 2010). Figure 1 illustrates how ROUGE-1 scores change when α and K vary on the development set (DUC-03).

Daumé III and Marcu (2006)	6.98	-
Best system in DUC-05 (peer 15)	7.44	7.43

5.2 Query-focused summarization

We evaluated our approach on the task of query-focused summarization using DUC 05-07 data. In DUC-05 and DUC-06, participants were given 50 document clusters, where each cluster contains 25 news articles related to the same topic. Participants were asked to generate summaries of at most 250 words for each cluster. For each cluster, a title and a narrative describing a user's information need are provided. The narrative is usually composed of a set of questions or a multi-sentence task description. The main task in DUC-07 is the same as in DUC-06.

In DUC 05-07, ROUGE-2 was the primary criterion for evaluation, and thus we also report ROUGE-2[3] (both recall R, and precision F). Documents were processed as in Section 5.1. We used both the title and the narrative as query, where stop words, including some function words (e.g., "describe") that appear frequently in the query, were removed. All queries were then stemmed using the Porter Stemmer.

Note that there are several ways to incorporate query-focused information into both the coverage and diversity reward objectives. For instance, $\mathcal{C}_i(S)$ could be query-dependent in how it measures how much query-dependent information in i is covered by S. Also, the coefficient α could be query and sentence dependent, where it takes larger value when a sentence is more relevant to query (i.e., a larger value of α means later truncation, and therefore more possible coverage). Similarly, sentence clustering and singleton rewards in the diversity function can also

Toutanova et al. (2007)	11.89	11.89
Haghighi and Vanderwende (2009)	11.80	-
Celikyilmaz and Hakkani-tür (2010)	11.40	-
Best system in DUC-07 (peer 15)	12.45	12.29

be query-dependent. In this experiment, we explore an objective with a query-independent coverage function ($\mathcal{R}_1(S)$), indicating prior importance, combined with a query-dependent diversity reward function, where the latter is defined as:

$$\mathcal{R}_Q(S) = \sum_{k=1}^{K} \sqrt{\sum_{j \in S \cap P_k} \left(\frac{\beta}{N} \sum_{i \in V} w_{i,j} + (1-\beta) r_{j,Q} \right)},$$

where $0 \leq \beta \leq 1$, and $r_{j,Q}$ represents the relevance between sentence j to query Q. This query-dependent reward function is derived by using a singleton reward that is expressed as a convex combination of the query-independent score ($\frac{1}{N}\sum_{i \in V} w_{i,j}$) and the query-dependent score ($r_{j,Q}$) of a sentence. We simply used the number of terms (up to a bi-gram) that sentence j overlaps the query Q as $r_{j,Q}$, where the IDF weighting is not used (i.e., every term in the query, after stop word removal, was treated as equally important). Both query-independent and query-dependent scores were then normalized by their largest value respectively such that they had roughly the same dynamic range.

To better estimate of the relevance between query and sentences, we further expanded sentences with synonyms and hypernyms of its constituent words. In particular, part-of-speech tags were obtained for each sentence using the maximum entropy part-of-speech tagger (Ratnaparkhi, 1996), and all nouns were then

expanded with their synonyms and hypernyms using WordNet (Fellbaum, 1998). Note that these expanded documents were only used in the estimation $r_{j,Q}$, and we plan to further explore whether there is benefit to use the expanded documents either in sentence similarity estimation or in sentence clustering in our future work. We also tried to expand the query with synonyms and observed a performance decrease, presumably due to noisy information in a query expression.

While it is possible to use an approach that is similar to (Toutanova et al., 2007) to learn the coefficients in our objective function, we trained all coefficients to maximize ROUGE-2 F-measure score using the Nelder-Mead (derivative-free) method. Using $\mathcal{L}_1(S)+\lambda\mathcal{R}_Q(S)$ as the objective and with the same sentence clustering algorithm as in the generic summarization experiment ($K = 0.2N$), our system, when both trained and tested on DUC-05 (results in Table 2), outperforms the Bayesian query-focused summarization approach and the search-based structured prediction approach, which were also trained and tested on DUC-05 (Daumé et al., 2009). Note that the system in (Daumé et al., 2009) that achieves its best performance (8.24% in ROUGE-2 recall) is a so called "vine-growth" system, which can be seen as an abstractive approach, whereas our system is *purely* an extractive system. Comparing to the extractive system in (Daumé et al., 2009), our system performs much better (8.38% v.s. 7.67%). More importantly, when trained only on DUC-06 and tested on DUC-05 (results in Table 3), our approach outperforms the best system in DUC-05 significantly.

We further tested the system trained on DUC-05 on both DUC-06 and DUC-07. The results on DUC-06 are shown in Table. 4. Our system outperforms the best system in DUC-06, as well as two recent approaches (Shen and Li, 2010; Celikyilmaz and Hakkani-tür, 2010). On DUC-07, in terms of ROUGE-2 score, our system outperforms PYTHY (Toutanova et al., 2007), a state-of-the-art supervised summarization system, as well as two recent systems including a generative summarization system based on topic models (Haghighi and Vanderwende, 2009), and a hybrid hierarchical summarization system (Celikyilmaz and Hakkani-tür, 2010). It also achieves comparable performance to the best DUC-07 system. Note that in the best DUC-07 system (Pingali et al., 2007; Jagarlamudi et al., 2006), an external web search engine (Yahoo!) was used to estimate a language model for query relevance. In our system, no such web search expansion was used.

To further improve the performance of our system, we used both DUC-05 and DUC-06 as a training set, and introduced three diversity reward terms into the objective where three different sentence clusterings with different resolutions were produced (with sizes $0.3N, 0.15N$ and $0.05N$). Denoting a diversity reward corresponding to clustering κ as $\mathcal{R}_{Q,\kappa}(S)$, we model the summary quality as $\mathcal{L}_1(S) + \sum_{\kappa=1}^{3} \lambda_\kappa \mathcal{R}_{Q,\kappa}(S)$. As shown in Table 5, using this objective function with multi-resolution diversity rewards improves our results further, and outperforms the best system in DUC-07 in terms of ROUGE-2 F-measure score.

6 Conclusion and discussion

In this paper, we show that submodularity naturally arises in document summarization. Not only do many existing automatic summarization methods correspond to submodular function optimization, but also the widely used ROUGE evaluation is closely related to submodular functions. As the corresponding submodular optimization problem can be solved efficiently and effectively, the remaining question is then how to design a submodular objective that best models the task. To address this problem, we introduce a powerful class of monotone submodular functions that are well suited to document summarization by modeling two important properties of a summary, fidelity and diversity. While more advanced NLP techniques could be easily incorporated into our functions (e.g., language models could define a better $\mathcal{C}_i(S)$, more advanced relevance estimations for the singleton rewards r_i, and better and/or overlapping clustering algorithms for our diversity reward), we already show top results on standard benchmark evaluations using fairly basic NLP methods (e.g., term weighting and WordNet expansion), all, we believe, thanks to the power and generality of submodular functions. As information retrieval and web search are closely related to query-focused summarization, our approach might be beneficial in those areas as well.

Semi-supervised Relation Extraction with Large-scale Word Clustering

Ang Sun **Ralph Grishman** **Satoshi Sekine**

Abstract

We present a simple semi-supervised relation extraction system with large-scale word clustering. We focus on systematically exploring the effectiveness of different cluster-based features. We also propose several statistical methods for selecting clusters at an appropriate level of granularity. When training on different sizes of data, our semi-supervised approach consistently outperformed a state-of-the-art supervised baseline system.

1 Introduction

Relation extraction is an important information extraction task in natural language processing (NLP), with many practical applications. The goal of relation extraction is to detect and characterize semantic relations between pairs of entities in text. For example, a relation extraction system needs to be able to extract an *Employment* relation between the entities *US soldier* and *US* in the phrase *US soldier*.

Current supervised approaches for tackling this problem, in general, fall into two categories: feature based and kernel based. Given an entity pair and a sentence containing the pair, both approaches usually start with multiple level analyses of the sentence such as tokenization, partial or full syntactic parsing, and dependency parsing. Then the feature based method explicitly extracts a variety of lexical, syntactic and semantic features for statistical learning, either generative or discriminative (Miller et al., 2000; Kambhatla, 2004; Boschee et al., 2005; Grishman et al., 2005; Zhou et al., 2005; Jiang and Zhai, 2007). In contrast, the kernel based method does not explicitly extract features; it designs kernel functions over the structured sentence representations (sequence, dependency or parse tree) to capture the similarities between different relation instances (Zelenko et al., 2003; Bunescu and Mooney, 2005a; Bunescu and Mooney, 2005b; Zhao and Grishman, 2005; Zhang et al., 2006; Zhou et al., 2007; Qian et al., 2008). Both lines of work depend on effective features, either explicitly or implicitly.

The performance of a supervised relation extraction system is usually degraded by the sparsity of lexical features. For example, unless the example *US soldier* has previously been seen in the training data, it would be difficult for both the feature based and the kernel based systems to detect whether there is an *Employment* relation or not. Because the syntactic feature of the phrase *US soldier* is simply a noun-noun compound which is quite general, the words in it are crucial for extracting the relation.

This motivates our work to use word clusters as additional features for relation extraction. The assumption is that even if the word *soldier* may never have been seen in the annotated *Employment* relation instances, other words which share the same cluster membership with *soldier* such as *president* and *ambassador* may have been observed in the *Employment* instances. The absence of lexical features can be compensated by

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 521–529,
Portland, Oregon, June 19-24, 2011.

the cluster features. Moreover, word clusters may implicitly correspond to different relation classes. For example, the cluster of *president* may be related to the *Employment* relation as in *US president* while the cluster of *businessman* may be related to the *Affiliation* relation as in *US businessman*.

The main contributions of this paper are: we explore the cluster-based features in a systematic way and propose several statistical methods for selecting effective clusters. We study the impact of the size of training data on cluster features and analyze the performance improvements through an extensive experimental study.

The rest of this paper is organized as follows: Section 2 presents related work and Section 3 provides the background of the relation extraction task and the word clustering algorithm. Section 4 describes in detail a state-of-the-art supervised baseline system. Section 5 describes the cluster-based features and the cluster selection methods. We present experimental results in Section 6 and conclude in Section 7.

2 Related Work

The idea of using word clusters as features in discriminative learning was pioneered by Miller et al. (2004), who augmented name tagging training data with hierarchical word clusters generated by the Brown clustering algorithm (Brown et al., 1992) from a large unlabeled corpus. They used different thresholds to cut the word hierarchy to obtain clusters of various granularities for feature decoding. Ratinov and Roth (2009) and Turian et al. (2010) also explored this approach for name tagging. Though all of them used the same hierarchical word clustering algorithm for the task of name tagging and reported improvements, we noticed that the clusters used by Miller et al. (2004) were quite different from that of Ratinov and Roth (2009) and Turian et al. (2010). To our knowledge, there has not been work on selecting clusters in a principled way. We move a step further to explore several methods in choosing effective clusters. A second difference between this work and the above ones is that we utilize word clusters in the task of relation extraction which is very different from sequence labeling tasks such as name tagging and chunking.

Though Boschee et al. (2005) and Chan and Roth (2010) used word clusters in relation extraction, they shared the same limitation as the above approaches in choosing clusters. For example, Boschee et al. (2005) chose clusters of different granularities and Chan and Roth (2010) simply used a single threshold for cutting the word hierarchy. Moreover, Boschee et al. (2005) only augmented the *predicate* (typically a verb or a noun of the most importance in a relation in their definition) with word clusters while Chan and Roth (2010) performed this for any lexical feature consisting of a single word. In this paper, we systematically explore the effectiveness of adding word clusters to different lexical features.

3 Background

3.1 Relation Extraction

One of the well defined relation extraction tasks is the Automatic Content Extraction[1] (ACE) program sponsored by the U.S. government. ACE 2004 defined 7 major entity types: PER (Person), ORG (Organization), FAC (Facility), GPE (Geo-Political Entity: countries, cities, etc.), LOC (Location), WEA (Weapon) and VEH (Vehicle). An entity has three types of mention: NAM (proper name), NOM (nominal) or PRO (pronoun). A relation was defined over a pair of entity mentions within a single sentence. The 7 major relation types with examples are shown in Table 1. ACE 2004 also defined 23 relation subtypes. Following most of the previous work, this paper only focuses on relation extraction of major types.

Given a relation instance $x = (s, m_i, m_j)$, where m_i and m_j are a pair of mentions and s is the sentence containing the pair, the goal is to learn a function which maps the instance x to a type c, where c is one of the 7 defined relation types or the type *Nil* (no relation exists). There are two commonly used learning paradigms for relation extraction:

Flat: This strategy performs relation detection and classification at the same time. One multi-class classifier is trained to discriminate among the 7 relation types plus the *Nil* type.

Hierarchical: This one separates relation detection from relation classification. One binary

[1] Task definition: http://www.itl.nist.gov/iad/894.01/tests/ace/
ACE guidelines: http://projects.ldc.upenn.edu/ace/

classifier is trained first to distinguish between relation instances and non-relation instances. This can be done by grouping all the instances of the 7 relation types into a positive class and the instances of *Nil* into a negative class. Then the thresholded output of this binary classifier is used as training data for learning a multi-class classifier for the 7 relation types (Bunescu and Mooney, 2005b).

Type	Example
EMP-ORG	*US president*
PHYS	*a military base in Germany*
GPE-AFF	*U.S. businessman*
PER-SOC	*a spokesman for the senator*
DISC	*each of whom*
ART	*US helicopters*
OTHER-AFF	*Cuban-American people*

Table 1: ACE relation types and examples from the annotation guideline[2]. The heads of the two entity mentions are marked. Types are listed in decreasing order of frequency of occurrence in the ACE corpus.

3.2 Brown Word Clustering

The Brown algorithm is a hierarchical clustering algorithm which initially assigns each word to its own cluster and then repeatedly merges the two clusters which cause the least loss in average mutual information between adjacent clusters based on bigram statistics. By tracing the pairwise merging steps, one can obtain a word hierarchy which can be represented as a binary tree. A word can be compactly represented as a bit string by following the path from the root to itself in the tree, assigning a 0 for each left branch, and a 1 for each right branch. A cluster is just a branch of that tree. A high branch may correspond to more general concepts while the lower branches it includes might correspond to more specific ones.

Brown et al. (1992) described an efficient implementation based on a greedy algorithm which initially assigned only the most frequent words into distinct clusters. It is worth pointing out that in this implementation each word occupies a leaf in the hierarchy, but each leaf might contain more than one word as can be seen from Table 2. The lengths of the bit strings also vary among different words.

Table 2: An example of words and their bit string representations obtained in this paper. Words in bold are head words that appeared in Table 1.

4 Feature Based Relation Extraction

Given a pair of entity mentions $< m_i, m_j >$ and the sentence containing the pair, a feature based system extracts a feature vector v which contains diverse lexical, syntactic and semantic features. The goal is to learn a function which can estimate the conditional probability $p(c \mid v)$, the probability of a relation type c given the feature vector v. The type with the highest probability will be output as the *class label* for the mention pair.

We now describe a supervised baseline system with a very large set of features and its learning strategy.

4.1 Baseline Feature Set

We first adopted the full feature set from Zhou et al. (2005), a state-of-the-art feature based relation extraction system. For space reasons, we only show the lexical features as in Table 3 and refer the reader to the paper for the rest of the features.

At the lexical level, a relation instance can be seen as a sequence of tokens which form a five tuple *<Before, M1, Between, M2, After>*. Tokens of the five members and the interaction between the heads of the two mentions can be extracted as features as shown in Table 3.

In addition, we cherry-picked the following features which were not included in Zhou et al. (2005) but were shown to be quite effective for relation extraction.

Bigram of the words between the two mentions: This was extracted by both Zhao and Grishman (2005) and Jiang and Zhai (2007), aiming to

provide more order information of the tokens between the two mentions.

Patterns: There are three types of patterns: 1) the sequence of the tokens between the two mentions as used in Boschee et al. (2005); 2) the sequence of the heads of the constituents between the two mentions as used by Grishman et al. (2005); 3) the shortest dependency path between the two mentions in a dependency tree as adopted by Bunescu and Mooney (2005a). These patterns can provide more structured information of how the two mentions are connected.

Title list: This is tailored for the EMP-ORG type of relations as the head of one of the mentions is usually a title. The features are decoded in a way similar to that of Sun (2009).

Position	Feature	Description
Before	BM1F	*first word before* M1
	BM1L	*second word before* M1
M1	WM1	*bag-of-words in* M1
	HM1	*head*[3] *word of* M1
Between	WBNULL	*when no word in between*
	WBFL	*the only word in between when only one word in between*
	WBF	*first word in between when at least two words in between*
	WBL	*last word in between when at least two words in between*
	WBO	*other words in between except first and last words when at least three words in between*
M2	WM2	*bag-of-words in* M2
	HM2	*head word of* M2
M12	HM12	*combination of* HM1 *and* HM2
After	AM2F	*first word after* M2
	AM2L	*second word after* M2

Table 3: Lexical features for relation extraction.

4.2 Baseline Learning Strategy

We employ a simple learning framework that is similar to the *hierarchical* learning strategy as described in Section 3.1. Specifically, we first train a binary classifier to distinguish between relation instances and non-relation instances. Then rather than using the thresholded output of this binary classifier as training data, we use only the annotated relation instances to train a multi-class classifier for the 7 relation types. In the test phase, given a test instance x, we first apply the binary classifier to it for relation detection; if it is detected as a relation instance we then apply the multi-class relation classifier to classify it[4].

5 Cluster Feature Selection

The selection of cluster features aims to answer the following two questions: which lexical features should be augmented with word clusters to improve generalization accuracy? How to select clusters at an appropriate level of granularity? We will describe our solutions in Section 5.1 and 5.2.

5.1 Cluster Feature Decoding

While each one of the lexical features in Table 3 used by the baseline can potentially be augmented with word clusters, we believe the effectiveness of a lexical feature with augmentation of word clusters should be tested either individually or incrementally according to a rank of its *importance* as shown in Table 4. We will show the effectiveness of each cluster feature in the experiment section.

Importance	Lexical Feature	Description of lexical feature	Cluster Feature
1	HM	*HM1, HM2 and HM12*	HM1_WC, HM2_WC, HM12_WC
2	BagWM	*WM1 and WM2*	BagWM_WC
3	HC	*a head*[5] *of a chunk in context*	HC_WC
4	BagWC	*word of context*	BagWC_WC

Table 4: Cluster features ordered by *importance*.

The *importance* is based on linguistic intuitions and observations of the contributions of different lexical features from various feature based systems. Table 4 simplifies a relation instance as a three tuple <*Context*, *M1*, *M2*> where the *Context* includes the *Before*, *Between* and *After* from the

[3] The head word of a mention is normally set as the last word of the mention as in Zhou et al. (2005).

[4] Both the binary and multi-class classifiers output normalized probabilities in the range [0,1]. When the binary classifier's prediction probability is greater than 0.5, we take the prediction with the highest probability of the multi-class classifier as the final class label. When it is in the range [0.3,0.5], we only consider as the final class label the prediction of the multi-class classifier with a probability which is greater than 0.9. All other cases are taken as non-relation instances.

[5] The head of a chunk is defined as the last word in the chunk.

five tuple representation. As a relation in ACE is usually short, the words of the two entity mentions can provide more critical indications for relation classification than the words from the context. Within the two entity mentions, the head word of each mention is usually more important than other words of the mention; the conjunction of the two heads can provide an additional clue. And in general words other than the chunk head in the context do not contribute to establishing a relationship between the two entity mentions.

The cluster based semi-supervised system works by adding an additional layer of lexical features that incorporate word clusters as shown in column 4 of Table 4. Take the *US soldier* as an example, if we decide to use a length of 10 as a threshold to cut the Brown word hierarchy to generate word clusters, we will extract a cluster feature *HM1_WC10=1101111101* in addition to the lexical feature *HM1=soldier* given that the full bit string of *soldier* is *1101111101100* in Table 2. (Note that the cluster feature is a nominal feature, not to be confused with an integer feature.)

5.2 Selection of Clusters

Given the bit string representations of all the words in a vocabulary, researchers usually use prefixes of different lengths of the bit strings to produce word clusters of various granularities. However, how to choose the set of prefix lengths in a principled way? This has not been answered by prior work.

Our main idea is to learn the best set of prefix lengths, perhaps through the validation of their effectiveness on a development set of data. To our knowledge, previous research simply uses ad-hoc prefix lengths and lacks this training procedure. The training procedure can be extremely slow for reasons to be explained below.

Formally, let l be the set of available prefix lengths ranging from 1 bit to the length of the longest bit string in the Brown word hierarchy and let m be the set of prefix lengths we want to use in decoding cluster features, then the problem of selecting effective clusters transforms to finding a $|m|$-combination of the set l which maximizes system performance. The training procedure can be extremely time consuming if we enumerate every possible $|m|$-combination of l, given that $|m|$ can range from 1 to the size of l and the size of l equals the length of the longest bit string which is usually 20 when inducing 1,000 clusters using the Brown algorithm.

One way to achieve better efficiency is to consider only a subset of l instead of the full set. In addition, we limit ourselves to use sizes 3 and 4 for m for matching prior work. This keeps the cluster features to a manageable size considering that every word in your vocabulary could contribute to a lexical feature. For picking a subset of l, we propose below two statistical measures for computing the *importance* of a certain prefix length.

Information Gain (IG): IG measures the quality or *importance* of a feature *f* by computing the difference between the prior entropy of classes *C* and the posterior entropy, given values *V* of the feature *f* (Hunt et al., 1966; Quinlan, 1986). For our purpose, *C* is the set of relation types, *f* is a cluster-based feature with a certain prefix length such as *HM1_WC** where * means the prefix length and a value *v* is the prefix of the bit string representation of *HM1*. More formally, the IG of *f* is computed as follows:

$$IG(f) = -\sum_{c \in C} p(c) \log p(c) - \sum_{v \in V} (-p(v) \times \sum_{c \in C} p(c \mid v) \log p(c \mid v)) \quad (1)$$

where the first and second terms refer to the prior and posterior entropies respectively.

For each prefix length in the set l, we can compute its IG for a type of cluster feature and then rank the prefix lengths based on their IGs for that cluster feature. For simplicity, we rank the prefix lengths for a group of cluster features (a group is a row from column 4 in Table 4) by collapsing the individual cluster features into a single cluster feature. For example, we collapse the 3 types: *HM1_WC*, *HM2_WC* and *HM12_WC* into a single type *HM_WC* for computing the IG.

Prefix Coverage (PC): If we use a short prefix then the clusters produced correspond to the high branches in the word hierarchy and would be very general. The cluster features may not provide more informative information than the words themselves. Similarly, if we use a long prefix such as the length of the longest bit string, then maybe only a few of the lexical features can be *covered* by clusters. To capture this intuition, we define the PC of a prefix length *i* as below:

$$PC(i) = \frac{count(f_{c_i})}{count(f_l)} \quad (2)$$

where f_l stands for a lexical feature such as *HM1* and f_{c_i} a cluster feature with prefix length *i* such as *HM1_WCi*, $count(*)$ is the number of occurrences of that feature in training data.

Similar to IG, we compute PC for a group of cluster features, not for each individual feature.

In our experiments, the top 10 ranked prefix lengths based on IG and prefix lengths with PC values in the range [0.4, 0.9] were used.

In addition to the above two statistical measures, for comparison, we introduce another two simple but extreme measures for the selection of clusters.

Use All Prefixes (UA): UA produces a cluster feature at every available bit length with the hope that the underlying supervised system can *learn* proper weights of different cluster features during training. For example, if the full bit representation of "Apple" is "000", UA would produce three cluster features: *prefix1=0*, *prefix2=00* and *prefix3=000*. Because this method does not need validation on the development set, it is the laziest but the fastest method for *selecting* clusters.

Exhaustive Search (ES): ES works by trying every possible combination of the set *l* and picking the one that works the best for the development set. This is the most cautious and the slowest method for selecting clusters.

6 Experiments

In this section, we first present details of our unsupervised word clusters, the relation extraction data set and its preprocessing. We then present a series of experiments coupled with result analyses.

We used the English portion of the TDT5 corpora (LDC2006T18) as our unlabeled data for inducing word clusters. It contains roughly 83 million words in 3.4 million sentences with a vocabulary size of 450K. We left case intact in the corpora. Following previous work, we used Liang's implementation of the Brown clustering algorithm (Liang, 2005). We induced 1,000 word clusters for words that appeared at least twice in the corpora. The reduced vocabulary contains 255K unique words. The clusters are available at http://www.cs.nyu.edu/~asun/data/TDT5_BrownWC.tar.gz.

For relation extraction, we used the benchmark ACE 2004 training data. Following most of the previous research, we used in experiments the *nwire* (newswire) and *bnews* (broadcast news) genres of the data containing 348 documents and 4374 relation instances. We extracted an instance for every pair of mentions in the same sentence which were separated by no more than two other mentions. The non-relation instances generated were about 8 times more than the relation instances.

Preprocessing of the ACE documents: We used the Stanford parser[6] for syntactic and dependency parsing. We used chunklink[7] to derive chunking information from the Stanford parsing. Because some *bnews* documents are in lower case, we recover the case for the head of a mention if its type is NAM by making the first character into its upper case. This is for better matching between the words in ACE and the words in the unsupervised word clusters.

We used the OpenNLP [8] maximum entropy (maxent) package as our machine learning tool. We choose to work with maxent because the training is fast and it has a good support for multi-class classification.

6.1 Baseline Performance

Following previous work, we did 5-fold cross-validation on the 348 documents with hand-annotated entity mentions. Our results are shown in Table 5 which also lists the results of another three state-of-the-art feature based systems. For this and the following experiments, all the results were computed at the relation mention level.

System	P(%)	R(%)	F(%)
Zhou et al. (2007)[9]	78.2	63.4	70.1
Zhao and Grishman (2005)[10]	69.2	71.5	70.4
Our Baseline	73.4	67.7	70.4
Jiang and Zhai (2007) [11]	72.4	70.2	71.3

Table 5: Performance comparison on the ACE 2004 data over the 7 relation types.

[6] http://nlp.stanford.edu/software/lex-parser.shtml
[7] http://ilk.uvt.nl/team/sabine/chunklink/README.html
[8] http://opennlp.sourceforge.net/
[9] Zhou et al. (2005) tested their system on the ACE 2003 data; Zhou et al. (2007) tested their system on the ACE 2004 data.
[10] The paper gives a recall value of 70.5, which is not consistent with the given values of P and F. An examination of the correspondence in preparing this paper indicates that the correct recall value is 71.5.
[11] The result is from using the *All* features in Jiang and Zhai (2007). It is not quite clear from the paper that whether they used the 348 documents or the whole 2004 training data.

Note that although all the 4 systems did 5-fold cross-validation on the ACE 2004 data, the detailed data partition might be different. Also, we were doing cross-validation at the document level which we believe was more natural than the instance level. Nonetheless, we believe our baseline system has achieved very competitive performance.

6.2 The Effectiveness of Cluster Selection Methods

We investigated the tradeoff between performance and training time of each proposed method in selecting clusters. In this experiment, we randomly selected 70 documents from the 348 documents as test data which roughly equaled the size of 1 fold in the baseline in Section 6.1. For the baseline in this section, all the rest of the documents were used as training data. For the semi-supervised system, 70 percent of the rest of the documents were randomly selected as training data and 30 percent as development data. The set of prefix lengths that worked the best for the development set was chosen to select clusters. We only used the cluster feature *HM_WC* in this experiment.

System	F	△	Training Time (in minute)
Baseline	70.70		1
UA	71.19	+0.49	1.5
PC3	71.65	+0.95	30
PC4	71.72	+1.02	46
IG3	71.65	+0.95	45
IG4	71.68	+0.98	78
ES3	71.66	+0.96	465
ES4	71.60	+0.90	1678

Table 6: The tradeoff between performance and training time of each method in selecting clusters. PC3 means using 3 prefixes with the PC method. △ in this paper means the difference between a system and the baseline.

Table 6 shows that all the 4 proposed methods improved baseline performance, with UA as the fastest and ES as the slowest. It was interesting that ES did not always outperform the two statistical methods which might be because of its overfitting to the development set. In general, both PC and IG had good balances between performance and training time. There was no dramatic difference in performance between using 3 and 4 prefix lengths.

For the rest of this paper, we will only use PC4 as our method in selecting clusters.

6.3 The Effectiveness of Cluster Features

The baseline here is the same one used in Section 6.1. For the semi-supervised system, each test fold was the same one used in the baseline and the other 4 folds were further split into a training set and a development set in a ratio of 7:3 for selecting clusters. We first added the cluster features individually into the baseline and then added them incrementally according to the order specified in Table 4.

System		F	△
1	Baseline	70.4	
2	1 + HM_WC	71.5	+ 1.1
3	1 + BagWM_WC	71.0	+ 0.6
4	1 + HC_WC	69.6	- 0.8
5	1 + BagWC_WC	46.1	- 24.3
6	2 + BagWM_WC	71.0	+ 0.6
7	6 + HC_WC	70.6	+ 0.2
8	7+ BagWC_WC	50.3	- 20.1

Table 7: Performance [12] of the baseline and using different cluster features with PC4 over the 7 types.

We found that adding clusters to the heads of the two mentions was the most effective way of introducing cluster features. Adding clusters to the words of the mentions can also help, though not as good as the heads. We were surprised that the heads of chunks in context did not help. This might be because ACE relations are usually short and the limited number of long relations is not sufficient in generalizing cluster features. Adding clusters to every word in context hurt the performance a lot. Because of the behavior of each individual feature, it was not surprising that adding them incrementally did not give more performance gain.

For the rest of this paper, we will only use *HM_WC* as cluster features.

6.4 The Impact of Training Size

We studied the impact of training data size on cluster features as shown in Table 8. The test data was always the same as the 5-fold used in the baseline in Section 6.1. no matter the size of the training data. The training documents for the

[12] All the improvements of F in Table 7, 8 and 9 were significant at confidence levels >= 95%.

Table 9: Performance of each individual relation type based on 5-fold cross-validation.

current size setup were randomly selected and added to the previous size setup (if applicable). For example, we randomly selected another 25 documents and added them to the previous 50 documents to get 75 documents. We made sure that every document participated in this experiment. The training documents for each size setup were split into a real training set and a development set in a ratio of 7:3 for selecting clusters.

There are some clear trends in Table 8. Under each training size, PC4 consistently outperformed the baseline and the system Prefix10 for relation classification. For PC4, the gain for classification was more pronounced than detection. The mixed detection results of Prefix10 indicated that only using a single prefix may not be stable.

We did not observe the same trend in the reduction of annotation need with cluster-based features as in Koo et al. (2008) for dependency parsing. PC4 with sizes 50, 125, 175 outperformed the baseline with sizes 75, 175, 225 respectively. But this was not the case when PC4 was tested with sizes 75 and 225. This might due to the complexity of the relation extraction task.

6.5 Analysis

There were on average 69 cross-type errors in the baseline in Section 6.1 which were reduced to 56 by using PC4. Table 9 showed that most of the improvements involved EMP-ORG, GPE-AFF, DISC, ART and OTHER-AFF. The performance gain for PER-SOC was not as pronounced as the other five types. The five types of relations are ambiguous as they share the same entity type GPE while the PER-SOC relation only holds between PER and PER. This reflects that word clusters can help to distinguish between ambiguous relation types.

As mentioned earlier the gain of relation detection was not as pronounced as classification as shown in Table 8. The unbalanced distribution of relation instances and non-relation instances remains as an obstacle for pushing the performance of relation extraction to the next level.

7 Conclusion and Future Work

We have described a semi-supervised relation extraction system with large-scale word clustering. We have systematically explored the effectiveness of different cluster-based features. We have also demonstrated that the two proposed statistical methods are both effective and efficient in selecting clusters at an appropriate level of granularity through an extensive experimental study.

Based on the experimental results, we plan to investigate additional ways to improve the performance of relation detection. Moreover, extending word clustering to phrase clustering (Lin and Wu, 2009) and pattern clustering (Sun and Grishman, 2010) is worth future investigation for relation extraction.

Abstract

We present a novel approach to discovering relations and their instantiations from a collection of documents in a single domain. Our approach learns relation types by exploiting *meta-constraints* that characterize the general qualities of a good relation in any domain. These constraints state that instances of a single relation should exhibit regularities at multiple levels of linguistic structure, including lexicography, syntax, and document-level context. We capture these regularities via the structure of our probabilistic model as well as a set of declaratively-specified constraints enforced during posterior inference. Across two domains our approach successfully recovers hidden relation structure, comparable to or outperforming previous state-of-the-art approaches. Furthermore, we find that a small set of constraints is applicable across the domains, and that using domain-specific constraints can further improve performance. [1]

1 Introduction

In this paper, we introduce a novel approach for the unsupervised learning of relations and their instantiations from a set of in-domain documents. Given a collection of news articles about earthquakes, for example, our method discovers relations such as the earthquake's location and resulting damage, and extracts phrases representing the relations' instantiations. Clusters of similar in-domain documents are increasingly available in forms such as Wikipedia article categories, financial reports, and biographies.

A strong earthquake rocked the Philippine island of Mindoro early Tuesday, [destroying]$_{ind}$ [some homes]$_{arg}$ ...
A strong earthquake hit the China-Burma border early Wednesday ... The official Xinhua News Agency said [some houses]$_{arg}$ were [damaged]$_{ind}$ ...
A strong earthquake with a preliminary magnitude of 6.6 shook northwestern Greece on Saturday, ... [destroying]$_{ind}$ [hundreds of old houses]$_{arg}$ ...

Figure 1: Excerpts from newswire articles about earthquakes. The indicator and argument words for the *damage* relation are highlighted.

In contrast to previous work, our approach learns from *domain-independent meta-constraints* on relation expression, rather than supervision specific to particular relations and their instances. In particular, we leverage the linguistic intuition that documents in a single domain exhibit regularities in how they express their relations. These regularities occur both in the relations' lexical and syntactic realizations as well as at the level of document structure. For instance, consider the *damage* relation excerpted from earthquake articles in Figure 1. Lexically, we observe similar words in the instances and their contexts, such as "destroying" and "houses." Syntactically, in two instances the relation instantiation is the dependency child of the word "destroying." On the discourse level, these instances appear toward the beginning of their respective documents. In general, valid relations in many domains are characterized by these coherence properties.

We capture these regularities using a Bayesian model where the underlying relations are repre-

sented as latent variables. The model takes as input a constituent-parsed corpus and explains how the constituents arise from the latent variables. Each relation instantiation is encoded by the variables as a relation-evoking *indicator* word (*e.g.*, "destroying") and corresponding *argument* constituent (*e.g.*, "some homes").[2] Our approach capitalizes on relation regularity in two ways. First, the model's generative process encourages coherence in the local features and placement of relation instances. Second, we apply posterior regularization (Graça et al., 2007) during inference to enforce higher-level declarative constraints, such as requiring indicators and arguments to be syntactically linked.

We evaluate our approach on two domains previously studied for high-level document structure analysis, news articles about earthquakes and financial markets. Our results demonstrate that we can successfully identify domain-relevant relations. We also study the importance and effectiveness of the declaratively-specified constraints. In particular, we find that a small set of declarative constraints are effective across domains, while additional domain-specific constraints yield further benefits.

2 Related Work

Extraction with Reduced Supervision Recent research in information extraction has taken large steps toward reducing the need for labeled data. Examples include using bootstrapping to amplify small seed sets of example outputs (Agichtein and Gravano, 2000; Yangarber et al., 2000; Bunescu and Mooney, 2007; Zhu et al., 2009), leveraging existing databases that overlap with the text (Mintz et al., 2009; Yao et al., 2010), and learning general domain-independent knowledge bases by exploiting redundancies in large web and news corpora (Hasegawa et al., 2004; Shinyama and Sekine, 2006; Banko et al., 2007; Yates and Etzioni, 2009).

Our approach is distinct in both the supervision and data we operate over. First, in contrast to bootstrapping and database matching approaches, we learn from meta-qualities, such as low variability in syntactic patterns, that characterize a good relation. We hypothesize that these properties hold across relations in different domains. Second, in contrast to work that builds general relation databases from heterogeneous corpora, our focus is on learning the relations salient in a single domain. Our setup is more germane to specialized domains expressing information not broadly available on the web.

Earlier work in unsupervised information extraction has also leveraged meta-knowledge independent of specific relation types, such as declaratively-specified syntactic patterns (Riloff, 1996), frequent dependency subtree patterns (Sudo et al., 2003), and automatic clusterings of syntactic patterns (Lin and Pantel, 2001; Zhang et al., 2005) and contexts (Chen et al., 2005; Rosenfeld and Feldman, 2007). Our approach incorporates a broader range of constraints and balances constraints with underlying patterns learned from the data, thereby requiring more sophisticated machinery for modeling and inference.

Extraction with Constraints Previous work has recognized the appeal of applying declarative constraints to extraction. In a supervised setting, Roth and Yih (2004) induce relations by using linear programming to impose global declarative constraints on the output from a set of classifiers trained on local features. Chang et al. (2007) propose an objective function for semi-supervised extraction that balances likelihood of labeled instances and constraint violation on unlabeled instances. Recent work has also explored how certain kinds of supervision can be formulated as constraints on model posteriors. Such constraints are not declarative, but instead based on annotations of words' majority relation labels (Mann and McCallum, 2008) and pre-existing databases with the desired output schema (Bellare and McCallum, 2009). In contrast to previous work, our approach explores a different class of constraints that does not rely on supervision that is specific to particular relation types and their instances.

3 Model

Our work performs in-domain relation discovery by leveraging regularities in relation expression at the lexical, syntactic, and discourse levels. These regularities are captured via two components: a probabilistic model that explains how documents are generated from latent relation variables and a technique

[2] We do not use the word "argument" in the syntactic sense—a relation's argument may or may not be the syntactic dependency argument of its indicator.

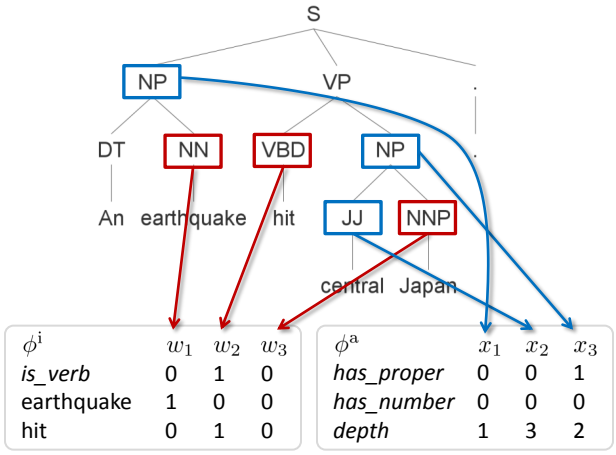

Figure 2: Words w and constituents x of syntactic parses are represented with indicator features ϕ^{i} and argument features ϕ^{a} respectively. A single relation instantiation is a pair of indicator w and argument x; we filter w to be nouns and verbs and x to be noun phrases and adjectives.

for biasing inference to adhere to declaratively-specified constraints on relation expression. This section describes the generative process, while Sections 4 and 5 discuss declarative constraints.

3.1 Problem Formulation

Our input is a corpus of constituent-parsed documents and a number K of relation types. The output is K clusters of semantically related relation instantiations. We represent these instantiations as a pair of *indicator* word and *argument* sequence from the same sentence. The indicator's role is to anchor a relation and identify its type. We only allow nouns or verbs to be indicators. For instance, in the earthquake domain a likely indicator for *damage* would be "destroyed." The argument is the actual relation value, *e.g.*, "some homes," and corresponds to a noun phrase or adjective.[3]

Along with the document parse trees, we utilize a set of features $\phi^{\text{i}}(w)$ and $\phi^{\text{a}}(x)$ describing each potential indicator word w and argument constituent x, respectively. An example feature representation is shown in Figure 2. These features can encode words, part-of-speech tags, context, and so on. Indicator and argument feature definitions need not be the same (*e.g.*, *has_number* is important for arguments but irrelevant for indicators).[4]

3.2 Generative Process

Our model associates each relation type k with a set of *feature distributions* θ_k and a *location distribution* λ_k. Each instantiation's indicator and argument, and its position within a document, are drawn from these distributions. By sharing distributions within each relation, the model places high probability mass on clusters of instantiations that are coherent in features and position. Furthermore, we allow at most one instantiation per document and relation, so as to target relations that are relevant to the entire document.

There are three steps to the generative process. First, we draw feature and location distributions for each relation. Second, an instantiation is selected for every pair of document d and relation k. Third, the indicator features of each word and argument features of each constituent are generated based on the relation parameters and instantiations. Figure 3 presents a reference for the generative process.

Generating Relation Parameters Each relation k is associated with four feature distribution parameter vectors: θ^{i}_k for indicator words, θ^{bi}_k for non-indicator words, θ^{a}_k for argument constituents, and θ^{ba}_k for non-argument constituents. Each of these is a set of multinomial parameters per feature drawn from a symmetric Dirichlet prior. A likely indicator word should have features that are highly probable according to θ^{i}_k, and likewise for arguments and θ^{a}_k. Parameters θ^{bi}_k and θ^{ba}_k represent *background* distributions for non-relation words and constituents, similar in spirit to other uses of background distributions that filter out irrelevant words (Che, 2006).[5] By drawing each instance from these distributions, we encourage the relation to be coherent in local lexical and syntactic properties.

Each relation type k is also associated with a parameter vector λ_k over document segments drawn from a symmetric Dirichlet prior. Documents are divided into L equal-length segments; λ_k states how likely relation k is for each segment, with one null outcome for the relation not occurring in the document. Because λ_k is shared within a relation, its

[3] In this paper we focus on unary relations; binary relations can be modeled with extensions of the hidden variables and constraints.

[4] We consider only categorical features here, though the extension to continuous or ordinal features is straightforward.

[5] We use separate background distributions for each relation to make inference more tractable.

For each relation type k:

- For each indicator feature ϕ^{i} draw feature distributions $\theta^{\text{i}}_{k,\phi^{\text{i}}}, \theta^{\text{bi}}_{k,\phi^{\text{i}}} \sim \text{Dir}(\theta_0)$
- For each argument feature ϕ^{a} draw feature distributions $\theta^{\text{a}}_{k,\phi^{\text{a}}}, \theta^{\text{ba}}_{k,\phi^{\text{a}}} \sim \text{Dir}(\theta_0)$
- Draw location distribution $\lambda_k \sim \text{Dir}(\lambda_0)$

For each relation type k and document d:

- Select document segment $s_{d,k} \sim \text{Mult}(\lambda_k)$
- Select sentence $z_{d,k}$ uniformly from segment $s_{d,k}$, and indicator $i_{d,k}$ and argument $a_{d,k}$ uniformly from sentence $z_{d,k}$

For each word w in every document d:

- Draw each indicator feature $\phi^{\text{i}}(w) \sim \text{Mult}\left(\frac{1}{Z}\prod_{k=1}^{K}\theta_{k,\phi^{\text{i}}}\right)$, where $\theta_{k,\phi^{\text{i}}}$ is $\theta^{\text{i}}_{k,\phi^{\text{i}}}$ if $i_{d,k} = w$ and $\theta^{\text{bi}}_{k,\phi^{\text{i}}}$ otherwise

For each constituent x in every document d:

- Draw each argument feature $\phi^{\text{a}}(x) \sim \text{Mult}\left(\frac{1}{Z}\prod_{k=1}^{K}\theta_{k,\phi^{\text{a}}}\right)$, where $\theta_{k,\phi^{\text{a}}}$ is $\theta^{\text{a}}_{k,\phi^{\text{a}}}$ if $a_{d,k} = x$ and $\theta^{\text{ba}}_{k,\phi^{\text{a}}}$ otherwise

Figure 3: The generative process for model parameters and features. In the above Dir and Mult refer respectively to the Dirichlet distribution and multinomial distribution. Fixed hyperparameters are subscripted with zero.

instances will tend to occur in the same relative positions across documents. The model can learn, for example, that a particular relation typically occurs in the first quarter of a document (if $L = 4$).

Generating Relation Instantiations For every relation type k and document d, we first choose which portion of the document (if any) contains the instantiation by drawing a document segment $s_{d,k}$ from λ_k. Our model only draws one instantiation per pair of k and d, so each discovered instantiation within a document is a separate relation. We then choose the specific sentence $z_{d,k}$ uniformly from within the segment, and the indicator word $i_{d,k}$ and argument constituent $a_{d,k}$ uniformly from within that sentence.

Generating Text Finally, we draw the feature values. We make a Naïve Bayes assumption between features, drawing each independently conditioned on relation structure. For a word w, we want all relations to be able to influence its generation. Toward this end, we compute the element-wise product of feature parameters across relations $k = 1, \ldots, K$, using indicator parameters θ^{i}_k if relation k selected w as an indicator word (if $i_{d,k} = w$) and background parameters θ^{bi}_k otherwise. The result is then normalized to form a valid multinomial that produces word w's features. Constituents are drawn similarly from every relations' argument distributions.

4 Inference with Constraints

The model presented above leverages relation regularities in local features and document placement. However, it is unable to specify global syntactic preferences about relation expression, such as indicators and arguments being in the same clause. Another issue with this model is that different relations could overlap in their indicators and arguments.[6]

To overcome these obstacles, we apply declarative constraints by imposing inequality constraints on expectations of the posterior during inference using *posterior regularization* (Graça et al., 2007). In this section we present the technical details of the approach; Section 5 explains the specific linguistically-motivated constraints we consider.

4.1 Inference with Posterior Regularization

We first review how posterior regularization impacts the variational inference procedure in general. Let θ, z, and x denote the parameters, hidden structure, and observations of an arbitrary model. We are interested in estimating the posterior distribution $p(\theta, z \mid x)$ by finding a distribution $q(\theta, z) \in \mathcal{Q}$ that is minimal in KL-divergence to the true posterior:

$$\begin{aligned}&\text{KL}(q(\theta, z) \parallel p(\theta, z \mid x)) \\ &= \int q(\theta, z) \log \frac{q(\theta, z)}{p(\theta, z, x)} d\theta dz + \log p(x). \quad (1)\end{aligned}$$

For tractability, variational inference typically makes a mean-field assumption that restricts the set $\mathcal{Q}$ to distributions where θ and z are independent, *i.e.*, $q(\theta, z) = q(\theta)q(z)$. We then optimize equation 1 by coordinate-wise descent on $q(\theta)$ and $q(z)$.

To incorporate constraints into inference, we further restrict $\mathcal{Q}$ to distributions that satisfy a given

[6] In fact, a true *maximum a posteriori* estimate of the model parameters would find the same most salient relation over and over again for every k, rather than finding K different relations.

set of inequality constraints, each of the form $\mathbb{E}_q[f(z)] \leq b$. Here, $f(z)$ is a deterministic function of z and b is a user-specified threshold. Inequalities in the opposite direction simply require negating $f(z)$ and b. For example, we could apply a syntactic constraint of the form $\mathbb{E}_q[f(z)] \geq b$, where $f(z)$ counts the number of indicator/argument pairs that are syntactically connected in a pre-specified manner (*e.g.*, the indicator and argument modify the same verb), and b is a fixed threshold.

Given a set $\mathcal{C}$ of constraints with functions $f_c(z)$ and thresholds b_c, the updates for $q(\theta)$ and $q(z)$ from equation 1 are as follows:

$$q(\theta) = \underset{q(\theta)}{\operatorname{argmin}} \operatorname{KL}\big(q(\theta) \parallel q'(\theta)\big), \tag{2}$$

where $q'(\theta) \propto \exp \mathbb{E}_{q(z)}[\log p(\theta, z, x)]$, and

$$q(z) = \underset{q(z)}{\operatorname{argmin}} \operatorname{KL}\big(q(z) \parallel q'(z)\big) \quad s.t. \quad \mathbb{E}_{q(z)}[f_c(z)] \leq b_c, \ \ \forall c \in \mathcal{C}, \tag{3}$$

where $q'(z) \propto \exp \mathbb{E}_{q(\theta)}[\log p(\theta, z, x)]$. Equation 2 is not affected by the posterior constraints and is updated by setting $q(\theta)$ to $q'(\theta)$. We solve equation 3 in its dual form (Graça et al., 2007):

$$\underset{\kappa}{\operatorname{argmin}} \sum_{c \in \mathcal{C}} \kappa_c b_c + \log \sum_z q'(z) e^{-\sum_{c \in \mathcal{C}} \kappa_c f_c(z)} \quad s.t. \quad \kappa_c \geq 0, \ \ \forall c \in \mathcal{C}. \tag{4}$$

With the box constraints of equation 4, a numerical optimization procedure such as L-BFGS-B (Byrd et al., 1995) can be used to find optimal dual parameters κ^*. The original $q(z)$ is then updated to $q'(z) \exp\big(-\sum_{c \in \mathcal{C}} \kappa_c^* f_c(z)\big)$ and renormalized.

4.2 Updates for our Model

Our model uses this mean-field factorization:

$$q(\theta, \lambda, z, a, i) = \prod_{k=1}^{K} q(\lambda_k; \hat{\lambda}_k) q(\theta_k^{\text{i}}; \hat{\theta}_k^{\text{i}}) q(\theta_k^{\text{bi}}; \hat{\theta}_k^{\text{bi}}) q(\theta_k^{\text{a}}; \hat{\theta}_k^{\text{a}}) q(\theta_k^{\text{ba}}; \hat{\theta}_k^{\text{ba}}) \times \prod_d q(z_{d,k}, a_{d,k}, i_{d,k}; \hat{c}_{d,k}) \tag{5}$$

In the above, $\hat{\lambda}$ and $\hat{\theta}$ are Dirichlet distribution parameters, and $\hat{c}$ are multinomial parameters. Note that we do not factorize the distribution of z, i, and a for a single document and relation, instead representing their joint distribution with a single set of variational parameters $\hat{c}$. This is tractable because a single relation occurs only once per document, reducing the joint search space of z, i, and a. The factors in equation 5 are updated one at a time while holding the other factors fixed.

Updating $\hat{\theta}$ Due to the Naïve Bayes assumption between features, each feature's $q(\theta)$ distributions can be updated separately. However, the product between feature parameters of different relations introduces a nonconjugacy in the model, precluding a closed form update. Instead we numerically optimize equation 1 with respect to each $\hat{\theta}$, similarly to previous work (Boyd-Graber and Blei, 2008). For instance, $\hat{\theta}^{\text{i}}_{k,\phi}$ of relation k and feature ϕ is updated by finding the gradient of equation 1 with respect to $\hat{\theta}^{\text{i}}_{k,\phi}$ and applying L-BFGS. Parameters $\hat{\theta}^{\text{bi}}$, $\hat{\theta}^{\text{a}}$, and $\hat{\theta}^{\text{ba}}$ are updated analogously.

Updating $\hat{\lambda}$ This update follows the standard closed form for Dirichlet parameters:

$$\hat{\lambda}_{k,\ell} = \lambda_0 + \mathbb{E}_{q(z,a,i)}[C_\ell(z, a, i)], \tag{6}$$

where C_ℓ counts the number of times z falls into segment ℓ of a document.

Updating $\hat{c}$ Parameters $\hat{c}$ are updated by first computing an unconstrained update $q'(z, a, i; \hat{c}')$:

$$\hat{c}'_{d,k,(z,a,i)} \propto \exp\Bigg(\mathbb{E}_{q(\lambda_k)}[\log p(z, a, i \mid \lambda_k)] + \mathbb{E}_{q(\theta^{\text{i}}_k)}[\log p(i \mid \theta^{\text{i}}_k)] + \sum_{w \neq i} \mathbb{E}_{q(\theta^{\text{bi}}_k)}[\log p(w \mid \theta^{\text{bi}}_k)] + \mathbb{E}_{q(\theta^{\text{a}}_k)}[\log p(a \mid \theta^{\text{a}}_k)] + \sum_{x \neq a} \mathbb{E}_{q(\theta^{\text{ba}}_k)}[\log p(x \mid \theta^{\text{ba}}_k)] \Bigg)$$

We then perform the minimization on the dual in equation 4 under the provided constraints to derive a final update to the constrained $\hat{c}$.

Simplifying Approximation The update for $\hat{\theta}$ requires numerical optimization due to the nonconjugacy introduced by the point-wise product in feature generation. If instead we have every relation type separately generate a copy of the corpus, the $\hat{\theta}$

	Quantity	$f(z, a, i)$	$\leq$ or $\geq$	b
Syntax	$\forall k$	Counts i, a of relation k that match a pattern (see text)	$\geq$	$0.8D$
Prevalence	$\forall k$	Counts instantiations of relation k	$\geq$	$0.8D$
Separation (ind)	$\forall w$	Counts times w selected as i	$\leq$	2
Separation (arg)	$\forall w$	Counts times w selected as part of a	$\leq$	1

Table 1: Each constraint takes the form $\mathbb{E}_q[f(z, a, i)] \leq b$ or $\mathbb{E}_q[f(z, a, i)] \geq b$; D denotes the number of corpus documents, $\forall k$ means one constraint per relation type, and $\forall w$ means one constraint per token in the corpus.

updates becomes closed-form expressions similar to equation 6. This approximation yields similar parameter estimates as the true updates while vastly improving speed, so we use it in our experiments.

5 Declarative Constraints

We now have the machinery to incorporate a variety of declarative constraints during inference. The classes of domain-independent constraints we study are summarized in Table 1. For the proportion constraints we arbitrarily select a threshold of 80% without any tuning, in the spirit of building a domain-independent approach.

Syntax As previous work has observed, most relations are expressed using a limited number of common syntactic patterns (Riloff, 1996; Banko and Etzioni, 2008). Our syntactic constraint captures this insight by requiring that a certain proportion of the induced instantiations for each relation match one of these syntactic patterns:

- The indicator is a verb and the argument's headword is either the child or grandchild of the indicator word in the dependency tree.
- The indicator is a noun and the argument is a modifier or complement.
- The indicator is a noun in a verb's subject and the argument is in the corresponding object.

Prevalence For a relation to be domain-relevant, it should occur in numerous documents across the corpus, so we institute a constraint on the number of times a relation is instantiated. Note that the effect of this constraint could also be achieved by tuning the prior probability of a relation not occurring in a document. However, this prior would need to be adjusted every time the number of documents or feature selection changes; using a constraint is an appealing alternative that is portable across domains.

Separation The separation constraint encourages diversity in the discovered relation types by restricting the number of times a single word can serve as either an indicator or part of the argument of a relation instance. Specifically, we require that every token of the corpus occurs at most once as a word in a relation's argument in expectation. On the other hand, a single word can sometimes be evocative of multiple relations (*e.g.*, "occurred" signals both *date* and *time* in "occurred on Friday at 3pm"). Thus, we allow each word to serve as an indicator more than once, arbitrarily fixing the limit at two.

6 Experimental Setup

Datasets and Metrics We evaluate on two datasets, financial market reports and newswire articles about earthquakes, previously used in work on high-level content analysis (Barzilay and Lee, 2004; Lapata, 2006). *Finance* articles chronicle daily market movements of currencies and stock indexes, and *earthquake* articles document specific earthquakes. Constituent parses are obtained automatically using the Stanford parser (Klein and Manning, 2003) and then converted to dependency parses using the PennConvertor tool (Johansson and Nugues, 2007). We manually annotated relations for both corpora, selecting relation types that occurred frequently in each domain. We found 15 types for *finance* and 9 for *earthquake*. Corpus statistics are summarized below, and example relation types are shown in Table 2.

	Docs	Sent/Doc	Tok/Doc	Vocab
Finance	100	12.1	262.9	2918
Earthquake	200	9.3	210.3	3155

In our task, annotation conventions for desired output relations can greatly impact token-level performance, and the model cannot learn to fit a particular convention by looking at example data. For example, earthquakes times are frequently reported in both local and GMT, and either may be arbitrarily chosen as correct. Moreover, the baseline we

Finance	Bond	104.58 yen, 98.37 yen
	Dollar Change	up 0.52 yen, down 0.01 yen
	Tokyo Index Change	down 5.38 points or 0.41 percent, up 0.16 points, insignificant in percentage terms
Earthquake	Damage	about 10000 homes, some buildings, no information
	Epicenter	Patuca about 185 miles (300 kilometers) south of Quito, 110 kilometers (65 miles) from shore under the surface of the Flores sea in the Indonesian archipelago
	Magnitude	5.7, 6, magnitude-4

Table 2: Example relation types identified in the *finance* and *earthquake* datasets with example instance arguments.

compare against produces lambda calculus formulas rather than spans of text as output, so a token-level comparison requires transforming its output.

For these reasons, we evaluate on both *sentence-level* and *token-level* precision, recall, and F-score. Precision is measured by mapping every induced relation cluster to its closest gold relation and computing the proportion of predicted sentences or words that are correct. Conversely, for recall we map every gold relation to its closest predicted relation and find the proportion of gold sentences or words that are predicted. This mapping technique is based on the many-to-one scheme used for evaluating unsupervised part-of-speech induction (Johnson, 2007). Note that sentence-level scores are always at least as high as token-level scores, since it is possible to select a sentence correctly but none of its true relation tokens while the opposite is not possible.

Domain-specific Constraints On top of the cross-domain constraints from Section 5, we study whether imposing basic domain-specific constraints can be beneficial. The *finance* dataset is heavily quantitative, so we consider applying a single domain-specific constraint stating that most relation arguments should include a number. Likewise, *earthquake* articles are typically written with a majority of the relevant information toward the beginning of the document, so its domain-specific constraint is that most relations should occur in the first two sentences of a document. Note that these domain-specific constraints are not specific to individual relations or instances, but rather encode a preference across all relation types. In both cases, we again use an 80% threshold without tuning.

Features For indicators, we use the word, part of speech, and word stem. For arguments, we use the word, syntactic constituent label, the head word of the parent constituent, and the dependency label of the argument to its parent.

Baselines We compare against three alternative unsupervised approaches. Note that the first two only identify relation-bearing sentences, not the specific words that participate in the relation.

Clustering (CLUTO): A straightforward way of identifying sentences bearing the same relation is to simply cluster them. We implement a clustering baseline using the CLUTO toolkit with word and part-of-speech features. As with our model, we set the number of clusters K to the true number of relation types.

Mallows Topic Model (MTM): Another technique for grouping similar sentences is the Mallows-based topic model of Chen et al. (2009). The datasets we consider here exhibit high-level regularities in content organization, so we expect that a topic model with global constraints could identify plausible clusters of relation-bearing sentences. Again, K is set to the true number of relation types.

Unsupervised Semantic Parsing (USP): Our final unsupervised comparison is to USP, an unsupervised deep semantic parser introduced by Poon and Domingos (2009). USP induces a lambda calculus representation of an entire corpus and was shown to be competitive with open information extraction approaches (Lin and Pantel, 2001; Banko et al., 2007). We give USP the required Stanford dependency format as input (de Marneffe and Manning, 2008). We find that the results are sensitive to the cluster granularity prior, so we tune this parameter and report the best-performing runs.

We recognize that USP targets a different output representation than ours: a hierarchical semantic structure over the entirety of a dependency-parsed text. In contrast, we focus on discovering a limited number K of domain-relevant relations expressed as constituent phrases. Despite these differences, both

methods ultimately aim to capture domain-specific relations expressed with varying verbalizations, and both operate over in-domain input corpora supplemented with syntactic information. For these reasons, USP provides a clear and valuable point of comparison. For this comparison, we transform USP's lambda calculus formulas to relation spans as follows. First, we group lambda forms by a combination of core form, argument form, and the parent's core form.[7] We then filter to the K relations that appear in the most documents. For token-level evaluation we take the dependency tree fragment corresponding to the lambda form. For example, in the sentence "a strong earthquake rocked the Philippines island of Mindoro early Tuesday," USP learns that the word "Tuesday" has a core form corresponding to words {*Tuesday*, *Wednesday*, *Saturday*}, a parent form corresponding to words {*shook*, *rock*, *hit*, *jolt*}, and an argument form of TMOD; all phrases with this same combination are grouped as a relation.

Training Regimes and Hyperparameters For each run of our model we perform three random restarts to convergence and select the posterior with lowest final free energy. We fix K to the true number of annotated relation types for both our model and USP and L (the number of document segments) to five. Dirichlet hyperparameters are set to 0.1.

7 Results

Table 3's first two sections present the results of our main evaluation. For *earthquake*, the far more difficult domain, our base model with only the domain-independent constraints strongly outperforms all three baselines across both metrics. For *finance*, the CLUTO and USP baselines achieve performance comparable to or slightly better than our base model. Our approach, however, has the advantage of providing a formalism for seamlessly incorporating additional arbitrary domain-specific constraints. When we add such constraints (denoted as *model+DSC*), we achieve consistently higher performance than all baselines across both datasets and metrics, demonstrating that this approach provides a simple and effective framework for injecting domain knowledge into relation discovery.

The first two baselines correspond to a setup where the number of sentence clusters K is set to the true number of relation types. This has the effect of lowering precision because each sentence must be assigned a cluster. To mitigate this impact, we experimented with using $K + N$ clusters, with N ranging from 1 to 30. In each case, we then keep only the K largest clusters. For the *earthquake* dataset, increasing N improves performance until some point, after which performance degrades. However, the best F-Score corresponding to the optimal number of clusters is 42.2, still far below our model's 66.0 F-score. For the *finance* domain, increasing the number of clusters hurts performance.

Our results show a large gap in F-score between the sentence and token-level evaluations for both the USP baseline and our model. A qualitative analysis of the results indicates that our model often picks up on regularities that are difficult to distinguish without relation-specific supervision. For *earthquake*, a *location* may be annotated as "the Philippine island of Mindoro" while we predict just the word "Mindoro." For *finance*, an *index change* can be annotated as "30 points, or 0.8 percent," while our model identifies "30 points" and "0.8 percent" as separate relations. In practice, these outputs are all plausible discoveries, and a practitioner desiring specific outputs could impose additional constraints to guide relation discovery toward them.

The Impact of Constraints To understand the impact of the declarative constraints, we perform an ablation analysis on the constraint sets. We consider removing the constraints on syntactic patterns (*no-syn*) and the constraints disallowing relations to overlap (*no-sep*) from the full domain-independent model.[8] We also try a version with hard syntactic constraints (*hard-syn*), which requires that *every* extraction match one of the three syntactic patterns specified by the syntactic constraint.

Table 3's bottom section presents the results of this evaluation. The model's performance degrades when either of the two constraint sets are removed, demonstrating that the constraints are in fact beneficial for relation discovery. Additionally, in the *hard-syn* case, performance drops dramatically for *finance*

[7] This grouping mechanism yields better results than only grouping by core form.

[8] Prevalence constraints are always enforced, as otherwise the prior on not instantiating a relation would need to be tuned.

	Finance						Earthquake					
	Sentence-level			Token-level			Sentence-level			Token-level		
	Prec	Rec	F1	Prec	Rec	F1	Prec	Rec	F1	Prec	Rec	F1

Table 3: Top section: our model, with and without domain-specific constraints (DSC). Middle section: The three baselines. Bottom section: ablation analysis of constraint sets for our model. For all scores, higher is better.

while remaining almost unchanged for *earthquake*. This suggests that formulating constraints as soft inequalities on posterior expectations gives our model the flexibility to accommodate both the underlying signal in the data and the declarative constraints.

Comparison against Supervised CRF Our final set of experiments compares a *semi-supervised* version of our model against a conditional random field (CRF) model. The CRF model was trained using the same features as our model's argument features. To incorporate training examples in our model, we simply treat annotated relation instances as observed variables. For both the baselines and our model, we experiment with using up to 10 annotated documents. At each of those levels of supervision, we average results over 10 randomly drawn training sets.

At the sentence level, our model compares very favorably to the supervised CRF. For *finance*, it takes at least 10 annotated documents (corresponding to roughly 130 annotated relation instances) for the CRF to match the semi-supervised model's performance. For *earthquake*, using even 10 annotated documents (about 71 relation instances) is not sufficient to match our model's performance.

At the token level, the supervised CRF baseline is far more competitive. Using a single labeled document (13 relation instances) yields superior performance to either of our model variants for *finance*, while four labeled documents (29 relation instances) do the same for *earthquake*. This result is not surprising—our model makes strong domain-independent assumptions about how underlying patterns of regularities in the text connect to relation expression. Without domain-specific supervision such assumptions are necessary, but they can prevent the model from fully utilizing available labeled instances. Moreover, being able to annotate even a single document requires a broad understanding of every relation type germane to the domain, which can be infeasible when there are many unfamiliar, complex domains to process.

In light of our strong sentence-level performance, this suggests a possible human-assisted application: use our model to identify promising relation-bearing sentences in a new domain, then have a human annotate those sentences for use by a supervised approach to achieve optimal token-level extraction.

8 Conclusions

This paper has presented a constraint-based approach to in-domain relation discovery. We have shown that a generative model augmented with declarative constraints on the model posterior can successfully identify domain-relevant relations and their instantiations. Furthermore, we found that a single set of constraints can be used across divergent domains, and that tailoring constraints specific to a domain can yield further performance benefits.

Knowledge-Based Weak Supervision for Information Extraction of Overlapping Relations

Abstract

Information extraction (IE) holds the promise of generating a large-scale knowledge base from the Web's natural language text. Knowledge-based weak supervision, using structured data to heuristically label a training corpus, works towards this goal by enabling the automated learning of a potentially unbounded number of relation extractors. Recently, researchers have developed multi-instance learning algorithms to combat the noisy training data that can come from heuristic labeling, but their models assume relations are *disjoint* — for example they cannot extract the pair `Founded(Jobs, Apple)` and `CEO-of(Jobs, Apple)`.

This paper presents a novel approach for multi-instance learning with overlapping relations that combines a sentence-level extraction model with a simple, corpus-level component for aggregating the individual facts. We apply our model to learn extractors for NY Times text using weak supervision from Freebase. Experiments show that the approach runs quickly and yields surprising gains in accuracy, at both the aggregate and sentence level.

1 Introduction

Information-extraction (IE), the process of generating relational data from natural-language text, continues to gain attention. Many researchers dream of creating a large repository of high-quality extracted tuples, arguing that such a knowledge base could benefit many important tasks such as question answering and summarization. Most approaches to IE use supervised learning of relation-specific examples, which can achieve high precision and recall. Unfortunately, however, fully supervised methods are limited by the availability of training data and are unlikely to scale to the thousands of relations found on the Web.

A more promising approach, often called "weak" or "distant" supervision, creates its own training data by heuristically matching the contents of a database to corresponding text (Craven and Kumlien, 1999). For example, suppose that $r(e_1, e_2) =$ `Founded(Jobs,Apple)` is a ground tuple in the database and $s =$"Steve Jobs founded Apple, Inc." is a sentence containing synonyms for both $e_1 =$ `Jobs` and $e_2 =$ `Apple`, then s may be a natural language expression of the fact that $r(e_1, e_2)$ holds and could be a useful training example.

While weak supervision works well when the textual corpus is tightly aligned to the database contents (*e.g.*, matching Wikipedia infoboxes to associated articles (Hoffmann et al., 2010)), Riedel *et al.* (2010) observe that the heuristic leads to noisy data and poor extraction performance when the method is applied more broadly (*e.g.*, matching Freebase records to NY Times articles). To fix this problem they cast weak supervision as a form of multi-instance learning, assuming only that *at least one* of the sentences containing e_1 and e_2 are expressing $r(e_1, e_2)$, and their method yields a substantial improvement in extraction performance.

However, Riedel *et al.*'s model (like that of previous systems (Mintz et al., 2009)) assumes that *relations do not overlap* — there cannot exist two facts $r(e_1, e_2)$ and $q(e_1, e_2)$ that are both true for any pair of entities, e_1 and e_2. Unfortunately, this assumption is often violated;

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 541–550,
Portland, Oregon, June 19-24, 2011.

for example both `Founded(Jobs, Apple)` and `CEO-of(Jobs, Apple)` are clearly true. Indeed, 18.3% of the weak supervision facts in Freebase that match sentences in the NY Times 2007 corpus have overlapping relations.

This paper presents MULTIR, a novel model of weak supervision that makes the following contributions:

- MULTIR introduces a probabilistic, graphical model of multi-instance learning which handles overlapping relations.
- MULTIR also produces accurate sentence-level predictions, decoding individual sentences as well as making corpus-level extractions.
- MULTIR is computationally tractable. Inference reduces to weighted set cover, for which it uses a greedy approximation with worst case running time $O(|\mathrm{R}| \cdot |\mathrm{S}|)$ where R is the set of possible relations and S is largest set of sentences for any entity pair. In practice, MULTIR runs very quickly.
- We present experiments showing that MULTIR outperforms a reimplementation of Riedel *et al.* (2010)'s approach on both aggregate (corpus as a whole) and sentential extractions. Additional experiments characterize aspects of MULTIR's performance.

2 Weak Supervision from a Database

Given a corpus of text, we seek to extract facts about *entities*, such as the company `Apple` or the city `Boston`. A *ground fact* (or *relation instance*), is an expression $r(\mathbf{e})$ where r is a relation name, for example `Founded` or `CEO-of`, and $\mathbf{e} = e_1, \ldots, e_n$ is a list of entities.

An *entity mention* is a contiguous sequence of textual tokens denoting an entity. In this paper we assume that there is an *oracle* which can identify all entity mentions in a corpus, but the oracle doesn't normalize or disambiguate these mentions. We use $e_i \in E$ to denote both an entity and its name (*i.e.*, the tokens in its mention).

A *relation mention* is a sequence of text (including one or more entity mentions) which states that some ground fact $r(\mathbf{e})$ is true. For example, "Steve Ballmer, CEO of Microsoft, spoke recently at CES." contains three entity mentions as well as a relation mention for `CEO-of(Steve Ballmer, Microsoft)`. In this paper we restrict our attention to binary relations. Furthermore, we assume that both entity mentions appear as noun phrases in a single sentence.

The task of *aggregate extraction* takes two inputs, Σ, a set of sentences comprising the corpus, and an extraction model; as output it should produce a set of ground facts, I, such that each fact $r(\mathbf{e}) \in I$ is expressed somewhere in the corpus.

Sentential extraction takes the same input and likewise produces I, but in addition it also produces a function, $\Gamma : I \rightarrow \mathcal{P}(\Sigma)$, which identifies, for each $r(\mathbf{e}) \in I$, the set of sentences in Σ that contain a mention describing $r(\mathbf{e})$. In general, the corpus-level extraction problem is easier, since it need only make aggregate predictions, perhaps using corpus-wide statistics. In contrast, sentence-level extraction must justify each extraction with *every* sentence which expresses the fact.

The *knowledge-based weakly supervised learning* problem takes as input (1) Σ, a training corpus, (2) E, a set of entities mentioned in that corpus, (3) R, a set of relation names, and (4), Δ, a set of ground facts of relations in R. As output the learner produces an extraction model.

3 Modeling Overlapping Relations

We define an undirected graphical model that allows joint reasoning about aggregate (corpus-level) and sentence-level extraction decisions. Figure 1(a) shows the model in plate form.

3.1 Random Variables

There exists a connected component for each pair of entities $\mathbf{e} = (e_1, e_2) \in \mathrm{E} \times \mathrm{E}$ that models all of the extraction decisions for this pair. There is one Boolean output variable Y^r for each relation name $r \in \mathrm{R}$, which represents whether the ground fact $r(\mathbf{e})$ is true. Including this set of binary random variables enables our model to extract overlapping relations.

Let $S_{(e_1,e_2)} \subset \Sigma$ be the set of sentences which contain mentions of both of the entities. For each sentence $x_i \in S_{(e_1,e_2)}$ there exists a latent variable Z_i which ranges over the relation names $r \in R$ and,

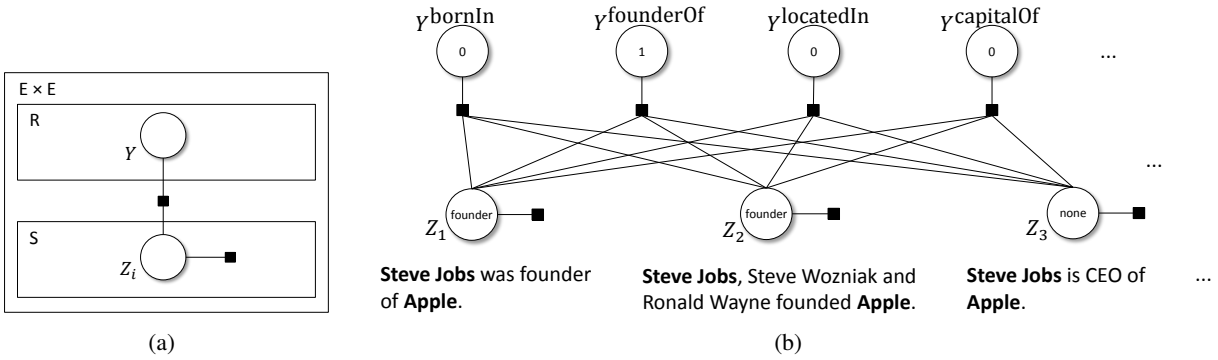

Figure 1: (a) Network structure depicted as plate model and (b) an example network instantiation for the pair of entities `Steve Jobs`, `Apple`.

importantly, also the distinct value `none`. Z_i should be assigned a value $r \in R$ only when x_i expresses the ground fact $r(\mathbf{e})$, thereby modeling sentence-level extraction.

Figure 1(b) shows an example instantiation of the model with four relation names and three sentences.

3.2 A Joint, Conditional Extraction Model

We use a conditional probability model that defines a joint distribution over all of the extraction random variables defined above. The model is undirected and includes repeated factors for making sentence level predictions as well as globals factors for aggregating these choices.

For each entity pair $\mathbf{e} = (e_1, e_2)$, define $\mathbf{x}$ to be a vector concatenating the individual sentences $x_i \in S_{(e_1,e_2)}$, $\mathbf{Y}$ to be vector of binary Y^r random variables, one for each $r \in R$, and $\mathbf{Z}$ to be the vector of Z_i variables, one for each sentence x_i. Our conditional extraction model is defined as follows:

$$p(\mathbf{Y} = \mathbf{y}, \mathbf{Z} = \mathbf{z}|\mathbf{x}; \theta) \stackrel{\text{def}}{=} \frac{1}{Z_x} \prod_r \Phi^{\text{join}}(y^r, \mathbf{z}) \prod_i \Phi^{\text{extract}}(z_i, x_i)$$

where the parameter vector θ is used, below, to define the factor Φ^{extract}.

The factors Φ^{join} are deterministic OR operators

$$\Phi^{\text{join}}(y^r, \mathbf{z}) \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } y^r = true \wedge \exists i : z_i = r \\ 0 & \text{otherwise} \end{cases}$$

which are included to ensure that the ground fact $r(\mathbf{e})$ is predicted at the aggregate level for the assignment $Y^r = y^r$ only if at least one of the sentence level assignments $Z_i = z_i$ signals a mention of $r(\mathbf{e})$.

The extraction factors Φ^{extract} are given by

$$\Phi^{\text{extract}}(z_i, x_i) \stackrel{\text{def}}{=} \exp\left(\sum_j \theta_j \phi_j(z_i, x_i)\right)$$

where the features ϕ_j are sensitive to the relation name assigned to extraction variable z_i, if any, and cues from the sentence x_i. We will make use of the Mintz *et al.* (2009) sentence-level features in the expeiments, as described in Section 7.

3.3 Discussion

This model was designed to provide a joint approach where extraction decisions are almost entirely driven by sentence-level reasoning. However, defining the Y^r random variables and tying them to the sentence-level variables, Z_i, provides a direct method for modeling weak supervision. We can simply train the model so that the Y variables match the facts in the database, treating the Z_i as hidden variables that can take any value, as long as they produce the correct aggregate predictions.

This approach is related to the multi-instance learning approach of Riedel *et al.* (2010), in that both models include sentence-level and aggregate random variables. However, their sentence level variables are binary and they only have a single aggregate variable that takes values $r \in R \cup \{\texttt{none}\}$, thereby ruling out overlapping relations. Additionally, their aggregate decisions make use of Mintz-style aggregate features (Mintz et al., 2009), that collect evidence from multiple sentences, while we use

Inputs:
(1) Σ, a set of sentences,
(2) E, a set of entities mentioned in the sentences,
(3) R, a set of relation names, and
(4) Δ, a database of atomic facts of the form $r(e_1, e_2)$ for $r \in R$ and $e_i \in E$.

Definitions:
We define the training set $\{(\mathbf{x}_i, \mathbf{y}_i)|i = 1 \ldots n\}$, where i is an index corresponding to a particular entity pair (e_j, e_k) in Δ, $\mathbf{x}_i$ contains all of the sentences in Σ with mentions of this pair, and $\mathbf{y}_i =$ **relVector**(e_j, e_k).

Computation:
initialize parameter vector $\mathbf{\Theta} \leftarrow \mathbf{0}$
for $t = 1...T$ **do**
  for $i = 1...n$ **do**
    $(\mathbf{y}', \mathbf{z}') \leftarrow \arg\max_{\mathbf{y},\mathbf{z}} p(\mathbf{y}, \mathbf{z}|\mathbf{x_i}; \theta)$
    if $\mathbf{y}' \neq \mathbf{y_i}$ **then**
      $\mathbf{z}^* \leftarrow \arg\max_{\mathbf{z}} p(\mathbf{z}|\mathbf{x_i}, \mathbf{y_i}; \theta)$
      $\mathbf{\Theta} \leftarrow \mathbf{\Theta} + \phi(\mathbf{x_i}, \mathbf{z}^*) - \phi(\mathbf{x_i}, \mathbf{z}')$
    end if
  end for
end for

only the deterministic OR nodes. Perhaps surprising, we are still able to improve performance at both the sentential and aggregate extraction tasks.

4 Learning

We now present a multi-instance learning algorithm for our weak-supervision model that treats the sentence-level extraction random variables Z_i as latent, and uses facts from a database (*e.g.*, Freebase) as supervision for the aggregate-level variables Y^r.

As input we have (1) Σ, a set of sentences, (2) E, a set of entities mentioned in the sentences, (3) R, a set of relation names, and (4) Δ, a database of atomic facts of the form $r(e_1, e_2)$ for $r \in R$ and $e_i \in E$. Since we are using weak learning, the Y^r variables in $\mathbf{Y}$ are not directly observed, but can be approximated from the database Δ. We use a procedure, **relVector**(e_1, e_2) to return a bit vector whose j^{th} bit is one if $r_j(e_1, e_2) \in \Delta$. The vector does *not* have a bit for the special *none* relation; if there is no relation between the two entities, all bits are zero.

Finally, we can now define the training set to be pairs $\{(\mathbf{x}_i, \mathbf{y}_i)|i = 1 \ldots n\}$, where i is an index corresponding to a particular entity pair (e_j, e_k), $\mathbf{x}_i$ contains all of the sentences with mentions of this pair, and $\mathbf{y}_i =$ **relVector**(e_j, e_k).

Given this form of supervision, we would like to find the setting for θ with the highest likelihood:

$$O(\theta) = \prod_i p(\mathbf{y}_i|\mathbf{x}_i; \theta) = \prod_i \sum_{\mathbf{z}} p(\mathbf{y}_i, \mathbf{z}|\mathbf{x}_i; \theta)$$

However, this objective would be difficult to optimize exactly, and algorithms for doing so would be unlikely to scale to data sets of the size we consider. Instead, we make two approximations, described below, leading to a Perceptron-style additive (Collins, 2002) parameter update scheme which has been modified to reason about hidden variables, similar in style to the approaches of (Liang et al., 2006; Zettlemoyer and Collins, 2007), but adapted for our specific model. This approximate algorithm is computationally efficient and, as we will see, works well in practice.

Our first modification is to do online learning instead of optimizing the full objective. Define the feature sums $\phi(\mathbf{x}, \mathbf{z}) = \sum_j \phi(x_j, z_j)$ which range over the sentences, as indexed by j. Now, we can define an update based on the gradient of the local log likelihood for example i:

$$\frac{\partial \log O_i(\theta)}{\partial \theta_j} = E_{p(\mathbf{z}|\mathbf{x}_i, \mathbf{y}_i; \theta)}[\phi_j(\mathbf{x}_i, \mathbf{z})] - E_{p(\mathbf{y}, \mathbf{z}|\mathbf{x}_i; \theta)}[\phi_j(\mathbf{x}_i, \mathbf{z})]$$

where the deterministic OR Φ^{join} factors ensure that the first expectation assigns positive probability only to assignments that produce the labeled facts $\mathbf{y}_i$ but that the second considers all valid sets of extractions.

Of course, these expectations themselves, especially the second one, would be difficult to compute exactly. Our second modification is to do a Viterbi approximation, by replacing the expectations with maximizations. Specifically, we compute the most likely sentence extractions for the label facts $\arg\max_{\mathbf{z}} p(\mathbf{z}|\mathbf{x}_i, \mathbf{y}_i; \theta)$ and the most likely extraction for the input, without regard to the labels, $\arg\max_{\mathbf{y},\mathbf{z}} p(\mathbf{y}, \mathbf{z}|\mathbf{x}_i; \theta)$. We then compute the features for these assignments and do a simple additive update. The final algorithm is detailed in Figure 2.

5 Inference

To support learning, as described above, we need to compute assignments $\arg\max_{\mathbf{z}} p(\mathbf{z}|\mathbf{x}, \mathbf{y}; \theta)$ and $\arg\max_{\mathbf{y},\mathbf{z}} p(\mathbf{y}, \mathbf{z}|\mathbf{x}; \theta)$. In this section, we describe algorithms for both cases that use the deterministic OR nodes to simplify the required computations.

Predicting the most likely joint extraction $\arg\max_{\mathbf{y},\mathbf{z}} p(\mathbf{y}, \mathbf{z}|\mathbf{x}; \theta)$ can be done efficiently given the structure of our model. In particular, we note that the factors Φ^{join} represent deterministic dependencies between $\mathbf{Z}$ and $\mathbf{Y}$, which when satisfied do not affect the probability of the solution. It is thus sufficient to independently compute an assignment for each sentence-level extraction variable Z_i, ignoring the deterministic dependencies. The optimal setting for the aggregate variables $\mathbf{Y}$ is then simply the assignment that is consistent with these extractions. The time complexity is $O(|\mathrm{R}| \cdot |\mathrm{S}|)$.

Predicting sentence level extractions given weak supervision facts, $\arg\max_{\mathbf{z}} p(\mathbf{z}|\mathbf{x}, \mathbf{y}; \theta)$, is more challenging. We start by computing extraction scores $\Phi^{\text{extract}}(x_i, z_i)$ for each possible extraction assignment $Z_i = z_i$ at each sentence $x_i \in \mathrm{S}$, and storing the values in a dynamic programming table. Next, we must find the most likely assignment $\mathbf{z}$ that respects our output variables $\mathbf{y}$. It turns out that this problem is a variant of the weighted, edge-cover problem, for which there exist polynomial time optimal solutions.

Let $G = (\mathcal{E}, \mathcal{V} = \mathcal{V}^{\mathrm{S}} \cup \mathcal{V}^{\mathbf{y}})$ be a complete weighted bipartite graph with one node $v_i^{\mathrm{S}} \in \mathcal{V}^{\mathrm{S}}$ for each sentence $x_i \in \mathrm{S}$ and one node $v_r^{\mathbf{y}} \in \mathcal{V}^{\mathbf{y}}$ for each relation $r \in \mathrm{R}$ where $y^r = 1$. The edge weights are given by $c((v_i^{\mathrm{S}}, v_r^{\mathbf{y}})) \stackrel{\text{def}}{=} \Phi^{\text{extract}}(\mathbf{x}_i, z_i)$. Our goal is to select a subset of the edges which maximizes the sum of their weights, subject to each node $v_i^{\mathrm{S}} \in \mathcal{V}^{\mathrm{S}}$ being incident to exactly one edge, and each node $v_r^{\mathbf{y}} \in \mathcal{V}^{\mathbf{y}}$ being incident to at least one edge.

Exact Solution An exact solution can be obtained by first computing the maximum weighted bipartite matching, and adding edges to nodes which are not incident to an edge. This can be computed in time $O(|\mathcal{V}|(|\mathcal{E}| + |\mathcal{V}| \log |\mathcal{V}|))$, which we can rewrite as $O((|\mathrm{R}| + |\mathrm{S}|)(|\mathrm{R}||\mathrm{S}| + (|\mathrm{R}| + |\mathrm{S}|) \log(|\mathrm{R}| + |\mathrm{S}|)))$.

Approximate Solution An approximate solution can be obtained by iterating over the nodes in $\mathcal{V}^{\mathbf{y}}$, and each time adding the highest weight incident edge whose addition doesn't violate a constraint. The running time is $O(|\mathrm{R}||\mathrm{S}|)$. This greedy search guarantees each fact is extracted at least once and allows any additional extractions that increase the overall probability of the assignment. Given the computational advantage, we use it in all of the experimental evaluations.

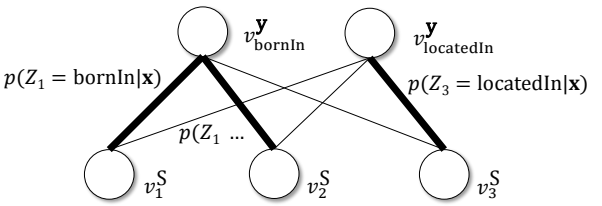

Figure 3: Inference of $\arg\max_{\mathbf{z}} p(\mathbf{Z} = \mathbf{z}|\mathbf{x}, \mathbf{y})$ requires solving a weighted, edge-cover problem.

6 Experimental Setup

We follow the approach of Riedel *et al.* (2010) for generating weak supervision data, computing features, and evaluating aggregate extraction. We also introduce new metrics for measuring sentential extraction performance, both relation-independent and relation-specific.

6.1 Data Generation

We used the same data sets as Riedel *et al.* (2010) for weak supervision. The data was first tagged with the Stanford NER system (Finkel et al., 2005) and then entity mentions were found by collecting each continuous phrase where words were tagged identically (*i.e.*, as a person, location, or organization). Finally, these phrases were matched to the names of Freebase entities.

Given the set of matches, define Σ to be set of NY Times sentences with two matched phrases, E to be the set of Freebase entities which were mentioned in one or more sentences, Δ to be the set of Freebase facts whose arguments, e_1 and e_2 were mentioned in a sentence in Σ, and R to be set of relations names used in the facts of Δ. These sets define the weak supervision data.

6.2 Features and Initialization

We use the set of sentence-level features described by Riedel *et al.* (2010), which were originally de-

veloped by Mintz *et al.* (2009). These include indicators for various lexical, part of speech, named entity, and dependency tree path properties of entity mentions in specific sentences, as computed with the Malt dependency parser (Nivre and Nilsson, 2004) and OpenNLP POS tagger[1]. However, unlike the previous work, we did not make use of any features that explicitly aggregate these properties across multiple mention instances.

The MULTIR algorithm has a single parameter T, the number of training iterations, that must be specified manually. We used $T = 50$ iterations, which performed best in development experiments.

6.3 Evaluation Metrics

Evaluation is challenging, since only a small percentage (approximately 3%) of sentences match facts in Freebase, and the number of matches is highly unbalanced across relations, as we will see in more detail later. We use the following metrics.

Aggregate Extraction Let Δ^e be the set of extracted relations for any of the systems; we compute aggregate precision and recall by comparing Δ^e with Δ. This metric is easily computed but underestimates extraction accuracy because Freebase is incomplete and some true relations in Δ^e will be marked wrong.

Sentential Extraction Let S^e be the sentences where some system extracted a relation and S^F be the sentences that match the arguments of a fact in Δ. We manually compute sentential extraction accuracy by sampling a set of 1000 sentences from $S^e \cup S^F$ and manually labeling the correct extraction decision, either a relation $r \in R$ or $none$. We then report precision and recall for each system on this set of sampled sentences. These results provide a good approximation to the true precision but can overestimate the actual recall, since we did not manually check the much larger set of sentences where no approach predicted extractions.

6.4 Precision / Recall Curves

To compute precision / recall curves for the tasks, we ranked the MULTIR extractions as follows. For sentence-level evaluations, we ordered according to the extraction factor score $\Phi^{\text{extract}}(z_i, x_i)$. For aggregate comparisons, we set the score for an extraction $Y^r = true$ to be the max of the extraction factor scores for the sentences where r was extracted.

[1] http://opennlp.sourceforge.net/

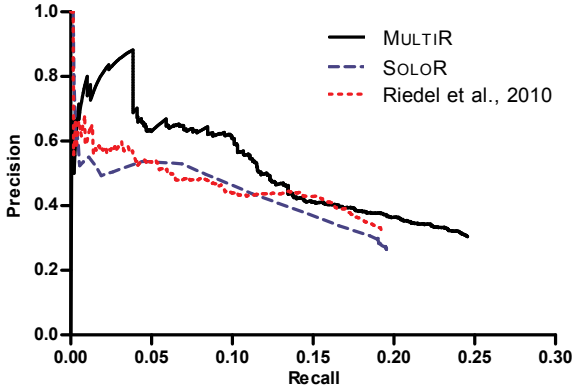

Figure 4: Aggregate extraction precision / recall curves for Riedel *et al.* (2010), a reimplementation of that approach (SOLOR), and our algorithm (MULTIR).

7 Experiments

To evaluate our algorithm, we first compare it to an existing approach for using multi-instance learning with weak supervision (Riedel et al., 2010), using the same data and features. We report both aggregate extraction and sentential extraction results. We then investigate relation-specific performance of our system. Finally, we report running time comparisons.

7.1 Aggregate Extraction

Figure 4 shows approximate precision / recall curves for three systems computed with aggregate metrics (Section 6.3) that test how closely the extractions match the facts in Freebase. The systems include the original results reported by Riedel *et al.* (2010) as well as our new model (MULTIR). We also compare with SOLOR, a reimplementation of their algorithm, which we built in Factorie (McCallum et al., 2009), and will use later to evaluate sentential extraction.

MULTIR achieves competitive or higher precision over all ranges of recall, with the exception of the very low recall range of approximately 0-1%. It also significantly extends the highest recall achieved, from 20% to 25%, with little loss in precision. To investigate the low precision in the 0-1% recall range, we manually checked the ten highest con-

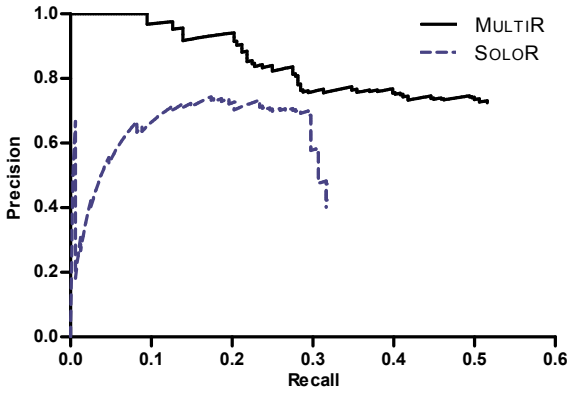

Figure 5: Sentential extraction precision / recall curves for MULTIR and SOLOR.

fidence extractions produced by MULTIR that were marked wrong. We found that all ten were true facts that were simply missing from Freebase. A manual evaluation, as we perform next for sentential extraction, would remove this dip.

7.2 Sentential Extraction

Although their model includes variables to model sentential extraction, Riedel *et al.* (2010) did not report sentence level performance. To generate the precision / recall curve we used the joint model assignment score for each of the sentences that contributed to the aggregate extraction decision.

Figure 4 shows approximate precision / recall curves for MULTIR and SOLOR computed against manually generated sentence labels, as defined in Section 6.3. MULTIR achieves significantly higher recall with a consistently high level of precision. At the highest recall point, MULTIR reaches 72.4% precision and 51.9% recall, for an F1 score of 60.5%.

7.3 Relation-Specific Performance

Since the data contains an unbalanced number of instances of each relation, we also report precision and recall for each of the ten most frequent relations. Let S_r^M be the sentences where MULTIR extracted an instance of relation $r \in R$, and let S_r^F be the sentences that match the arguments of a fact about relation r in Δ. For each r, we sample 100 sentences from both S_r^M and S_r^F and manually check accuracy. To estimate precision $\tilde{P}_r$ we compute the ratio of true relation mentions in S_r^M, and to estimate recall $\tilde{R}_r$ we take the ratio of true relation mentions in S_r^F which are returned by our system.

Table 1 presents this approximate precision and recall for MULTIR on each of the relations, along with statistics we computed to measure the quality of the weak supervision. Precision is high for the majority of relations but recall is consistently lower. We also see that the Freebase matches are highly skewed in quantity and can be low quality for some relations, with very few of them actually corresponding to true extractions. The approach generally performs best on the relations with a sufficiently large number of true matches, in many cases even achieving precision that outperforms the accuracy of the heuristic matches, at reasonable recall levels.

7.4 Overlapping Relations

Table 1 also highlights some of the effects of learning with overlapping relations. For example, in the data, almost all of the matches for the administrative_divisions relation overlap with the contains relation, because they both model relationships for a pair of locations. Since, in general, sentences are much more likely to describe a contains relation, this overlap leads to a situation were almost none of the administrate_division matches are true ones, and we cannot accurately learn an extractor. However, we can still learn to accurately extract the contains relation, despite the distracting matches. Similarly, the place_of_birth and place_of_death relations tend to overlap, since it is often the case that people are born and die in the same city. In both cases, the precision outperforms the labeling accuracy and the recall is relatively high.

To measure the impact of modeling overlapping relations, we also evaluated a simple, restricted baseline. Instead of labeling each entity pair with the set of all true Freebase facts, we created a dataset where each true relation was used to create a different training example. Training MULTIR on this data simulates effects of conflicting supervision that can come from not modeling overlaps. On average across relations, precision increases 12 points but recall drops 26 points, for an overall reduction in F1 score from 60.5% to 40.3%.

7.5 Running Time

One final advantage of our model is the modest running time. Our implementation of the

Relation	Freebase Matches		MULTIR	
	#sents	% true	$\tilde{P}$	$\tilde{R}$
/business/person/company	302	89.0	100.0	25.8
/people/person/place_lived	450	60.0	80.0	6.7
/location/location/contains	2793	51.0	100.0	56.0
/business/company/founders	95	48.4	71.4	10.9
/people/person/nationality	723	41.0	85.7	15.0
/location/neighborhood/neighborhood_of	68	39.7	100.0	11.1
/people/person/children	30	80.0	100.0	8.3
/people/deceased_person/place_of_death	68	22.1	100.0	20.0
/people/person/place_of_birth	162	12.0	100.0	33.0
/location/country/administrative_divisions	424	0.2	N/A	0.0

Table 1: Estimated precision and recall by relation, as well as the number of matched sentences (#sents) and accuracy (% true) of matches between sentences and facts in Freebase.

Riedel *et al.* (2010) approach required approximately 6 hours to train on NY Times 05-06 and 4 hours to test on the NY Times 07, each without preprocessing. Although they do sampling for inference, the global aggregation variables require reasoning about an exponentially large (in the number of sentences) sample space.

In contrast, our approach required approximately one minute to train and less than one second to test, on the same data. This advantage comes from the decomposition that is possible with the deterministic OR aggregation variables. For test, we simply consider each sentence in isolation and during training our approximation to the weighted assignment problem is linear in the number of sentences.

7.6 Discussion

The sentential extraction results demonstrates the advantages of learning a model that is primarily driven by sentence-level features. Although previous approaches have used more sophisticated features for aggregating the evidence from individual sentences, we demonstrate that aggregating strong sentence-level evidence with a simple deterministic OR that models overlapping relations is more effective, and also enables training of a sentence extractor that runs with no aggregate information.

While the Riedel *et al.* approach does include a model of which sentences express relations, it makes significant use of aggregate features that are primarily designed to do entity-level relation predictions and has a less detailed model of extractions at the individual sentence level. Perhaps surprisingly, our model is able to do better at both the sentential and aggregate levels.

8 Related Work

Supervised-learning approaches to IE were introduced in (Soderland et al., 1995) and are too numerous to summarize here. While they offer high precision and recall, these methods are unlikely to scale to the thousands of relations found in text on the Web. Open IE systems, which perform self-supervised learning of relation-independent extractors (*e.g.*, Preemptive IE (Shinyama and Sekine, 2006), TEXTRUNNER (Banko et al., 2007; Banko and Etzioni, 2008) and WOE (Wu and Weld, 2010)) can scale to millions of documents, but don't output canonicalized relations.

8.1 Weak Supervision

Weak supervision (also known as distant- or self supervision) refers to a broad class of methods, but we focus on the increasingly-popular idea of using a store of structured data to heuristicaly label a textual corpus. Craven and Kumlien (1999) introduced the idea by matching the Yeast Protein Database (YPD) to the abstracts of papers in PubMed and training a naive-Bayes extractor. Bellare and McCallum (2007) used a database of BibTex records to train a CRF extractor on 12 bibliographic relations. The KYLIN system aplied weak supervision to learn relations from Wikipedia, treating infoboxes as the associated database (Wu and Weld, 2007); Wu *et al.* (2008) extended the system to use smoothing over an automatically generated infobox taxon-

omy. Mintz *et al.* (2009) used Freebase facts to train 100 relational extractors on Wikipedia. Hoffmann *et al.* (2010) describe a system similar to KYLIN, but which dynamically generates lexicons in order to handle sparse data, learning over 5000 Infobox relations with an average F1 score of 61%. Yao *et al.* (2010) perform weak supervision, while using selectional preference constraints to a jointly reason about entity types.

The NELL system (Carlson et al., 2010) can also be viewed as performing weak supervision. Its initial knowledge consists of a selectional preference constraint and 20 ground fact seeds. NELL then matches entity pairs from the seeds to a Web corpus, but instead of learning a probabilistic model, it bootstraps a set of extraction patterns using semi-supervised methods for multitask learning.

8.2 Multi-Instance Learning

Multi-instance learning was introduced in order to combat the problem of ambiguously-labeled training data when predicting the activity of different drugs (Dietterich et al., 1997). Bunescu and Mooney (2007) connect weak supervision with multi-instance learning and extend their relational extraction kernel to this context.

Riedel *et al.* (2010), combine weak supervision and multi-instance learning in a more sophisticated manner, training a graphical model, which assumes only that *at least one* of the matches between the arguments of a Freebase fact and sentences in the corpus is a true relational mention. Our model may be seen as an extension of theirs, since both models include sentence-level and aggregate random variables. However, Riedel *et al.* have only a single aggregate variable that takes values $r \in R \cup \{\texttt{none}\}$, thereby ruling out overlapping relations. We have discussed the comparison in more detail throughout the paper, including in the model formulation section and experiments.

9 Conclusion

We argue that weak supervision is promising method for scaling information extraction to the level where it can handle the myriad, different relations on the Web. By using the contents of a database to heuristically label a training corpus, we may be able to automatically learn a nearly unbounded number of relational extractors. Since the processs of matching database tuples to sentences is inherently heuristic, researchers have proposed multi-instance learning algorithms as a means for coping with the resulting noisy data. Unfortunately, previous approaches assume that all relations are *disjoint* — for example they cannot extract the pair `Founded(Jobs, Apple)` and `CEO-of(Jobs, Apple)`, because two relations are not allowed to have the same arguments.

This paper presents a novel approach for multi-instance learning with overlapping relations that combines a sentence-level extraction model with a simple, corpus-level component for aggregating the individual facts. We apply our model to learn extractors for NY Times text using weak supervision from Freebase. Experiments show improvements for both sentential and aggregate (corpus level) extraction, and demonstrate that the approach is computationally efficient.

Our early progress suggests many interesting directions. By joining two or more Freebase tables, we can generate many more matches and learn more relations. We also wish to refine our model in order to improve precision. For example, we would like to add type reasoning about entities and selectional preference constraints for relations. Finally, we are also interested in applying the overall learning approaches to other tasks that could be modeled with weak supervision, such as coreference and named entity classification.

The source code of our system, its output, and all data annotations are available at `http://cs.uw.edu/homes/raphaelh/mr`.

Exploiting Syntactico-Semantic Structures for Relation Extraction

Yee Seng Chan and **Dan Roth**
University of Illinois at Urbana-Champaign
{chanys,danr}@illinois.edu

Abstract

In this paper, we observe that there exists a second dimension to the relation extraction (RE) problem that is orthogonal to the relation type dimension. We show that most of these second dimensional structures are relatively constrained and not difficult to identify. We propose a novel algorithmic approach to RE that starts by first identifying these structures and then, within these, identifying the semantic type of the relation. In the real RE problem where relation arguments need to be identified, exploiting these structures also allows reducing pipelined propagated errors. We show that this RE framework provides significant improvement in RE performance.

1 Introduction

Relation extraction (RE) has been defined as the task of identifying a given set of semantic binary relations in text. For instance, given the span of text "... the Seattle zoo ...", one would like to extract the relation that "the Seattle zoo" is located-at "Seattle". RE has been frequently studied over the last few years as a supervised learning task, learning from spans of text that are annotated with a set of semantic relations of interest. However, most approaches to RE have assumed that the relations' arguments are given as input (Chan and Roth, 2010; Jiang and Zhai, 2007; Jiang, 2009; Zhou et al., 2005), and therefore offer only a partial solution to the problem.

Conceptually, this is a rather simple approach as *all* spans of texts are treated uniformly and are being mapped to one of several relation types of interest. However, these approaches to RE require a large amount of manually annotated training data to achieve good performance, making it difficult to expand the set of target relations. Moreover, as we show, these approaches become brittle when the relations' arguments are not given but rather need to be identified in the data too.

In this paper we build on the observation that there exists a second dimension to the relation extraction problem that is orthogonal to the *relation type* dimension: all relation types are expressed in one of several constrained syntactico-semantic structures. As we show, identifying where the text span is on the *syntactico-semantic structure* dimension first, can be leveraged in the RE process to yield improved performance. Moreover, working in the second dimension provides robustness to the *real* RE problem, that of identifying arguments along with the relations between them.

For example, in "the Seattle zoo", the entity mention "Seattle" modifies the noun "zoo". Thus, the two mentions "Seattle" and "the Seattle zoo", are involved in what we later call a *premodifier relation*, one of several syntactico-semantic structures we identify in Section 3.

We highlight that all relation types can be expressed in one of several syntactico-semantic structures – Premodifiers, Possessive, Preposition, Formulaic and Verbal. As it turns out, most of these structures are relatively constrained and are not difficult to identify. This suggests a novel algorithmic approach to RE that starts by first identifying these structures and then, within these, identifying the semantic type of the relation. Not only does this approach provide significantly improved RE perfor-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 551–560,
Portland, Oregon, June 19-24, 2011.

mance, it carries with it two additional advantages.

First, leveraging the syntactico-semantic structure is especially beneficial in the presence of small amounts of data. Second, and more important, is the fact that exploiting the syntactico-semantic dimension provides several new options for dealing with the *full* RE problem – incorporating the argument identification into the problem. We explore one of these possibilities, making use of the constrained structures as a way to aid in the identification of the relations' arguments. We show that this already provides significant gain, and discuss other possibilities that can be explored. The contributions of this paper are summarized below:

- We highlight that all relation types are expressed as one of several syntactico-semantic structures and show that most of these are relatively constrained and not difficult to identify. Consequently, working first in this structural dimension can be leveraged in the RE process to improve performance.
- We show that when one does not have a large number of training examples, exploiting the syntactico-semantic structures is crucial for RE performance.
- We show how to leverage these constrained structures to improve RE when the relations' arguments are not given. The constrained structures allow us to jointly entertain argument candidates and relations built with them as arguments. Specifically, we show that considering argument candidates which otherwise would have been discarded (provided they exist in syntactico-semantic structures), we reduce error propagation along a standard pipeline RE architecture, and that this joint inference process leads to improved RE performance.

In the next section, we describe our relation extraction framework that leverages the syntactico-semantic structures. We then present these structures in Section 3. We describe our mention entity typing system in Section 4 and features for the RE system in Section 5. We present our RE experiments in Section 6 and perform analysis in Section 7, before concluding in Section 8.

  if $p \in \mathcal{S} \vee (m_i, m_j)$ was annotated with a $\mathcal{S}$ structure
    $\mathcal{D}_s = \mathcal{D}_s \cup (m_i, m_j)$
done
RE_s = RE classifier trained on $\mathcal{D}_s$

Output: RE_{base} and RE_s

Figure 1: Training a regular baseline RE classifier RE_{base} and a RE classifier leveraging syntactico-semantic structures RE_s.

2 Relation Extraction Framework

In Figure 1, we show the algorithm for training a typical baseline RE classifier (RE_{base}), and for training a RE classifier that leverages the syntactico-semantic structures (RE_s).

During evaluation and when the *gold* mentions are already annotated, we apply RE_s as follows. When given a test example mention pair (x_i,x_j), we perform structure inference on it using the patterns described in Section 3. If (x_i,x_j) is identified as having any of the four syntactico-semantic structures $\mathcal{S}$, apply RE_s to predict the relation label, else apply RE_{base}.

Next, we show in Figure 2 our joint inference algorithmic framework that leverages the syntactico-semantic structures for RE, when mentions need to be *predicted*. Since the structures are fairly constrained, we can use them to consider mention candidates that are originally predicted as non mentions. As shown in Figure 2, we conservatively include such mentions when forming mention pairs, provided their null labels are predicted with a low probability t[1].

[1] In this work, we arbitrary set t=0.2. After the experiments, and in our own analysis, we observe that t=0.25 achieves better performance. Besides using the probability of the 1-best prediction, one could also for instance, use the probability difference between the first and second best predictions. However, selecting an optimal t value is not the main focus of this work.

$\mathcal{S}$ = {premodifier, possessive, preposition, formulaic}
candidate mentions $\mathcal{M}_{cand}$
Let $L_m = \underset{y}{\text{argmax}} P_{MET}(y|m,\theta), m \in \mathcal{M}_{cand}$
selected mentions $\mathcal{M}_{sel} = \{m \in \mathcal{M}_{cand} \mid$
$L_m \neq null \vee P_{MET}(null|m,\theta) \leq t\}$
$\mathcal{Q}_{hasNull} = \{(m_i, m_j) \in \mathcal{M}_{sel} \times \mathcal{M}_{sel} \mid$
m_i in same sentence as $m_j \wedge i \neq j \wedge i < j \wedge$
$(L_{m_i} \neq null \vee L_{m_j} \neq null)\}$
Let pool of relation predictions $\mathcal{R} = \emptyset$

for each $(m_i, m_j) \in \mathcal{Q}_{hasNull}$
do
p = structure inference on (m_i, m_j) using patterns
if $p \in \mathcal{S}$
r = relation prediction for (m_i, m_j) using RE_s
$\mathcal{R} = \mathcal{R} \cup r$
else if $L_{m_i} \neq null \wedge L_{m_j} \neq null$
r = relation prediction for (m_i, m_j) using RE_{base}
$\mathcal{R} = \mathcal{R} \cup r$
done

Output: $\mathcal{R}$

Figure 2: RE using predicted mentions and patterns. Abbreviations: L_m: predicted entity label for mention m using the mention entity typing (MET) classifier described in Section 4; P_{MET}: prediction probability according to the MET classifier; t: used for thresholding.

There is a large body of work in using patterns to extract relations (Fundel et al., 2007; Greenwood and Stevenson, 2006; Zhu et al., 2009). However, these works operate along the first dimension, that of using patterns to mine for *relation type* examples. In contrast, in our RE framework, we apply patterns to identify the syntactico-semantic structure dimension first, and leverage this in the RE process. In (Roth and Yih, 2007), the authors used entity types to constrain the (first dimensional) relation types allowed among them. In our work, although a few of our patterns involve semantic type comparison, most of the patterns are syntactic in nature.

In this work, we performed RE evaluation on the NIST Automatic Content Extraction (ACE) corpus. Most prior RE evaluation on ACE data assumed that mentions are already pre-annotated and given as input (Chan and Roth, 2010; Jiang and Zhai, 2007; Zhou et al., 2005). An exception is the work of (Kambhatla, 2004), where the author evaluated on the ACE-2003 corpus. In that work, the author did not address the pipelined errors propagated from the mention identification process.

3 Syntactico-Semantic Structures

In this paper, we performed RE on the ACE-2004 corpus. In ACE-2004 when the annotators tagged a pair of mentions with a relation, they also specified the type of syntactico-semantic structure[2]. ACE-2004 identified five types of structures: premodifier, possessive, preposition, formulaic, and verbal. We are unaware of any previous computational approaches that recognize these structures automatically in text, as we do, and use it in the context of RE (or any other problem). In (Qian et al., 2008), the authors reported the recall scores of their RE system on the various syntactico-semantic structures. But they do not attempt to recognize nor leverage these structures.

In this work, we focus on detecting the first four structures. These four structures cover 80% of the mention pairs having valid semantic relations (we give the detailed breakdown in Section 7) and we show that they are relatively easy to identify using simple rules or patterns. In this section, we indicate mentions using square bracket pairs, and use m_i and m_j to represent a mention pair. We now describe the four structures.

Premodifier relations specify the proper adjective or proper noun premodifier and the following noun it modifies, e.g.: [the [Seattle] zoo]

Possessive indicates that the first mention is in a possessive case, e.g.: [[California] 's Governor]

Preposition indicates that the two mentions are semantically related via the existence of a preposition, e.g.: [officials] in [California]

Formulaic The ACE04 annotation guideline[3] indicates the annotation of several formulaic relations, including for example address: [Medford] , [Massachusetts]

[2] ACE-2004 termed it as lexical condition. We use the term syntactico-semantic structure in this paper as the mention pair exists in specific syntactic structures, and we use rules or patterns that are syntactically and semantically motivated to detect these structures.

Structure type	Pattern
Premodifier	Basic pattern: [u* [v+] w+] , where u, v, w represent words Each w is a noun or adjective If u* is not empty, then u*: JJ+ ∨ JJ "and" JJ? ∨ CD JJ* ∨ RB DT JJ? ∨ RB CD JJ ∨ DT (RB|JJ|VBG|VBD|VBN|CD)? Let w_1 = first word in w+. $w_1 \neq$ "'s" and POS tag of $w_1 \neq$ POS Let v_l = last word in v+. POS tag of $v_l \neq$ PRP$ nor WP$
Possessive	Basic pattern: [u? [v+] w+] , where u, v, w represent words Let w_1 = first word in w+. If w_1 = "'s" ∨ POS tag of w_1 = POS, accept mention pair Let v_l = last word in v+. If POS tag of v_l = PRP$ or WP$, accept mention pair
Preposition	Basic pattern: [m_i] v* [m_j], where v represent words and number of prepositions in the text span v* between them = 0, 1, or 2 If satisfy pattern: IN [m_i][m_j], accept mention pair If satisfy pattern: [m_i] (IN|TO) [m_j], accept mention pair If all labels in $\mathcal{L}_d$ start with "prep", accept mention pair
Formulaic	If satisfy pattern: [m_i] / [m_j] ∧ $E_c(m_i)$ = PER ∧ $E_c(m_j)$ = ORG, accept mention pair If satisfy pattern: [m_i][m_j] If $E_c(m_i)$ = PER ∧ $E_c(m_j)$ = ORG ∨ GPE, accept mention pair

Table 1: Rules and patterns for the four syntactico-semantic structures. Regular expression notations: '*' matches the preceding element zero or more times; '+' matches the preceding element one or more times; '?' indicates that the preceding element is optional; '|' indicates or. Abbreviations: $E_c(m)$: coarse-grained entity type of mention m; $\mathcal{L}_d$: labels in dependency path between the headword of two mentions. We use square brackets '[' and ']' to denote mention boundaries. The '/' in the *Formulaic* row denotes the occurrence of a lexical '/' in text.

In this rest of this section, we present the rules/patterns for detecting the above four syntactico-semantic structure, giving an overview of them in Table 1. We plan to release all of the rules/patterns along with associated code[4]. Notice that the patterns are intuitive and mostly syntactic in nature.

3.1 Premodifier Structures

- We require that one of the mentions completely include the other mention. Thus, the basic pattern is [u* [v+] w+].
- If u* is not empty, we require that it satisfies any of the following POS tag sequences: JJ+ ∨ JJ and JJ? ∨ CD JJ*, etc. These are (optional) POS tag sequences that normally start a valid noun phrase.
- We use two patterns to differentiate between premodifier relations and possessive relations, by checking for the existence of POS tags PRP$, WP$, POS, and the word "'s".

[4]http://cogcomp.cs.illinois.edu/page/publications

3.2 Possessive Structures

- The basic pattern for possessive is similar to that for premodifier: [u? [v+] w+]
- If the word immediately following v+ is "'s" or its POS tag is "POS", we accept the mention pair. If the POS tag of the last word in v+ is either PRP$ or WP$, we accept the mention pair.

3.3 Preposition Structures

- We first require the two mentions to be non-overlapping, and check for the existence of patterns such as "IN [m_i] [m_j]" and "[m_i] (IN|TO) [m_j]".
- If the only dependency labels in the dependency path between the head words of m_i and m_j are "prep" (prepositional modifier), accept the mention pair.

3.4 Formulaic Structures

- The ACE-2004 annotator guidelines specify that several relations such as reporter signing off, addresses, etc. are often specified in standard structures. We check for the existence of patterns such as "[m_i] / [m_j]", "[m_i] [m_j]",

Category	Feature
For every word w_k in mention m_i	POS of w_k and offset from lw
	w_k and offset from lw
	POS of w_k, w_k, and offset from lw
	POS of w_k, offset from lw, and lw
	$Bc(w_k)$ and offset from lw
	POS of w_k, $Bc(w_k)$, and offset from lw
	POS of w_k, offset from lw, and $Bc(lw)$
Contextual	$C_{-1,-1}$ of m_i
	$C_{+1,+1}$ of m_i
	$P_{-1,-1}$ of m_i
	$P_{+1,+1}$ of m_i
NE tags	tag of NE, if lw of NE coincides with lw of m_i in the sentence
Syntactic parse	parse-label of parse tree constituent that exactly covers m_i
	parse-labels of parse tree constituents covering m_i

Table 2: Features used in our mention entity typing (MET) system. The abbreviations are as follows. lw: last word in the mention; $Bc(w)$: the brown cluster bit string representing w; NE: named entity

and whether they satisfy certain semantic entity type constraints.

4 Mention Extraction System

As part of our experiments, we perform RE using predicted mentions. We first describe the features (an overview is given in Table 2) and then describe how we extract candidate mentions from sentences during evaluation.

4.1 Mention Extraction Features

Features for every word in the mention For every word w_k in a mention m_i, we extract seven features. These are a combination of w_k itself, its POS tag, and its integer offset from the last word (lw) in the mention. For instance, given the mention "the operation room", the offsets for the three words in the mention are -2, -1, and 0 respectively. These features are meant to capture the word and POS tag sequences in mentions.

We also use word clusters which are automatically generated from unlabeled texts, using the Brown clustering (Bc) algorithm of (Brown et al., 1992). This algorithm outputs a binary tree where words are leaves in the tree. Each word (leaf) in the tree can be represented by its unique path from the root and this path can be represented as a simple bit string. As part of our features, we use the cluster bit string representation of w_k and lw.

Category	Feature
POS	POS of single word between m_1, m_2
	hw of m_i, m_j and $P_{-1,-1}$ of m_i, m_j
	hw of m_i, m_j and $P_{-1,-1}$ of m_i, m_j
	hw of m_i, m_j and $P_{+1,+1}$ of m_i, m_j
	hw of m_i, m_j and $P_{-2,-1}$ of m_i, m_j
	hw of m_i, m_j and $P_{-1,+1}$ of m_i, m_j
	hw of m_i, m_j and $P_{+1,+2}$ of m_i, m_j
Base chunk	any base phrase chunk between m_i, m_j

Table 3: Additional RE features.

Contextual We extract the word $C_{-1,-1}$ immediately before m_i, the word $C_{+1,+1}$ immediately after m_i, and their associated POS tags P.

NE tags We automatically annotate the sentences with named entity (NE) tags using the named entity tagger of (Ratinov and Roth, 2009). This tagger annotates *proper nouns* with the tags PER (person), ORG (organization), LOC (location), or MISC (miscellaneous). If the lw of m_i coincides (actual token offset) with the lw of any NE annotated by the NE tagger, we extract the NE tag as a feature.

Syntactic parse We parse the sentences using the syntactic parser of (Klein and Manning, 2003). We extract the label of the parse tree constituent (if it exists) that *exactly covers* the mention, and also labels of all constituents that *covers* the mention.

4.2 Extracting Candidate Mentions

From a sentence, we gather the following as candidate mentions: all nouns and possessive pronouns, all named entities annotated by the the NE tagger (Ratinov and Roth, 2009), all base noun phrase (NP) chunks, all chunks satisfying the pattern: NP (PP NP)+, all NP constituents in the syntactic parse tree, and from each of these constituents, all substrings consisting of two or more words, provided the substrings do not start nor end on punctuation marks. These mention candidates are then fed to our mention entity typing (MET) classifier for type prediction (more details in Section 6.3).

5 Relation Extraction System

We build a supervised RE system using sentences annotated with entity mentions and predefined target relations. During evaluation, when given a pair of mentions m_i, m_j, the system predicts whether any of the predefined target relation holds between the mention pair.

Most of our features are based on the work of (Zhou et al., 2005; Chan and Roth, 2010). Due to space limitations, we refer the reader to our prior work (Chan and Roth, 2010) for the lexical, structural, mention-level, entity type, and dependency features. Here, we only describe the features that were not used in that work.

As part of our RE system, we need to extract the head word (hw) of a mention (m), which we heuristically determine as follows: if m contains a preposition and a noun preceding the preposition, we use the noun as the hw. If there is no preposition in m, we use the last noun in m as the hw.

POS features If there is a single word between the two mentions, we extract its POS tag. Given the hw of m, $P_{i,j}$ refers to the sequence of POS tags in the immediate context of hw (we exclude the POS tag of hw). The offsets *i* and *j* denote the position (relative to hw) of the first and last POS tag respectively. For instance, $P_{-2,-1}$ denotes the sequence of two POS tags on the immediate left of hw, and $P_{-1,+1}$ denotes the POS tag on the immediate left of hw and the POS tag on the immediate right of hw.

Base phrase chunk We add a boolean feature to detect whether there is any base phrase chunk in the text span between the two mentions.

6 Experiments

We use the ACE-2004 dataset (catalog LDC2005T09 from the Linguistic Data Consortium) to conduct our experiments. Following prior work, we use the news wire (nwire) and broadcast news (bnews) corpora of ACE-2004 for our experiments, which consists of 345 documents.

To build our RE system, we use the LIBLINEAR (Fan et al., 2008) package, with its default settings of L2-loss SVM (dual) as the solver, and we use an epsilon of 0.1. To ensure that this baseline RE system based on the features in Section 5 is competitive, we compare against the state-of-the-art feature-based RE systems of (Jiang and Zhai, 2007) and (Chan and Roth, 2010). In these works, the authors reported performance on undirected coarse-grained RE. Performing 5-fold cross validation on the nwire and bnews corpora, (Jiang and Zhai, 2007) and (Chan and Roth, 2010) reported F-measures of 71.5 and 71.2, respectively. Using the same evaluation setting, our baseline RE system achieves a competitive 71.4 F-measure.

We build three RE classifiers: *binary*, *coarse*, *fine*. Lumping all the predefined target relations into a single label, we build a *binary* classifier to predict whether any of the predefined relations exists between a given mention pair.

In this work, we model the argument order of the mentions when performing RE, since relations are usually asymmetric in nature. For instance, we consider m_i:EMP-ORG:m_j and m_j:EMP-ORG:m_i to be distinct relation types. In our experiments, we extracted a total of 55,520 examples or mention pairs. Out of these, 4,011 are positive relation examples annotated with 6 coarse-grained relation types and 22 fine-grained relation types[5].

We build a *coarse-grained* classifier to disambiguate between 13 relation labels (two asymmetric labels for each of the 6 coarse-grained relation types and a null label). We similarly build a *fine-grained* classifier to disambiguate between 45 relation labels.

6.1 Evaluation Method

For our experiments, we adopt the experimental setting in our prior work (Chan and Roth, 2010) of ensuring that all examples from a single document are either all used for training, or all used for evaluation.

In that work, we also highlight that ACE annotators rarely duplicate a relation link for coreferent mentions. For instance, assume mentions m_i, m_j, and m_k are in the same sentence, mentions m_i and m_j are coreferent, and the annotators tag the mention pair m_j, m_k with a particular relation r. The annotators will rarely duplicate the same (implicit)

[5]We omit a single relation: Discourse (DISC). The ACE-2004 annotation guidelines states that the DISC relation is established only for the purposes of the discourse and does not reference an official entity relevant to world knowledge. In this work, we focus on semantically meaningful relations. Furthermore, the DISC relation is dropped in ACE-2005.

relation r between m_i and m_k, thus leaving the gold relation label as null. Whether this is correct or not is debatable. However, to avoid being penalized when our RE system actually correctly predicts the label of an implicit relation, we take the following approach.

During evaluation, if our system correctly predicts an implicit label, we simply switch its prediction to the null label. Since the RE recall scores only take into account non-null relation labels, this scoring method does not change the recall, but could marginally increase the precision scores by decreasing the count of RE predictions. In our experiments, we observe that both the usual and our scoring method give very similar RE results and the experimental trends remain the same. Of course, using this scoring method requires coreference information, which is available in the ACE data.

6.2 RE Evaluation Using Gold Mentions

To perform our experiments, we split the 345 documents into 5 equal sets. In each of the 5 folds, 4 sets (276 documents) are reserved for drawing training examples, while the remaining set (69 documents) is used as evaluation data. In the experiments described in this section, we use the gold mentions available in the data.

When one only has a small amount of training data, it is crucial to take advantage of external knowledge such as the syntactico-semantic structures. To simulate this setting, in each fold, we randomly selected 10 documents from the fold's available training documents (about 3% of the total 345 documents) as training data. We built one binary, one coarse-grained, and one fine-grained classifier for each fold.

In Section 2, we described how we trained a baseline RE classifier (RE_{base}) and a RE classifier using the syntactico-semantic patterns (RE_s).

We first apply RE_{base} on each test example mention pair (m_i,m_j) to obtain the RE baseline results, showing these in Table 4 under the column "10 documents", and in the rows "Binary", "Coarse", and "Fine". We then applied RE_s on the test examples as described in Section 2, showing the results in the rows "Binary+Patterns", "Coarse+Patterns", and "Fine+Patterns". The results show that by using syntactico-semantic structures, we obtain significant F-measure improvements of **8.3**, **7.2**, and **5.5** for binary, coarse-grained, and fine-grained relation predictions respectively.

6.3 RE Evaluation Using Predicted Mentions

Next, we perform our experiments using predicted mentions. ACE-2004 defines 7 coarse-grained *entity* types, each of which are then refined into 43 fine-

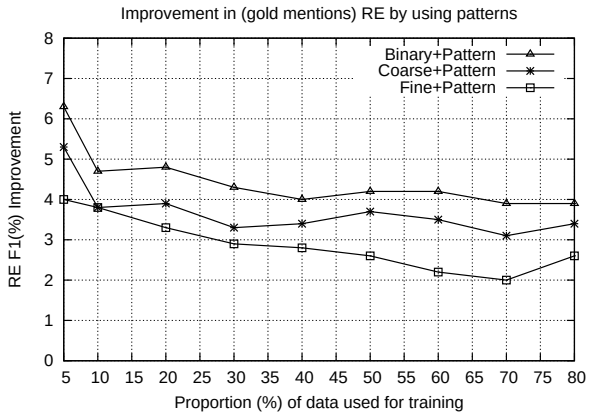

Figure 3: Improvement in (gold mention) RE.

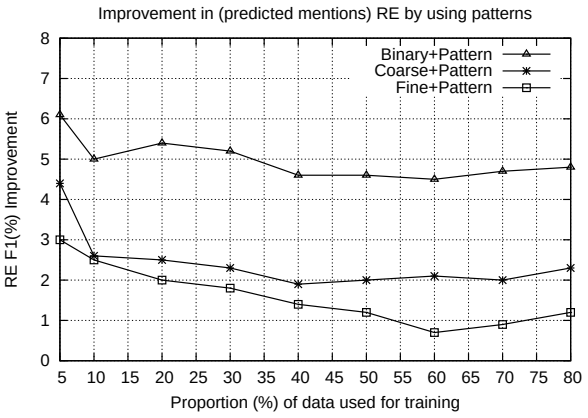

Figure 4: Improvement in (predicted mention) RE.

grained *entity* types. Using the ACE data annotated with mentions and predefined entity types, we build a fine-grained mention entity typing (MET) classifier to disambiguate between 44 labels (43 fine-grained and a null label to indicate not a mention). To obtain the coarse-grained entity type predictions from the classifier, we simply check which coarse-grained type the fine-grained prediction belongs to. We use the LIBLINEAR package with the same settings as earlier specified for the RE system. In each fold, we build a MET classifier using all the (276) training documents in that fold.

We apply RE_{base} on all mention pairs (m_i,m_j) where both m_i and m_j have non null entity type predictions. We show these baseline results in the Rows "Binary", "Coarse", and "Fine" of Table 5.

In Section 2, we described our algorithmic approach (Figure 2) that takes advantage of the structures with predicted mentions. We show the results of this approach in the Rows "Binary+Patterns", "Coarse+Patterns", and "Fine+Patterns" of Table 5. The results show that by leveraging syntactico-semantic structures, we obtain significant F-measure improvements of **8.2**, **4.6**, and **3.6** for binary, coarse-grained, and fine-grained relation predictions respectively.

7 Analysis

We first show statistics regarding the syntactico-semantic structures. In Section 3, we mentioned that ACE-2004 identified five types of structures: premodifier, possessive, preposition, formulaic, and verbal. On the 4,011 examples that we experimented on, premodifiers are the most frequent, accounting for 30.5% of the examples (or about 1,224 examples). The occurrence distributions of the other structures are 18.9% (possessive), 23.9% (preposition), 7.2% (formulaic), and 19.5% (verbal). Hence, the four syntactico-semantic structures that we focused on in this paper account for a large majority (80%) of the relations.

Pattern type	Rec%	Pre%
PreMod	86.8	79.7
Poss	94.3	88.3
Prep	94.6	20.0
Formula	85.5	62.2

Table 6: Recall and precision of the patterns.

In Section 6, we note that out of 55,520 mention pairs, only 4,011 exhibit valid relations. Thus, the proportion of positive relation examples is very sparse at 7.2%. If we can effectively identify and discard most of the negative relation examples, it should improve RE performance, including yielding training data with a more balanced label distribution.

We now analyze the utility of the patterns. As shown in Table 6, the patterns are effective in inferring the structure of mention pairs. For instance, applying the premodifier patterns on the 55,520 mention pairs, we correctly identified 86.8% of the 1,224 premodifier occurrences as premodifiers, while incurring a false-positive rate of only about 20%[6]. We

[6]Random selection will give a precision of about 2.2% (1,224 out of 55,520) and thus a false-positive rate of 97.8%

note that preposition structures are relatively harder to identify. Some of the reasons are due to possibly multiple prepositions in between a mention pair, preposition sense ambiguity, pp-attachment ambiguity, etc. However, in general, we observe that inferring the structures allows us to discard a large portion of the mention pairs which have no valid relation between them. The intuition behind this is the following: if we infer that there is a syntactico-semantic structure between a mention pair, then it is likely that the mention pair exhibits a valid relation. Conversely, if there is a valid relation between a mention pair, then it is likely that there exists a syntactico-semantic structure between the mentions.

Next, we repeat the experiments in Section 6.2 and Section 6.3, while gradually increasing the amount of training data used for training the RE classifiers. The detailed results of using 5% and 80% of all available data are shown in Table 4 and Table 5. Note that these settings are with respect to all 345 documents and thus the 80% setting represents using all 276 training documents in each fold. We plot the intermediate results in Figure 3 and Figure 4. We note that leveraging the structures provides improvements on all experimental settings. Also, intuitively, the *binary* predictions benefit the most from leveraging the structures. How to further exploit this is a possible future work.

8 Conclusion

In this paper, we propose a novel algorithmic approach to RE by exploiting syntactico-semantic structures. We show that this approach provides several advantages and improves RE performance. There are several interesting directions for future work. There are probably many near misses when we apply our structure patterns on predicted mentions. For instance, for both premodifier and possessive structures, we require that one mention completely includes the other. Relaxing this might potentially recover additional valid mention pairs and improve performance. We could also try to learn classifiers to automatically identify and disambiguate between the different syntactico-semantic structures. It will also be interesting to feedback the predictions of the structure patterns to the mention entity typing classifier and possibly retrain to obtain a better classifier.

Abstract

Recent work on bilingual Word Sense Disambiguation (WSD) has shown that a resource deprived language (L_1) can benefit from the annotation work done in a resource rich language (L_2) via parameter projection. However, this method assumes the presence of sufficient annotated data in one resource rich language which may not always be possible. Instead, we focus on the situation where there are two resource deprived languages, both having a very small amount of seed annotated data and a large amount of untagged data. We then use ***bilingual bootstrapping***, wherein, a model trained using the seed annotated data of L_1 is used to annotate the untagged data of L_2 and vice versa using parameter projection. The untagged instances of L_1 and L_2 which get annotated with high confidence are then added to the seed data of the respective languages and the above process is repeated. Our experiments show that such a bilingual bootstrapping algorithm when evaluated on two different domains with ***small seed sizes*** using Hindi (L_1) and Marathi (L_2) as the language pair performs better than monolingual bootstrapping and significantly reduces annotation cost.

1 Introduction

The high cost of collecting sense annotated data for supervised approaches (Ng and Lee, 1996; Lee et al., 2004) has always remained a matter of concern for some of the resource deprived languages of the world. The problem is even more hard-hitting for multilingual regions (*e.g.*, India which has more than 20 constitutionally recognized languages). To circumvent this problem, unsupervised and knowledge based approaches (Lesk, 1986; Walker and Amsler, 1986; Agirre and Rigau, 1996; McCarthy et al., 2004; Mihalcea, 2005) have been proposed as an alternative but they have failed to deliver good accuracies. Semi-supervised approaches (Yarowsky, 1995) which use a small amount of annotated data and a large amount of untagged data have shown promise albeit for a limited set of target words. The above situation highlights the need for high accuracy resource conscious approaches to all-words multilingual WSD.

Recent work by Khapra et al. (2010) in this direction has shown that it is possible to perform cost effective WSD in a target language (L_2) without compromising much on accuracy by leveraging on the annotation work done in another language (L_1). This is achieved with the help of a novel synset-aligned multilingual dictionary which facilitates the projection of parameters learned from the Wordnet and annotated corpus of L_1 to L_2. This approach thus obviates the need for collecting large amounts of annotated corpora in multiple languages by relying on sufficient annotated corpus in one resource rich language. However, in many situations such a pivot resource rich language itself may not be available. Instead, we might have two or more languages having a small amount of annotated corpus and a large amount of untagged corpus. Addressing such situations is the main focus of this work. Specifically, we address the following question:

> *In the absence of a pivot resource rich language is it possible for two resource deprived languages to mutually benefit from each other's annotated data?*

While addressing the above question we assume that

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 561–569,
Portland, Oregon, June 19-24, 2011.

even though it is hard to obtain large amounts of annotated data in multiple languages, it should be fairly easy to obtain a large amount of untagged data in these languages. We leverage on such untagged data by employing a bootstrapping strategy. The idea is to train an initial model using a small amount of annotated data in both the languages and iteratively expand this seed data by including untagged instances which get tagged with a high confidence in successive iterations. Instead of using monolingual bootstrapping, we use bilingual bootstrapping via parameter projection. In other words, the parameters learned from the annotated data of L_1 (and L_2 respectively) are projected to L_2 (and L_1 respectively) and the projected model is used to tag the untagged instances of L_2 (and L_1 respectively).

Such a bilingual bootstrapping strategy when tested on two domains, *viz.*, Tourism and Health using Hindi (L_1) and Marathi (L_2) as the language pair, consistently does better than a baseline strategy which uses only seed data for training without performing any bootstrapping. Further, it consistently performs better than monolingual bootstrapping. A simple and intuitive explanation for this is as follows. In monolingual bootstrapping a language can benefit only from its own seed data and hence can tag only those instances with high confidence which it has already seen. On the other hand, in bilingual bootstrapping a language can benefit from the seed data available in the other language which was not previously seen in its self corpus. This is very similar to the process of co-training (Blum and Mitchell, 1998) wherein the annotated data in the two languages can be seen as two different views of the same data. Hence, the classifier trained on one view can be improved by adding those untagged instances which are tagged with a high confidence by the classifier trained on the other view.

The remainder of this paper is organized as follows. In section 2 we present related work. Section 3 describes the Synset aligned multilingual dictionary which facilitates parameter projection. Section 4 discusses the work of Khapra et al. (2009) on parameter projection. In section 5 we discuss bilingual bootstrapping which is the main focus of our work followed by a brief discussion on monolingual bootstrapping. Section 6 describes the experimental setup. In section 7 we present the results followed by discussion in section 8. Section 9 concludes the paper.

2 Related Work

Bootstrapping for Word Sense Disambiguation was first discussed in (Yarowsky, 1995). Starting with a very small number of seed collocations an initial decision list is created. This decisions list is then applied to untagged data and the instances which get tagged with a high confidence are added to the seed data. This algorithm thus proceeds iteratively increasing the seed size in successive iterations. This monolingual bootstrapping method showed promise when tested on a limited set of target words but was not tried for all-words WSD.

The failure of monolingual approaches (Ng and Lee, 1996; Lee et al., 2004; Lesk, 1986; Walker and Amsler, 1986; Agirre and Rigau, 1996; McCarthy et al., 2004; Mihalcea, 2005) to deliver high accuracies for all-words WSD at low costs created interest in bilingual approaches which aim at reducing the annotation effort. Recent work in this direction by Khapra et al. (2009) aims at reducing the annotation effort in multiple languages by leveraging on existing resources in a pivot language. They showed that it is possible to project the parameters learned from the annotation work of one language to another language provided aligned Wordnets for the two languages are available. However, they do not address situations where two resource deprived languages have aligned Wordnets but neither has sufficient annotated data. In such cases bilingual bootstrapping can be used so that the two languages can mutually benefit from each other's small annotated data.

Li and Li (2004) proposed a bilingual bootstrapping approach for the more specific task of Word Translation Disambiguation (WTD) as opposed to the more general task of WSD. This approach does not need parallel corpora (just like our approach) and relies only on in-domain corpora from two languages. However, their work was evaluated only on a handful of target words (9 nouns) for WTD as opposed to the broader task of WSD. Our work instead focuses on improving the performance of all words WSD for two resource deprived languages using bilingual bootstrapping. At the heart of our work lies ***parameter projection*** facilitated by a synset aligned

multilingual dictionary described in the next section.

3 Synset Aligned Multilingual Dictionary

A novel and effective method of storage and use of dictionary in a multilingual setting was proposed by Mohanty et al. (2008). For the purpose of current discussion, we will refer to this multilingual dictionary framework as *MultiDict*. One important departure in this framework from the traditional dictionary is that **synsets are linked, and after that the words inside the synsets are linked**. The basic mapping is thus between synsets and thereafter between the words.

Concepts	L1 (English)	L2 (Hindi)	L3 (Marathi)
04321: a youthful male person	{male child, boy}	{लड़का *(ladkaa)*, बालक *(baalak)*, बच्चा *(bachchaa)*}	{मुलगा *(mulgaa)*, पोरगा *(porgaa)*, पोर *(por)*}

Table 1: Multilingual Dictionary Framework

Table 1 shows the structure of MultiDict, with one example row standing for the concept of *boy*. The first column is the pivot describing a concept with a unique ID. The subsequent columns show the words expressing the concept in respective languages (in the example table, *English, Hindi and Marathi*). After the synsets are linked, cross linkages are set up manually from the words of a synset to the words of a linked synset of the pivot language. For example, for the Marathi word मुलगा *(mulgaa)*, "a youthful male person", the correct lexical substitute from the corresponding Hindi synset is लड़का *(ladkaa)*. The average number of such links per synset per language pair is approximately 3. However, since our work takes place in a semi-supervised setting, we do not assume the presence of these manual cross linkages between synset members. Instead, in the above example, we assume that all the words in the Hindi synset are equally probable translations of every word in the corresponding Marathi synset. Such cross-linkages between synset members facilitate parameter projection as explained in the next section.

4 Parameter Projection

Khapra et al. (2009) proposed that the various parameters essential for domain-specific Word Sense Disambiguation can be broadly classified into two categories:

Wordnet-dependent parameters:

- belongingness-to-dominant-concept
- conceptual distance
- semantic distance

Corpus-dependent parameters:

- sense distributions
- corpus co-occurrence

They proposed a scoring function (Equation (1)) which combines these parameters to identify the correct sense of a word in a context:

$$S^* = \arg\max_i(\theta_i V_i + \sum_{j \in J} W_{ij} * V_i * V_j) \qquad (1)$$

where,

$$\begin{aligned} i &\in \textit{Candidate Synsets} \\ J &= \textit{Set of disambiguated words} \\ \theta_i &= BelongingnessToDominantConcept(S_i) \\ V_i &= P(S_i|word) \\ W_{ij} &= CorpusCooccurrence(S_i, S_j) \\ &\quad * 1/WNConceptualDistance(S_i, S_j) \\ &\quad * 1/WNSemanticGraphDistance(S_i, S_j) \end{aligned}$$

The first component $\theta_i V_i$ of Equation (1) captures influence of the corpus specific sense of a word in a domain. The other component $W_{ij} * V_i * V_j$ captures the influence of interaction of the candidate sense with the senses of context words weighted by factors of co-occurrence, conceptual distance and semantic distance.

Wordnet-dependent parameters depend on the structure of the Wordnet whereas the ***Corpus-dependent parameters*** depend on various statistics learned from a sense marked corpora. Both the tasks of (a) constructing a Wordnet from scratch and (b) collecting sense marked corpora for multiple languages are tedious and expensive. Khapra et

al. (2009) observed that by ***projecting relations*** from the Wordnet of a language and by ***projecting corpus statistics*** from the sense marked corpora of the language to those of the target language, *the effort required in constructing semantic graphs for multiple Wordnets and collecting sense marked corpora for multiple languages can be avoided or reduced*. At the heart of their work lies the *MultiDict* described in previous section which facilitates parameter projection in the following manner:

1. By linking with the synsets of a pivot resource rich language (Hindi, in our case), the cost of building Wordnets of other languages is partly reduced (semantic relations are inherited). The Wordnet parameters of Hindi Wordnet now become projectable to other languages.
2. For calculating corpus specific sense distributions, $P(Sense\ S_i|Word\ W)$, we need the counts, $\#(S_i, W)$. By using cross linked words in the synsets, these counts become projectable to the target language (Marathi, in our case) as they can be approximated by the counts of the cross linked Hindi words calculated from the Hindi sense marked corpus as follows:

$$P(S_i|W) = \frac{\#(S_i, marathi\_word)}{\sum_j \#(S_j, marathi\_word)}$$

$$P(S_i|W) \approx \frac{\#(S_i, cross\_linked\_hindi\_word)}{\sum_j \#(S_j, cross\_linked\_hindi\_word)}$$

The rationale behind the above approximation is the observation that within a domain the counts of cross-linked words will remain the same across languages.

This parameter projection strategy as explained above lies at the heart of our work and allows us to perform bilingual bootstrapping by projecting the models learned from one language to another.

5 Bilingual Bootstrapping

We now come to the main contribution of our work, *i.e.*, bilingual bootstrapping. As shown in Algorithm 1, we start with a small amount of seed data (LD_1 and LD_2) in the two languages. Using this data we learn the parameters described in the previous section. We collectively refer to the parameters learned from the seed data as models θ_1 and θ_2 for L_1 and L_2 respectively. The parameter projection strategy described in the previous section is then applied to θ_1 and θ_2 to obtain the projected models $\hat{\theta}_2$ and $\hat{\theta}_1$ respectively. These projected models are then applied to the untagged data of L_1 and L_2 and the instances which get labeled with a high confidence are added to the labeled data of the respective languages. This process is repeated till we reach convergence, *i.e.*, till it is no longer possible to move any data from UD_1 (and UD_2) to LD_1 (and LD_2 respectively).

We compare our algorithm with monolingual bootstrapping where the self models θ_1 and θ_2 are directly used to annotate the unlabeled instances in L_1 and L_2 respectively instead of using the projected models $\hat{\theta}_1$ and $\hat{\theta}_2$. The process of monolingual boot-

      UD_2 := UD_2 - u_2
    end if
  end for
until *convergence*

strapping is shown in Algorithm 2.

6 Experimental Setup

We used the publicly available dataset[1] described in Khapra et al. (2010) for all our experiments. The data was collected from two domains, *viz.*, Tourism and Health. The data for Tourism domain was collected by manually translating English documents downloaded from Indian Tourism websites into Hindi and Marathi. Similarly, English documents for Health domain were obtained from two doctors and were manually translated into Hindi and Marathi. The entire data was then manually annotated by three lexicographers adept in Hindi and Marathi. The various statistics pertaining to the total number of words, number of words per POS category and average degree of polysemy are described in Tables 2 to 5.

Although Tables 2 and 3 also report the num-

ber of monosemous words, we would like to clearly state that we do not consider monosemous words while evaluating the performance of our algorithms (as monosemous words do not need any disambiguation).

We did a 4-fold cross validation of our algorithm using the above described corpora. Note that even though the corpora were parallel we did not use this property in any way in our experiments or algorithm. In fact, the documents in the two languages were randomly split into 4 folds without ensuring that the parallel documents remain in the same folds for the two languages. We experimented with different seed sizes varying from 0 to 5000 in steps of 250. The seed annotated data and untagged instances for bootstrapping are extracted from 3 folds of the data and the final evaluation is done on the held-out data in the 4th fold.

We ran both the bootstrapping algorithms (*i.e.*, *monolingual bootstrapping* and *bilingual bootstrapping*) for 10 iterations but, we observed that after 1-2 iterations the algorithms converge. In each iteration only those words for which $P(assigned\_sense|word) > 0.6$ get moved to the labeled data. Ideally, this threshold (0.6) should have been selected using a development set. However, since our work focuses on resource scarce languages we did not want to incur the additional cost of using a development set. Hence, we used a fixed threshold of 0.6 so that in each iteration only those words get moved to the labeled data for which the assigned sense is clearly a majority sense ($P > 0.6$).

Language-Domain	Algorithm	F-score(%)	No. of tagged words needed to achieve this F-score	% Reduction in annotation cost
Hindi-Health	*Biboot*	57.70	1250	
	OnlySeed	57.99	2250	$\frac{(2250+2250)-(1250+1750)}{(2250+2250)} * 100 = 33.33\%$

	OnlySeed	59.83	2000	$\frac{(2000+2000)-(1000+1250)}{(2000+2000)} * 100 = 43.75\%$
Marathi-Tourism	*Biboot*	61.90	1250	
	OnlySeed	61.68	2000	

Table 6: Reduction in annotation cost achieved using Bilingual Bootstrapping

7 Results

The results of our experiments are summarized in Figures 1 to 4. The x-axis represents the amount of seed data used and the y-axis represents the F-scores obtained. The different curves in each graph are as follows:

a. ***BiBoot***: This curve represents the F-score obtained after 10 iterations by using bilingual bootstrapping with different amounts of seed data.

b. ***MonoBoot***: This curve represents the F-score obtained after 10 iterations by using monolingual bootstrapping with different amounts of seed data.

c. ***OnlySeed***: This curve represents the F-score obtained by training on the seed data alone without using any bootstrapping.

d. ***WFS***: This curve represents the F-score obtained by simply selecting the first sense from Wordnet, a typically reported baseline.

8 Discussions

In this section we discuss the important observations made from Figures 1 to 4.

8.1 Performance of Bilingual bootstrapping

For small seed sizes, the F-score of bilingual bootstrapping is consistently better than the F-score obtained by training only on the seed data without using any bootstrapping. This is true for both the languages in both the domains. Further, bilingual bootstrapping also does better than monolingual bootstrapping for small seed sizes. As explained earlier, this better performance can be attributed to the fact that in monolingual bootstrapping the algorithm can tag only those instances with high confidence which it has already seen in the training data. Hence, in successive iterations, very little new information becomes available to the algorithm. This is clearly evident from the fact that the curve of monolingual bootstrapping (*MonoBoot*) is always close to the curve of *OnlySeed*.

8.2 Effect of seed size

The benefit of bilingual bootstrapping is clearly felt for small seed sizes. However, as the seed size increases the performance of the 3 algorithms, *viz.*, *MonoBoot*, *BiBoot* and *OnlySeed* is more or less the same. This is intuitive, because, as the seed size increases the algorithm is able to see more and more tagged instances in its self corpora and hence does not need any assistance from the other language. In other words, the annotated data in L_1 is not able to add any new information to the training process of L_2 and vice versa.

8.3 Bilingual bootstrapping reduces annotation cost

The performance boost obtained at small seed sizes suggests that bilingual bootstrapping helps to reduce the overall annotation costs for both the languages. To further illustrate this, we take some sample points from the graph and compare the number of tagged words needed by *BiBoot* and *OnlySeed* to reach the same (or nearly the same) F-score. We present this comparison in Table 6.

The rows for *Hindi-Health* and *Marathi-Health* in Table 6 show that when *BiBoot* is employed we need 1250 tagged words in Hindi and 1750 tagged words in Marathi to attain F-scores of 57.70% and 64.97% respectively. On the other hand, in the absence of bilingual bootstrapping, (*i.e.*, using *OnlySeed*) we need 2250 tagged words each in Hindi and Marathi to achieve similar F-scores. *BiBoot* thus gives a reduction of 33.33% in the overall annotation cost ($\{1250 + 1750\}$ v/s $\{2250 + 2250\}$) while achieving similar F-scores. Similarly, the results for *Hindi-Tourism* and *Marathi-Tourism* show that *BiBoot* gives a reduction of 43.75% in the overall annotation cost while achieving similar F-scores. Further, since the results of *MonoBoot* are almost the same as *OnlySeed*, the above numbers indicate that *BiBoot* provides a reduction in cost when compared to *MonoBoot* also.

8.4 Contribution of monosemous words in the performance of *BiBoot*

As mentioned earlier, monosemous words in the test set are not considered while evaluating the performance of our algorithm but, we add monosemous words to the seed data. However, we do not count monosemous words while calculating the seed size as there is no manual annotation cost associated with monosemous words (they can be tagged automatically by fetching their singleton sense id from the wordnet). We observed that the monosemous words of L_1 help in boosting the performance of L_2 and vice versa. This is because for a given monosemous word in L_2 (or L_1 respectively) the corresponding cross-linked word in L_1 (or L_2 respectively) need not necessarily be monosemous. In such cases, the cross-linked polysemous word in L_2 (or L_1 respectively) benefits from the projected statistics of a monosemous word in L_1 (or L_2 respectively). This explains why *BiBoot* gives an F-score of 35-52% even at zero seed size even though the F-score of *OnlySeed* is only 2-5% (see Figures 1 to 4).

9 Conclusion

We presented a bilingual bootstrapping algorithm for Word Sense Disambiguation which allows two resource deprived languages to mutually benefit from each other's data via parameter projection. The algorithm consistently performs better than monolingual bootstrapping. It also performs better than using only monolingual seed data without using any bootstrapping. The benefit of bilingual bootstrapping is felt prominently when the seed size in the two languages is very small thus highlighting the usefulness of this algorithm in highly resource constrained scenarios.

Abstract

Resolving polysemy and synonymy is required for high-quality information extraction. We present ConceptResolver, a component for the Never-Ending Language Learner (NELL) (Carlson et al., 2010) that handles both phenomena by identifying the latent concepts that noun phrases refer to. ConceptResolver performs both word sense induction and synonym resolution on relations extracted from text using an ontology and a small amount of labeled data. Domain knowledge (the ontology) guides concept creation by defining a set of possible semantic types for concepts. Word sense induction is performed by inferring a set of semantic types for each noun phrase. Synonym detection exploits redundant information to train several domain-specific synonym classifiers in a semi-supervised fashion. When ConceptResolver is run on NELL's knowledge base, 87% of the word senses it creates correspond to real-world concepts, and 85% of noun phrases that it suggests refer to the same concept are indeed synonyms.

1 Introduction

Many information extraction systems construct knowledge bases by extracting structured assertions from free text (e.g., NELL (Carlson et al., 2010), TextRunner (Banko et al., 2007)). A major limitation of many of these systems is that they fail to distinguish between noun phrases and the underlying concepts they refer to. As a result, a polysemous phrase like "apple" will refer sometimes to the concept *Apple Computer (the company)*, and other times to the concept *apple (the fruit)*. Furthermore, two synonymous noun phrases like "apple" and "Apple Computer" can refer to the same underlying concept. The result of ignoring this many-to-many mapping between noun phrases and underlying concepts (see Figure 1) is confusion about the meaning of extracted information. To minimize such confusion, a system must separately represent noun phrases, the underlying concepts to which they can refer, and the many-to-many "can refer to" relation between them.

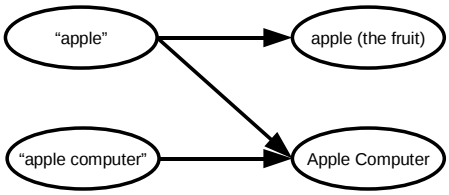

Figure 1: An example mapping from noun phrases (left) to a set of underlying concepts (right). Arrows indicate which noun phrases can refer to which concepts.

Figure 2: A random sample of concepts created by ConceptResolver. The first 10 concepts are from **company**, while the second 10 are from **athlete**.

The relations extracted by systems like NELL actually apply to concepts, not to noun phrases. Say

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 570–580,
Portland, Oregon, June 19-24, 2011.

the system extracts the relation **ceoOf**(x_1, x_2) between the noun phrases x_1 and x_2. The correct interpretation of this extracted relation is that there exist concepts c_1 and c_2 such that x_1 can refer to c_1, x_2 can refer to c_2, and **ceoOf**(c_1, c_2). If the original relation were **ceoOf**("steve", "apple"), then c_1 would be *Steve Jobs*, and c_2 would be *Apple Computer*. A similar interpretation holds for one-place category predicates like **person**(x_1). We define *concept discovery* as the problem of (1) identifying concepts like c_1 and c_2 from extracted predicates like **ceoOf**(x_1, x_2) and (2) mapping noun phrases like x_1, x_2 to the concepts they can refer to.

The main input to ConceptResolver is a set of extracted category and relation instances over noun phrases, like **person**(x_1) and **ceoOf**(x_1, x_2), produced by running NELL. Here, any individual noun phrase x_i can be labeled with multiple categories and relations. The output of ConceptResolver is a set of concepts, $\{c_1, c_2, ..., c_n\}$, and a mapping from each noun phrase in the input to the set of concepts it can refer to. Like many other systems (Miller, 1995; Yates and Etzioni, 2007; Lin and Pantel, 2002), ConceptResolver represents each output concept c_i as a set of synonymous noun phrases, i.e., $c_i = \{x_{i1}, x_{i2}, ..., x_{im}\}$. For example, Figure 2 shows several concepts output by ConceptResolver; each concept clearly reveals which noun phrases can refer to it. Each concept also has a semantic type that corresponds to a category in ConceptResolver's ontology; for instance, the first 10 concepts in Figure 2 belong to the category **company**.

Previous approaches to concept discovery use little prior knowledge, clustering noun phrases based on co-occurrence statistics (Pantel and Lin, 2002). In comparison, ConceptResolver uses a knowledge-rich approach. In addition to the extracted relations, ConceptResolver takes as input two other sources of information: an ontology, and a small number of labeled synonyms. The ontology contains a schema for the relation and category predicates found in the input instances, including properties of predicates like type restrictions on its domain and range. The category predicates are used to assign semantic types to each concept, and the properties of relation predicates are used to create evidence for synonym resolution. The labeled synonyms are used as training data during synonym resolution, where they are used to train a semi-supervised classifier.

1. **Induce Word Senses**
   i. Use extracted category instances to create one or more senses per noun phrase.
   ii. Use argument type constraints to produce relation evidence for synonym resolution.
2. **Cluster Synonymous Senses**
   For each category C defined in the ontology:
   i. Train a semi-supervised classifier to predict synonymy.
   ii. Cluster word senses with semantic type C using classifier's predictions.
   iii. Output sense clusters as concepts with semantic type C.

Figure 3: High-level outline of ConceptResolver's algorithm.

ConceptResolver discovers concepts using the process outlined in Figure 3. It first performs word sense induction, using the extracted category instances to create one or more unambiguous word senses for each noun phrase in the knowledge base. Each word sense is a copy of the original noun phrase paired with a semantic type (a category) that restricts the concepts it can refer to. ConceptResolver then performs synonym resolution on these word senses. This step treats the senses of each semantic type independently, first training a synonym classifier then clustering the senses based on the classifier's decisions. The result of this process is clusters of synonymous word senses, which are output as concepts. Concepts inherit the semantic type of the word senses they contain.

We evaluate ConceptResolver using a subset of NELL's knowledge base, presenting separate results for the concepts of each semantic type. The evaluation shows that, on average, 87% of the word senses created by ConceptResolver correspond to real-world concepts. We additionally find that, on average, 85% of the noun phrases in each concept refer to the same real-world entity.

2 Prior Work

Previous work on concept discovery has focused on the subproblems of word sense induction and synonym resolution. Word sense induction is typically performed using unsupervised clustering. In the SemEval word sense induction and disambigua-

tion task (Agirre and Soroa, 2007; Manandhar et al., 2010), all of the submissions in 2007 created senses by clustering the contexts each word occurs in, and the 2010 event explicitly disallowed the use of external resources like ontologies. Other systems cluster words to find both word senses and concepts (Pantel and Lin, 2002; Lin and Pantel, 2002). ConceptResolver's category-based approach is quite different from these clustering approaches. Snow et al. (2006) describe a system which adds new word senses to WordNet. However, Snow et al. assume the existence of an oracle which provides the senses of each word. In contrast, ConceptResolver automatically determines the number of senses for each word.

Synonym resolution on relations extracted from web text has been previously studied by Resolver (Yates and Etzioni, 2007), which finds synonyms in relation triples extracted by TextRunner (Banko et al., 2007). In contrast to our system, Resolver is unsupervised and does not have a schema for the relations. Due to different inputs, ConceptResolver and Resolver are not precisely comparable. However, our evaluation shows that ConceptResolver has higher synonym resolution precision than Resolver, which we attribute to our semi-supervised approach and the known relation schema.

Synonym resolution also arises in record linkage (Winkler, 1999; Ravikumar and Cohen, 2004) and citation matching (Bhattacharya and Getoor, 2007; Bhattacharya and Getoor, 2006; Poon and Domingos, 2007). As with word sense induction, many approaches to these problems are unsupervised. A problem with these algorithms is that they require the authors to define domain-specific similarity heuristics to achieve good performance. Other synonym resolution work is fully supervised (Singla and Domingos, 2006; McCallum and Wellner, 2004; Snow et al., 2007), training models using manually constructed sets of synonyms. These approaches use large amounts of labeled data, which can be difficult to create. ConceptResolver's approach lies between these two extremes: we label a small number of synonyms (10 pairs), then use semi-supervised training to learn a similarity function. We think our technique is a good compromise, as it avoids much of the manual effort of the other approaches: tuning the similarity function in one case, and labeling a large amount of data in the other

ConceptResolver uses a novel algorithm for semi-supervised clustering which is conceptually similar to other work in the area. Like other approaches (Basu et al., 2004; Xing et al., 2003; Klein et al., 2002), we learn a similarity measure for clustering based on a set of must-link and cannot-link constraints. Unlike prior work, our algorithm exploits multiple views of the data to improve the similarity measure. As far as we know, ConceptResolver is the first application of semi-supervised clustering to relational data – where the items being clustered are connected by relations (Getoor and Diehl, 2005). Interestingly, the relational setting also provides us with the independent views that are beneficial to semi-supervised training.

Concept discovery is also related to coreference resolution (Ng, 2008; Poon and Domingos, 2008). The difference between the two problems is that coreference resolution finds noun phrases that refer to the same concept within a specific document. We think the concepts produced by a system like ConceptResolver could be used to improve coreference resolution by providing prior knowledge about noun phrases that can refer to the same concept. This knowledge could be especially helpful for cross-document coreference resolution systems (Haghighi and Klein, 2010), which actually represent concepts and track mentions of them across documents.

3 Background: Never-Ending Language Learner

ConceptResolver is designed as a component for the Never-Ending Language Learner (NELL) (Carlson et al., 2010). In this section, we provide some pertinent background information about NELL that influenced the design of ConceptResolver [1].

NELL is an information extraction system that has been running 24x7 for over a year, using coupled semi-supervised learning to populate an ontology from unstructured text found on the web. The ontology defines two types of predicates: *categories* (e.g., **company** and **CEO**) and *relations* (e.g., **ceoOfCompany**). Categories are single-argument predicates, and relations are two-argument predicates.

[1] More information about NELL, including browsable and downloadable versions of its knowledge base, is available from `http://rtw.ml.cmu.edu`.

NELL's *knowledge base* contains both definitions for predicates and extracted instances of each predicate. At present, NELL's knowledge base defines approximately 500 predicates and contains over half a million extracted instances of these predicates with an accuracy of approximately 0.85.

Relations between predicates are an important component of NELL's ontology. For ConceptResolver, the most important relations are **domain** and **range**, which define argument types for each relation predicate. For example, the first argument of **ceoOfCompany** must be a **CEO** and the second argument must be a **company**. Argument type restrictions inform ConceptResolver's word sense induction process (Section 4.1).

Multiple sources of information are used to populate each predicate with high precision. The system runs four independent extractors for each predicate: the first uses web co-occurrence statistics, the second uses HTML structures on webpages, the third uses the morphological structure of the noun phrase itself, and the fourth exploits empirical regularities within the knowledge base. These subcomponents are described in more detail by Carlson et al. (2010) and Wang and Cohen (2007). NELL learns using a bootstrapping process, iteratively re-training these extractors using instances in the knowledge base, then adding some predictions of the learners to the knowledge base. This iterative learning process can be viewed as a discrete approximation to EM which does not explicitly instantiate every latent variable.

As in other information extraction systems, the category and relation instances extracted by NELL contain polysemous and synonymous noun phrases. ConceptResolver was developed to reduce the impact of these phenomena.

4 ConceptResolver

This section describes ConceptResolver, our new component which creates concepts from NELL's extractions. It uses a two-step procedure, first creating one or more senses for each noun phrase, then clustering synonymous senses to create concepts.

4.1 Word Sense Induction

ConceptResolver induces word senses using a simple assumption about noun phrases and concepts. If a noun phrase has multiple senses, the senses should be distinguishable from context. People can determine the sense of an ambiguous word given just a few surrounding words (Kaplan, 1955). We hypothesize that local context enables sense disambiguation by defining the semantic type of the ambiguous word. ConceptResolver makes the simplifying assumption that *all* word senses can be distinguished on the basis of semantic type. As the category predicates in NELL's ontology define a set of possible semantic types, this assumption is equivalent to the *one-sense-per-category assumption*: a noun phrase refers to at most one concept in each category of NELL's ontology. For example, this means that a noun phrase can refer to a **company** and a **fruit**, but not multiple companies.

ConceptResolver uses the extracted category assertions to define word senses. Each word sense is represented as a tuple containing a noun phrase and a category. In synonym resolution, the category acts like a type constraint, and only senses with the same category type can be synonymous. To create senses, the system interprets each extracted category predicate $c(x)$ as evidence that category c contains a concept denoted by noun phrase x. Because it assumes that there is at most one such concept, ConceptResolver creates one sense of x for each extracted category predicate. As a concrete example, say the input assertions contain **company**("apple") and **fruit**("apple"). Sense induction creates two senses for "apple": ("apple", company) and ("apple", fruit).

The second step of sense induction produces evidence for synonym resolution by creating relations between word senses. These relations are created from input relations and the ontology's argument type constraints. Each extracted relation is mapped to all possible sense relations that satisfy the argument type constraints. For example, the noun phrase relation **ceoOfCompany**("steve jobs", "apple") would map to **ceoOfCompany**(("steve jobs", ceo), ("apple", company)). It would not map to a similar relation with ("apple", fruit), however, as ("apple", fruit) is not in the range of **ceoOfCompany**. This process is effective because the relations in the ontology have restrictive domains and ranges, so only a small fraction of sense pairs satisfy the argument type restrictions. It is also not vital that this mapping be perfect, as the sense relations are only

used as evidence for synonym resolution. The final output of sense induction is a sense-disambiguated knowledge base, where each noun phrase has been converted into one or more word senses, and relations hold between pairs of senses.

4.2 Synonym Resolution

After mapping each noun phrase to one or more senses (each with a distinct category type), ConceptResolver performs semi-supervised clustering to find synonymous senses. As only senses with the same category type can be synonymous, our synonym resolution algorithm treats senses of each type independently. For each category, ConceptResolver trains a semi-supervised synonym classifier then uses its predictions to cluster word senses.

Our key insight is that semantic relations and string attributes provide independent views of the data: we can predict that two noun phrases are synonymous either based on the similarity of their text strings, or based on similarity in the relations NELL has extracted about them. As a concrete example, we can decide that ("apple computer", company) and ("apple", company) are synonymous because the text string "apple" is similar to "apple computer," or because we have learned that ("steve jobs", ceo) is the CEO of both companies. ConceptResolver exploits these two independent views using co-training (Blum and Mitchell, 1998) to produce an accurate synonym classifier using only a handful of labels.

4.2.1 Co-Training the Synonym Classifier

For each category, ConceptResolver co-trains a pair of synonym classifiers using a handful of labeled synonymous senses and a large number of automatically created unlabeled sense pairs. Co-training is a semi-supervised learning algorithm for data sets where each instance can be classified from two (or more) independent sets of features. That is, the features of each instance x_i can be partitioned into two views, $x_i = (x_i^1, x_i^2)$, and there exist functions in each view, f^1, f^2, such that $f^1(x_i^1) = f^2(x_i^2) = y_i$. The co-training algorithm uses a bootstrapping procedure to train f^1, f^2 using a small set of labeled examples L and a large pool of unlabeled examples U. The training process repeatedly trains each classifier on the labeled examples, then allows each classifier to label some examples in the unlabeled data pool. Co-training also has PAC-style theoretical guarantees which show that it can learn classifiers with arbitrarily high accuracy under appropriate conditions (Blum and Mitchell, 1998).

Figure 4 provides high-level pseudocode for co-training in the context of ConceptResolver. In ConceptResolver, an instance x_i is a pair of senses (e.g., <("apple", company), ("microsoft", company)>), the two views x_i^1 and x_i^2 are derived from string attributes and semantic relations, and the output y_i is whether the senses are synonyms. (The features of each view are described later in this section.) L is initialized with a small number of labeled sense pairs. Ideally, U would contain all pairs of senses in the category, but this set grows quadratically in category size. Therefore, ConceptResolver uses the canopies algorithm (McCallum et al., 2000) to initialize U with a subset of the sense pairs that are more likely to be synonymous.

Both the string similarity classifier and the relation classifier are trained using L_2-regularized logistic regression. The regularization parameter λ is automatically selected on each iteration by searching for a value which maximizes the loglikelihood of a validation set, which is constructed by randomly sampling 25% of L on each iteration. λ is re-selected on each iteration because the initial labeled data set is extremely small, so the initial validation set is not necessarily representative of the actual data. In our experiments, the initial validation set contains only 15 instances.

The string similarity classifier bases its decision on the original noun phrase which mapped to each sense. We use several string similarity measures as features, including SoftTFIDF (Cohen et al., 2003), Level 2 JaroWinkler (Cohen et al., 2003), Fellegi-Sunter (Fellegi and Sunter, 1969), and Monge-Elkan (Monge and Elkan, 1996). The first three algorithms produce similarity scores by matching words in the two phrases and the fourth is an edit distance. We also use a heuristic abbreviation detection algorithm (Schwartz and Hearst, 2003) and convert its output into a score by dividing the length of the detected abbreviation by the total length of the string.

The relation classifier's features capture several intuitive ways to determine that two items are synonyms from the items they are related to. The relation view contains three features for each relation

For each category C:

1. Initialize labeled data L with 10 positive and 50 negative examples (pairs of senses)
2. Initialize unlabeled data U by running canopies (McCallum et al., 2000) on all senses in C.
3. Repeat 50 times:
   i. Train the string similarity classifier on L
   ii. Train the relation classifier on L
   iii. Label U with each classifier
   iv. Add the most confident 5 positive and 25 negative predictions of both classifiers to L

Figure 4: The co-training algorithm for learning synonym classifiers.

r whose domain is compatible with the current category. Consider the sense pair (s, t), and let $r(s)$ denote s's values for relation r (i.e., $r(s) = \{v : r(s, v)\}$). For each relation r, we instantiate the following features:

- **(Senses which share values are synonyms)** The percent of values of r shared by both s and t, that is $\frac{|r(s) \cap r(t)|}{|r(s) \cup r(t)|}$.
- **(Senses with different values are not synonyms)** The percent of values of r not shared by s and t, or $1 - \frac{|r(s) \cap r(t)|}{|r(s) \cup r(t)|}$. The feature is set to 0 if either $r(s)$ or $r(t)$ is empty. This feature is only instantiated if the ontology specifies that r has at most one value per sense.
- **(Some relations indicate synonymy)** A boolean feature which is true if $t \in r(s)$ or $s \in r(t)$.

The output of co-training is a pair of classifiers for each category. We combine their predictions using the assumption that the two views X^1, X^2 are conditionally independent given Y. As we trained both classifiers using logistic regression, we have models for the probabilities $P(Y|X^1)$ and $P(Y|X^2)$. The conditional independence assumption implies that we can combine their predictions using the formula:

$$P(Y = 1|X^1, X^2) = \frac{P(Y = 1|X^1)P(Y = 1|X^2)P(Y = 0)}{\sum_{y=0,1} P(Y = y|X^1)P(Y = y|X^2)(1 - P(Y = y))}$$

The above formula involves a prior term, $P(Y)$, because the underlying classifiers are discriminative. We set $P(Y = 1) = .5$ in our experiments as this setting reduces our dependence on the (typically poorly calibrated) probability estimates of logistic regression. We also limited the probability predictions of each classifier to lie in $[.01, .99]$ to avoid divide-by-zero errors. The probability $P(Y|X^1, X^2)$ is the final synonym classifier which is used for agglomerative clustering.

4.2.2 Agglomerative Clustering

The second step of our algorithm runs agglomerative clustering to enforce transitivity constraints on the predictions of the co-trained synonym classifier. As noted in previous works (Snow et al., 2006), synonymy is a transitive relation. If a and b are synonyms, and b and c are synonyms, then a and c must also be synonyms. Unfortunately, co-training is not guaranteed to learn a function that satisfies these transitivity constraints. We enforce the constraints by running agglomerative clustering, as clusterings of instances trivially satisfy the transitivity property.

ConceptResolver uses the clustering algorithm described by Snow et al. (2006), which defines a probabilistic model for clustering and a procedure to (locally) maximize the likelihood of the final clustering. The algorithm is essentially bottom-up agglomerative clustering of word senses using a similarity score derived from $P(Y|X^1, X^2)$. The similarity score for two senses is defined as:

$$\log \frac{P(Y = 0)P(Y = 1|X^1, X^2)}{P(Y = 1)P(Y = 0|X^1, X^2)}$$

The similarity score for two clusters is the sum of the similarity scores for all pairs of senses. The agglomerative clustering algorithm iteratively merges the two most similar clusters, stopping when the score of the best possible pair is below 0. The clusters of word senses produced by this process are the concepts for each category.

5 Evaluation

We perform several experiments to measure ConceptResolver's performance at each of its respective tasks. The first experiment evaluates word sense induction using Freebase as a canonical set of concepts. The second experiment evaluates synonym resolution by comparing ConceptResolver's sense clusters to a gold standard clustering.

For both experiments, we used a knowledge base created by running 140 iterations of NELL. We preprocessed this knowledge base by removing all noun

phrases with zero extracted relations. As ConceptResolver treats the instances of each category predicate independently, we chose 7 categories from NELL's ontology to use in the evaluation. The categories were selected on the basis of the number of extracted relations that ConceptResolver could use to detect synonyms. The number of noun phrases in each category is shown in Table 2. We manually labeled 10 pairs of synonymous senses for each of these categories. The system automatically synthesized 50 negative examples from the positive examples by assuming each pair represents a distinct concept, so senses in different pairs are not synonyms.

5.1 Word Sense Induction Evaluation

Our first experiment evaluates the performance of ConceptResolver's category-based word sense induction. We estimate two quantities: (1) *sense precision*, the fraction of senses created by our system that correspond to real-world entities, and (2) *sense recall*, the fraction of real-world entities that ConceptResolver creates senses for. Sense recall is only measured over entities which are represented by a noun phrase in ConceptResolver's input assertions – it is a measure of ConceptResolver's ability to create senses for the noun phrases it is given. Sense precision is directly determined by how frequently NELL's extractors propose correct senses for noun phrases, while sense recall is related to the correctness of the one-sense-per-category assumption.

Precision and recall were evaluated by comparing the senses created by ConceptResolver to concepts in Freebase (Bollacker et al., 2008). We sampled 100 noun phrases from each category and matched each noun phrase to a set of Freebase concepts. We interpret each matching Freebase concept as a sense of the noun phrase. We chose Freebase because it had good coverage for our evaluation categories.

To align ConceptResolver's senses with Freebase, we first matched each of our categories with a set of similar Freebase categories[2]. We then used a combination of Freebase's search API and Mechanical Turk to align noun phrases with Freebase concepts: we searched for the noun phrase in Freebase, then had Mechanical Turk workers label which of the top 10 resulting Freebase concepts the noun phrase could refer to. After obtaining the list of matching Freebase concepts for each noun phrase, we computed sense precision as the number of noun phrases matching ≥ 1 Freebase concept divided by 100, the total number of noun phrases. Sense recall is the reciprocal of the average number of Freebase concepts per noun phrase. Noun phrases matching 0 Freebase concepts were not included in this computation.

Category	Precision	Recall	Freebase concepts per Phrase
athlete	0.95	0.56	1.76
city	0.97	0.25	3.86
coach	0.86	0.94	1.06
company	0.85	0.41	2.41
country	0.74	0.56	1.77
sportsteam	0.89	0.30	3.28
stadiumoreventvenue	0.83	0.61	1.63

Table 1: ConceptResolver's word sense induction performance

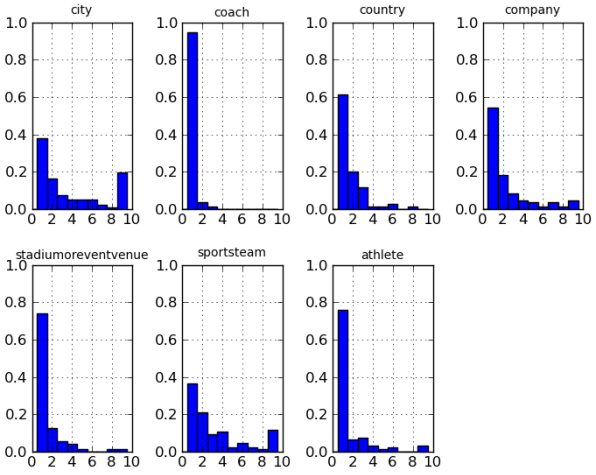

Figure 5: Empirical distribution of the number of Freebase concepts per noun phrase in each category

The results of the evaluation in Table 1 show that ConceptResolver's word sense induction works quite well for many categories. Most categories have high precision, while recall varies by category. Categories like **coach** are relatively unambiguous, with almost exactly 1 sense per noun phrase. Other categories have almost 4 senses per noun phrase. However, this average is somewhat misleading. Figure 5 shows the distribution of the number of concepts per noun phrase in each category. The distribution shows that most noun phrases are unambiguous, but a small number of noun phrases have a large number of senses. In many cases, these noun phrases

[2]In Freebase, concepts are called Topics and categories are called Types. For clarity, we use our terminology throughout.

are generic terms for many items in the category; for example, "palace" in **stadiumoreventvenue** refers to 10 Freebase concepts. Freebase's category definitions are also overly technical in some cases – for example, Freebase's version of **company** has a concept for each registered corporation. This definition means that some companies like *Volkswagen* have more than one concept (in this case, 9 concepts). These results suggest that the one-sense-per-category assumption holds for most noun phrases.

An important footnote to this evaluation is that the categories in NELL's ontology are somewhat arbitrary, and that creating subcategories would improve sense recall. For example, we could define subcategories of **sportsteam** for various sports (e.g., **football team**); these new categories would allow ConceptResolver to distinguish between teams with the same name that play different sports. Creating subcategories could improve performance in categories with a high level of polysemy.

5.2 Synonym Resolution Evaluation

Our second experiment evaluates synonym resolution by comparing the concepts created by ConceptResolver to a gold standard set of concepts. Although this experiment is mainly designed to evaluate ConceptResolver's ability to detect synonyms, it is somewhat affected by the word sense induction process. Specifically, the gold standard clustering contains noun phrases that refer to multiple concepts within the same category. (It is unclear how to create a gold standard clustering without allowing such mappings.) The word sense induction process produces only one of these mappings, which limits maximum possible recall in this experiment.

For this experiment, we report two different measures of clustering performance. The first measure is the precision and recall of pairwise synonym decisions, typically known as cluster precision and recall. We dub this the clustering metric. We also adopt the precision/recall measure from Resolver (Yates and Etzioni, 2007), which we dub the Resolver metric. The Resolver metric aligns each proposed cluster containing $\geq$ 2 senses with a gold standard cluster (i.e., a real-world concept) by selecting the cluster that a plurality of the senses in the proposed cluster refer to. Precision is then the fraction of senses in the proposed cluster which are also in the gold standard cluster; recall is computed analogously by swapping the roles of the proposed and gold standard clusters. Resolver precision can be interpreted as the probability that a randomly sampled sense (in a cluster with at least 2 senses) is in a cluster representing its true meaning. Incorrect senses were removed from the data set before evaluating precision; however, these senses may still affect performance by influencing the clustering process.

Precision was evaluated by sampling 100 random concepts proposed by ConceptResolver, then manually scoring each concept using both of the metrics above. This process mimics aligning each sampled concept with its best possible match in a gold standard clustering, then measuring precision with respect to the gold standard.

Recall was evaluated by comparing the system's output to a manually constructed set of concepts for each category. To create this set, we randomly sampled noun phrases from each category and manually matched each noun phrase to one or more real-world entities. We then found other noun phrases which referred to each entity and created a concept for each entity with at least one unambiguous reference. This process can create multiple senses for a noun phrase, depending on the real-world entities represented in the input assertions. We only included concepts containing at least 2 senses in the test set, as singleton concepts do not contribute to either recall metric. The size of each recall test set is listed in Table 2; we created smaller test sets for categories where synonyms were harder to find. Incorrectly categorized noun phrases were not included in the gold standard as they do not correspond to any real-world entities.

Table 2 shows the performance of ConceptResolver on each evaluation category. For each category, we also report the baseline recall achieved by placing each sense in its own cluster. ConceptResolver has high precision for several of the categories. Other categories like **athlete** and **city** have somewhat lower precision. To make this difference concrete, Figure 2 (first page) shows a random sample of 10 concepts from both **company** and **athlete**. Recall varies even more widely across categories, partly because the categories have varying levels of polysemy, and partly due to differences in average concept size. The differences in average concept size are reflected in the baseline recall numbers.

Category	# of Phrases	Recall Set Size	Resolver Metric				Clustering Metric			
			Precision	Recall	F1	Baseline Recall	Precision	Recall	F1	Baseline Recall
athlete	3886	80	0.69	0.69	0.69	0.46	0.41	0.45	0.43	0.00
city	5710	50	0.66	0.52	0.58	0.42	0.30	0.10	0.15	0.00
coach	889	60	0.90	0.93	0.91	0.43	0.83	0.88	0.85	0.00
company	3553	60	0.93	0.71	0.81	0.39	0.79	0.44	0.57	0.00
country	693	60	0.98	0.50	0.66	0.30	0.94	0.15	0.26	0.00
sportsteam	2085	100	0.95	0.48	0.64	0.29	0.87	0.15	0.26	0.00
stadiumoreventvenue	1662	100	0.84	0.73	0.78	0.39	0.65	0.49	0.56	0.00

Table 2: Synonym resolution performance of ConceptResolver

We attribute the differences in precision across categories to the different relations available for each category. For example, none of the relations for **athlete** uniquely identify a single athlete, and therefore synonymy cannot be accurately represented in the relation view. Adding more relations to NELL's ontology may improve performance in these cases.

We note that the synonym resolution portion of ConceptResolver is tuned for precision, and that perfect recall is not necessarily attainable. Many word senses participate in only one relation, which may not provide enough evidence to detect synonymy. As NELL continually extracts more knowledge, it is reasonable for ConceptResolver to abstain from these decisions until more evidence is available.

6 Discussion

In order for information extraction systems to accurately represent knowledge, they must represent noun phrases, concepts, and the many-to-many mapping from noun phrases to concepts they denote. We present ConceptResolver, a system which takes extracted relations between noun phrases and identifies latent concepts that the noun phrases refer to. Two lessons from ConceptResolver are that (1) ontologies aid word sense induction, as the senses of polysemous words tend to have distinct semantic types, and (2) redundant information, in the form of string similarity and extracted relations, helps train accurate synonym classifiers.

An interesting aspect of ConceptResolver is that its performance should improve as NELL's ontology and knowledge base grow in size. Defining finer-grained categories will improve performance at word sense induction, as more precise categories will contain fewer ambiguous noun phrases. Both extracting more relation instances and adding new relations to the ontology will improve synonym resolution. These scaling properties allow manual effort to be spent on high-level ontology operations, not on labeling individual instances. We are interested in observing ConceptResolver's performance as NELL's ontology and knowledge base grow.

For simplicity of exposition, we have implicitly assumed thus far that the categories in NELL's ontology are mutually exclusive. However, the ontology contains compatible categories like **male** and **politician**, where a single concept can belong to both categories. In these situations, the one-sense-per-category assumption may create too many word senses. We currently address this problem with a heuristic post-processing step: we merge all pairs of concepts that belong to compatible categories and share at least one referring noun phrase. This heuristic typically works well, however there are problems. An example of a problematic case is "obama," which NELL believes is a **male**, **female**, and **politician**. In this case, the heuristic cannot decide which "obama" (the male or female) is the politician. As such cases are fairly rare, we have not developed a more sophisticated solution to this problem.

ConceptResolver has been integrated into NELL's continual learning process. NELL's current set of concepts can be viewed through the knowledge base browser on NELL's website, `http://rtw.ml.cmu.edu`.

Semantic Representation of Negation Using Focus Detection

Eduardo Blanco and **Dan Moldovan**
Human Language Technology Research Institute
The University of Texas at Dallas
Richardson, TX 75080 USA
{eduardo,moldovan}@hlt.utdallas.edu

Abstract

Negation is present in all human languages and it is used to reverse the polarity of part of statements that are otherwise affirmative by default. A negated statement often carries positive implicit meaning, but to pinpoint the positive part from the negative part is rather difficult. This paper aims at thoroughly representing the semantics of negation by revealing implicit positive meaning. The proposed representation relies on focus of negation detection. For this, new annotation over PropBank and a learning algorithm are proposed.

1 Introduction

Understanding the meaning of text is a long term goal in the natural language processing community. Whereas philosophers and linguists have proposed several theories, along with models to represent the meaning of text, the field of computational linguistics is still far from doing this automatically. The ambiguity of language, the need to detect implicit knowledge, and the demand for commonsense knowledge and reasoning are a few of the difficulties to overcome. Substantial progress has been made, though, especially on detection of semantic relations, ontologies and reasoning methods.

Negation is present in all languages and it is always the case that statements are affirmative by default. Negation is marked and it typically signals something unusual or an exception. It may be present in all units of language, e.g., words (*in*credible), clauses (*He does*n't *have friends*). Negation and its correlates (truth values, lying, irony, false or contradictory statements) are exclusive characteristics of humans (Horn, 1989; Horn and Kato, 2000).

Negation is fairly well-understood in grammars; the valid ways to express a negation are documented. However, there has not been extensive research on detecting it, and more importantly, on representing the semantics of negation. Negation has been largely ignored within the area of semantic relations.

At first glance, one would think that interpreting negation could be reduced to finding negative keywords, detect their scope using syntactic analysis and reverse its polarity. Actually, it is more complex. Negation plays a remarkable role in text understanding and it poses considerable challenges.

Detecting the scope of negation in itself is challenging: *All vegetarians do not eat meat* means that vegetarians do not eat meat and yet *All that glitters is not gold* means that it is not the case that all that glitters is gold (so out of all things that glitter, some are gold and some are not). In the former example, the universal quantifier *all* has scope over the negation; in the latter, the negation has scope over *all*.

In logic, two negatives always cancel each other out. On the other hand, in language this is only theoretically the case: *she is not unhappy* does not mean that *she is happy*; it means that *she is not fully unhappy, but she is not happy either*.

Some negated statements carry a positive implicit meaning. For example, *cows do not eat meat* implies that *cows eat something other than meat*. Otherwise, the speaker would have stated *cows do not eat*. A clearer example is the correct and yet puzzling statement *tables do not eat meat*. This sentence sounds

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 581–589,
Portland, Oregon, June 19-24, 2011.

unnatural because of the underlying positive statement (i.e., *tables eat something other than meat*).

Negation can express *less than* or *in between* when used in a scalar context. For example, *John does not have three children* probably means that he has either one or two children. Contrasts may use negation to disagree about a statement and not to negate it, e.g., *That place is not big, it is massive* defines the place as *massive*, and therefore, *big*.

2 Related Work

Negation has been widely studied outside of computational linguistics. In logic, negation is usually the simplest unary operator and it reverses the truth value. The seminal work by Horn (1989) presents the main thoughts in philosophy and psychology. Linguists have found negation a complex phenomenon; Huddleston and Pullum (2002) dedicate over 60 pages to it. Negation interacts with quantifiers and anaphora (Hintikka, 2002), and influences reasoning (Dowty, 1994; Sánchez Valencia, 1991). Zeijlstra (2007) analyzes the position and form of negative elements and negative concords.

Rooth (1985) presented a theory of focus in his dissertation and posterior publications (e.g., Rooth (1992)). In this paper, we follow the insights on scope and focus of negation by Huddleston and Pullum (2002) rather than Rooth's (1985).

Within natural language processing, negation has drawn attention mainly in sentiment analysis (Wilson et al., 2009; Wiegand et al., 2010) and the biomedical domain. Recently, the Negation and Speculation in NLP Workshop (Morante and Sporleder, 2010) and the CoNLL-2010 Shared Task (Farkas et al., 2010) targeted negation mostly on those subfields. Morante and Daelemans (2009) and Özgür and Radev (2009) propose scope detectors using the BioScope corpus. Councill et al. (2010) present a supervised scope detector using their own annotation. Some NLP applications deal indirectly with negation, e.g., machine translation (van Munster, 1988), text classification (Rose et al., 2003) and recognizing entailments (Bos and Markert, 2005).

Regarding corpora, the BioScope corpus annotates negation marks and linguistic scopes exclusively on biomedical texts. It does not annotate focus and it purposely ignores negations such as *(talking about the reaction of certain elements) in NK3.3 cells is not always identical* (Vincze et al., 2008), which carry the kind of positive meaning this work aims at extracting (in NK3.3 cells *is often* identical). PropBank (Palmer et al., 2005) only indicates the verb to which a negation mark attaches; it does not provide any information about the scope or focus. FrameNet (Baker et al., 1998) does not consider negation and FactBank (Saurí and Pustejovsky, 2009) only annotates degrees of factuality for events.

None of the above references aim at detecting or annotating the focus of negation in natural language. Neither do they aim at carefully representing the meaning of negated statements nor extracting implicit positive meaning from them.

3 Negation in Natural Language

Simply put, negation is a process that turns a statement into its opposite. Unlike affirmative statements, negation is marked by words (e.g., *not, no, never*) or affixes (e.g., *-n't, un-*). Negation can interact with other words in special ways. For example, negated clauses use different connective adjuncts that positive clauses do: *neither, nor* instead of *either, or*. The so-called *negatively-oriented polarity-sensitive items* (Huddleston and Pullum, 2002) include, among many others, words starting with *any-* (*anybody*, *anyone*, *anywhere*, etc.), the modal auxiliaries *dare* and *need* and the grammatical units *at all*, *much* and *till*. Negation in verbs usually requires an auxiliary; if none is present, the auxiliary *do* is inserted (*I read the paper* vs. *I didn't read the paper*).

3.1 Meaning of Negated Statements

State-of-the-art semantic role labelers (e.g., the ones trained over PropBank) do not completely represent the meaning of negated statements. Given *John didn't build a house to impress Mary*, they encode AGENT(*John, build*), THEME(*a house, build*), PURPOSE(*to impress Mary, build*), NEGATION(*n't, build*). This representation corresponds to the interpretation *it is not the case that John built a house to impress Mary*, ignoring that it is implicitly stated that *John did build a house*.

Several examples are shown Table 1. For all statements *s*, current role labelers would only encode *it is not the case that* s. However, examples (1–7)

	Statement	Interpretation
1	John didn't build a house to impress Mary.	John built a house for other purpose.
2	I don't have a watch with me.	I have a watch, but it is not with me.
3	We don't have an evacuation plan for flooding.	We have an evacuation plan for something else (e.g., fire).
4	They didn't release the UFO files until 2008.	They released the UFO files in 2008.
5	John doesn't know exactly how they met.	John knows how they met, but not exactly.
6	His new job doesn't require driving.	His new job has requirements, but it does not require driving.
7	His new job doesn't require driving yet.	His new job requires driving in the future.
8	His new job doesn't require anything.	His new job has no requirements.
9	A panic on Wall Street doesn't exactly inspire confidence.	A panic on Wall Streen discourages confidence.

Table 1: Examples of negated statements and their interpretations considering underlying positive meaning. A wavy underline indicates the focus of negation (Section 3.3); examples (8, 9) do not carry any positive meaning.

carry positive meaning underneath the direct meaning. Regarding (4), encoding that the UFO files *were released in 2008* is crucial to fully interpret the statement. (6–8) show that different verb arguments modify the interpretation and even signal the existence of positive meaning. Examples (5, 9) further illustrate the difficulty of the task; they are very similar (both have AGENT, THEME and MANNER) and their interpretation is altogether different. Note that (8, 9) do not carry any positive meaning; even though their interpretations do not contain a verbal negation, the meaning remains negative. Some examples could be interpreted differently depending on the context (Section 4.2.1).

This paper aims at thoroughly representing the semantics of negation by revealing implicit positive meaning. The main contributions are: (1) interpretation of negation using focus detection; (2) focus of negation annotation over all PropBank negated sentences[1]; (3) feature set to detect the focus of negation; and (4) model to semantically represent negation and reveal its underlying positive meaning.

3.2 Negation Types

Huddleston and Pullum (2002) distinguish four contrasts for negation:

- Verbal if the marker of negation is grammatically associated with the verb (*I did not see anything at all*); non-verbal if it is associated with a dependent of the verb (*I saw nothing at all*).
- Analytic if the sole function of the negated mark is to mark negation (*Bill did not go*); synthetic if it has some other function as well (*[Nobody]*$_{\text{AGENT}}$ *went to the meeting*).
- Clausal if the negation yields a negative clause (*She didn't have a large income*); subclausal otherwise (*She had a not inconsiderable income*).
- Ordinary if it indicates that something is not the case, e.g., (1) *She didn't have lunch with my old man: he couldn't make it*; metalinguistic if it does not dispute the truth but rather reformulates a statement, e.g., (2) *She didn't have lunch with your 'old man': she had lunch with your father*. Note that in (1) the lunch never took place, whereas in (2) a lunch did take place.

In this paper, we focus on verbal, analytic, clausal, and both metalinguistic and ordinary negation.

3.3 Scope and Focus

Negation has both scope and focus and they are extremely important to capture its semantics. Scope is the part of the meaning that is negated. Focus is that part of the scope that is most prominently or explicitly negated (Huddleston and Pullum, 2002).

Both concepts are tightly connected. Scope corresponds to all elements any of whose individual falsity would make the negated statement true. Focus is the element of the scope that is *intended* to be interpreted as false to make the overall negative true.

Consider (1) *Cows don't eat meat* and its positive counterpart (2) *Cows eat meat*. The truth conditions of (2) are: (a) somebody eats something; (b) cows are the ones who eat; and (c) meat is what is eaten.

In order for (2) to be true, (a–c) have to be true. And the falsity of any of them is sufficient to make (1) true. In other words, (1) would be true if *nobody eats*, *cows don't eat* or *meat is not eaten*. Therefore, all three statements (a–c) are inside the scope of (1).

The focus is more difficult to identify, especially

[1] Annotation will be available on the author's website

1	AGENT(*the cow, didn't eat*)	THEME(*grass, didn't eat*)	INSTRUMENT(*with a fork, didn't eat*)
2	NOT[AGENT(*the cow, ate*)	THEME(*grass, ate*)	INSTRUMENT(*with a fork, ate*)]
3	NOT[AGENT(*the cow, ate*)]	THEME(*grass, ate*)	INSTRUMENT(*with a fork, ate*)
4	AGENT(*the cow, ate*)	NOT[THEME(*grass, ate*)]	INSTRUMENT(*with a fork, ate*)
5	AGENT(*the cow, ate*)	THEME(*grass, ate*)	NOT[INSTRUMENT(*with a fork, ate*)]

Table 2: Possible semantic representations for *The cow didn't eat grass with a fork*.

without knowing stress or intonation. Text understanding is needed and context plays an important role. The most probable focus for (1) is *meat*, which corresponds to the interpretation *cows eat something else than meat*. Another possible focus is *cows*, which yields *someone eats meat, but not cows*.

Both scope and focus are primarily semantic, highly ambiguous and context-dependent. More examples can be found in Tables 1 and 3 and (Huddleston and Pullum, 2002, Chap. 9).

4 Approach to Semantic Representation of Negation

Negation does not stand on its own. To be useful, it should be added as part of another existing knowledge representation. In this Section, we outline how to incorporate negation into semantic relations.

4.1 Semantic Relations

Semantic relations capture connections between concepts and label them according to their nature. It is out of the scope of this paper to define them in depth, establish a set to consider or discuss their detection. Instead, we use generic semantic roles.

Given *s: The cow didn't eat grass with a fork*, typical semantic roles encode AGENT(*the cow, eat*), THEME(*grass, eat*), INSTRUMENT(*with a fork, eat*) and NEGATION(*n't, eat*). This representation only differs on the last relation from the positive counterpart. Its interpretation is *it is not the case that* s.

Several options arise to thoroughly represent *s*. First, we find it useful to consider the semantic representation of the affirmative counterpart: AGENT(*the cow, ate*), THEME(*grass, ate*), and INSTRUMENT(*with a fork, ate*). Second, we believe detecting the focus of negation is useful. Even though it is open to discussion, the focus corresponds to INSTRUMENT(*with a fork, ate*) Thus, the negated statement should be interpreted as *the cow ate grass, but it did not do so using a fork*.

Table 2 depicts five different possible semantic representations. Option (1) does not incorporate any explicit representation of negation. It attaches the negated mark and auxiliary to *eat*; the negation is part of the relation arguments. This option fails to detect any underlying positive meaning and corresponds to the interpretation *the cow did not eat, grass was not eaten* and *a fork was not used to eat*.

Options (2–5) embody negation into the representation with the *pseudo-relation* NOT. NOT takes as its argument an instantiated relation or set of relations and indicates that they do not hold.

Option (2) includes all the scope as the argument of NOT and corresponds to the interpretation *it is not the case that the cow ate grass with a fork*. Like typical semantic roles, option (2) does not reveal the implicit positive meaning carried by statement *s*. Options (3–5) encode different interpretations:

- (3) negates the AGENT; it corresponds to *the cow didn't eat, but grass was eaten with a fork.*
- (4) applies NOT to the THEME; it corresponds to *the cow ate something with a fork, but not grass*.
- (5) denies the INSTRUMENT, encoding the meaning *the cow ate grass, but it did not use a fork*.

Option (5) is preferred since it captures the best implicit positive meaning. It corresponds to the semantic representation of the affirmative counterpart after applying the pseudo-relation NOT over the focus of the negation. This fact justifies and motivates the detection of the focus of negation.

4.2 Annotating the Focus of Negation

Due to the lack of corpora containing annotation for focus of negation, new annotation is needed. An obvious option is to add it to any text collection. However, building on top of publicly available resources is a better approach: they are known by the community, they contain useful information for detecting the focus of negation and tools have already been developed to predict their annotation.

	Statement	V	A0	A1	A2	A4	TMP	MNR	ADV	LOC	PNC	EXT	DIS	MOD

Table 3: Negated statements from PropBank and their interpretation considering underlying positive meaning. Focus is underlined; '+' indicates that the role is present, '-' that it is not and '⋆' that it corresponds to the focus of negation.

We decided to work over PropBank. Unlike other resources (e.g., FrameNet), gold syntactic trees are available. Compared to the BioScope corpus, PropBank provides semantic annotation and is not limited to the biomedical domain. On top of that, there has been active research on predicting PropBank roles for years. The additional annotation can be readily used by any system trained with PropBank, quickly incorporating interpretation of negation.

4.2.1 Annotation Guidelines

The focus of a negation involving verb v is resolved as:

- If it cannot be inferred that an action v occurred, focus is role MNEG.
- Otherwise, focus is the role that is most prominently negated.

All decisions are made considering as context the previous and next sentence. The mark -NOT is used to indicate the focus. Consider the following statement (file wsj_2282, sentence 16).

> [While profitable]$_{MADV_{1,2}}$, [it]$_{A1_1,A0_2}$ "was[n't]$_{MNEG_1}$ [growing]$_{v_1}$ and was[n't]$_{MNEG_2}$ [providing]$_{v_2}$ [a satisfactory return on invested capital]$_{A1_2}$," he says.

The previous sentence is *Applied, then a closely held company, was stagnating under the management of its controlling family*. Regarding the first verb (*growing*), one cannot infer that anything was growing, so focus is MNEG. For the second verb (*providing*), it is implicitly stated that the company was providing *a not satisfactory return on investment*, therefore, focus is A1.

The guidelines assume that the focus corresponds to a single role or the verb. In cases where more than one role could be selected, the most likely focus is chosen; context and text understanding are key. We define the most likely focus as the one that yields the most meaningful implicit information.

For example, in (Table 3, example 2) *[He]*$_{A0}$ could be chosen as focus, yielding *someone can stomach the taste of Heinz, but not him*. However, given the previous sentence (*[...] her husband is*

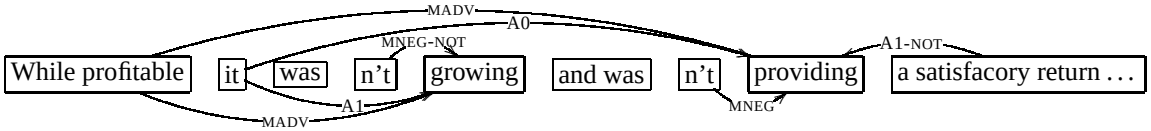

Figure 1: Example of focus annotation (marked with -NOT). Its interpretation is explained in Section 4.2.2.

adamant about eating only Hunt's ketchup), it is clear that the best option is A1. Example (5) has a similar ambiguity between A0 and A2, example (9) between MTMP and A4, etc. The role that yields the most useful positive implicit information given the context is always chosen as focus.

Table 3 provides several examples having as their focus different roles. Example (1) does not carry any positive meaning, the focus is V. In (2–10) the verb must be interpreted as affirmative, as well as all roles except the one marked with '⋆' (i.e., the focus). For each example, we provide PropBank annotation (top), the new annotation (i.e., the focus, bottom right) and its interpretation (bottom left).

4.2.2 Interpretation of -NOT

The mark -NOT is interpreted as follows:

- If MNEG-NOT(x, y), then verb y must be negated; the statement does not carry positive meaning.
- If any other role is marked with -NOT, ROLE-NOT(x, y) must be interpreted as *it is not the case that x is* ROLE *of y*.

Unmarked roles are interpreted positive; they correspond to implicit positive meaning. Role labels (A0, MTMP, etc.) maintain the same meaning from PropBank (Palmer et al., 2005). MNEG can be ignored since it is overwritten by -NOT.

The new annotation for the example (Figure 1) must be interpreted as: *While profitable, it (the company) was not growing and was providing a not satisfactory return on investment*. Paraphrasing, *While profitable, it was shrinking or idle and was providing an unsatisfactory return on investment*. We discover an entailment and an implicature respectively.

4.3 Annotation Process

We annotated the 3,993 verbal negations signaled with MNEG in PropBank. Before annotation began, all semantic information was removed by mapping all role labels to ARG. This step is necessary to ensure that focus selection is not biased by the semantic labels provided by PropBank.

Role	#Inst.	Focus
		# – %
A1	2,930	1,194 – 40.75
MNEG	3,196	1,109 – 34.70
MTMP	609	246 – 40.39
MMNR	250	190 – 76.00
A2	501	179 – 35.73
MADV	466	94 – 20.17
A0	2,163	73 – 3.37
MLOC	114	22 – 19.30
MEXT	25	22 – 88.00
A4	26	22 – 84.62
A3	48	18 – 37.50
MDIR	35	13 – 37.14
MPNC	87	9 – 10.34
MDIS	287	6 – 2.09

Table 4: Roles, total instantiations and counts corresponding to focus over training and held-out instances.

As annotation tool, we use Jubilee (Choi et al., 2010). For each instance, annotators decide the focus given the full syntactic tree, as well as the previous and next sentence. A post-processing step incorporates focus annotation to the original PropBank by adding -NOT to the corresponding role.

In a first round, 50% of instances were annotated twice. Inter-annotator agreement was 0.72. After careful examination of the disagreements, they were resolved and annotators were given clearer instructions. The main point of conflict was selecting a focus that yields valid implicit meaning, but not the most valuable (Section 4.2.1). Due to space constraints, we cannot elaborate more on this issue. The remaining instances were annotated once. Table 4 depicts counts for each role.

5 Learning Algorithm

We propose a supervised learning approach. Each sentence from PropBank containing a verbal negation becomes an instance. The decision to be made is to choose the role that corresponds to the focus.

No.	Feature	Values	Explanation
1	role-present	{y, n}	is role present?
2	role-f-pos	{DT, NNP, ...}	First POS tag of role
3	role-f-word	{This, to, overseas, ...}	First word of role
4	role-length	$\mathbb{N}$	number fo words in role
5	role-posit	$\mathbb{N}$	position within the set of roles
6	A1-top	{NP, SBAR, PP, ...}	syntactic node of A1
7	A1-postag	{y, n}	does A1 contain the tag *postag*?
8	A1-keyword	{y, n}	does A1 cotain the word *keyword*?
9	first-role	{A1, MLOC, ...}	label of the first role
10	last-role	{A1, MLOC, ...}	label of the last role
11	verb-word	{appear, describe, ...}	main verb
12	verb-postag	{VBN, VBZ, ...}	POS tag main verb
13	VP-words	{were-n't, be-quickly, ...}	sequence of words of VP until verb
14	VP-postags	{VBP-RB-RB-VBG, VBN-VBG, ...}	sequence of POS tags of VP until verb
15	VP-has-CC	{y, n}	does the VP contain a CC?
16	VP-has-RB	{y, n}	does the VP contain a RB?
17	predicate	{rule-out, come-up, ...}	predicate
18	them-role-A0	{preparer, assigner, ...}	thematic role for A0
19	them-role-A1	{effort, container, ...}	thematic role for A1
20	them-role-A2	{audience, loaner, ...}	thematic role for A2
21	them-role-A3	{intensifier, collateral, ...}	thematic role for A3
22	them-role-A4	{beneficiary, end point, ...}	thematic role for A4

Table 5: Full set of features. Features (1–5) are extracted for all roles, (7, 8) for all POS tags and keywords detected.

The 3,993 annotated instances are divided into training (70%), held-out (10%) and test (20%). The held-out portion is used to tune the feature set and results are reported for the test split only, i.e., using unseen instances. Because PropBank adds semantic role annotation on top of the Penn TreeBank, we have available syntactic annotation and semantic role labels for all instances.

5.1 Baselines

We implemented four baselines to measure the difficulty of the task:

- A1: select A1, if not present then MNEG.
- FIRST: select first role.
- LAST: select last role.
- BASIC: same than FOC-DET but only using features *last_role* and flags indicating the presence of roles.

5.2 Selecting Features

The BASIC baseline obtains a respectable accuracy of 61.38 (Table 6). Most errors correspond to instances having as focus the two most likely foci: A1 and MNEG (Table 4). We improve BASIC with an extended feature set which targets especially A1 and the verb (Table 5).

Features (1–5) are extracted for each role and capture their presence, first POS tag and word, length and position within the roles present for that instance. Features (6–8) further characterize A1. A1-postag is extracted for the following POS tags: DT, JJ, PRP, CD, RB, VB and WP; A1-keyword for the following words: *any*, *anybody*, *anymore*, *anyone*, *anything*, *anytime*, *anywhere*, *certain*, *enough*, *full*, *many*, *much*, *other*, *some*, *specifics*, *too* and *until*. These lists of POS tags and keywords were extracted after manual examination of training examples and aim at signaling whether this role correspond to the focus. Examples of A1 corresponding to the focus and including one of the POS tags or keywords are:

- *[Apparently]*$_{\text{MADV}}$, *[the respondents]*$_{A0}$ *do n't think [that an economic slowdown would harm the major investment markets very*^{RB} *much]*$_{\text{A1}}$. (i.e., the responders think it would harm the investements little).

- *[The oil company]*$_{\text{A0}}$ *does n't anticipate [any*^{keyword} *additional charges]*$_{\text{A1}}$ (i.e., *the company anticipates no additional charges*).
- *[Money managers and other bond buyers]*$_{\text{A0}}$ *haven't [shown]*$_{\text{V}}$ *[much*^{keyword} *interest in the Refcorp bonds]*$_{\text{A1}}$ (i.e., *they have shown little interest in the bonds*).
- *He concedes H&R Block is well-entrenched and a great company, but says "[it]*$_{\text{A1}}$ *doesn't [grow]*$_{\text{V}}$ *[fast enough*^{keyword} *for us]*$_{\text{A1}}$*"* (i.e., it is growing too slow for us).
- [We]$_{A0}$ don't [see]$_{\text{V}}$ [a domestic source for some^{keyword} of our HDTV requirements]$_{\text{A1}}$, and that's a source of concern [. . .] (i.e., we see a domestic source for some other of our HDTV requirements)

Features (11–16) correspond to the main verb. `VP-words` (`VP-postag`) captures the full sequence of words (POS tags) from the beginning of the VP until the main verb. Features (15–16) check for POS tags as the presence of certain tags usually signal that the verb is not the focus of negation (e.g., *[Thus]*$_{\text{MDIS}}$*, he asserts, [Lloyd's]*$_{\text{A0}}$ *[[ca]*$_{\text{MMOD}}$*n't [react]*$_{v}$ *[quickly*^{RB}*]*$_{MMNR}$ *[to competition]*$_{\text{A1}}$*]*$_{VP}$).

Features (17–22) tackle the predicate, which includes the main verb and may include other words (typically prepositions). We consider the words in the predicate, as well as the specific thematic roles for each numbered argument. This is useful since PropBank uses different numbered arguments for the same thematic role depending on the frame (e.g., A3 is used as PURPOSE in *authorize.01* and as INSTRUMENT in *avert.01*).

6 Experiments and Results

As a learning algorithm, we use bagging with C4.5 decision trees. This combination is fast to train and test, and typically provides good performance. More features than the ones depicted were tried, but we only report the final set. For example, the parent node for all roles was considered and discarded. We name the model considering all features and trained using bagging with C4.5 trees `FOC-DET`.

Results over the test split are depicted in Table 6. Simply choosing A1 as the focus yields an accuracy of 42.11. A better baseline is to always pick the last role (58.39 accuracy). Feeding the learning algorithm exclusively the label corresponding to the last role and flags indicating the presence of roles yields 61.38 accuracy (`BASIC` baseline).

System	Accuracy
`A1`	42.11
`FIRST`	7.00
`LAST`	58.39
`BASIC`	61.38
`FOC-DET`	65.50

Table 6: Accuracies over test split.

Having an agreement of 0.72, there is still room for improvement. The full set of features yields 65.50 accuracy. The difference in accuracy between `BASIC` and `FOC-DET` (4.12) is statistically significant (Z-value $= 1.71$). We test the significance of the difference in performance between two systems i and j on a set of ins instances with the Z-score test, where $z = \frac{abs(err_i, err_j)}{\sigma_d}$, err_k is the error made using set k and $\sigma_d = \sqrt{\frac{err_i(1-err_i)}{ins} + \frac{err_j(1-err_j)}{ins}}$.

7 Conclusions

In this paper, we present a novel way to semantically represent negation using focus detection. Implicit positive meaning is identified, giving a thorough interpretation of negated statements.

Due to the lack of corpora annotating the focus of negation, we have added this information to all the negations marked with MNEG in PropBank. A set of features is depicted and a supervised model proposed. The task is highly ambiguous and semantic features have proven helpful.

A verbal negation is interpreted by considering all roles positive except the one corresponding to the focus. This has proven useful as shown in several examples. In some cases, though, it is not easy to obtain the meaning of a negated role.

Consider (Table 3, example 5) *P&G hasn't sold coffee to airlines*. The proposed representation encodes *P&G has sold coffee, but not to airlines*. However, it is not said that the buyers are likely to have been other kinds of companies. Even without fully identifying the buyer, we believe it is of utmost importance to detect that *P&G has sold coffee*. Empirical data (Table 4) shows that over 65% of negations in PropBank carry implicit positive meaning.

Learning Dependency-Based Compositional Semantics

Abstract

Compositional question answering begins by mapping questions to logical forms, but training a semantic parser to perform this mapping typically requires the costly annotation of the target logical forms. In this paper, we learn to map questions to answers via latent logical forms, which are induced automatically from question-answer pairs. In tackling this challenging learning problem, we introduce a new semantic representation which highlights a parallel between dependency syntax and efficient evaluation of logical forms. On two standard semantic parsing benchmarks (GEO and JOBS), our system obtains the highest published accuracies, despite requiring no annotated logical forms.

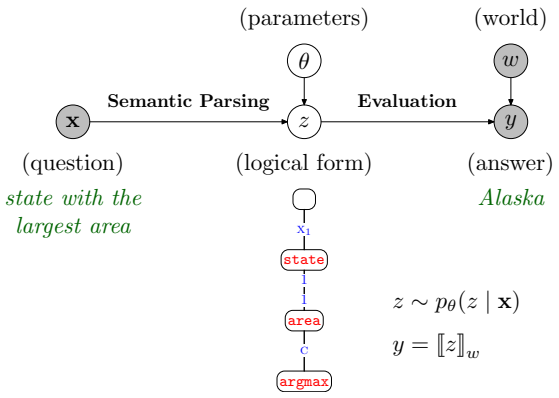

Figure 1: Our probabilistic model: a question $\mathbf{x}$ is mapped to a latent logical form z, which is then evaluated with respect to a world w (database of facts), producing an answer y. We represent logical forms z as labeled trees, induced automatically from $(\mathbf{x}, y)$ pairs.

1 Introduction

What is the total population of the ten largest capitals in the US? Answering these types of complex questions compositionally involves first mapping the questions into logical forms (semantic parsing). Supervised semantic parsers (Zelle and Mooney, 1996; Tang and Mooney, 2001; Ge and Mooney, 2005; Zettlemoyer and Collins, 2005; Kate and Mooney, 2007; Zettlemoyer and Collins, 2007; Wong and Mooney, 2007; Kwiatkowski et al., 2010) rely on manual annotation of logical forms, which is expensive. On the other hand, existing unsupervised semantic parsers (Poon and Domingos, 2009) do not handle deeper linguistic phenomena such as quantification, negation, and superlatives.

As in Clarke et al. (2010), we obviate the need for annotated logical forms by considering the end-to-end problem of mapping questions to answers. However, we still model the logical form (now as a latent variable) to capture the complexities of language. Figure 1 shows our probabilistic model: We want to induce latent logical forms z (and parameters θ) given only question-answer pairs $(\mathbf{x}, y)$, which is much cheaper to obtain than $(\mathbf{x}, z)$ pairs.

The core problem that arises in this setting is program induction: finding a logical form z (over an exponentially large space of possibilities) that produces the target answer y. Unlike standard semantic parsing, our end goal is only to generate the correct y, so we are free to choose the representation for z. Which one should we use?

The dominant paradigm in compositional semantics is Montague semantics, which constructs lambda calculus forms in a bottom-up manner. CCG is one instantiation (Steedman, 2000), which is used by many semantic parsers, e.g., Zettlemoyer and Collins (2005). However, the logical forms there can become quite complex, and in the context of program induction, this would lead to an unwieldy search space. At the same time, representations such as FunQL (Kate et al., 2005), which was used in

Portland, Oregon, June 19-24, 2011.

Clarke et al. (2010), are simpler but lack the full expressive power of lambda calculus.

The main technical contribution of this work is a new semantic representation, *dependency-based compositional semantics* (DCS), which is both simple and expressive (Section 2). The logical forms in this framework are trees, which is desirable for two reasons: (i) they parallel syntactic dependency trees, which facilitates parsing and learning; and (ii) evaluating them to obtain the answer is computationally efficient.

We trained our model using an EM-like algorithm (Section 3) on two benchmarks, GEO and JOBS (Section 4). Our system outperforms all existing systems despite using no annotated logical forms.

2 Semantic Representation

We first present a basic version (Section 2.1) of dependency-based compositional semantics (DCS), which captures the core idea of using trees to represent formal semantics. We then introduce the full version (Section 2.2), which handles linguistic phenomena such as quantification, where syntactic and semantic scope diverge.

We start with some definitions, using US geography as an example domain. Let $\mathcal{V}$ be the set of all *values*, which includes primitives (e.g., $3, \texttt{CA} \in \mathcal{V}$) as well as sets and tuples formed from other values (e.g., $3, \{3,4,7\}, (\texttt{CA}, \{5\}) \in \mathcal{V}$). Let $\mathcal{P}$ be a set of *predicates* (e.g., $\texttt{state}, \texttt{count} \in \mathcal{P}$), which are just symbols.

A *world* w is mapping from each predicate $p \in \mathcal{P}$ to a set of tuples; for example, $w(\texttt{state}) = \{(\texttt{CA}), (\texttt{OR}), \dots\}$. Conceptually, a world is a relational database where each predicate is a relation (possibly infinite). Define a special predicate $\emptyset$ with $w(\emptyset) = \mathcal{V}$. We represent functions by a set of input-output pairs, e.g., $w(\texttt{count}) = \{(S, n) : n = |S|\}$. As another example, $w(\texttt{average}) = \{(S, \bar{x}) : \bar{x} = |S_1|^{-1} \sum_{x \in S_1} S(x)\}$, where a set of pairs S is treated as a set-valued function $S(x) = \{y : (x, y) \in S\}$ with domain $S_1 = \{x : (x, y) \in S\}$.

The logical forms in DCS are called *DCS trees*, where nodes are labeled with predicates, and edges are labeled with relations. Formally:

Definition 1 (DCS trees) *Let $\mathcal{Z}$ be the set of DCS trees, where each $z \in \mathcal{Z}$ consists of (i) a predicate $z.p \in \mathcal{P}$ and (ii) a sequence of edges $z.e_1, \dots, z.e_m$, each edge e consisting of a relation $e.r \in \mathcal{R}$ (see Table 1) and a child tree $e.c \in \mathcal{Z}$.*

Relations $\mathcal{R}$

$\frac{j}{j'}$	(join)	E	(extract)
Σ	(aggregate)	Q	(quantify)
$\mathrm{X}_{\mathbf{i}}$	(execute)	C	(compare)

Table 1: Possible relations appearing on the edges of a DCS tree. Here, $j, j' \in \{1, 2, \dots\}$ and $\mathbf{i} \in \{1, 2, \dots\}^*$.

We write a DCS tree z as $\langle p; r_1 : c_1; \dots; r_m : c_m \rangle$. Figure 2(a) shows an example of a DCS tree. Although a DCS tree is a logical form, note that it looks like a syntactic dependency tree with predicates in place of words. It is this transparency between syntax and semantics provided by DCS which leads to a simple and streamlined compositional semantics suitable for program induction.

2.1 Basic Version

The basic version of DCS restricts $\mathcal{R}$ to join and aggregate relations (see Table 1). Let us start by considering a DCS tree z with only join relations. Such a z defines a constraint satisfaction problem (CSP) with nodes as variables. The CSP has two types of constraints: (i) $x \in w(p)$ for each node x labeled with predicate $p \in \mathcal{P}$; and (ii) $x_j = y_{j'}$ (the j-th component of x must equal the j'-th component of y) for each edge (x, y) labeled with $\frac{j}{j'} \in \mathcal{R}$.

A solution to the CSP is an assignment of nodes to values that satisfies all the constraints. We say a value v is *consistent* for a node x if there exists a solution that assigns v to x. The *denotation* $[\![z]\!]_w$ (z evaluated on w) is the set of consistent values of the root node (see Figure 2 for an example).

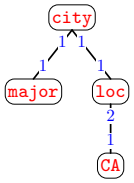
Computation We can compute the denotation $[\![z]\!]_w$ of a DCS tree z by exploiting dynamic programming on trees (Dechter, 2003). The recurrence is as follows:

$$[\![\left\langle p; \tfrac{j_1}{j'_1} : c_1; \cdots; \tfrac{j_m}{j'_m} : c_m \right\rangle]\!]_w = w(p) \cap \bigcap_{i=1}^{m} \{v : v_{j_i} = t_{j'_i}, t \in [\![c_i]\!]_w\}. \quad (1)$$

At each node, we compute the set of tuples v consistent with the predicate at that node ($v \in w(p)$), and

Example: *major city in California*

$z = \langle \texttt{city}; \frac{1}{1}:\langle \texttt{major}\rangle ; \frac{1}{1}:\langle \texttt{loc}; \frac{2}{1}:\langle \texttt{CA}\rangle\rangle\rangle$

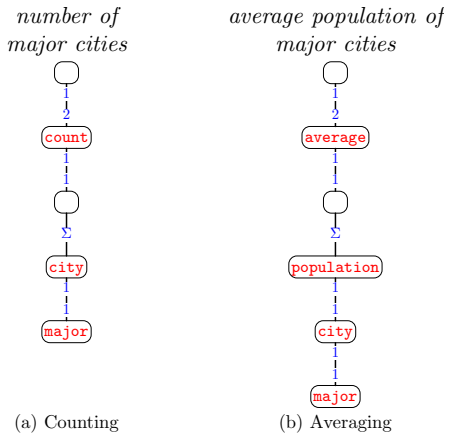


$$\lambda c\, \exists m\, \exists \ell\, \exists s\,.\ \texttt{city}(c) \wedge \texttt{major}(m) \wedge \texttt{loc}(\ell) \wedge \texttt{CA}(s) \wedge c_1 = m_1 \wedge c_1 = \ell_1 \wedge \ell_2 = s_1$$

(a) DCS tree (b) Lambda calculus formula

(c) Denotation: $[\![z]\!]_w = \{\texttt{SF}, \texttt{LA}, \ldots\}$

Figure 2: (a) An example of a DCS tree (written in both the mathematical and graphical notation). Each node is labeled with a predicate, and each edge is labeled with a relation. (b) A DCS tree z with only join relations encodes a constraint satisfaction problem. (c) The denotation of z is the set of consistent values for the root node.



(a) Counting (b) Averaging

Figure 3: Examples of DCS trees that use the aggregate relation (Σ) to (a) compute the cardinality of a set and (b) take the average over a set.

for each child i, the j_i-th component of v must equal the j'_i-th component of some t in the child's denotation ($t \in [\![c_i]\!]_w$). This algorithm is linear in the number of nodes times the size of the denotations.[1]

Now the dual importance of trees in DCS is clear: We have seen that trees parallel syntactic dependency structure, which will facilitate parsing. In addition, trees enable efficient computation, thereby establishing a new connection between dependency syntax and efficient semantic evaluation.

Aggregate relation DCS trees that only use join relations can represent arbitrarily complex compositional structures, but they cannot capture higher-order phenomena in language. For example, consider the phrase *number of major cities*, and suppose that *number* corresponds to the `count` predicate. It is impossible to represent the semantics of this phrase with just a CSP, so we introduce a new *aggregate relation*, notated Σ. Consider a tree $\langle \Sigma : c \rangle$, whose root is connected to a child c via Σ. If the denotation of c is a set of values s, the parent's denotation is then a singleton set containing s. Formally:

$$[\![\langle \Sigma : c \rangle]\!]_w = \{[\![c]\!]_w\}. \quad (2)$$

Figure 3(a) shows the DCS tree for our running example. The denotation of the middle node is $\{s\}$, where s is all major cities. Having instantiated s as a value, everything above this node is an ordinary CSP: s constrains the `count` node, which in turns constrains the root node to $|s|$.

A DCS tree that contains only join and aggregate relations can be viewed as a collection of tree-structured CSPs connected via aggregate relations. The tree structure still enables us to compute denotations efficiently based on (1) and (2).

2.2 Full Version

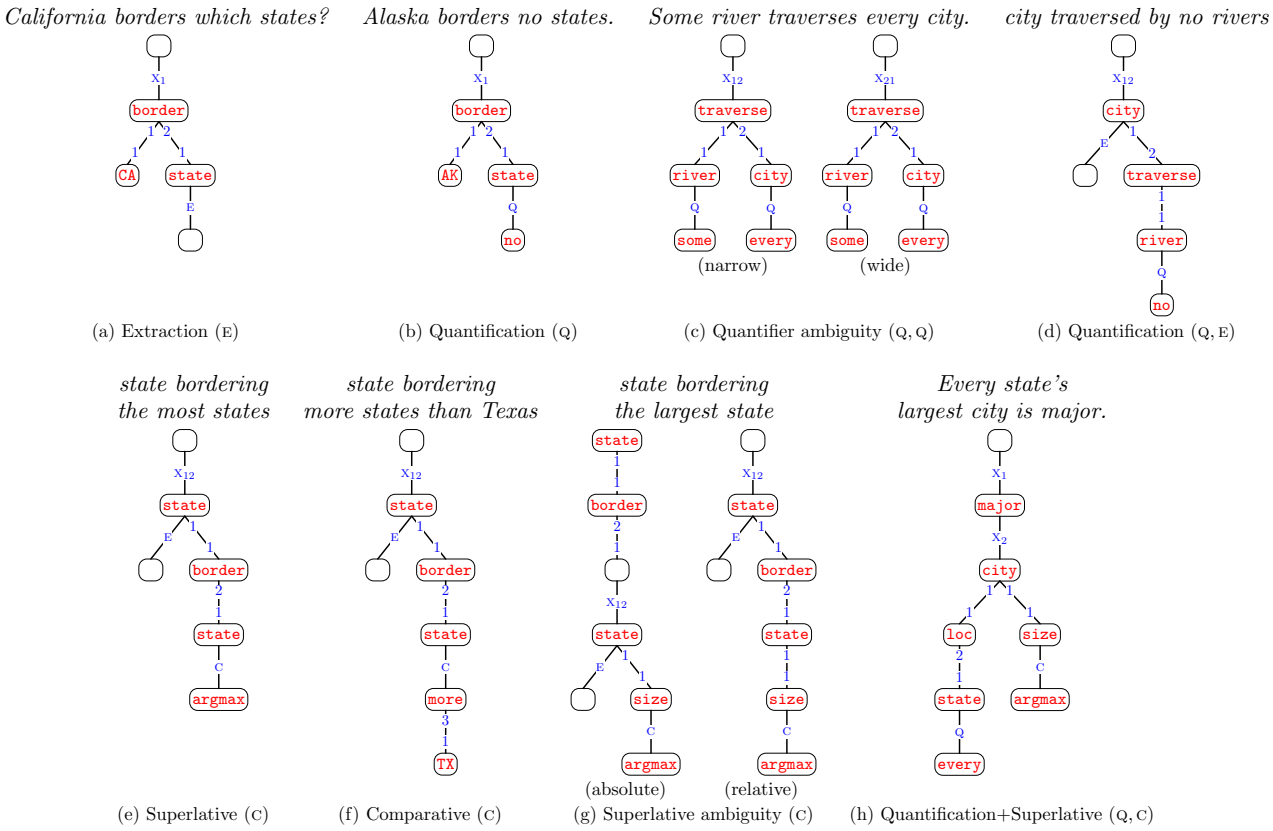
The basic version of DCS described thus far handles a core subset of language. But consider Figure 4: (a) is headed by *borders*, but *states* needs to be extracted; in (b), the quantifier *no* is syntactically dominated by the head verb *borders* but needs to take wider scope. We now present the full version of DCS which handles this type of divergence between syntactic and semantic scope.

The key idea that allows us to give semantically-scoped denotations to syntactically-scoped trees is as follows: We mark a node low in the tree with a *mark relation* (one of E, Q, or C). Then higher up in the tree, we invoke it with an *execute relation* $\text{X}_\mathbf{i}$ to create the desired semantic scope.[2]

This mark-execute construct acts non-locally, so to maintain compositionality, we must augment the

[1] Infinite denotations (such as $[\![<]\!]_w$) are represented as implicit sets on which we can perform membership queries. The intersection of two sets can be performed as long as at least one of the sets is finite.

[2] Our mark-execute construct is analogous to Montague's quantifying in, Cooper storage, and Carpenter's scoping constructor (Carpenter, 1998).



(a) Extraction (E) (b) Quantification (Q) (c) Quantifier ambiguity (Q, Q) (d) Quantification (Q, E)

(e) Superlative (C) (f) Comparative (C) (g) Superlative ambiguity (C) (h) Quantification+Superlative (Q, C)

Figure 4: Example DCS trees for utterances in which syntactic and semantic scope diverge. These trees reflect the syntactic structure, which facilitates parsing, but importantly, these trees also precisely encode the correct semantic scope. The main mechanism is using a mark relation (E, Q, or C) low in the tree paired with an execute relation ($\mathrm{X}_\mathbf{i}$) higher up at the desired semantic point.

denotation $d = [\![z]\!]_w$ to include any information about the marked nodes in z that can be accessed by an execute relation later on. In the basic version, d was simply the consistent assignments to the root. Now d contains the consistent joint assignments to the *active nodes* (which include the root and all marked nodes), as well as information stored about each marked node. Think of d as consisting of n *columns*, one for each active node according to a pre-order traversal of z. Column 1 always corresponds to the root node. Formally, a denotation is defined as follows (see Figure 5 for an example):

Definition 2 (Denotations) *Let $\mathcal{D}$ be the set of denotations, where each $d \in \mathcal{D}$ consists of*

- *a set of arrays $d.A$, where each array $\mathbf{a} = [a_1, \ldots, a_n] \in d.A$ is a sequence of n tuples ($a_i \in \mathcal{V}^*$); and*
- *a list of n* stores *$d.\boldsymbol{\alpha} = (d.\alpha_1, \ldots, d.\alpha_n)$, where each store α contains a mark relation $\alpha.r \in \{\mathrm{E}, \mathrm{Q}, \mathrm{C}, \emptyset\}$, a base denotation $\alpha.b \in \mathcal{D} \cup \{\emptyset\}$, and a child denotation $\alpha.c \in \mathcal{D} \cup \{\emptyset\}$.*

We write d as $\langle\!\langle A; (r_1, b_1, c_1); \ldots; (r_n, b_n, c_n) \rangle\!\rangle$. We use $d\{r_i = x\}$ to mean d with $d.r_i = d.\alpha_i.r = x$ (similar definitions apply for $d\{\alpha_i = x\}$, $d\{b_i = x\}$, and $d\{c_i = x\}$).

The denotation of a DCS tree can now be defined recursively:

$$[\![\langle p \rangle]\!]_w = \langle\!\langle \{[v] : v \in w(p)\}; \emptyset \rangle\!\rangle, \quad (3)$$

$$[\![\left\langle p; \mathbf{e}; \begin{smallmatrix} j \\ j' \end{smallmatrix} : c \right\rangle]\!]_w = [\![p; \mathbf{e}]\!]_w \bowtie_{j,j'} [\![c]\!]_w, \quad (4)$$

$$[\![\langle p; \mathbf{e}; \Sigma : c \rangle]\!]_w = [\![p; \mathbf{e}]\!]_w \bowtie_{*,*} \Sigma\left([\![c]\!]_w\right), \quad (5)$$

$$[\![\langle p; \mathbf{e}; \mathrm{X}_\mathbf{i} : c \rangle]\!]_w = [\![p; \mathbf{e}]\!]_w \bowtie_{*,*} \mathbf{X_i}([\![c]\!]_w), \quad (6)$$

$$[\![\langle p; \mathbf{e}; \mathrm{E} : c \rangle]\!]_w = \mathbf{M}([\![p; \mathbf{e}]\!]_w, \mathrm{E}, c), \quad (7)$$

$$[\![\langle p; \mathbf{e}; \mathrm{C} : c \rangle]\!]_w = \mathbf{M}([\![p; \mathbf{e}]\!]_w, \mathrm{C}, c), \quad (8)$$

$$[\![\langle p; \mathrm{Q} : c; \mathbf{e} \rangle]\!]_w = \mathbf{M}([\![p; \mathbf{e}]\!]_w, \mathrm{Q}, c). \quad (9)$$

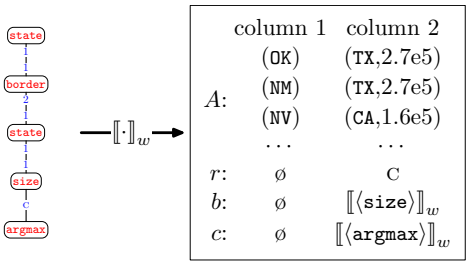


Figure 5: Example of the denotation for a DCS tree with a compare relation C. This denotation has two columns, one for each active node—the root node `state` and the marked node `size`.

The base case is defined in (3): if z is a single node with predicate p, then the denotation of z has one column with the tuples $w(p)$ and an empty store. The other six cases handle different edge relations. These definitions depend on several operations ($\bowtie_{\mathbf{j},\mathbf{j}'}, \Sigma, \mathbf{X_i}, \mathbf{M}$) which we will define shortly, but let us first get some intuition.

Let z be a DCS tree. If the last child c of z's root is a join ($\binom{j}{j'}$), aggregate (Σ), or execute ($\mathrm{X}_\mathbf{i}$) relation ((4)–(6)), then we simply recurse on z with c removed and join it with some transformation (identity, Σ, or $\mathrm{X}_\mathbf{i}$) of c's denotation. If the last (or first) child is connected via a mark relation E, C (or Q), then we strip off that child and put the appropriate information in the store by invoking $\mathbf{M}$.

We now define the operations $\bowtie_{\mathbf{j},\mathbf{j}'}, \Sigma, \mathbf{X_i}, \mathbf{M}$. Some helpful notation: For a sequence $\mathbf{v} = (v_1, \ldots, v_n)$ and indices $\mathbf{i} = (i_1, \ldots, i_k)$, let $\mathbf{v_i} = (v_{i_1}, \ldots, v_{i_k})$ be the projection of $\mathbf{v}$ onto $\mathbf{i}$; we write $\mathbf{v}_{-\mathbf{i}}$ to mean $\mathbf{v}_{[1,\ldots,n]\setminus\mathbf{i}}$. Extending this notation to denotations, let $\langle\!\langle A; \boldsymbol{\alpha} \rangle\!\rangle[\mathbf{i}] = \langle\!\langle \{\mathbf{a_i} : \mathbf{a} \in A\}; \boldsymbol{\alpha_i} \rangle\!\rangle$. Let $d[-\emptyset] = d[-\mathbf{i}]$, where $\mathbf{i}$ are the columns with empty stores. For example, for d in Figure 5, $d[1]$ keeps column 1, $d[-\emptyset]$ keeps column 2, and $d[2,-2]$ swaps the two columns.

Join The *join* of two denotations d and d' with respect to components $\mathbf{j}$ and $\mathbf{j}'$ ($*$ means all components) is formed by concatenating all arrays $\mathbf{a}$ of d with all compatible arrays $\mathbf{a}'$ of d', where compatibility means $a_{1\mathbf{j}} = a'_{1\mathbf{j}'}$. The stores are also concatenated ($\boldsymbol{\alpha} + \boldsymbol{\alpha}'$). Non-initial columns with empty stores are projected away by applying $\cdot[1,-\emptyset]$. The full definition of join is as follows:

$$\langle\!\langle A; \boldsymbol{\alpha} \rangle\!\rangle \bowtie_{\mathbf{j},\mathbf{j}'} \langle\!\langle A'; \boldsymbol{\alpha}' \rangle\!\rangle = \langle\!\langle A''; \boldsymbol{\alpha} + \boldsymbol{\alpha}' \rangle\!\rangle[1,-\emptyset],$$
$$A'' = \{\mathbf{a} + \mathbf{a}' : \mathbf{a} \in A, \mathbf{a}' \in A', a_{1\mathbf{j}} = a'_{1\mathbf{j}'}\}. \quad (10)$$

Aggregate The aggregate operation takes a denotation and forms a set out of the tuples in the first column for each setting of the rest of the columns:

$$\Sigma(\langle\!\langle A; \boldsymbol{\alpha} \rangle\!\rangle) = \langle\!\langle A' \cup A''; \boldsymbol{\alpha} \rangle\!\rangle \quad (11)$$
$$A' = \{[S(\mathbf{a}), a_2, \ldots, a_n] : \mathbf{a} \in A\}$$
$$S(\mathbf{a}) = \{a'_1 : [a'_1, a_2, \ldots, a_n] \in A\}$$
$$A'' = \{[\emptyset, a_2, \ldots, a_n] : \neg\exists a_1, \mathbf{a} \in A,$$
$$\forall 2 \le i \le n, [a_i] \in d.b_i[1].A\}.$$

2.2.1 Mark and Execute

Now we turn to the mark ($\mathbf{M}$) and execute ($\mathbf{X_i}$) operations, which handles the divergence between syntactic and semantic scope. In some sense, this is the technical core of DCS. Marking is simple: When a node (e.g., `size` in Figure 5) is marked (e.g., with relation C), we simply put the relation r, current denotation d and child c's denotation into the store of column 1:

$$\mathbf{M}(d, r, c) = d\{r_1 = r, b_1 = d, c_1 = [\![c]\!]_w\}. \quad (12)$$

The execute operation $\mathbf{X_i}(d)$ processes columns $\mathbf{i}$ in reverse order. It suffices to define $\mathbf{X}_i(d)$ for a single column i. There are three cases:

Extraction ($d.r_i = \mathrm{E}$) In the basic version, the denotation of a tree was always the set of consistent values of the root node. Extraction allows us to return the set of consistent values of a marked non-root node. Formally, extraction simply moves the i-th column to the front: $\mathbf{X}_i(d) = d[i, -(i, \emptyset)]\{\alpha_1 = \emptyset\}$. For example, in Figure 4(a), before execution, the denotation of the DCS tree is $\langle\!\langle \{[(\texttt{CA}, \texttt{OR}), (\texttt{OR})], \ldots\}; \emptyset; (\mathrm{E}, [\![\langle \texttt{state} \rangle]\!]_w, \emptyset) \rangle\!\rangle$; after applying X_1, we have $\langle\!\langle \{[(\texttt{OR})], \ldots\}; \emptyset \rangle\!\rangle$.

Generalized Quantification ($d.r_i = \mathrm{Q}$) Generalized quantifiers are predicates on two sets, a restrictor A and a nuclear scope B. For example, $w(\texttt{no}) = \{(A, B) : A \cap B = \emptyset\}$ and $w(\texttt{most}) = \{(A, B) : |A \cap B| > \frac{1}{2}|A|\}$.

In a DCS tree, the quantifier appears as the child of a Q relation, and the restrictor is the parent (see Figure 4(b) for an example). This information is retrieved from the store when the

quantifier in column i is executed. In particular, the restrictor is $A = \Sigma(d.b_i)$ and the nuclear scope is $B = \Sigma(d[i, -(i, \emptyset)])$. We then apply $d.c_i$ to these two sets (technically, denotations) and project away the first column: $\mathbf{X}_i(d) = ((d.c_i \bowtie_{1,1} A) \bowtie_{2,1} B)[-1]$.

For the example in Figure 4(b), the denotation of the DCS tree before execution is $\langle\langle \emptyset; \emptyset; (\texttt{Q}, [\![\langle \texttt{state} \rangle]\!]_w, [\![\langle \texttt{no} \rangle]\!]_w) \rangle\rangle$. The restrictor set ($A$) is the set of all states, and the nuclear scope (B) is the empty set. Since (A, B) exists in no, the final denotation, which projects away the actual pair, is $\langle\langle \{[]\} \rangle\rangle$ (our representation of true).

Figure 4(c) shows an example with two interacting quantifiers. The quantifier scope ambiguity is resolved by the choice of execute relation; $\texttt{X}_{12}$ gives the narrow reading and $\texttt{X}_{21}$ gives the wide reading. Figure 4(d) shows how extraction and quantification work together.

Comparatives and Superlatives ($d.r_i = \texttt{C}$) To compare entities, we use a set S of (x, y) pairs, where x is an entity and y is a number. For superlatives, the argmax predicate denotes pairs of sets and the set's largest element(s): $w(\texttt{argmax}) = \{(S, x^*) : x^* \in \text{argmax}_{x \in S_1} \max S(x)\}$. For comparatives, $w(\texttt{more})$ contains triples (S, x, y), where x is "more than" y as measured by S; formally: $w(\texttt{more}) = \{(S, x, y) : \max S(x) > \max S(y)\}$.

In a superlative/comparative construction, the root x of the DCS tree is the entity to be compared, the child c of a C relation is the comparative or superlative, and its parent p contains the information used for comparison (see Figure 4(e) for an example). If d is the denotation of the root, its i-th column contains this information. There are two cases: (i) if the i-th column of d contains pairs (e.g., size in Figure 5), then let $d' = [\![\langle \emptyset \rangle]\!]_w \bowtie_{1,2} d[i, -i]$, which reads out the second components of these pairs; (ii) otherwise (e.g., state in Figure 4(e)), let $d' = [\![\langle \emptyset \rangle]\!]_w \bowtie_{1,2} [\![\langle \texttt{count} \rangle]\!]_w \bowtie_{1,1} \Sigma(d[i, -i])$, which counts the number of things (e.g., states) that occur with each value of the root x. Given d', we construct a denotation S by concatenating ($+_\mathbf{i}$) the second and first columns of d' ($S = \Sigma(+_{2,1}(d'\{\alpha_2 = \emptyset\}))$) and apply the superlative/comparative: $\mathbf{X}_i(d) = ([\![\langle \emptyset \rangle]\!]_w \bowtie_{1,2} (d.c_i \bowtie_{1,1} S))\{\alpha_1 = d.\alpha_1\}$.

Figure 4(f) shows that comparatives are handled using the exact same machinery as superlatives. Figure 4(g) shows that we can naturally account for superlative ambiguity based on where the scope-determining execute relation is placed.

3 Semantic Parsing

We now turn to the task of mapping natural language utterances to DCS trees. Our first question is: given an utterance $\mathbf{x}$, what trees $z \in \mathcal{Z}$ are permissible? To define the search space, we first assume a fixed set of *lexical triggers* L. Each trigger is a pair $(\mathbf{x}, p)$, where $\mathbf{x}$ is a sequence of words (usually one) and p is a predicate (e.g., $\mathbf{x}$ = *California* and p = CA). We use $L(\mathbf{x})$ to denote the set of predicates p triggered by $\mathbf{x}$ ($(\mathbf{x}, p) \in L$). Let $L(\epsilon)$ be the set of *trace predicates*, which can be introduced without an overt lexical trigger.

Given an utterance $\mathbf{x} = (x_1, \ldots, x_n)$, we define $\mathcal{Z}_L(\mathbf{x}) \subset \mathcal{Z}$, the set of permissible DCS trees for $\mathbf{x}$. The basic approach is reminiscent of projective labeled dependency parsing: For each span $i..j$, we build a set of trees $C_{i,j}$ and set $\mathcal{Z}_L(\mathbf{x}) = C_{0,n}$. Each set $C_{i,j}$ is constructed recursively by combining the trees of its subspans $C_{i,k}$ and $C_{k',j}$ for each pair of split points k, k' (words between k and k' are ignored). These combinations are then augmented via a function A and filtered via a function F, to be specified later. Formally, $C_{i,j}$ is defined recursively as follows:

$$C_{i,j} = F\Big(A\Big(L(\mathbf{x}_{i+1..j}) \cup \bigcup_{\substack{i \le k \le k' < j \\ a \in C_{i,k} \\ b \in C_{k',j}}} T_1(a, b)\Big)\Big). \tag{13}$$

In (13), $L(\mathbf{x}_{i+1..j})$ is the set of predicates triggered by the phrase under span $i..j$ (the base case), and $T_d(a, b) = \vec{T}_d(a, b) \cup \overleftarrow{T}_d(b, a)$, which returns all ways of combining trees a and b where b is a descendant of a ($\vec{T}_d$) or vice-versa ($\overleftarrow{T}_d$). The former is defined recursively as follows: $\vec{T}_0(a, b) = \emptyset$, and

$$\vec{T}_d(a, b) = \bigcup_{\substack{r \in \mathcal{R} \\ p \in L(\epsilon)}} \{\langle a; r : b \rangle\} \cup \vec{T}_{d-1}(a, \langle p; r : b \rangle).$$

The latter ($\overleftarrow{T}_k$) is defined similarly. Essentially, $\vec{T}_d(a, b)$ allows us to insert up to d trace predicates between the roots of a and b. This is useful for modeling relations in noun compounds (e.g.,

California cities), and it also allows us to underspecify L. In particular, our L will not include verbs or prepositions; rather, we rely on the predicates corresponding to those words to be triggered by traces.

The augmentation function A takes a set of trees and optionally attaches $\texttt{E}$ and $\texttt{X}_\texttt{i}$ relations to the root (e.g., $A(\langle \texttt{city} \rangle) = \{\langle \texttt{city} \rangle, \langle \texttt{city}; \texttt{E}\!:\!\emptyset \rangle\}$). The filtering function F rules out improperly-typed trees such as $\langle \texttt{city}; {}^{0}_{0}\!:\langle \texttt{state} \rangle \rangle$. To further reduce the search space, F imposes a few additional constraints, e.g., limiting the number of marked nodes to 2 and only allowing trace predicates between arity 1 predicates.

Model We now present our discriminative semantic parsing model, which places a log-linear distribution over $z \in \mathcal{Z}_L(\mathbf{x})$ given an utterance $\mathbf{x}$. Formally, $p_\theta(z \mid \mathbf{x}) \propto e^{\phi(\mathbf{x},z)^\top \theta}$, where θ and $\phi(\mathbf{x}, z)$ are parameter and feature vectors, respectively. As a running example, consider $\mathbf{x}$ = *city that is in California* and $z = \langle \texttt{city}; {}^{1}_{1}\!:\langle \texttt{loc}; {}^{2}_{1}\!:\langle \texttt{CA} \rangle \rangle \rangle$, where *city* triggers `city` and *California* triggers `CA`.

To define the features, we technically need to augment each tree $z \in \mathcal{Z}_L(\mathbf{x})$ with alignment information—namely, for each predicate in z, the span in $\mathbf{x}$ (if any) that triggered it. This extra information is already generated from the recursive definition in (13).

The feature vector $\phi(\mathbf{x}, z)$ is defined by sums of five simple indicator feature templates: ($\mathbf{F}_1$) a word triggers a predicate (e.g., $[\textit{city}, \texttt{city}]$); ($\mathbf{F}_2$) a word is under a relation (e.g., $[\textit{that}, {}^{1}_{1}]$); ($\mathbf{F}_3$) a word is under a trace predicate (e.g., $[\textit{in}, \texttt{loc}]$); ($\mathbf{F}_4$) two predicates are linked via a relation in the left or right direction (e.g., $[\texttt{city}, {}^{1}_{1}, \texttt{loc}, \text{RIGHT}]$); and ($\mathbf{F}_5$) a predicate has a child relation (e.g., $[\texttt{city}, {}^{1}_{1}]$).

Learning Given a training dataset $\mathcal{D}$ containing $(\mathbf{x}, y)$ pairs, we define the regularized marginal log-likelihood objective $\mathcal{O}(\theta) = \sum_{(\mathbf{x},y)\in\mathcal{D}} \log p_\theta([\![z]\!]_w = y \mid \mathbf{x}, z \in \mathcal{Z}_L(\mathbf{x})) - \lambda\|\theta\|_2^2$, which sums over all DCS trees z that evaluate to the target answer y.

Our model is arc-factored, so we can sum over all DCS trees in $\mathcal{Z}_L(\mathbf{x})$ using dynamic programming. However, in order to learn, we need to sum over $\{z \in \mathcal{Z}_L(\mathbf{x}) : [\![z]\!]_w = y\}$, and unfortunately, the additional constraint $[\![z]\!]_w = y$ does not factorize. We therefore resort to beam search. Specifically, we truncate each $C_{i,j}$ to a maximum of K candidates sorted by decreasing score based on parameters θ. Let $\tilde{\mathcal{Z}}_{L,\theta}(\mathbf{x})$ be this approximation of $\mathcal{Z}_L(\mathbf{x})$.

Our learning algorithm alternates between (i) using the current parameters θ to generate the K-best set $\tilde{\mathcal{Z}}_{L,\theta}(\mathbf{x})$ for each training example $\mathbf{x}$, and (ii) optimizing the parameters to put probability mass on the correct trees in these sets; sets containing no correct answers are skipped. Formally, let $\tilde{\mathcal{O}}(\theta, \theta')$ be the objective function $\mathcal{O}(\theta)$ with $\mathcal{Z}_L(\mathbf{x})$ replaced with $\tilde{\mathcal{Z}}_{L,\theta'}(\mathbf{x})$. We optimize $\tilde{\mathcal{O}}(\theta, \theta')$ by setting $\theta^{(0)} = \vec{0}$ and iteratively solving $\theta^{(t+1)} = \text{argmax}_\theta \tilde{\mathcal{O}}(\theta, \theta^{(t)})$ using L-BFGS until $t = T$. In all experiments, we set $\lambda = 0.01$, $T = 5$, and $K = 100$. After training, given a new utterance $\mathbf{x}$, our system outputs the most likely y, summing out the latent logical form z: $\text{argmax}_y\, p_{\theta^{(T)}}(y \mid \mathbf{x}, z \in \tilde{\mathcal{Z}}_{L,\theta^{(T)}})$.

4 Experiments

We tested our system on two standard datasets, GEO and JOBS. In each dataset, each sentence $\mathbf{x}$ is annotated with a Prolog logical form, which we use only to evaluate and get an answer y. This evaluation is done with respect to a world w. Recall that a world w maps each predicate $p \in \mathcal{P}$ to a set of tuples $w(p)$. There are three types of predicates in $\mathcal{P}$: *generic* (e.g., `argmax`), *data* (e.g., `city`), and *value* (e.g., `CA`). GEO has 48 non-value predicates and JOBS has 26. For GEO, w is the standard US geography database that comes with the dataset. For JOBS, if we use the standard Jobs database, close to half the y's are empty, which makes it uninteresting. We therefore generated a random Jobs database instead as follows: we created 100 job IDs. For each data predicate p (e.g., `language`), we add each possible tuple (e.g., $(\texttt{job37}, \texttt{Java})$) to $w(p)$ independently with probability 0.8.

We used the same training-test splits as Zettlemoyer and Collins (2005) (600+280 for GEO and 500+140 for JOBS). During development, we further held out a random 30% of the training sets for validation.

Our lexical triggers L include the following: (i) predicates for a small set of $\approx$ 20 function words (e.g., $(\textit{most}, \texttt{argmax})$), (ii) (x, x) for each value

System	Accuracy
Clarke et al. (2010) w/answers	73.2
Clarke et al. (2010) w/logical forms	80.4
Our system (DCS with L)	78.9
Our system (DCS with L^+)	**87.2**

Table 2: Results on GEO with 250 training and 250 test examples. Our results are averaged over 10 random 250+250 splits taken from our 600 training examples. Of the three systems that do not use logical forms, our two systems yield significant improvements. Our better system even outperforms the system that uses logical forms.

predicate x in w (e.g., $(\textit{Boston}, \texttt{Boston})$), and (iii) predicates for each POS tag in $\{\text{JJ}, \text{NN}, \text{NNS}\}$ (e.g., $(\text{JJ}, \texttt{size})$, $(\text{JJ}, \texttt{area})$, etc.).[3] Predicates corresponding to verbs and prepositions (e.g., `traverse`) are not included as overt lexical triggers, but rather in the trace predicates $L(\epsilon)$.

We also define an augmented lexicon L^+ which includes a prototype word x for each predicate appearing in (iii) above (e.g., $(\textit{large}, \texttt{size})$), which cancels the predicates triggered by x's POS tag. For GEO, there are 22 prototype words; for JOBS, there are 5. Specifying these triggers requires minimal domain-specific supervision.

Results We first compare our system with Clarke et al. (2010) (henceforth, SEMRESP), which also learns a semantic parser from question-answer pairs. Table 2 shows that our system using lexical triggers L (henceforth, DCS) outperforms SEMRESP (78.9% over 73.2%). In fact, although neither DCS nor SEMRESP uses logical forms, DCS uses even less supervision than SEMRESP. SEMRESP requires a lexicon of 1.42 words per non-value predicate, WordNet features, and syntactic parse trees; DCS requires only words for the domain-independent predicates (overall, around 0.5 words per non-value predicate), POS tags, and very simple indicator features. In fact, DCS performs comparably to even the version of SEMRESP trained using logical forms. If we add prototype triggers (use L^+), the resulting system (DCS$^+$) outperforms both versions of SEMRESP by a significant margin (87.2% over 73.2% and 80.4%).

[3]We used the Berkeley Parser (Petrov et al., 2006) to perform POS tagging. The triggers $L(x)$ for a word x thus include $L(t)$ where t is the POS tag of x.

System	GEO	JOBS
Tang and Mooney (2001)	79.4	79.8
Wong and Mooney (2007)	86.6	–
Zettlemoyer and Collins (2005)	79.3	79.3
Zettlemoyer and Collins (2007)	81.6	–
Kwiatkowski et al. (2010)	88.2	–
Kwiatkowski et al. (2010)	88.9	–
Our system (DCS with L)	88.6	91.4
Our system (DCS with L^+)	**91.1**	**95.0**

Table 3: Accuracy (recall) of systems on the two benchmarks. The systems are divided into three groups. Group 1 uses 10-fold cross-validation; groups 2 and 3 use the independent test set. Groups 1 and 2 measure accuracy of logical form; group 3 measures accuracy of the answer; but there is very small difference between the two as seen from the Kwiatkowski et al. (2010) numbers. Our best system improves substantially over past work, despite using no logical forms as training data.

Next, we compared our systems (DCS and DCS$^+$) with the state-of-the-art semantic parsers on the full dataset for both GEO and JOBS (see Table 3). All other systems require logical forms as training data, whereas ours does not. Table 3 shows that even DCS, which does not use prototypes, is comparable to the best previous system (Kwiatkowski et al., 2010), and by adding a few prototypes, DCS$^+$ offers a decisive edge (91.1% over 88.9% on GEO). Rather than using lexical triggers, several of the other systems use IBM word alignment models to produce an initial word-predicate mapping. This option is not available to us since we do not have annotated logical forms, so we must instead rely on lexical triggers to define the search space. Note that having lexical triggers is a much weaker requirement than having a CCG lexicon, and far easier to obtain than logical forms.

Intuitions How is our system learning? Initially, the weights are zero, so the beam search is essentially unguided. We find that only for a small fraction of training examples do the K-best sets contain any trees yielding the correct answer (29% for DCS on GEO). However, training on just these examples is enough to improve the parameters, and this 29% increases to 66% and then to 95% over the next few iterations. This bootstrapping behavior occurs naturally: The "easy" examples are processed first, where easy is defined by the ability of the current

model to generate the correct answer using any tree.

Our system learns lexical associations between words and predicates. For example, *area* (by virtue of being a noun) triggers many predicates: `city`, `state`, `area`, etc. Inspecting the final parameters (DCS on GEO), we find that the feature $[\textit{area}, \texttt{area}]$ has a much higher weight than $[\textit{area}, \texttt{city}]$. Trace predicates can be inserted anywhere, but the features favor some insertions depending on the words present (for example, $[\textit{in}, \texttt{loc}]$ has high weight).

The errors that the system makes stem from multiple sources, including errors in the POS tags (e.g., *states* is sometimes tagged as a verb, which triggers no predicates), confusion of Washington state with Washington D.C., learning the wrong lexical associations due to data sparsity, and having an insufficiently large K.

5 Discussion

A major focus of this work is on our semantic representation, DCS, which offers a new perspective on compositional semantics. To contrast, consider CCG (Steedman, 2000), in which semantic parsing is driven from the lexicon. The lexicon encodes information about how each word can used in context; for example, the lexical entry for *borders* is $\text{S}\backslash\text{NP}/\text{NP} : \lambda y.\lambda x.\texttt{border}(x, y)$, which means *borders* looks right for the first argument and left for the second. These rules are often too stringent, and for complex utterances, especially in free word-order languages, either disharmonic combinators are employed (Zettlemoyer and Collins, 2007) or words are given multiple lexical entries (Kwiatkowski et al., 2010).

In DCS, we start with lexical triggers, which are more basic than CCG lexical entries. A trigger for *borders* specifies only that `border` can be used, but not how. The combination rules are encoded in the features as soft preferences. This yields a more factorized and flexible representation that is easier to search through and parametrize using features. It also allows us to easily add new lexical triggers without becoming mired in the semantic formalism.

Quantifiers and superlatives significantly complicate scoping in lambda calculus, and often type raising needs to be employed. In DCS, the mark-execute construct provides a flexible framework for dealing with scope variation. Think of DCS as a higher-level programming language tailored to natural language, which results in programs (DCS trees) which are much simpler than the logically-equivalent lambda calculus formulae.

The idea of using CSPs to represent semantics is inspired by Discourse Representation Theory (DRT) (Kamp and Reyle, 1993; Kamp et al., 2005), where variables are discourse referents. The restriction to trees is similar to economical DRT (Bos, 2009).

The other major focus of this work is program induction—inferring logical forms from their denotations. There has been a fair amount of past work on this topic: Liang et al. (2010) induces combinatory logic programs in a non-linguistic setting. Eisenstein et al. (2009) induces conjunctive formulae and uses them as features in another learning problem. Piantadosi et al. (2008) induces first-order formulae using CCG in a small domain assuming observed lexical semantics. The closest work to ours is Clarke et al. (2010), which we discussed earlier.

The integration of natural language with denotations computed against a world (grounding) is becoming increasingly popular. Feedback from the world has been used to guide both syntactic parsing (Schuler, 2003) and semantic parsing (Popescu et al., 2003; Clarke et al., 2010). Past work has also focused on aligning text to a world (Liang et al., 2009), using text in reinforcement learning (Branavan et al., 2009; Branavan et al., 2010), and many others. Our work pushes the grounded language agenda towards deeper representations of language—think grounded compositional semantics.

6 Conclusion

We built a system that interprets natural language utterances much more accurately than existing systems, despite using no annotated logical forms. Our system is based on a new semantic representation, DCS, which offers a simple and expressive alternative to lambda calculus. Free from the burden of annotating logical forms, we hope to use our techniques in developing even more accurate and broader-coverage language understanding systems.

Acknowledgments We thank Luke Zettlemoyer and Tom Kwiatkowski for providing us with data and answering questions.

Abstract

We describe a novel approach for inducing unsupervised part-of-speech taggers for languages that have no labeled training data, but have translated text in a resource-rich language. Our method does not assume any knowledge about the target language (in particular no tagging dictionary is assumed), making it applicable to a wide array of resource-poor languages. We use graph-based label propagation for cross-lingual knowledge transfer and use the projected labels as features in an unsupervised model (Berg-Kirkpatrick et al., 2010). Across eight European languages, our approach results in an average absolute improvement of 10.4% over a state-of-the-art baseline, and 16.7% over vanilla hidden Markov models induced with the Expectation Maximization algorithm.

1 Introduction

Supervised learning approaches have advanced the state-of-the-art on a variety of tasks in natural language processing, resulting in highly accurate systems. Supervised part-of-speech (POS) taggers, for example, approach the level of inter-annotator agreement (Shen et al., 2007, 97.3% accuracy for English). However, supervised methods rely on labeled training data, which is time-consuming and expensive to generate. Unsupervised learning approaches appear to be a natural solution to this problem, as they require only unannotated text for training models. Unfortunately, the best completely unsupervised English POS tagger (that does not make use of a tagging dictionary) reaches only 76.1% accuracy (Christodoulopoulos et al., 2010), making its practical usability questionable at best.

To bridge this gap, we consider a practically motivated scenario, in which we want to leverage existing resources from a resource-rich language (like English) when building tools for resource-poor foreign languages.[1] We assume that absolutely no labeled training data is available for the foreign language of interest, but that we have access to parallel data with a resource-rich language. This scenario is applicable to a large set of languages and has been considered by a number of authors in the past (Alshawi et al., 2000; Xi and Hwa, 2005; Ganchev et al., 2009). Naseem et al. (2009) and Snyder et al. (2009) study related but different multilingual grammar and tagger induction tasks, where it is assumed that no labeled data at all is available.

Our work is closest to that of Yarowsky and Ngai (2001), but differs in two important ways. First, we use a novel graph-based framework for projecting syntactic information across language boundaries. To this end, we construct a bilingual graph over word types to establish a connection between the two languages (§3), and then use graph label propagation to project syntactic information from English to the foreign language (§4). Second, we treat the projected labels as features in an unsuper-

*This research was carried out during an internship at Google Research.

[1] For simplicity of exposition we refer to the resource-poor language as the "foreign language." Similarly, we use English as the resource-rich language, but any other language with labeled resources could be used instead.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 600–609,
Portland, Oregon, June 19-24, 2011.

vised model (§5), rather than using them directly for supervised training. To make the projection practical, we rely on the twelve *universal part-of-speech tags* of Petrov et al. (2011). Syntactic universals are a well studied concept in linguistics (Carnie, 2002; Newmeyer, 2005), and were recently used in similar form by Naseem et al. (2010) for multilingual grammar induction. Because there might be some controversy about the exact definitions of such universals, this set of coarse-grained POS categories is defined operationally, by collapsing language (or treebank) specific distinctions to a set of categories that exists across all languages. These universal POS categories not only facilitate the transfer of POS information from one language to another, but also relieve us from using controversial evaluation metrics,[2] by establishing a direct correspondence between the induced hidden states in the foreign language and the observed English labels.

We evaluate our approach on eight European languages (§6), and show that both our contributions provide consistent and statistically significant improvements. Our final average POS tagging accuracy of 83.4% compares very favorably to the average accuracy of Berg-Kirkpatrick et al.'s monolingual unsupervised state-of-the-art model (73.0%), and considerably bridges the gap to fully supervised POS tagging performance (96.6%).

2 Approach Overview

The focus of this work is on building POS taggers for foreign languages, assuming that we have an English POS tagger and some parallel text between the two languages. Central to our approach (see Algorithm 1) is a bilingual similarity graph built from a sentence-aligned parallel corpus. As discussed in more detail in §3, we use two types of vertices in our graph: on the foreign language side vertices correspond to trigram types, while the vertices on the English side are individual word types. Graph construction does not require any labeled data, but makes use of two similarity functions. The edge weights between the foreign language trigrams are computed using a co-occurence based similarity function, designed to indicate how syntactically similar the middle words of the connected trigrams are (§3.2). To establish a soft correspondence between the two languages, we use a second similarity function, which leverages standard unsupervised word alignment statistics (§3.3).[3]

Algorithm 1 Bilingual POS Induction

Require: Parallel English and foreign language data $\mathcal{D}^e$ and $\mathcal{D}^f$, unlabeled foreign training data Γ^f; English tagger.

Ensure: Θ^f, a set of parameters learned using a constrained unsupervised model (§5).

1: $\mathcal{D}^{e \leftrightarrow f} \leftarrow \textsf{word-align-bitext}(\mathcal{D}^e, \mathcal{D}^f)$
2: $\widehat{\mathcal{D}^e} \leftarrow \textsf{pos-tag-supervised}(\mathcal{D}^e)$
3: $\mathcal{A} \leftarrow \textsf{extract-alignments}(\mathcal{D}^{e \leftrightarrow f}, \widehat{\mathcal{D}^e})$
4: $\mathsf{G} \leftarrow \textsf{construct-graph}(\Gamma^f, \mathcal{D}^f, \mathcal{A})$
5: $\tilde{\mathsf{G}} \leftarrow \textsf{graph-propagate}(\mathsf{G})$
6: $\Delta \leftarrow \textsf{extract-word-constraints}(\tilde{\mathsf{G}})$
7: $\Theta^f \leftarrow \textsf{pos-induce-constrained}(\Gamma^f, \Delta)$
8: Return Θ^f

Since we have no labeled foreign data, our goal is to project syntactic information from the English side to the foreign side. To initialize the graph we tag the English side of the parallel text using a supervised model. By aggregating the POS labels of the English tokens to types, we can generate label distributions for the English vertices. Label propagation can then be used to transfer the labels to the *peripheral* foreign vertices (i.e. the ones adjacent to the English vertices) first, and then among all of the foreign vertices (§4). The POS distributions over the foreign trigram types are used as features to learn a better unsupervised POS tagger (§5). The following three sections elaborate these different stages is more detail.

3 Graph Construction

In graph-based learning approaches one constructs a graph whose vertices are labeled and unlabeled examples, and whose weighted edges encode the degree to which the examples they link have the same label (Zhu et al., 2003). Graph construction for structured prediction problems such as POS tagging is non-trivial: on the one hand, using individual words as the vertices throws away the context

[2] See Christodoulopoulos et al. (2010) for a discussion of metrics for evaluating unsupervised POS induction systems.

[3] The word alignment methods do not use POS information.

necessary for disambiguation; on the other hand, it is unclear how to define (sequence) similarity if the vertices correspond to entire sentences. Altun et al. (2005) proposed a technique that uses graph based similarity between labeled and unlabeled parts of structured data in a discriminative framework for semi-supervised learning. More recently, Subramanya et al. (2010) defined a graph over the cliques in an underlying structured prediction model. They considered a semi-supervised POS tagging scenario and showed that one can use a graph over trigram types, and edge weights based on distributional similarity, to improve a supervised conditional random field tagger.

3.1 Graph Vertices

We extend Subramanya et al.'s intuitions to our bilingual setup. Because the information flow in our graph is asymmetric (from English to the foreign language), we use different types of vertices for each language. The foreign language vertices (denoted by V_f) correspond to foreign trigram types, exactly as in Subramanya et al. (2010). On the English side, however, the vertices (denoted by V_e) correspond to word types. Because all English vertices are going to be labeled, we do not need to disambiguate them by embedding them in trigrams. Furthermore, we do not connect the English vertices to each other, but only to foreign language vertices.[4]

The graph vertices are extracted from the different sides of a parallel corpus ($\mathcal{D}^e$, $\mathcal{D}^f$) and an additional unlabeled monolingual foreign corpus Γ^f, which will be used later for training. We use two different similarity functions to define the edge weights among the foreign vertices and between vertices from different languages.

3.2 Monolingual Similarity Function

Our monolingual similarity function (for connecting pairs of foreign trigram types) is the same as the one used by Subramanya et al. (2010). We briefly review it here for completeness. We define a symmetric similarity function $\mathrm{K}(u_i, u_j)$ over two foreign language vertices $u_i, u_j \in V_f$ based on the co-occurrence statistics of the nine feature concepts given in Table 1. Each feature concept is akin to a random variable and its occurrence in the text corresponds to a particular instantiation of that random variable. For each trigram type $x_2\ x_3\ x_4$ in a sequence $x_1\ x_2\ x_3\ x_4\ x_5$, we count how many times that trigram type co-occurs with the different instantiations of each concept, and compute the point-wise mutual information (PMI) between the two.[5] The similarity between two trigram types is given by summing over the PMI values over feature instantiations that they have in common. This is similar to stacking the different feature instantiations into long (sparse) vectors and computing the cosine similarity between them. Finally, note that while most feature concepts are lexicalized, others, such as the suffix concept, are not.

Description	Feature
Trigram + Context	$x_1\ x_2\ x_3\ x_4\ x_5$
Trigram	$x_2\ x_3\ x_4$
Left Context	$x_1\ x_2$
Right Context	$x_4\ x_5$
Center Word	x_3
Trigram − Center Word	$x_2\ x_4$
Left Word + Right Context	$x_2\ x_4\ x_5$
Left Context + Right Word	$x_1\ x_2\ x_4$
Suffix	HasSuffix(x_3)

Table 1: Various features used for computing edge weights between foreign trigram types.

Given this similarity function, we define a nearest neighbor graph, where the edge weight for the n most similar vertices is set to the value of the similarity function and to 0 for all other vertices. We use $\mathcal{N}(u)$ to denote the neighborhood of vertex u, and fixed $n = 5$ in our experiments.

3.3 Bilingual Similarity Function

To define a similarity function between the English and the foreign vertices, we rely on high-confidence word alignments. Since our graph is built from a parallel corpus, we can use standard word alignment techniques to align the English sentences $\mathcal{D}^e$

[4] This is because we are primarily interested in learning foreign language taggers, rather than improving supervised English taggers. Note, however, that it would be possible to use our graph-based framework also for completely unsupervised POS induction in both languages, similar to Snyder et al. (2009).

[5] Note that many combinations are impossible giving a PMI value of 0; e.g., when the trigram type and the feature instantiation don't have words in common.

and their foreign language translations $\mathcal{D}^f$.[6] Label propagation in the graph will provide coverage and high recall, and we therefore extract only intersected high-confidence (> 0.9) alignments $\mathcal{D}^{e \leftrightarrow f}$.

Based on these high-confidence alignments we can extract tuples of the form $[u \leftrightarrow v]$, where u is a foreign trigram type, whose middle word aligns to an English word type v. Our bilingual similarity function then sets the edge weights in proportion to these tuple counts.

3.4 Graph Initialization

So far the graph has been completely unlabeled. To initialize the graph for label propagation we use a supervised English tagger to label the English side of the bitext.[7] We then simply count the individual labels of the English tokens and normalize the counts to produce tag distributions over English word types. These tag distributions are used to initialize the label distributions over the English vertices in the graph. Note that since all English vertices were extracted from the parallel text, we will have an initial label distribution for all vertices in V_e.

3.5 Graph Example

A very small excerpt from an Italian-English graph is shown in Figure 1. As one can see, only the trigrams [suo **incarceramento** ,], [suo **iter** ,] and [suo **carattere** ,] are connected to English words. In this particular case, all English vertices are labeled as nouns by the supervised tagger. In general, the neighborhoods can be more diverse and we allow a soft label distribution over the vertices. It is worth noting that the middle words of the Italian trigrams are nouns too, which exhibits the fact that the similarity metric connects types having the same syntactic category. In the label propagation stage, we propagate the automatic English tags to the aligned Italian trigram types, followed by further propagation solely among the Italian vertices.

[6] We ran six iterations of IBM Model 1 (Brown et al., 1993), followed by six iterations of the HMM model (Vogel et al., 1996) in both directions.

[7] We used a tagger based on a trigram Markov model (Brants, 2000) trained on the Wall Street Journal portion of the Penn Treebank (Marcus et al., 1993), for its fast speed and reasonable accuracy (96.7% on sections 22-24 of the treebank, but presumably much lower on the (out-of-domain) parallel corpus).

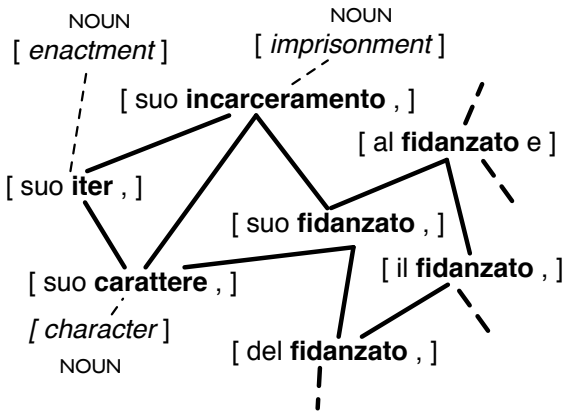

Figure 1: An excerpt from the graph for Italian. Three of the Italian vertices are connected to an automatically labeled English vertex. Label propagation is used to propagate these tags inwards and results in tag distributions for the middle word of each Italian trigram.

4 POS Projection

Given the bilingual graph described in the previous section, we can use label propagation to project the English POS labels to the foreign language. We use label propagation in two stages to generate soft labels on all the vertices in the graph. In the first stage, we run a single step of label propagation, which transfers the label distributions from the English vertices to the connected foreign language vertices (say, V_f^l) at the periphery of the graph. Note that because we extracted only high-confidence alignments, many foreign vertices will not be connected to any English vertices. This stage of label propagation results in a tag distribution r_i over labels y, which encodes the proportion of times the middle word of $u_i \in V_f$ aligns to English words v_y tagged with label y:

$$\mathrm{r}_i(y) = \frac{\sum_{v_y} \#[u_i \leftrightarrow v_y]}{\sum_{y'} \sum_{v_{y'}} \#[u_i \leftrightarrow v_{y'}]} \quad (1)$$

The second stage consists of running traditional label propagation to propagate labels from these peripheral vertices V_f^l to all foreign language vertices

in the graph, optimizing the following objective:

$$\begin{aligned}\mathcal{C}(\mathrm{q}) &= \sum_{u_i \in V_f \setminus V_f^l, u_j \in \mathcal{N}(u_i)} w_{ij} \|\mathrm{q}_i - \mathrm{q}_j\|^2 \\ &+ \nu \sum_{u_i \in V_f \setminus V_f^l} \|\mathrm{q}_i - U\|^2 \\ \text{s.t.} \quad & \sum_y \mathrm{q}_i(y) = 1 \; \forall u_i \\ & \mathrm{q}_i(y) \geq 0 \; \forall u_i, y \\ & \mathrm{q}_i = \mathrm{r}_i \; \forall u_i \in V_f^l \end{aligned} \tag{2}$$

where the q_i ($i = 1, \ldots, |V_f|$) are the label distributions over the foreign language vertices and μ and ν are hyperparameters that we discuss in §6.4. We use a squared loss to penalize neighboring vertices that have different label distributions: $\|\mathrm{q}_i - \mathrm{q}_j\|^2 = \sum_y (\mathrm{q}_i(y) - \mathrm{q}_j(y))^2$, and additionally regularize the label distributions towards the uniform distribution U over all possible labels $\mathcal{Y}$. It can be shown that this objective is convex in q.

The first term in the objective function is the graph smoothness regularizer which encourages the distributions of similar vertices (large w_{ij}) to be similar. The second term is a regularizer and encourages all type marginals to be uniform to the extent that is allowed by the first two terms (cf. maximum entropy principle). If an unlabeled vertex does not have a path to any labeled vertex, this term ensures that the converged marginal for this vertex will be uniform over all tags, allowing the middle word of such an unlabeled vertex to take on any of the possible tags.

While it is possible to derive a closed form solution for this convex objective function, it would require the inversion of a matrix of order $|V_f|$. Instead, we resort to an iterative update based method. We formulate the update as follows:

$$\mathrm{q}_i^{(m)}(y) = \begin{cases} \mathrm{r}_i(y) & \text{if } u_i \in V_f^l \\ \dfrac{\gamma_i(y)}{\kappa_i} & \text{otherwise} \end{cases} \tag{3}$$

where $\forall u_i \in V_f \setminus V_f^l$, $\gamma_i(y)$ and κ_i are defined as:

$$\gamma_i(y) = \sum_{u_j \in \mathcal{N}(u_i)} w_{ij} \mathrm{q}_j^{(m-1)}(y) + \nu \, U(y) \tag{4}$$

$$\kappa_i = \nu + \sum_{u_j \in \mathcal{N}(u_i)} w_{ij} \tag{5}$$

We ran this procedure for 10 iterations.

5 POS Induction

After running label propagation (LP), we compute tag probabilities for foreign word types x by marginalizing the POS tag distributions of foreign trigrams $u_i = x_- \; x \; x_+$ over the left and right context words:

$$p(y|x) = \frac{\sum_{x_-, x_+} \mathrm{q}_i(y)}{\sum_{x_-, x_+, y'} \mathrm{q}_i(y')} \tag{6}$$

We then extract a set of possible tags $\mathtt{t}_x(y)$ by eliminating labels whose probability is below a threshold value τ:

$$\mathtt{t}_x(y) = \begin{cases} 1 & \text{if } p(y|x) \geq \tau \\ 0 & \text{otherwise} \end{cases} \tag{7}$$

We describe how we choose τ in §6.4. This vector $\mathtt{t}_x$ is constructed for every word in the foreign vocabulary and will be used to provide features for the unsupervised foreign language POS tagger.

We develop our POS induction model based on the feature-based HMM of Berg-Kirkpatrick et al. (2010). For a sentence $\mathbf{x}$ and a state sequence $\mathbf{z}$, a first order Markov model defines a distribution:

$$\begin{aligned} P_\Theta(\mathbf{X} = \mathbf{x}, \mathbf{Z} = \mathbf{z}) &= P_\Theta(Z_1 = z_1) \cdot \\ \prod_{i=1}^{|\mathbf{x}|} & \underbrace{P_\Theta(Z_{i+1} = z_{i+1} \mid Z_i = z_i)}_{\text{transition}} \cdot \\ & \underbrace{P_\Theta(X_i = x_i \mid Z_i = z_i)}_{\text{emission}} \end{aligned} \tag{8}$$

In a traditional Markov model, the emission distribution $P_\Theta(X_i = x_i \mid Z_i = z_i)$ is a set of multinomials. The feature-based model replaces the emission distribution with a log-linear model, such that:

$$P_\Theta(X = x \mid Z = z) = \frac{\exp \Theta^\top \mathbf{f}(x, z)}{\sum_{x' \in \text{Val}(X)} \exp \Theta^\top \mathbf{f}(x', z)} \tag{9}$$

where $\text{Val}(X)$ corresponds to the entire vocabulary. This locally normalized log-linear model can look at various aspects of the observation x, incorporating overlapping features of the observation. In our experiments, we used the same set of features as Berg-Kirkpatrick et al. (2010): an indicator feature based

on the word identity x, features checking whether x contains digits or hyphens, whether the first letter of x is upper case, and suffix features up to length 3. All features were conjoined with the state z.

We trained this model by optimizing the following objective function:

$$\mathcal{L}(\Theta) = \sum_{i=1}^{N} \log \sum_{\mathbf{z}} P_\Theta(\mathbf{X} = \mathbf{x}^{(i)}, \mathbf{Z} = \mathbf{z}^{(i)}) - C\|\Theta\|_2^2 \quad (10)$$

Note that this involves marginalizing out all possible state configurations $\mathbf{z}$ for a sentence $\mathbf{x}$, resulting in a non-convex objective. To optimize this function, we used L-BFGS, a quasi-Newton method (Liu and Nocedal, 1989). For English POS tagging, Berg-Kirkpatrick et al. (2010) found that this direct gradient method performed better (>7% absolute accuracy) than using a feature-enhanced modification of the Expectation-Maximization (EM) algorithm (Dempster et al., 1977).[8] Moreover, this route of optimization outperformed a vanilla HMM trained with EM by 12%.

We adopted this state-of-the-art model because it makes it easy to experiment with various ways of incorporating our novel *constraint* feature into the log-linear emission model. This feature $\mathsf{f_t}$ incorporates information from the smoothed graph and prunes hidden states that are inconsistent with the thresholded vector t_x. The function $\lambda : \mathsf{F} \rightarrow \mathsf{C}$ maps from the language specific fine-grained tagset F to the coarser universal tagset C and is described in detail in §6.2:

$$\mathsf{f_t}(x, z) = \log(\mathsf{t}_x(y)), \text{ if } \lambda(z) = y \quad (11)$$

Note that when $\mathsf{t}_x(y) = 1$ the feature value is 0 and has no effect on the model, while its value is $-\infty$ when $\mathsf{t}_x(y) = 0$ and constrains the HMM's state space. This formulation of the constraint feature is equivalent to the use of a tagging dictionary extracted from the graph using a threshold τ on the posterior distribution of tags for a given word type (Eq. 7). It would have therefore also been possible to use the integer programming (IP) based approach of Ravi and Knight (2009) instead of the feature-HMM for POS induction on the foreign side. However, we do not explore this possibility in the current work.

[8] See §3.1 of Berg-Kirkpatrick et al. (2010) for more details about their modification of EM, and how gradients are computed for L-BFGS.

6 Experiments and Results

Before presenting our results, we describe the datasets that we used, as well as two baselines.

6.1 Datasets

We utilized two kinds of datasets in our experiments: (i) monolingual treebanks[9] and (ii) large amounts of parallel text with English on one side. The availability of these resources guided our selection of foreign languages. For monolingual treebank data we relied on the CoNLL-X and CoNLL-2007 shared tasks on dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007). The parallel data came from the Europarl corpus (Koehn, 2005) and the ODS United Nations dataset (UN, 2006). Taking the intersection of languages in these resources, and selecting languages with large amounts of parallel data, yields the following set of eight Indo-European languages: Danish, Dutch, German, Greek, Italian, Portuguese, Spanish and Swedish.

Of course, we are primarily interested in applying our techniques to languages for which no labeled resources are available. However, we needed to restrict ourselves to these languages in order to be able to evaluate the performance of our approach. We paid particular attention to minimize the number of free parameters, and used the same hyperparameters for all language pairs, rather than attempting language-specific tuning. We hope that this will allow practitioners to apply our approach directly to languages for which no resources are available.

6.2 Part-of-Speech Tagset and HMM States

We use the universal POS tagset of Petrov et al. (2011) in our experiments.[10] This set C consists of the following 12 coarse-grained tags: NOUN (nouns), VERB (verbs), ADJ (adjectives), ADV (adverbs), PRON (pronouns), DET (determiners), ADP (prepositions or postpositions), NUM (numerals), CONJ (conjunctions), PRT (particles), PUNC

[9] We extracted only the words and their POS tags from the treebanks.

[10] Available at http://code.google.com/p/universal-pos-tags/.

(punctuation marks) and X (a catch-all for other categories such as abbreviations or foreign words). While there might be some controversy about the exact definition of such a tagset, these 12 categories cover the most frequent part-of-speech and exist in one form or another in all of the languages that we studied.

For each language under consideration, Petrov et al. (2011) provide a mapping λ from the fine-grained language specific POS tags in the foreign treebank to the universal POS tags. The supervised POS tagging accuracies (on this tagset) are shown in the last row of Table 2. The taggers were trained on datasets labeled with the universal tags.

The number of latent HMM states for each language in our experiments was set to the number of fine tags in the language's treebank. In other words, the set of hidden states F was chosen to be the fine set of treebank tags. Therefore, the number of fine tags varied across languages for our experiments; however, one could as well have fixed the set of HMM states to be a constant across languages, and created one mapping to the universal POS tagset.

6.3 Various Models

To provide a thorough analysis, we evaluated three baselines and two oracles in addition to two variants of our graph-based approach. We were intentionally lenient with our baselines:

- **EM-HMM:** A traditional HMM baseline, with multinomial emission and transition distributions estimated by the Expectation Maximization algorithm. We evaluated POS tagging accuracy using the lenient many-to-1 evaluation approach (Johnson, 2007).
- **Feature-HMM:** The vanilla feature-HMM of Berg-Kirkpatrick et al. (2010) (i.e. no additional constraint feature) served as a second baseline. Model parameters were estimated with L-BFGS and evaluation again used a greedy many-to-1 mapping.
- **Projection:** Our third baseline incorporates bilingual information by projecting POS tags directly across alignments in the parallel data. For unaligned words, we set the tag to the most frequent tag in the corresponding treebank. For each language, we took the same number of sentences from the bitext as there are in its treebank, and trained a *supervised* feature-HMM. This can be seen as a rough approximation of Yarowsky and Ngai (2001).

We tried two versions of our graph-based approach:

- **No LP:** Our first version takes advantage of our bilingual graph, but extracts the constraint feature after the first stage of label propagation (Eq. 1). Because many foreign word types are not aligned to an English word (see Table 3), and we do not run label propagation on the foreign side, we expect the projected information to have less coverage. Furthermore we expect the label distributions on the foreign to be fairly noisy, because the graph constraints have not been taken into account yet.
- **With LP:** Our full model uses both stages of label propagation (Eq. 2) before extracting the constraint features. As a result, we are able to extract the constraint feature for all foreign word types and furthermore expect the projected tag distributions to be smoother and more stable.

Our oracles took advantage of the labeled treebanks:

- **TB Dictionary:** We extracted tagging dictionaries from the treebanks and and used them as constraint features in the feature-based HMM. Evaluation was done using the prespecified mappings.
- **Supervised:** We trained the supervised model of Brants (2000) on the original treebanks and mapped the language-specific tags to the universal tags for evaluation.

6.4 Experimental Setup

While we tried to minimize the number of free parameters in our model, there are a few hyperparameters that need to be set. Fortunately, performance was stable across various values, and we were able to use the same hyperparameters for all languages.

We used $C = 1.0$ as the L_2 regularization constant in (Eq. 10) and trained both EM and L-BFGS for 1000 iterations. When extracting the vector

	Model	Danish	Dutch	German	Greek	Italian	Portuguese	Spanish	Swedish	**Avg**

t_x used to compute the constraint feature from the graph, we tried three threshold values for τ (see Eq. 7). Because we don't have a separate development set, we used the training set to select among them and found 0.2 to work slightly better than 0.1 and 0.3. For seven out of eight languages a threshold of 0.2 gave the best results for our final model, which indicates that for languages without any validation set, $\tau = 0.2$ can be used. For graph propagation, the hyperparameter ν was set to 2×10^{-6} and was not tuned. The graph was constructed using 2 million trigrams; we chose these by truncating the parallel datasets up to the number of sentence pairs that contained 2 million trigrams.

6.5 Results

Table 2 shows our complete set of results. As expected, the vanilla HMM trained with EM performs the worst. The feature-HMM model works better for all languages, generalizing the results achieved for English by Berg-Kirkpatrick et al. (2010). Our "Projection" baseline is able to benefit from the bilingual information and greatly improves upon the monolingual baselines, but falls short of the "No LP" model by 2.5% on an average. The "No LP" model does not outperform direct projection for German and Greek, but performs better for six out of eight languages. Overall, it gives improvements ranging from 1.1% for German to 14.7% for Italian, for an average improvement of 8.3% over the unsupervised feature-HMM model. For comparison, the completely unsupervised feature-HMM baseline accuracy on the universal POS tags for English is 79.4%, and goes up to 88.7% with a treebank dictionary.

Our full model ("With LP") outperforms the unsupervised baselines and the "No LP" setting for all languages. It falls short of the "Projection" baseline for German, but is statistically indistinguishable in terms of accuracy. As indicated by bolding, for seven out of eight languages the improvements of the "With LP" setting are statistically significant with respect to the other models, including the "No LP" setting.[11] Overall, it performs 10.4% better than the hitherto state-of-the-art feature-HMM baseline, and 4.6% better than direct projection, when we macro-average the accuracy over all languages.

6.6 Discussion

Our full model outperforms the "No LP" setting because it has better vocabulary coverage and allows the extraction of a larger set of constraint features. We tabulate this increase in Table 3. For all languages, the vocabulary sizes increase by several thousand words. Although the tag distributions of the foreign words (Eq. 6) are noisy, the results confirm that label propagation within the foreign language part of the graph adds significant quality for every language.

Figure 2 shows an excerpt of a sentence from the Italian test set and the tags assigned by four different models, as well as the gold tags. While the first three models get three to four tags wrong, our best model gets only one word wrong and is the most accurate among the four models for this example. Examining the word *fidanzato* for the "No LP" and "With LP" models is particularly instructive. As Figure 1 shows, this word has no high-confidence alignment in the Italian-English bitext. As a result, its POS tag needs to be induced in the "No LP" case, while the

correct tag is available as a constraint feature in the "With LP" case.

7 Conclusion

We have shown the efficacy of graph-based label propagation for projecting part-of-speech information across languages. Because we are interested in applying our techniques to languages for which no labeled resources are available, we paid particular attention to minimize the number of free parameters and used the same hyperparameters for all language pairs. Our results suggest that it is possible to learn accurate POS taggers for languages which do not have any annotated data, but have translations into a resource-rich language. Our results outperform strong unsupervised baselines as well as approaches that rely on direct projections, and bridge the gap between purely supervised and unsupervised POS tagging models.

Acknowledgements

We would like to thank Ryan McDonald for numerous discussions on this topic. We would also like to thank Amarnag Subramanya for helping us with the implementation of label propagation and Shankar Kumar for access to the parallel data. Finally, we thank Kuzman Ganchev and the three anonymous reviewers for helpful suggestions and comments on earlier drafts of this paper.

Abstract

Extensive knowledge bases of entailment rules between predicates are crucial for applied semantic inference. In this paper we propose an algorithm that utilizes transitivity constraints to learn a globally-optimal set of entailment rules for typed predicates. We model the task as a graph learning problem and suggest methods that scale the algorithm to larger graphs. We apply the algorithm over a large data set of extracted predicate instances, from which a resource of typed entailment rules has been recently released (Schoenmackers et al., 2010). Our results show that using global transitivity information substantially improves performance over this resource and several baselines, and that our scaling methods allow us to increase the scope of global learning of entailment-rule graphs.

1 Introduction

Generic approaches for applied semantic inference from text gained growing attention in recent years, particularly under the Textual Entailment (TE) framework (Dagan et al., 2009). TE is a generic paradigm for semantic inference, where the objective is to recognize whether a target meaning can be inferred from a given text. A crucial component of inference systems is extensive resources of *entailment rules*, also known as *inference rules*, i.e., rules that specify a directional inference relation between fragments of text. One important type of rule is rules that specify entailment relations between predicates and their arguments. For example, the rule *'X annex Y → X control Y'* helps recognize that the text *'Japan annexed Okinawa'* answers the question *'Which country controls Okinawa?'*. Thus, acquisition of such knowledge received considerable attention in the last decade (Lin and Pantel, 2001; Sekine, 2005; Szpektor and Dagan, 2009; Schoenmackers et al., 2010).

Most past work took a "local learning" approach, learning each entailment rule independently of others. It is clear though, that there are global interactions between predicates. Notably, entailment is a *transitive* relation and so the rules $A \rightarrow B$ and $B \rightarrow C$ imply $A \rightarrow C$.

Recently, Berant et al. (2010) proposed a *global* graph optimization procedure that uses *Integer Linear Programming (ILP)* to find the best set of entailment rules under a transitivity constraint. Imposing this constraint raised two challenges. The first of *ambiguity:* transitivity does not always hold when predicates are ambiguous, e.g., *X buy Y → X acquire Y* and *X acquire Y → X learn Y*, but *X buy Y ↛ X learn Y* since these two rules correspond to two different senses of *acquire*. The second challenge is *scalability:* ILP solvers do not scale well since ILP is an NP-complete problem. Berant et al. circumvented these issues by learning rules where one of the predicate's arguments is instantiated (e.g., *'X reduce nausea → X affect nausea'*), which is useful for learning small graphs on-the-fly, given a target concept such as *nausea*. While rules may be effectively learned when needed, their scope is narrow and they are not useful as a generic knowledge resource.

This paper aims to take global rule learning one step further. To this end, we adopt the representation suggested by Schoenmackers et al. (2010), who learned inference rules between *typed predicates*, i.e., predicates where the argument types (e.g., *city* or *drug*) are specified. Schoenmackers et al. uti-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 610–619,
Portland, Oregon, June 19-24, 2011.

lized typed predicates since they were dealing with noisy and ambiguous web text. Typing predicates helps disambiguation and filtering of noise, while still maintaining rules of wide-applicability. Their method employs a local learning approach, while the number of predicates in their data is too large to be handled directly by an ILP solver.

In this paper we suggest applying global optimization learning to open domain typed entailment rules. To that end, we show how to construct a structure termed *typed entailment graph*, where the nodes are typed predicates and the edges represent entailment rules. We suggest scaling techniques that allow to optimally learn such graphs over a large set of typed predicates by first *decomposing* nodes into components and then applying *incremental ILP* (Riedel and Clarke, 2006). Using these techniques, the obtained algorithm is guaranteed to return an optimal solution. We ran our algorithm over the data set of Schoenmackers et al. and release a resource of 30,000 rules[1] that achieves substantially higher recall without harming precision. To the best of our knowledge, this is the first resource of that scale to use global optimization for learning predicative entailment rules. Our evaluation shows that global transitivity improves the F_1 score of rule learning by 27% over several baselines and that our scaling techniques allow dealing with larger graphs, resulting in improved coverage.

2 Background

Most work on learning entailment rules between predicates considered each rule independently of others, using two sources of information: *lexicographic resources* and *distributional similarity*.

Lexicographic resources are manually-prepared knowledge bases containing semantic information on predicates. A widely-used resource is WordNet (Fellbaum, 1998), where relations such as *synonymy* and *hyponymy* can be used to generate rules. Other resources include NomLex (Macleod et al., 1998; Szpektor and Dagan, 2009) and FrameNet (Baker and Lowe, 1998; Ben Aharon et al., 2010).

Lexicographic resources are accurate but have low coverage. Distributional similarity algorithms use large corpora to learn broader resources by assuming that semantically similar predicates appear with similar arguments. These algorithms usually represent a predicate with one or more vectors and use some function to compute argument similarity. Distributional similarity algorithms differ in their *feature representation*: Some use a *binary* representation: each predicate is represented by one feature vector where each feature is a pair of arguments (Szpektor et al., 2004; Yates and Etzioni, 2009). This representation performs well, but suffers when data is sparse. The *binary-DIRT* representation deals with sparsity by representing a predicate with a pair of vectors, one for each argument (Lin and Pantel, 2001). Last, a richer form of representation, termed *unary*, has been suggested where a different predicate is defined for each argument (Szpektor and Dagan, 2008). Different algorithms also differ in their similarity function. Some employ symmetric functions, geared towards *paraphrasing* (bi-directional entailment), while others choose directional measures more suited for entailment (Bhagat et al., 2007). In this paper, We employ several such functions, such as *Lin* (Lin and Pantel, 2001), and *BInc* (Szpektor and Dagan, 2008).

Schoenmackers et al. (2010) recently used distributional similarity to learn rules between *typed predicates*, where the left-hand-side of the rule may contain more than a single predicate (horn clauses). In their work, they used Hearst-patterns (Hearst, 1992) to extract a set of 29 million *(argument, type)* pairs from a large web crawl. Then, they employed several filtering methods to clean this set and automatically produced a mapping of 1.1 million arguments into 156 types. Examples for *(argument, type)* pairs are *(EXODUS, book)*, *(CHINA, country)* and *(ASTHMA, disease)*. Schoenmackers et al. then utilized the types, the mapped arguments and tuples from TextRunner (Banko et al., 2007) to generate 10,672 typed predicates (such as *conquer(country,city)* and *common in(disease,place)*), and learn 30,000 rules between these predicates[2]. In this paper we will learn entailment rules over the same data set, which was generously provided by

Schoenmackers et al.

As mentioned above, Berant et al. (2010) used global transitivity information to learn small *entailment graphs*. Transitivity was also used as an information source in other fields of NLP: Taxonomy Induction (Snow et al., 2006), Co-reference Resolution (Finkel and Manning, 2008), Temporal Information Extraction (Ling and Weld, 2010), and Unsupervised Ontology Induction (Poon and Domingos, 2010). Our proposed algorithm applies to any sparse transitive relation, and so might be applicable in these fields as well.

Last, we formulate our optimization problem as an Integer Linear Program (ILP). ILP is an optimization problem where a linear objective function over a set of integer variables is maximized under a set of linear constraints. Scaling ILP is challenging since it is an NP-complete problem. ILP has been extensively used in NLP lately (Clarke and Lapata, 2008; Martins et al., 2009; Do and Roth, 2010).

3 Typed Entailment Graphs

Given a set of typed predicates, entailment rules can only exist between predicates that share the same (unordered) pair of types (such as *place* and *country*)[3]. Hence, every pair of types defines a graph that describes the entailment relations between predicates sharing those types (Figure 1). Next, we show how to represent entailment rules between typed predicates in a structure termed *typed entailment graph*, which will be the learning goal of our algorithm.

A typed entailment graph is a directed graph where the nodes are *typed predicates*. A typed predicate is a triple $p(t_1, t_2)$ representing a predicate in natural language. p is the lexical realization of the predicate and the types t_1, t_2 are variables representing argument types. These are taken from a set of types T, where each type $t \in T$ is a bag of natural language words or phrases. Examples for typed predicates are: *conquer(country,city)* and *contain(product,material)*. An *instance* of a typed predicate is a triple $p(a_1, a_2)$, where $a_1 \in t_1$ and $a_2 \in t_2$ are termed *arguments*. For example, *be common in(ASTHMA,AUSTRALIA)* is an instance of *be common in(disease,place)*. For brevity, we refer to typed entailment graphs and typed predicates as *entailment graphs* and *predicates* respectively.

Edges in typed entailment graphs represent entailment rules: an edge (u, v) means that predicate u entails predicate v. If the type t_1 is different from the type t_2, mapping of arguments is straightforward, as in the rule '*be find in(material,product)* $\rightarrow$ *contain(product,material)*'. We term this *a two-types entailment graph*. When t_1 and t_2 are equal, mapping of arguments is ambiguous: we distinguish *direct-mapping edges* where the first argument on the left-hand-side (LHS) is mapped to the first argument on the right-hand-side (RHS), as in '*beat(team,team)* $\xrightarrow{d}$ *defeat(team,team)*', and *reversed-mapping edges* where the LHS first argument is mapped to the RHS second argument, as in '*beat(team,team)* $\xrightarrow{r}$ *lose to(team,team)*'. We term this *a single-type entailment graph*. Note that in single-type entailment graphs reversed-mapping loops are possible as in '*play(team,team)* $\xrightarrow{r}$ *play(team,team)*': if team A plays team B, then team B plays team A.

Since entailment is a transitive relation, typed-entailment graphs are transitive: if the edges (u, v) and (v, w) are in the graph so is the edge (u, w). Note that in single-type entailment graphs one needs to consider whether mapping of edges is direct or reversed: if mapping of both (u, v) and (v, w) is either direct or reversed, mapping of (u, w) is direct, otherwise it is reversed.

Typing plays an important role in rule transitivity: if predicates are ambiguous, transitivity does not necessarily hold. However, typing predicates helps disambiguate them and so the problem of ambiguity is greatly reduced.

4 Learning Typed Entailment Graphs

Our learning algorithm is composed of two steps: (1) Given a set of typed predicates and their instances extracted from a corpus, we train a (local) *entailment classifier* that estimates for every pair of predicates whether one entails the other. (2) Using the classifier scores we perform global optimization, i.e., learn the set of edges over the nodes that maximizes the global score of the graph under transitivity and background-knowledge constraints.

Section 4.1 describes the local classifier training

[3] Otherwise, the rule would contain unbound variables.

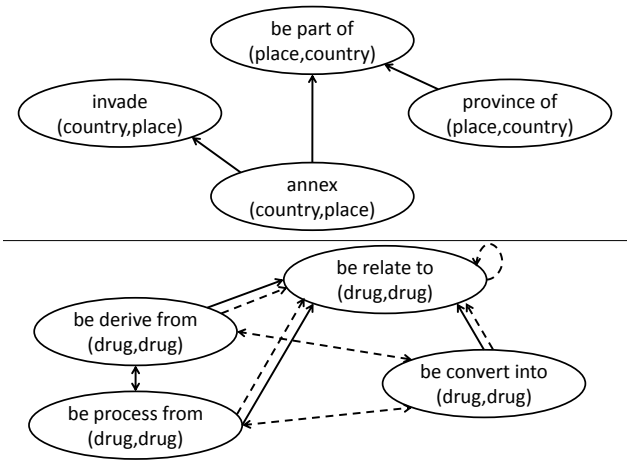

Figure 1: *Top:* A fragment of a two-types entailment graph. *bottom:* A fragment of a single-type entailment graph. Mapping of solid edges is direct and of dashed edges is reversed.

procedure. Section 4.2 gives an ILP formulation for the optimization problem. Sections 4.3 and 4.4 propose scaling techniques that exploit graph sparsity to optimally solve larger graphs.

4.1 Training an entailment classifier

Similar to the work of Berant et al. (2010), we use "distant supervision". Given a lexicographic resource (WordNet) and a set of predicates with their instances, we perform the following three steps (see Table 1):

1) Training set generation We use WordNet to generate positive and negative examples, where each example is a pair of predicates. Let P be the set of input typed predicates. For every predicate $p(t_1, t_2) \in P$ such that p is a single word, we extract from WordNet the set S of synonyms and direct hypernyms of p. For every $p' \in S$, if $p'(t_1, t_2) \in P$ then $p(t_1, t_2) \rightarrow p'(t_1, t_2)$ is taken as a positive example.

Negative examples are generated in a similar manner, with direct co-hyponyms of p (sister nodes in WordNet) and hyponyms at distance 2 instead of synonyms and direct hypernyms. We also generate negative examples by randomly sampling pairs of typed predicates that share the same types.

2) Feature representation Each example pair of predicates (p_1, p_2) is represented by a feature vector, where each feature is a specific distributional similarity score estimating whether p_1 entails p_2. We compute 11 distributional similarity scores for each pair of predicates based on the arguments appearing in the extracted arguments. The first 6 scores are computed by trying all combinations of the similarity functions *Lin* and *BInc* with the feature representations *unary*, *binary-DIRT* and *binary* (see Section 2). The other 5 scores were provided by Schoenmackers et al. (2010) and include *SR* (Schoenmackers et al., 2010), *LIME* (McCreath and Sharma, 1997), *M-estimate* (Dzeroski and Brakto, 1992), the standard *G-test* and a simple implementation of *Cover* (Weeds and Weir, 2003). Overall, the rationale behind this representation is that combining various scores will yield a better classifier than each single measure.

Type	example
hyper.	*beat(team,team)* $\rightarrow$ *play(team,team)*
syno.	*reach(team,game)* $\rightarrow$ *arrive at(team,game)*
cohypo.	*invade(country,city)* $\nrightarrow$ *bomb(country,city)*
hypo.	*defeat(city,city)* $\nrightarrow$ *eliminate(city,city)*
random	*hold(place,event)* $\nrightarrow$ *win(place,event)*

Table 1: Automatically generated training set examples.

3) Training We train over an equal number of positive and negative examples, as classifiers tend to perform poorly on the minority class when trained on imbalanced data (Van Hulse et al., 2007; Nikulin, 2008).

4.2 ILP formulation

Once the classifier is trained, we would like to learn all edges (entailment rules) of each typed entailment graph. Given a set of predicates V and an entailment score function $f : V \times V \rightarrow \mathbb{R}$ derived from the classifier, we want to find a graph $G = (V, E)$ that respects transitivity and maximizes the sum of edge weights $\sum_{(u,v)\in E} f(u, v)$. This problem is NP-hard by a reduction from the NP-hard *Transitive Subgraph* problem (Yannakakis, 1978). Thus, employing ILP is an appealing approach for obtaining an optimal solution.

For two-types entailment graphs the formulation is simple: The ILP variables are indicators X_{uv} denoting whether an edge (u, v) is in the graph, with the following ILP:

$$\hat{G} = arg\,max \sum_{u \neq v} f(u,v) \cdot X_{uv} \quad (1)$$

$$\text{s.t. } \forall_{u,v,w \in V}\ X_{uv} + X_{vw} - X_{uw} \leq 1 \quad (2)$$

$$\forall_{u,v \in A_{yes}}\ X_{uv} = 1 \quad (3)$$

$$\forall_{u,v \in A_{no}}\ X_{uv} = 0 \quad (4)$$

$$\forall_{u \neq v}\ X_{uv} \in \{0,1\} \quad (5)$$

The objective in Eq. 1 is a sum over the weights of the eventual edges. The constraint in Eq. 2 states that edges must respect transitivity. The constraints in Eq. 3 and 4 state that for known node pairs, defined by A_{yes} and A_{no}, we have background knowledge indicating whether entailment holds or not. We elaborate on how A_{yes} and A_{no} were constructed in Section 5. For a graph with n nodes we get $n(n-1)$ variables and $n(n-1)(n-2)$ transitivity constraints.

The simplest way to expand this formulation for single-type graphs is to duplicate each predicate node, with one node for each order of the types, and then the ILP is unchanged. However, this is inefficient as it results in an ILP with $2n(2n-1)$ variables and $2n(2n-1)(2n-2)$ transitivity constraints. Since our main goal is to scale the use of ILP, we modify it a little. We denote a direct-mapping edge (u,v) by the indicator X_{uv} and a reversed-mapping edge (u,v) by Y_{uv}. The functions f_d and f_r provide scores for direct and reversed mappings respectively. The objective in Eq. 1 and the constraint in Eq. 2 are replaced by (Eq. 3, 4 and 5 still exist and are carried over in a trivial manner):

$$arg\,max \sum_{u \neq v} f_d(u,v) X_{uv} + \sum_{u,v} f_r(u,v) Y_{uv} \quad (6)$$

$$\text{s.t. } \forall_{u,v,w \in V}\ X_{uv} + X_{vw} - X_{uw} \leq 1$$

$$\forall_{u,v,w \in V}\ X_{uv} + Y_{vw} - Y_{uw} \leq 1$$

$$\forall_{u,v,w \in V}\ Y_{uv} + X_{vw} - Y_{uw} \leq 1$$

$$\forall_{u,v,w \in V}\ Y_{uv} + Y_{vw} - X_{uw} \leq 1$$

The modified constraints capture the transitivity behavior of direct-mapping and reversed-mapping edges, as described in Section 3. This results in $2n^2 - n$ variables and about $4n^3$ transitivity constraints, cutting the ILP size in half.

Next, we specify how to derive the function f from the trained classifier using a probabilistic formulation[4]. Following Snow et al. (2006) and Berant et al. (2010), we utilize a probabilistic entailment classifier that computes the posterior $P_{uv} = P(X_{uv} = 1|F_{uv})$. We want to use P_{uv} to derive the posterior $P(G|F)$, where $F = \cup_{u \neq v} F_{uv}$ and F_{uv} is the feature vector for a node pair (u,v).

Since the classifier was trained on a balanced training set, the prior over the two entailment classes is uniform and so by Bayes rule $P_{uv} \propto P(F_{uv}|X_{uv} = 1)$. Using that and the exact same three independence assumptions described by Snow et al. (2006) and Berant et al. (2010) we can show that (for brevity, we omit the full derivation):

$$\hat{G} = arg\,max_G \log P(G|F) = \quad (7)$$

$$arg\,max \sum_{u \neq v} (\log \frac{P_{uv} \cdot P(X_{uv}=1)}{(1-P_{uv})P(X_{uv}=0)}) X_{uv}$$

$$= arg\,max \sum_{u \neq v} (\log \frac{P_{uv}}{1-P_{uv}}) X_{uv} + \log \eta \cdot |E|$$

where $\eta = \frac{P(X_{uv}=1)}{P(X_{uv}=0)}$ is the prior odds ratio for an edge in the graph. Comparing Eq. 1 and 7 we see that $f(u,v) = \log \frac{P_{uv} \cdot P(X_{uv}=1)}{(1-P_{uv})P(X_{uv}=0)}$. Note that f is composed of a likelihood component and an *edge prior* expressed by $P(X_{uv} = 1)$, which we assume to be some constant. This constant is a parameter that affects graph sparsity and controls the trade-off between recall and precision.

Next, we show how sparsity is exploited to scale the use of ILP solvers. We discuss two-types entailment graphs, but generalization is simple.

4.3 Graph decomposition

Though ILP solvers provide an optimal solution, they substantially restrict the size of graphs we can work with. The number of constraints is $O(n^3)$, and solving graphs of size > 50 is often not feasible. To overcome this, we take advantage of graph sparsity: most predicates in language do not entail one another. Thus, it might be possible to decompose graphs into small components and solve each

[4]We describe two-types graphs but extending to single-type graphs is straightforward.

Algorithm 1 Decomposed-ILP

Input: A set V and a function $f : V \times V \rightarrow \mathbf{R}$
Output: An optimal set of directed edges E^*

1: $E' = \{(u, v) : f(u, v) > 0 \vee f(v, u) > 0\}$
2: $V_1, V_2, ..., V_k \leftarrow$ connected components of $G' = (V, E')$
3: **for** $i = 1$ **to** k **do**
4: $\quad E_i \leftarrow$ ApplyILPSolve(V_i,f)
5: **end for**
6: $E^* \leftarrow \bigcup_{i=1}^{k} E_i$

component separately. This is formalized in the next proposition.

Proposition 1. *If we can partition a set of nodes V into disjoint sets U, W such that for any crossing edge (u, w) between them (in either direction), $f(u, w) < 0$, then the optimal set of edges E_{opt} does not contain any crossing edge.*

Proof Assume by contradiction that E_{opt} contains a set of crossing edges E_{cross}. We can construct $E_{new} = E_{opt} \setminus E_{cross}$. Clearly $\sum_{(u,v)\in E_{new}} f(u, v) > \sum_{(u,v)\in E_{opt}} f(u, v)$, as $f(u, v) < 0$ for any crossing edge.

Next, we show that E_{new} does not violate transitivity constraints. Assume it does, then the violation is caused by omitting the edges in E_{cross}. Thus, there must be a node $u \in U$ and $w \in W$ (w.l.o.g) such that for some node v, (u, v) and (v, w) are in E_{new}, but (u, w) is not. However, this means either (u, v) or (v, w) is a crossing edge, which is impossible since we omitted all crossing edges. Thus, E_{new} is a better solution than E_{opt}, contradiction. □

This proposition suggests a simple algorithm (see Algorithm 1): Add to the graph an undirected edge for any node pair with a positive score, then find the connected components, and apply an ILP solver over the nodes in each component. The edges returned by the solver provide an optimal (not approximate) solution to the optimization problem.

The algorithm's complexity is dominated by the ILP solver, as finding connected components takes $O(V^2)$ time. Thus, efficiency depends on whether the graph is sparse enough to be decomposed into small components. Note that the edge prior plays an important role: low values make the graph sparser and easier to solve. In Section 5 we empirically test how typed entailment graphs benefit from decomposition given different prior values.

From a more general perspective, this algorithm can be applied to any problem of learning a sparse transitive binary relation. Such problems include Co-reference Resolution (Finkel and Manning, 2008) and Temporal Information Extraction (Ling and Weld, 2010). Last, the algorithm can be easily parallelized by solving each component on a different core.

Algorithm 2 Incremental-ILP

Input: A set V and a function $f : V \times V \rightarrow \mathbf{R}$
Output: An optimal set of directed edges E^*

1: ACT,VIO $\leftarrow \phi$
2: **repeat**
3: $\quad E^* \leftarrow$ ApplyILPSolve(V,f,ACT)
4: $\quad$ VIO $\leftarrow$ violated(V, E^*)
5: $\quad$ ACT $\leftarrow$ ACT $\cup$ VIO
6: **until** |VIO| $= 0$

4.4 Incremental ILP

Another solution for scaling ILP is to employ incremental ILP, which has been used in dependency parsing (Riedel and Clarke, 2006). The idea is that even if we omit the transitivity constraints, we still expect most transitivity constraints to be satisfied, given a good local entailment classifier. Thus, it makes sense to avoid specifying the constraints ahead of time, but rather add them when they are violated. This is formalized in Algorithm 2.

Line 1 initializes an *active* set of constraints and a *violated* set of constraints (*ACT;VIO*). Line 3 applies the ILP solver with the active constraints. Lines 4 and 5 find the violated constraints and add them to the active constraints. The algorithm halts when no constraints are violated. The solution is clearly optimal since we obtain a maximal solution for a less-constrained problem.

A pre-condition for using incremental ILP is that computing the violated constraints (Line 4) is efficient, as it occurs in every iteration. We do that in a straightforward manner: For every node v, and edges (u, v) and (v, w), if $(u, w) \notin E^*$ we add (u, v, w) to the violated constraints. This is cubic in worst-case but assuming the degree of nodes is bounded by a constant it is linear, and performs very

fast in practice.

Combining *Incremental-ILP* and *Decomposed-ILP* is easy: We decompose any large graph into its components and apply Incremental ILP on each component. We applied this algorithm on our evaluation data set (Section 5) and found that it converges in at most 6 iterations and that the maximal number of active constraints in large graphs drops from $\sim 10^6$ to $\sim 10^3 - 10^4$.

5 Experimental Evaluation

In this section we empirically answer the following questions: (1) Does transitivity improve rule learning over typed predicates? (Section 5.1) (2) Do *Decomposed-ILP* and *Incremental-ILP* improve scalability? (Section 5.2)

5.1 Experiment 1

A data set of 1 million TextRunner tuples (Banko et al., 2007), mapped to 10,672 distinct typed predicates over 156 types was provided by Schoenmackers et al. (2010). Readers are referred to their paper for details on mapping of tuples to typed predicates. Since entailment only occurs between predicates that share the same types, we decomposed predicates by their types (e.g., all predicates with the types *place* and *disease*) into 2,303 *typed entailment graphs*. The largest graph contains 118 nodes and the total number of potential rules is 263,756.

We generated a training set by applying the procedure described in Section 4.1, yielding 2,644 examples. We used SVMperf (Joachims, 2005) to train a Gaussian kernel classifier and computed P_{uv} by projecting the classifier output score, S_{uv}, with the sigmoid function: $P_{uv} = \frac{1}{1+exp(-S_{uv})}$. We tuned two SVM parameters using 5-fold cross validation and a development set of two typed entailment graphs.

Next, we used our algorithm to learn rules. As mentioned in Section 4.2, we integrate background knowledge using the sets A_{yes} and A_{no} that contain predicate pairs for which we know whether entailment holds. A_{yes} was constructed with syntactic rules: We normalized each predicate by omitting the first word if it is a modal and turning passives to actives. If two normalized predicates are equal they are synonymous and inserted into A_{yes}. A_{no} was constructed from 3 sources (1) Predicates differing by a single pair of words that are WordNet antonyms (2) Predicates differing by a single word of negation (3) Predicates $p(t_1, t_2)$ and $p(t_2, t_1)$ where p is a transitive verb (e.g., *beat)* in VerbNet (Kipper-Schuler et al., 2000).

We compared our algorithm (termed *ILP*$_{scale}$) to the following baselines. First, to 10,000 rules released by Schoenmackers et al. (2010) (*Sherlock*), where the LHS contains a single predicate (Schoenmackers et al. released 30,000 rules but 20,000 of those have more than one predicate on the LHS, see Section 2), as we learn rules over the same data set. Second, to distributional similarity algorithms: (a) *SR:* the score used by Schoenmackers et al. as part of the *Sherlock* system. (b) *DIRT:* (Lin and Pantel, 2001) a widely-used rule learning algorithm. (c) *BInc:* (Szpektor and Dagan, 2008) a directional rule learning algorithm. Third, we compared to the entailment classifier with no transitivity constraints (*clsf*) to see if combining distributional similarity scores improves performance over single measures. Last, we added to all baselines background knowledge with A_{yes} and A_{no} (adding the subscript X_k to their name).

To evaluate performance we manually annotated all edges in 10 typed entailment graphs - 7 two-types entailment graphs containing 14, 22, 30, 53, 62, 86 and 118 nodes, and 3 single-type entailment graphs containing 7, 38 and 59 nodes. This annotation yielded 3,427 edges and 35,585 non-edges, resulting in an empirical edge density of 9%. We evaluate the algorithms by comparing the set of edges learned by the algorithms to the gold standard edges.

Figure 2 presents the precision-recall curve of the algorithms. The curve is formed by varying a score threshold in the baselines and varying the edge prior in ILP$_{scale}$[5]. For figure clarity, we omit *DIRT* and *SR*, since *BInc* outperforms them.

Table 2 shows micro-recall, precision and F_1 at the point of maximal F_1, and the Area Under the Curve (AUC) for recall in the range of 0-0.45 for all algorithms, given background knowledge (knowledge consistently improves performance by a few points for all algorithms). The table also shows results for the rules from *Sherlock*$_k$.

[5] we stop raising the prior when run time over the graphs exceeds 2 hours. Often when the solver does not terminate in 2 hours, it also does not terminate after 24 hours or more.

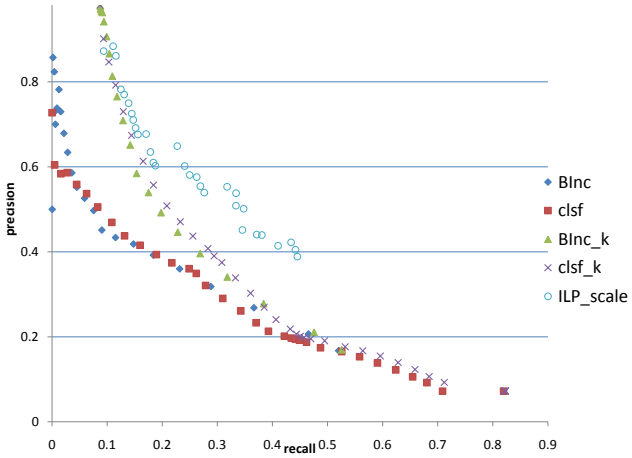

Figure 2: Precision-recall curve for the algorithms.

	micro-average			
	R (%)	P (%)	F_1 (%)	AUC
ILP_{scale}	**43.4**	42.2	**42.8**	**0.22**
$clsf_k$	30.8	37.5	33.8	0.17
$Sherlock_k$	20.6	**43.3**	27.9	N/A
$BInc_k$	31.8	34.1	32.9	0.17
SR_k	38.4	23.2	28.9	0.14
$DIRT_k$	25.7	31.0	28.1	0.13

Table 2: micro-average F_1 and AUC for the algorithms.

Results show that using global transitivity information substantially improves performance. ILP_{scale} is better than all other algorithms by a large margin starting from recall .2, and improves AUC by 29% and the maximal F_1 by 27%. Moreover, ILP_{scale} doubles recall comparing to the rules from the *Sherlock* resource, while maintaining comparable precision.

5.2 Experiment 2

We want to test whether using our scaling techniques, *Decomposed-ILP* and *Incremental-ILP*, allows us to reach the optimal solution in graphs that otherwise we could not solve, and consequently increase the number of learned rules and the overall recall. To check that, we run ILP_{scale}, with and without these scaling techniques (termed ILP^{-}).

We used the same data set as in Experiment 1 and learned edges for all 2,303 entailment graphs in the data set. If the ILP solver was unable to hold the ILP in memory or took more than 2 hours for some graph, we did not attempt to learn its edges. We ran ILP_{scale} and ILP^{-} in three density modes to examine the behavior of the algorithms for different graph densities: (a) $\log \eta = -0.6$: the configuration that achieved the best recall/precision/F_1 of 43.4/42.2/42.8. (b) $\log \eta = -1$ with recall/precision/F_1 of 31.8/55.3/40.4. (c) $\log \eta = -1.75$: A high precision configuration with recall/precision/F_1 of 0.15/0.75/0.23 [6].

$\log \eta$	# unlearned	# rules	$\triangle$	Red.
-1.75	9/0	6,242 / 7,466	20%	75%
-1	9/1	16,790 / 19,396	16%	29%
-0.6	9/3	26,330 / 29,732	13%	14%

Table 3: Impact of scaling techinques (ILP^{-}/ILP_{scale}).

In each run we counted the number of graphs that could not be learned and the number of rules learned by each algorithm. In addition, we looked at the 20 largest graphs in our data (49-118 nodes) and measured the ratio r between the size of the largest component after applying *Decomposed-ILP* and the original size of the graph. We then computed the average $1-r$ over the 20 graphs to examine how graph size drops due to decomposition.

Table 3 shows the results. Column *# unlearned* and *# rules* describe the number of unlearned graphs and the number of learned rules. Column $\triangle$ shows relative increase in the number of rules learned and column *Red.* shows the average $1-r$.

ILP_{scale} increases the number of graphs that we are able to learn: in our best configuration ($\log \eta = -0.6$) only 3 graphs could not be handled comparing to 9 graphs when omitting our scaling techniques. Since the unlearned graphs are among the largest in the data set, this adds 3,500 additional rules. We compared the precision of rules learned only by ILP_{scale} with that of the rules learned by both, by randomly sampling 100 rules from each and found precision to be comparable. Thus, the additional rules learned translate into a 13% increase in relative recall without harming precision.

Also note that as density increases, the number of rules learned grows and the effectiveness of decomposition decreases. This shows how *Decomposed-ILP* is especially useful for sparse graphs. We re-

[6] Experiment was run on an Intel i5 CPU with 4GB RAM.

lease the 29,732 rules learned by the configuration $\log \eta = -0.6$ as a resource.

To sum up, our scaling techniques allow us to learn rules from graphs that standard ILP can not handle and thus considerably increase recall without harming precision.

6 Conclusions and Future Work

This paper proposes two contributions over two recent works: In the first, Berant et al. (2010) presented a *global* optimization procedure to learn entailment rules between predicates using transitivity, and applied this algorithm over small graphs where all predicates have one argument instantiated by a target concept. Consequently, the rules they learn are of limited applicability. In the second, Schoenmackers et al. learned rules of wider applicability by using *typed predicates*, but utilized a *local* approach.

In this paper we developed an algorithm that uses *global* optimization to learn widely-applicable entailment rules between typed predicates (where *both* arguments are variables). This was achieved by appropriately defining entailment graphs for typed predicates, formulating an ILP representation for them, and introducing scaling techniques that include graph decomposition and incremental ILP. Our algorithm is guaranteed to provide an optimal solution and we have shown empirically that it substantially improves performance over Schoenmackers et al.'s recent resource and over several baselines.

In future work, we aim to scale the algorithm further and learn entailment rules between untyped predicates. This would require explicit modeling of predicate ambiguity and using approximation techniques when an optimal solution cannot be attained.

Acknowledgments

This work was performed with financial support from the Turing Center at The University of Washington during a visit of the first author (NSF grant IIS-0803481). We deeply thank Oren Etzioni and Stefan Schoenmackers for providing us with the data sets for this paper and for numerous helpful discussions. We would also like to thank the anonymous reviewers for their useful comments. This work was developed under the collaboration of FBK-irst/University of Haifa and was partially supported by the Israel Science Foundation grant 1112/08. Abstract

This paper describes a novel technique for incorporating syntactic knowledge into phrase-based machine translation through incremental syntactic parsing. Bottom-up and top-down parsers typically require a completed string as input. This requirement makes it difficult to incorporate them into phrase-based translation, which generates partial hypothesized translations from left-to-right. Incremental syntactic language models score sentences in a similar left-to-right fashion, and are therefore a good mechanism for incorporating syntax into phrase-based translation. We give a formal definition of one such linear-time syntactic language model, detail its relation to phrase-based decoding, and integrate the model with the Moses phrase-based translation system. We present empirical results on a constrained Urdu-English translation task that demonstrate a significant BLEU score improvement and a large decrease in perplexity.

1 Introduction

Early work in statistical machine translation viewed translation as a noisy channel process comprised of a translation model, which functioned to posit adequate translations of source language words, and a target language model, which guided the fluency of generated target language strings (Brown et al., 1990). Drawing on earlier successes in speech recognition, research in statistical machine translation has effectively used n-gram word sequence models as language models.

Modern phrase-based translation using large scale n-gram language models generally performs well in terms of lexical choice, but still often produces ungrammatical output. Syntactic parsing may help produce more grammatical output by better modeling structural relationships and long-distance dependencies. Bottom-up and top-down parsers typically require a completed string as input; this requirement makes it difficult to incorporate these parsers into phrase-based translation, which generates hypothesized translations incrementally, from left-to-right.[1] As a workaround, parsers can rerank the translated output of translation systems (Och et al., 2004).

On the other hand, incremental parsers (Roark, 2001; Henderson, 2004; Schuler et al., 2010; Huang and Sagae, 2010) process input in a straightforward left-to-right manner. We observe that incremental parsers, used as structured language models, provide an appropriate algorithmic match to incremental phrase-based decoding. We directly integrate incremental syntactic parsing into phrase-based translation. This approach re-exerts the role of the language model as a mechanism for encouraging syntactically fluent translations.

The contributions of this work are as follows:

- A novel method for integrating syntactic LMs into phrase-based translation (§3)
- A formal definition of an incremental parser for

2 Related Work

Neither phrase-based (Koehn et al., 2003) nor hierarchical phrase-based translation (Chiang, 2005) take explicit advantage of the syntactic structure of either source or target language. The translation models in these techniques define *phrases* as contiguous word sequences (with gaps allowed in the case of hierarchical phrases) which may or may not correspond to any linguistic constituent. Early work in statistical phrase-based translation considered whether restricting translation models to use only syntactically well-formed constituents might improve translation quality (Koehn et al., 2003) but found such restrictions failed to improve translation quality.

Significant research has examined the extent to which syntax can be usefully incorporated into statistical tree-based translation models: string-to-tree (Yamada and Knight, 2001; Gildea, 2003; Imamura et al., 2004; Galley et al., 2004; Graehl and Knight, 2004; Melamed, 2004; Galley et al., 2006; Huang et al., 2006; Shen et al., 2008), tree-to-string (Liu et al., 2006; Liu et al., 2007; Mi et al., 2008; Mi and Huang, 2008; Huang and Mi, 2010), tree-to-tree (Abeillé et al., 1990; Shieber and Schabes, 1990; Poutsma, 1998; Eisner, 2003; Shieber, 2004; Cowan et al., 2006; Nesson et al., 2006; Zhang et al., 2007; DeNeefe et al., 2007; DeNeefe and Knight, 2009; Liu et al., 2009; Chiang, 2010), and treelet (Ding and Palmer, 2005; Quirk et al., 2005) techniques use syntactic information to inform the translation model. Recent work has shown that parsing-based machine translation using syntax-augmented (Zollmann and Venugopal, 2006) hierarchical translation grammars with rich nonterminal sets can demonstrate substantial gains over hierarchical grammars for certain language pairs (Baker et al., 2009). In contrast to the above tree-based translation models, our approach maintains a standard (non-syntactic) phrase-based translation model. Instead, we incorporate syntax into the language model.

Traditional approaches to language models in speech recognition and statistical machine translation focus on the use of n-grams, which provide a simple finite-state model approximation of the target language. Chelba and Jelinek (1998) proposed that syntactic structure could be used as an alternative technique in language modeling. This insight has been explored in the context of speech recognition (Chelba and Jelinek, 2000; Collins et al., 2005). Hassan et al. (2007) and Birch et al. (2007) use supertag n-gram LMs. Syntactic language models have also been explored with tree-based translation models. Charniak et al. (2003) use syntactic language models to rescore the output of a tree-based translation system. Post and Gildea (2008) investigate the integration of parsers as syntactic language models during binary bracketing transduction translation (Wu, 1997); under these conditions, both syntactic phrase-structure and dependency parsing language models were found to improve oracle-best translations, but did not improve actual translation results. Post and Gildea (2009) use tree substitution grammar parsing for language modeling, but do not use this language model in a translation system. Our work, in contrast to the above approaches, explores the use of incremental syntactic language models in conjunction with phrase-based translation models.

Our syntactic language model fits into the family of linear-time dynamic programming parsers described in (Huang and Sagae, 2010). Like (Galley and Manning, 2009) our work implements an incremental syntactic language model; our approach differs by calculating syntactic LM scores over all available phrase-structure parses at each hypothesis instead of the 1-best dependency parse.

The syntax-driven reordering model of Ge (2010) uses syntax-driven features to influence word order within standard phrase-based translation. The syntactic cohesion features of Cherry (2008) encourages the use of syntactically well-formed translation phrases. These approaches are fully orthogonal to our proposed incremental syntactic language model, and could be applied in concert with our work.

3 Parser as Syntactic Language Model in Phrase-Based Translation

Parsing is the task of selecting the representation $\hat{\tau}$ (typically a tree) that best models the structure of

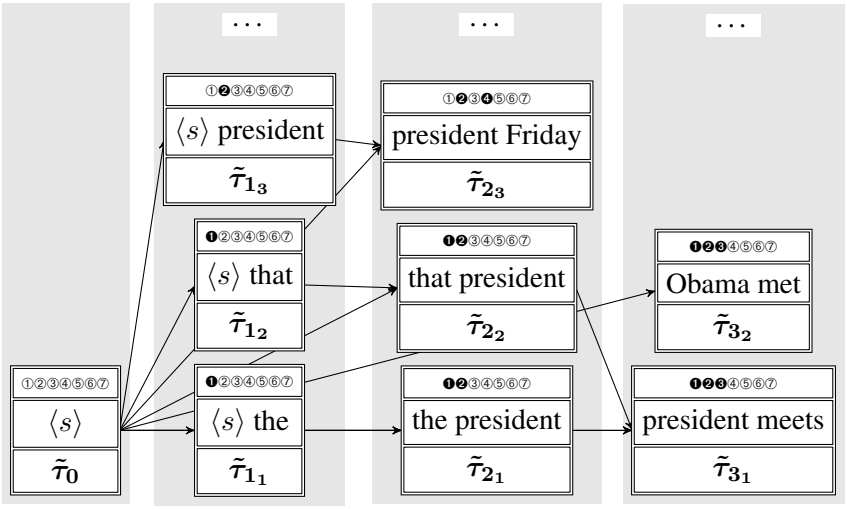

Figure 1: Partial decoding lattice for standard phrase-based decoding stack algorithm translating the German sentence *Der Präsident trifft am Freitag den Vorstand*. Each node h in decoding stack t represents the application of a translation option, and includes the source sentence coverage vector, target language n-gram state, and syntactic language model state $\tilde{\boldsymbol{\tau}}_{\boldsymbol{t_h}}$. Hypothesis combination is also shown, indicating where lattice paths with identical n-gram histories converge. We use the English translation *The president meets the board on Friday* as a running example throughout all Figures.

sentence $\mathbf{e}$, out of all such possible representations $\boldsymbol{\tau}$. This set of representations may be all phrase structure trees or all dependency trees allowed by the parsing model. Typically, tree $\hat{\tau}$ is taken to be:

$$\hat{\tau} = \underset{\tau}{\operatorname{argmax}}\, \mathsf{P}(\tau \,|\, \mathbf{e}) \tag{1}$$

We define a syntactic language model $\mathsf{P}(\mathbf{e})$ based on the total probability mass over all possible trees for string $\mathbf{e}$. This is shown in Equation 2 and decomposed in Equation 3.

$$\mathsf{P}(\mathbf{e}) = \sum_{\tau \in \boldsymbol{\tau}} \mathsf{P}(\tau, \mathbf{e}) \tag{2}$$

$$\mathsf{P}(\mathbf{e}) = \sum_{\tau \in \boldsymbol{\tau}} \mathsf{P}(\mathbf{e} \,|\, \tau)\mathsf{P}(\tau) \tag{3}$$

3.1 Incremental syntactic language model

An incremental parser processes each token of input sequentially from the beginning of a sentence to the end, rather than processing input in a top-down (Earley, 1968) or bottom-up (Cocke and Schwartz, 1970; Kasami, 1965; Younger, 1967) fashion. After processing the tth token in string $\mathbf{e}$, an incremental parser has some internal representation of possible hypothesized (incomplete) trees, $\boldsymbol{\tau_t}$. The syntactic language model probability of a partial sentence $e_1 ... e_t$ is defined:

$$\mathsf{P}(e_1 ... e_t) = \sum_{\tau \in \boldsymbol{\tau_t}} \mathsf{P}(e_1 ... e_t \,|\, \tau)\mathsf{P}(\tau) \tag{4}$$

In practice, a parser may constrain the set of trees under consideration to $\tilde{\boldsymbol{\tau}}_{\boldsymbol{t}}$, that subset of analyses or partial analyses that remains after any pruning is performed. An incremental syntactic language model can then be defined by a probability mass function (Equation 5) and a transition function δ (Equation 6). The role of δ is explained in §3.3 below. Any parser which implements these two functions can serve as a syntactic language model.

$$\mathsf{P}(e_1 ... e_t) \approx \mathsf{P}(\tilde{\boldsymbol{\tau}}_t) = \sum_{\tau \in \tilde{\boldsymbol{\tau}}_t} \mathsf{P}(e_1 ... e_t \,|\, \tau)\mathsf{P}(\tau) \tag{5}$$

$$\delta(e_t, \tilde{\boldsymbol{\tau}}_{t-1}) \rightarrow \tilde{\boldsymbol{\tau}}_t \tag{6}$$

3.2 Decoding in phrase-based translation

Given a source language input sentence $\mathbf{f}$, a trained source-to-target translation model, and a target language model, the task of translation is to find the maximally probable translation $\hat{\boldsymbol{e}}$ using a linear combination of j feature functions $\boldsymbol{h}$ weighted according to tuned parameters $\boldsymbol{\lambda}$ (Och and Ney, 2002).

$$\hat{\boldsymbol{e}} = \underset{\mathbf{e}}{\operatorname{argmax}} \exp(\sum_{j} \lambda_j h_j(\boldsymbol{e}, \boldsymbol{f})) \quad (7)$$

Phrase-based translation constructs a set of translation options — hypothesized translations for contiguous portions of the source sentence — from a trained phrase table, then incrementally constructs a lattice of partial target translations (Koehn, 2010). To prune the search space, lattice nodes are organized into beam stacks (Jelinek, 1969) according to the number of source words translated. An n-gram language model history is also maintained at each node in the translation lattice. The search space is further trimmed with hypothesis recombination, which collapses lattice nodes that share a common coverage vector and n-gram state.

3.3 Incorporating a Syntactic Language Model

Phrase-based translation produces target language words in an incremental left-to-right fashion, generating words at the beginning of a translation first and words at the end of a translation last. Similarly, incremental parsers process sentences in an incremental fashion, analyzing words at the beginning of a sentence first and words at the end of a sentence last. As such, an incremental parser with transition function δ can be incorporated into the phrase-based decoding process in a straightforward manner. Each node in the translation lattice is augmented with a syntactic language model state $\tilde{\boldsymbol{\tau}}_t$.

The hypothesis at the root of the translation lattice is initialized with $\tilde{\boldsymbol{\tau}}_0$, representing the internal state of the incremental parser before any input words are processed. The phrase-based translation decoding process adds nodes to the lattice; each new node contains one or more target language words. Each node contains a backpointer to its parent node, in which $\tilde{\boldsymbol{\tau}}_{t-1}$ is stored. Given a new target language word e_t and $\tilde{\boldsymbol{\tau}}_{t-1}$, the incremental parser's transition function δ calculates $\tilde{\boldsymbol{\tau}}_t$. Figure 1 illustrates

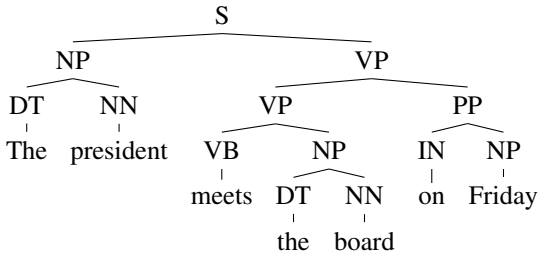

Figure 2: Sample binarized phrase structure tree.

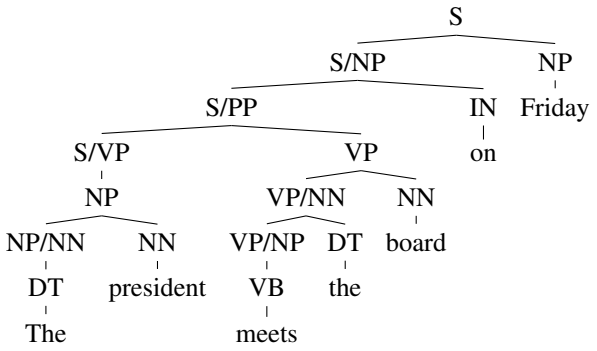

Figure 3: Sample binarized phrase structure tree after application of right-corner transform.

a sample phrase-based decoding lattice where each translation lattice node is augmented with syntactic language model state $\tilde{\boldsymbol{\tau}}_t$.

In phrase-based translation, many translation lattice nodes represent multi-word target language phrases. For such translation lattice nodes, δ will be called once for each newly hypothesized target language word in the node. Only the final syntactic language model state in such sequences need be stored in the translation lattice node.

4 Incremental Bounded-Memory Parsing with a Time Series Model

Having defined the framework by which any incremental parser may be incorporated into phrase-based translation, we now formally define a specific incremental parser for use in our experiments.

The parser must process target language words incrementally as the phrase-based decoder adds hypotheses to the translation lattice. To facilitate this incremental processing, ordinary phrase-structure trees can be transformed into right-corner recur-

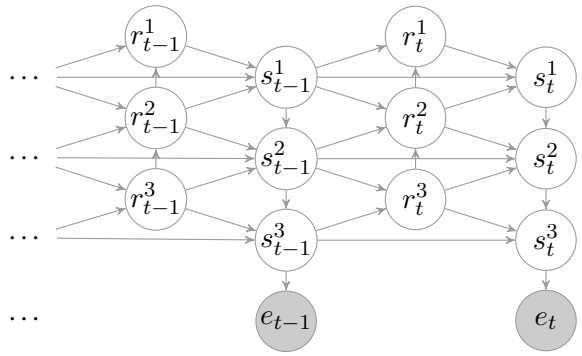

Figure 4: Graphical representation of the dependency structure in a standard Hierarchic Hidden Markov Model with $D = 3$ hidden levels that can be used to parse syntax. Circles denote random variables, and edges denote conditional dependencies. Shaded circles denote variables with observed values.

sive phrase structure trees using the tree transforms in Schuler et al. (2010). Constituent nonterminals in right-corner transformed trees take the form of *incomplete constituents* $c_\eta/c_{\eta\iota}$ consisting of an 'active' constituent c_η lacking an 'awaited' constituent $c_{\eta\iota}$ yet to come, similar to non-constituent categories in a Combinatory Categorial Grammar (Ades and Steedman, 1982; Steedman, 2000). As an example, the parser might consider VP/NN as a possible category for input "meets the".

A sample phrase structure tree is shown before and after the right-corner transform in Figures 2 and 3. Our parser operates over a right-corner transformed probabilistic context-free grammar (PCFG). Parsing runs in linear time on the length of the input. This model of incremental parsing is implemented as a Hierarchical Hidden Markov Model (HHMM) (Murphy and Paskin, 2001), and is equivalent to a probabilistic pushdown automaton with a bounded pushdown store. The parser runs in O(n) time, where n is the number of words in the input. This model is shown graphically in Figure 4 and formally defined in §4.1 below.

The incremental parser assigns a probability (Eq. 5) for a partial target language hypothesis, using a bounded store of incomplete constituents $c_\eta/c_{\eta\iota}$. The phrase-based decoder uses this probability value as the syntactic language model feature score.

4.1 Formal Parsing Model: Scoring Partial Translation Hypotheses

This model is essentially an extension of an HHMM, which obtains a most likely sequence of hidden store states, $\hat{s}^{1..D}_{1..T}$, of some length T and some maximum depth D, given a sequence of observed tokens (e.g. generated target language words), $e_{1..T}$, using HHMM state transition model θ_A and observation symbol model θ_B (Rabiner, 1990):

$$\hat{s}^{1..D}_{1..T} \stackrel{\text{def}}{=} \underset{s^{1..D}_{1..T}}{\operatorname{argmax}} \prod_{t=1}^{T} \mathsf{P}_{\theta_\text{A}}(s^{1..D}_t \mid s^{1..D}_{t-1}) \cdot \mathsf{P}_{\theta_\text{B}}(e_t \mid s^{1..D}_t) \tag{8}$$

The HHMM parser is equivalent to a probabilistic pushdown automaton with a bounded pushdown store. The model generates each successive store (using store model θ_S) only after considering whether each nested sequence of incomplete constituents has completed and reduced (using reduction model θ_R):

$$\begin{aligned}\mathsf{P}_{\theta_\text{A}}(s^{1..D}_t \mid s^{1..D}_{t-1}) \stackrel{\text{def}}{=} \\ \sum_{r^1_t..r^D_t} \prod_{d=1}^{D} & \mathsf{P}_{\theta_\text{R}}(r^d_t \mid r^{d+1}_t s^d_{t-1} s^{d-1}_{t-1}) \\ & \cdot \mathsf{P}_{\theta_\text{S}}(s^d_t \mid r^{d+1}_t r^d_t\, s^d_{t-1} s^{d-1}_t)\end{aligned} \tag{9}$$

Store elements are defined to contain only the active (c_η) and awaited ($c_{\eta\iota}$) constituent categories necessary to compute an incomplete constituent probability:

$$s^d_t \stackrel{\text{def}}{=} \langle c_\eta, c_{\eta\iota} \rangle \tag{10}$$

Reduction states are defined to contain only the complete constituent category $c_{r^d_t}$ necessary to compute an inside likelihood probability, as well as a flag $f_{r^d_t}$ indicating whether a reduction has taken place (to end a sequence of incomplete constituents):

$$r^d_t \stackrel{\text{def}}{=} \langle c_{r^d_t}, f_{r^d_t} \rangle \tag{11}$$

The model probabilities for these store elements and reduction states can then be defined (from Murphy and Paskin 2001) to expand a new incomplete constituent after a reduction has taken place ($f_{r^d_t} = 1$; using depth-specific store state expansion model $\theta_{\text{S-E},d}$), transition along a sequence of store elements

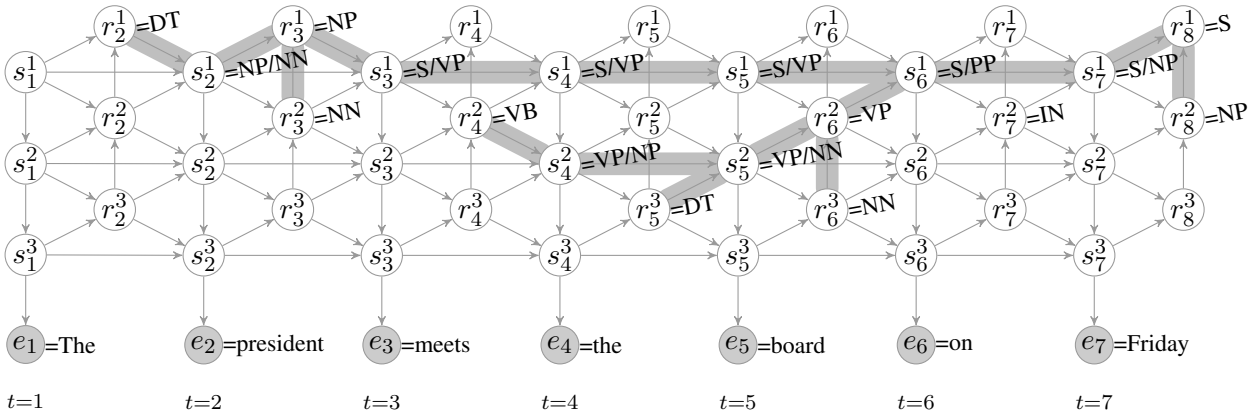

Figure 5: Graphical representation of the Hierarchic Hidden Markov Model after parsing input sentence *The president meets the board on Friday*. The shaded path through the parse lattice illustrates the recognized right-corner tree structure of Figure 3.

if no reduction has taken place ($f_{r_t^d}=0$; using depth-specific store state transition model $\theta_{\text{S-T},d}$): [2]

$$\mathsf{P}_{\theta_{\text{S}}}(s_t^d \mid r_t^{d+1} r_t^d \; s_{t-1}^d s_t^{d-1}) \stackrel{\text{def}}{=} \begin{cases} \text{if } f_{r_t^{d+1}}=1,\; f_{r_t^d}=1 : \mathsf{P}_{\theta_{\text{S-E},d}}(s_t^d \mid s_t^{d-1}) \\ \text{if } f_{r_t^{d+1}}=1,\; f_{r_t^d}=0 : \mathsf{P}_{\theta_{\text{S-T},d}}(s_t^d \mid r_t^{d+1} r_t^d \; s_{t-1}^d s_t^{d-1}) \\ \text{if } f_{r_t^{d+1}}=0,\; f_{r_t^d}=0 : [\![s_t^d = s_{t-1}^d]\!] \end{cases} \tag{12}$$

and possibly reduce a store element (terminate a sequence) if the store state below it has reduced ($f_{r_t^{d+1}}=1$; using depth-specific reduction model $\theta_{\text{R},d}$):

$$\mathsf{P}_{\theta_{\text{R}}}(r_t^d \mid r_t^{d+1} s_{t-1}^d s_{t-1}^{d-1}) \stackrel{\text{def}}{=} \begin{cases} \text{if } f_{r_t^{d+1}}=0 : [\![r_t^d = \mathbf{r}_\perp]\!] \\ \text{if } f_{r_t^{d+1}}=1 : \mathsf{P}_{\theta_{\text{R},d}}(r_t^d \mid r_t^{d+1} \; s_{t-1}^d \; s_{t-1}^{d-1}) \end{cases} \tag{13}$$

where $\mathbf{r}_\perp$ is a null state resulting from the failure of an incomplete constituent to complete, and constants are defined for the edge conditions of s_t^0 and r_t^{D+1}. Figure 5 illustrates this model in action.

These pushdown automaton operations are then refined for right-corner parsing (Schuler, 2009), distinguishing *active* transitions (model $\theta_{\text{S-T-A},d}$, in which an incomplete constituent is completed, but not reduced, and then immediately expanded to a new incomplete constituent in the same store element) from *awaited* transitions (model $\theta_{\text{S-T-W},d}$, which involve no completion):

$$\mathsf{P}_{\theta_{\text{S-T},d}}(s_t^d \mid r_t^{d+1} r_t^d \; s_{t-1}^d s_t^{d-1}) \stackrel{\text{def}}{=} \begin{cases} \text{if } r_t^d \neq \mathbf{r}_\perp : \mathsf{P}_{\theta_{\text{S-T-A},d}}(s_t^d \mid s_t^{d-1} r_t^d) \\ \text{if } r_t^d = \mathbf{r}_\perp : \mathsf{P}_{\theta_{\text{S-T-W},d}}(s_t^d \mid s_{t-1}^d r_t^{d+1}) \end{cases} \tag{14}$$

$$\mathsf{P}_{\theta_{\text{R},d}}(r_t^d \mid r_t^{d+1} s_{t-1}^d s_{t-1}^{d-1}) \stackrel{\text{def}}{=} \begin{cases} \text{if } c_{r_t^{d+1}} \neq x_t : [\![r_t^d = \mathbf{r}_\perp]\!] \\ \text{if } c_{r_t^{d+1}} = x_t : \mathsf{P}_{\theta_{\text{R-R},d}}(r_t^d \mid s_{t-1}^d s_{t-1}^{d-1}) \end{cases} \tag{15}$$

These HHMM right-corner parsing operations are then defined in terms of branch- and depth-specific PCFG probabilities $\theta_{\text{G-R},d}$ and $\theta_{\text{G-L},d}$: [3]

$$\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{0} c_{\eta 0} \ldots) \stackrel{\text{def}}{=} \sum_{c_{\eta 1}} \mathsf{P}_{\theta_{\text{G-R},d}}(c_\eta \rightarrow c_{\eta 0} \; c_{\eta 1}) \tag{16}$$

$$\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{k} c_{\eta 0^k 0} \ldots) \stackrel{\text{def}}{=} \sum_{c_{\eta 0^k}} \mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{k-1} c_{\eta 0^k} \ldots) \cdot \sum_{c_{\eta 0^k 1}} \mathsf{P}_{\theta_{\text{G-L},d}}(c_{\eta 0^k} \rightarrow c_{\eta 0^k 0} \; c_{\eta 0^k 1}) \tag{17}$$

$$\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{*} c_{\eta\iota} \ldots) \stackrel{\text{def}}{=} \sum_{k=0}^{\infty} \mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{k} c_{\eta\iota} \ldots) \tag{18}$$

$$\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{+} c_{\eta\iota} \ldots) \stackrel{\text{def}}{=} \mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{*} c_{\eta\iota} \ldots) - \mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{0} c_{\eta\iota} \ldots) \tag{19}$$

[2] An indicator function $[\![\cdot]\!]$ is used to denote deterministic probabilities: $[\![\phi]\!] = 1$ if ϕ is true, 0 otherwise.

[3] Model probabilities are also defined in terms of left-progeny probability distribution $\mathsf{E}_{\theta_{\text{G-RL}^*,d}}$ which is itself defined in terms of PCFG probabilities:

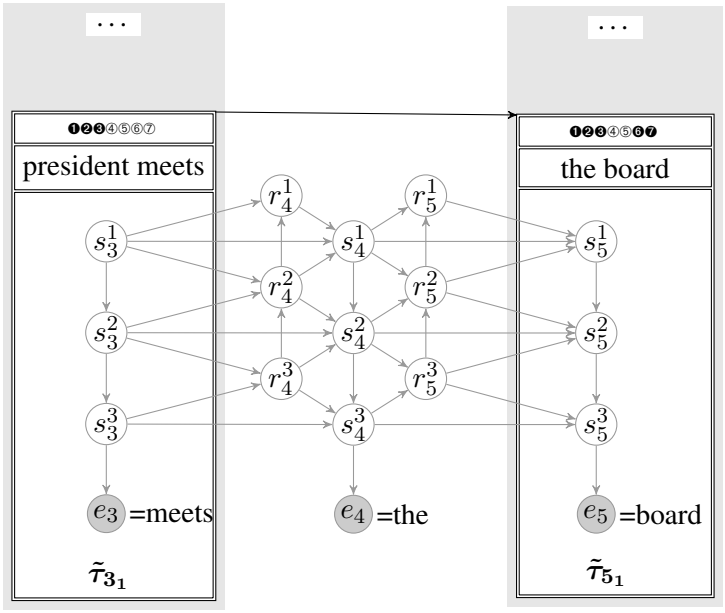

Figure 6: A hypothesis in the phrase-based decoding lattice from Figure 1 is expanded using translation option *the board* of source phrase *den Vorstand*. Syntactic language model state $\tilde{\boldsymbol{\tau}}_{\mathbf{3_1}}$ contains random variables $s_3^{1..3}$; likewise $\tilde{\boldsymbol{\tau}}_{\mathbf{5_1}}$ contains $s_5^{1..3}$. The intervening random variables $r_4^{1..3}$, $s_4^{1..3}$, and $r_5^{1..3}$ are calculated by transition function δ (Eq. 6, as defined by §4.1), but are not stored. Observed random variables ($e_3..e_5$) are shown for clarity, but are not explicitly stored in any syntactic language model state.

- for expansions:

$$\mathsf{P}_{\theta_{\text{S-E},d}}(\langle c_{\eta\iota}, c'_{\eta\iota}\rangle \mid \langle -, c_\eta\rangle) \stackrel{\text{def}}{=} \mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{*} c_{\eta\iota}\ ...) \cdot [\![x_{\eta\iota} = c'_{\eta\iota} = c_{\eta\iota}]\!] \quad (20)$$

- for awaited transitions:

$$\mathsf{P}_{\theta_{\text{S-T-W},d}}(\langle c_\eta, c_{\eta\iota 1}\rangle \mid \langle c'_\eta, c_{\eta\iota}\rangle\ c_{\eta\iota 0}) \stackrel{\text{def}}{=} [\![c_\eta = c'_\eta]\!] \cdot \frac{\mathsf{P}_{\theta_{\text{G-R},d}}(c_{\eta\iota} \rightarrow c_{\eta\iota 0}\ c_{\eta\iota 1})}{\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_{\eta\iota} \xrightarrow{0} c_{\eta\iota 0}\ ...)} \quad (21)$$

- for active transitions:

$$\mathsf{P}_{\theta_{\text{S-T-A},d}}(\langle c_{\eta\iota}, c_{\eta\iota 1}\rangle \mid \langle -, c_\eta\rangle\ c_{\eta\iota 0}) \stackrel{\text{def}}{=} \frac{\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{*} c_{\eta\iota}\ ...) \cdot \mathsf{P}_{\theta_{\text{G-L},d}}(c_{\eta\iota} \rightarrow c_{\eta\iota 0}\ c_{\eta\iota 1})}{\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{+} c_{\eta\iota 0}\ ...)} \quad (22)$$

- for cross-element reductions:

$$\mathsf{P}_{\theta_{\text{R-R},d}}(c_{\eta\iota}, \mathbf{1} \mid \langle -, c_\eta\rangle\ \langle c'_{\eta\iota}, -\rangle) \stackrel{\text{def}}{=} [\![c_{\eta\iota} = c'_{\eta\iota}]\!] \cdot \frac{\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{0} c_{\eta\iota}\ ...)}{\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{*} c_{\eta\iota}\ ...)} \quad (23)$$

- for in-element reductions:

$$\mathsf{P}_{\theta_{\text{R-R},d}}(c_{\eta\iota}, \mathbf{0} \mid \langle -, c_\eta\rangle\ \langle c'_{\eta\iota}, -\rangle) \stackrel{\text{def}}{=} [\![c_{\eta\iota} = c'_{\eta\iota}]\!] \cdot \frac{\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{+} c_{\eta\iota}\ ...)}{\mathsf{E}_{\theta_{\text{G-RL}^*,d}}(c_\eta \xrightarrow{*} c_{\eta\iota}\ ...)} \quad (24)$$

We use the parser implementation of (Schuler, 2009; Schuler et al., 2010).

5 Phrase Based Translation with an Incremental Syntactic Language Model

The phrase-based decoder is augmented by adding additional state data to each hypothesis in the de-

coder's hypothesis stacks. Figure 1 illustrates an excerpt from a standard phrase-based translation lattice. Within each decoder stack t, each hypothesis h is augmented with a syntactic language model state $\tilde{\boldsymbol{\tau}}_{\boldsymbol{t_h}}$. Each syntactic language model state is a random variable store, containing a slice of random variables from the HHMM. Specifically, $\tilde{\boldsymbol{\tau}}_{\boldsymbol{t_h}}$ contains those random variables $s_t^{1..D}$ that maintain distributions over syntactic elements.

By maintaining these syntactic random variable stores, each hypothesis has access to the current language model probability for the partial translation ending at that hypothesis, as calculated by an incremental syntactic language model defined by the HHMM. Specifically, the random variable store at hypothesis h provides $\mathsf{P}(\tilde{\boldsymbol{\tau}}_{\boldsymbol{t_h}}) = \mathsf{P}(e_{1..t}^h, s_{1..t}^{1..D})$, where $e_{1..t}^h$ is the sequence of words in a partial hypothesis ending at h which contains t target words, and where there are D syntactic random variables in each random variable store (Eq. 5).

During stack decoding, the phrase-based decoder progressively constructs new hypotheses by extending existing hypotheses. New hypotheses are placed in appropriate hypothesis stacks. In the simplest case, a new hypothesis extends an existing hypothesis by exactly one target word. As the new hypothesis is constructed by extending an existing stack element, the store and reduction state random variables are processed, along with the newly hypothesized word. This results in a new store of syntactic random variables (Eq. 6) that are associated with the new stack element.

When a new hypothesis extends an existing hypothesis by more than one word, this process is first carried out for the first new word in the hypothesis. It is then repeated for the remaining words in the hypothesis extension. Once the final word in the hypothesis has been processed, the resulting random variable store is associated with that hypothesis. The random variable stores created for the non-final words in the extending hypothesis are discarded, and need not be explicitly retained.

Figure 6 illustrates this process, showing how a syntactic language model state $\tilde{\boldsymbol{\tau}}_{\mathbf{5_1}}$ in a phrase-based decoding lattice is obtained from a previous syntactic language model state $\tilde{\boldsymbol{\tau}}_{\mathbf{3_1}}$ (from Figure 1) by parsing the target language words from a phrase-based translation option.

LM	In-domain WSJ 23 ppl	Out-of-domain ur-en dev ppl

Interp. Giga 5-gr + WSJ 5-gram	174.88	321.05

Figure 7: Average per-word perplexity values. HHMM was run with beam size of 2000. **Bold** indicates best single-model results for LMs trained on WSJ sections 2-21. Best overall in ***italics***.

Our syntactic language model is integrated into the current version of Moses (Koehn et al., 2007).

6 Results

As an initial measure to compare language models, average per-word perplexity, ppl, reports how surprised a model is by test data. Equation 25 calculates ppl using log base b for a test set of T tokens.

$$ppl = b^{\frac{-log_b \mathsf{P}(e_1 \ldots e_T)}{T}} \quad (25)$$

We trained the syntactic language model from §4 (HHMM) and an interpolated n-gram language model with modified Kneser-Ney smoothing (Chen and Goodman, 1998); models were trained on sections 2-21 of the Wall Street Journal (WSJ) treebank (Marcus et al., 1993). The HHMM outperforms the n-gram model in terms of out-of-domain test set perplexity when trained on the same WSJ data; the best perplexity results for in-domain and out-of-domain test sets[4] are found by interpolating

[4]In-domain is WSJ Section 23. Out-of-domain are the English reference translations of the dev section , set aside in (Baker et al., 2009) for parameter tuning, of the NIST Open MT 2008 Urdu-English task.

Sentence length	Moses	+HHMM beam=50	+HHMM beam=2000
10	0.21	533	1143
20	0.53	1193	2562
30	0.85	1746	3749
40	1.13	2095	4588

Figure 8: Mean per-sentence decoding time (in seconds) for dev set using Moses with and without syntactic language model. HHMM parser beam sizes are indicated for the syntactic LM.

HHMM and n-gram LMs (Figure 7). To show the effects of training an LM on more data, we also report perplexity results on the 5-gram LM trained for the GALE Arabic-English task using the English Gigaword corpus. In all cases, including the HHMM significantly reduces perplexity.

We trained a phrase-based translation model on the full NIST Open MT08 Urdu-English translation model using the full training data. We trained the HHMM and n-gram LMs on the WSJ data in order to make them as similar as possible. During tuning, Moses was first configured to use just the n-gram LM, then configured to use both the n-gram LM and the syntactic HHMM LM. MERT consistently assigned positive weight to the syntactic LM feature, typically slightly less than the n-gram LM weight.

In our integration with Moses, incorporating a syntactic language model dramatically slows the decoding process. Figure 8 illustrates a slowdown around three orders of magnitude. Although speed remains roughly linear to the size of the source sentence (ruling out exponential behavior), it is with an extremely large constant time factor. Due to this slowdown, we tuned the parameters using a constrained dev set (only sentences with 1-20 words), and tested using a constrained devtest set (only sentences with 1-20 words). Figure 9 shows a statistically significant improvement to the BLEU score when using the HHMM and the n-gram LMs together on this reduced test set.

Moses LM(s)	BLEU
n-gram only	18.78
HHMM + n-gram	**19.78**

Figure 9: Results for Ur-En devtest (only sentences with 1-20 words) with HHMM beam size of 2000 and Moses settings of distortion limit 10, stack size 200, and ttable_limit 20.

7 Discussion

This paper argues that incremental syntactic languages models are a straightforward and appropriate algorithmic fit for incorporating syntax into phrase-based statistical machine translation, since both process sentences in an incremental left-to-right fashion. This means incremental syntactic LM scores can be calculated during the decoding process, rather than waiting until a complete sentence is posited, which is typically necessary in top-down or bottom-up parsing.

We provided a rigorous formal definition of incremental syntactic languages models, and detailed what steps are necessary to incorporate such LMs into phrase-based decoding. We integrated an incremental syntactic language model into Moses. The translation quality significantly improved on a constrained task, and the perplexity improvements suggest that interpolating between n-gram and syntactic LMs may hold promise on larger data sets.

The use of very large n-gram language models is typically a key ingredient in the best-performing machine translation systems (Brants et al., 2007). Our n-gram model trained only on WSJ is admittedly small. Our future work seeks to incorporate large-scale n-gram language models in conjunction with incremental syntactic language models.

The added decoding time cost of our syntactic language model is very high. By increasing the beam size and distortion limit of the baseline system, future work may examine whether a baseline system with comparable runtimes can achieve comparable translation quality.

A more efficient implementation of the HHMM parser would speed decoding and make more extensive and conclusive translation experiments possible. Various additional improvements could include caching the HHMM LM calculations, and exploiting properties of the right-corner transform that limit the number of decisions between successive time steps.

Abstract

We present an unsupervised model for joint phrase alignment and extraction using nonparametric Bayesian methods and inversion transduction grammars (ITGs). The key contribution is that phrases of many granularities are included directly in the model through the use of a novel formulation that memorizes phrases generated not only by terminal, but also non-terminal symbols. This allows for a completely probabilistic model that is able to create a phrase table that achieves competitive accuracy on phrase-based machine translation tasks directly from unaligned sentence pairs. Experiments on several language pairs demonstrate that the proposed model matches the accuracy of traditional two-step word alignment/phrase extraction approach while reducing the phrase table to a fraction of the original size.

1 Introduction

The training of translation models for phrase-based statistical machine translation (SMT) systems (Koehn et al., 2003) takes unaligned bilingual training data as input, and outputs a scored table of phrase pairs. This phrase table is traditionally generated by going through a pipeline of two steps, first generating word (or minimal phrase) alignments, then extracting a phrase table that is consistent with these alignments.

However, as DeNero and Klein (2010) note, this two step approach results in word alignments that are not optimal for the final task of generating phrase tables that are used in translation. As a solution to this, they proposed a supervised discriminative model that performs joint word alignment and phrase extraction, and found that joint estimation of word alignments and extraction sets improves both word alignment accuracy and translation results.

In this paper, we propose the first *unsupervised* approach to joint alignment and extraction of phrases at multiple granularities. This is achieved by constructing a generative model that includes phrases at many levels of granularity, from minimal phrases all the way up to full sentences. The model is similar to previously proposed phrase alignment models based on inversion transduction grammars (ITGs) (Cherry and Lin, 2007; Zhang et al., 2008; Blunsom et al., 2009), with one important change: ITG symbols and phrase pairs are generated in the opposite order. In traditional ITG models, the branches of a biparse tree are generated from a non-terminal distribution, and each leaf is generated by a word or phrase pair distribution. As a result, only minimal phrases are directly included in the model, while larger phrases must be generated by heuristic extraction methods. In the proposed model, at each branch in the tree, we first attempt to generate a phrase pair from the phrase pair distribution, falling back to ITG-based divide and conquer strategy to generate phrase pairs that do not exist (or are given low probability) in the phrase distribution.

We combine this model with the Bayesian nonparametric Pitman-Yor process (Pitman and Yor, 1997; Teh, 2006), realizing ITG-based divide and conquer through a novel formulation where the Pitman-Yor process uses two copies of itself as a

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 632–641,
Portland, Oregon, June 19-24, 2011.

base measure. As a result of this modeling strategy, phrases of multiple granularities are generated, and thus memorized, by the Pitman-Yor process. This makes it possible to directly use probabilities of the phrase model as a replacement for the phrase table generated by heuristic extraction techniques.

Using this model, we perform machine translation experiments over four language pairs. We observe that the proposed joint phrase alignment and extraction approach is able to meet or exceed results attained by a combination of GIZA++ and heuristic phrase extraction with significantly smaller phrase table size. We also find that it achieves superior BLEU scores over previously proposed ITG-based phrase alignment approaches.

2 A Probabilistic Model for Phrase Table Extraction

The problem of SMT can be defined as finding the most probable target sentence $\mathbf{e}$ for the source sentence $\mathbf{f}$ given a parallel training corpus $\langle \mathcal{E}, \mathcal{F} \rangle$

$$\hat{\mathbf{e}} = \underset{\mathbf{e}}{\text{argmax}} P(\mathbf{e}|\mathbf{f}, \langle \mathcal{E}, \mathcal{F} \rangle).$$

We assume that there is a hidden set of parameters θ learned from the training data, and that $\mathbf{e}$ is conditionally independent from the training corpus given θ. We take a Bayesian approach, integrating over all possible values of the hidden parameters:

$$P(\mathbf{e}|\mathbf{f}, \langle \mathcal{E}, \mathcal{F} \rangle) = \int_{\theta} P(\mathbf{e}|\mathbf{f}, \theta) P(\theta|\langle \mathcal{E}, \mathcal{F} \rangle). \quad (1)$$

If θ takes the form of a scored phrase table, we can use traditional methods for phrase-based SMT to find $P(\mathbf{e}|\mathbf{f}, \theta)$ and concentrate on creating a model for $P(\theta|\langle \mathcal{E}, \mathcal{F} \rangle)$. We decompose this posterior probability using Bayes law into the corpus likelihood and parameter prior probabilities

$$P(\theta|\langle \mathcal{E}, \mathcal{F} \rangle) \propto P(\langle \mathcal{E}, \mathcal{F} \rangle|\theta) P(\theta).$$

In Section 3 we describe an existing method, and in Section 4 we describe our proposed method for modeling these two probabilities.

3 Flat ITG Model

There has been a significant amount of work in many-to-many alignment techniques (Marcu and Wong (2002), DeNero et al. (2008), *inter alia*), and in particular a number of recent works (Cherry and Lin, 2007; Zhang et al., 2008; Blunsom et al., 2009) have used the formalism of inversion transduction grammars (ITGs) (Wu, 1997) to learn phrase alignments. By slightly limit reordering of words, ITGs make it possible to exactly calculate probabilities of phrasal alignments in polynomial time, which is a computationally hard problem when arbitrary reordering is allowed (DeNero and Klein, 2008).

The traditional flat ITG generative probability for a particular phrase (or sentence) pair $P_{flat}(\langle e, f \rangle; \theta_x, \theta_t)$ is parameterized by a phrase table θ_t and a symbol distribution θ_x. We use the following generative story as a representative of the flat ITG model.

1. Generate symbol x from the multinomial distribution $P_x(x; \theta_x)$. x can take the values TERM, REG, or INV.

2. According to the x take the following actions.

   (a) If $x =$ TERM, generate a phrase pair from the phrase table $P_t(\langle e, f \rangle; \theta_t)$.

   (b) If $x =$ REG, a regular ITG rule, generate phrase pairs $\langle e_1, f_1 \rangle$ and $\langle e_2, f_2 \rangle$ from P_{flat}, and concatenate them into a single phrase pair $\langle e_1 e_2, f_1 f_2 \rangle$.

   (c) If $x =$ INV, an inverted ITG rule, follows the same process as (b), but concatenate f_1 and f_2 in reverse order $\langle e_1 e_2, f_2 f_1 \rangle$.

By taking the product of P_{flat} over every sentence in the corpus, we are able to calculate the likelihood

$$P(\langle \mathcal{E}, \mathcal{F} \rangle|\theta) = \prod_{\langle e,f \rangle \in \langle \mathcal{E}, \mathcal{F} \rangle} P_{flat}(\langle e, f \rangle; \theta).$$

We will refer to this model as FLAT.

3.1 Bayesian Modeling

While the previous formulation can be used as-is in maximum likelihood training, this leads to a degenerate solution where every sentence is memorized as a single phrase pair. Zhang et al. (2008) and others propose dealing with this problem by putting a prior probability $P(\theta_x, \theta_t)$ on the parameters.

We assign θ_x a Dirichlet prior[1], and assign the phrase table parameters θ_t a prior using the Pitman-Yor process (Pitman and Yor, 1997; Teh, 2006), which is a generalization of the Dirichlet process prior used in previous research. It is expressed as

$$\theta_t \sim PY(d, s, P_{base}) \quad (2)$$

where d is the discount parameter, s is the strength parameter, and P_{base} is the base measure. The discount d is subtracted from observed counts, and when it is given a large value (close to one), less frequent phrase pairs will be given lower relative probability than more common phrase pairs. The strength s controls the overall sparseness of the distribution, and when it is given a small value the distribution will be sparse. P_{base} is the prior probability of generating a particular phrase pair, which we describe in more detail in the following section.

Non-parametric priors are well suited for modeling the phrase distribution because every time a phrase is generated by the model, it is "memorized" and given higher probability. Because of this, common phrase pairs are more likely to be re-used (the *rich-get-richer* effect), which results in the induction of phrase tables with fewer, but more helpful phrases. It is important to note that only phrases generated by P_t are actually memorized and given higher probability by the model. In FLAT, only minimal phrases generated after P_x outputs the terminal symbol TERM are generated from P_t, and thus only minimal phrases are memorized by the model.

While the Dirichlet process is simply the Pitman-Yor process with $d = 0$, it has been shown that the discount parameter allows for more effective modeling of the long-tailed distributions that are often found in natural language (Teh, 2006). We confirmed in preliminary experiments (using the data described in Section 7) that the Pitman-Yor process with automatically adjusted parameters results in superior alignment results, outperforming the sparse Dirichlet process priors used in previous research[2]. The average gain across all data sets was approximately 0.8 BLEU points.

[1]The value of α had little effect on the results, so we arbitrarily set $\alpha = 1$.

[2]We put weak priors on s ($Gamma(\alpha = 2, \beta = 1)$) and d ($Beta(\alpha = 2, \beta = 2)$) for the Pitman-Yor process, and set $\alpha = 1^{-10}$ for the Dirichlet process.

3.2 Base Measure

P_{base} in Equation (2) indicates the prior probability of phrase pairs according to the model. By choosing this probability appropriately, we can incorporate prior knowledge of what phrases tend to be aligned to each other. We calculate P_{base} by first choosing whether to generate an unaligned phrase pair (where $|e| = 0$ or $|f| = 0$) according to a fixed probability p_u[3], then generating from P_{ba} for aligned phrase pairs, or P_{bu} for unaligned phrase pairs.

For P_{ba}, we adopt a base measure similar to that used by DeNero et al. (2008):

$$P_{ba}(\langle e, f \rangle) = M_0(\langle e, f \rangle) P_{pois}(|e|; \lambda) P_{pois}(|f|; \lambda)$$
$$M_0(\langle e, f \rangle) = (P_{m1}(f|e) P_{uni}(e) P_{m1}(e|f) P_{uni}(f))^{\frac{1}{2}}.$$

P_{pois} is the Poisson distribution with the average length parameter λ. As long phrases lead to sparsity, we set λ to a relatively small value to allow us to bias against overly long phrases[4]. P_{m1} is the word-based Model 1 (Brown et al., 1993) probability of one phrase given the other, which incorporates word-based alignment information as prior knowledge in the phrase translation probability. We take the geometric mean[5]of the Model 1 probabilities in both directions to encourage alignments that are supported by both models (Liang et al., 2006). It should be noted that while Model 1 probabilities are used, they are only soft constraints, compared with the hard constraint of choosing a single word alignment used in most previous phrase extraction approaches.

For P_{bu}, if g is the non-null phrase in e and f, we calculate the probability as follows:

$$P_{bu}(\langle e, f \rangle) = P_{uni}(g) P_{pois}(|g|; \lambda)/2.$$

Note that P_{bu} is divided by 2 as the probability is considering null alignments in both directions.

4 Hierarchical ITG Model

While in FLAT only minimal phrases were memorized by the model, as DeNero et al. (2008) note

[3]We choose 10^{-2}, 10^{-3}, or 10^{-10} based on which value gave the best accuracy on the development set.

[4]We tune λ to 1, 0.1, or 0.01 based on which value gives the best performance on the development set.

[5]The probabilities of the geometric mean do not add to one, but we found empirically that even when left unnormalized, this provided much better results than the using the arithmetic mean, which is more theoretically correct.

and we confirm in the experiments in Section 7, using only minimal phrases leads to inferior translation results for phrase-based SMT. Because of this, previous research has combined FLAT with heuristic phrase extraction, which exhaustively combines all adjacent phrases permitted by the word alignments (Och et al., 1999). We propose an alternative, fully statistical approach that directly models phrases at multiple granularities, which we will refer to as HIER. By doing so, we are able to do away with heuristic phrase extraction, creating a fully probabilistic model for phrase probabilities that still yields competitive results.

Similarly to FLAT, HIER assigns a probability $P_{hier}(\langle e, f\rangle; \theta_x, \theta_t)$ to phrase pairs, and is parameterized by a phrase table θ_t and a symbol distribution θ_x. The main difference from the generative story of the traditional ITG model is that symbols and phrase pairs are generated in the opposite order. While FLAT first generates branches of the derivation tree using P_x, then generates leaves using the phrase distribution P_t, HIER first attempts to generate the full sentence as a single phrase from P_t, then falls back to ITG-style derivations to cope with sparsity. We allow for this within the Bayesian ITG context by defining a new base measure P_{dac} ("divide-and-conquer") to replace P_{base} in Equation (2), resulting in the following distribution for θ_t.

$$\theta_t \sim PY(d, s, P_{dac}) \tag{3}$$

P_{dac} essentially breaks the generation of a single longer phrase into two generations of shorter phrases, allowing even phrase pairs for which $c(\langle e, f\rangle) = 0$ to be given some probability. The generative process of P_{dac}, similar to that of P_{flat} from the previous section, is as follows:

1. Generate symbol x from $P_x(x; \theta_x)$. x can take the values BASE, REG, or INV.

2. According to x take the following actions.

   (a) If $x =$ BASE, generate a new phrase pair directly from P_{base} of Section 3.2.

   (b) If $x =$ REG, generate $\langle e_1, f_1\rangle$ and $\langle e_2, f_2\rangle$ from P_{hier}, and concatenate them into a single phrase pair $\langle e_1 e_2, f_1 f_2\rangle$.

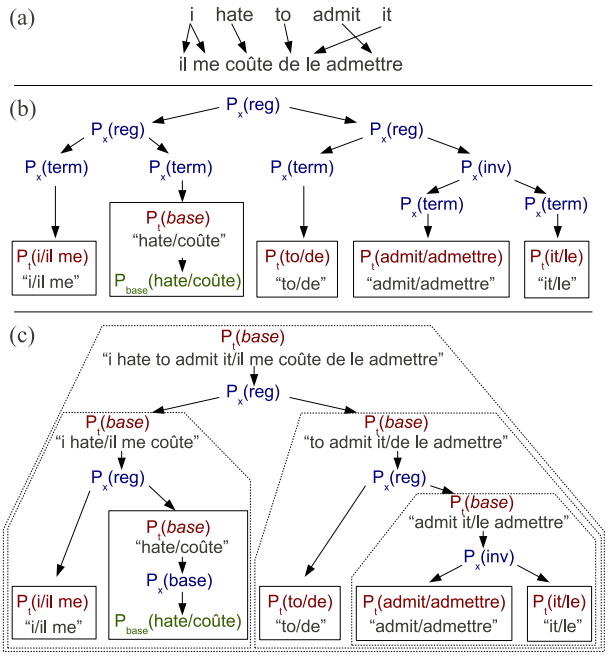

Figure 1: A word alignment (a), and its derivations according to FLAT (b), and HIER (c). Solid and dotted lines indicate minimal and non-minimal pairs respectively, and phrases are written under their corresponding instance of P_t. The pair hate/coûte is generated from P_{base}.

   (c) If $x =$ INV, follow the same process as (b), but concatenate f_1 and f_2 in reverse order $\langle e_1 e_2, f_2 f_1\rangle$.

A comparison of derivation trees for FLAT and HIER is shown in Figure 1. As previously described, FLAT first generates from the symbol distribution P_x, then from the phrase distribution P_t, while HIER generates directly from P_t, which falls back to divide-and-conquer based on P_x when necessary. It can be seen that while P_t in FLAT only generates minimal phrases, P_t in HIER generates (and thus memorizes) phrases at all levels of granularity.

4.1 Length-based Parameter Tuning

There are still two problems with HIER, one theoretical, and one practical. Theoretically, HIER contains itself as its base measure, and stochastic process models that include themselves as base measures are deficient, as noted in Cohen et al. (2010). Practically, while the Pitman-Yor process in HIER shares the parameters s and d over all phrase pairs in the model, long phrase pairs are much more sparse

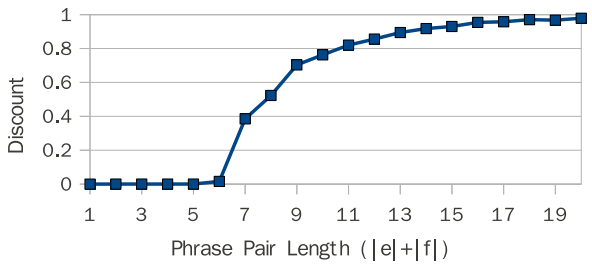

Figure 2: Learned discount values by phrase pair length.

than short phrase pairs, and thus it is desirable to appropriately adjust the parameters of Equation (2) according to phrase pair length.

In order to solve these problems, we reformulate the model so that each phrase length $l = |f|+|e|$ has its own phrase parameters $\theta_{t,l}$ and symbol parameters $\theta_{x,l}$, which are given separate priors:

$$\theta_{t,l} \sim PY(s, d, P_{dac,l})$$
$$\theta_{x,l} \sim Dirichlet(\alpha)$$

We will call this model HLEN.

The generative story is largely similar to HIER with a few minor changes. When we generate a sentence, we first choose its length l according to a uniform distribution over all possible sentence lengths

$$l \sim Uniform(1, L),$$

where L is the size $|e| + |f|$ of the longest sentence in the corpus. We then generate a phrase pair from the probability $P_{t,l}(\langle e, f \rangle)$ for length l. The base measure for HLEN is identical to that of HIER, with one minor change: when we fall back to two shorter phrases, we choose the length of the left phrase from $l_l \sim Uniform(1, l-1)$, set the length of the right phrase to $l_r = l - l_l$, and generate the smaller phrases from P_{t,l_l} and P_{t,l_r} respectively.

It can be seen that phrases at each length are generated from different distributions, and thus the parameters for the Pitman-Yor process will be different for each distribution. Further, as l_l and l_r must be smaller than l, $P_{t,l}$ no longer contains itself as a base measure, and is thus not deficient.

An example of the actual discount values learned in one of the experiments described in Section 7 is shown in Figure 2. It can be seen that, as expected, the discounts for short phrases are lower than those of long phrases. In particular, phrase pairs of length up to six (for example, $|e| = 3$, $|f| = 3$) are given discounts of nearly zero while larger phrases are more heavily discounted. We conjecture that this is related to the observation by Koehn et al. (2003) that using phrases where $\max(|e|, |f|) \leq 3$ cause significant improvements in BLEU score, while using larger phrases results in diminishing returns.

4.2 Implementation

Previous research has used a variety of sampling methods to learn Bayesian phrase based alignment models (DeNero et al., 2008; Blunsom et al., 2009; Blunsom and Cohn, 2010). All of these techniques are applicable to the proposed model, but we choose to apply the sentence-based blocked sampling of Blunsom and Cohn (2010), which has desirable convergence properties compared to sampling single alignments. As exhaustive sampling is too slow for practical purpose, we adopt the beam search algorithm of Saers et al. (2009), and use a probability beam, trimming spans where the probability is at least 10^{10} times smaller than that of the best hypothesis in the bucket.

One important implementation detail that is different from previous models is the management of phrase counts. As a phrase pair t_a may have been generated from two smaller component phrases t_b and t_c, when a sample containing t_a is removed from the distribution, it may also be necessary to decrement the counts of t_b and t_c as well. The Chinese Restaurant Process representation of P_t (Teh, 2006) lends itself to a natural and easily implementable solution to this problem. For each table representing a phrase pair t_a, we maintain not only the number of customers sitting at the table, but also the identities of phrases t_b and t_c that were originally used when generating the table. When the count of the table t_a is reduced to zero and the table is removed, the counts of t_b and t_c are also decremented.

5 Phrase Extraction

In this section, we describe both traditional heuristic phrase extraction, and the proposed model-based extraction method.

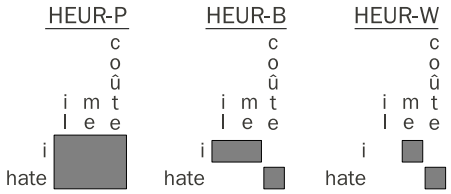

Figure 3: The phrase, block, and word alignments used in heuristic phrase extraction.

5.1 Heuristic Phrase Extraction

The traditional method for heuristic phrase extraction from word alignments exhaustively enumerates all phrases up to a certain length consistent with the alignment (Och et al., 1999). Five features are used in the phrase table: the conditional phrase probabilities in both directions estimated using maximum likelihood $P_{ml}(f|e)$ and $P_{ml}(e|f)$, lexical weighting probabilities (Koehn et al., 2003), and a fixed penalty for each phrase. We will call this heuristic extraction from word alignments HEUR-W. These word alignments can be acquired through the standard GIZA++ training regimen.

We use the combination of our ITG-based alignment with traditional heuristic phrase extraction as a second baseline. An example of these alignments is shown in Figure 3. In model HEUR-P, minimal phrases generated from P_t are treated as aligned, and we perform phrase extraction on these alignments. However, as the proposed models tend to align relatively large phrases, we also use two other techniques to create smaller alignment chunks that prevent sparsity. We perform regular sampling of the trees, but if we reach a minimal phrase generated from P_t, we continue traveling down the tree until we reach either a one-to-many alignment, which we will call HEUR-B as it creates alignments similar to the block ITG, or an at-most-one alignment, which we will call HEUR-W as it generates word alignments. It should be noted that forcing alignments smaller than the model suggests is only used for generating alignments for use in heuristic extraction, and does not affect the training process.

5.2 Model-Based Phrase Extraction

We also propose a method for phrase table extraction that directly utilizes the phrase probabilities $P_t(\langle e, f\rangle)$. Similarly to the heuristic phrase tables, we use conditional probabilities $P_t(f|e)$ and $P_t(e|f)$, lexical weighting probabilities, and a phrase penalty. Here, instead of using maximum likelihood, we calculate conditional probabilities directly from P_t probabilities:

$$P_t(f|e) = P_t(\langle e, f\rangle) / \sum_{\{\tilde{f}: c(\langle e,\tilde{f}\rangle)\geq 1\}} P_t(\langle e, \tilde{f}\rangle)$$

$$P_t(e|f) = P_t(\langle e, f\rangle) / \sum_{\{\tilde{e}: c(\langle \tilde{e},f\rangle)\geq 1\}} P_t(\langle \tilde{e}, f\rangle).$$

To limit phrase table size, we include only phrase pairs that are aligned at least once in the sample.

We also include two more features: the phrase pair joint probability $P_t(\langle e, f\rangle)$, and the average posterior probability of each span that generated $\langle e, f\rangle$ as computed by the inside-outside algorithm during training. We use the span probability as it gives a hint about the reliability of the phrase pair. It will be high for common phrase pairs that are generated directly from the model, and also for phrases that, while not directly included in the model, are composed of two high probability child phrases.

It should be noted that while for FLAT and HIER P_t can be used directly, as HLEN learns separate models for each length, we must combine these probabilities into a single value. We do this by setting

$$P_t(\langle e, f\rangle) = P_{t,l}(\langle e, f\rangle) c(l) / \sum_{\tilde{l}=1}^{L} c(\tilde{l})$$

for every phrase pair, where $l = |e| + |f|$ and $c(l)$ is the number of phrases of length l in the sample.

We call this model-based extraction method MOD.

5.3 Sample Combination

As has been noted in previous works, (Koehn et al., 2003; DeNero et al., 2006) exhaustive phrase extraction tends to out-perform approaches that use syntax or generative models to limit phrase boundaries. DeNero et al. (2006) state that this is because generative models choose only a single phrase segmentation, and thus throw away many good phrase pairs that are in conflict with this segmentation.

Luckily, in the Bayesian framework it is simple to overcome this problem by combining phrase tables

from multiple samples. This is equivalent to approximating the integral over various parameter configurations in Equation (1). In MOD, we do this by taking the average of the joint probability and span probability features, and re-calculating the conditional probabilities from the averaged joint probabilities.

6 Related Work

In addition to the previously mentioned phrase alignment techniques, there has also been a significant body of work on phrase extraction (Moore and Quirk (2007), Johnson et al. (2007a), *inter alia*). DeNero and Klein (2010) presented the first work on joint phrase alignment and extraction at multiple levels. While they take a supervised approach based on discriminative methods, we present a fully unsupervised generative model.

A generative probabilistic model where longer units are built through the binary combination of shorter units was proposed by de Marcken (1996) for monolingual word segmentation using the minimum description length (MDL) framework. Our work differs in that it uses Bayesian techniques instead of MDL, and works on two languages, not one.

Adaptor grammars, models in which nonterminals memorize subtrees that lie below them, have been used for word segmentation or other monolingual tasks (Johnson et al., 2007b). The proposed method could be thought of as synchronous adaptor grammars over two languages. However, adaptor grammars have generally been used to specify only two or a few levels as in the FLAT model in this paper, as opposed to recursive models such as HIER or many-leveled models such as HLEN. One exception is the variational inference method for adaptor grammars presented by Cohen et al. (2010) that is applicable to recursive grammars such as HIER. We plan to examine variational inference for the proposed models in future work.

7 Experimental Evaluation

We evaluate the proposed method on translation tasks from four languages, French, German, Spanish, and Japanese, into English.

Table 1: The number of words in each corpus for TM and LM training, tuning, and testing.

7.1 Experimental Setup

The data for French, German, and Spanish are from the 2010 Workshop on Statistical Machine Translation (Callison-Burch et al., 2010). We use the news commentary corpus for training the TM, and the news commentary and Europarl corpora for training the LM. For Japanese, we use data from the NTCIR patent translation task (Fujii et al., 2008). We use the first 100k sentences of the parallel corpus for the TM, and the whole parallel corpus for the LM. Details of both corpora can be found in Table 1. Corpora are tokenized, lower-cased, and sentences of over 40 words on either side are removed for TM training. For both tasks, we perform weight tuning and testing on specified development and test sets.

We compare the accuracy of our proposed method of joint phrase alignment and extraction using the FLAT, HIER and HLEN models, with a baseline of using word alignments from GIZA++ and heuristic phrase extraction. Decoding is performed using Moses (Koehn and others, 2007) using the phrase tables learned by each method under consideration, as well as standard bidirectional lexical reordering probabilities (Koehn et al., 2005). Maximum phrase length is limited to 7 in all models, and for the LM we use an interpolated Kneser-Ney 5-gram model.

For GIZA++, we use the standard training regimen up to Model 4, and combine alignments with `grow-diag-final-and`. For the proposed models, we train for 100 iterations, and use the final sample acquired at the end of the training process for our experiments using a single sample[6]. In addition,

[6]For most models, while likelihood continued to increase gradually for all 100 iterations, BLEU score gains plateaued after 5-10 iterations, likely due to the strong prior information

we also try averaging the phrase tables from the last ten samples as described in Section 5.3.

7.2 Experimental Results

The results for these experiments can be found in Table 2. From these results we can see that when using a single sample, the combination of using HIER and model probabilities achieves results approximately equal to GIZA++ and heuristic phrase extraction. This is the first reported result in which an unsupervised phrase alignment model has built a phrase table directly from model probabilities and achieved results that compare to heuristic phrase extraction. It can also be seen that the phrase table created by the proposed method is approximately 5 times smaller than that obtained by the traditional pipeline.

In addition, HIER significantly outperforms FLAT when using the model probabilities. This confirms that phrase tables containing only minimal phrases are not able to achieve results that compete with phrase tables that use multiple granularities.

Somewhat surprisingly, HLEN consistently slightly underperforms HIER. This indicates potential gains to be provided by length-based parameter tuning were outweighed by losses due to the increased complexity of the model. In particular, we believe the necessity to combine probabilities from multiple $P_{t,l}$ models into a single phrase table may have resulted in a distortion of the phrase probabilities. In addition, the assumption that phrase lengths are generated from a uniform distribution is likely too strong, and further gains could likely be achieved by more accurate modeling of phrase lengths. We leave further adjustments to the HLEN model to future work.

provided by P_{base}. As iterations took 1.3 hours on a single processor, good translation results can be achieved in approximately 13 hours, which could further reduced using distributed sampling (Newman et al., 2009; Blunsom et al., 2009).

	FLAT		HIER	
MOD	17.97	117k	21.50	751k
HEUR-W	21.52	5.65M	21.68	5.39M

HEUR-P	21.56	4.88M	21.47	1.62M

Table 3: Translation results and phrase table size for various phrase extraction techniques (French-English).

It can also be seen that combining phrase tables from multiple samples improved the BLEU score for HLEN, but not for HIER. This suggests that for HIER, most of the useful phrase pairs discovered by the model are included in every iteration, and the increased recall obtained by combining multiple samples does not consistently outweigh the increased confusion caused by the larger phrase table.

We also evaluated the effectiveness of model-based phrase extraction compared to heuristic phrase extraction. Using the alignments from HIER, we created phrase tables using model probabilities (MOD), and heuristic extraction on words (HEUR-W), blocks (HEUR-B), and minimal phrases (HEUR-P) as described in Section 5. The results of these experiments are shown in Table 3. It can be seen that model-based phrase extraction using HIER outperforms or insignificantly underperforms heuristic phrase extraction over all experimental settings, while keeping the phrase table to a fraction of the size of most heuristic extraction methods.

Finally, we varied the size of the parallel corpus for the Japanese-English task from 50k to 400k sen-

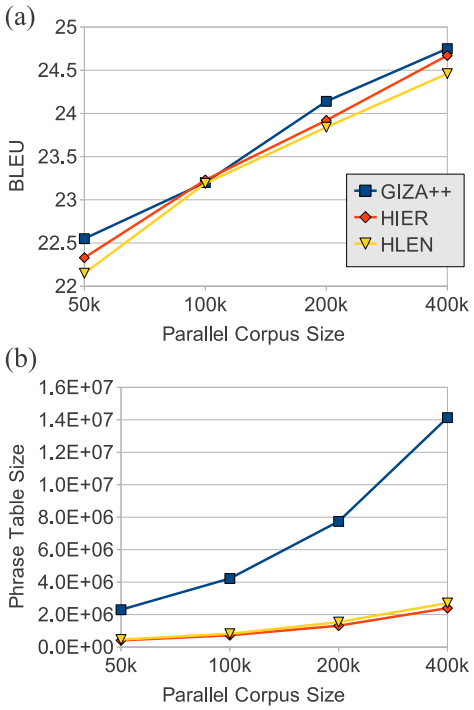

Figure 4: The effect of corpus size on the accuracy (a) and phrase table size (b) for each method (Japanese-English).

tences and measured the effect of corpus size on translation accuracy. From the results in Figure 4 (a), it can be seen that at all corpus sizes, the results from all three methods are comparable, with insignificant differences between GIZA++ and HIER at all levels, and HLEN lagging slightly behind HIER. Figure 4 (b) shows the size of the phrase table induced by each method over the various corpus sizes. It can be seen that the tables created by GIZA++ are significantly larger at all corpus sizes, with the difference being particularly pronounced at larger corpus sizes.

8 Conclusion

In this paper, we presented a novel approach to joint phrase alignment and extraction through a hierarchical model using non-parametric Bayesian methods and inversion transduction grammars. Machine translation systems using phrase tables learned directly by the proposed model were able to achieve accuracy competitive with the traditional pipeline of word alignment and heuristic phrase extraction, the first such result for an unsupervised model.

For future work, we plan to refine HLEN to use a more appropriate model of phrase length than the uniform distribution, particularly by attempting to bias against phrase pairs where one of the two phrases is much longer than the other. In addition, we will test probabilities learned using the proposed model with an ITG-based decoder. We will also examine the applicability of the proposed model in the context of hierarchical phrases (Chiang, 2007), or in alignment using syntactic structure (Galley et al., 2006). It is also worth examining the plausibility of variational inference as proposed by Cohen et al. (2010) in the alignment context.

Abstract

While it is generally accepted that many translation phenomena are correlated with linguistic structures, employing linguistic syntax for translation has proven a highly non-trivial task. The key assumption behind many approaches is that translation is guided by the source and/or target language parse, employing rules extracted from the parse tree or performing tree transformations. These approaches enforce strict constraints and might overlook important translation phenomena that cross linguistic constituents. We propose a novel flexible modelling approach to introduce linguistic information of varying granularity from the source side. Our method induces joint probability synchronous grammars and estimates their parameters, by selecting and weighing together linguistically motivated rules according to an objective function directly targeting generalisation over future data. We obtain statistically significant improvements across 4 different language pairs with English as source, mounting up to +1.92 BLEU for Chinese as target.

1 Introduction

Recent advances in Statistical Machine Translation (SMT) are widely centred around two concepts: (a) hierarchical translation processes, frequently employing Synchronous Context Free Grammars (SCFGs) and (b) transduction or synchronous rewrite processes over a linguistic syntactic tree. SCFGs in the form of the Inversion-Transduction Grammar (ITG) were first introduced by (Wu, 1997) as a formalism to recursively describe the translation process. The Hiero system (Chiang, 2005) utilised an ITG-flavour which focused on hierarchical phrase-pairs to capture context-driven translation and reordering patterns with 'gaps', offering competitive performance particularly for language pairs with extensive reordering. As Hiero uses a single non-terminal and concentrates on overcoming translation lexicon sparsity, it barely explores the recursive nature of translation past the lexical level. Nevertheless, the successful employment of SCFGs for phrase-based SMT brought translation models assuming latent syntactic structure to the spotlight.

Simultaneously, mounting efforts have been directed towards SMT models employing linguistic syntax on the source side (Yamada and Knight, 2001; Quirk et al., 2005; Liu et al., 2006), target side (Galley et al., 2004; Galley et al., 2006) or both (Zhang et al., 2008; Liu et al., 2009; Chiang, 2010). Hierarchical translation was combined with target side linguistic annotation in (Zollmann and Venugopal, 2006). Interestingly, early on (Koehn et al., 2003) exemplified the difficulties of integrating linguistic information in translation systems. Syntax-based MT often suffers from inadequate constraints in the translation rules extracted, or from striving to combine these rules together towards a full derivation. Recent research tries to address these issues, by re-structuring training data parse trees to better suit syntax-based SMT training (Wang et al., 2010), or by moving from linguistically motivated synchronous grammars to systems where linguistic plausibility of the translation is assessed through additional features in a phrase-based system (Venugopal et al., 2009; Chiang et al., 2009), obscuring the impact of higher level syntactic processes.

While it is assumed that linguistic structure does correlate with some translation phenomena, in this

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 642–652,
Portland, Oregon, June 19-24, 2011.

work we do not employ it as the backbone of translation. In place of linguistically *constrained* translation imposing syntactic parse structure, we opt for linguistically *motivated* translation. We learn latent hierarchical structure, taking advantage of linguistic annotations but shaped and trained for translation.

We start by labelling each phrase-pair span in the word-aligned training data with multiple linguistically motivated categories, offering multi-grained abstractions from its lexical content. These phrase-pair label charts are the input of our learning algorithm, which extracts the linguistically motivated rules and estimates the probabilities for a stochastic SCFG, without arbitrary constraints such as phrase or span sizes. Estimating such grammars under a Maximum Likelihood criterion is known to be plagued by strong overfitting leading to degenerate estimates (DeNero et al., 2006). In contrast, our learning objective not only avoids overfitting the training data but, most importantly, learns joint stochastic synchronous grammars which directly aim at generalisation towards yet unseen instances.

By advancing from structures which mimic linguistic syntax, to learning linguistically aware latent recursive structures targeting translation, we achieve significant improvements in translation quality for 4 different language pairs in comparison with a strong hierarchical translation baseline.

Our key contributions are presented in the following sections. Section 2 discusses the weak independence assumptions of SCFGs and introduces a joint translation model which addresses these issues and separates hierarchical translation structure from phrase-pair emission. In section 3 we consider a chart over phrase-pair spans filled with source-language linguistically motivated labels. We show how we can employ this crucial input to extract and train a hierarchical translation structure model with millions of rules. Section 4 demonstrates decoding with the model by constraining derivations to linguistic hints of the source sentence and presents our empirical results. We close with a discussion of related work and our conclusions.

2 Joint Translation Model

Our model is based on a probabilistic Synchronous CFG (Wu, 1997; Chiang, 2005). SCFGs define a language over string pairs, which are generated beginning from a start symbol S and recursively expanding pairs of linked non-terminals across the two strings using the grammar's rule set. By crossing the links between the non-terminals of the two sides reordering phenomena are captured. We employ binary SCFGs, i.e. grammars with a maximum of two non-terminals on the right-hand side. Also, for this work we only used grammars with either purely lexical or purely abstract rules involving one or two non-terminal pairs. An example can be seen in Figure 1, using an ITG-style notation and assuming the same non-terminal labels for both sides.

$$\text{SBAR} \rightarrow [\text{WHNP}\ \ \text{SBAR}\backslash\text{WHNP}] \quad \text{(a)}$$
$$\text{SBAR}\backslash\text{WHNP} \rightarrow \langle \text{VP/NP}^{\mathbf{L}}\ \ \text{NP}^{\mathbf{R}} \rangle \quad \text{(b)}$$
$$\text{NP}^{\mathbf{R}} \rightarrow [\text{NP}\ \ \text{PP}] \quad \text{(c)}$$
$$\text{WHNP} \rightarrow \text{WHNP}_{\mathbf{P}} \quad \text{(d)}$$
$$\text{WHNP}_{\mathbf{P}} \rightarrow \text{which} \ / \ \text{der} \quad \text{(e)}$$
$$\text{VP/NP}^{\mathbf{L}} \rightarrow \text{VP/NP}^{\mathbf{L}}_{\mathbf{P}} \quad \text{(f)}$$
$$\text{VP/NP}^{\mathbf{L}}_{\mathbf{P}} \rightarrow \text{is} \ / \ \text{ist} \quad \text{(g)}$$
$$\text{NP}^{\mathbf{R}} \rightarrow \text{NP}^{\mathbf{R}}_{\mathbf{P}} \quad \text{(h)}$$
$$\text{NP}^{\mathbf{R}}_{\mathbf{P}} \rightarrow \text{the solution} \ / \ \text{die Lösung} \quad \text{(i)}$$
$$\text{NP} \rightarrow \text{NP}_{\mathbf{P}} \quad \text{(j)}$$
$$\text{NP}_{\mathbf{P}} \rightarrow \text{the solution} \ / \ \text{die Lösung} \quad \text{(k)}$$
$$\text{PP} \rightarrow \text{PP}_{\mathbf{P}} \quad \text{(l)}$$
$$\text{PP}_{\mathbf{P}} \rightarrow \text{to the problem} \ / \ \text{für das Problem} \quad \text{(m)}$$

Figure 1: English-German SCFG rules for the relative clause(s) 'which is the solution (to the problem) / der die Lösung (für das Problem) ist', [ ] signify monotone translation, ⟨ ⟩ a swap reordering.

We utilise *probabilistic* SCFGs, where each rule is assigned a conditional probability of expanding the left-hand side symbol with the rule's right-hand side. Phrase-pairs are emitted jointly and the overall probabilistic SCFG is a *joint* model over parallel strings.

2.1 SCFG Reordering Weaknesses

An interesting feature of all probabilistic SCFGs (i.e. not only binary ones), which has received surprisingly little attention, is that the reordering pat-

tern between the non-terminal pairs (or in the case of ITGs the choice between monotone and swap expansion) are not conditioned on any other part of a derivation. The result is that, the reordering pattern with the highest probability will *always* be preferred (e.g. in the Viterbi derivation) over the rest, irrespective of lexical or abstract context. As an example, a probabilistic SCFG will always assign a higher probability to derivations swapping or monotonically translating nouns and adjectives between English and French, only depending on which of the two rules $NP \rightarrow [NN \;\; JJ]$, $NP \rightarrow \langle NN \;\; JJ \rangle$ has a higher probability. The rest of the (sometimes thousands of) rule-specific features usually added to SCFG translation models do not directly help either, leaving reordering decisions disconnected from the rest of the derivation.

While in a decoder this is somehow mitigated by the use of a language model, we believe that the weakness of straightforward applications of SCFGs to model reordering structure at the sentence level misses a chance to learn this crucial part of the translation process during grammar induction. As (Mylonakis and Sima'an, 2010) note, 'plain' SCFGs seem to perform worse than the grammars described next, mainly due to wrong long-range reordering decisions for which the language model can hardly help.

2.2 Hierarchical Reordering SCFG

We address the weaknesses mentioned above by relying on an SCFG grammar design that is similar to the 'Lexicalised Reordering' grammar of (Mylonakis and Sima'an, 2010). As in the rules of Figure 1, we separate non-terminals according to the reordering patterns in which they participate. Non-terminals such as $\mathrm{B}^{\mathbf{L}}$, $\mathrm{C}^{\mathbf{R}}$ take part only in swapping right-hand sides $\langle \mathrm{B}^{\mathbf{L}} \;\; \mathrm{C}^{\mathbf{R}} \rangle$ (with $\mathrm{B}^{\mathbf{L}}$ swapping from the source side's left to the target side's right, $\mathrm{C}^{\mathbf{R}}$ swapping in the opposite direction), while non-terminals such as B, C take part solely in monotone right-hand side expansions [B C]. These non-terminal categories can appear also on the left-hand side of a rule, as in rule (c) of Figure 1.

In contrast with (Mylonakis and Sima'an, 2010), monotone and swapping non-terminals do not emit phrase-pairs themselves. Rather, each non-terminal NT is expanded to a dedicated phrase-pair emitting non-terminal $\mathrm{NT}_{\mathbf{P}}$, which generates all phrase-pairs for it and nothing more. In this way, the preference of non-terminals to either expand towards a (long) phrase-pair or be further analysed recursively is explicitly modelled. Furthermore, this set of *pre-terminals* allows us to separate the higher order translation structure from the process that emits phrase-pairs, a feature we employ next.

$$

\mathrm{A}^{\mathbf{L}} \rightarrow [\mathrm{B} \;\; \mathrm{C}] & \mathrm{A}^{\mathbf{L}} \rightarrow \langle \mathrm{B}^{\mathbf{L}} \;\; \mathrm{C}^{\mathbf{R}} \rangle \\
\mathrm{A}^{\mathbf{R}} \rightarrow [\mathrm{B} \;\; \mathrm{C}] & \mathrm{A}^{\mathbf{R}} \rightarrow \langle \mathrm{B}^{\mathbf{L}} \;\; \mathrm{C}^{\mathbf{R}} \rangle \\
\mathrm{A} \rightarrow \mathrm{A}_{\mathbf{P}} & \mathrm{A}_{\mathbf{P}} \rightarrow \alpha \;/\; \beta \\
\mathrm{A}^{\mathbf{L}} \rightarrow \mathrm{A}^{\mathbf{L}}_{\mathbf{P}} & \mathrm{A}^{\mathbf{L}}_{\mathbf{P}} \rightarrow \alpha \;/\; \beta \\
\mathrm{A}^{\mathbf{R}} \rightarrow \mathrm{A}^{\mathbf{R}}_{\mathbf{P}} & \mathrm{A}^{\mathbf{R}}_{\mathbf{P}} \rightarrow \alpha \;/\; \beta
\end{array}
$$

Figure 2: Recursive Reordering Grammar rule categories; A, B, C non-terminals; α, β source and target strings respectively.

In (Mylonakis and Sima'an, 2010) this grammar design mainly contributed to model lexical reordering preferences. While we retain this function, for the rich linguistically-motivated grammars used in this work this design effectively propagates reordering preferences above and below the current rule application (e.g. Figure 1, rules (a)-(c)), allowing to learn and apply complex reordering patterns.

The different types of grammar rules are summarised in abstract form in Figure 2. We will subsequently refer to this grammar structure as Hierarchical Reordering SCFG (HR-SCFG).

2.3 Generative Model

We arrive at a probabilistic SCFG model which jointly generates source $\mathbf{e}$ and target $\mathbf{f}$ strings, by augmenting each grammar rule with a probability, summing up to one for every left-hand side. The probability of a derivation D of tuple $\langle \mathbf{e}, \mathbf{f} \rangle$ beginning from start symbol S is equal to the product of the probabilities of the rules used to recursively generate it.

We separate the structural part of the derivation D, down to the pre-terminals $\mathrm{NT}_{\mathbf{P}}$, from the phrase-emission part. The grammar rules pertaining to the

Figure 3: The label chart for the source fragment 'which is the problem'. Only a sample of the entries is listed.

structural part and their associated probabilities define a model $p(\sigma)$ over the latent variable σ determining the recursive, reordering and phrase-pair segmenting structure of translation, as in Figure 4. Given σ, the phrase-pair emission part merely generates the phrase-pairs utilising distributions from every $\text{NT}_\mathbf{P}$ to the phrase-pairs that it covers, thereby defining a model over all sentence-pairs generated given each translation structure. The probabilities of a derivation and of a sentence-pair are then as follows:

$$p(D) = p(\sigma)p(\mathbf{e}, \mathbf{f}|\sigma) \quad (1)$$

$$p(\mathbf{e}, \mathbf{f}) = \sum_{D:D\overset{*}{\Rightarrow}\langle \mathbf{e},\mathbf{f}\rangle} p(D) \quad (2)$$

By splitting the joint model in a hierarchical structure model and a lexical emission one we facilitate estimating the two models separately. The following section discusses this.

3 Learning Translation Structure

3.1 Phrase-Pair Label Chart

The input to our learning algorithm is a word-aligned parallel corpus. We consider as phrase-pair spans those that obey the word-alignment constraints of (Koehn et al., 2003). For every training sentence-pair, we also input a chart containing one or more labels for every synchronous span, such as that of Figure 3. Each label describes different properties of the phrase pair (syntactic, semantic etc.), possibly in relation to its context, or supplying varying levels of abstraction (phrase-pair, determiner with noun, noun-phrase, sentence etc.). We aim to induce a recursive translation structure explaining the joint generation of the source and target sentence taking advantage of these phrase-pair span labels.

For this work we employ the linguistically motivated labels of (Zollmann and Venugopal, 2006), albeit for the source language. Given a parse of the source sentence, each span is assigned the following kind of labels:

Phrase-Pair All phrase-pairs are assigned the X label

Constituent Source phrase is a constituent A

Concatenation of Constituents Source phrase labelled A+B as a concatenation of constituents A and B, similarly for 3 constituents.

Partial Constituents Categorial grammar (Bar-Hillel, 1953) inspired labels A/B, A\B, indicating a partial constituent A missing constituent B right or left respectively.

An important point is that we assign all applicable labels to every span. In this way, each label set captures the features of the source side's parse-tree without being bounded by the actual parse structure, as well as provides a coarse to fine-grained view of the source phrase.

3.2 Grammar Extraction

From every word-aligned sentence-pair and its label chart, we extract SCFG rules as those of Figure 2. Binary rules are extracted from adjoining synchronous spans up to the whole sentence-pair level, with the non-terminals of both left and right-hand side derived from the label names plus their reordering function (monotone, left/right swapping) in the span examined. A single unary rule per non-terminal NT generates the phrase-pair emitting $\text{NT}_\mathbf{P}$. Unary rules $\text{NT}_\mathbf{P} \rightarrow \alpha \ / \ \beta$ generating the phrase-pair are created for all the labels covering it.

While we label the phrase-pairs similarly to (Zollmann and Venugopal, 2006), the extracted grammar is rather different. We do not employ rules that are grounded to lexical context ('gap' rules), relying instead on the reordering-aware non-terminal set and related unary and binary rules. The result is a grammar which can both capture a rich array of translation phenomena based on linguistic and lexical grounds and explicitly model the balance between

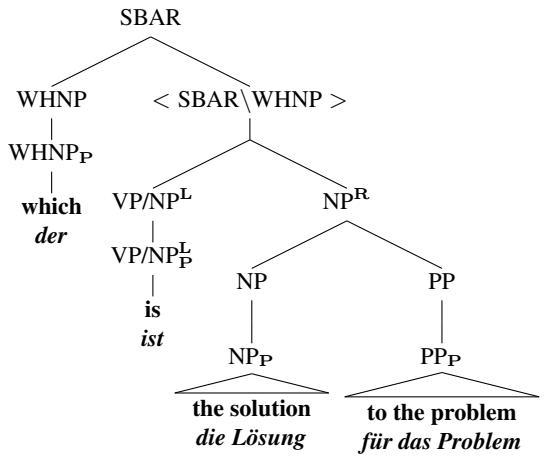

Figure 4: A derivation of a sentence fragment with the grammar of Figure 1.

memorising long phrase-pairs and generalising over yet unseen ones, as shown in the next example.

The derivation in Figure 4 illustrates some of the formalism's features. A preference to reorder based on lexical *content* is applied for is / ist. Noun phrase NP$^{\mathbf{R}}$ is recursively constructed with a preference to constitute the right branch of an order swapping non-terminal expansion. This is matched with VP/NP$^{\mathbf{L}}$ which reorders in the opposite direction. The labels VP/NP and SBAR\WHNP allow linguistic syntax *context* to influence the lexical and reordering translation choices. Crucially, *all* these lexical, attachment and reordering preferences (as encoded in the model's rules and probabilities) must be matched together to arrive at the analysis in Figure 4.

3.3 Parameter Estimation

We estimate the parameters for the phrase-emission model $p(\mathbf{e}, \mathbf{f}|\sigma)$ using Relative Frequency Estimation (RFE) on the *label charts* induced for the training sentence-pairs, after the labels have been augmented by the reordering indications. In the RFE estimate, every rule $\mathrm{NT}_{\mathbf{P}} \rightarrow \alpha \ / \ \beta$ receives a probability in proportion with the times that $\alpha \ / \ \beta$ was covered by the NT label.

On the other hand, estimating the parameters under Maximum-Likelihood Estimation (MLE) for the latent translation structure model $p(\sigma)$ is bound to overfit towards memorising whole sentence-pairs as discussed in (Mylonakis and Sima'an, 2010), with the resulting grammar estimate not being able to generalise past the training data. However, apart from overfitting towards long phrase-pairs, a grammar with millions of structural rules is also liable to overfit towards degenerate latent structures which, while fitting the training data well, have limited applicability to unseen sentences.

We avoid both pitfalls by estimating the grammar probabilities with the Cross-Validating Expectation-Maximization algorithm (CV-EM) (Mylonakis and Sima'an, 2008; Mylonakis and Sima'an, 2010). CV-EM is a cross-validating instance of the well known EM algorithm (Dempster et al., 1977). It works iteratively on a partition of the training data, climbing the likelihood of the training data while cross-validating the latent variable values, considering for every training data point only those which can be produced by models built from the rest of the data excluding the current part. As a result, the estimation process simulates maximising future data likelihood, using the training data to directly aim towards strong generalisation of the estimate.

For our probabilistic SCFG-based translation structure variable σ, implementing CV-EM boils down to a synchronous version of the Inside-Outside algorithm, modified to enforce the CV criterion. In this way we arrive at cross-validated ML estimate of the σ parameters while keeping the phrase-emission parameters of $p(\mathbf{e}, \mathbf{f}|\sigma)$ fixed. The CV-criterion, apart from avoiding overfitting, results in discarding the structural rules which are only found in a single part of the training corpus, leading to a more compact grammar while still retaining millions of structural rules that are more hopeful to generalise.

Unravelling the joint generative process, by modelling latent hierarchical structure separately from phrase-pair emission, allows us to concentrate our inference efforts towards the hidden, higher-level translation mechanism.

4 Experiments

4.1 Decoding Model

The induced joint translation model can be used to recover $\arg\max_{\mathbf{e}} p(\mathbf{e}|\mathbf{f})$, as it is equal to $\arg\max_{\mathbf{e}} p(\mathbf{e}, \mathbf{f})$. We employ the induced probabilistic HR-SCFG $\mathbf{G}$ as the backbone of a log-linear, feature based translation model, with the derivation probability $p(D)$ under the grammar estimate being

one of the features. This is augmented with a small number n of additional smoothing features ϕ_i for derivation rules r: (a) conditional phrase translation probabilities, (b) lexical phrase translation probabilities, (c) word generation penalty, and (d) a count of swapping reordering operations. Features (a), (b) and (c) are applicable to phrase-pair emission rules and features for both translation directions are used, while (d) is only triggered by structural rules.

These extra features assess translation quality past the synchronous grammar derivation and learning general reordering or word emission preferences for the language pair. As an example, while our probabilistic HR-SCFG maintains a separate joint phrase-pair emission distribution per non-terminal, the smoothing features (a) above assess the conditional translation of surface phrases irrespective of any notion of recursive translation structure.

The final feature is the language model score for the target sentence, mounting up to the following model used at decoding time, with the feature weights λ trained by Minimum Error Rate Training (MERT) (Och, 2003) on a development corpus.

$$p(D \stackrel{*}{\Rightarrow} \langle \mathbf{e}, \mathbf{f} \rangle) \propto p(\mathbf{e})^{\lambda_{lm}} p_{\mathbf{G}}(D)^{\lambda_{\mathbf{G}}} \prod_{i=1}^{n} \prod_{r \in D} \phi_i(r)^{\lambda_i}$$

4.2 Decoding Modifications

We use a customised version of the Joshua SCFG decoder (Li et al., 2009) to translate, with the following modifications:

Source Labels Constraints As for this work the phrase-pair labels used to extract the grammar are based on the linguistic analysis of the source side, we can construct the label chart for every input sentence from its parse. We subsequently use it to consider only derivations with synchronous spans which are covered by non-terminals matching one of the labels for those spans. This applies both for the non-terminals covering phrase-pairs as well as the higher level parts of the derivation.

In this manner we not only constrain the translation hypotheses resulting in faster decoding time, but, more importantly, we may ground the hypotheses more closely to the available linguistic information of the source sentence. This is of particular interest as we move up the derivation tree, where an initial wrong choice below could propagate towards hypotheses wildly diverging from the input sentence's linguistic annotation.

Per Non-Terminal Pruning The decoder uses a combination of beam and cube-pruning (Huang and Chiang, 2007). As our grammar uses non-terminals in the hundreds of thousands, it is important not to prune away prematurely non-terminals covering smaller spans and to leave more options to be considered as we move up the derivation tree.

For this, for every cell in the decoder's chart, we keep a separate bin per non-terminal and prune together hypotheses leading to the same non-terminal covering a cell. This allows full derivations to be found for all input sentences, as well as avoids aggressive pruning at an early stage. Given the source label constraint discussed above, this does not increase running times or memory demands considerably as we allow only up to a few tens of non-terminals per span.

Expected Counts Rule Pruning To compact the hierarchical structure part of the grammar prior to decoding, we prune rules that fail to accumulate 10^{-8} expected counts during the last CV-EM iteration. For English to German, this brings the structural rules from 15M down to 1.2M. Note that we do not prune the phrase-pair emitting rules. Overall, we consider this a much more informed pruning criterion than those based on probability values (that are not comparable across left-hand sides) or right-hand side counts (frequent symbols need many more expansions than a highly specialised one).

4.3 Experimental Setting & Baseline

We evaluate our method on four different language pairs with English as the source language and French, German, Dutch and Chinese as target. The data for the first three language pairs are derived from parliament proceedings sourced from the Europarl corpus (Koehn, 2005), with WMT-07 development and test data for French and German. The data for the English to Chinese task is composed of parliament proceedings and news articles. For all language pairs we employ 200K and 400K sentence pairs for training, 2K for development and 2K for testing (single reference per source sentence). Both the baseline and our method decode

with a 3-gram language model smoothed with modified Knesser-Ney discounting (Chen and Goodman, 1998), trained on around 1M sentences per target language. The parses of the source sentences employed by our system during training and decoding are created with the Charniak parser (Charniak, 2000).

We compare against a state-of-the-art hierarchical translation (Chiang, 2005) baseline, based on the Joshua translation system under the default training and decoding settings (`josh-base`). Apart of evaluating against a state-of-the-art system, especially on the English-Chinese language pair, the comparison has an added interesting aspect. The heuristically trained baseline takes advantage of 'gap rules' to reorder based on lexical context cues, but makes very limited use of the hierarchical structure above the lexical surface. In contrast, our method induces a grammar with no such rules, relying on lexical content and the strength of a higher level translation structure instead.

4.4 Training & Decoding Details

To train our Latent Translation Structure (LTS) system, we used the following settings. CV-EM cross-validated on a 10-part partition of the training data and performed 10 iterations. The structural rule probabilities were initialised to uniform per left-hand side.

The decoder does not employ any 'glue grammar' as is usual with hierarchical translation systems to limit reordering up to a certain cut-off length. Instead, we rely on our LTS grammar to reorder and construct the translation output up to the full sentence length.

In summary, our system's experimental pipeline is as follows. All input sentences are parsed and label charts are created from these parses. The Hierarchical Reordering SCFG is extracted and its parameters are estimated employing CV-EM. The structural rules of the estimate are pruned according to their expected counts and smoothing features are added to all rules. We train the feature weights under MERT and decode with the resulting log-linear model.

The overall training and decoding setup is appealing also regarding computational demands. On an 8-core 2.3GHz system, training on 200K sentence-pairs demands 4.5 hours while decoding runs on 25 sentences per minute.

4.5 Results

Table 1 presents the results for the baseline and our method for the 4 language pairs, for training sets of both 200K and 400K sentence pairs. Our system (`lts`) outperforms the baseline for all 4 language pairs for both BLEU and NIST scores, by a margin which scales up to +1.92 BLEU points for English to Chinese translation when training on the 400K set. In addition, increasing the size of the training data from 200K to 400K sentence pairs widens the performance margin between the baseline and our system, in some cases considerably. All but one of the performance improvements are found to be statistically significant (Koehn, 2004) at the 95% confidence level, most of them also at the 99% level.

We selected an array of target languages of increasing reordering complexity with English as source. Examining the results across the target languages, LTS performance gains increase the more challenging the sentence structure of the target language is in relation to the source's, highlighted when translating to Chinese. Even for Dutch and German, which pose additional challenges such as compound words and morphology which we do not explicitly treat in the current system, LTS still delivers significant improvements in performance. Additionally,

	System	200K	400K
(a)	lts-nolabels	22.50	24.24
	lts	**23.67****	**25.16****
(b)	josh-base-lm4	23.81	24.77
	lts-lm4	**24.48****	**26.35****

Table 2: Additional experiments for English to Chinese translation examining (a) the impact of the linguistic annotations in the LTS system (lts), when compared with an instance not employing such annotations (lts-nolabels) and (b) decoding with a 4th-order language model (-lm4). BLEU scores for 200K and 400K training sentence pairs.

the robustness of our system is exemplified by delivering significant performance increases for all language pairs.

For the English to Chinese translation task, we performed further experiments along two axes. We first investigate the contribution of the linguistic annotations, by comparing our complete system (lts) with an otherwise identical implementation (lts-nolabels) which does not employ any linguistically motivated labels. The latter system then uses a labels chart as that of Figure 3, which however labels all phrase-pair spans solely with the generic X label. The results in Table 2(a) indicate that a large part of the performance improvement can be attributed to the use of the linguistic annotations extracted from the source parse trees, indicating the potential of the LTS system to take advantage of such additional annotations to deliver better translations.

The second additional experiment relates to the impact of employing a stronger language model during decoding, which may increase performance but slows down decoding speed. Notably, as can be seen in Table 2(b), switching to a 4-gram LM results in performance gains for both the baseline and our system and while the margin between the two systems decreases, our system continues to deliver a considerable and significant improvement in translation BLEU scores.

5 Related Work

In this work, we focus on the combination of learning latent structure with syntax and linguistic annotations, exploring the crossroads of machine learning, linguistic syntax and machine translation. Training a joint probability model was first discussed in (Marcu and Wong, 2002). We show that a translation system based on such a joint model can perform competitively in comparison with conditional probability models, when it is augmented with a rich latent hierarchical structure trained adequately to avoid overfitting.

Earlier approaches for linguistic syntax-based translation such as (Yamada and Knight, 2001; Galley et al., 2006; Huang et al., 2006; Liu et al., 2006) focus on memorising and reusing parts of the structure of the source and/or target parse trees and constraining decoding by the input parse tree. In contrast to this approach, we choose to employ linguistic annotations in the form of unambiguous synchronous span labels, while discovering ambiguous translation structure taking advantage of them.

Later work (Marton and Resnik, 2008; Venugopal et al., 2009; Chiang et al., 2009) takes a more flexible approach, influencing translation output using linguistically motivated features, or features based on source-side linguistically-guided latent syntactic categories (Huang et al., 2010). A feature-based approach and ours are not mutually exclusive, as we also employ a limited set of features next to our trained model during decoding. We find augmenting our system with a more extensive feature set an interesting research direction for the future.

An array of recent work (Chiang, 2010; Zhang et al., 2008; Liu et al., 2009) sets off to utilise source *and* target syntax for translation. While for this work we constrain ourselves to source language syntax annotations, our method can be directly applied to employ labels taking advantage of linguistic annotations from both sides of translation. The decoding constraints of section 4.2 can then still be applied on the source part of hybrid source-target labels.

For the experiments in this paper we employ a label set similar to the non-terminals set of (Zollmann and Venugopal, 2006). However, the synchronous grammars we learn share few similarities with those that they heuristically extract. The HR-SCFG we adopt allows capturing more complex reordering phenomena and, in contrast to both (Chiang, 2005; Zollmann and Venugopal, 2006), is not exposed to the issues highlighted in section 2.1. Nevertheless, our results underline the capacity of linguistic anno-

tations similar to those of (Zollmann and Venugopal, 2006) as part of latent translation variables.

Most of the aforementioned work does concentrate on *learning* hierarchical, linguistically motivated translation models. Cohn and Blunsom (2009) sample rules of the form proposed in (Galley et al., 2004) from a Bayesian model, employing Dirichlet Process priors favouring smaller rules to avoid overfitting. Their grammar is however also based on the target parse-tree structure, with their system surpassing a weak baseline by a small margin. In contrast to the Bayesian approach which imposes external priors to lead estimation away from degenerate solutions, we take a *data-driven* approach to arrive to estimates which generalise well. The rich linguistically motivated latent variable learnt by our method delivers translation performance that compares favourably to a state-of-the-art system.

Mylonakis and Sima'an (2010) also employ the CV-EM algorithm to estimate the parameters of an SCFG, albeit a much simpler one based on a handful of non-terminals. In this work we employ some of their grammar design principles for an immensely more complex grammar with millions of hierarchical latent structure rules and show how such grammar can be learnt and applied taking advantage of source language linguistic annotations.

6 Conclusions

In this work we contribute a method to learn and apply latent hierarchical translation structure. To this end, we take advantage of source-language linguistic annotations to motivate instead of constrain the translation process. An input chart over phrase-pair spans, with each cell filled with multiple linguistically motivated labels, is coupled with the HR-SCFG design to arrive at a rich synchronous grammar with millions of structural rules and the capacity to capture complex linguistically conditioned translation phenomena. We address overfitting issues by cross-validating climbing the likelihood of the training data and propose solutions to increase the efficiency and accuracy of decoding.

An interesting aspect of our work is delivering competitive performance for difficult language pairs such as English-Chinese with a joint probability generative model and an SCFG without 'gap rules'. Instead of employing hierarchical phrase-pairs, we invest in learning the higher-order hierarchical synchronous structure behind translation, up to the full sentence length. While these choices and the related results challenge current MT research trends, they are not mutually exclusive with them. Future work directions include investigating the impact of hierarchical phrases for our models as well as any gains from additional features in the log-linear decoding model.

Smoothing the HR-SCFG grammar estimates could prove a possible source of further performance improvements. Learning translation and reordering behaviour with respect to linguistic cues is facilitated in our approach by keeping separate phrase-pair emission distributions per emitting non-terminal and reordering pattern, while the employment of the generic X non-terminals already allows backing off to more coarse-grained rules. Nevertheless, we still believe that further smoothing of these sparse distributions, e.g. by interpolating them with less sparse ones, could in the future lead to an additional increase in translation quality.

Finally, we discuss in this work how our method can already utilise hundreds of thousands of phrase-pair labels and millions of structural rules. A further promising direction is broadening this set with labels taking advantage of both source and target-language linguistic annotation or categories exploring additional phrase-pair properties past the parse trees such as semantic annotations.

Abstract

Community-based question answer (Q&A) has become an important issue due to the popularity of Q&A archives on the web. This paper is concerned with the problem of question retrieval. Question retrieval in Q&A archives aims to find historical questions that are semantically equivalent or relevant to the queried questions. In this paper, we propose a novel phrase-based translation model for question retrieval. Compared to the traditional word-based translation models, the phrase-based translation model is more effective because it captures contextual information in modeling the translation of phrases as a whole, rather than translating single words in isolation. Experiments conducted on real Q&A data demonstrate that our proposed phrase-based translation model significantly outperforms the state-of-the-art word-based translation model.

1 Introduction

Over the past few years, large scale question and answer (Q&A) archives have become an important information resource on the Web. These include the traditional Frequently Asked Questions (FAQ) archives and the emerging community-based Q&A services, such as Yahoo! Answers[1], Live QnA[2], and Baidu Zhidao[3].

[3]http://zhidao.baidu.com/

Community-based Q&A services can directly return answers to the queried questions instead of a list of relevant documents, thus provide an effective alternative to the traditional adhoc information retrieval. To make full use of the large scale archives of question-answer pairs, it is critical to have functionality helping users to retrieve historical answers (Duan et al., 2008). Therefore, it is a meaningful task to retrieve the questions that are semantically equivalent or relevant to the queried questions. For example in Table 1, given question Q_1, Q_2 can be returned and their answers will then be used to answer Q_1 because the answer of Q_2 is expected to partially satisfy the queried question Q_1. This is what we called *question retrieval* in this paper.

The major challenge for Q&A retrieval, as for most information retrieval models, such as vector space model (VSM) (Salton et al., 1975), Okapi model (Robertson et al., 1994), language model (LM) (Ponte and Croft, 1998), is the *lexical gap* (or *lexical chasm*) between the queried questions and the historical questions in the archives (Jeon et al., 2005; Xue et al., 2008). For example in Table 1, Q_1 and Q_2 are two semantically similar questions, but they have very few words in common. This prob-

Query:
Q_1: How to get rid of **stuffy nose**?
Expected:
Q_2: What is the best way to prevent a cold?
Not Expected:
Q_3: How do I air out my stuffy room?
Q_4: How do you make a nose bleed stop quicker?

Table 1: An example on question retrieval

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 653–662,
Portland, Oregon, June 19-24, 2011.

lem is more serious for Q&A retrieval, since the question-answer pairs are usually short and there is little chance of finding the same content expressed using different wording (Xue et al., 2008). To solve the lexical gap problem, most researchers regarded the question retrieval task as a statistical machine translation problem by using IBM model 1 (Brown et al., 1993) to learn the word-to-word translation probabilities (Berger and Lafferty, 1999; Jeon et al., 2005; Xue et al., 2008; Lee et al., 2008; Bernhard and Gurevych, 2009). Experiments consistently reported that the word-based translation models could yield better performance than the traditional methods (e.g., VSM. Okapi and LM). However, all these existing approaches are considered to be *context independent* in that they do not take into account any contextual information in modeling word translation probabilities. For example in Table 1, although neither of the individual word pair (e.g., "stuffy"/"cold" and "nose"/"cold") might have a high translation probability, the sequence of words "stuffy nose" can be easily translated from a single word "cold" in Q_2 with a relative high translation probability.

In this paper, we argue that it is beneficial to capture contextual information for question retrieval. To this end, inspired by the phrase-based statistical machine translation (SMT) systems (Koehn et al., 2003; Och and Ney, 2004), we propose a phrase-based translation model (P-Trans) for question retrieval, and we assume that question retrieval should be performed at the phrase level. This model learns the probability of translating one sequence of words (e.g., phrase) into another sequence of words, e.g., translating a phrase in a historical question into another phrase in a queried question. Compared to the traditional word-based translation models that account for translating single words in isolation, the phrase-based translation model is potentially more effective because it captures some contextual information in modeling the translation of phrases as a whole. More precise translation can be determined for phrases than for words. It is thus reasonable to expect that using such phrase translation probabilities as ranking features is likely to improve the question retrieval performance, as we will show in our experiments.

Unlike the general natural language translation, the parallel sentences between questions and answers in community-based Q&A have very different lengths, leaving many words in answers unaligned to any word in queried questions. Following (Berger and Lafferty, 1999), we restrict our attention to those phrase translations consistent with a good word-level alignment.

Specifically, we make the following contributions:

- we formulate the question retrieval task as a phrase-based translation problem by modeling the contextual information (in Section 3.1).
- we linearly combine the phrase-based translation model for the question part and answer part (in Section 3.2).
- we propose a linear ranking model framework for question retrieval in which different models are incorporated as features because the phrase-based translation model cannot be interpolated with a unigram language model (in Section 3.3).
- finally, we conduct the experiments on community-based Q&A data for question retrieval. The results show that our proposed approach significantly outperforms the baseline methods (in Section 4).

The remainder of this paper is organized as follows. Section 2 introduces the existing state-of-the-art methods. Section 3 describes our phrase-based translation model for question retrieval. Section 4 presents the experimental results. In Section 5, we conclude with ideas for future research.

2 Preliminaries

2.1 Language Model

The unigram language model has been widely used for question retrieval on community-based Q&A data (Jeon et al., 2005; Xue et al., 2008; Cao et al., 2010). To avoid zero probability, we use Jelinek-Mercer smoothing (Zhai and Lafferty, 2001) due to its good performance and cheap computational cost. So the ranking function for the query likelihood language model with Jelinek-Mercer smoothing can be

written as:

$$Score(\mathbf{q}, D) = \prod_{w \in \mathbf{q}} (1-\lambda) P_{ml}(w|D) + \lambda P_{ml}(w|C) \quad (1)$$

$$P_{ml}(w|D) = \frac{\#(w, D)}{|D|}, \;\; P_{ml}(w|C) = \frac{\#(w, C)}{|C|} \quad (2)$$

where $\mathbf{q}$ is the queried question, D is a document, C is background collection, λ is smoothing parameter. $\#(t, D)$ is the frequency of term t in D, $|D|$ and $|C|$ denote the length of D and C respectively.

2.2 Word-Based Translation Model

Previous work (Berger et al., 2000; Jeon et al., 2005; Xue et al., 2008) consistently reported that the word-based translation models (Trans) yielded better performance than the traditional methods (VSM, Okapi and LM) for question retrieval. These models exploit the word translation probabilities in a language modeling framework. Following Jeon et al. (2005) and Xue et al. (2008), the ranking function can be written as:

$$Score(\mathbf{q}, D) = \prod_{w \in \mathbf{q}} (1-\lambda) P_{tr}(w|D) + \lambda P_{ml}(w|C) \quad (3)$$

$$P_{tr}(w|D) = \sum_{t \in D} P(w|t) P_{ml}(t|D), \;\; P_{ml}(t|D) = \frac{\#(t, D)}{|D|} \quad (4)$$

where $P(w|t)$ denotes the translation probability from word t to word w.

2.3 Word-Based Translation Language Model

Xue et al. (2008) proposed to linearly mix two different estimations by combining language model and word-based translation model into a unified framework, called TransLM. The experiments show that this model gains better performance than both the language model and the word-based translation model. Following Xue et al. (2008), this model can be written as:

$$Score(\mathbf{q}, D) = \prod_{w \in \mathbf{q}} (1-\lambda) P_{mx}(w|D) + \lambda P_{ml}(w|C) \quad (5)$$

$$P_{mx}(w|D) = \alpha \sum_{t \in D} P(w|t) P_{ml}(t|D) + (1-\alpha) P_{ml}(w|D) \quad (6)$$

3 Our Approach: Phrase-Based Translation Model for Question Retrieval

3.1 Phrase-Based Translation Model

Phrase-based machine translation models (Koehn et al., 2003; D. Chiang, 2005; Och and Ney, 2004) have shown superior performance compared to word-based translation models. In this paper, the goal of phrase-based translation model is to translate a document[4] D into a queried question $\mathbf{q}$. Rather than translating single words in isolation, the phrase-based model translates one sequence of words into another sequence of words, thus incorporating contextual information. For example, we might learn that the phrase "stuffy nose" can be translated from "cold" with relative high probability, even though neither of the individual word pairs (e.g., "stuffy"/"cold" and "nose"/"cold") might have a high word translation probability. Inspired by the work of (Sun et al., 2010; Gao et al., 2010), we assume the following generative process: first the document D is broken into K non-empty word sequences $\mathbf{t}_1, \ldots, \mathbf{t}_K$, then each $\mathbf{t}$ is translated into a new non-empty word sequence $\mathbf{w}_1, \ldots, \mathbf{w}_K$, and finally these phrases are permutated and concatenated to form the queried questions $\mathbf{q}$, where $\mathbf{t}$ and $\mathbf{w}$ denote the phrases or consecutive sequence of words.

To formulate this generative process, let E denote the segmentation of D into K phrases $\mathbf{t}_1, \ldots, \mathbf{t}_K$, and let F denote the K translation phrases $\mathbf{w}_1, \ldots, \mathbf{w}_K$ —we refer to these $(\mathbf{t}_i, \mathbf{w}_i)$ pairs as *bi-phrases*. Finally, let M denote a permutation of K elements representing the final reordering step. Figure 1 describes an example of the generative procedure.

Next let us place a probability distribution over rewrite pairs. Let $B(D, \mathbf{q})$ denote the set of E,

[4] In this paper, a document has the same meaning as a historical question-answer pair in the Q&A archives.

F, M triples that translate D into $\mathbf{q}$. Here we assume a uniform probability over segmentations, so the phrase-based translation model can be formulated as:

$$P(\mathbf{q}|D) \propto \sum_{\substack{(E,F,M)\in \\ B(D,\mathbf{q})}} P(F|D,E) \cdot P(M|D,E,F) \quad (7)$$

As is common practice in SMT, we use the maximum approximation to the sum:

$$P(\mathbf{q}|D) \approx \max_{\substack{(E,F,M)\in \\ B(D,\mathbf{q})}} P(F|D,E) \cdot P(M|D,E,F) \quad (8)$$

Although we have defined a generative model for translating D into $\mathbf{q}$, our goal is to calculate the ranking score function over existing $\mathbf{q}$ and D, rather than generating new queried questions. Equation (8) cannot be used directly for document ranking because $\mathbf{q}$ and D are often of very different lengths, leaving many words in D unaligned to any word in $\mathbf{q}$. This is the key difference between the community-based question retrieval and the general natural language translation. As pointed out by Berger and Lafferty (1999) and Gao et al. (2010), document-query translation requires a *distillation* of the document, while translation of natural language tolerates little being thrown away.

Thus we attempt to extract the *key document words* that form the distillation of the document, and assume that a queried question is translated only from the *key document words*. In this paper, the key document words are identified via word alignment. We introduce the "hidden alignments" $A = a_1 \dots a_j \dots a_J$, which describe the mapping from a word position j in queried question to a document word position $i = a_j$. The different alignment models we present provide different decompositions of $P(\mathbf{q}, A|D)$. We assume that the position of the *key document words* are determined by the Viterbi alignment, which can be obtained using IBM model 1 as follows:

$$\begin{aligned}\hat{A} &= \arg\max_{A} P(\mathbf{q}, A|D) \\ &= \arg\max_{A} \Big\{ P(J|I) \prod_{j=1}^{J} P(w_j|t_{a_j}) \Big\} \\ &= \Big[\arg\max_{a_j} P(w_j|t_{a_j}) \Big]_{j=1}^{J} \end{aligned} \quad (9)$$

Given $\hat{A}$, when scoring a given Q&A pair, we restrict our attention to those E, F, M triples that are consistent with $\hat{A}$, which we denote as $B(D, \mathbf{q}, \hat{A})$. Here, consistency requires that if two words are aligned in $\hat{A}$, then they must appear in the same bi-phrase $(\mathbf{t}_i, \mathbf{w}_i)$. Once the word alignment is fixed, the final permutation is uniquely determined, so we can safely discard that factor. Thus equation (8) can be written as:

$$P(\mathbf{q}|D) \approx \max_{(E,F,M)\in B(D,\mathbf{q},\hat{A})} P(F|D,E) \quad (10)$$

For the sole remaining factor $P(F|D,E)$, we make the assumption that a segmented queried question $F = \mathbf{w}_1, \dots, \mathbf{w}_K$ is generated from left to right by translating each phrase $\mathbf{t}_1, \dots, \mathbf{t}_K$ independently:

$$P(F|D,E) = \prod_{k=1}^{K} P(\mathbf{w}_k|\mathbf{t}_k) \quad (11)$$

where $P(\mathbf{w}_k|\mathbf{t}_k)$ is a phrase translation probability, the estimation will be described in Section 3.3.

To find the maximum probability assignment efficiently, we use a dynamic programming approach, somewhat similar to the monotone decoding algorithm described in (Och, 2002). We define α_j to be the probability of the most likely sequence of phrases covering the first j words in a queried question, then the probability can be calculated using the following recursion:

(1) Initialization:

$$\alpha_0 = 1 \quad (12)$$

(2) Induction:

$$\alpha_j = \sum_{j'<j, \mathbf{w}=w_{j'+1}\dots w_j} \Big\{ \alpha_{j'} P(\mathbf{w}|\mathbf{t}_{\mathbf{w}}) \Big\} \quad (13)$$

(3) Total:

$$P(\mathbf{q}|D) = \alpha_J \quad (14)$$

3.2 Phrase-Based Translation Model for Question Part and Answer Part

In Q&A, a document D is decomposed into $(\bar{\mathbf{q}}, \bar{\mathbf{a}})$, where $\bar{\mathbf{q}}$ denotes the question part of the historical question in the archives and $\bar{\mathbf{a}}$ denotes the answer part. Although it has been shown that doing Q&A retrieval based solely on the answer part does not perform well (Jeon et al., 2005; Xue et al., 2008), the answer part should provide additional evidence about relevance and, therefore, it should be combined with the estimation based on the question part.

In this combined model, $P(\mathbf{q}|\bar{\mathbf{q}})$ and $P(\mathbf{q}|\bar{\mathbf{a}})$ are calculated with equations (12) to (14). So $P(\mathbf{q}|D)$ will be written as:

$$P(\mathbf{q}|D) = \mu_1 P(\mathbf{q}|\bar{\mathbf{q}}) + \mu_2 P(\mathbf{q}|\bar{\mathbf{a}}) \quad (15)$$

where $\mu_1 + \mu_2 = 1$.

In equation (15), the relative importance of question part and answer part is adjusted through μ_1 and μ_2. When $\mu_1 = 1$, the retrieval model is based on phrase-based translation model for the question part. When $\mu_2 = 1$, the retrieval model is based on phrase-based translation model for the answer part.

3.3 Parameter Estimation

3.3.1 Parallel Corpus Collection

In Q&A archives, question-answer pairs can be considered as a type of parallel corpus, which is used for estimating the translation probabilities. Unlike the bilingual machine translation, the questions and answers in a Q&A archive are written in the same language, the translation probability can be calculated through setting either as the source and the other as the target. In this paper, $P(\bar{\mathbf{a}}|\bar{\mathbf{q}})$ is used to denote the translation probability with the question as the source and the answer as the target. $P(\bar{\mathbf{q}}|\bar{\mathbf{a}})$ is used to denote the opposite configuration.

For a given word or phrase, the related words or phrases differ when it appears in the question or in the answer. Following Xue et al. (2008), a pooling strategy is adopted. First, we pool the question-answer pairs used to learn $P(\bar{\mathbf{a}}|\bar{\mathbf{q}})$ and the answer-question pairs used to learn $P(\bar{\mathbf{q}}|\bar{\mathbf{a}})$, and then use IBM model 1 (Brown et al., 1993) to learn the combined translation probabilities. Suppose we use the collection $\{(\bar{\mathbf{q}}, \bar{\mathbf{a}})_1, \ldots, (\bar{\mathbf{q}}, \bar{\mathbf{a}})_m\}$ to learn $P(\bar{\mathbf{a}}|\bar{\mathbf{q}})$ and use the collection $\{(\bar{\mathbf{a}}, \bar{\mathbf{q}})_1, \ldots, (\bar{\mathbf{a}}, \bar{\mathbf{q}})_m\}$ to learn $P(\bar{\mathbf{q}}|\bar{\mathbf{a}})$, then $\{(\bar{\mathbf{q}}, \bar{\mathbf{a}})_1, \ldots, (\bar{\mathbf{q}}, \bar{\mathbf{a}})_m, (\bar{\mathbf{a}}, \bar{\mathbf{q}})_1, \ldots, (\bar{\mathbf{a}}, \bar{\mathbf{q}})_m\}$ is used here to learn the combination translation probability $P_{pool}(w_i|t_j)$.

3.3.2 Parallel Corpus Preprocessing

Unlike the bilingual parallel corpus used in SMT, our parallel corpus is collected from Q&A archives, which is more noisy. Directly using the IBM model 1 can be problematic, it is possible for translation model to contain "unnecessary" translations (Lee et al., 2008). In this paper, we adopt a variant of TextRank algorithm (Mihalcea and Tarau, 2004) to identify and eliminate unimportant words from parallel corpus, assuming that a word in a question or answer is unimportant if it holds a relatively low significance in the parallel corpus.

Following (Lee et al., 2008), the ranking algorithm proceeds as follows. First, all the words in a given document are added as vertices in a graph G. Then edges are added between words if the words co-occur in a fixed-sized window. The number of co-occurrences becomes the weight of an edge. When the graph is constructed, the score of each vertex is initialized as 1, and the PageRank-based ranking algorithm is run on the graph iteratively until convergence. The TextRank score of a word w in document D at kth iteration is defined as follows:

$$R^k_{w,D} = (1-d) + d \cdot \sum_{\forall j:(i,j)\in G} \frac{e_{i,j}}{\sum_{\forall l:(j,l)\in G} e_{j,l}} R^{k-1}_{w,D} \quad (16)$$

where d is a damping factor usually set to 0.85, and $e_{i,j}$ is an edge weight between i and j.

We use average *TextRank score* as threshold: words are removed if their scores are lower than the average score of all words in a document.

3.3.3 Translation Probability Estimation

After preprocessing the parallel corpus, we will calculate $P(\mathbf{w}|\mathbf{t})$, following the method commonly used in SMT (Koehn et al., 2003; Och, 2002) to extract bi-phrases and estimate their translation probabilities.

First, we learn the word-to-word translation probability using IBM model 1 (Brown et al., 1993). Then, we perform Viterbi word alignment according to equation (9). Finally, the bi-phrases that are consistent with the word alignment are extracted using the heuristics proposed in (Och, 2002). We set the maximum phrase length to five in our experiments.

After gathering all such bi-phrases from the training data, we can estimate conditional relative frequency estimates without smoothing:

$$P(\mathbf{w}|\mathbf{t}) = \frac{N(\mathbf{t}, \mathbf{w})}{N(\mathbf{t})} \quad (17)$$

where $N(\mathbf{t}, \mathbf{w})$ is the number of times that $\mathbf{t}$ is aligned to $\mathbf{w}$ in training data. These estimates are

source	stuffy nose	internet explorer
1	stuffy nose	internet explorer
2	cold	ie
3	stuffy	internet browser
4	sore throat	explorer
5	sneeze	browser

Table 2: Phrase translation probability examples. Each column shows the top 5 target phrases learned from the word-aligned question-answer pairs.

useful for contextual lexical selection with sufficient training data, but can be subject to data sparsity issues (Sun et al., 2010; Gao et al., 2010). An alternate translation probability estimate not subject to data sparsity is the so-called *lexical weight* estimate (Koehn et al., 2003). Let $P(w|t)$ be the word-to-word translation probability, and let A be the word alignment between $\mathbf{w}$ and $\mathbf{t}$. Here, the word alignment contains (i, j) pairs, where $i \in 1 \ldots |\mathbf{w}|$ and $j \in 0 \ldots |\mathbf{t}|$, with 0 indicating a null word. Then we use the following estimate:

$$P_t(\mathbf{w}|\mathbf{t}, A) = \prod_{i=1}^{|\mathbf{w}|} \frac{1}{|\{j|(j,i) \in A\}|} \sum_{\forall (i,j) \in A} P(w_i|t_j) \tag{18}$$

We assume that for each position in $\mathbf{w}$, there is either a single alignment to 0, or multiple alignments to non-zero positions in $\mathbf{t}$. In fact, equation (18) computes a product of per-word translation scores; the per-word scores are the averages of all the translations for the alignment links of that word. The word translation probabilities are calculated using IBM 1, which has been widely used for question retrieval (Jeon et al., 2005; Xue et al., 2008; Lee et al., 2008; Bernhard and Gurevych, 2009). These word-based scores of bi-phrases, though not as effective in contextual selection, are more robust to noise and sparsity.

A sample of the resulting phrase translation examples is shown in Table 2, where the top 5 target phrases are translated from the source phrases according to the phrase-based translation model. For example, the term "explorer" used alone, most likely refers to a person who engages in scientific exploration, while the phrase "internet explorer" has a very different meaning.

3.4 Ranking Candidate Historical Questions

Unlike the word-based translation models, the phrase-based translation model cannot be interpolated with a unigram language model. Following (Sun et al., 2010; Gao et al., 2010), we resort to a linear ranking framework for question retrieval in which different models are incorporated as features.

We consider learning a relevance function of the following general, linear form:

$$Score(\mathbf{q}, D) = \boldsymbol{\theta}^T \cdot \boldsymbol{\Phi}(\mathbf{q}, D) \tag{19}$$

where the feature vector $\boldsymbol{\Phi}(\mathbf{q}, D)$ is an arbitrary function that maps $(\mathbf{q}, D)$ to a real value, i.e., $\boldsymbol{\Phi}(\mathbf{q}, D) \in \mathbb{R}$. $\boldsymbol{\theta}$ is the corresponding weight vector, we optimize this parameter for our evaluation metrics directly using the Powell Search algorithm (Paul et al., 1992) via cross-validation.

The features used in this paper are as follows:

- **Phrase translation features (PT)**: $\boldsymbol{\Phi}_{PT}(\mathbf{q}, D, A) = \log P(\mathbf{q}|D)$, where $P(\mathbf{q}|D)$ is computed using equations (12) to (15), and the phrase translation probability $P(\mathbf{w}|\mathbf{t})$ is estimated using equation (17).

- **Inverted Phrase translation features (IPT)**: $\boldsymbol{\Phi}_{IPT}(D, \mathbf{q}, A) = \log P(D|\mathbf{q})$, where $P(D|\mathbf{q})$ is computed using equations (12) to (15) except that we set $\mu_2 = 0$ in equation (15), and the phrase translation probability $P(\mathbf{w}|\mathbf{t})$ is estimated using equation (17).

- **Lexical weight feature (LW)**: $\boldsymbol{\Phi}_{LW}(\mathbf{q}, D, A) = \log P(\mathbf{q}|D)$, here $P(\mathbf{q}|D)$ is computed by equations (12) to (15), and the phrase translation probability is computed as lexical weight according to equation (18).

- **Inverted Lexical weight feature (ILW)**: $\boldsymbol{\Phi}_{ILW}(D, \mathbf{q}, A) = \log P(D|\mathbf{q})$, here $P(D|\mathbf{q})$ is computed by equations (12) to (15) except that we set $\mu_2 = 0$ in equation (15), and the phrase translation probability is computed as lexical weight according to equation (18).

- **Phrase alignment features (PA)**: $\boldsymbol{\Phi}_{PA}(\mathbf{q}, D, B) = \sum_2^K |a_k - b_{k-1} - 1|$, where B is a set of K bi-phrases, a_k is the start position of the phrase in D that was translated

into the kth phrase in queried question, and b_{k-1} is the end position of the phrase in D that was translated into the $(k-1)$th phrase in queried question. The feature, inspired by the distortion model in SMT (Koehn et al., 2003), models the degree to which the queried phrases are reordered. For all possible B, we only compute the feature value according to the Viterbi alignment, $\hat{B} = \arg\max_B P(\mathbf{q}, B|D)$. We find $\hat{B}$ using the Viterbi algorithm, which is almost identical to the dynamic programming recursion of equations (12) to (14), except that the *sum* operator in equation (13) is replaced with the *max* operator.

- **Unaligned word penalty features (UWP)**: $\mathbf{\Phi}_{UWP}(\mathbf{q}, D)$, which is defined as the ratio between the number of unaligned words and the total number of words in queried questions.

- **Language model features (LM)**: $\mathbf{\Phi}_{LM}(\mathbf{q}, D, A) = \log P_{LM}(\mathbf{q}|D)$, where $P_{LM}(\mathbf{q}|D)$ is the unigram language model with Jelinek-Mercer smoothing defined by equations (1) and (2).

- **Word translation features (WT)**: $\mathbf{\Phi}_{WT}(\mathbf{q}, D) = \log P(\mathbf{q}|D)$, where $P(\mathbf{q}|D)$ is the word-based translation model defined by equations (3) and (4).

4 Experiments

4.1 Data Set and Evaluation Metrics

We collect the questions from Yahoo! Answers and use the *getByCategory* function provided in Yahoo! Answers API[5] to obtain Q&A threads from the Yahoo! site. More specifically, we utilize the *resolved* questions under the top-level category at Yahoo! Answers, namely "Computers & Internet". The resulting question repository that we use for question retrieval contains 518,492 questions. To learn the translation probabilities, we use about one million question-answer pairs from another data set.[6]

In order to create the test set, we randomly select 300 questions for this category, denoted as "CI_TST". To obtain the ground-truth of question retrieval, we employ the Vector Space Model (VSM) (Salton et al., 1975) to retrieve the top 20 results and obtain manual judgements. The top 20 results don't include the queried question itself. Given a returned result by VSM, an annotator is asked to label it with "relevant" or "irrelevant". If a returned result is considered semantically equivalent to the queried question, the annotator will label it as "relevant"; otherwise, the annotator will label it as "irrelevant". Two annotators are involved in the annotation process. If a conflict happens, a third person will make judgement for the final result. In the process of manually judging questions, the annotators are presented only the questions. Table 3 provides the statistics on the final test set.

	#queries	#returned	#relevant
CI_TST	300	6,000	798

Table 3: Statistics on the Test Data

We evaluate the performance of our approach using **Mean Average Precision (MAP)**. We perform a significant test, i.e., a t-test with a default significant level of 0.05. Following the literature, we set the parameters $\lambda = 0.2$ (Cao et al., 2010) in equations (1), (3) and (5), and $\alpha = 0.8$ (Xue et al., 2008) in equation (6).

4.2 Question Retrieval Results

We randomly divide the test questions into five subsets and conduct 5-fold cross-validation experiments. In each trial, we tune the parameters μ_1 and μ_2 with four of the five subsets and then apply it to one remaining subset. The experiments reported below are those averaged over the five trials.

Table 4 presents the main retrieval performance. Row 1 to row 3 are baseline systems, all these methods use word-based translation models and obtain the state-of-the-art performance in previous work (Jeon et al., 2005; Xue et al., 2008). Row 3 is similar to row 2, the only difference is that TransLM only considers the question part, while Xue et al. (2008) incorporates the question part and answer part. Row 4 and row 5 are our proposed phrase-based translation model with maximum phrase length of five. Row 4 is phrase-based translation model purely based on question part, this model is equivalent to

#	Methods	Trans Prob	MAP
1	Jeon et al. (2005)	P_{pool}	0.289
2	TransLM	P_{pool}	0.324
3	Xue et al. (2008)	P_{pool}	0.352
4	P-Trans ($\mu_1 = 1, l = 5$)	P_{pool}	0.366
5	**P-Trans** ($l = 5$)	P_{pool}	**0.391**

Table 4: Comparison with different methods for question retrieval.

setting $\mu_1 = 1$ in equation (15). Row 5 is the phrase-based combination model which linearly combines the question part and answer part. As expected, different parts can play different roles: a phrase to be translated in queried questions may be translated from the question part or answer part. All these methods use pooling strategy to estimate the translation probabilities. There are some clear trends in the result of Table 4:

(1) Word-based translation language model (TransLM) significantly outperforms word-based translation model of Jeon et al. (2005) (row 1 vs. row 2). Similar observations have been made by Xue et al. (2008).

(2) Incorporating the answer part into the models, either word-based or phrase-based, can significantly improve the performance of question retrieval (row 2 vs. row 3; row 4 vs. row 5).

(3) Our proposed phrase-based translation model (P-Trans) significantly outperforms the state-of-the-art word-based translation models (row 2 vs. row 4 and row 3 vs. row 5, all these comparisons are statistically significant at $p < 0.05$).

4.3 Impact of Phrase Length

Our proposed phrase-based translation model, due to its capability of capturing contextual information, is more effective than the state-of-the-art word-based translation models. It is important to investigate the impact of the phrase length on the final retrieval performance. Table 5 shows the results, it is seen that using the longer phrases up to the maximum length of five can consistently improve the retrieval performance. However, using much longer phrases in the phrase-based translation model does not seem to produce significantly better performance (row 8 and row 9 vs. row 10 are not statistically significant).

#	Systems	MAP
6	P-Trans ($l = 1$)	0.352
7	P-Trans ($l = 2$)	0.373
8	P-Trans ($l = 3$)	0.386
9	P-Trans ($l = 4$)	0.390
10	P-Trans ($l = 5$)	0.391

Table 5: The impact of the phrase length on retrieval performance.

P-Trans ($l = 5$)	11	Initial	69	0.380
	12	TextRank	24	0.391

Table 6: Effectiveness of parallel corpus preprocessing.

4.4 Effectiveness of Parallel Corpus Preprocessing

Question-answer pairs collected from Yahoo! answers are very noisy, it is possible for translation models to contain "unnecessary" translations. In this paper, we attempt to identify and decrease the proportion of unnecessary translations in a translation model by using TextRank algorithm. This kind of "unnecessary" translation between words will eventually affect the bi-phrase translation.

Table 6 shows the effectiveness of parallel corpus preprocessing. Row 11 reports the average number of translations per word and the question retrieval performance when only stopwords [7] are removed. When using the TextRank algorithm for parallel corpus preprocessing, the average number of translations per word is reduced from 69 to 24, but the performance of question retrieval is significantly improved (row 11 vs. row 12). Similar results have been made by Lee et al. (2008).

4.5 Impact of Pooling Strategy

The correspondence of words or phrases in the question-answer pair is not as strong as in the bilingual sentence pair, thus noise will be inevitably introduced for both $P(\bar{\mathbf{a}}|\bar{\mathbf{q}})$ and $P(\bar{\mathbf{q}}|\bar{\mathbf{a}})$.

To see how much the pooling strategy benefit the question retrieval, we introduce two baseline methods for comparison. The first method (denoted as $P(\bar{\mathbf{a}}|\bar{\mathbf{q}})$) is used to denote the translation probability with the question as the source and the answer as

[7] http://truereader.com/manuals/onix/stopwords1.html

Model	#	Trans Prob	MAP
P-Trans ($l = 5$)	13	$P(\bar{\mathbf{a}}\|\bar{\mathbf{q}})$	0.387
	14	$P(\bar{\mathbf{q}}\|\bar{\mathbf{a}})$	0.381
	15	P_{pool}	0.391

Table 7: The impact of pooling strategy for question retrieval.

the target. The second (denoted as $P(\bar{\mathbf{a}}|\bar{\mathbf{q}})$) is used to denote the translation probability with the answer as the source and the question as the target. Table 7 provides the comparison. From this Table, we see that the pooling strategy significantly outperforms the two baseline methods for question retrieval (row 13 and row 14 vs. row 15).

5 Conclusions and Future Work

In this paper, we propose a novel phrase-based translation model for question retrieval. Compared to the traditional word-based translation models, the proposed approach is more effective in that it can capture contextual information instead of translating single words in isolation. Experiments conducted on real Q&A data demonstrate that the phrase-based translation model significantly outperforms the state-of-the-art word-based translation models.

There are some ways in which this research could be continued. First, question structure should be considered, so it is necessary to combine the proposed approach with other question retrieval methods (e.g., (Duan et al., 2008; Wang et al., 2009; Bunescu and Huang, 2010)) to further improve the performance. Second, we will try to investigate the use of the proposed approach for other kinds of data set, such as categorized questions from forum sites and FAQ sites.

Neutralizing Linguistically Problematic Annotations in Unsupervised Dependency Parsing Evaluation

Abstract

Dependency parsing is a central NLP task. In this paper we show that the common evaluation for unsupervised dependency parsing is highly sensitive to problematic annotations. We show that for three leading unsupervised parsers (Klein and Manning, 2004; Cohen and Smith, 2009; Spitkovsky et al., 2010a), a small set of parameters can be found whose modification yields a significant improvement in standard evaluation measures. These parameters correspond to local cases where no linguistic consensus exists as to the proper gold annotation. Therefore, the standard evaluation does not provide a true indication of algorithm quality. We present a new measure, *Neutral Edge Direction* (NED), and show that it greatly reduces this undesired phenomenon.

1 Introduction

Unsupervised induction of dependency parsers is a major NLP task that attracts a substantial amount of research (Klein and Manning, 2004; Cohen et al., 2008; Headden et al., 2009; Spitkovsky et al., 2010a; Gillenwater et al., 2010; Berg-Kirkpatrick et al., 2010; Blunsom and Cohn, 2010, *inter alia*). Parser quality is usually evaluated by comparing its output to a gold standard whose annotations are linguistically motivated. However, there are cases in which there is no linguistic consensus as to what the correct annotation is (Kübler et al., 2009). Examples include which verb is the head in a verb group structure (e.g., "can" or "eat" in "can eat"), and which noun is the head in a sequence of proper nouns (e.g., "John" or "Doe" in "John Doe"). We refer to such annotations as (*linguistically*) *problematic*. For such cases, evaluation measures should not punish the algorithm for deviating from the gold standard.

In this paper we show that the evaluation measures reported in current works are highly sensitive to the annotation in problematic cases, and propose a simple new measure that greatly neutralizes the problem.

We start from the following observation: for three leading algorithms (Klein and Manning, 2004; Cohen and Smith, 2009; Spitkovsky et al., 2010a), a small set (at most 18 out of a few thousands) of parameters can be found whose modification dramatically improves the standard evaluation measures (the attachment score measure by 9.3-15.1%, and the undirected measure by a smaller but still significant 1.3-7.7%). The phenomenon is implementation independent, occurring with several algorithms based on a fundamental probabilistic dependency model[1].

We show that these parameter changes can be mapped to edge direction changes in local structures in the dependency graph, and that these correspond to problematic annotations. Thus, the standard evaluation measures do not reflect the true quality of the evaluated algorithm.

We explain why the standard undirected evaluation measure is in fact sensitive to such edge direc-

Portland, Oregon, June 19-24, 2011.

tion changes, and present a new evaluation measure, *Neutral Edge Direction* (NED), which greatly alleviates the problem by ignoring the edge direction in local structures. Using NED, manual modifications of model parameters always yields small performance differences. Moreover, NED sometimes punishes such manual parameter tweaking by yielding worse results. We explain this behavior using an experiment revealing that NED always prefers the structures that are more consistent with the modeling assumptions lying in the basis of the algorithm. When manual parameter modification is done against this preference, the NED results decrease.

The contributions of this paper are as follows. First, we show the impact of a small number of annotation decisions on the performance of unsupervised dependency parsers. Second, we observe that often these decisions are linguistically controversial and therefore this impact is misleading. This reveals a problem in the common evaluation of unsupervised dependency parsing. This is further demonstrated by noting that recent papers evaluate the task using three gold standards which differ in such decisions and which yield substantially different results. Third, we present the NED measure, which is agnostic to errors arising from choosing the non-gold direction in such cases.

Section 2 reviews related work. Section 3 describes the performed parameter modifications. Section 4 discusses the linguistic controversies in annotating problematic dependency structures. Section 5 presents NED. Section 6 describes experiments with it. A discussion is given in Section 7.

2 Related Work

Grammar induction received considerable attention over the years (see (Clark, 2001; Klein, 2005) for reviews). For unsupervised dependency parsing, the *Dependency Model with Valence (DMV)* (Klein and Manning, 2004) was the first to beat the simple right-branching baseline. A technical description of DMV is given at the end of this section.

The great majority of recent works, including those experimented with in this paper, are elaborations of DMV. Smith and Eisner (2005) improved the DMV results by generalizing the function maximized by DMV's EM training algorithm. Smith and Eisner (2006) used a structural locality bias, experimenting on five languages. Cohen et al. (2008) extended DMV by using a variational EM training algorithm and adding logistic normal priors. Cohen and Smith (2009, 2010) further extended it by using a *shared* logistic normal prior which provided a new way to encode the knowledge that some POS tags are more similar than others. A bilingual joint learning further improved their performance.

Headden et al. (2009) obtained the best reported results on WSJ10 by using a lexical extension of DMV. Gillenwater et al. (2010) used posterior regularization to bias the training towards a small number of parent-child combinations. Berg-Kirkpatrick et al. (2010) added new features to the M step of the DMV EM procedure. Berg-Kirkpatrick and Klein (2010) used a phylogenetic tree to model parameter drift between different languages. Spitkovsky et al. (2010a) explored several training protocols for DMV. Spitkovsky et al. (2010c) showed the benefits of Viterbi ("hard") EM to DMV training. Spitkovsky et al. (2010b) presented a novel *lightly-supervised* approach that used hyper-text mark-up annotation of web-pages to train DMV.

A few non-DMV-based works were recently presented. Daumé III (2009) used shift-reduce techniques. Blunsom and Cohn (2010) used tree substitution grammar to achieve best results on WSJ$^\infty$.

Druck et al. (2009) took a semi-supervised approach, using a set of rules such as "A noun is usually the parent of a determiner which is to its left", experimenting on several languages. Naseem et al. (2010) further extended this idea by using a single set of rules which globally applies to six different languages. The latter used a model similar to DMV.

The controversial nature of some dependency structures was discussed in (Nivre, 2006; Kübler et al., 2009). Klein (2005) discussed controversial constituency structures and the evaluation problems stemming from them, stressing the importance of a consistent standard of evaluation.

A few works explored the effects of annotation conventions on parsing performance. Nilsson et al. (2006) transformed the dependency annotations of coordinations and verb groups in the Prague TreeBank. They trained the supervised MaltParser (Nivre et al., 2006) on the transformed data, parsed the test data and re-transformed the resulting parse,

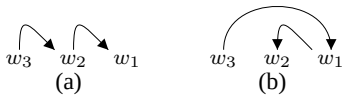

Figure 1: A dependency structure on the words w_1, w_2, w_3 before (Figure 1(a)) and after (Figure 1(b)) an *edge-flip* of $w_2 \rightarrow w_1$.

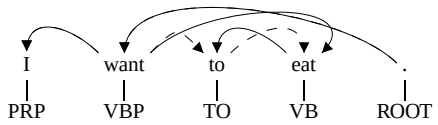

Figure 2: A parse of the sentence "I want to eat", before (straight line) and after (dashed line) an *edge-flip* of the edge "to"←"eat".

thus improving performance. Klein and Manning (2004) observed that a large portion of their errors is caused by predicting the wrong direction of the edge between a noun and its determiner. Kübler (2005) compared two different conversion schemes in German supervised constituency parsing and found one to have positive influence on parsing quality.

Dependency Model with Valence (DMV). DMV (Klein and Manning, 2004) defines a probabilistic grammar for unlabeled dependency structures. It is defined as follows: the root of the sentence is first generated, and then each head recursively generates its right and left dependents. The parameters of the model are of two types: P_{STOP} and P_{ATTACH}. $P_{STOP}(dir, h, adj)$ determines the probability to stop generating arguments, and is conditioned on 3 arguments: the head h, the direction dir ($(L)eft$ or $(R)ight$) and adjacency adj (whether the head already has dependents ($(Y)es$) in direction dir or not ($(N)o$)). $P_{ATTACH}(arg|h, dir)$ determines the probability to generate arg as head h's dependent in direction dir.

3 Significant Effects of Edge Flipping

In this section we present recurring error patterns in some of the leading unsupervised dependency parsers. These patterns are all local, confined to a sequence of up to three words (but mainly of just two consecutive words). They can often be mended by changing the directions of a few types of edges.

The modified parameters described in this section were handpicked to improve performance: we examined the local parser errors occurring the largest number of times, and found the corresponding parameters. Note that this is a valid methodology, since our goal is not to design a new algorithm but to demonstrate that modifying a small set of parameters can yield a major performance boost and eventually discover problems with evaluation methods or algorithms.

We start with a few definitions. Consider Figure 1(a) that shows a dependency structure on the words w_1, w_2, w_3. Edge flipping (henceforth, *edge-flip*) the edge $w_2 \rightarrow w_1$ is the following modification of a parse tree: (1) setting w_2's parent as w_1 (instead of the other way around), and (2) setting w_1's parent as w_3 (instead of the edge $w_3 \rightarrow w_2$). Figure 1(b) shows the dependency structure after the *edge-flip*.

Note that (1) imposes setting a new parent to w_2, as otherwise it would have had no parent. Setting this parent to be w_3 is the minimal modification of the original parse, since it does not change the attachment of the structure $[w_2, w_1]$ to the rest of the sentence, but only the direction of the internal edge.

Figure 2 presents a parse of the sentence "I want to eat", before and after an *edge-flip* of the edge "to"←"eat".

Since unsupervised dependency parsers are generally structure prediction models, the predictions of the parse edges are not independent. Therefore, there is no single parameter which completely controls the edge direction, and hence there is no direct way to perform an *edge-flip* by parameter modification. However, setting extreme values for the parameters controlling the direction of a certain edge type creates a strong preference towards one of the directions, and effectively determines the edge direction. This procedure is henceforth termed *parameter-flip*.

We show that by performing a few *parameter-flips*, a substantial improvement in the attachment score can be obtained. Results are reported for three algorithms.

Parameter Changes. All the works experimented with in this paper are not lexical and use sequences of POS tags as their input. In addition, they all use the DMV parameter set (P_{STOP} and P_{ATTACH}) for parsing. We will henceforth refer to this set, conditioned on POS tags, as the model parameter set.

We show how an edge in the dependency graph is encoded using the DMV parameters. Say the

model prefers setting "to" (POS tag: TO) as a dependent of the infinitive verb (POS tag: VB) to its right (e.g., "to eat"). This is reflected by a high value of $P_{ATTACH}(TO|VB, L)$, a low value of $P_{ATTACH}(VB|TO, R)$, since "to" tends to be a left dependent of the verb and not the other way around, and a low value of $P_{STOP}(VB, L, N)$, as the verb usually has at least one left argument (i.e., "to").

A *parameter-flip* of $w_1 \rightarrow w_2$ is hence performed by setting $P_{ATTACH}(w_2|w_1, R)$ to a very low value and $P_{ATTACH}(w_1|w_2, L)$ to a very high value. When the modifications to P_{ATTACH} are insufficient to modify the edge direction, $P_{STOP}(w_2, L, N)$ is set to a very low value and $P_{STOP}(w_1, R, N)$ to a very high value[2].

Table 1 describes the changes made for the three algorithms. The '+' signs in the table correspond to edges in which the algorithm disagreed with the gold standard, and were thus modified. Similarly, the '–' signs in the table correspond to edges in which the algorithm agreed with the gold standard, and were thus not modified. The number of modified parameters does not exceed 18 (out of a few thousands).

The *Freq*. column in the table shows the percentage of the tokens in sections 2-21 of PTB WSJ that participate in each structure. Equivalently, the percentage of edges in the corpus which are of either of the types appearing in the *Orig*. *Edge* column. As the table shows, the modified structures cover a significant portion of the tokens. Indeed, 42.9% of the tokens in the corpus participate in at least one of them[3].

Experimenting with Edge Flipping. We experimented with three DMV-based algorithms: a replication of (Klein and Manning, 2004), as appears in (Cohen et al., 2008) (henceforth, *km04*), Cohen and Smith (2009) (henceforth, *cs09*), and Spitkovsky et al. (2010a) (henceforth, *saj10a*). Decoding is done using the Viterbi algorithm[4]. For each of these algorithms we present the performance gain when compared to the original parameters.

The training set is sections 2-21 of the Wall Street Journal Penn TreeBank (Marcus et al., 1993). Testing is done on section 23. The constituency annotation was converted to dependencies using the rules of (Yamada and Matsumoto, 2003)[5].

Following standard practice, we present the attachment score (i.e., percentage of words that have a correct head) of each algorithm, with both the original parameters and the modified ones. We present results both on all sentences and on sentences of length ≤ 10, excluding punctuation.

Table 2 shows results for all algorithms[6]. The performance difference between the original and the modified parameter set is considerable for all data sets, where differences exceed 9.3%, and go up to 15.1%. These are enormous differences from the perspective of current algorithm evaluation results.

Structure	Freq.	Orig. Edge	*km04*	*cs09*	*saj10a*
Coordination ("John & Mary")	2.9%	$CC \rightarrow NNP$	–	+	–
Prepositional Phrase ("in the house")	32.7%	$DT \rightarrow NN$	+	+	+
		$DT \rightarrow NNP$	–	+	+
		$DT \rightarrow NNS$	–	–	+
		$IN \rightarrow DT$	+	+	–
		$IN \leftarrow NN$	+	+	–
		$IN \leftarrow NNP$	+	–	–
		$IN \leftarrow NNS$	–	+	–
		$PRP\$ \rightarrow NN$	–	–	+
Modal Verb ("can eat")	2.4%	$MD \leftarrow VB$	–	+	–
Infinitive Verb ("to eat")	4.5%	$TO \rightarrow VB$	–	+	+
Proper Name Sequence ("John Doe")	18.5%	$NNP \rightarrow NNP$	+	–	–

Table 1: Parameter changes for the three algorithms. The Freq. column shows what percentage of the tokens in sections 2-21 of PTB WSJ participate in each structure. The Orig. column indicates the original edge. The modified edge is of the opposite direction. The other columns show the different algorithms: *km04*: basic DMV model (replication of (Klein and Manning, 2004)); *cs09*; (Cohen and Smith, 2009); *saj10a*: (Spitkovsky et al., 2010a).

4 Linguistically Problematic Annotations

In this section, we discuss the controversial nature of the annotation in the modified structures (Kübler

[2]Note that this yields unnormalized models. Again, this is justified since the resulting model is only used as a basis for discussion and is not a fully fledged algorithm.

[3]Some tokens participate in more than one structure.

[4]http://www.cs.cmu.edu/∼scohen/parser.html.

[5]http://www.jaist.ac.jp/∼h-yamada/

[6]Results are slightly worse than the ones published in the original papers due to the different decoding algorithms (*cs09* use MBR while we used Viterbi) and a different conversion procedure (*saj10a* used (Collins, 1999) and not (Yamada and Matsumoto, 2003)) ; see Section 5.

Algo.	≤ 10			$\leq \infty$		
	$Orig.$	$Mod.$	Δ	$Orig.$	$Mod.$	Δ
km04	45.8	59.8	14	34.6	43.9	9.3
cs09	60.9	72.9	12	39.9	54.6	14.7
saj10a	54.7	69.8	15.1	41.6	54.3	12.7

Table 2: Results of the original ($Orig.$ columns), the modified ($Mod.$ columns) parameter sets and their difference (Δ columns) for the three algorithms.

et al., 2009). We remind the reader that structures for which no linguistic consensus exists as to their correct annotation are referred to as (linguistically) problematic.

We begin by showing that all the structures modified are indeed linguistically problematic. We then note that these controversies are reflected in the evaluation of this task, resulting in three, significantly different, gold standards currently in use.

Coordination Structures are composed of two proper nouns, separated by a conjunctor (e.g., "John and Mary"). It is not clear which token should be the head of this structure, if any (Nilsson et al., 2006).

Prepositional Phrases (e.g., "in the house" or "in Rome"), where every word is a reasonable candidate to head this structure. For example, in the annotation scheme used by (Collins, 1999) the preposition is the head, in the scheme used by (Johansson and Nugues, 2007) the noun is the head, while TUT annotation, presented in (Bosco and Lombardo, 2004), takes the determiner to be the noun's head.

Verb Groups are composed of a verb and an auxiliary or a modal verb (e.g., "can eat"). Some schemes choose the modal as the head (Collins, 1999), others choose the verb (Rambow et al., 2002).

Infinitive Verbs (e.g., "to eat") are also in controversy, as in (Yamada and Matsumoto, 2003) the verb is the head while in (Collins, 1999; Bosco and Lombardo, 2004) the "to" token is the head.

Sequences of Proper Nouns (e.g., "John Doe") are also subject to debate, as PTB's scheme takes the last proper noun as the head, and BIO's scheme defines a more complex scheme (Dredze et al., 2007).

Evaluation Inconsistency Across Papers. A fact that may not be recognized by some readers is that comparing the results of unsupervised dependency parsers across different papers is not directly possible, since different papers use different gold standard annotations *even when they are all derived from the Penn Treebank constituency annotation*. This happens because they use different rules for converting constituency annotation to dependency annotation. A probable explanation for this fact is that people have tried to correct linguistically problematic annotations in different ways, which is why we note this issue here[7].

There are three different annotation schemes in current use: (1) Collins head rules (Collins, 1999), used in e.g., (Berg-Kirkpatrick et al., 2010; Spitkovsky et al., 2010a); (2) Conversion rules of (Yamada and Matsumoto, 2003), used in e.g., (Cohen and Smith, 2009; Gillenwater et al., 2010); (3) Conversion rules of (Johansson and Nugues, 2007) used, e.g., in the CoNLL shared task 2007 (Nivre et al., 2007) and in (Blunsom and Cohn, 2010).

The differences between the schemes are substantial. For instance, 14.4% of section 23 is tagged differently by (1) and (2)[8].

5 The Neutral Edge Direction (NED) Measure

As shown in the previous sections, the annotation of problematic edges can substantially affect performance. This was briefly discussed in (Klein and Manning, 2004), which used undirected evaluation as a measure which is less sensitive to alternative annotations. Undirected accuracy was commonly used since to assess the performance of unsupervised parsers (e.g., (Smith and Eisner, 2006; Headden et al., 2008; Spitkovsky et al., 2010a)) but also of supervised ones (Wang et al., 2005; Wang et al., 2006). In this section we discuss why this measure is in fact not indifferent to *edge-flips* and propose a new measure, Neutral Edge Direction (NED).

[7] Indeed, half a dozen flags in the LTH Constituent-to-Dependency Conversion Tool (Johansson and Nugues, 2007) are used to control the conversion in problematic cases.

[8] In our experiments we used the scheme of (Yamada and Matsumoto, 2003), see Section 3. The significant effects of edge flipping were observed with the other two schemes as well.

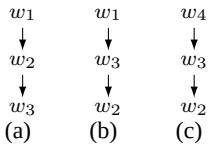

Figure 3: A dependency structure on the words w_1, w_2, w_3 before (Figure 3(a)) and after (Figure 3(b)) an *edge-flip* of $w_2 \rightarrow w_3$, and when the direction of the edge between w_2 and w_3 is switched and the new parent of w_3 is set to be some other word, w_4 (Figure 3(c)).

Undirected Evaluation. The measure is defined as follows: traverse over the tokens and mark a correct attachment if the token's induced parent is either (1) its gold parent or (2) its gold child. The score is the ratio of correct attachments and the number of tokens.

We show that this measure does not ignore *edge-flips*. Consider Figure 3 that shows a dependency structure on the words w_1, w_2, w_3 before (Figure 3(a)) and after (Figure 3(b)) an *edge-flip* of $w_2 \rightarrow w_3$. Assume that 3(a) is the gold standard and that 3(b) is the induced parse. Consider w_2. Its induced parent (w_3) is its gold child, and thus undirected evaluation does not consider it an error. On the other hand, w_3 is assigned w_2's gold parent, w_1. This is considered an error, since w_1 is neither w_3's gold parent (as it is w_2), nor its gold child[9]. Therefore, one of the two tokens involved in the *edge-flip* is penalized by the measure.

Recall the example "I want to eat" and the *edge-flip* of the edge "to"←"eat" (Figure 2). As "to"'s parent in the induced graph ("want") is neither its gold parent nor its gold child, the undirected evaluation measure marks it as an error. This is an example where an *edge-flip* in a problematic edge, which should not be considered an error, was in fact considered an error by undirected evaluation.

Neutral Edge Direction (NED). The NED measure is a simple extension of the undirected evaluation measure[10]. Unlike undirected evaluation, NED ignores all errors directly resulting from an *edge-flip*.

NED is defined as follows: traverse over the tokens and mark a correct attachment if the token's induced parent is either (1) its gold parent (2) its gold child or (3) its gold grandparent. The score is the ratio of correct attachments and the number of tokens.

NED, by its definition, ignores *edge-flips*. Consider again Figure 3, where we assume that 3(a) is the gold standard and that 3(b) is the induced parse. Much like undirected evaluation, NED will mark the attachment of w_2 as correct, since its induced parent is its gold child. However, unlike undirected evaluation, w_3's induced attachment will also be marked as correct, as its induced parent is its gold grandparent.

Now consider another induced parse in which the direction of the edge between w_2 and w_3 is switched and the w_3's parent is set to be some other word, w_4 (Figure 3(c)). This should be marked as an error, even if the direction of the edge between w_2 and w_3 is controversial, since the structure $[w_2, w_3]$ is no longer a dependent of w_1. It is indeed a NED error. Note that undirected evaluation gives the parses in Figure 3(b) and Figure 3(c) the same score, while if the structure $[w_2, w_3]$ is problematic, there is a major difference in their correctness.

Discussion. Problematic structures are ubiquitous, with more than 40% of the tokens in PTB WSJ appearing in at least one of them (see Section 3). Therefore, even a substantial difference in the attachment between two parsers is not necessarily indicative of a true quality difference. However, an attachment score difference that persists under NED is an indication of a true quality difference, since generally problematic structures are local (i.e., obtained by an *edge-flip*) and NED ignores such errors.

Reporting NED alone is insufficient, as obviously the edge direction does matter in some cases. For example, in adjective–noun structures (e.g., "big house"), the correct edge direction is widely agreed upon ("big"←"house") (Kübler et al., 2009), and thus choosing the wrong direction should be considered an error. Therefore, we suggest evaluating using both NED and attachment score in order to get a full picture of the parser's performance.

A possible criticism on NED is that it is only indifferent to alternative annotations in structures of size 2 (e.g., "to eat") and does not necessarily handle larger problematic structures, such as coordinations

[9] Otherwise, the gold parse would have contained a $w_1 \rightarrow w_2 \rightarrow w_3 \rightarrow w_1$ cycle.

[10] An implementation of NED is available at http://www.cs.huji.ac.il/∼roys02/software/ned.html

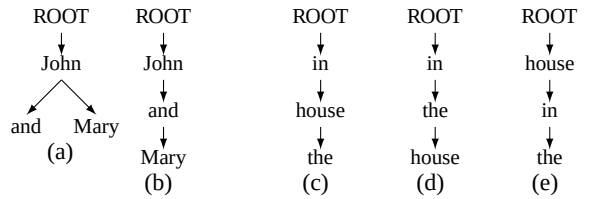

Figure 4: Alternative parses of "John and Mary" and "in the house". Figure 4(a) follows (Collins, 1999), Figure 4(b) follows (Johansson and Nugues, 2007). Figure 4(c) follows (Collins, 1999; Yamada and Matsumoto, 2003). Figure 4(d) and Figure 4(e) show induced parses made by (*km04*,*saj10a*) and *cs09*, respectively.

(see Section 4). For example, Figure 4(a) and Figure 4(b) present two alternative annotations of the sentence "John and Mary". Assume the parse in Figure 4(a) is the gold parse and that in Figure 4(b) is the induced parse. The word "Mary" is a NED error, since its induced parent ("and") is neither its gold child nor its gold grandparent. Thus, NED does not accept all possible annotations of structures of size 3. On the other hand, using a method which accepts all possible annotations of structures of size 3 seems too permissive. A better solution may be to modify the gold standard annotation, so to explicitly annotate problematic structures as such. We defer this line of research to future work.

NED is therefore an evaluation measure which is indifferent to *edge-flips*, and is consequently less sensitive to alternative annotations. We now show that NED is indifferent to the differences between the structures originally learned by the algorithms mentioned in Section 3 and the gold standard annotation in all the problematic cases we consider.

Most of the modifications made are *edge-flips*, and are therefore ignored by NED. The exceptions are coordinations and prepositional phrases which are structures of size 3. In the former, the alternative annotations differ only in a single *edge-flip* (i.e., $CC \rightarrow NNP$), and are thus not NED errors. Regarding prepositional phrases, Figure 4(c) presents the gold standard of "in the house", Figure 4(d) the parse induced by *km04* and *saj10a* and Figure 4(e) the parse induced by *cs09*. As the reader can verify, both induced parses receive a perfect NED score.

In order to further demonstrate NED's insensitivity to alternative annotations, we took two of the three common gold standard annotations (see Section 4) and evaluated them one against the other. We considered section 23 of WSJ following the scheme of (Yamada and Matsumoto, 2003) as the gold standard and of (Collins, 1999) as the evaluated set. Results show that the attachment score is only 85.6%, the undirected accuracy is improved to 90.3%, while the NED score is 95.3%. This shows that NED is significantly less sensitive to the differences between the different annotation schemes, compared to the other evaluation measures.

6 Experimenting with NED

In this section we show that NED indeed reduces the performance difference between the original and the modified parameter sets, thus providing empirical evidence for its validity. For brevity, we present results only for the entire WSJ corpus. Results on WSJ10 are similar. The datasets and decoding algorithms are the same as those used in Section 3.

Table 3 shows the score differences between the parameter sets using attachment score, undirected evaluation and NED. A substantial difference persists under undirected evaluation: a gap of 7.7% in *cs09*, of 3.5% in *saj10a* and of 1.3% in *km04*.

The differences are further reduced using NED. This is consistent with our discussion in Section 5, and shows that undirected evaluation only ignores some of the errors inflicted by *edge-flips*.

For *cs09*, the difference is substantially reduced, but a 4.2% performance gap remains. For *km04* and *saj10a*, the original parameters outperform the new ones by 3.6% and 1% respectively.

We can see that even when ignoring *edge-flips*, some difference remains, albeit not necessarily in the favor of the modified models. This is because we did not directly perform *edge-flips*, but rather *parameter-flips*. The difference is thus a result of second-order effects stemming from the *parameter-flips*. In the next section, we explain why the remaining difference is positive for some algorithms (*cs09*) and negative for others (*km04, saj10a*).

For completeness, Table 4 shows a comparison of some of the current state-of-the-art algorithms, using attachment score, undirected evaluation and NED. The training and test sets are those used in Section 3. The table shows that the relative orderings of the algorithms under NED is different than under the other

Algo.	$Mod. - Orig.$		
	Attach.	Undir.	NED
km04	9.3 (43.9–34.6)	1.3 (54.2–52.9)	–3.6 (63–66.6)
cs09	14.7 (54.6–39.9)	7.7 (56.9–49.2)	4.2 (66.8–62.6)
saj10a	12.7 (54.3–41.6)	3.5 (59.4–55.9)	–1 (66.8–67.8)

Table 3: Differences between the modified and original parameter sets when evaluated using attachment score (*Attach.*), undirected evaluation (*Undir.*), and NED.

measures. This is an indication that NED provides a different perspective on algorithm quality[11].

Algo.	Att_{10}	Att_{∞}	Un_{10}	Un_{∞}	NED_{10}	NED_{∞}

Table 4: A comparison of recent works, using Att (*attachment score*) Un (*undirected evaluation*) and NED, on sentences of length $\leq$ 10 (excluding punctuation) and on all sentences. The gold standard is obtained using the rules of (Yamada and Matsumoto, 2003). *bbdk10*: (Berg-Kirkpatrick et al., 2010), *bc10*: (Blunsom and Cohn, 2010), *cs09*: (Cohen and Smith, 2009), *gggtp10*: (Gillenwater et al., 2010), *km04*: A replication of (Klein and Manning, 2004), *saj10a*: (Spitkovsky et al., 2010a), *saj10c*: (Spitkovsky et al., 2010c), *saj10b**: A lightly-supervised algorithm (Spitkovsky et al., 2010b).

7 Discussion

In this paper we explored two ways of dealing with cases in which there is no clear theoretical justification to prefer one dependency structure over another. Our experiments suggest that it is crucial to deal with such structures if we would like to have a proper evaluation of unsupervised parsing algorithms against a gold standard.

The first way was to modify the parameters of the parsing algorithms so that in cases where such problematic decisions are to be made they follow the gold standard annotation. Indeed, this modification leads to a substantial improvement in the attachment score of the algorithms.

[11]Results may be different than the ones published in the original papers due to the different conversion procedures used in each work. See Section 4 for discussion.

The second way was to change the evaluation. The NED measure we proposed does not punish for differences between gold and induced structures in the problematic cases. Indeed, in Section 6 (Table 3) we show that the differences between the original and modified models are much smaller when evaluating with NED compared to when evaluating with the traditional attachment score.

As Table 3 reveals, however, even when evaluating with NED, there is still some difference between the original and the modified model, for each of the algorithms we consider. Moreover, for two of the algorithms (*km04* and *saj10a*) NED prefers the original model while for one (*cs09*) it prefers the modified version. In this section we explain these patterns and show that they are both consistent and predictable.

Our hypothesis, for which we provide empirical justification, is that in cases where there is no theoretically preferred annotation, NED prefers the structures that are more learnable by DMV. That is, NED gives higher scores to the annotations that better fit the assumptions and modeling decisions of DMV, the model that lies in the basis of the parsing algorithms.

To support our hypothesis we perform an experiment requiring two preparatory steps for each algorithm. First, we construct a supervised version of the algorithm. This supervised version consists of the same statistical model as the original unsupervised algorithm, but the parameters are estimated to maximize the likelihood of a *syntactically annotated* training corpus, rather than of a plain text corpus.

Second, we construct two corpora for the algorithm, both consist of the same text and differ only in their syntactic annotation. The first is annotated with the gold standard annotation. The second is similarly annotated except in the linguistically problematic structures. We replace these structures with the ones that would have been created with the unsupervised version of the algorithm (see Table 1 for the relevant structures for each algorithm)[12]. Each

[12]In cases the structures are comprised of a single edge, the second corpus is obtained from the gold standard by an *edge-flip*. The only exceptions are the cases of the prepositional phrases. Their gold standard and the learned structures for each of the algorithms are shown in Figure 4. In this case, the second corpus is obtained from the gold standard by replacing each prepositional phrase in the gold standard with the corresponding

corpus is divided into a training and a test set.

We then train the supervised version of the algorithms on each of the training sets. We parse the test data twice, once with each of the resulting models. We evaluate both parsed corpora against the corpus annotation from which they originated.

The training set of each corpus consists of sections 2–21 of WSJ20 (i.e., WSJ sentences of length $\leq$20, excluding punctuation)[13] and the test set is section 23 of WSJ$^{\infty}$. Evaluation is performed using both NED and attachment score. The patterns we observed are very similar for both. For brevity, we report only attachment score results.

	km04		*cs09*		*saj10a*	
	Orig.	*Gold*	*Orig.*	*Gold*	*Orig.*	*Gold*
NED, Unsup.	**66.6**	63	62.6	**66.8**	**67.8**	66.8
Sup.	**71.3**	69.9	63.3	**69.9**	**71.8**	69.9

Table 5: The first line shows the NED results from Section 6, when using the original parameters (*Orig.* columns) and the modified parameters (*Gold* columns). The second line shows the results of the supervised versions of the algorithms using the corpus which agrees with the unsupervised model in the problematic cases (*Orig.*) and the gold standard (*Gold*).

The results of our experiment are presented in Table 5 along with a comparison to the NED scores from Section 6. The table clearly demonstrates that a set of parameters (original or modified) is preferred by NED in the unsupervised experiments reported in Section 6 (top line) if and only if the structures produced by this set are better learned by the supervised version of the algorithm (bottom line).

This observation supports our hypothesis that in cases where there is no theoretical preference for one structure over the other, NED (unlike the other measures) prefers the structures that are more consistent with the modeling assumptions lying in the basis of the algorithm. We consider this to be a desired property of a measure since a more consistent model should be preferred where no theoretical preference exists.

learned structure.

[13] In using WSJ20, we follow (Spitkovsky et al., 2010a), which showed that training the DMV on sentences of bounded length yields a higher score than using the entire corpus. We use it as we aim to use an optimal setting.

8 Conclusion

In this paper we showed that the standard evaluation of unsupervised dependency parsers is highly sensitive to problematic annotations. We modified a small set of parameters that controls the annotation in such problematic cases in three leading parsers. This resulted in a major performance boost, which is unindicative of a true difference in quality.

We presented *Neutral Edge Direction* (NED), a measure that is less sensitive to the annotation of local structures. As the problematic structures are generally local, NED is less sensitive to their alternative annotations. In the future, we suggest reporting NED along with the current measures.

Acknowledgements. We would like to thank Shay Cohen for his assistance with his implementation of the DMV parser and Taylor Berg-Kirkpatrick, Phil Blunsom and Jennifer Gillenwater for providing us with their data sets. We would also like to thank Valentin I. Spitkovsky for his comments and for providing us with his data sets.

Abstract

We develop a general dynamic programming technique for the tabulation of transition-based dependency parsers, and apply it to obtain novel, polynomial-time algorithms for parsing with the arc-standard and arc-eager models. We also show how to reverse our technique to obtain new transition-based dependency parsers from existing tabular methods. Additionally, we provide a detailed discussion of the conditions under which the feature models commonly used in transition-based parsing can be integrated into our algorithms.

1 Introduction

Dynamic programming algorithms, also known as tabular or chart-based algorithms, are at the core of many applications in natural language processing. When applied to formalisms such as context-free grammar, they provide polynomial-time parsing algorithms and polynomial-space representations of the resulting parse forests, even in cases where the size of the search space is exponential in the length of the input string. In combination with appropriate semirings, these packed representations can be exploited to compute many values of interest for machine learning, such as best parses and feature expectations (Goodman, 1999; Li and Eisner, 2009).

In this paper, we follow the line of investigation started by Huang and Sagae (2010) and apply dynamic programming to (projective) transition-based dependency parsing (Nivre, 2008). The basic idea, originally developed in the context of push-down automata (Lang, 1974; Tomita, 1986; Billot and Lang, 1989), is that while the number of computations of a transition-based parser may be exponential in the length of the input string, several portions of these computations, when appropriately represented, can be shared. This can be effectively implemented through dynamic programming, resulting in a packed representation of the set of all computations.

The contributions of this paper can be summarized as follows. We provide (declarative specifications of) novel, polynomial-time algorithms for two widely-used transition-based parsing models: arc-standard (Nivre, 2004; Huang and Sagae, 2010) and arc-eager (Nivre, 2003; Zhang and Clark, 2008). Our algorithm for the arc-eager model is the first tabular algorithm for this model that runs in polynomial time. Both algorithms are derived using the same general technique; in fact, we show that this technique is applicable to all transition-parsing models whose transitions can be classified into "shift" and "reduce" transitions. We also show how to reverse the tabulation to derive a new transition system from an existing tabular algorithm for dependency parsing, originally developed by Gómez-Rodríguez et al. (2008). Finally, we discuss in detail the role of feature information in our algorithms, and in particular the conditions under which the feature models traditionally used in transition-based dependency parsing can be integrated into our framework.

While our general approach is the same as the one of Huang and Sagae (2010), we depart from their framework by not representing the computations of a parser as a graph-structured stack in the sense of Tomita (1986). We instead simulate computations as in Lang (1974), which results in simpler algorithm specifications, and also reveals deep similarities between transition-based systems for dependency parsing and existing tabular methods for lexicalized context-free grammars.

2 Transition-Based Dependency Parsing

We start by briefly introducing the framework of transition-based dependency parsing; for details, we refer to Nivre (2008).

2.1 Dependency Graphs

Let $w = w_0 \cdots w_{n-1}$ be a string over some fixed alphabet, where $n \geq 1$ and w_0 is the special token ROOT. A *dependency graph* for w is a directed graph $G = (V_w, A)$, where $V_w = \{0, \ldots, n-1\}$ is the set of nodes, and $A \subseteq V_w \times V_w$ is the set of arcs. Each node in V_w encodes the position of a token in w, and each arc in A encodes a dependency relation between two tokens. To denote an arc $(i, j) \in A$, we write $i \rightarrow j$; here, the node i is the head, and the node j is the dependent. A sample dependency graph is given in the left part of Figure 2.

2.2 Transition Systems

A *transition system* is a structure $S = (C, T, I, C_t)$, where C is a set of *configurations*, T is a finite set of *transitions*, which are partial functions $t : C \rightharpoonup C$, I is a total *initialization function* mapping each input string to a unique initial configuration, and $C_t \subseteq C$ is a set of *terminal configurations*.

The transition systems that we investigate in this paper differ from each other only with respect to their sets of transitions, and are identical in all other aspects. In each of them, a configuration is defined relative to a string w as above, and is a triple $c = (\sigma, \beta, A)$, where σ and β are disjoint lists of nodes from V_w, called *stack* and *buffer*, respectively, and $A \subseteq V_w \times V_w$ is a set of arcs. We denote the stack, buffer and arc set associated with c by $\sigma(c)$, $\beta(c)$, and $A(c)$, respectively. We follow a standard convention and write the stack with its topmost element to the right, and the buffer with its first element to the left; furthermore, we indicate concatenation in the stack and in the buffer by a vertical bar. The initialization function maps each string w to the initial configuration $([], [0, \ldots, |w|-1], \emptyset)$. The set of terminal configurations contains all configurations of the form $([0], [], A)$, where A is some set of arcs.

Given an input string w, a parser based on S processes w from left to right, starting in the initial configuration $I(w)$. At each point, it applies one of the transitions, until at the end it reaches a terminal configuration; the dependency graph defined by the arc set associated with that configuration is then returned as the analysis for w. Formally, a *computation* of S on w is a sequence $\gamma = c_0, \ldots, c_m$, $m \geq 0$, of configurations (defined relative to w) in which each configuration is obtained as the value of the preceding one under some transition. It is called *complete* whenever $c_0 = I(w)$, and $c_m \in C_t$. We note that a computation can be uniquely specified by its initial configuration c_0 and the sequence of its transitions, understood as a string over T. Complete computations, where c_0 is fixed, can be specified by their transition sequences alone.

$$
\begin{aligned}
(\sigma, i|\beta, A) &\vdash (\sigma|i, \beta, A) && \text{(sh)} \\
(\sigma|i|j, \beta, A) &\vdash (\sigma|j, \beta, A \cup \{j \rightarrow i\}) && \text{(la)} \\
(\sigma|i|j, \beta, A) &\vdash (\sigma|i, \beta, A \cup \{i \rightarrow j\}) && \text{(ra)}
\end{aligned}
$$

Figure 1: Transitions in the arc-standard model.

3 Arc-Standard Model

To introduce the core concepts of the paper, we first look at a particularly simple model for transition-based dependency parsing, known as the *arc-standard model*. This model has been used, in slightly different variants, by a number of parsers (Nivre, 2004; Attardi, 2006; Huang and Sagae, 2010).

3.1 Transition System

The arc-standard model uses three types of transitions: SHIFT (sh) removes the first node in the buffer and pushes it to the stack. LEFT-ARC (la) creates a new arc with the topmost node on the stack as the head and the second-topmost node as the dependent, and removes the second-topmost node from the stack. RIGHT-ARC (ra) is symmetric to LEFT-ARC in that it creates an arc with the second-topmost node as the head and the topmost node as the dependent, and removes the topmost node.

The three transitions can be formally specified as in Figure 1. The right half of Figure 2 shows a complete computation of the arc-standard transition system, specified by its transition sequence. The picture also shows the contents of the stack over the course of the computation; more specifically, column i shows the stack $\sigma(c_i)$ associated with the configuration c_i.

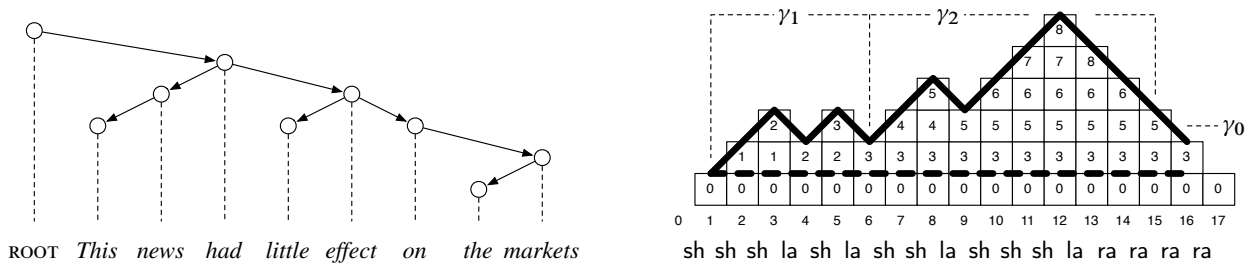

Figure 2: A dependency tree (left) and a computation generating this tree in the arc-standard system (right).

3.2 Push Computations

The key to the tabulation of transition-based dependency parsers is to find a way to decompose computations into smaller, shareable parts. For the arc-standard model, as well as for the other transition systems that we consider in this paper, we base our decomposition on the concept of *push computations*. By this, we mean computations

$$\gamma = c_0, \ldots, c_m, \quad m \geq 1,$$

on some input string w with the following properties:

(P1) The initial stack $\sigma(c_0)$ is not modified during the computation, and is not even exposed after the first transition: For every $1 \leq i \leq m$, there exists a non-empty stack σ_i such that $\sigma(c_i) = \sigma(c_0)|\sigma_i$.

(P2) The overall effect of the computation is to push a single node to the stack: The stack $\sigma(c_m)$ can be written as $\sigma(c_m) = \sigma(c_0)|h$, for some $h \in V_w$.

We can verify that the computation in Figure 2 is a push computation. We can also see that it contains shorter computations that are push computations; one example is the computation $\gamma_0 = c_1, \ldots, c_{16}$, whose overall effect is to push the node 3. In Figure 2, this computation is marked by the zig-zag path traced in bold. The dashed line delineates the stack $\sigma(c_1)$, which is not modified during γ_0.

Every computation that consists of a single sh transition is a push computation. Starting from these atoms, we can build larger push computations by means of two (partial) binary operations f_{la} and f_{ra}, defined as follows. Let $\gamma_1 = c_{10}, \ldots, c_{1m_1}$ and $\gamma_2 = c_{20}, \ldots, c_{2m_2}$ be push computations on the same input string w such that $c_{1m_1} = c_{20}$. Then

$$f_{\mathsf{ra}}(\gamma_1, \gamma_2) = c_{10}, \ldots, c_{1m_1}, c_{21}, \ldots, c_{2m_2}, c,$$

where c is obtained from c_{2m_2} by applying the ra transition. (The operation f_{la} is defined analogously.) We can verify that $f_{\mathsf{ra}}(\gamma_1, \gamma_2)$ is another push computation. For instance, with respect to Figure 2, $f_{\mathsf{ra}}(\gamma_1, \gamma_2) = \gamma_0$. Conversely, we say that the push computation γ_0 can be *decomposed* into the subcomputations γ_1 and γ_2, and the operation f_{ra}.

3.3 Deduction System

Building on the compositional structure of push computations, we now construct a deduction system (in the sense of Shieber et al. (1995)) that tabulates the computations of the arc-standard model for a given input string $w = w_0 \cdots w_{n-1}$. For $0 \leq i \leq n$, we shall write β_i to denote the buffer $[i, \ldots, n-1]$. Thus, β_0 denotes the full buffer, associated with the initial configuration $I(w)$, and β_n denotes the empty buffer, associated with a terminal configuration $c \in C_t$.

Item form. The items of our deduction system take the form $[i, h, j]$, where $0 \leq i \leq h < j \leq n$. The intended interpretation of an item $[i, h, j]$ is: For every configuration c_0 with $\beta(c_0) = \beta_i$, there exists a push computation $\gamma = c_0, \ldots, c_m$ such that $\beta(c_m) = \beta_j$, and $\sigma(c_m) = \sigma(c_0)|h$.

Goal. The only goal item is $[0, 0, n]$, asserting that there exists a complete computation for w.

Axioms. For every stack σ, position $i < n$ and arc set A, by a single sh transition we obtain the push computation $(\sigma, \beta_i, A), (\sigma|i, \beta_{i+1}, A)$. Therefore we can take the set of all items of the form $[i, i, i+1]$ as the axioms of our system.

Inference rules. The inference rules parallel the composition operations f_{la} and f_{ra}. Suppose that we have deduced the items $[i, h_1, k]$ and $[k, h_2, j]$, where $0 \leq i \leq h_1 < k \leq h_2 < j \leq n$. The item $[i, h_1, k]$ asserts that for every configuration c_{10}

$$\textbf{Item form: } [i,h,j]\,,\ 0 \le i \le h < j \le |w| \qquad \textbf{Goal: } [0,0,|w|] \qquad \textbf{Axioms: } [i,i,i+1]$$

$$\textbf{Inference rules: } \frac{[i,h_1,k] \quad [k,h_2,j]}{[i,h_2,j]}\ (\mathsf{la}; h_2 \to h_1) \qquad \frac{[i,h_1,k] \quad [k,h_2,j]}{[i,h_1,j]}\ (\mathsf{ra}; h_1 \to h_2)$$

Figure 3: Deduction system for the arc-standard model.

with $\beta(c_{10}) = \beta_i$, there exists a push computation $\gamma_1 = c_{10}, \ldots, c_{1m_1}$ such that $\beta(c_{1m_1}) = \beta_k$, and $\sigma(c_{1m_1}) = \sigma(c_{10})|h_1$. Using the item $[k, h_2, j]$, we deduce the existence of a second push computation $\gamma_2 = c_{20}, \ldots, c_{2m_2}$ such that $c_{20} = c_{1m_1}$, $\beta(c_{2m_2}) = \beta_j$, and $\sigma(c_{2m_2}) = \sigma(c_{10})|h_1|h_2$. By means of f_{ra}, we can then compose γ_1 and γ_2 into a new push computation

$$f_{\mathsf{ra}}(\gamma_1, \gamma_2) \;=\; c_{10}, \ldots, c_{1m_1}, c_{21}, \ldots, c_{2m_2}, c\,.$$

Here, $\beta(c) = \beta_j$, and $\sigma(c) = \sigma(c_{10})|h_1$. Therefore, we may generate the item $[i, h_1, j]$. The inference rule for la can be derived analogously.

Figure 3 shows the complete deduction system.

3.4 Completeness and Non-Ambiguity

We have informally argued that our deduction system is sound. To show completeness, we prove the following lemma: For all $0 \le i \le h < j \le |w|$ and every push computation $\gamma = c_0, \ldots, c_m$ on w with $\beta(c_0) = \beta_i$, $\beta(c_m) = \beta_j$ and $\sigma(c_m) = \sigma(c_0)|h$, the item $[i, h, j]$ is generated. The proof is by induction on m, and there are two cases:

$m = 1$. In this case, γ consists of a single sh transition, $h = i$, $j = i + 1$, and we need to show that the item $[i, i, i + 1]$ is generated. This holds because this item is an axiom.

$m \ge 2$. In this case, γ ends with either a la or a ra transition. Let c be the rightmost configuration in γ that is different from c_m and whose stack size is one larger than the size of $\sigma(c_0)$. The computations

$$\gamma_1 = c_0, \ldots, c \quad \text{and} \quad \gamma_2 = c, \ldots, c_{m-1}$$

are both push computations with strictly fewer transitions than γ. Suppose that the last transition in γ is ra. In this case, $\beta(c) = \beta_k$ for some $i < k < j$, $\sigma(c) = \sigma(c_0)|h$ with $h < k$, $\beta(c_{m-1}) = \beta_j$, and $\sigma(c_{m-1}) = \sigma(c_0)|h|h'$ for some $k \le h' < j$. By induction, we may assume that we have generated items $[i, h, k]$ and $[k, h', j]$. Applying the inference rule for ra, we deduce the item $[i, h, j]$. An analogous argument can be made for f_{la}.

Apart from being sound and complete, our deduction system also has the property that it assigns at most one derivation to a given item. To see this, note that in the proof of the lemma, the choice of c is uniquely determined: If we take any other configuration c' that meets the selection criteria, then the computation $\gamma_2' = c', \ldots, c_{m-1}$ is not a push computation, as it contains c as an intermediate configuration, and thereby violates property P1.

3.5 Discussion

Let us briefly take stock of what we have achieved so far. We have provided a deduction system capable of tabulating the set of all computations of an arc-standard parser on a given input string, and proved the correctness of this system relative to an interpretation based on push computations. Inspecting the system, we can see that its generic implementation takes space in $\mathcal{O}(|w|^3)$ and time in $\mathcal{O}(|w|^5)$.

Our deduction system is essentially the same as the one for the CKY algorithm for bilexicalized context-free grammar (Collins, 1996; Gómez-Rodríguez et al., 2008). This equivalence reveals a deep correspondence between the arc-standard model and bilexicalized context-free grammar, and, via results by Eisner and Satta (1999), to head automata. In particular, Eisner's and Satta's "hook trick" can be applied to our tabulation to reduce its runtime to $\mathcal{O}(|w|^4)$.

4 Adding Features

The main goal with the tabulation of transition-based dependency parsers is to obtain a representation based on which semiring values such as the highest-scoring computation for a given input (and with it, a dependency tree) can be calculated. Such computations involve the use of feature information. In this section, we discuss how our tabulation of the arc-standard system can be extended for this purpose.

$$\frac{[i, h_1, k; \langle x_2, x_1\rangle, \langle x_1, x_3\rangle] : v_1 \quad [k, h_2, j; \langle x_1, x_3\rangle, \langle x_3, x_4\rangle] : v_2}{[i, h_1, j; \langle x_2, x_1\rangle, \langle x_1, x_3\rangle] : v_1 + v_2 + \langle x_3, x_4\rangle \cdot \vec{\alpha}_{\mathsf{ra}}} \ (\mathsf{ra})$$

$$\frac{[i, h, j; \langle x_2, x_1\rangle, \langle x_1, x_3\rangle] : v}{[j, j, j+1; \langle x_1, x_3\rangle, \langle x_3, w_j\rangle] : \langle x_1, x_3\rangle \cdot \vec{\alpha}_{\mathsf{sh}}} \ (\mathsf{sh})$$

Figure 4: Extended inference rules under the feature model $\Phi = \langle \mathsf{s}_1.\mathsf{w}, \mathsf{s}_0.\mathsf{w}\rangle$. The annotations indicate how to calculate a candidate for an update of the Viterbi score of the conclusion using the Viterbi scores of the premises.

4.1 Scoring Computations

For the sake of concreteness, suppose that we want to score computations based on the following model, taken from Zhang and Clark (2008). The score of a computation γ is broken down into a sum of scores $score(t, c_t)$ for combinations of a transition t in the transition sequence associated with γ and the configuration c_t in which t was taken:

$$score(\gamma) \ = \ \sum_{t \in \gamma} score(t, c_t) \qquad (1)$$

The score $score(t, c_t)$ is defined as the dot product of the feature representation of c_t relative to a *feature model* Φ and a transition-specific weight vector $\vec{\alpha}_t$:

$$score(t, c_t) \ = \ \Phi(c_t) \cdot \vec{\alpha}_t$$

The feature model Φ is a vector $\langle \phi_1, \ldots, \phi_n\rangle$ of elementary *feature functions*, and the feature representation $\Phi(c)$ of a configuration c is a vector $\vec{x} = \langle \phi_1(c), \ldots, \phi_n(c)\rangle$ of atomic values. Two examples of feature functions are the word form associated with the topmost and second-topmost node on the stack; adopting the notation of Huang and Sagae (2010), we will write these functions as $\mathsf{s}_0.\mathsf{w}$ and $\mathsf{s}_1.\mathsf{w}$, respectively. Feature functions like these have been used in several parsers (Nivre, 2006; Zhang and Clark, 2008; Huang et al., 2009).

4.2 Integration of Feature Models

To integrate feature models into our tabulation of the arc-standard system, we can use extended items of the form $[i, h, j; \vec{x}_L, \vec{x}_R]$ with the same intended interpretation as the old items $[i, h, j]$, except that the initial configuration of the asserted computations $\gamma = c_0, \ldots, c_m$ now is required to have the feature representation $\vec{x}_L$, and the final configuration is required to have the representation $\vec{x}_R$:

$$\Phi(c_0) = \vec{x}_L \quad \text{and} \quad \Phi(c_m) = \vec{x}_R$$

We shall refer to the vectors $\vec{x}_L$ and $\vec{x}_R$ as the *left-context vector* and the *right-context vector* of the computation γ, respectively.

We now need to change the deduction rules so that they become faithful to the extended interpretation. Intuitively speaking, we must ensure that the feature values can be computed along the inference rules. As a concrete example, consider the feature model $\Phi = \langle \mathsf{s}_1.\mathsf{w}, \mathsf{s}_0.\mathsf{w}\rangle$. In order to integrate this model into our tabulation, we change the rule for ra as in Figure 4, where $x_1, \ldots, x_4$ range over possible word forms. The shared variable occurrences in this rule capture the constraints that hold between the feature values of the subcomputations γ_1 and γ_2 asserted by the premises, and the computations $f_{\mathsf{ra}}(\gamma_1, \gamma_2)$ asserted by the conclusion. To illustrate this, suppose that γ_1 and γ_2 are as in Figure 2. Then the three occurrences of x_3 for instance encode that

$$[\mathsf{s}_0.\mathsf{w}](c_6) = [\mathsf{s}_1.\mathsf{w}](c_{15}) = [\mathsf{s}_0.\mathsf{w}](c_{16}) = w_3 \,.$$

We also need to extend the axioms, which correspond to computations consisting of a single sh transition. The most conservative way to do this is to use a generate-and-test technique: Extend the existing axioms by all valid choices of left-context and right-context vectors, that is, by all pairs $\vec{x}_L, \vec{x}_R$ such that there exists a configuration c with $\Phi(c) = \vec{x}_L$ and $\Phi(\mathsf{sh}(c)) = \vec{x}_R$. The task of filtering out useless guesses can then be delegated to the deduction system.

A more efficient way is to only have one axiom, for the case where $c = I(w)$, and to add to the deduction system a new, unary inference rule for sh as in Figure 4. This rule only creates items whose left-context vector is the right-context vector of some other item, which prevents the generation of useless items. In the following, we take this second approach, which is also the approach of Huang and Sagae (2010).

$$\frac{[i, h, j; \langle x_2, x_1\rangle, \langle x_1, x_3\rangle] : (p, v)}{[j, j, j+1; \langle x_1, x_3\rangle, \langle x_3, w_j\rangle] : (p+\sigma, \sigma)}\ (\mathsf{sh})\,,\ \text{where } \sigma = \langle x_1, x_3\rangle \cdot \vec{\alpha}_{\mathsf{sh}}$$

$$\frac{[i, h_1, k; \langle x_2, x_1\rangle, \langle x_1, x_3\rangle] : (p_1, v_1) \quad [k, h_2, j; \langle x_1, x_3\rangle, \langle x_3, x_4\rangle] : (p_2, v_2)}{[i, h_1, j; \langle x_2, x_1\rangle, \langle x_1, x_3\rangle] : (p_1 + v_2 + \rho, v_1 + v_2 + \rho)}\ (\mathsf{ra})\,,\ \text{where } \rho = \langle x_3, x_4\rangle \cdot \vec{\alpha}_{\mathsf{ra}}$$

Figure 5: Extended inference rules under the feature model $\Phi = \langle \mathsf{s}_0.\mathsf{w}, \mathsf{s}_1.\mathsf{w}\rangle$. The annotations indicate how to calculate a candidate for an update of the prefix score and Viterbi score of the conclusion.

4.3 Computing Viterbi Scores

Once we have extended our deduction system with feature information, many values of interest can be computed. One simple example is the *Viterbi score* for an input w, defined as

$$\arg\max_{\gamma \in \Gamma(w)} \mathit{score}(\gamma)\,, \tag{2}$$

where $\Gamma(w)$ denotes the set of all complete computations for w. The score of a complex computation $f_t(\gamma_1, \gamma_2)$ is the sum of the scores of its subcomputations γ_1, γ_2, plus the transition-specific dot product. Since this dot product only depends on the feature representation of the final configuration of γ_2, the Viterbi score can be computed on top of the inference rules using standard techniques. The crucial calculation is indicated in Figure 4.

4.4 Computing Prefix Scores

Another interesting value is the *prefix score* of an item, which, apart from the Viterbi score, also includes the cost of the best search path leading to the item. Huang and Sagae (2010) use this quantity to order the items in a beam search on top of their dynamic programming method. In our framework, prefix scores can be computed as indicated in Figure 5. Alternatively, we can also use the more involved calculation employed by Huang and Sagae (2010), which allows them to get rid of the left-context vector from their items.[1]

4.5 Compatibility

So far we have restricted our attention to a concrete and extremely simplistic feature model. The feature models that are used in practical systems are considerably more complex, and not all of them are compatible with our framework in the sense that they can be integrated into our deduction system in the way described in Section 4.2.

For a simple example of a feature model that is incompatible with our tabulation, consider the model $\Phi' = \langle \mathsf{s}_0.\mathsf{rc}.\mathsf{w}\rangle$, whose single feature function extracts the word form of the right child (rc) of the topmost node on the stack. Even if we know the values of this feature for two computations γ_1, γ_2, we have no way to compute its value for the composed computation $f_{\mathsf{ra}}(\gamma_1, \gamma_2)$: This value coincides with the word form of the topmost node on the stack associated with γ_2, but in order to have access to it in the context of the ra rule, our feature model would need to also include the feature function $\mathsf{s}_0.\mathsf{w}$.

The example just given raises the question whether there is a general criterion based on which we can decide if a given feature model is compatible with our tabulation. An attempt to provide such a criterion has been made by Huang and Sagae (2010), who define a constraint on feature models called "monotonicity" and claim that this constraint guarantees that feature values can be computed using their dynamic programming approach. Unfortunately, this claim is wrong. In particular, the feature model Φ' given above is "monotonic", but cannot be tabulated, neither in our nor in their framework. In general, it seems clear that the question of compatibility is a question about the *relation* between the tabulation and the feature model, and not about the feature model alone. To find practically useful characterizations of compatibility is an interesting avenue for future research.

5 Arc-Eager Model

Up to now, we have only discussed the arc-standard model. In this section, we show that the framework of push computations also provides a tabulation of another widely-used model for dependency parsing, the *arc-eager model* (Nivre, 2003).

[1] The essential idea in the calculation by Huang and Sagae (2010) is to delegate (in the computation of the Viterbi score) the scoring of sh transitions to the inference rules for la/ra.

$$(\sigma, i|\beta, A) \vdash (\sigma|i, \beta, A) \quad (\mathsf{sh})$$
$$(\sigma|i, j|\beta, A) \vdash (\sigma, j|\beta, A \cup \{j \rightarrow i\}) \quad (\mathsf{la_e})$$
only if i does not have an incoming arc
$$(\sigma|i, j|\beta, A) \vdash (\sigma|i|j, \beta, A \cup \{i \rightarrow j\}) \quad (\mathsf{ra_e})$$
$$(\sigma|i, \beta, A) \vdash (\sigma, \beta, A) \quad (\mathsf{re})$$
only if i has an incoming arc

Figure 6: Transitions in the arc-eager model.

5.1 Transition System

The arc-eager model has three types of transitions, shown in Figure 6: SHIFT (sh) works just like in arc-standard, moving the first node in the buffer to the stack. LEFT-ARC ($\mathsf{la_e}$) creates a new arc with the first node in the buffer as the head and the topmost node on the stack as the dependent, and pops the stack. It can only be applied if the topmost node on the stack has not already been assigned a head, so as to preserve the single-head constraint. RIGHT-ARC ($\mathsf{ra_e}$) creates an arc in the opposite direction as LEFT-ARC, and moves the first node in the buffer to the stack. Finally, REDUCE (re) simply pops the stack; it can only be applied if the topmost node on the stack has already been assigned a head.

Note that, unlike in the case of arc-standard, the parsing process in the arc-eager model is not bottom-up: the right dependents of a node are attached before they have been assigned their own right dependents.

5.2 Shift-Reduce Parsing

If we look at the specification of the transitions of the arc-standard and the arc-eager model and restrict our attention to the effect that they have on the stack and the buffer, then we can see that all seven transitions fall into one of three types:

$$(\sigma, i|\beta) \vdash (\sigma|i, \beta) \quad \mathsf{sh}, \mathsf{ra_e} \quad \text{(T1)}$$
$$(\sigma|i|j, \beta) \vdash (\sigma|j, \beta) \quad \mathsf{la} \quad \text{(T2)}$$
$$(\sigma|i, \beta) \vdash (\sigma, \beta) \quad \mathsf{ra}, \mathsf{la_e}, \mathsf{re} \quad \text{(T3)}$$

We refer to transitions of type T1 as *shift* and to transitions of type T2 and T3 as *reduce transitions*.

The crucial observation now is that the concept of push computations and the approach to their tabulation that we have taken for the arc-standard system can easily be generalized to other transition systems whose transitions are of the type *shift* or *reduce*. In particular, the proof of the correctness of our deduction system that we gave in Section 3 still goes through if instead of sh we write "shift" and instead of la and ra we write "reduce".

5.3 Deduction System

Generalizing our construction for the arc-standard model along these lines, we obtain a tabulation of the arc-eager model. Just like in the case of arc-standard, each single shift transition in that model (be it sh or $\mathsf{ra_e}$) constitutes a push computation, while the reduce transitions induce operations $f_{\mathsf{la_e}}$ and f_{re}. The only difference is that the preconditions of $\mathsf{la_e}$ and re must be met. Therefore, $f_{\mathsf{la_e}}(\gamma_1, \gamma_2)$ is only defined if the topmost node on the stack in the final configuration of γ_2 has not yet been assigned a head, and $f_{\mathsf{re}}(\gamma_1, \gamma_2)$ is only defined in the opposite case.

Item form. In our deduction system for the arc-eager model we use items of the form $[i, h^b, j]$, where $0 \leq i \leq h < j \leq |w|$, and $b \in \{0, 1\}$. An item $[i, h^b, j]$ has the same meaning as the corresponding item in our deduction system for arc-standard, but also keeps record of whether the node h has been assigned a head ($b = 1$) or not ($b = 0$).

Goal. The only goal item is $[0, 0^0, |w|]$. (The item $[0, 0^1, |w|]$ asserts that the node 0 has a head, which never happens in a complete computation.)

Axioms. Reasoning as in arc-standard, the axioms of the deduction system for the arc-eager model are the items of the form $[i, i^0, i + 1]$ and $[j, j^1, j + 1]$, where $j > 0$: the former correspond to the push computations obtained from a single sh, the latter to those obtained from a single $\mathsf{ra_e}$, which apart from shifting a node also assigns it a head.

Inference rules. Also analogously to arc-standard, if we know that there exists a push computation γ_1 of the form asserted by the item $[i, h^b, k]$, and a push computation γ_2 of the form asserted by $[k, g^0, j]$, where $j < |w|$, then we can build the push computation $f_{\mathsf{la_e}}(\gamma_1, \gamma_2)$ of the form asserted by the item $[i, h^b, j]$. Similarly, if γ_2 is of the form asserted by $[k, g^1, j]$, then we can build $f_{\mathsf{re}}(\gamma_1, \gamma_2)$, which again is of the form by asserted $[i, h^b, j]$. Thus:

$$\frac{[i, i^b, k] \quad [k, k^0, j]}{[i, i^b, j]} \ (\mathsf{la_e}), \qquad \frac{[i, i^b, k] \quad [k, k^1, j]}{[i, i^b, j]} \ (\mathsf{re}).$$

Item form: $[i^b, j]\,, 0 \leq i < j \leq |w|\,, b \in \{0,1\}$ **Goal:** $[0^0, |w|]$ **Axioms:** $[0^0, 1]$

$$\frac{[i^b, j]}{[j^0, j+1]}\ (\mathsf{sh}) \qquad \frac{[i^b, k]\ \ [k^0, j]}{[i^b, j]}\ (\mathsf{la_e}; j \rightarrow k)\,, j < |w| \qquad \frac{[i^b, j]}{[j^1, j+1]}\ (\mathsf{ra_e}; i \rightarrow j) \qquad \frac{[i^b, k]\ \ [k^1, j]}{[i^b, j]}\ (\mathsf{re})$$

Figure 7: Deduction system for the arc-eager model.

As mentioned above, the correctness and non-ambiguity of the system can be proved as in Section 3. Features can be added in the same way as discussed in Section 4.

5.4 Computational Complexity

Looking at the inference rules, it is clear that an implementation of the deduction system for arc-eager takes space in $\mathcal{O}(|w|^3)$ and time in $\mathcal{O}(|w|^5)$, just like in the case of arc-standard. However, a closer inspection reveals that we can give even tighter bounds.

In all derivable items $[i, h^b, j]$, it holds that $i = h$. This can easily be shown by induction: The property holds for the axioms, and the first two indexes of a consequent of a deduction rule coincide with the first two indexes of the left antecedent. Thus, if we use the notation $[i^b, k]$ as a shorthand for $[i, i^b, k]$, then we can rewrite the inference rules for the arc-eager system as in Figure 7, where, additionally, we have added unary rules for sh and ra and restricted the set of axioms along the lines set out in Section 4.2. With this formulation, it is apparent that the space complexity of the generic implementation of the deduction system is in fact even in $\mathcal{O}(|w|^2)$, and its time complexity is in $\mathcal{O}(|w|^3)$.

6 Hybrid Model

We now reverse the approach that we have taken in the previous sections: Instead of tabulating a transition system in order to get a dynamic-programming parser that simulates its computations, we start with a tabular parser and derive a transition system from it. In the new model, dependency trees are built bottom-up as in the arc-standard model, but the set of all computations in the system can be tabulated in space $\mathcal{O}(|w|^2)$ and time $\mathcal{O}(|w|^3)$, as in arc-eager.

6.1 Deduction System

Gómez-Rodríguez et al. (2008) present a deductive version of the dependency parser of Yamada and Matsumoto (2003); their deduction system is given in Figure 8. The generic implementation of the deduction system takes space $\mathcal{O}(|w|^2)$ and time $\mathcal{O}(|w|^3)$.

In the original interpretation of the deduction system, an item $[i, j]$ asserts the existence of a pair of (projective) dependency trees: the first tree rooted at token w_i, having all nodes in the substring $w_i \cdots w_{k-1}$ as descendants, where $i < k \leq j$; and the second tree rooted at token w_j, having all nodes in the substring $w_k \cdots w_j$ as descendants. (Note that we use fencepost indexes, while Gómez-Rodríguez et al. (2008) indexes positions.)

6.2 Transition System

In the context of our tabulation framework, we adopt a new interpretation of items: An item $[i, j]$ has the same meaning as an item $[i, i, j]$ in the tabulation of the arc-standard model; for every configuration c with $\beta(c) = \beta_i$, it asserts the existence of a push computation that starts with c and ends with a configuration c' for which $\beta(c') = \beta_j$ and $\sigma(c') = \sigma(c)|i$.

If we interpret the inference rules of the system in terms of composition operations on push computations as usual, and also take the intended direction of the dependency arcs into account, then this induces a transition system with three transitions:

$$\begin{aligned}
(\sigma, i\,|\beta, A) &\vdash (\sigma|i, \beta, A) && (\mathsf{sh})\\
(\sigma|i, j\,|\beta, A) &\vdash (\sigma, j\,|\beta, A \cup \{j \rightarrow i\}) && (\mathsf{la_h})\\
(\sigma|i\,|j, \beta, A) &\vdash (\sigma|i, \beta, A \cup \{i \rightarrow j\}) && (\mathsf{ra})
\end{aligned}$$

We call this transition system the *hybrid model*, as sh and ra are just like in arc-standard, while $\mathsf{la_h}$ is like the LEFT-ARC transition in the arc-eager model ($\mathsf{la_e}$), except that it does not have the precondition. Like the arc-standard but unlike the arc-eager model, the hybrid model builds dependencies bottom-up.

7 Conclusion

In this paper, we have provided a general technique for the tabulation of transition-based dependency parsers, and applied it to obtain dynamic programming algorithms for two widely-used parsing models,

Item form: $[i, j]\,, 0 \leq i < j \leq |w|$ **Goal:** $[0, |w|]$ **Axioms:** $[0, 1]$

Inference rules: $\dfrac{[i, j]}{[j, j+1]}$ (sh) $\quad \dfrac{[i, k] \quad [k, j]}{[i, j]}$ $(\mathsf{la_h}; j \rightarrow k)\,, j < |w|$ $\quad \dfrac{[i, k] \quad [k, j]}{[i, j]}$ $(\mathsf{ra}; i \rightarrow k)$

Figure 8: Deduction system for the hybrid model.

arc-standard and (for the first time) arc-eager. The basic idea behind our technique is the same as the one implemented by Huang and Sagae (2010) for the special case of the arc-standard model, but instead of their graph-structured stack representation we use a tabulation akin to Lang's approach to the simulation of pushdown automata (Lang, 1974). This considerably simplifies both the presentation and the implementation of parsing algorithms. It has also enabled us to give simple proofs of correctness and establish relations between transition-based parsers and existing parsers based on dynamic programming.

While this paper has focused on the theoretical aspects and the analysis of dynamic programming versions of transition-based parsers, an obvious avenue for future work is the evaluation of the empirical performance and efficiency of these algorithms in connection with specific feature models. The feature models used in transition-based dependency parsing are typically very expressive, and exhaustive search with them quickly becomes impractical even for our cubic-time algorithms of the arc-eager and hybrid model. However, Huang and Sagae (2010) have provided evidence that the use of dynamic programming on top of a transition-based dependency parser can improve accuracy even without exhaustive search. The tradeoff between expressivity of the feature models on the one hand and the efficiency of the search on the other is a topic that we find worth investigating. Another interesting observation is that dynamic programming makes it possible to use predictive features, which cannot easily be integrated into a non-tabular transition-based parser. This could lead to the development of parsing models that cross the border between transition-based and tabular parsing.

Abstract

CCGs are directly compatible with binary-branching bottom-up parsing algorithms, in particular CKY and shift-reduce algorithms. While the chart-based approach has been the dominant approach for CCG, the shift-reduce method has been little explored. In this paper, we develop a shift-reduce CCG parser using a discriminative model and beam search, and compare its strengths and weaknesses with the chart-based C&C parser. We study different errors made by the two parsers, and show that the shift-reduce parser gives competitive accuracies compared to C&C. Considering our use of a small beam, and given the high ambiguity levels in an automatically-extracted grammar and the amount of information in the CCG lexical categories which form the shift actions, this is a surprising result.

1 Introduction

Combinatory Categorial Grammar (CCG; Steedman (2000)) is a lexicalised theory of grammar which has been successfully applied to a range of problems in NLP, including treebank creation (Hockenmaier and Steedman, 2007), syntactic parsing (Hockenmaier, 2003; Clark and Curran, 2007), logical form construction (Bos et al., 2004) and surface realization (White and Rajkumar, 2009). From a parsing perspective, the C&C parser (Clark and Curran, 2007) has been shown to be competitive with state-of-the-art statistical parsers on a variety of test suites, including those consisting of grammatical relations (Clark and Curran, 2007), Penn Treebank phrase-structure trees (Clark and Curran, 2009), and unbounded dependencies (Rimell et al., 2009).

The binary branching nature of CCG means that it is naturally compatible with bottom-up parsing algorithms such as shift-reduce and CKY (Ades and Steedman, 1982; Steedman, 2000). However, the parsing work by Clark and Curran (2007), and also Hockenmaier (2003) and Fowler and Penn (2010), has only considered chart-parsing. In this paper we fill a gap in the CCG literature by developing a shift-reduce parser for CCG.

Shift-reduce parsers have become popular for dependency parsing, building on the initial work of Yamada and Matsumoto (2003) and Nivre and Scholz (2004). One advantage of shift-reduce parsers is that the scoring model can be defined over actions, allowing highly efficient parsing by using a greedy algorithm in which the highest scoring action (or a small number of possible actions) is taken at each step. In addition, high accuracy can be maintained by using a model which utilises a rich set of features for making each local decision (Nivre et al., 2006).

Following recent work applying global discriminative models to large-scale structured prediction problems (Collins and Roark, 2004; Miyao and Tsujii, 2005; Clark and Curran, 2007; Finkel et al., 2008), we build our shift-reduce parser using a global linear model, and compare it with the chart-based C&C parser. Using standard development and test sets from CCGbank, our shift-reduce parser gives a labeled F-measure of 85.53%, which is competitive with the 85.45% F-measure of the C&C parser on recovery of predicate-argument dependencies from CCGbank. Hence our work shows that

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 683–692,
Portland, Oregon, June 19-24, 2011.

transition-based parsing can be successfully applied to CCG, improving on earlier attempts such as Hassan et al. (2008). Detailed analysis shows that our shift-reduce parser yields a higher precision, lower recall and higher F-score on most of the common CCG dependency types compared to C&C.

One advantage of the shift-reduce parser is that it easily handles sentences for which it is difficult to find a spanning analysis, which can happen with CCG because the lexical categories at the leaves of a derivation place strong contraints on the set of possible derivations, and the supertagger which provides the lexical categories sometimes makes mistakes. Unlike the C&C parser, the shift-reduce parser naturally produces fragmentary analyses when appropriate (Nivre et al., 2006), and can produce sensible local structures even when a full spanning analysis cannot be found.[1]

Finally, considering this work in the wider parsing context, it provides an interesting comparison between heuristic beam search using a rich set of features, and optimal dynamic programming search where the feature range is restricted. We are able to perform this comparison because the use of the CCG supertagger means that the C&C parser is able to build the complete chart, from which it can find the optimal derivation, with no pruning whatsoever at the parsing stage. In contrast, the shift-reduce parser uses a simple beam search with a relatively small beam. Perhaps surprisingly, given the ambiguity levels in an automatically-extracted grammar, and the amount of information in the CCG lexical categories which form the shift actions, the shift-reduce parser using heuristic beam search is able to outperform the chart-based parser.

2 CCG Parsing

CCG, and the application of CCG to wide-coverage parsing, is described in detail elsewhere (Steedman, 2000; Hockenmaier, 2003; Clark and Curran, 2007). Here we provide only a short description.

During CCG parsing, adjacent categories are combined using CCG's combinatory rules. For example, a verb phrase in English ($S\backslash NP$) can combine with an NP to its left using function application:

$$NP \;\; S\backslash NP \Rightarrow S$$

Categories can also combine using function composition, allowing the combination of "may" $((S\backslash NP)/(S\backslash NP))$ and "like" $((S\backslash NP)/NP)$ in coordination examples such as "John may like but may detest Mary":

$$(S\backslash NP)/(S\backslash NP) \;\; (S\backslash NP)/NP \Rightarrow (S\backslash NP)/NP$$

In addition to binary rules, such as function application and composition, there are also unary rules which operate on a single category in order to change its type. For example, forward type-raising can change a subject NP into a complex category looking to the right for a verb phrase:

$$NP \Rightarrow S/(S\backslash NP)$$

An example CCG derivation is given in Section 3.

The resource used for building wide-coverage CCG parsers of English is CCGbank (Hockenmaier and Steedman, 2007), a version of the Penn Treebank in which each phrase-structure tree has been transformed into a normal-form CCG derivation. There are two ways to extract a grammar from this resource. One approach is to extract a lexicon, i.e. a mapping from words to sets of lexical categories, and then manually define the combinatory rule schemas, such as functional application and composition, which combine the categories together. The derivations in the treebank are then used to provide training data for the statistical disambiguation model. This is the method used in the C&C parser.[2]

The second approach is to read the complete grammar from the derivations, by extracting combinatory rule *instances* from the local trees consisting of a parent category and one or two child categories, and applying only those instances during parsing. (These rule instances also include rules to deal with punctuation and unary type-changing rules, in addition to instances of the combinatory rule schemas.) This is the method used by Hockenmaier (2003) and is the method we adopt in this paper.

Fowler and Penn (2010) demonstrate that the second extraction method results in a context-free approximation to the grammar resulting from the first

[1] See e.g. Riezler et al. (2002) and Zhang et al. (2007) for chart-based parsers which can produce fragmentary analyses.

[2] Although the C&C default mode applies a restriction for efficiency reasons in which only rule instances seen in CCGbank can be applied, making the grammar of the second type.

method, which has the potential to produce a mildly-context sensitive grammar (given the existence of certain combinatory rules) (Weir, 1988). However, it is important to note that the advantages of CCG, in particular the tight relationship between syntax and semantic interpretation, are still maintained with the second approach, as Fowler and Penn (2010) argue.

3 The Shift-reduce CCG Parser

Given an input sentence, our parser uses a stack of partial derivations, a queue of incoming words, and a series of actions—derived from the rule instances in CCGbank—to build a derivation tree. Following Clark and Curran (2007), we assume that each input word has been assigned a POS-tag (from the Penn Treebank tagset) and a set of CCG lexical categories. We use the same maximum entropy POS-tagger and supertagger as the C&C parser. The derivation tree can be transformed into CCG dependencies or grammatical relations by a post-processing step, which essentially runs the C&C parser deterministically over the derivation, interpreting the derivation and generating the required output.

The configuration of the parser, at each step of the parsing process, is shown in part (a) of Figure 1, where the stack holds the partial derivation trees that have been built, and the queue contains the incoming words that have not been processed. In the figure, $\mathtt{S}_{(\mathtt{H})}$ represents a category S on the stack with head word H, while $\mathtt{Q}_i$ represents a word in the incoming queue.

The set of action types used by the parser is as follows: {SHIFT, COMBINE, UNARY, FINISH}. Each action type represents a set of possible actions available to the parser at each step in the process.

The SHIFT-X action pushes the next incoming word onto the stack, and assigns the lexical category X to the word (Figure 1(b)). The label X can be any lexical category from the set assigned to the word being shifted by the supertagger. Hence the shift action performs lexical category disambiguation. This is in contrast to a shift-reduce dependency parser in which a shift action typically just pushes a word onto the stack.

The COMBINE-X action pops the top two nodes off the stack, and combines them into a new node, which is pushed back on the stack. The category of the new node is X. A COMBINE action corresponds to a combinatory rule in the CCG grammar (or one of the additional punctuation or type-changing rules), which is applied to the categories of the top two nodes on the stack.

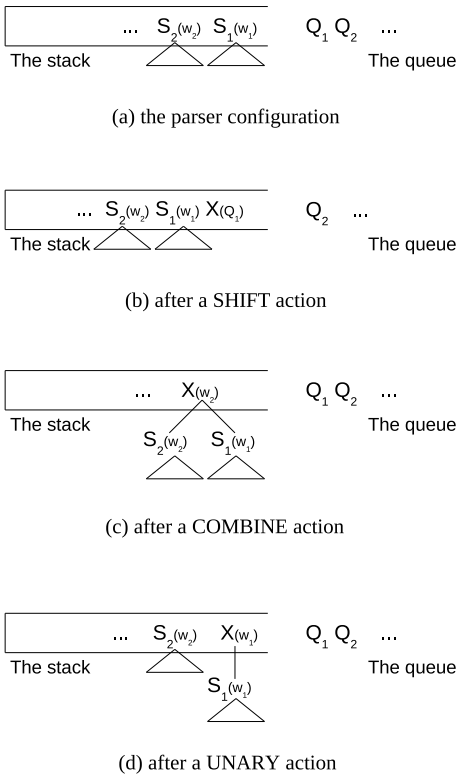

Figure 1: The parser configuration and set of actions.

The UNARY-X action pops the top of the stack, transforms it into a new node with category X, and pushes the new node onto the stack. A UNARY action corresponds to a unary type-changing or type-raising rule in the CCG grammar, which is applied to the category on top of the stack.

The FINISH action terminates the parsing process; it can be applied when all input words have been shifted onto the stack. Note that the FINISH action can be applied when the stack contains more than one node, in which case the parser produces a set of partial derivation trees, each corresponding to a node on the stack. This sometimes happens when a full derivation tree cannot be built due to supertagging errors, and provides a graceful solution to the problem of producing high-quality fragmentary parses when necessary.

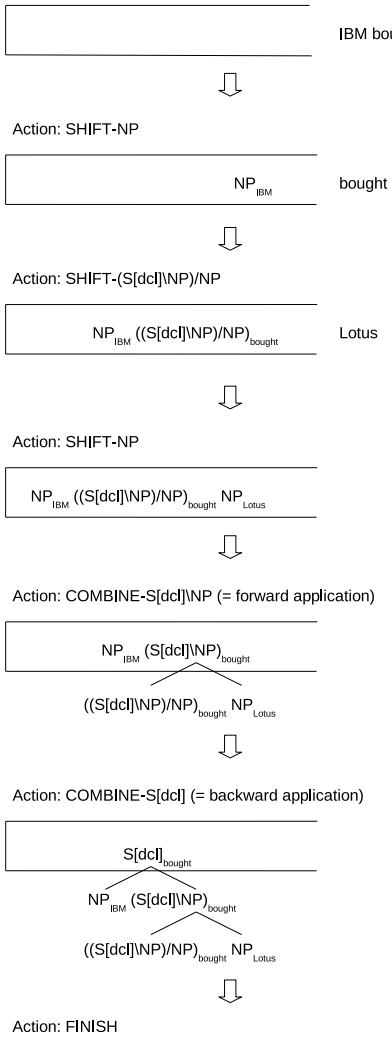

Figure 2: An example parsing process.

Figure 2 shows the shift-reduce parsing process for the example sentence "IBM bought Lotus". First the word "IBM" is shifted onto the stack as an NP; then "bought" is shifted as a transitive verb looking for its object NP on the right and subject NP on the left ((S[dcl]\NP)/NP); and then "Lotus" is shifted as an NP. Then "bought" is combined with its object "Lotus" resulting in a verb phrase looking for its subject on the left (S[dcl]\NP). Finally, the resulting verb phrase is combined with its subject, resulting in a declarative sentence (S[dcl]).

A key difference with previous work on shift-reduce dependency (Nivre et al., 2006) and CFG (Sagae and Lavie, 2006b) parsing is that, for CCG, there are many more shift actions – a shift action for each word-lexical category pair. Given the amount of syntactic information in the lexical categories, the choice of correct category, from those supplied by the supertagger, is often a difficult one, and often a choice best left to the parsing model. The C&C parser solves this problem by building the complete packed chart consistent with the lexical categories supplied by the supertagger, leaving the selection of the lexical categories to the Viterbi algorithm. For the shift-reduce parser the choice is also left to the parsing model, but in contrast to C&C the correct lexical category could be lost at any point in the heuristic search process. Hence it is perhaps surprising that we are able to achieve a high parsing accuracy of 85.5%, given a relatively small beam size.

4 Decoding

Greedy local search (Yamada and Matsumoto, 2003; Sagae and Lavie, 2005; Nivre and Scholz, 2004) has typically been used for decoding in shift-reduce parsers, while beam-search has recently been applied as an alternative to reduce error-propagation (Johansson and Nugues, 2007; Zhang and Clark, 2008; Zhang and Clark, 2009; Huang et al., 2009). Both greedy local search and beam-search have linear time complexity. We use beam-search in our CCG parser.

To formulate the decoding algorithm, we define a *candidate item* as a tuple $\langle S, Q, F \rangle$, where S represents the stack with partial derivations that have been built, Q represents the queue of incoming words that have not been processed, and F is a boolean value that represents whether the candidate item has been finished. A candidate item is *finished* if and only if the `FINISH` action has been applied to it, and no more actions can be applied to a candidate item after it reaches the finished status. Given an input sentence, we define the *start item* as the unfinished item with an empty stack and the whole input sentence as the incoming words. A derivation is built from the start item by repeated applications of actions until the item is finished.

To apply beam-search, an agenda is used to hold the N-best partial (unfinished) candidate items at each parsing step. A separate *candidate output* is

```
function DECODE(input, agenda, list, N,
                grammar, candidate_output):
  agenda.clear()
  agenda.insert(GETSTARTITEM(input))
  candidate_output = NONE
  while not agenda.empty():
    list.clear()
    for item in agenda:
      for action in grammar.getActions(item):
        item' = item.apply(action)
        if item'.F == TRUE:
          if candidate_output == NONE or
            item'.score > candidate_output.score:
            candidate_output = item'
          else:
            list.append(item')
    agenda.clear()
    agenda.insert(list.best(N))
```

Table 1: Feature templates.

used to record the current best finished item that has been found, since candidate items can be finished at different steps. Initially the agenda contains only the start item, and the *candidate output* is set to none. At each step during parsing, each candidate item from the agenda is extended in all possible ways by applying one action according to the grammar, and a number of new candidate items are generated. If a newly generated candidate is finished, it is compared with the current *candidate output*. If the candidate output is none or the score of the newly generated candidate is higher than the score of the candidate output, the candidate output is replaced with the newly generated item; otherwise the newly generated item is discarded. If the newly generated candidate is unfinished, it is appended to a *list* of newly generated partial candidates. After all candidate items from the agenda have been processed, the agenda is cleared and the N-best items from the list are put on the agenda. Then the list is cleared and the parser moves on to the next step. This process repeats until the agenda is empty (which means that no new items have been generated in the previous step), and the candidate output is the final derivation. Pseudocode for the algorithm is shown in Figure 3.

5 Model and Training

We use a global linear model to score candidate items, trained discriminatively with the averaged perceptron (Collins, 2002). Features for a (finished or partial) candidate are extracted from each action that have been applied to build the candidate. Following Collins and Roark (2004), we apply the "early update" strategy to perceptron training: at any step during decoding, if neither the candidate output nor any item in the agenda is correct, decoding is stopped and the parameters are updated using the current highest scored item in the agenda or the candidate output, whichever has the higher score.

Table 1 shows the feature templates used by the parser. The symbols S_0, S_1, S_2 and S_3 in the table represent the top four nodes on the stack (if existent), and Q_0, Q_1, Q_2 and Q_3 represent the front four words in the incoming queue (if existent). S_0H and S_1H represent the subnodes of S_0 and S_1 that have the lexical head of S_0 and S_1, respectively. S_0L represents the left subnode of S_0, when the lexical head is from the right subnode. S_0R and S_1R represent the right subnode of S_0 and S_1, respectively,

when the lexical head is from the left subnode. If S_0 is built by a UNARY action, S_0U represents the only subnode of S_0. The symbols w, p and c represent the word, the POS, and the CCG category, respectively.

These rich feature templates produce a large number of features: 36 million after the first training iteration, compared to around 0.5 million in the C&C parser.

6 Experiments

Our experiments were performed using CCGBank (Hockenmaier and Steedman, 2007), which was split into three subsets for training (Sections 02–21), development testing (Section 00) and the final test (Section 23). Extracted from the training data, the CCG grammar used by our parser consists of 3070 binary rule instances and 191 unary rule instances.

We compute F-scores over labeled CCG dependencies and also lexical category accuracy. CCG dependencies are defined in terms of lexical categories, by numbering each argument slot in a complex category. For example, the first NP in a transitive verb category is a CCG dependency relation, corresponding to the subject of the verb. Clark and Curran (2007) gives a more precise definition. We use the `generate` script from the C&C tools[3] to transform derivations into CCG dependencies.

There is a mismatch between the grammar that `generate` uses, which is the same grammar as the C&C parser, and the grammar we extract from CCGbank, which contains more rule instances. Hence `generate` is unable to produce dependencies for some of the derivations our shift-reduce parser produces. In order to allow `generate` to process all derivations from the shift-reduce parser, we repeatedly removed rules that the `generate` script cannot handle from our grammar, until all derivations in the development data could be dealt with. In fact, this procedure potentially reduces the accuracy of the shift-reduce parser, but the effect is comparatively small because only about 4% of the development and test sentences contain rules that are not handled by the `generate` script.

All experiments were performed using automatically assigned POS-tags, with 10-fold cross validation used to assign POS-tags and lexical categories to the training data. At the supertagging stage, multiple lexical categories are assigned to each word in the input. For each word, the supertagger assigns all lexical categories whose forward-backward probability is above $\beta \cdot max$, where max is the highest lexical category probability for the word, and β is a threshold parameter. To give the parser a reasonable freedom in lexical category disambiguation, we used a small β value of 0.0001, which results in 3.6 lexical categories being assigned to each word on average in the training data. For training, but not testing, we also added the correct lexical category to the list of lexical categories for a word in cases when it was not provided by the supertagger.

Increasing the size of the beam in the parser beam search leads to higher accuracies but slower running time. In our development experiments, the accuracy improvement became small when the beam size reached 16, and so we set the size of the beam to 16 for the remainder of the experiments.

6.1 Development test accuracies

Table 2 shows the labeled precision (lp), recall (lr), F-score (lf), sentence-level accuracy (lsent) and lexical category accuracy (cats) of our parser and the C&C parser on the development data. We ran the C&C parser using the normal-form model (we reproduced the numbers reported in Clark and Curran (2007)), and copied the results of the hybrid model from Clark and Curran (2007), since the hybrid model is not part of the public release.

The accuracy of our parser is much better when evaluated on all sentences, partly because C&C failed on 0.94% of the data due to the failure to produce a spanning analysis. Our shift-reduce parser does not suffer from this problem because it produces fragmentary analyses for those cases. When evaluated on only those sentences that C&C could analyze, our parser gave 0.29% higher F-score. Our shift-reduce parser also gave higher accuracies on lexical category assignment. The sentence accuracy of our shift-reduce parser is also higher than C&C, which confirms that our shift-reduce parser produces reasonable sentence-level analyses, despite the possibility for fragmentary analysis.

[3] Available at http://svn.ask.it.usyd.edu.au/trac/candc/wiki; we used the `generate` and `evaluate` scripts, as well as the C&C parser, for evaluation and comparison.

	lp.	lr.	lf.	lsent.	cats.	evaluated on
shift-reduce	87.15%	82.95%	85.00%	33.82%	92.77%	all sentences
C&C (normal-form)	85.22%	82.52%	83.85%	31.63%	92.40%	all sentences
shift-reduce	87.55%	83.63%	85.54%	34.14%	93.11%	99.06% (C&C coverage)
C&C (hybrid)	–	–	85.25%	–	–	99.06% (C&C coverage)
C&C (normal-form)	85.22%	84.29%	84.76%	31.93%	92.83%	99.06% (C&C coverage)

Table 2: Accuracies on the development test data.

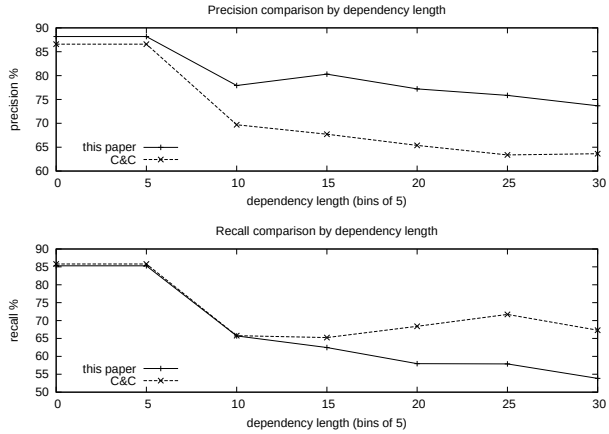

Figure 4: P & R scores relative to dependency length.

6.2 Error comparison with C&C parser

Our shift-reduce parser and the chart-based C&C parser offer two different solutions to the CCG parsing problem. The comparison reported in this section is similar to the comparison between the chart-based MSTParser (McDonald et al., 2005) and shift-reduce MaltParser (Nivre et al., 2006) for dependency parsing. We follow McDonald and Nivre (2007) and characterize the errors of the two parsers by sentence and dependency length and dependency type.

We measured precision, recall and F-score relative to different sentence lengths. Both parsers performed better on shorter sentences, as expected. Our shift-reduce parser performed consistently better than C&C on all sentence lengths, and there was no significant difference in the rate of performance degradation between the parsers as the sentence length increased.

Figure 4 shows the comparison of labeled precision and recall relative to the dependency length (i.e. the number of words between the head and dependent), in bins of size 5 (e.g. the point at x=5 shows the precision or recall for dependency lengths 1 – 5). This experiment was performed using the normal-form version of the C&C parser, and the evaluation was on the sentences for which C&C gave an analysis. The number of dependencies drops when the dependency length increases; there are 141, 180 and 124 dependencies from the gold-standard, C&C output and our shift-reduce parser output, respectively, when the dependency length is between 21 and 25, inclusive. The numbers drop to 47, 56 and 36 when the dependency length is between 26 and 30. The recall of our parser drops more quickly as the dependency length grows beyond 15. A likely reason is that the recovery of longer-range dependencies requires more processing steps, increasing the chance of the correct structure being thrown off the beam. In contrast, the precision did not drop more quickly than C&C, and in fact is consistently higher than C&C across all dependency lengths, which reflects the fact that the long range dependencies our parser managed to recover are comparatively reliable.

Table 3 shows the comparison of labeled precision (lp), recall (lr) and F-score (lf) for the most common CCG dependency types. The numbers for C&C are for the hybrid model, copied from Clark and Curran (2007). While our shift-reduce parser gave higher precision for almost all categories, it gave higher recall on only half of them, but higher F-scores for all but one dependency type.

6.3 Final results

Table 4 shows the accuracies on the test data. The numbers for the normal-form model are evaluated by running the publicly available parser, while those for the hybrid dependency model are from Clark and Curran (2007). Evaluated on all sentences, the accuracies of our parser are much higher than the C&C parser, since the C&C parser failed to produce any output for 10 sentences. When evaluating both

Table 4: Comparison with C&C; final test. * – not directly comparable.

parsers on the sentences for which C&C produces an analysis, our parser still gave the highest accuracies. The shift-reduce parser gave higher precision, and lower recall, than C&C; it also gave higher sentence-level and lexical category accuracy.

The last two rows in the table show the accuracies of Fowler and Penn (2010) (F&P), who applied the CFG parser of Petrov and Klein (2007) to CCG, and the corresponding accuracies for the C&C parser on the same test sentences. F&P can be treated as another chart-based parser; their evaluation is based on the sentences for which both their parser and C&C produced dependencies (or more specifically those sentences for which `generate` could produce dependencies), and is not directly comparable with ours, especially considering that their test set is smaller and potentially slightly easier.

The final comparison is parser speed. The shift-reduce parser is linear-time (in both sentence length and beam size), and can analyse over 10 sentences per second on a 2GHz CPU, with a beam of 16, which compares very well with other constituency parsers. However, this is no faster than the chart-based C&C parser, although speed comparisons are difficult because of implementation differences (C&C uses heavily engineered C++ with a focus on efficiency).

7 Related Work

Sagae and Lavie (2006a) describes a shift-reduce parser for the Penn Treebank parsing task which uses best-first search to allow some ambiguity into the parsing process. Differences with our approach are that we use a beam, rather than best-first, search; we use a global model rather than local models chained together; and finally, our results surpass the best published results on the CCG parsing task, whereas Sagae and Lavie (2006a) matched the best PTB results only by using a parser combination.

Matsuzaki et al. (2007) describes similar work to ours but using an automatically-extracted HPSG, rather than CCG, grammar. They also use the generalised perceptron to train a disambiguation model. One difference is that Matsuzaki et al. (2007) use an approximating CFG, in addition to the supertagger, to improve the efficiency of the parser.

Ninomiya et al. (2009) (and Ninomiya et al. (2010)) describe a greedy shift-reduce parser for HPSG, in which a single action is chosen at each parsing step, allowing the possibility of highly efficient parsing. Since the HPSG grammar has relatively tight constraints, similar to CCG, the possibility arises that a spanning analysis cannot be found for some sentences. Our approach to this problem was to allow the parser to return a fragmentary analysis; Ninomiya et al. (2009) adopt a different approach based on default unification.

Finally, our work is similar to the comparison of the chart-based MSTParser (McDonald et al., 2005) and shift-reduce MaltParser (Nivre et al., 2006) for dependency parsing. MSTParser can perform exhaustive search, given certain feature restrictions, because the complexity of the parsing task is lower than for constituent parsing. C&C can perform exhaustive search because the supertagger has already reduced the search space. We also found that approximate heuristic search for shift-reduce parsing, utilising a rich feature space, can match the performance of the optimal chart-based parser, as well as similar error profiles for the two CCG parsers compared to the two dependency parsers.

8 Conclusion

This is the first work to present competitive results for CCG using a transition-based parser, filling a gap in the CCG parsing literature. Considered in terms of the wider parsing problem, we have shown that state-of-the-art parsing results can be obtained using a global discriminative model, one of the few papers to do so without using a generative baseline as a feature. The comparison with C&C also allowed us to compare a shift-reduce parser based on heuristic beam search utilising a rich feature set with an optimal chart-based parser whose features are restricted by dynamic programming, with favourable results for the shift-reduce parser.

The complementary errors made by the chart-based and shift-reduce parsers opens the possibility of effective parser combination, following similar work for dependency parsing.

The parser code can be downloaded at `http://www.sourceforge.net/projects/zpar`, version 0.5.

Web-Scale Features for Full-Scale Parsing

Mohit Bansal and **Dan Klein**

Abstract

Counts from large corpora (like the web) can be powerful syntactic cues. Past work has used web counts to help resolve isolated ambiguities, such as binary noun-verb PP attachments and noun compound bracketings. In this work, we first present a method for generating web count features that address the full range of syntactic attachments. These features encode both surface evidence of lexical affinities as well as paraphrase-based cues to syntactic structure. We then integrate our features into full-scale dependency and constituent parsers. We show relative error reductions of 7.0% over the second-order dependency parser of McDonald and Pereira (2006), 9.2% over the constituent parser of Petrov et al. (2006), and 3.4% over a non-local constituent reranker.

1 Introduction

Current state-of-the art syntactic parsers have achieved accuracies in the range of 90% F1 on the Penn Treebank, but a range of errors remain. From a dependency viewpoint, structural errors can be cast as incorrect attachments, even for constituent (phrase-structure) parsers. For example, in the Berkeley parser (Petrov et al., 2006), about 20% of the errors are prepositional phrase attachment errors as in Figure 1, where a preposition-headed (IN) phrase was assigned an incorrect parent in the implied dependency tree. Here, the Berkeley parser (solid blue edges) incorrectly attaches *from debt* to the noun phrase *$ 30 billion* whereas the correct attachment (dashed gold edges) is to the verb *raising*. However, there are a range of error types, as shown in Figure 2. Here, (a) is a non-canonical PP

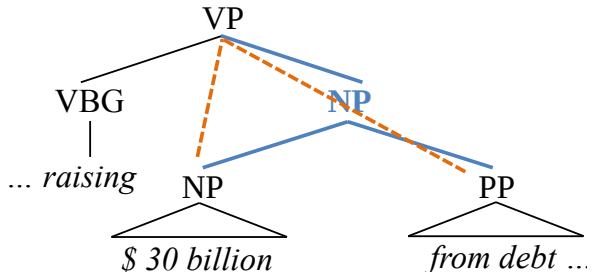

Figure 1: A PP attachment error in the parse output of the Berkeley parser (on Penn Treebank). Guess edges are in solid blue, gold edges are in dashed gold and edges common in guess and gold parses are in black.

attachment ambiguity where *by yesterday afternoon* should attach to *had already*, (b) is an NP-internal ambiguity where *half a* should attach to *dozen* and not to *newspapers*, and (c) is an adverb attachment ambiguity, where *just* should modify *fine* and not the verb *'s*.

Resolving many of these errors requires information that is simply not present in the approximately 1M words on which the parser was trained. One way to access more information is to exploit surface counts from large corpora like the web (Volk, 2001; Lapata and Keller, 2004). For example, the phrase *raising from* is much more frequent on the Web than *$ x billion from*. While this 'affinity' is only a surface correlation, Volk (2001) showed that comparing such counts can often correctly resolve tricky PP attachments. This basic idea has led to a good deal of successful work on disambiguating isolated, binary PP attachments. For example, Nakov and Hearst (2005b) showed that looking for *paraphrase* counts can further improve PP resolution. In this case, the existence of reworded phrases like *raising it from* on the Web also imply a verbal at-

tachment. Still other work has exploited Web counts for other isolated ambiguities, such as NP coordination (Nakov and Hearst, 2005b) and noun-sequence bracketing (Nakov and Hearst, 2005a; Pitler et al., 2010). For example, in (b), *half dozen* is more frequent than *half newspapers*.

In this paper, we show how to apply these ideas to all attachments in full-scale parsing. Doing so requires three main issues to be addressed. First, we show how features can be generated for arbitrary head-argument configurations. Affinity features are relatively straightforward, but paraphrase features, which have been hand-developed in the past, are more complex. Second, we integrate our features into full-scale parsing systems. For dependency parsing, we augment the features in the second-order parser of McDonald and Pereira (2006). For constituent parsing, we rerank the output of the Berkeley parser (Petrov et al., 2006). Third, past systems have usually gotten their counts from web search APIs, which does not scale to quadratically-many attachments in each sentence. Instead, we consider how to efficiently mine the Google n-grams corpus.

Given the success of Web counts for isolated ambiguities, there is relatively little previous research in this direction. The most similar work is Pitler et al. (2010), which use Web-scale n-gram counts for multi-way noun bracketing decisions, though that work considers only sequences of nouns and uses only affinity-based web features. Yates et al. (2006) use Web counts to filter out certain 'semantically bad' parses from extraction candidate sets but are not concerned with distinguishing amongst top parses. In an important contrast, Koo et al. (2008) smooth the sparseness of lexical features in a discriminative dependency parser by using cluster-based word-senses as intermediate abstractions in addition to POS tags (also see Finkel et al. (2008)). Their work also gives a way to tap into corpora beyond the training data, through cluster membership rather than explicit corpus counts and paraphrases.

This work uses a large web-scale corpus (Google n-grams) to compute features for the full parsing task. To show end-to-end effectiveness, we incorporate our features into state-of-the-art dependency and constituent parsers. For the dependency case, we can integrate them into the dynamic programming of a base parser; we use the discriminatively-trained MST dependency parser (McDonald et al., 2005; McDonald and Pereira, 2006). Our first-order web-features give 7.0% relative error reduction over the second-order dependency baseline of McDonald and Pereira (2006). For constituent parsing, we use a reranking framework (Charniak and Johnson, 2005; Collins and Koo, 2005; Collins, 2000) and show 9.2% relative error reduction over the Berkeley parser baseline. In the same framework, we also achieve 3.4% error reduction over the non-local syntactic features used in Huang (2008). Our web-scale features reduce errors for a range of attachment types. Finally, we present an analysis of influential features. We not only reproduce features suggested in previous work but also discover a range of new ones.

2 Web-count Features

Structural errors in the output of state-of-the-art parsers, constituent or dependency, can be viewed as attachment errors, examples of which are Figure 1 and Figure 2.[1] One way to address attachment errors is through features which factor over head-argument

[1]For constituent parsers, there can be minor tree variations which can result in the same set of induced dependencies, but these are rare in comparison.

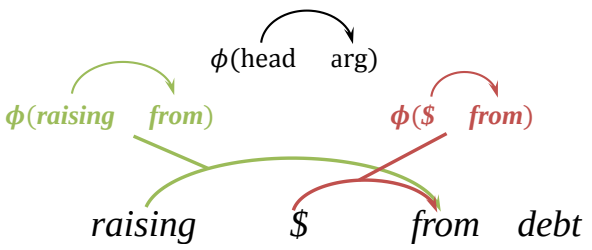

Figure 3: Features factored over head-argument pairs.

pairs, as is standard in the dependency parsing literature (see Figure 3). Here, we discuss which web-count based features $\phi(h, a)$ should fire over a given head-argument pair (we consider the words h and a to be indexed, and so features can be sensitive to their order and distance, as is also standard).

2.1 Affinity Features

Affinity statistics, such as lexical co-occurrence counts from large corpora, have been used previously for resolving individual attachments at least as far back as Lauer (1995) for noun-compound bracketing, and later for PP attachment (Volk, 2001; Lapata and Keller, 2004) and coordination ambiguity (Nakov and Hearst, 2005b). The approach of Lauer (1995), for example, would be to take an ambiguous noun sequence like *hydrogen ion exchange* and compare the various counts (or associated conditional probabilities) of n-grams like *hydrogen ion* and *hydrogen exchange*. The attachment with the greater score is chosen. More recently, Pitler et al. (2010) use web-scale n-grams to compute similar association statistics for longer sequences of nouns.

Our *affinity features* closely follow this basic idea of association statistics. However, because a real parser will not have access to gold-standard knowledge of the competing attachment sites (see Atterer and Schutze (2007)'s criticism of previous work), we must instead compute features for all possible head-argument pairs from our web corpus. Moreover, when there are only two competing attachment options, one can do things like directly compare two count-based heuristics and choose the larger. Integration into a parser requires features to be functions of single attachments, not pairwise comparisons between alternatives. A learning algorithm can then weight features so that they compare appropriately across parses.

We employ a collection of affinity features of varying specificity. The basic feature is the core adjacency count feature ADJ, which fires for all (h, a) pairs. What is specific to a particular (h, a) is the value of the feature, not its identity. For example, in a naive approach, the value of the ADJ feature might be the count of the query issued to the web-corpus – the 2-gram $q = ha$ or $q = ah$ depending on the order of h and a in the sentence. However, it turns out that there are several problems with this approach. First, rather than a single all-purpose feature like ADJ, the utility of such query counts will vary according to aspects like the parts-of-speech of h and a (because a high adjacency count is not equally informative for all kinds of attachments). Hence, we add more refined affinity features that are specific to each pair of POS tags, i.e. ADJ $\wedge$ POS(h) $\wedge$ POS(a). The values of these POS-specific features, however, are still derived from the same queries as before. Second, using real-valued features did not work as well as binning the query-counts (we used $b = floor(\log_r(\text{count})/5) * 5)$ and then firing indicator features ADJ $\wedge$ POS(h) $\wedge$ POS(a) $\wedge$ b for values of b defined by the query count. Adding still more complex features, we conjoin to the preceding features the order of the words h and a as they occur in the sentence, and the (binned) distance between them. For features which mark distances, wildcards ($\star$) are used in the query $q = h \star a$, where the number of wildcards allowed in the query is proportional to the binned distance between h and a in the sentence. Finally, we also include unigram variants of the above features, which are sensitive to only one of the head or argument. For all features used, we add cumulative variants where indicators are fired for all count bins b' up to query count bin b.

2.2 Paraphrase Features

In addition to measuring counts of the words present in the sentence, there exist clever ways in which paraphrases and other accidental indicators can help resolve specific ambiguities, some of which are discussed in Nakov and Hearst (2005a), Nakov and Hearst (2005b). For example, finding attestations of *eat : spaghetti with sauce* suggests a nominal attachment in *Jean ate spaghetti with sauce*. As another example, one clue that the example in Figure 1 is

a verbal attachment is that the proform paraphrase *raising it from* is commonly attested. Similarly, the attestation of *be noun prep* suggests nominal attachment.

These paraphrase features hint at the correct attachment decision by looking for web n-grams with special contexts that reveal syntax superficially. Again, while effective in their isolated disambiguation tasks, past work has been limited by both the range of attachments considered and the need to intuit these special contexts. For instance, frequency of the pattern *The noun prep* suggests noun attachment and of the pattern *verb adverb prep* suggests verb attachment for the preposition in the phrase *verb noun prep*, but these features were not in the manually brainstormed list.

In this work, we automatically generate a large number of paraphrase-style features for arbitrary attachment ambiguities. To induce our list of features, we first mine useful context words. We take each (correct) training dependency relation (h, a) and consider web n-grams of the form cha, hca, and hac. Aggregating over all h and a (of a given POS pair), we determine which context words c are most frequent in each position. For example, for h = *raising* and a = *from* (see Figure 1), we look at web n-grams of the form *raising c from* and see that one of the most frequent values of c on the web turns out to be the word *it*.

Once we have collected context words (for each position p in {BEFORE, MIDDLE, AFTER}), we turn each context word c into a collection of features of the form PARA $\wedge$ POS(h) $\wedge$ POS(a) $\wedge$ c $\wedge$ p $\wedge$ dir, where dir is the linear order of the attachment in the sentence. Note that h and a are head and argument words and so actually occur in the sentence, but c is a context word that generally does not. For such features, the queries that determine their values are then of the form cha, hca, and so on. Continuing the previous example, if the test set has a possible attachment of two words like h = *lowering* and a = *with*, we will fire a feature PARA $\wedge$ VBG $\wedge$ IN $\wedge$ *it* $\wedge$ MIDDLE $\wedge$ $\rightarrow$ with value (indicator bins) set according to the results of the query *lowering it with*. The idea is that if frequent occurrences of *raising it from* indicated a correct attachment between *raising* and *from*, frequent occurrences of *lowering it with* will indicate the correctness of an attachment between *lowering* and *with*. Finally, to handle the cases where no induced context word is helpful, we also construct abstracted versions of these paraphrase features where the context words c are collapsed to their parts-of-speech POS(c), obtained using a unigram-tagger trained on the parser training set. As discussed in Section 5, the top features learned by our learning algorithm duplicate the hand-crafted configurations used in previous work (Nakov and Hearst, 2005b) but also add numerous others, and, of course, apply to many more attachment types.

3 Working with Web n-Grams

Previous approaches have generally used search engines to collect count statistics (Lapata and Keller, 2004; Nakov and Hearst, 2005b; Nakov and Hearst, 2008). Lapata and Keller (2004) uses the number of page hits as the web-count of the queried n-gram (which is problematic according to Kilgarriff (2007)). Nakov and Hearst (2008) post-processes the first 1000 result snippets. One challenge with this approach is that an external search API is now embedded into the parser, raising issues of both speed and daily query limits, especially if all possible attachments trigger queries. Such methods also create a dependence on the quality and post-processing of the search results, limitations of the query process (for instance, search engines can ignore punctuation (Nakov and Hearst, 2005b)).

Rather than working through a search API (or scraper), we use an offline web corpus – the Google n-gram corpus (Brants and Franz, 2006) – which contains English n-grams (n = 1 to 5) and their observed frequency counts, generated from nearly 1 trillion word tokens and 95 billion sentences. This corpus allows us to efficiently access huge amounts of web-derived information in a compressed way, though in the process it limits us to local queries. In particular, we only use counts of n-grams of the form $x \star y$ where the gap length is ≤ 3.

Our system requires the counts from a large collection of these n-gram queries (around 4.5 million). The most basic queries are counts of head-argument pairs in contiguous *h a* and gapped *h* $\star$ *a* configurations.[2] Here, we describe how we process queries

[2]Paraphrase features give situations where we query $\star$ *h a*

of the form (q_1, q_2) with some number of wildcards in between. We first collect all such queries over all trees in preprocessing (so a new test set requires a new query-extraction phase). Next, we exploit a simple but efficient trie-based hashing algorithm to efficiently answer all of them in one pass over the n-grams corpus.

Consider Figure 4, which illustrates the data structure which holds our queries. We first create a trie of the queries in the form of a nested hashmap. The key of the outer hashmap is the first word q_1 of the query. The entry for q_1 points to an inner hashmap whose key is the final word q_2 of the query bigram. The values of the inner map is an array of 4 counts, to accumulate each of $(q_1 q_2)$, $(q_1 \star q_2)$, $(q_1 \star\star q_2)$, and $(q_1 \star\star\star q_2)$, respectively. We use k-grams to collect counts of $(q_1 ... q_2)$ with gap length = $k-2$, i.e. 2-grams to get $count(q_1 q_2)$, 3-grams to get $count(q_1 \star q_2)$ and so on.

With this representation of our collection of queries, we go through the web n-grams (n = 2 to 5) one by one. For an n-gram $w_1 ... w_n$, if the first n-gram word w_1 doesn't occur in the outer hashmap, we move on. If it does match (say $\bar{q}_1 = w_1$), then we look into the inner map for $\bar{q}_1$ and check for the final word w_n. If we have a match, we increment the appropriate query's result value.

In similar ways, we also mine the most frequent words that occur before, in between and after the head and argument query pairs. For example, to collect mid words, we go through the 3-grams $w_1 w_2 w_3$; if w_1 matches $\bar{q}_1$ in the outer hashmap and w_3 occurs in the inner hashmap for $\bar{q}_1$, then we store w_2 and the count of the 3-gram. After the sweep, we sort the context words in decreasing order of count. We also collect unigram counts of the head and argument words by sweeping over the unigrams once.

In this way, our work is linear in the size of the n-gram corpus, but essentially constant in the number of queries. Of course, if the number of queries is expected to be small, such as for a one-off parse of a single sentence, other solutions might be more appropriate; in our case, a large-batch setting, the number of queries was such that this formulation was chosen. Our main experiments (with no parallelization) took 115 minutes to sweep over the 3.8 billion

and *h a* $\star$; these are handled similarly.

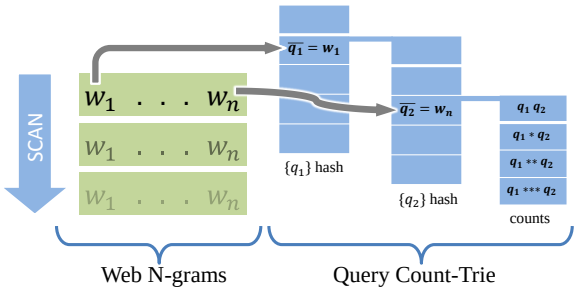

Figure 4: Trie-based nested hashmap for collecting ngram web-counts of queries.

n-grams (n = 1 to 5) to compute the answers to 4.5 million queries, much less than the time required to train the baseline parsers.

4 Parsing Experiments

Our features are designed to be used in full-sentence parsing rather than for limited decisions about isolated ambiguities. We first integrate our features into a dependency parser, where the integration is more natural and pushes all the way into the underlying dynamic program. We then add them to a constituent parser in a reranking approach. We also verify that our features contribute on top of standard reranking features.[3]

4.1 Dependency Parsing

For dependency parsing, we use the discriminatively-trained MSTParser[4], an implementation of first and second order MST parsing models of McDonald et al. (2005) and McDonald and Pereira (2006). We use the standard splits of Penn Treebank into training (sections 2-21), development (section 22) and test (section 23). We used the 'pennconverter'[5] tool to convert Penn trees from constituent format to dependency format. Following Koo et al. (2008), we used the MXPOST tagger (Ratnaparkhi, 1996) trained on the full training data to provide part-of-speech tags for the development

[3] All reported experiments are run on *all* sentences, i.e. without any length limit.

[4] http://sourceforge.net/projects/mstparser

[5] This supersedes 'Penn2Malt' and is available at http://nlp.cs.lth.se/software/treebank_converter. We follow its recommendation to patch WSJ data with NP bracketing by Vadas and Curran (2007).

and the test set, and we used 10-way jackknifing to generate tags for the training set.

We added our first-order Web-scale features to the MSTParser system to evaluate improvement over the results of McDonald and Pereira (2006).[6] Table 1 shows unlabeled attachments scores (UAS) for their second-order projective parser and the improved numbers resulting from the addition of our Web-scale features. Our first-order web-scale features show significant improvement even over their non-local *second*-order features.[7] Additionally, our web-scale features are at least an order of magnitude fewer in number than even their first-order base features.

4.2 Constituent Parsing

We also evaluate the utility of web-scale features on top of a state-of-the-art constituent parser – the Berkeley parser (Petrov et al., 2006), an unlexicalized phrase-structure parser. Because the underlying parser does not factor along lexical attachments, we instead adopt the discriminative reranking framework, where we generate the top-k candidates from the baseline system and then rerank this k-best list using (generally non-local) features.

Our baseline system is the Berkeley parser, from which we obtain k-best lists for the development set (WSJ section 22) and test set (WSJ section 23) using a grammar trained on all the training data (WSJ sections 2-21).[8] To get k-best lists for the training set, we use 3-fold jackknifing where we train a grammar on 2 folds to get parses for the third fold.[9] The oracle scores of the k-best lists (for different values of k) for the development and test sets are shown in Table 2. Based on these results, we used 50-best lists in our experiments. For discriminative learning, we used the averaged perceptron (Collins, 2002; Huang, 2008).

Our core feature is the log conditional likelihood of the underlying parser.[10] All other features are indicator features. First, we add all the Web-scale features as defined above. These features alone achieve a 9.2% relative error reduction. The affinity and paraphrase features contribute about two-fifths and three-fifths of this improvement, respectively. Next, we rerank with only the features (both local and non-local) from Huang (2008), a simplified merge of Charniak and Johnson (2005) and Collins (2000) (here *configurational*). These features alone achieve around the same improvements over the baseline as our web-scale features, even though they are highly non-local and extensive. Finally, we rerank with both our Web-scale features and the configurational features. When combined, our web-scale features give a further error reduction of 3.4% over the configurational reranker (and a combined error reduction of 12.2%). All results are shown in Table 3.[11]

5 Analysis

Table 4 shows error counts and relative reductions that our web features provide over the 2nd-order dependency baseline. While we do see substantial gains for classic PP (IN) attachment cases, we see equal or greater error reductions for a range of attachment types. Further, Table 5 shows how the to-

[6] Their README specifies 'training-k:5 iters:10 loss-type:nopunc decode-type:proj', which we used for all final experiments; we used the faster 'training-k:1 iters:5' setting for most development experiments.

[7] Work such as Smith and Eisner (2008), Martins et al. (2009), Koo and Collins (2010) has been exploring more non-local features for dependency parsing. It will be interesting to see how these features interact with our web features.

[8] Settings: 6 iterations of split and merge with smoothing.

[9] Default: we ran the Berkeley parser in its default 'fast' mode; the output k-best lists are ordered by max-rule-score.

[10] This is output by the flag -confidence. Note that baseline results with just this feature are slightly worse than 1-best results because the k-best lists are generated by max-rule-score. We report both numbers in Table 3.

[11] We follow Collins (1999) for head rules.

tal errors break down by gold head. For example, the 12.1% total error reduction for attachments of an IN argument (which includes PPs as well as complementized SBARs) includes many errors where the gold attachments are to both noun and verb heads. Similarly, for an NN-headed argument, the major corrections are for attachments to noun and verb heads, which includes both object-attachment ambiguities and coordination ambiguities.

We next investigate the features that were given high weight by our learning algorithm (in the constituent parsing case). We first threshold features by a minimum training count of 400 to focus on frequently-firing ones (recall that our features are not bilexical indicators and so are quite a bit more frequent). We then sort them by descending (signed) weight.

Table 6 shows which affinity features received the highest weights, as well as examples of training set attachments for which the feature fired (for concreteness), suppressing both features involving punctuation and the features' count and distance bins. With the standard caveats that interpreting feature weights in isolation is always to be taken for what it is, the first feature (RB→IN) indicates that high counts for an adverb occurring adjacent to a preposition (like *back into the spotlight*) is a useful indicator that the adverb actually modifies that preposition. The second row (NN→IN) indicates that whether a preposition is appropriate to attach to a noun is well captured by how often that preposition follows that noun. The fifth row (VB→NN) indicates that when considering an NP as the object of a verb, it is a good sign if that NP's head frequently occurs immediately following that verb. All of these features essentially state cases where local surface counts are good indi-

cators of (possibly non-adjacent) attachments.

A subset of paraphrase features, which in the automatically-extracted case don't really correspond to paraphrases at all, are shown in Table 7. Here we show features for verbal heads and IN arguments. The mid-words m which rank highly are those where the occurrence of hma as an n-gram is a good indicator that a attaches to h (m of course does not have to actually occur in the sentence). Interestingly, the top such features capture exactly the intuition from Nakov and Hearst (2005b), namely that if the verb h and the preposition a occur with a pronoun in between, we have evidence that a attaches to h (it certainly can't attach to the pronoun). However, we also see other indicators that the preposition is selected for by the verb, such as adverbs like *directly*.

As another example of known useful features being learned automatically, Table 8 shows the previous-context-word paraphrase features for a noun head and preposition argument (N $\rightarrow$ IN). Nakov and Hearst (2005b) suggested that the attestation of *be* N IN is a good indicator of attachment to the noun (the IN cannot generally attach to forms of auxiliaries). One such feature occurs on this top list – for the context word *have* – and others occur farther down. We also find their surface marker / punctuation cues of *:* and *,* preceding the noun. However, we additionally find other cues, most notably that if the N IN sequence occurs following a capitalized determiner, it tends to indicate a nominal attachment (in the n-gram, the preposition cannot attach leftward to anything else because of the beginning of the sentence).

In Table 9, we see the top-weight paraphrase features that had a conjunction as a middle-word cue. These features essentially say that if two heads w_1 and w_2 occur in the direct coordination n-gram w_1 *and* w_2, then they are good heads to coordinate (coordination unfortunately looks the same as complementation or modification to a basic dependency model). These features are relevant to a range of coordination ambiguities.

Finally, Table 10 depicts the high-weight, high-count general paraphrase-cue features for arbitrary head and argument categories, with those shown in previous tables suppressed. Again, many interpretable features appear. For example, the top entry (*the* JJ NNS) shows that when considering attaching an adjective a to a noun h, it is a good sign if the

Table 10: The high-weight high-count (thresholded at a count of 2000) general features of the mid and before paraphrase schema (examples show head and arg in linear order with arrow from head to arg).

trigram *the a h* is frequent – in that trigram, the adjective attaches to the noun. The second entry (NN - NN) shows that one noun is a good modifier of another if they frequently appear together hyphenated (another punctuation-based cue mentioned in previous work on noun bracketing, see Nakov and Hearst (2005a)). While they were motivated on separate grounds, these features can also compensate for inapplicability of the affinity features. For example, the third entry (VBD *this* NN) is a case where even if the head (a VBD like *adopted*) actually selects strongly for the argument (a NN like *plan*), the bigram *adopted plan* may not be as frequent as expected, because it requires a determiner in its minimal analogous form *adopted the plan*.

6 Conclusion

Web features are a way to bring evidence from a large unlabeled corpus to bear on hard disambiguation decisions that are not easily resolvable based on limited parser training data. Our approach allows revealing features to be mined for the entire range of attachment types and then aggregated and balanced in a full parsing setting. Our results show that these web features resolve ambiguities not correctly handled by current state-of-the-art systems.

The impact of language models and loss functions on repair disfluency detection

Simon Zwarts and Mark Johnson
Centre for Language Technology
Macquarie University
{simon.zwarts|mark.johnson|}@mq.edu.au

Abstract

Unrehearsed spoken language often contains disfluencies. In order to correctly interpret a spoken utterance, any such disfluencies must be identified and removed or otherwise dealt with. Operating on transcripts of speech which contain disfluencies, we study the effect of language model and loss function on the performance of a linear reranker that rescores the 25-best output of a noisy-channel model. We show that language models trained on large amounts of non-speech data improve performance more than a language model trained on a more modest amount of speech data, and that optimising f-score rather than log loss improves disfluency detection performance.

Our approach uses a log-linear reranker, operating on the top n analyses of a noisy channel model. We use large language models, introduce new features into this reranker and examine different optimisation strategies. We obtain a disfluency detection f-scores of 0.838 which improves upon the current state-of-the-art.

1 Introduction

Most spontaneous speech contains disfluencies such as partial words, filled pauses (e.g., "uh", "um", "huh"), explicit editing terms (e.g., "I mean"), parenthetical asides and repairs. Of these, repairs pose particularly difficult problems for parsing and related Natural Language Processing (NLP) tasks. This paper presents a model of disfluency detection based on the noisy channel framework, which specifically targets the repair disfluencies. By combining language models and using an appropriate loss function in a log-linear reranker we are able to achieve f-scores which are higher than previously reported.

Often in natural language processing algorithms, more data is more important than better algorithms (Brill and Banko, 2001). It is this insight that drives the first part of the work described in this paper. This paper investigates how we can use language models trained on large corpora to increase repair detection accuracy performance.

There are three main innovations in this paper. First, we investigate the use of a variety of language models trained from text or speech corpora of various genres and sizes. The largest available language models are based on written text: we investigate the effect of written text language models as opposed to language models based on speech transcripts. Second, we develop a new set of reranker features explicitly designed to capture important properties of speech repairs. Many of these features are lexically grounded and provide a large performance increase. Third, we utilise a loss function, approximate expected f-score, that explicitly targets the asymmetric evaluation metrics used in the disfluency detection task. We explain how to optimise this loss function, and show that this leads to a marked improvement in disfluency detection. This is consistent with Jansche (2005) and Smith and Eisner (2006), who observed similar improvements when using approximate f-score loss for other problems. Similarly we introduce a loss function based on the edit-f-score in our domain.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 703–711,
Portland, Oregon, June 19-24, 2011.

Together, these three improvements are enough to boost detection performance to a higher f-score than previously reported in literature. Zhang et al. (2006) investigate the use of 'ultra large feature spaces' as an aid for disfluency detection. Using over 19 million features, they report a final f-score in this task of 0.820. Operating on the same body of text (Switchboard), our work leads to an f-score of 0.838, this is a 9% relative improvement in residual f-score.

The remainder of this paper is structured as follows. First in Section 2 we describe related work. Then in Section 3 we present some background on disfluencies and their structure. Section 4 describes appropriate evaluation techniques. In Section 5 we describe the noisy channel model we are using. The next three sections describe the new additions: Section 6 describe the corpora used for language models, Section 7 describes features used in the log-linear model employed by the reranker and Section 8 describes appropriate loss functions which are critical for our approach. We evaluate the new model in Section 9. Section 10 draws up a conclusion.

2 Related work

A number of different techniques have been proposed for automatic disfluency detection. Schuler et al. (2010) propose a Hierarchical Hidden Markov Model approach; this is a statistical approach which builds up a syntactic analysis of the sentence and marks those subtrees which it considers to be made up of disfluent material. Although they are interested not only in disfluency but also a syntactic analysis of the utterance, including the disfluencies being analysed, their model's final f-score for disfluency detection is lower than that of other models.

Snover et al. (2004) investigate the use of purely lexical features combined with part-of-speech tags to detect disfluencies. This approach is compared to approaches which use primarily prosodic cues, and appears to perform equally well. However, the authors note that this model finds it difficult to identify disfluencies which by themselves are very fluent. As we will see later, the individual components of a disfluency do not have to be disfluent by themselves. This can occur when a speaker edits her speech for meaning-related reasons, rather than errors that arise from performance. The edit repairs which are the focus of our work typically have this characteristic.

Noisy channel models have done well on the disfluency detection task in the past; the work of Johnson and Charniak (2004) first explores such an approach. Johnson et al. (2004) adds some handwritten rules to the noisy channel model and use a maximum entropy approach, providing results comparable to Zhang et al. (2006), which are state-of-the art results.

Kahn et al. (2005) investigated the role of prosodic cues in disfluency detection, although the main focus of their work was accurately recovering and parsing a fluent version of the sentence. They report a 0.782 f-score for disfluency detection.

3 Speech Disfluencies

We follow the definitions of Shriberg (1994) regarding speech disfluencies. She identifies and defines three distinct parts of a speech disfluency, referred to as the *reparandum*, the *interregnum* and the *repair*. Consider the following utterance:

$$\overbrace{\underbrace{\textit{I want a flight}}_{}\ \textit{to Boston}}^{\text{reparandum}},\ \underbrace{\textit{uh, I mean}}_{\text{interregnum}}\ \underbrace{\textit{to Denver}}_{\text{repair}}\ \textit{on Friday} \tag{1}$$

The reparandum *to Boston* is the part of the utterance that is 'edited out'; the interregnum *uh, I mean* is a filled pause, which need not always be present; and the repair *to Denver* replaces the reparandum.

Shriberg and Stolcke (1998) studied the location and distribution of repairs in the Switchboard corpus (Godfrey and Holliman, 1997), the primary corpus for speech disfluency research, but did not propose an actual model of repairs. They found that the overall distribution of speech disfluencies in a large corpus can be fit well by a model that uses only information on a very local level. Our model, as explained in section 5, follows from this observation.

As our domain of interest we use the Switchboard corpus. This is a large corpus consisting of transcribed telephone conversations between two partners. In the Treebank III (Marcus et al., 1999) corpus there is annotation available for the Switchboard corpus, which annotates which parts of utterances

are in a reparandum, interregnum or repair.

4 Evaluation metrics for disfluency detection systems

Disfluency detection systems like the one described here identify a subset of the word tokens in each transcribed utterance as "edited" or disfluent. Perhaps the simplest way to evaluate such systems is to calculate the accuracy of labelling they produce, i.e., the fraction of words that are correctly labelled (i.e., either "edited" or "not edited"). However, as Charniak and Johnson (2001) observe, because only 5.9% of words in the Switchboard corpus are "edited", the trivial baseline classifier which assigns all words the "not edited" label achieves a labelling accuracy of 94.1%.

Because the labelling accuracy of the trivial baseline classifier is so high, it is standard to use a different evaluation metric that focuses more on the detection of "edited" words. We follow Charniak and Johnson (2001) and report the f-score of our disfluency detection system. The f-score f is:

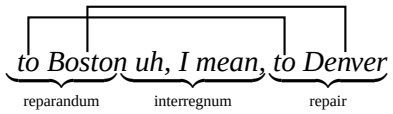
$$f = \frac{2c}{g+e} \quad (2)$$

where g is the number of "edited" words in the gold test corpus, e is the number of "edited" words proposed by the system on that corpus, and c is the number of the "edited" words proposed by the system that are in fact correct. A perfect classifier which correctly labels every word achieves an f-score of 1, while the trivial baseline classifiers which label every word as "edited" or "not edited" respectively achieve a very low f-score.

Informally, the f-score metric focuses more on the "edited" words than it does on the "not edited" words. As we will see in section 8, this has implications for the choice of loss function used to train the classifier.

5 Noisy Channel Model

Following Johnson and Charniak (2004), we use a noisy channel model to propose a 25-best list of possible speech disfluency analyses. The choice of this model is driven by the observation that the repairs frequently seem to be a "rough copy" of the reparandum, often incorporating the same or very similar words in roughly the same word order. That is, they seem to involve "crossed" dependencies between the reparandum and the repair. Example (3) shows the crossing dependencies. As this example also shows, the repair often contains many of the same words that appear in the reparandum. In fact, in our Switchboard training corpus we found that 62reparandum also appeared in the associated repair,



(3)

5.1 Informal Description

Given an observed sentence Y we wish to find the most likely source sentence $\hat{X}$, where

$$\hat{X} = \operatorname*{argmax}_X P(Y|X)P(X) \quad (4)$$

In our model the unobserved X is a substring of the complete utterance Y.

Noisy-channel models are used in a similar way in statistical speech recognition and machine translation. The language model assigns a probability $P(X)$ to the string X, which is a substring of the observed utterance Y. The channel model $P(Y|X)$ generates the utterance Y, which is a potentially disfluent version of the source sentence X. A repair can potentially begin before any word of X. When a repair has begun, the channel model incrementally processes the succeeding words from the start of the repair. Before each succeeding word either the repair can end or else a sequence of words can be inserted in the reparandum. At the end of each repair, a (possibly null) interregnum is appended to the reparandum.

We will look at these two components in the next two Sections in more detail.

5.2 Language Model

Informally, the task of language model component of the noisy channel model is to assess fluency of the sentence with disfluency removed. Ideally we would like to have a model which assigns a very high probability to disfluency-free utterances and a lower probability to utterances still containing disfluencies. For computational complexity reasons, as described in the next section, inside the noisy channel model we use a bigram language model. This

bigram language model is trained on the fluent version of the Switchboard corpus (training section).

We realise that a bigram model might not be able to capture more complex language behaviour. This motivates our investigation of a range of additional language models, which are used to define features used in the log-linear reranker as described below.

5.3 Channel Model

The intuition motivating the channel model design is that the words inserted into the reparandum are very closely related to those in the repair. Indeed, in our training data we find that 62% of the words in the reparandum are exact copies of words in the repair; this identity is strong evidence of a repair. The channel model is designed so that exact copy reparandum words will have high probability.

Because these repair structures can involve an unbounded number of crossed dependencies, they cannot be described by a context-free or finite-state grammar. This motivates the use of a more expressive formalism to describe these repair structures.

We assume that X is a substring of Y, i.e., that the source sentence can be obtained by deleting words from Y, so for a fixed observed utterance Y there are only a finite number of possible source sentences. However, the number of possible source sentences, X, grows exponentially with the length of Y, so exhaustive search is infeasible. Tree Adjoining Grammars (TAG) provide a systematic way of formalising the channel model, and their polynomial-time dynamic programming parsing algorithms can be used to search for likely repairs, at least when used with simple language models like a bigram language model. In this paper we first identify the 25 most likely analyses of each sentence using the TAG channel model together with a bigram language model.

Further details of the noisy channel model can be found in Johnson and Charniak (2004).

5.4 Reranker

To improve performance over the standard noisy channel model we use a reranker, as previously suggest by Johnson and Charniak (2004). We rerank a 25-best list of analyses. This choice is motivated by an oracle experiment we performed, probing for the location of the best analysis in a 100-best list. This experiment shows that in 99.5% of the cases the best analysis is located within the first 25, and indicates that an f-score of 0.958 should be achievable as the upper bound on a model using the first 25 best analyses. We therefore use the top 25 analyses from the noisy channel model in the remainder of this paper and use a reranker to choose the most suitable candidate among these.

6 Corpora for language modelling

We would like to use additional data to model the fluent part of spoken language. However, the Switchboard corpus is one of the largest widely-available disfluency-annotated speech corpora. It is reasonable to believe that for effective disfluency detection Switchboard is not large enough and more text can provide better analyses. Schwartz et al. (1994), although not focusing on disfluency detection, show that using written language data for modelling spoken language can improve performance. We turn to three other bodies of text and investigate the use of these corpora for our task, disfluency detection. We will describe these corpora in detail here.

The predictions made by several language models are likely to be strongly correlated, even if the language models are trained on different corpora. This motivates the choice for log-linear learners, which are built to handle features which are not necessarily independent. We incorporate information from the external language models by defining a reranker feature for each external language model. The value of this feature is the log probability assigned by the language model to the candidate underlying fluent substring X

For each of our corpora (including Switchboard) we built a 4-gram language model with Kneser-Ney smoothing (Kneser and Ney, 1995). For each analysis we calculate the probability under that language model for the candidate underlying fluent substring X. We use this log probability as a feature in the reranker. We use the SRILM toolkit (Stolcke, 2002) both for estimating the model from the training corpus as well as for computing the probabilities of the underlying fluent sentences X of the different analysis.

As previously described, **Switchboard** is our pri-

mary corpus for our model. The language model part of the noisy channel model already uses a bigram language model based on Switchboard, but in the reranker we would like to also use 4-grams for reranking. Directly using Switchboard to build a 4-gram language model is slightly problematic. When we use the training data of Switchboard both for language fluency prediction and the same training data also for the loss function, the reranker will overestimate the weight associated with the feature derived from the Switchboard language model, since the fluent sentence itself is part of the language model training data. We solve this by dividing the Switchboard training data into 20 folds. For each fold we use the 19 other folds to construct a language model and then score the utterance in this fold with that language model.

The largest widely-available corpus for language modelling is the **Web 1T 5-gram** corpus (Brants and Franz, 2006). This data set, collected by Google Inc., contains English word n-grams and their observed frequency counts. Frequency counts are produced from this billion-token corpus of web text. Because of the noise[1] present in this corpus there is an ongoing debate in the scientific community of the use of this corpus for serious language modelling.

The **Gigaword** Corpus (Graff and Cieri, 2003) is a large body of newswire text. The corpus contains $1.6 \cdot 10^9$ tokens, however fluent newswire text is not necessarily of the same domain as disfluency removed speech.

The **Fisher** corpora Part I (David et al., 2004) and Part II (David et al., 2005) are large bodies of transcribed text. Unlike Switchboard there is no disfluency annotation available for Fisher. Together the two Fisher corpora consist of $2.2 \cdot 10^7$ tokens.

7 Features

The log-linear reranker, which rescores the 25-best lists produced by the noisy-channel model, can also include additional features besides the noisy-channel log probabilities. As we show below, these additional features can make a substantial improvement to disfluency detection performance. Our reranker incorporates two kinds of features. The first are log-probabilities of various scores computed by the noisy-channel model and the external language models. We only include features which occur at least 5 times in our training data.

The noisy channel and language model features consist of:

1. LMP: 4 features indicating the probabilities of the underlying fluent sentences under the language models, as discussed in the previous section.

2. NCLogP: The Log Probability of the entire noisy channel model. Since by itself the noisy channel model is already doing a very good job, we do not want this information to be lost.

3. LogFom: This feature is the log of the "figure of merit" used to guide search in the noisy channel model when it is producing the 25-best list for the reranker. The log figure of merit is the sum of the log language model probability and the log channel model probability plus 1.5 times the number of edits in the sentence. This feature is redundant, i.e., it is a linear combination of other features available to the reranker model: we include it here so the reranker has direct access to all of the features used by the noisy channel model.

4. NCTransOdd: We include as a feature parts of the noisy channel model itself, i.e. the channel model probability. We do this so that the task to choosing appropriate weights of the channel model and language model can be moved from the noisy channel model to the log-linear optimisation algorithm.

The boolean indicator features consist of the following 3 groups of features operating on words and their edit status; the latter indicated by one of three possible flags: _ when the word is not part of a disfluency or E when it is part of the reparandum or I when it is part of the interregnum.

1. CopyFlags_X_Y: When there is an exact copy in the input text of length X ($1 \leq X \leq 3$) and the gap between the copies is Y ($0 \leq Y \leq 3$) this feature is the sequence of flags covering the two copies. Example: `CopyFlags_1_0 (E`

[1] We do not mean speech disfluencies here, but noise in web-text; web-text is often poorly written and unedited text.

_) records a feature when two identical words are present, directly consecutive and the first one is part of a disfluency (**E**dited) while the second one is not. There are 745 different instances of these features.

2. WordsFlags_L_n_R: This feature records the immediate area around an n-gram ($n \leq 3$). L denotes how many flags to the left and R ($0 \leq R \leq 1$) how many to the right are includes in this feature (Both L and R range over 0 and 1). Example: `WordsFlags_1_1_0 (need _)` is a feature that fires when a fluent word is followed by the word 'need' (one flag to the left, none to the right). There are 256808 of these features present.

3. SentenceEdgeFlags_B_L: This feature indicates the location of a disfluency in an utterance. The Boolean B indicates whether this features records sentence initial or sentence final behaviour, L ($1 \leq L \leq 3$) records the length of the flags. Example `SentenceEdgeFlags_1_1 (I)` is a feature recording whether a sentence ends on an interregnum. There are 22 of these features present.

We give the following analysis as an example:

but E *but _ that _ does _ n't _ work _*

The language model features are the probability calculated over the fluent part. NCLogP, LogFom and NCTransOdd are present with their associated value. The following binary flags are present:
`CopyFlags_1_0 (E _)`
`WordsFlags:0:1:0 (but E)`
`WordsFlags:0:1:0 (but _)`
`WordsFlags:1:1:0 (E but _)`
`WordsFlags:1:1:0 (_ that _)`
`WordsFlags:0:2:0 (but E but _)` etc.[2]
`SentenceEdgeFlags:0:1 (E)`
`SentenceEdgeFlags:0:2 (E _)`
`SentenceEdgeFlags:0:3 (E _ _)`

These three kinds of boolean indicator features together constitute the *extended feature set*.

[2] An exhaustive list here would be too verbose.

8 Loss functions for reranker training

We formalise the reranker training procedure as follows. We are given a training corpus T containing information about n possibly disfluent sentences. For the ith sentence T specifies the sequence of words x_i, a set $\mathcal{Y}_i$ of 25-best candidate "edited" labellings produced by the noisy channel model, as well as the correct "edited" labelling $y_i^\star \in \mathcal{Y}_i$.[3]

We are also given a vector $\mathbf{f} = (f_1, \ldots, f_m)$ of *feature functions*, where each f_j maps a word sequence x and an "edit" labelling y for x to a real value $f_j(x, y)$. Abusing notation somewhat, we write $\mathbf{f}(x, y) = (f_1(x, y), \ldots, f_m(x, y))$. We interpret a vector $\mathbf{w} = (w_1, \ldots, w_m)$ of *feature weights* as defining a conditional probability distribution over a candidate set $\mathcal{Y}$ of "edited" labellings for a string x as follows:

$$\mathrm{P}_{\mathbf{w}}(y \mid x, \mathcal{Y}) = \frac{\exp(\mathbf{w} \cdot \mathbf{f}(x, y))}{\sum_{y' \in \mathcal{Y}} \exp(\mathbf{w} \cdot \mathbf{f}(x, y'))}$$

We estimate the feature weights $\mathbf{w}$ from the training data T by finding a feature weight vector $\widehat{\mathbf{w}}$ that optimises a regularised objective function:

$$\widehat{\mathbf{w}} = \operatorname*{argmin}_{\mathbf{w}} L_T(\mathbf{w}) + \alpha \sum_{j=1}^{m} w_j^2$$

Here α is the *regulariser weight* and L_T is a *loss function*. We investigate two different loss functions in this paper. $LogLoss$ is the negative log conditional likelihood of the training data:

$$LogLoss_T(\mathbf{w}) = \sum_{i=1}^{m} -\log \mathrm{P}(y_i^\star \mid x_i, \mathcal{Y}_i)$$

Optimising $LogLoss$ finds the $\widehat{\mathbf{w}}$ that define (regularised) conditional Maximum Entropy models.

It turns out that optimising $LogLoss$ yields suboptimal weight vectors $\widehat{\mathbf{w}}$ here. $LogLoss$ is a symmetric loss function (i.e., each mistake is equally weighted), while our f-score evaluation metric weights "edited" labels more highly, as explained in section 4. Because our data is so skewed (i.e., "edited" words are comparatively infrequent), we

[3] In the situation where the true "edited" labelling does not appear in the 25-best list $\mathcal{Y}_i$ produced by the noisy-channel model, we choose $y_i^\star$ to be a labelling in $\mathcal{Y}_i$ closest to the true labelling.

can improve performance by using an asymmetric loss function.

Inspired by our evaluation metric, we devised an *approximate expected f-score loss function* $FLoss$.

$$FLoss_T(\mathbf{w}) \;=\; 1 - \frac{2\mathrm{E}_{\mathbf{w}}[c]}{g + \mathrm{E}_{\mathbf{w}}[e]}$$

This approximation assumes that the expectations approximately distribute over the division: see Jansche (2005) and Smith and Eisner (2006) for other approximations to expected f-score and methods for optimising them. We experimented with other asymmetric loss functions (e.g., the expected error rate) and found that they gave very similar results.

An advantage of $FLoss$ is that it and its derivatives with respect to $\mathbf{w}$ (which are required for numerical optimisation) are easy to calculate exactly. For example, the expected number of correct "edited" words is:

$$\begin{aligned}\mathrm{E}_{\mathbf{w}}[c] &= \sum_{i=1}^{n} \mathrm{E}_{\mathbf{w}}[c_{y_i^\star} \mid \mathcal{Y}_i], \text{ where:} \\ \mathrm{E}_{\mathbf{w}}[c_{y_i^\star} \mid \mathcal{Y}_i] &= \sum_{y \in \mathcal{Y}_i} c_{y_i^\star}(y)\, \mathrm{P}_{\mathbf{w}}(y \mid x_i, \mathcal{Y}_i)\end{aligned}$$

and $c_{y^\star}(y)$ is the number of correct "edited" labels in y given the gold labelling $y^\star$. The derivatives of $FLoss$ are:

$$\frac{\partial FLoss_T}{\partial w_j}(\mathbf{w}) \;=\; \frac{1}{g + \mathrm{E}_{\mathbf{w}}[e]} \left(FLoss_T(\mathbf{w}) \frac{\partial \mathrm{E}_{\mathbf{w}}[e]}{\partial w_j} - 2 \frac{\partial \mathrm{E}_{\mathbf{w}}[c]}{\partial w_j} \right)$$

where:

$$\frac{\partial \mathrm{E}_{\mathbf{w}}[c]}{\partial w_j} \;=\; \sum_{i=1}^{n} \frac{\partial \mathrm{E}_{\mathbf{w}}[c_{y_i^\star} \mid x_i, \mathcal{Y}_i]}{\partial w_j}$$

$$\frac{\partial \mathrm{E}_{\mathbf{w}}[c_{y^\star} \mid x, \mathcal{Y}]}{\partial w_j} \;=\; \mathrm{E}_{\mathbf{w}}[f_j c_{y^\star} \mid x, \mathcal{Y}] - \mathrm{E}_{\mathbf{w}}[f_j \mid x, \mathcal{Y}]\, \mathrm{E}_{\mathbf{w}}[c_{y^\star} \mid x, \mathcal{Y}].$$

$\partial \mathrm{E}[e] / \partial w_j$ is given by a similar formula.

9 Results

We follow Charniak and Johnson (2001) and split the corpus into main training data, held-out training data and test data as follows: main training consisted of all sw[23]$*$.dps files, held-out training consisted of all sw4[5-9]$*$.dps files and test consisted of all sw4[0-1]$*$.dps files. However, we follow (Johnson and Charniak, 2004) in deleting all partial words and punctuation from the training and test data (they argued that this is more realistic in a speech processing application).

Table 1 shows the results for the different models on held-out data. To avoid over-fitting on the test data, we present the f-scores over held-out training data instead of test data. We used the held-out data to select the best-performing set of reranker features, which consisted of features for all of the language models plus the extended (i.e., indicator) features, and used this model to analyse the test data. The f-score of this model on test data was 0.838. In this table, the set of *Extended Features* is defined as all the boolean features as described in Section 7.

We first observe that adding different external language models does increase the final score. The difference between the external language models is relatively small, although the differences in choice are several orders of magnitude. Despite the putative noise in the corpus, a language model built on Google's Web1T data seems to perform very well. Only the model where Switchboard 4-grams are used scores slightly lower, we explain this because the internal bigram model of the noisy channel model is already trained on Switchboard and so this model adds less new information to the reranker than the other models do.

Including additional features to describe the problem space is very productive. Indeed the best performing model is the model which has all extended features and all language model features. The differences among the different language models when extended features are present are relatively small. We assume that much of the information expressed in the language models overlaps with the lexical features.

We find that using a loss function related to our evaluation metric, rather than optimising $LogLoss$, consistently improves edit-word f-score. The standard $LogLoss$ function, which estimates the "maximum entropy" model, consistently performs worse than the loss function minimising expected errors.

The best performing model (Base + Ext. Feat. + All LM, using expected f-score loss) scores an f-score of **0.838** on **test data**. The results as indicated by the f-score outperform state-of-the-art models re-

Model	F-score

Table 1: Edited word detection f-score on held-out data for a variety of language models and loss functions

ported in literature operating on identical data, even though we use vastly less features than other do.

10 Conclusion and Future work

We have described a disfluency detection algorithm which we believe improves upon current state-of-the-art competitors. This model is based on a noisy channel model which scores putative analyses with a language model; its channel model is inspired by the observation that reparandum and repair are often very similar. As Johnson and Charniak (2004) noted, although this model performs well, a log-linear reranker can be used to increase performance.

We built language models from a variety of speech and non-speech corpora, and examine the effect they have on disfluency detection. We use language models derived from different larger corpora effectively in a maximum reranker setting. We show that the actual choice for a language model seems to be less relevant and newswire text can be used equally well for modelling fluent speech.

We describe different features to improve disfluency detection even further. Especially these features seem to boost performance significantly.

Finally we investigate the effect of different loss functions. We observe that using a loss function directly optimising our interest yields a performance increase which is at least at large as the effect of using very large language models.

We obtained an f-score which outperforms other models reported in literature operating on identical data, even though we use vastly fewer features than others do.

Abstract

Large vocabulary speech recognition systems fail to recognize words beyond their vocabulary, many of which are information rich terms, like named entities or foreign words. Hybrid word/sub-word systems solve this problem by adding sub-word units to large vocabulary word based systems; new words can then be represented by combinations of sub-word units. Previous work heuristically created the sub-word lexicon from phonetic representations of text using simple statistics to select common phone sequences. We propose a probabilistic model to *learn* the sub-word lexicon optimized for a given task. We consider the task of out of vocabulary (OOV) word detection, which relies on output from a hybrid model. A hybrid model with our learned sub-word lexicon reduces error by 6.3% and 7.6% (absolute) at a 5% false alarm rate on an English Broadcast News and MIT Lectures task respectively.

1 Introduction

Most automatic speech recognition systems operate with a large but limited vocabulary, finding the most likely words in the vocabulary for the given acoustic signal. While large vocabulary continuous speech recognition (LVCSR) systems produce high quality transcripts, they fail to recognize out of vocabulary (OOV) words. Unfortunately, OOVs are often information rich nouns, such as named entities and foreign words, and mis-recognizing them can have a disproportionate impact on transcript coherence.

Hybrid word/sub-word recognizers can produce a sequence of *sub-word units* in place of OOV words. Ideally, the recognizer outputs a complete word for in-vocabulary (IV) utterances, and sub-word units for OOVs. Consider the word "Slobodan", the given name of the former president of Serbia. As an uncommon English word, it is unlikely to be in the vocabulary of an English recognizer. While a LVCSR system would output the closest known words (e.x. "slow it dawn"), a hybrid system could output a sequence of multi-phoneme units: `s_l_ow`, `b_ax`, `d_ae_n`. The latter is more useful for automatically recovering the word's orthographic form, identifying that an OOV was spoken, or improving performance of a spoken term detection system with OOV queries. In fact, hybrid systems have improved OOV spoken term detection (Mamou et al., 2007; Parada et al., 2009), achieved better phone error rates, especially in OOV regions (Rastrow et al., 2009b), and obtained state-of-the-art performance for OOV detection (Parada et al., 2010).

Hybrid recognizers vary in a number of ways: sub-word unit type: variable-length phoneme units (Rastrow et al., 2009a; Bazzi and Glass, 2001) or joint letter sound sub-words (Bisani and Ney, 2005); unit creation: data-driven or linguistically motivated (Choueiter, 2009); and how they are incorporated in LVCSR systems: hierarchical (Bazzi, 2002) or flat models (Bisani and Ney, 2005).

In this work, we consider how to optimally create sub-word units for a hybrid system. These units are variable-length phoneme sequences, although in principle our work can be use for other unit types. Previous methods for creating the sub-word lexi-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 712–721,
Portland, Oregon, June 19-24, 2011.

con have relied on simple statistics computed from the phonetic representation of text (Rastrow et al., 2009a). These units typically represent the most frequent phoneme sequences in English words. However, it isn't clear why these units would produce the best hybrid output. Instead, we introduce a probabilistic model for *learning* the optimal units for a given task. Our model learns a segmentation of a text corpus given some side information: a mapping between the vocabulary and a label set; learned units are predictive of class labels.

In this paper, we learn sub-word units optimized for OOV detection. OOV detection aims to identify regions in the LVCSR output where OOVs were uttered. Towards this goal, we are interested in selecting units such that the recognizer outputs them only for OOV regions while prefering to output a complete word for in-vocabulary regions. Our approach yields improvements over state-of-the-art results.

We begin by presenting our log-linear model for learning sub-word units with a simple but effective inference procedure. After reviewing existing OOV detection approaches, we detail how the learned units are integrated into a hybrid speech recognition system. We show improvements in OOV detection, and evaluate impact on phone error rates.

2 Learning Sub-Word Units

Given raw text, our objective is to produce a lexicon of sub-word units that can be used by a hybrid system for open vocabulary speech recognition. Rather than relying on the text alone, we also utilize side information: a mapping of words to classes so we can optimize learning for a specific task.

The provided mapping assigns labels Y to the corpus. We maximize the probability of the observed labeling sequence Y given the text W: $P(Y|W)$. We assume there is a latent segmentation S of this corpus which impacts Y. The complete data likelihood becomes: $P(Y|W) = \sum_S P(Y, S|W)$ during training. Since we are maximizing the observed Y, segmentation S must discriminate between different possible labels.

We learn variable-length multi-phone units by segmenting the phonetic representation of each word in the corpus. Resulting segments form the sub-word lexicon.[1] Learning input includes a list of words to segment taken from raw text, a mapping between words and classes (side information indicating whether token is IV or OOV), a pronunciation dictionary D, and a letter to sound model (L2S), such as the one described in Chen (2003). The corpus W is the list of types (unique words) in the raw text input. This forces each word to have a unique segmentation, shared by all common tokens. Words are converted into phonetic representations according to their most likely dictionary pronunciation; non-dictionary words use the L2S model.[2]

2.1 Model

Inspired by the morphological segmentation model of Poon et al. (2009), we assume $P(Y, S|W)$ is a log-linear model parameterized by Λ:

$$P_\Lambda(Y, S|W) = \frac{1}{Z(W)} u_\Lambda(Y, S, W) \qquad (1)$$

where $u_\Lambda(Y, S, W)$ defines the score of the proposed segmentation S for words W and labels Y according to model parameters Λ. Sub-word units σ compose S, where each σ is a phone sequence, including the full pronunciation for vocabulary words; the collection of σs form the lexicon. Each unit σ is present in a segmentation with some context $c = (\phi_l, \phi_r)$ of the form $\phi_l \sigma \phi_r$. Features based on the context and the unit itself parameterize u_Λ.

In addition to scoring a segmentation based on features, we include two priors inspired by the Minimum Description Length (MDL) principle suggested by Poon et al. (2009). The **lexicon prior** favors smaller lexicons by placing an exponential prior with negative weight on the length of the lexicon $\sum_\sigma |\sigma|$, where $|\sigma|$ is the length of the unit σ in number of phones. Minimizing the lexicon prior favors a trivial lexicon of only the phones. The **corpus prior** counters this effect, an exponential prior with negative weight on the number of units in each word's segmentation, where $|s_i|$ is the segmentation length and $|w_i|$ is the length of the word in phones. Learning strikes a balance between the two priors. Using these definitions, the segmentation score $u_\Lambda(Y, S, W)$ is given as:

[1] Since sub-word units can expand full-words, we refer to both words and sub-words simply as units.

[2] The model can also take multiple pronunciations (§3.1).

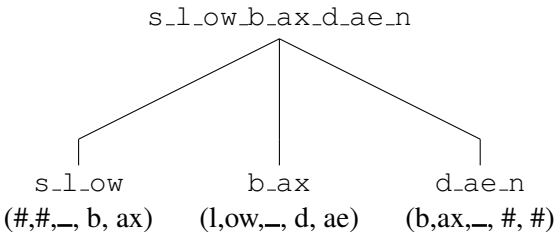

Figure 1: Units and bigram phone context (in parenthesis) for an example segmentation of the word "slobodan".

$$u_\Lambda(Y,S,W) = \exp\Bigg(\sum_{\sigma,y}\lambda_{\sigma,y}f_{\sigma,y}(S,Y) + \sum_{c,y}\lambda_{c,y}f_{c,y}(S,Y) + \alpha\cdot\sum_{\sigma\in S}|\sigma| + \beta\cdot\sum_{i\in W}|s_i|/|w_i|\Bigg) \quad (2)$$

$f_{\sigma,y}(S,Y)$ are the co-occurrence counts of the pair (σ,y) where σ is a unit under segmentation S and y is the label. $f_{c,y}(S,Y)$ are the co-occurrence counts for the context c and label y under S. The model parameters are $\Lambda=\{\lambda_{\sigma,y},\lambda_{c,y}:\forall\sigma,c,y\}$. The negative weights for the lexicon (α) and corpus priors (β) are tuned on development data. The normalizer Z sums over all possible segmentations and labels:

$$Z(W)=\sum_{S'}\sum_{Y'}u_\Lambda(Y',S',W) \quad (3)$$

Consider the example segmentation for the word "slobodan" with pronunciation s,l,ow,b,ax,d,ae,n (Figure 1). The bigram phone context as a four-tuple appears below each unit; the first two entries correspond to the left context, and last two the right context. The example corpus (Figure 2) demonstrates how unit features $f_{\sigma,y}$ and context features $f_{c,y}$ are computed.

3 Model Training

Learning maximizes the log likelihood of the observed labels Y^* given the words W:

$$\ell(Y^*|W)=\log\sum_S\frac{1}{Z(W)}u_\Lambda(Y^*,S,W) \quad (4)$$

We use the Expectation-Maximization algorithm, where the *expectation step* predicts segmentations S given the model's current parameters Λ (§3.1), and the *maximization step* updates these parameters using gradient ascent. The partial derivatives of the objective (4) with respect to each parameter λ_i are:

$$\frac{\partial\ell(Y^*|W)}{\partial\lambda_i}=E_{S|Y^*,W}[f_i]-E_{S,Y|W}[f_i] \quad (5)$$

The gradient takes the usual form, where we encourage the expected segmentation from the current model given the correct labels to equal the expected segmentation and expected labels. The next section discusses computing these expectations.

3.1 Inference

Inference is challenging since the lexicon prior renders all word segmentations interdependent. Consider a simple two word corpus: cesar (s,iy,z,er), and cesium (s,iy,z,iy,ax,m). Numerous segmentations are possible; each word has 2^{N-1} possible segmentations, where N is the number of phones in its pronunciation (i.e., $2^3\times2^5=256$). However, if we decide to segment the first word as: {s_iy, z_er}, then the segmentation for "cesium":{s_iy, z_iy_ax_m} will incur a lexicon prior penalty for including the new segment z_iy_ax_m. If instead we segment "cesar" as {s_iy_z, er}, the segmentation {s_iy, z_iy_ax_m} incurs double penalty for the lexicon prior (since we are including two new units in the lexicon: s_iy and z_iy_ax_m). This dependency requires joint segmentation of the entire corpus, which is intractable. Hence, we resort to approximations of the expectations in Eq. (5).

One approach is to use Gibbs Sampling: iterating through each word, sampling a new seg-

mentation conditioned on the segmentation of all other words. The sampling distribution requires enumerating all possible segmentations for each word (2^{N-1}) and computing the conditional probabilities for each segmentation: $P(S|Y^*, W) = P(Y^*, S|W)/P(Y^*|W)$ (the features are extracted from the remaining words in the corpus). Using M sampled segmentations $S_1, S_2, \ldots S_m$ we compute $E_{S|Y^*,W}[f_i]$ as follows:

$$E_{S|Y^*,W}[f_i] \approx \frac{1}{M} \sum_j f_i[S_j]$$

Similarly, to compute $E_{S,Y|W}$ we sample a segmentation and a label for each word. We compute the joint probability of $P(Y, S|W)$ for each segmentation-label pair using Eq. (1). A sampled segmentation can introduce new units, which may have higher probability than existing ones.

Using these approximations in Eq. (5), we update the parameters using gradient ascent:

$$\bar{\lambda}_{new} = \bar{\lambda}_{old} + \gamma \nabla \ell_{\bar{\lambda}}(Y^*|W)$$

where $\gamma > 0$ is the learning rate.

To obtain the best segmentation, we use deterministic annealing. Sampling operates as usual, except that the parameters are divided by a value, which starts large and gradually drops to zero. To make burn in faster for sampling, the sampler is initialized with the most likely segmentation from the previous iteration. To initialize the sampler the first time, we set all the parameters to zero (only the priors have non-zero values) and run deterministic annealing to obtain the first segmentation of the corpus.

3.2 Efficient Sampling

Sampling a segmentation for the corpus requires computing the normalization constant (3), which contains a summation over all possible corpus segmentations. Instead, we approximate this constant by sampling words independently, keeping fixed all other segmentations. Still, even sampling a single word's segmentation requires enumerating probabilities for all possible segmentations.

We sample a segmentation efficiently using dynamic programming. We can represent all possible segmentations for a word as a finite state machine (FSM) (Figure 3), where arcs weights arise from scoring the segmentation's features. This weight is the negative log probability of the resulting model after adding the corresponding features and priors.

However, the lexicon prior poses a problem for this construction since the penalty incurred by a new unit in the segmentation depends on whether that unit is present elsewhere in that segmentation. For example, consider the segmentation for the word ANJANI: AA_N, JH, AA_N, IY. If none of these units are in the lexicon, this segmentation yields the lowest prior penalty since it repeats the unit AA_N. [3] This global dependency means paths must encode the full unit history, making computing forward-backward probabilities inefficient.

Our solution is to use the *Metropolis-Hastings* algorithm, which samples from the true distribution $P(Y, S|W)$ by first sampling a new label and segmentation (y', s') from a simpler proposal distribution $Q(Y, S|W)$. The new assignment (y', s') is accepted with probability:

$$\alpha(Y', S'|Y, S, W) = \min\left(1, \frac{P(Y', S'|W)Q(Y, S|Y', S', W)}{P(Y, S|W)Q(Y', S'|Y, S, W)}\right)$$

We choose the proposal distribution $Q(Y, S|W)$ as Eq. (1) omitting the lexicon prior, removing the challenge for efficient computation. The probability of accepting a sample becomes:

$$\alpha(Y', S'|Y, S, W) = \min\left(1, \frac{\sum_{\sigma \in S'} |\sigma|}{\sum_{\sigma \in S} |\sigma|}\right) \quad (6)$$

We sample a path from the FSM by running the forward-backward algorithm, where the backward computations are carried out explicitly, and the forward pass is done through sampling, i.e. we traverse the machine only computing forward probabilities for arcs leaving the sampled state.[4] Once we sample a segmentation (and label) we accept it according to Eq. (6) or keep the previous segmentation if rejected.

Alg. 1 shows our full sub-word learning procedure, where `sampleSL` (Alg. 2) samples a segmentation and label sequence for the entire corpus from $P(Y, S|W)$, and `sampleS` samples a segmentation from $P(S|Y^*, W)$.

[3] Splitting at phone boundaries yields the same lexicon prior but a higher corpus prior.

[4] We use OpenFst's RandGen operation with a costumed arc-selector (http://www.openfst.org/).

4 OOV Detection Using Hybrid Models

To evaluate our model for learning sub-word units, we consider the task of out-of-vocabulary (OOV) word detection. OOV detection for ASR output can be categorized into two broad groups: 1) *hybrid (filler) models*: which explicitly model OOVs using either filler, sub-words, or generic word models (Bazzi, 2002; Schaaf, 2001; Bisani and Ney, 2005; Klakow et al., 1999; Wang, 2009); and 2) *confidence-based approaches*: which label unreliable regions as OOVs based on different confidence scores, such as acoustic scores, language models, and lattice scores (Lin et al., 2007; Burget et al., 2008; Sun et al., 2001; Wessel et al., 2001).

In the next section we detail the OOV detection approach we employ, which combines hybrid and confidence-based models, achieving state-of-the art performance for this task.

4.1 OOV Detection Approach

We use the state-of-the-art OOV detection model of Parada et al. (2010), a second order CRF with features based on the output of a hybrid recognizer. This detector processes hybrid recognizer output, so we can evaluate different sub-word unit lexicons for the hybrid recognizer and measure the change in OOV detection accuracy.

Our model (§2.1) can be applied to this task by using a dictionary D to label words as IV ($y_i = 0$ if $w_i \in D$) and OOV ($y_i = 1$ if $w_i \notin D$). This results in a labeled corpus, where the labeling sequence Y indicates the presence of out-of-vocabulary words (OOVs). For comparison we evaluate a baseline method (Rastrow et al., 2009b) for selecting units.

Given a sub-word lexicon, the word and sub-words are combined to form a hybrid language model (LM) to be used by the LVCSR system. This hybrid LM captures dependencies between word and sub-words. In the LM training data, all OOVs are represented by the smallest number of sub-words which corresponds to their pronunciation. Pronunciations for all OOVs are obtained using grapheme

to phone models (Chen, 2003).

Since sub-words represent OOVs while building the hybrid LM, the existence of sub-words in ASR output indicate an OOV region. A simple solution to the OOV detection problem would then be reduced to a search for the sub-words in the output of the ASR system. The search can be on the one-best transcripts, lattices or confusion networks. While lattices contain more information, they are harder to process; confusion networks offer a trade-off between richness (posterior probabilities are already computed) and compactness (Mangu et al., 1999).

Two effective indications of OOVs are the existence of sub-words (Eq. 7) and high entropy in a network region (Eq. 8), both of which are used as features in the model of Parada et al. (2010).

$$\text{Sub-word Posterior} = \sum_{\sigma \in t_j} p(\sigma|t_j) \quad (7)$$

$$\text{Word-Entropy} = -\sum_{w \in t_j} p(w|t_j) \log p(w|t_j) \quad (8)$$

t_j is the current bin in the confusion network and σ is a sub-word in the hybrid dictionary. Improving the sub-word unit lexicon, improves the quality of the confusion networks for OOV detection.

5 Experimental Setup

We used the data set constructed by Can et al. (2009) (OOVCORP) for the evaluation of Spoken Term Detection of OOVs since it focuses on the OOV problem. The corpus contains 100 hours of transcribed Broadcast News English speech. There are 1290 unique OOVs in the corpus, which were selected with a minimum of 5 acoustic instances per word and short OOVs inappropriate for STD (less than 4 phones) were explicitly excluded. Example OOVs include: NATALIE, PUTIN, QAEDA, HOLLOWAY, COROLLARIES, HYPERLINKED, etc. This resulted in roughly 24K (2%) OOV tokens.

For LVCSR, we used the IBM Speech Recognition Toolkit (Soltau et al., 2005)[5] to obtain a transcript of the audio. Acoustic models were trained on 300 hours of HUB4 data (Fiscus et al., 1998) and utterances containing OOV words as marked in OOVCORP were excluded. The language model was trained on 400M words from various text sources with a 83K word vocabulary. The LVCSR system's WER on the standard RT04 BN test set was 19.4%. Excluded utterances amount to 100hrs. These were divided into 5 hours of training for the OOV detector and 95 hours of test. Note that the OOV detector training set is different from the LVCSR training set.

We also use a hybrid LVCSR system, combining word and sub-word units obtained from either our approach or a state-of-the-art baseline approach (Rastrow et al., 2009a) (§5.2). Our hybrid system's lexicon has 83K words and 5K or 10K sub-words. Note that the word vocabulary is common to both systems and only the sub-words are selected using either approach. The word vocabulary used is close to most modern LVCSR system vocabularies for English Broadcast News; the resulting OOVs are more challenging but more realistic (i.e. mostly named entities and technical terms). The 1290 words are OOVs to both the word and hybrid systems.

In addition we report OOV detection results on a MIT lectures data set (Glass et al., 2010) consisting of 3 Hrs from two speakers with a 1.5% OOV rate. These were divided into 1 Hr for training the OOV detector and 2 Hrs for testing. Note that the LVCSR system is trained on Broadcast News data. This out-of-domain test-set help us evaluate the cross-domain performance of the proposed and baseline hybrid systems. OOVs in this data set correspond mainly to technical terms in computer science and math. e.g. ALGORITHM, DEBUG, COMPILER, LISP.

5.1 Learning parameters

For learning the sub-words we randomly selected from training 5,000 words which belong to the 83K vocabulary and 5,000 OOVs[6]. For development we selected an additional 1,000 IV and 1,000 OOVs. This was used to tune our model hyper parameters (set to $\alpha = -1$, $\beta = -20$). There is no overlap of OOVs in training, development and test sets. All feature weights were initialized to zero and had a Gaussian prior with variance $\sigma = 100$. Each of the words in training and development was converted to their most-likely pronunciation using the dictionary

[5]The IBM system used speaker adaptive training based on maximum likelihood with no discriminative training.

[6]This was used to obtain the 5K hybrid system. To learn sub-words for the 10K hybrid system we used 10K in-vocabulary words and 10K OOVs. All words were randomly selected from the LM training text.

for IV words or the L2S model for OOVs.[7]

The learning rate was $\gamma_k = \frac{\gamma}{(k+1+A)^\tau}$, where k is the iteration, A is the stability constant (set to $0.1K$), $\gamma = 0.4$, and $\tau = 0.6$. We used $K = 40$ iterations for learning and 200 samples to compute the expectations in Eq. 5. The sampler was initialized by sampling for 500 iterations with deterministic annealing for a temperature varying from 10 to 0 at 0.1 intervals. Final segmentations were obtained using $10,000$ samples and the same temperature schedule. We limit segmentations to those including units of at most 5 phones to speed sampling with no significant degradation in performance. We observed improved performance by dis-allowing whole word units.

5.2 Baseline Unit Selection

We used Rastrow et al. (2009a) as our baseline unit selection method, a data driven approach where the language model training text is converted into phones using the dictionary (or a letter-to-sound model for OOVs), and a N-gram phone LM is estimated on this data and pruned using a relative entropy based method. The hybrid lexicon includes resulting sub-words – ranging from unigrams to 5-gram phones, and the 83K word lexicon.

5.3 Evaluation

We obtain confusion networks from both the word and hybrid LVCSR systems. We align the LVCSR transcripts with the reference transcripts and tag each confusion region as either IV or OOV. The OOV detector classifies each region in the confusion network as IV/OOV. We report OOV detection accuracy using standard detection error tradeoff (DET) curves (Martin et al., 1997). DET curves measure tradeoffs between false alarms (x-axis) and misses (y-axis), and are useful for determining the optimal operating point for an application; lower curves are better. Following Parada et al. (2010) we separately evaluate unobserved OOVs.[8]

[7] In this work we ignore pronunciation variability and simply consider the most likely pronunciation for each word. It is straightforward to extend to multiple pronunciations by first sampling a pronunciation for each word and then sampling a segmentation for that pronunciation.

[8] Once an OOV word has been observed in the OOV detector training data, even if it was not in the LVCSR training data, it is no longer truly OOV.

6 Results

We compare the performance of a hybrid system with baseline units[9] (§5.2) and one with units learned by our model on OOV detection and phone error rate. We present results using a hybrid system with 5k and 10k sub-words.

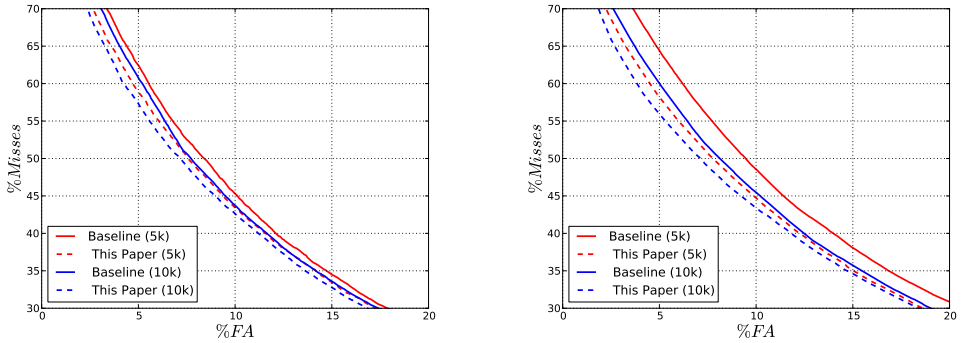
We evaluate the CRF OOV detector with two different feature sets. The first uses only Word Entropy and Sub-word Posterior (Eqs. 7 and 8) (Figure 4)[10]. The second (`context`) uses the extended context features of Parada et al. (2010) (Figure 5). Specifically, we include all trigrams obtained from the best hypothesis of the recognizer (a window of 5 words around current confusion bin). Predictions at different FA rates are obtained by varying a probability threshold.

At a 5% FA rate, our system (`This Paper 5k`) reduces the miss OOV rate by 6.3% absolute over the baseline (`Baseline 5k`) when evaluating all OOVs. For unobserved OOVs, it achieves 3.6% absolute improvement. A larger lexicon (`Baseline 10k` and `This Paper 10k`) shows similar relative improvements. Note that the features used so far do not necessarily provide an advantage for unobserved versus observed OOVs, since they ignore the decoded word/sub-word sequence. In fact, the performance on un-observed OOVs is better.

OOV detection improvements can be attributed to increased coverage of OOV regions by the learned sub-words compared to the baseline. Table 1 shows the percent of Hits: sub-word units predicted in OOV regions, and False Alarms: sub-word units predicted for in-vocabulary words. We can see that the proposed system increases the Hits by over 8% absolute, while increasing the False Alarms by 0.3%. Interestingly, the average sub-word length for the proposed units exceeded that of the baseline units by 0.3 phones (`Baseline 5K` average length was 2.92, while that of `This Paper 5K` was 3.2).

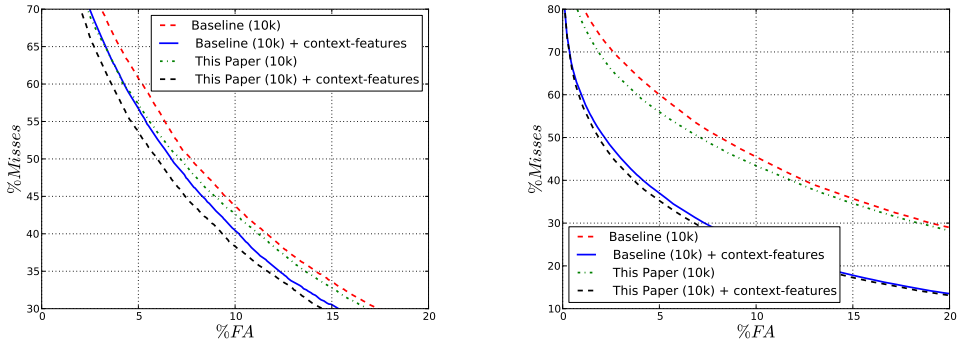
[9] Our baseline results differ from Parada et al. (2010). When implementing the lexicon baseline, we discovered that their hybrid units were mistakenly derived from text containing test OOVs. Once excluded, the relative improvements of previous work remain, but the absolute error rates are higher.

[10] All real-valued features were normalized and quantized using the uniform-occupancy partitioning described in White et al. (2007). We used 50 partitions with a minimum of 100 training values per partition.



(a) (b)

Figure 4: DET curves for OOV detection using baseline hybrid systems for different lexicon size and proposed discriminative hybrid system on **OOVCORP** data set. Evaluation on **un-observed** OOVs (a) and **all** OOVs (b).



(a) (b)

Figure 5: Effect of adding context features to baseline and discriminative hybrid systems on **OOVCORP** data set. Evaluation on **un-observed** OOVs (a) and **all** OOVs (b).

Consistent with previously published results, including context achieves large improvement in performance. The proposed hybrid system (This Paper 10k + context-features) still improves over the baseline (Baseline 10k + context-features), however the relative gain is reduced. In this case, we obtain larger gains for un-observed OOVs which benefit less from the context clues learned in training.

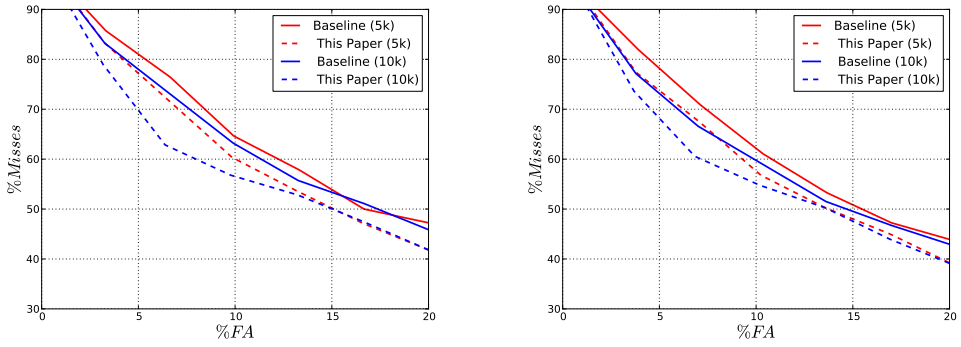
Lastly, we report OOV detection performance on MIT Lectures. Both the sub-word lexicon and the LVCSR models were trained on Broadcast News data, helping us evaluate the robustness of learned sub-words across domains. Note that the OOVs in these domains are quite different: MIT Lectures' OOVs correspond to technical computer science and math terms, while in Broadcast News they are mainly named-entities.

Hybrid System	**Hits**	**FAs**
Baseline (5k)	18.25	1.49
This Paper (5k)	26.78	1.78
Baseline (10k)	24.26	1.82
This Paper (10k)	28.96	1.92

Table 1: Coverage of OOV regions by baseline and proposed sub-words in OOVCORP.

Figure 6 and 7 show the OOV detection results in the MIT Lectures data set. For un-observed OOVs, the proposed system (`This Paper 10k`) reduces the miss OOV rate by 7.6% with respect to the baseline (`Baseline 10k`) at a 5% FA rate. Similar to Broadcast News results, we found that the learned sub-words provide larger coverage of OOV regions in MIT Lectures domain. These results suggest that the proposed sub-words are not simply modeling the training OOVs (named-entities) better than the baseline sub-words, but also describe better novel unexpected words. Furthermore, including context features does not seem as helpful. We conjecture that this is due to the higher WER[11] and the less structured nature of the domain: i.e. ungrammatical sentences, disfluencies, incomplete sentences, making it more difficult to predict OOVs based on context.

[11] $WER = 32.7\%$ since the LVCSR system was trained on Broadcast News data as described in Section 5.



(a) (b)

(a) (b)

Figure 7: Effect of adding context features to baseline and discriminative hybrid systems on **MIT Lectures** data set. Evaluation on **un-observed** OOVs (a) and **all** OOVs (b).

6.1 Improved Phonetic Transcription

We consider the hybrid lexicon's impact on Phone Error Rate (PER) with respect to the reference transcription. The reference phone sequence is obtained by doing *forced alignment* of the audio stream to the reference transcripts using acoustic models. This provides an alignment of the pronunciation variant of each word in the reference and the recognizer's one-best output. The aligned words are converted to the phonetic representation using the dictionary.

Table 2 presents PERs for the word and different hybrid systems. As previously reported (Rastrow et al., 2009b), the hybrid systems achieve better PER, specially in OOV regions since they predict sub-word units for OOVs. Our method achieves modest improvements in PER compared to the hybrid baseline. No statistically significant improvements in PER were observed on MIT Lectures.

System	OOV	IV	All
Word	1.62	6.42	8.04
Hybrid: Baseline (5k)	1.56	6.44	8.01
Hybrid: Baseline (10k)	1.51	6.41	7.92
Hybrid: This Paper (5k)	1.52	6.42	7.94
Hybrid: This Paper (10k)	1.45	6.39	7.85

Table 2: Phone Error Rate for OOVCORP.

7 Conclusions

Our probabilistic model learns sub-word units for hybrid speech recognizers by segmenting a text corpus while exploiting side information. Applying our method to the task of OOV detection, we obtain an absolute error reduction of 6.3% and 7.6% at a 5% false alarm rate on an English Broadcast News and MIT Lectures task respectively, when compared to a baseline system. Furthermore, we have confirmed previous work that hybrid systems achieve better phone accuracy, and our model makes modest improvements over a baseline with a similarly sized sub-word lexicon. We plan to further explore our new lexicon's performance for other languages and tasks, such as OOV spoken term detection.

Abstract

This paper focuses on identifying, extracting and evaluating features related to syntactic complexity of spontaneous spoken responses as part of an effort to expand the current feature set of an automated speech scoring system in order to cover additional aspects considered important in the construct of communicative competence.

Our goal is to find effective features, selected from a large set of features proposed previously and some new features designed in analogous ways from a syntactic complexity perspective that correlate well with human ratings of the same spoken responses, and to build automatic scoring models based on the most promising features by using machine learning methods.

On human transcriptions with manually annotated clause and sentence boundaries, our best scoring model achieves an overall Pearson correlation with human rater scores of r=0.49 on an unseen test set, whereas correlations of models using sentence or clause boundaries from automated classifiers are around r=0.2.

1 Introduction

Past efforts directed at automated scoring of speech have used mainly features related to fluen cy (e.g., speaking rate, length and distribution of pauses), pronunciation (e.g., using log-likelihood scores from the acoustic model of an Automatic Speech Recognition (ASR) system), or prosody (e.g., information related to pitch contours or syllable stress) (e.g., Bernstein, 1999; Bernstein et al., 2000; Bernstein et al., 2010; Cucchiarini et al., 1997; Cucchiarini et al., 2000; Franco et al., 2000a; Franco et al., 2000b; Zechner et al., 2007, Zechner et al., 2009).

While this approach is a good match to most of the important properties related to low entropy speech (i.e., speech which is highly predictable), such as reading a passage aloud, it lacks many important aspects of spontaneous speech which are relevant to be evaluated both by a human rater and an automated scoring system. Examples of such aspects of speech, which are considered part of the construct[1] of "communicative competence (Bachman, 1990), include grammatical accuracy, syntactic complexity, vocabulary diversity, and aspects of spoken discourse structure, e.g., coherence and cohesion. These different aspects of speaking proficiency are often highly correlated in a non-native speaker (Xi and Mollaun, 2006; Bernstein et al., 2010), and so scoring models built solely on features of fluency and pronunciation may achieve reasonably high correlations with holistic human rater scores. However, it is important to point out that such systems would still be unable to assess many important aspects of the speaking construct and therefore cannot be seen as ideal from a validity point of view.[2]

The purpose of this paper is to address one of these important aspects of spoken language in more detail, namely syntactic complexity. This paper can be seen as a first step toward including

[1] A construct is a set of knowledge, skills, and abilities measured by a test.

[2] "Construct validity" refers to the extent that a test measures what it is designed to measure, in this case, communicative competence via speaking.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 722–731,
Portland, Oregon, June 19-24, 2011.

features related to this part of the speaking construct into an already existing automated speech scoring system for spontaneous speech which so far mostly uses features related to fluency and pronunciation (Zechner et al., 2009).

We use data from the speaking section of the TOEFL® Practice Online (TPO) test, which is a low stakes practice test for non-native speakers where they are asked to provide six spontaneous speech samples of about one minute in length each in response to a variety of prompts. Some prompts may be simple questions, and others may involve reading or listening to passages first and then answering related questions. All responses were scored holistically by human raters according to pre-defined scoring rubrics (i.e., specific scoring guidelines) on a scale of 1 to 4, 4 being the highest proficiency level.

In our automated scoring system, the first component is an ASR system that decodes the digitized speech sample, generating a time-annotated hypothesis for every response. Next, fluency and pronunciation features are computed based on the ASR output hypotheses, and finally a multiple regression scoring model, trained on human rater scores, computes the score for a given spoken response (see Zechner et al. (2009) for more details). We conducted the study in three steps: (1) finding important measures of syntactic complexity from second language acquisition (SLA) and English language learning (ELL) literature, and extending this feature set based on our observations of the TPO data in analogous ways; (2) computing features based on transcribed speech responses and selecting features with highest correlations to human rater scores, also considering their comparative values for native speakers taking the same test; and (3) building scoring models for the selected sub-set of the features to generate a proficiency score for each speaker, using all six responses of that speaker.

In the remainder of the paper, we will address related work in syntactic complexity (Section 2), introduce the speech data sets of our study (Section 3), describe the methods we used for feature extraction (Section 4), provide the experiment design and results (Section 5), analyze and discuss the results in Section 6, before concluding the paper (Section 7).

2 Related Work

2.1 Literature on Syntactic Complexity

Syntactic complexity is defined as "the range of forms that surface in language production and the degree of sophistication of such forms" (Ortega, 2003). It is an important factor in the second language assessment construct as described in Bachman's (1990) conceptual model of language ability, and therefore is often used as an index of language proficiency and development status of L2 learners. Various studies have proposed and investigated measures of syntactic complexity as well as examined its predictiveness for language proficiency, in both L2 writing and speaking settings, which will be reviewed respectively.

Writing

Wolfe-Quintero et al. (1998) reviewed a number of grammatical complexity measures in L2 writing from thirty-nine studies, and their usage for predicting language proficiency was discussed. Some examples of syntactic complexity measures are: mean number of clauses per T-unit[3], mean length of clauses, mean number of verbs per sentence, etc. The various measures can be grouped into two categories: (1) clauses, sentences, and T-units in terms of each other; and (2) specific grammatical structures (e.g., passives, nominals) in relation to clauses, sentences, or T-units (Wolfe-Quintero et al., 1998). Three primary methods of calculating syntactic complexity measures are frequency, ratio, and index, where frequency is the count of occurrences of a specific grammatical structure, ratio is the number of one type of unit divided by the total number of another unit, and index is computing numeric scores by specific formulae (Wolfe-Quintero et al., 1998). For example, the measure "mean number of clauses per T-unit" is obtained by using the ratio calculation method and the clause and T-unit grammatical structures. Some structures such as clauses and T-units only need shallow linguistic processing to acquire, while some require parsing. There are numerous combinations for measures and we need empirical evi-

[3] T-units are defined as "shortest grammatically allowable sentences into which (writing can be split) or minimally terminable units" (Hunt, 1965:20).

dence to select measures with the highest performance.

There have been a series of empirical studies examining the relationship of syntactic complexity measures to L2 proficiency using real-world data (Cooper, 1976; Larsen-Freeman, 1978; Perkins, 1980; Ho-Peng, 1983; Henry, 1996; Ortega, 2003; Lu, 2010). The studies investigate measures that highly correlate with proficiency levels or distinguish between different proficiency levels. Many T-unit related measures were identified as statistically significant indicators to L2 proficiency, such as mean length of T-unit (Henry, 1996; Lu, 2010), mean number of clauses per T-unit (Cooper, 1976; Lu, 2010), mean number of complex nominals per T-unit (Lu, 2010), or the mean number of error-free T-units per sentence (Ho-Peng, 1983). Other significant measures are mean length of clause (Lu, 2010), or frequency of passives in composition (Kameen, 1979).

Speaking

Syntactic complexity analysis in speech mainly inherits measures from the writing domain, and the abovementioned measures can be employed in the same way on speech transcripts for complexity computation. A series of studies have examined relations between the syntactic complexity of speech and the speakers' holistic speaking proficiency levels (Halleck, 1995; Bernstein et al., 2010; Iwashita, 2006). Three objective measures of syntactic complexity, including mean T-unit length, mean error-free T-unit length, and percent of error-free T-units were found to correlate with holistic evaluations of speakers in Halleck (1995). Iwashita's (2006) study on Japanese L2 speakers found that length-based complexity features (i.e., number of T-units and number of clauses per T-unit) are good predictors for oral proficiency. In studies directly employing syntactic complexity measures in other contexts, ratio-based measures are frequently used. Examples are mean length of utterance (Condouris et al., 2003), word count or tree depth (Roll et al., 2007), or mean length of T-units and mean number of clauses per T-unit (Bernstein et al., 2010). Frequency-based measures were used less, such as number of full phrases in Roll et al. (2007).

The speaking output is usually less clean than writing data (e.g., considering disfluencies such as false starts, repetitions, filled pauses etc.). Therefore we may need to remove these disfluencies first before computing syntactic complexity features. Also, importantly, ASR output does not contain interpunctuation but both for sentential-based features as well as for parser-based features, the boundaries of clauses and sentences need to be known. For this purpose, we will use automated classifiers that are trained to predict clause and sentence boundaries, as described in Chen et al. (2010). With previous studies providing us a rich pool of complexity features, additionally we also develop features analogous to the ones from the literature, mostly by using different calculation methods. For instance, the frequency of Prepositional Phrases (PPs) is a feature from the literature, and we add some variants such as number of PPs per clause as a new feature to our extended feature set.

2.2 Devising the Initial Feature Set

Through this literature review, we identified some important features that were frequently used in previous studies in both L2 speaking and writing, such as length of sentences and number of clauses per sentence. In addition, we also collected candidate features that were less frequently mentioned in the literature, in order to start with a larger field of potential candidate features. We further extended the feature set by inspecting our data, described in the following section, and created suitable additional features by means of analogy. This process resulted in a set of 91 features, 11 of which are related to clausal and sentential unit measurements (frequency-based) and 80 to measurements within such units (ratio-based). From the perspective of extracting measures, in our study, some measures can be computed using only clause and sentence boundary information, and some can be derived only if the spoken responses are syntactically parsed. In our feature set, there are two types of features: clause and sentence boundary based (26 in total) and parsing based (65). The features will be described in detail in Section 4.

3 Data

Our data set contains (1) 1,060 non-native speech responses of 189 speakers from the TPO test (NN set), and (2) 100 responses from 48 native speakers that took the same test (Nat set). All responses were verbatim transcribed manually and scored

holistically by human raters. (We only made use of the scores for the non-native data set in this study, since we purposefully selected speakers with perfect or near perfect scores for the Nat set from a larger native speech data set.) As mentioned above, there are four proficiency levels for human scoring, levels 1 to 4, with higher levels indicating better speaking proficiency.

The NN set was randomly partitioned into a training (NN-train) and a test set with 760 and 300 responses, respectively, and no speaker overlap.

Data Set	**Responses**	**Speakers**	**Responses per Speaker (average)**
NN-train	760	137	5.55
	Description: used to train sentence and clause boundary detectors, evaluate features and train scoring models		
1: NN-test-1-Hum	300	52	5.77
	Description: human transcriptions and annotations of sentence and clause boundaries		
2: NN-test-2-CB	300	52	5.77
	Description: human transcriptions, automatically predicted clause boundaries		
3: NN-test-3-SB	300	52	5.77
	Description: human transcriptions, automatically predicted sentence boundaries		
4: NN-test-4-ASR-CB	300	52	5.77
	Description: ASR hypotheses, automatically predicted clause boundaries		
5: NN-test-5-ASR-SB	300	52	5.77
	Description: ASR hypotheses, automatically predicted sentence boundaries		

Table 1. Overview of non-native data sets.

A second version of the test set contains ASR hypotheses instead of human transcriptions. The word error rate (WER[4]) on this data set is 50.5%. We used a total of five variants of the test sets, as described in Table 1. Sets 1-3 are based on human transcriptions, whereas sets 4 and 5 are based on ASR output. Further, set 1 contains human annotated clause and sentence boundaries, whereas the other 4 sets have clause or sentence boundaries predicted by a classifier.

All human transcribed files from the NN data set were annotated for clause boundaries, clause types, and disfluencies by human annotators (see Chen et al. (2010)).

For the Nat data set, all of the 100 transcribed responses were annotated in the same manner by a human annotator. They are not used for any training purposes but serve as a comparative reference for syntactic complexity features derived from the non-native corpus.

The NN-train set was used both for training clause and sentence boundary classifiers, as well as for feature selection and training of the scoring models. The two boundary detectors were machine learning based Hidden Markov Models, trained by using a language model derived from the 760 training files which had sentence and clause boundary labels (NN-train; see also Chen et al. (2010)).

Since a speaker's response to a single test item can be quite short (fewer than 100 words in many cases), it may contain only very few syntactic complexity features we are looking for. (Note that much of the previous work focused on written language with much longer texts to be considered.) However, if we aggregate responses of a single speaker, we have a better chance of finding a larger number of syntactic complexity features in the aggregated file. Therefore we joined files from the same speaker to one file for the training set and the five test sets, resulting in 52 aggregated files in each test set. Accordingly, we averaged the response scores of a single speaker to obtain the total speaker score to be used later in scoring model training and evaluation (Section 5).[5]

While disfluencies were used for the training of the boundary detectors, they were removed afterwards from the annotated data sets to obtain a tran-

[4] Word error rate (WER) is the ratio of errors from a string between the ASR hypothesis and the reference transcript, where the sum of substitutions, insertions, and deletions is divided by the length of the reference. To obtain WER in percent, this ratio is multiplied by 100.0.

[5] Although in most operational settings, features are derived from single responses, this may not be true in all cases. Furthermore, scores of multiple responses are often combined for score reporting, which would make such an approach easier to implement and argue for operationally.

scription which is "cleaner" and lends itself better to most of the feature extraction methods we use.

4 Feature Extraction

4.1 Feature Set

As mentioned in Section 2, we gathered 91 candidate syntactic complexity features based on our literature review as initial feature set, which is grouped into two categories: (1) Clause and sentence Boundary based features (CB features); and (2) Parse Tree based features (PT features). Clause based features are based on both clause boundaries and clause types and can be generated from human clause annotations, e.g., "frequency of adjective clauses[6] per one thousand words", "mean number of dependent clauses per clause", etc. Parse tree based features refer to features that are generated from parse trees and cannot be extracted from human annotated clauses directly.

We first selected features showing high correlation to human assigned scores. In this process the CB features were computed from human labeled clause boundaries in transcripts for best accuracy, and PT features were calculated from using parsing and other tools because we did not have human parse tree annotations for our data.

We used the Stanford Parser (Klein and Manning, 2003) in conjunction with the Stanford Tregex package (Levy and Andrew, 2006) which supports using rules to extract specific configurations from parse trees, in a package put together by Lu (Lu, 2011). When given a sentence, the Stanford Parser outputs its grammatical structure by grouping words (and phrases) in a tree structure and identifies grammatical roles of words and phrases.

Tregex is a tree query tool that takes Stanford parser trees as input and queries the trees to find subtrees that meet specific rules written in Tregex syntax (Levy and Andrew, 2006). It uses relational operators regulated by Tregex, for example, "A << B" stands for "subtree A dominates subtree B". The operators primarily function in subtree precedence, dominance, negation, regular expression, tree node identity, headship, or variable groups, among others (Levy and Andrew, 2006).

Lu's tool (Lu, 2011), built upon the Stanford Parser and Tregex, does syntactic complexity analysis given textual data. Lu's tool contributed 8 of the initial CB features and 6 of the initial PT features, and we computed the remaining CB and PT features using Perl scripts, the Stanford Parser, and Tregex.

Table 2 lists the sub-set of 17 features (out of 91 features total) that were used for building the scoring models described later (Section 5).

4.2 Feature Selection

We determined the importance of the features by computing each feature's correlation with human raters' proficiency scores based on the training set NN-train. We also used criteria related to the speaking construct, comparisons with native speaker data, and feature inter-correlations. While approaches coming from a pure machine learning perspective would likely use the entire feature pool as input for a classifier, our goal here is to obtain an initial feature set by judicious and careful feature selection that can withstand the scrutiny of construct validity in assessment development.

As noted earlier, the disfluencies in the training set had been removed to obtain a "cleaner" text that looks somewhat more akin to a written passage and is easier to process by NLP modules such as parsers and part-of-speech (POS) taggers.[7] The extracted features partly were taken directly from proposals in the literature and partly were slightly modified to fit our clause annotation scheme. In order to have a unified framework for computing syntactic complexity features, we used a combination of the Stanford Parser and Tregex for computing both clause- and sentence-based features as well as parse-tree-based features, i.e., we did not make use of the human clause boundary label annotations here. The only exception to this

[6] An adjective clause is a clause that functions as an adjective in modifying a noun. E.g., "This cat is a cat that is difficult to deal with."

[7] We are aware that disfluencies can provide valuable clues about spoken proficiency in and of themselves; however, this study is focused exclusively on syntactic complexity analysis, and in this context, disfluencies would distort the picture considerably due to the introduction of parsing errors, e.g.

Name	Type[8]	Meaning	Correlation	Regression
MLS	CB	Mean length of sentences	0.329	0.101
MLT	CB	Mean length of T-units	0.300	-0.059
DC/C	CB	Mean number of dependent clauses per clause	0.291	2.873
SSfreq	CB	Frequency of simple sentences per 1000 words	-.0242	0.001
MLSS	CB	Mean length of simple sentences	0.255	0.040
ADJCfreq	CB	Frequency of adjective clauses per 1000 words	0.253	0.004
Ffreq	CB	Frequency of fragments per 1000 words	-0.386	-0.057
MLCC	CB	Mean length of coordinate clauses	0.224	0.017
CT/T	PT	Mean number of complex T-units per T-unit	0.248	0.908
PP_ling/S	PT	Mean number of linguistically meaningful prepositional phrases (PP) per sentence[9]	0.310	0.423
NP/S	PT	Mean number of noun phrases (NP) per sentence	0.244	-0.411
CN/S	PT	Mean number of complex nominal per sentence	0.325	0.653
VB _ling/T	PT	Mean number of linguistically meaningful[10] verb phrases per T-unit	0.273	-0.780
PAS/S	PT	Mean number of passives per sentence	0.260	1.520
DI/T	PT	Mean number of dependent infinitives per T-unit	0.325	1.550
MLev	PT	Mean number of parsing tree levels per sentence	0.306	-0.134
MPSam	PT	Mean P-based Sampson[11] per sentence	0.254	0.234

Table 2. List of syntactic complexity features selected to be included in building the scoring models.

is that we are using human clause and sentence labels to create a candidate set for the clause boundary features evaluated by the Stanford Parser and Tregex, as explained in the following subsection.

[8] Feature type: CB=Clause boundary based feature type, PT=Parse tree based feature type

[9] A "linguistically meaningful PP" (PP_ling) is defined as a PP immediately dominated by another PP in cases where a preposition contains a noun such as "in spite of" or "in front of". An example would be "she stood in front of a house" where "in front of a house" would be parsed as two embedded PPs but only the top PP would be counted in this case.

[10] A "linguistically meaningful VP" (VP_ling) is defined as a verb phrase immediately dominated by a clausal phrase, in order to avoid VPs embedded in another VP, e.g., "should go to work" is identified as one VP instead of two embedded VPs.

[11] The "P-based Sampson" is a raw production-based measure (Sampson, 1997), defined as "proportion of the daughters of a nonterminal node which are themselves nonterminal and nonrightmost, averaged over the nonterminals of a sentence".

Clause and Sentence based Features (CB features)

Firstly, we extracted all 26 initial CB features directly from human annotated data of NN-train, using information from the clause and sentence type labels. The reasoning behind this was to create an initial pool of clause-based features that reflects the distribution of clauses and sentences as accurately as possible, even though we did not plan to use this extraction method operationally, where the parser decides on clause and sentence types. After computing the values of each CB feature, we calculated correlations between each feature and human-rated scores. Then we created an initial CB feature pool by selecting features that met two criteria: (1) the absolute Pearson correlation coefficient with human scores was larger than 0.2; and (2) the mean value of the feature on non-native speakers was at least 20% lower than that for na-

tive speakers in case of positive correlation and at least by 20% higher than for native speakers in case of negative correlation, using the Nat data set for the latter criterion. Note that all of these features were computed without using a parser. This resulted in 13 important features.

Secondly, Tregex rules were developed based on Lu's tool to extract these 13 CB features from parsing results where the parser is provided with one sentence at a time. By applying the same selection criteria as before, except for allowing for correlations above 0.1 and giving preference to linguistically more meaningful features, we found 8 features that matched our criteria:
MLS, MLT, DC/C, SSfreq, MLSS, ADJCfreq, Ffreq, MLCC

All 28 pairwise inter-correlations between these 8 features were computed and inspected to avoid including features with high inter-correlations in the scoring model. Since we did not find any inter-correlations larger than 0.9, the features were considered moderately independent and none of them were removed from this set so it also maintains linguistic richness for the feature set.

Due to the importance of T-units in complexity analysis, we briefly introduce how we obtain them from annotations. Three types of clauses labeled in our transcript can serve as T-units, including simple sentences, independent clauses, and conjunct (coordination) clauses. These clauses were identified in the human-annotated text and extracted as T-units in this phase. T-units in parse trees are identified using rules in Lu's tool.

Parse Tree based Features (PT features)

We evaluated 65 features in total and selected features with highest importance using the following two criteria (which are very similar as before): (1) the absolute Pearson correlation coefficient with human scores is larger than 0.2; and (2) the feature mean value on native speakers (Nat) is higher than on score 4 for non-native speakers in case of positive correlation, or lower for negative correlation. 20 of 65 features were found to meet the requirements.

Next, we examined inter-correlations between these features and found some correlations larger than 0.85.[12] For each feature pair exhibiting high inter-correlation, we removed one feature according to the criterion that the removed feature should be linguistically less meaningful than the remaining one. After this filtering, the 9 remaining PT features are:
CT/T, PP_ling/S, NP/S, CN/S, VP_ling/T, PAS/S, DI/T, MLev, MPSam

In summary, as a result of the feature selection process, a total of 17 features were identified as important features to be used in scoring models for predicting speakers' proficiency scores. Among them 8 are clause boundary based and the other 9 are parse tree based.

5 Experiments and Results

In the previous section, we identified 17 syntactic features that show promising correlations with human rater speaking proficiency scores. These features as well as the human-rated scores will be used to build scoring models by using machine learning methods. As introduced in Section 3, we have one training set (N=137 speakers with all of their responses combined) for model building and five testing sets (N=52 for each of them) for evaluation.

The publicly available machine learning package Weka was used in our experiments (Hall et al. 2009). We experimented with two algorithms in Weka: multiple regression (called "LinearRegression" in Weka) and decision tree (called "M5P"in Weka). The score values to be predicted are real numbers (i.e., non-integer), because we have to compute the average score of one speaker's responses. Our initial runs showed that decision tree models were consistently outperformed by multiple regression (MR) models and thus decided to only focus on MR models henceforth.

We set the "AttributeSelectionMethod" parameter in Weka's LinearRegression algorithm to all 3 of its possible values in turn: (Model-1) M5 method; (Model-2) no attribute selection; and (Model-3) greedy method. The resulting three multiple regression models were then tested against the five testing sets. Overall, correlations for all models for the NN-test-1-Hum set were between 0.45 and 0.49, correlations for sets NN-test-2-CB and NN-

[12] The reason for using a lower threshold than above was to obtain a roughly equal number of CB and PT features in the end.

test-3-SB (human transcript based, and using automated boundaries) around 0.2, and for sets NN-test-4-ASR-CB and NN-test-5-ASR-SB (ASR hypotheses, and using automated boundaries), the correlations were not significant. Model-2 (using all 17 features) had the highest correlation on NN-test-1-Hum and we provide correlation results of this model in Table 3.

Test set	Correlation coefficient	Correlation significance ($p < 0.05$)
NN-test-1-Hum	0.488	Significant
NN-test-2-CB	0.220	Significant
NN-test-3-SB	0.170	Significant
NN-test-4-ASR-CB	-0.025	Not significant
NN-test-5-ASR-SB	-0.013	Not significant

Table 3. Multiple regression model testing results for Model-2.

6 Discussion

As we can see from the result table (Table 3) in the previous section, using only syntactic complexity features, based on clausal or parse tree information derived from human transcriptions of spoken test responses, can predict holistic human rater scores for combined speaker responses over a whole test with an overall correlation of r=0.49. While this is a promising result for this study with a focus on a broad spectrum of syntactic complexity features, the results also show significant limitations for an immediate operational use of such features. First, the imperfect prediction of clause and sentence boundaries by the two automatic classifiers causes a substantial degradation of scoring model performance to about r=0.2, and secondly, the rather high error rate of the ASR system (50.5%) does not allow for the computation of features that would result in any significant correlation with human scores. We want to note here that while ASR systems can be found that exhibit WERs below 10% for certain tasks, such as restricted dictation in low-noise environments by native speakers, our ASR task is significantly harder in several ways: (1) we have to recognize non-native speakers'rresponses where speakers have a number of different native language backgrounds; (2) the proficiency level of the test takers varies widely; and (3) the responses are spontaneous and unconstrained in terms of vocabulary.

As for the automatic clause and sentence boundary classifiers, we can observe (in Table 4) that although the sentence boundary classifier has a slightly higher F-score than the clause boundary classifier, errors in sentence boundary detection have more negative effects on the accuracy of score prediction than those made by the clause boundary classifier. In fact, the lower F-score of the latter is mainly due to its lower precision which indicates that there are more spurious clause boundaries in its output which apparently cause little harm to the feature extraction processes.

Among the 17 final features, 3 of them are frequency-based and the remaining 14 are ratio-based, which mirrors our findings from previous work that frequency features have been used less successfully than ratio features. As for ratio features, 5 of them are grammatical structure counts against sentence units, 4 are counts against T-units, and only 1 is based on counts against clause units. The feature set covers a wide range of grammatical structures, such as T-units, verb phrases, noun phrases, complex nominals, adjective clauses, coordinate clauses, prepositional phrases, etc. While this wide coverage provides for richness of the construct of syntactic complexity, some of the features exhibit relatively high correlation with each other which reduces their overall contributions to the scoring model's performance.

Going through the workflow of our system, we find at least five major stages that can generate errors which in turn can adversely affect feature computation and scoring model building. Errors may appear in each stage of our workflow, passing or even enlarging their effects from previous stages to later stages:

1) grammatical errors by the speakers (test takers);
2) errors by the ASR system;
3) sentence/clause boundary detection errors;
4) parser errors; and
5) rule extraction errors.

In future work we will need to address each error source to obtain a higher overall system performance.

Classifier	Accuracy	Precision	Recall	F score
Clause boundary	0.954	0.721	0.748	0.734
Sentence boundary	0.975	0.811	0.755	0.782

Table 4. Performance of clause and sentence boundary detectors.

7 Conclusion and Future Work

In this paper, we investigated associations between speakers' syntactic complexity features and their speaking proficiency scores provided by human raters. By exploring empirical evidence from non-native and native speakers' data sets of spontaneous speech test responses, we identified 17 features related to clause types and parse trees as effective predictors of human speaking scores. The features were implemented based on Lu's L2 Syntactic Complexity Analyzer toolkit (Lu, 2011) to be automatically extracted from human or ASR transcripts. Three multiple regression models were built from non-native speech training data with different parameter setup and were tested against five testing sets with different preprocessing steps. The best model used the complete set of 17 features and exhibited a correlation with human scores of r=0.49 on human transcripts with boundary annotations.

When using automated classifiers to predict clause or sentence boundaries, correlations with human scores are around r=0.2. Our experiments indicate that by enhancing the accuracy of the two main automated preprocessing components, namely ASR and automatic sentence and clause boundary detectors, scoring model performance will increase substantially, as well. Furthermore, this result demonstrates clearly that syntactic complexity features can be devised that are able to predict human speaking proficiency scores.

Since this is a preliminary study, there is ample space to improve all major stages in the feature extraction process. The errors listed in the previous section are potential working directions for preprocessing enhancements prior to machine learning. Among the five types of errors, we can work on improving the accuracy of the speech recognizer, sentence and clause boundary detectors, parser, and feature extraction rules; as for the grammatical errors produced by test takers, we are envisioning to automatically identify and correct such errors. We will further experiment with syntactic complexity measures to balance construct richness and model simplicity. Furthermore, we can also experiment with additional types of machine learning models and tune parameters to derive scoring models with better performance.

Acknowledgements

The authors wish to thank Lei Chen and Su-Youn Yoon for their help with the sentence and clause boundary classifiers. We also would like to thank our colleagues Jill Burstein, Keelan Evanini, Yoko Futagi, Derrick Higgins, Nitin Madnani, and Joel Tetreault, as well as the four anonymous ACL reviewers for their valuable and helpful feedback and comments on our paper.

Abstract

In this paper, we adopt an n-best rescoring scheme using pitch-accent patterns to improve automatic speech recognition (ASR) performance. The pitch-accent model is decoupled from the main ASR system, thus allowing us to develop it independently. N-best hypotheses from recognizers are rescored by additional scores that measure the correlation of the pitch-accent patterns between the acoustic signal and lexical cues. To test the robustness of our algorithm, we use two different data sets and recognition setups: the first one is English radio news data that has pitch accent labels, but the recognizer is trained from a small amount of data and has high error rate; the second one is English broadcast news data using a state-of-the-art SRI recognizer. Our experimental results demonstrate that our approach is able to reduce word error rate relatively by about 3%. This gain is consistent across the two different tests, showing promising future directions of incorporating prosodic information to improve speech recognition.

1 Introduction

Prosody refers to the suprasegmental features of natural speech, such as rhythm and intonation, since it normally extends over more than one phoneme segment. Speakers use prosody to convey paralinguistic information such as emphasis, intention, attitude, and emotion. Humans listening to speech with natural prosody are able to understand the content with low cognitive load and high accuracy. However, most modern ASR systems only use an acoustic model and a language model. Acoustic information in ASR is represented by spectral features that are usually extracted over a window length of a few tens of milliseconds. They miss useful information contained in the prosody of the speech that may help recognition.

Recently a lot of research has been done in automatic annotation of prosodic events (Wightman and Ostendorf, 1994; Sridhar et al., 2008; Ananthakrishnan and Narayanan, 2008; Jeon and Liu, 2009). They used acoustic and lexical-syntactic cues to annotate prosodic events with a variety of machine learning approaches and achieved good performance. There are also many studies using prosodic information for various spoken language understanding tasks. However, research using prosodic knowledge for speech recognition is still quite limited. In this study, we investigate leveraging prosodic information for recognition in an n-best rescoring framework.

Previous studies showed that prosodic events, such as pitch-accent, are closely related with acoustic prosodic cues and lexical structure of utterance. The pitch-accent pattern given acoustic signal is strongly correlated with lexical items, such as syllable identity and canonical stress pattern. Therefore as a first study, we focus on pitch-accent in this paper. We develop two separate pitch-accent detection models, using acoustic (observation model) and lexical information (expectation model) respectively, and propose a scoring method for the correlation of pitch-accent patterns between the two models for recognition hypotheses. The n-best list is rescored using the pitch-accent matching scores

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 732–741,
Portland, Oregon, June 19-24, 2011.

combined with the other scores from the ASR system (acoustic and language model scores). We show that our method yields a word error rate (WER) reduction of about 3.64% and 2.07% relatively on two baseline ASR systems, one being a state-of-the-art recognizer for the broadcast news domain. The fact that it holds across different baseline systems suggests the possibility that prosody can be used to help improve speech recognition performance.

The remainder of this paper is organized as follows. In the next section, we review previous work briefly. Section 3 explains the models and features for pitch-accent detection. We provide details of our n-best rescoring approach in Section 4. Section 5 describes our corpus and baseline ASR setup. Section 6 presents our experiments and results. The last section gives a brief summary along with future directions.

2 Previous Work

Prosody is of interest to speech researchers because it plays an important role in comprehension of spoken language by human listeners. The use of prosody in speech understanding applications has been quite extensive. A variety of applications have been explored, such as sentence and topic segmentation (Shriberg et al., 2000; Rosenberg and Hirschberg, 2006), word error detection (Litman et al., 2000), dialog act detection (Sridhar et al., 2009), speaker recognition (Shriberg et al., 2005), and emotion recognition (Benus et al., 2007), just to name a few.

Incorporating prosodic knowledge is expected to improve the performance of speech recognition. However, how to effectively integrate prosody within the traditional ASR framework is a difficult problem, since prosodic features are not well defined and they come from a longer region, which is different from spectral features used in current ASR systems. Various research has been conducted trying to incorporate prosodic information in ASR. One way is to directly integrate prosodic features into the ASR framework (Vergyri et al., 2003; Ostendorf et al., 2003; Chen and Hasegawa-Johnson, 2006). Such efforts include prosody dependent acoustic and pronunciation model (allophones were distinguished according to different prosodic phenomenon), language model (words were augmented by prosody events), and duration modeling (different prosodic events were modeled separately and combined with conventional HMM). This kind of integration has advantages in that spectral and prosodic features are more tightly coupled and jointly modeled. Alternatively, prosody was modeled independently from the acoustic and language models of ASR and used to rescore recognition hypotheses in the second pass. This approach makes it possible to independently model and optimize the prosodic knowledge and to combine with ASR hypotheses without any modification of the conventional ASR modules. In order to improve the rescoring performance, various prosodic knowledge was studied. (Ananthakrishnan and Narayanan, 2007) used acoustic pitch-accent pattern and its sequential information given lexical cues to rescore n-best hypotheses. (Kalinli and Narayanan, 2009) used acoustic prosodic cues such as pitch and duration along with other knowledge to choose a proper word among several candidates in confusion networks. Prosodic boundaries based on acoustic cues were used in (Szaszak and Vicsi, 2007).

We take a similar approach in this study as the second approach above in that we develop prosodic models separately and use them in a rescoring framework. Our proposed method differs from previous work in the way that the prosody model is used to help ASR. In our approach, we explicitly model the symbolic prosodic events based on acoustic and lexical information. We then capture the correlation of pitch-accent patterns between the two different cues, and use that to improve recognition performance in an n-best rescoring paradigm.

3 Prosodic Model

Among all the prosodic events, we use only pitch-accent pattern in this study, because previous studies have shown that acoustic pitch-accent is strongly correlated with lexical items, such as canonical stress pattern and syllable identity that can be easily acquired from the output of conventional ASR and pronunciation dictionary. We treat pitch-accent detection as a binary classification task, that is, a classifier is used to determine whether the base unit is prominent or not. Since pitch-accent is usually

carried by syllables, we use syllables as our units, and the syllable definition of each word is based on CMU pronunciation dictionary which has lexical stress and syllable boundary marks (Bartlett et al., 2009). We separately develop acoustic-prosodic and lexical-prosodic models and use the correlation between the two models for each syllable to rescore the n-best hypotheses of baseline ASR systems.

3.1 Acoustic-prosodic Features

Similar to most previous work, the prosodic features we use include pitch, energy, and duration. We also add delta features of pitch and energy. Duration information for syllables is derived from the speech waveform and phone-level forced alignment of the transcriptions. In order to reduce the effect by both inter-speaker and intra-speaker variation, both pitch and energy values are normalized (z-value) with utterance specific means and variances. For pitch, energy, and their delta values, we apply several categories of 12 functions to generate derived features.

- Statistics (7): minimum, maximum, range, mean, standard deviation, skewness and kurtosis value. These are used widely in prosodic event detection and emotion detection.
- Contour (5): This is approximated by taking 5 leading terms in the Legendre polynomial expansion. The approximation of the contour using the Legendre polynomial expansion has been successfully applied in quantitative phonetics (Grabe et al., 2003) and in engineering applications (Dehak et al., 2007). Each term models a particular aspect of the contour, such as the slope, and information about the curvature.

We use 6 duration features, that is, raw, normalized, and relative durations (ms) of the syllable and vowel. Normalization (z-value) is performed based on statistics for each syllable and vowel. The relative value is the difference between the normalized current duration and the following one.

In the above description, we assumed that the event of a syllable is only dependent on its observations, and did not consider contextual effect. To alleviate this restriction, we expand the features by incorporating information about the neighboring syllables. Based on the study in (Jeon and Liu, 2010) that evaluated using left and right contexts, we choose to use one previous and one following context in the features. The total number of features used in this study is 162.

3.2 Lexical-prosodic Features

There is a very strong correlation between pitch-accent in an utterance and its lexical information. Previous studies have shown that the lexical features perform well for pitch-accent prediction. The detailed features for training the lexical-prosodic model are as follows.

- Syllable identity: We kept syllables that appear more than 5 times in the training corpus. The other syllables that occur less are collapsed into one syllable representation.
- Vowel phone identity: We used vowel phone identity as a feature.
- Lexical stress: This is a binary feature to represent if the syllable corresponds to a lexical stress based on the pronunciation dictionary.
- Boundary information: This is a binary feature to indicate if there is a word boundary before the syllable.

For lexical features, based on the study in (Jeon and Liu, 2010), we added two previous and two following contexts in the final features.

3.3 Prosodic Model Training

We choose to use a support vector machine (SVM) classifier[1] for the prosodic model based on previous work on prosody labeling study in (Jeon and Liu, 2010). We use RBF kernel for the acoustic model, and 3-order polynomial kernel for the lexical model.

In our experiments, we investigate two kinds of training methods for prosodic modeling. The first one is a supervised method where models are trained using all the labeled data. The second is a semi-supervised method using co-training algorithm (Blum and Mitchell, 1998), described in Algorithm 1. Given a set L of labeled data and a set U of unlabeled data with two views, it then iterates in the

[1]LIBSVM – A Library for Support Vector Machines, location: http://www.csie.ntu.edu.tw/˜cjlin/libsvm/

Algorithm 1 Co-training algorithm.

Given:

- L: labeled examples; U: unlabeled examples
- there are two views V_1 and V_2 on an example x

Initialize:

- L_1=L, samples used to train classifiers h_1
- L_2=L, samples used to train classifiers h_2

Loop for *k* iterations

- create a small pool U' choosing from U
- use $V_1(L_1)$ to train classifier h_1 and $V_2(L_2)$ to train classifier h_2
- let h_1 label/select examples D_{h_1} from U'
- let h_2 label/select examples D_{h_2} from U'
- add self-labeled examples D_{h_1} to L_2 and D_{h_2} to L_1
- remove D_{h_1} and D_{h_2} from U

following procedure. The algorithm first creates a smaller pool U' containing unlabeled data from U. It uses L_i $(i = 1, 2)$ to train two distinct classifiers: the acoustic classifier h_1, and the lexical classifier h_2. We use function V_i $(i = 1, 2)$ to represent that only a single view is used for training h_1 or h_2. These two classifiers are used to make predictions for the unlabeled set U', and only when they agree on the prediction for a sample, their predicted class is used as the label for this sample. Then among these self-labeled samples, the most confident ones by one classifier are added to the data set L_i for training the other classifier. This iteration continues until reaching the defined number of iterations. In our experiment, the size of the pool U' is 5 times of the size of training data L_i, and the size of the added self-labeled example set, D_{h_i}, is 5% of L_i. For the newly selected D_{h_i}, the distribution of the positive and negative examples is the same as that of the training data L_i.

This co-training method is expected to cope with two problems in prosodic model training. The first problem is the different decision patterns between the two classifiers: the acoustic model has relatively higher precision, while the lexical model has relatively higher recall. The goal of the co-training algorithm is to learn from the difference of each classifier, thus it can improve the performance as well as reduce the mismatch of two classifiers. The second problem is the mismatch of data used for model training and testing, which often results in system performance degradation. Using co-training, we can use the unlabeled data from the domain that matches the test data, adapting the model towards test domain.

4 N-Best Rescoring Scheme

In order to leverage prosodic information for better speech recognition performance, we augment the standard ASR equation to include prosodic information as following:

$$\begin{aligned} \hat{W} &= \arg\max_W p(W|A_s, A_p) \\ &= \arg\max_W p(A_s, A_p|W)p(W) \end{aligned} \quad (1)$$

where A_s and A_p represent acoustic-spectral features and acoustic-prosodic features. We can further assume that spectral and prosodic features are conditionally independent given a word sequence W, therefore, Equation 1 can be rewritten as following:

$$\hat{W} \approx \arg\max_W p(A_s|W)p(W)p(A_p|W) \quad (2)$$

The first two terms stand for the acoustic and language models in the original ASR system, and the last term means the prosody model we introduce. Instead of using the prosodic model in the first pass decoding, we use it to rescore n-best candidates from a speech recognizer. This allows us to train the prosody models independently and better optimize the models.

For $p(A_p|W)$, the prosody score for a word sequence W, in this work we propose a method to estimate it, also represented as $score_{W-prosody}(W)$. The idea of scoring the prosody patterns is that there is some expectation of pitch-accent patterns given the lexical sequence (W), and the acoustic pitch-accent should match with this expectation. For instance, in the case of a prominent syllable, both acoustic and lexical evidence show pitch-accent, and vice versa. In order to maximize the agreement between the two sources, we measure how good the acoustic pitch-accent in speech signal matches the given lexical cues. For each syllable S_i in the n-best list, we use acoustic-prosodic cues (a_i) to estimate the posterior probability that the syllable is prominent (*P*), $p(P|a_i)$. Similarly, we use lexical cues (l_i)

to determine the syllable's pitch-accent probability $p(P|l_i)$. Then the prosody score for a syllable S_i is estimated by the match of the pitch-accent patterns between acoustic and lexical information using the difference of the posteriors from the two models:

$$score_{S-prosody}(S_i) \approx 1 - \mid p(P|a_i) - p(P|l_i) \mid \quad (3)$$

Furthermore, we take into account the effect due to varying durations for different syllables. We notice that syllables without pitch-accent have much shorter duration than the prominent ones, and the prosody scores for the short syllables tend to be high. This means that if a syllable is split into two consecutive non-prominent syllables, the agreement score may be higher than a long prominent syllable. Therefore, we introduce a weighting factor based on syllable duration ($dur(i)$). For a candidate word sequence (W) consisting of n syllables, its prosodic score is the sum of the prosodic scores for all the syllables in it weighted by their duration (measured using milliseconds), that is:

$$score_{W-prosody}(W) \approx \sum_{i=1}^{n} log(score_{S-prosody}(S_i)) \cdot dur(i) \quad (4)$$

We then combine this prosody score with the original acoustic and language model likelihood ($P(A_s|W)$ and $P(W)$ in Equation 2). In practice, we need to weight them differently, therefore, the combined score for a hypothesis W is:

$$\begin{aligned} Score(W) &= \lambda \cdot score_{W-prosody}(W) \\ &\quad + score_{ASR}(W) \end{aligned} \quad (5)$$

where $score_{ASR}(W)$ is generated by ASR systems (composed of acoustic and language model scores) and λ is optimized using held out data.

5 Data and Baseline Systems

Our experiments are carried out using two different data sets and two different recognition systems as well in order to test the robustness of our proposed method.

The first data set is the Boston University Radio News Corpus (BU) (Ostendorf et al., 1995), which consists of broadcast news style read speech. The BU corpus has about 3 hours of read speech from 7 speakers (3 female, 4 male). Part of the data has been labeled with ToBI-style prosodic annotations. In fact, the reason that we use this corpus, instead of other corpora typically used for ASR experiments, is because of its prosodic labels. We divided the entire data corpus into a training set and a test set. There was no speaker overlap between training and test sets. The training set has 2 female speakers (*f2* and *f3*) and 3 male ones (*m2*, *m3*, *m4*). The test set is from the other two speakers (*f1* and *m1*). We use 200 utterances for the recognition experiments. Each utterance in BU corpus consists of more than one sentences, so we segmented each utterance based on pause, resulting in a total number of 713 segments for testing. We divided the test set roughly equally into two sets, and used one for parameter tuning and the other for rescoring test. The recognizer used for this data set was based on Sphinx-3[2]. The context-dependent triphone acoustic models with 32 Gaussian mixtures were trained using the training partition of the BU corpus described above, together with the broadcast new data. A standard back-off trigram language model with Kneser-Ney smoothing was trained using the combined text from the training partition of the BU, Wall Street Journal data, and part of Gigaword corpus. The vocabulary size was about 10K words and the out-of-vocabulary (OOV) rate on the test set was 2.1%.

The second data set is from broadcast news (BN) speech used in the GALE program. The recognition test set contains 1,001 utterances. The n-best hypotheses for this data set are generated by a state-of-the-art SRI speech recognizer, developed for broadcast news speech (Stolcke et al., 2006; Zheng et al., 2007). This system yields much better performance than the first one. We also divided the test set roughly equally into two sets for parameter tuning and testing. From the data used for training the speech recognizer, we randomly selected 5.7 hours of speech (4,234 utterances) for the co-training algorithm for the prosodic models.

For prosodic models, we used a simple binary representation of pitch-accent in the form of presence versus absence. The reference labels are de-

[2]CMU Sphinx - Speech Recognition Toolkit, location: http://www.speech.cs.cmu.edu/sphinx/tutorial.html

rived from the ToBI annotation in the BU corpus, and the ratio of pitch-accented syllables is about 34%. Acoustic-prosodic and lexical-prosodic models were separately developed using the features described in Section 3. Feature extraction was performed at the syllable level from force-aligned data. For the supervised approach, we used those utterances in the training data partition with ToBI labels in the BU corpus (245 utterances, 14,767 syllables). For co-training, the labeled data from BU corpus is used as initial training, and the other unlabeled data from BU and BN are used as unlabeled data.

	Accuracy(%)		**Prosody score**

Table 1: Pitch accent detection results: performance of individual acoustic and lexical models, and the agreement between the two models (i.e., prosody score for a syllable, Equation 3) for positive and negative classes. Also shown is the reference result for pitch accent detection from Jeon and Liu (2009).

6 Experimental Results

6.1 Pitch-accent Detection

First we evaluate the performance of our acoustic-prosodic and lexical-prosodic models for pitch-accent detection. For rescoring, not only the accuracies of the two individual prosodic models are important, but also the pitch-accent agreement score between the two models (as shown in Equation 3) is critical, therefore, we present results using these two metrics. Table 1 shows the accuracy of each model for pitch-accent detection, and also the average prosody score of the two models (i.e., Equation 3) for positive and negative classes (using reference labels). These results are based on the BU labeled data in the test set. To compare our pitch accent detection performance with previous work, we include the result of (Jeon and Liu, 2009) as a reference. Compared to previous work, the acoustic model achieved similar performance, while the performance of lexical model is a bit lower. The lower performance of lexical model is mainly because we do not use part-of-speech (POS) information in the features, since we want to only use the word output from the ASR system (without additional POS tagging).

As shown in Table 1, when using the co-training algorithm, as described in Section 3.3, the overall accuracies improve slightly and therefore the prosody score is also increased. We expect this improved model will be more beneficial for rescoring.

6.2 N-Best Rescoring

For the rescoring experiment, we use 100-best hypotheses from the two different ASR systems, as described in Section 5. We apply the acoustic and lexical prosodic models to each hypothesis to obtain its prosody score, and combine it with ASR scores to find the top hypothesis. The weights were optimized using one test set and applied to the other. We report the average result of the two testings.

Table 2 shows the rescoring results using the first recognition system on BU data, which was trained with a relatively small amount of data. The 1-best baseline uses the first hypothesis that has the best ASR score. The oracle result is from the best hypothesis that gives the lowest WER by comparing all the candidates to the reference transcript. We used two prosodic models as described in Section 3.3. The first one is the base prosodic model using supervised training (*S-model*). The second is the prosodic model with the co-training algorithm (*C-model*). For these rescoring experiments, we tuned λ (in Equation 5) when combining the ASR acoustic and language model scores with the additional prosody score. The value in parenthesis in Table 2 means the relative WER reduction when compared to the baseline result. We show the WER results for both the development and the test set.

As shown in Table 2, we observe performance improvement using our rescoring method. Using the base *S-model* yields reasonable improvement, and *C-model* further reduces WER. Even though the prosodic event detection performance of these two prosodic models is similar, the improved prosody score between the acoustic and lexical prosodic models using co-training helps rescoring. After rescoring using prosodic knowledge, the WER is reduced by 0.82% (3.64% relative). Furthermore, we notice that the difference between development and

		WER (%)
1-best baseline		22.64
S-model	Dev	21.93 (3.11%)
	Test	22.10 (2.39%)
C-model	Dev	21.76 (3.88%)
	Test	21.81 (3.64%)
Oracle		15.58

Table 2: WER of the baseline system and after rescoring using prosodic models. Results are based on the first ASR system.

test data is smaller when using the *C-model* than *S-model*, which means that the prosodic model with co-training is more stable. In fact, we found that the optimal value of λ is 94 and 57 for the two folds using *S-model*, and is 99 and 110 for the *C-model*. These verify again that the prosodic scores contribute more in the combination with ASR likelihood scores when using the *C-model*, and are more robust across different tuning sets. Ananthakrishnan and Narayanan (2007) also used acoustic/lexical prosodic models to estimate a prosody score and reported 0.3% recognition error reduction on BU data when rescoring 100-best list (their baseline WER is 22.8%). Although there is some difference in experimental setup (data, classifier, features) between ours and theirs, our *S-model* showed comparable performance gain and the result of *C-model* is significantly better than theirs.

Next we test our n-best rescoring approach using a state-of-the-art SRI speech recognizer on BN data to verify if our approach can generalize to better ASR n-best lists. This is often the concern that improvements observed on a poor ASR system do not hold for better ASR systems. The rescoring results are shown in Table 3. We can see that the baseline performance of this recognizer is much better than that of the first ASR system (even though the recognition task is also harder). Our rescoring approach still yields performance gain even using this state-of-the-art system. The WER is reduced by 0.29% (2.07% relative). This error reduction is lower than that in the first ASR system. There are several possible reasons. First, the baseline ASR performance is higher, making further improvement hard; second, and more importantly, the prosody models do not match well to the test domain. We trained the prosody model using the BU data. Even though co-training is used to leverage unlabeled BN data to reduce data mismatch, it is still not as good as using labeled in-domain data for model training.

		WER (%)
1-best baseline		13.77
S-model	Dev	13.53 (1.78%)
	Test	13.55 (1.63%)
C-model	Dev	13.48 (2.16%)
	Test	13.49 (2.07%)
Oracle		9.23

Table 3: WER of the baseline system and after rescoring using prosodic models. Results are based on the second ASR system.

6.3 Analysis and Discussion

We also analyze what kinds of errors are reduced using our rescoring approach. Most of the error reduction came from substitution and insertion errors. Deletion error rate did not change much or sometimes even increased. For a better understanding of the improvement using the prosody model, we analyzed the pattern of corrections (the new hypothesis after rescoring is correct while the original 1-best is wrong) and errors. Table 4 shows some positive and negative examples from rescoring results using the first ASR system. In this table, each word is associated with some binary expressions inside a parenthesis, which stand for pitch-accent markers. Two bits are used for each syllable: the first one is for the acoustic-prosodic model and the second one is for the lexical-prosodic model. For both bits, 1 represents pitch-accent, and 0 indicates none. These hard decisions are obtained by setting a threshold of 0.5 for the posterior probabilities from the acoustic or lexical models. For example, when the acoustic classifier predicts a syllable as pitch-accented and the lexical one as not accented, '*10*' marker is assigned to the syllable. The number of such pairs of pitch-accent markers is the same as the number of syllables in a word. The bold words indicate correct words and italic means errors. As shown in the positive example of Table 4, we find that our prosodic model is effective at identifying an erroneous word when it is split into two words, resulting in different pitch-accent patterns. Language models are

Positive example	1-best :	most	*of*	*the*	massachusetts
		(11)	***(10)***	***(00)***	(11 00 01 00)
	rescored :	most	**other**		massachusetts
		(11)	**(11 00)**		(11 00 01 00)
Negative example	1-best :	robbery	and	**on**	**a** theft
		(11 00 00)	(00)	**(10)**	**(00)** (11)
	rescored :	robbery	and	*lot*	*of* theft
		(11 00 00)	(00)	***(11)***	***(00)*** (11)

Table 4: Examples of rescoring results. Binary expressions inside the parenthesis below a word represent pitch-accent markers for the syllables in the word.

not good at correcting this kind of errors since both word sequences are plausible. Our model also introduces some errors, as shown in the negative example, which is mainly due to the inaccurate prosody model.

We conducted more prosody rescoring experiments in order to understand the model behavior. These analyses are based on the n-best list from the first ASR system for the entire test set. In the first experiment, among the 100 hypotheses in n-best list, we gave a prosody score of 0 to the 100^{th} hypothesis, and used automatically obtained prosodic scores for the other hypotheses. A zero prosody score means the perfect agreement given acoustic and lexical cues. The original scores from the recognizer were combined with the prosodic scores for rescoring. This was to verify that the range of the weighting factor λ estimated on the development data (using the original, not the modified prosody scores for all candidates) was reasonable to choose proper hypothesis among all the candidates. We noticed that 27% of the times the last hypothesis on the list was selected as the best hypothesis. This hypothesis has the highest prosodic scores, but lowest ASR score. This result showed that if the prosodic models were accurate enough, the correct candidate could be chosen using our rescoring framework.

In the second experiment, we put the reference text together with the other candidates. We use the same ASR scores for all candidates, and generated prosodic scores using our prosody model. This was to test that our model could pick up correct candidate using only the prosodic score. We found that for 26% of the utterances, the reference transcript was chosen as the best one. This was significantly better than random selection (i.e., 1/100), suggesting the benefit of the prosody model; however, this percentage is not very high, implying the limitation of prosodic information for ASR or the current imperfect prosodic models.

In the third experiment, we replaced the 100^{th} candidate with the reference transcript and kept its ASR score. When using our prosody rescoring approach, we obtained a relative error rate reduction of 6.27%. This demonstrates again that our rescoring method works well – if the correct hypothesis is on the list, even though with a low ASR score, using prosodic information can help identify the correct candidate.

Overall the performance improvement we obtained from rescoring by incorporating prosodic information is very promising. Our evaluation using two different ASR systems shows that the improvement holds even when we use a state-of-the-art recognizer and the training data for the prosody model does not come from the same corpus. We believe the consistent improvements we observed for different conditions show that this is a direction worthy of further investigation.

7 Conclusion

In this paper, we attempt to integrate prosodic information for ASR using an n-best rescoring scheme. This approach decouples the prosodic model from the main ASR system, thus the prosodic model can be built independently. The prosodic scores that we use for n-best rescoring are based on the matching of pitch-accent patterns by acoustic and lexical features. Our rescoring method achieved a WER reduction of 3.64% and 2.07% relatively using two different ASR systems. The fact that the gain holds across different baseline systems (including a state-of-the-

art speech recognizer) suggests the possibility that prosody can be used to improve speech recognition performance.

As suggested by our experiments, better prosodic models can result in more WER reduction. The performance of our prosodic model was improved with co-training, but there are still problems, such as the imbalance of the two classifiers' prediction, as well as for the two events. In order to address these problems, we plan to improve the labeling and selection method in the co-training algorithm, and also explore other training algorithms to reduce domain mismatch. Furthermore, we are also interested in evaluating our approach on the spontaneous speech domain, which is quite different from the data we used in this study.

In this study, we used n-best rather than lattice rescoring. Since the prosodic features we use include cross-word contextual information, it is not straightforward to apply it directly to lattices. In our future work, we will develop models with only within-word context, and thus allowing us to explore lattice rescoring, which we expect will yield more performance gain.

Lexically-Triggered Hidden Markov Models for Clinical Document Coding

Svetlana Kiritchenko **Colin Cherry**

{Svetlana.Kiritchenko,Colin.Cherry}@nrc-cnrc.gc.ca

Abstract

The automatic coding of clinical documents is an important task for today's healthcare providers. Though it can be viewed as multi-label document classification, the coding problem has the interesting property that most code assignments can be supported by a single phrase found in the input document. We propose a Lexically-Triggered Hidden Markov Model (LT-HMM) that leverages these phrases to improve coding accuracy. The LT-HMM works in two stages: first, a lexical match is performed against a term dictionary to collect a set of candidate codes for a document. Next, a discriminative HMM selects the best subset of codes to assign to the document by tagging candidates as present or absent. By confirming codes proposed by a dictionary, the LT-HMM can share features across codes, enabling strong performance even on rare codes. In fact, we are able to recover codes that do not occur in the training set at all. Our approach achieves the best ever performance on the 2007 Medical NLP Challenge test set, with an F-measure of 89.84.

1 Introduction

The clinical domain presents a number of interesting challenges for natural language processing. Conventionally, most clinical documentation, such as doctor's notes, discharge summaries and referrals, are written in a free-text form. This narrative form is flexible, allowing healthcare professionals to express any kind of concept or event, but it is not particularly suited for large-scale analysis, search, or decision support. Converting clinical narratives into a structured form would support essential activities such as administrative reporting, quality control, biosurveillance and biomedical research (Meystre et al., 2008). One way of representing a document is to code the patient's conditions and the performed procedures into a nomenclature of clinical codes. The International Classification of Diseases, 9th and 10th revisions, Clinical Modification (ICD-9-CM, ICD-10-CM) are the official administrative coding schemes for healthcare organizations in several countries, including the US and Canada. Typically, coding is performed by trained coding professionals, but this process can be both costly and error-prone. Automated methods can speed-up the coding process, improve the accuracy and consistency of internal documentation, and even result in higher reimbursement for the healthcare organization (Benson, 2006).

Traditionally, statistical document coding is viewed as multi-class multi-label document classification, where each clinical free-text document is labelled with one or several codes from a pre-defined, possibly very large set of codes (Patrick et al., 2007; Suominen et al., 2008). One classification model is learned for each code, and then all models are applied in turn to a new document to determine which codes should be assigned to the document. The drawback of this approach is poor predictive performance on low-frequency codes, which are ubiquitous in the clinical domain.

This paper presents a novel approach to document coding that simultaneously models code-specific as well as general patterns in the data. This allows

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 742–751,
Portland, Oregon, June 19-24, 2011.

us to predict any code label, even codes for which no training data is available. Our approach, the lexically-triggered HMM (LT-HMM), is based on the fact that a code assignment is often indicated by short lexical triggers in the text. Consequently, a two-stage coding method is proposed. First, the LT-HMM identifies candidate codes by matching terms from a medical terminology dictionary. Then, it confirms or rejects each of the candidates by applying a discriminative sequence model. In this architecture, low-frequency codes can still be matched and confirmed using general characteristics of their trigger's local context, leading to better prediction performance on these codes.

2 Document Coding and Lexical Triggers

Document coding is a special case of multi-class multi-label text classification. Given a fixed set of possible codes, the ultimate goal is to assign a set of codes to documents, based on their content. Furthermore, we observe that for each code assigned to a document, there is generally at least one corresponding *trigger term* in the text that accounts for the code's assignment. For example, if an ICD-9-CM coding professional were to see "allergic bronchitis" somewhere in a clinical narrative, he or she would immediately consider adding code *493.9 (Asthma, unspecified)* to the document's code set. The presence of these trigger terms separates document coding from text classification tasks, such as topic or genre classification, where evidence for a particular label is built up throughout a document. However, this does not make document coding a term recognition task, concerned only with the detection of triggers. Codes are assigned to a document as a whole, and code assignment decisions within a document may interact. It is an interesting combination of sentence and document-level processing.

Formally, we define the document coding task as follows: given a set of documents X and a set of available codes C, assign to each document x_i a subset of codes $C_i \subset C$. We also assume access to a (noisy) mechanism to detect candidate triggers in a document. In particular, we will assume that an (incomplete) dictionary $D(c)$ exists for each code $c \in C$, which lists specific *code terms* associated with c.[1] To continue our running example: $D(\textit{493.9})$ would include the term "allergic bronchitis". Each code can have several corresponding terms while each term indicates the presence of exactly one code. A *candidate code* c is proposed each time a term from $D(c)$ is found in a document.

2.1 From triggers to codes

The presence of a term from $D(c)$ does not automatically imply the assignment of code c to a document. Even with extremely precise dictionaries, there are three main reasons why a candidate code may not appear in a document's code subset.

1. The context of the trigger term might indicate the irrelevancy of the code. In the clinical domain, such irrelevancy can be specified by a negative or speculative statement (e.g., "evaluate for pneumonia") or a family-related context (e.g., "family history of diabetes"). Only definite diagnosis of the patient should be coded.

2. There can be several closely related candidate codes; yet only one, the best fitted code should be assigned to the document. For example, the triggers "left-sided flank pain" (code *789.09*) and "abdominal pain" (code *789.00*) may both appear in the same clinical report, but only the most specific code, *789.09*, should end up in the document code set.

3. The domain can have code dependency rules. For example, the ICD-9-CM coding rules state that no symptom codes should be given to a document if a definite diagnosis is present. That is, if a document is coded with pneumonia, it should not be coded with a fever or cough. On the other hand, if the diagnosis is uncertain, then codes for the symptoms should be assigned.

This suggests a paradigm where a candidate code, suggested by a detected trigger term, is assessed in terms of both its local context (item 1) and the presence of other candidate codes for the document (items 2 and 3).

[1] Note that dictionary-based trigger detection could be replaced by tagging approaches similar to those used in named-entity-recognition or information extraction.

2.2 ICD-9-CM Coding

As a specific application we have chosen the task of assigning ICD-9-CM codes to free-form clinical narratives. We use the dataset collected for the 2007 Medical NLP Challenge organized by the Computational Medicine Center in Cincinnati, Ohio, hereafter refereed to as "CMC Challenge" (Pestian et al., 2007). For this challenge, 1954 radiology reports on outpatient chest x-ray and renal procedures were collected, disambiguated, and anonymized. The reports were annotated with ICD-9-CM codes by three coding companies, and the majority codes were selected as a gold standard. In total, 45 distinct codes were used.

For this task, our use of a dictionary to detect lexical triggers is quite reasonable. The medical domain is rich with manually-created and carefully-maintained knowledge resources. In particular, the ICD-9-CM coding guidelines come with an index file that contains hundreds of thousands of terms mapped to corresponding codes. Another valuable resource is Metathesaurus from the Unified Medical Language System (UMLS) (Lindberg et al., 1993). It has millions of terms related to medical problems, procedures, treatments, organizations, etc. Often, hospitals, clinics, and other healthcare organizations maintain their own vocabularies to introduce consistency in their internal and external documentation and to support reporting, reviewing, and meta-analysis.

This task has some very challenging properties. As mentioned above, the ICD-9-CM coding rules create strong code dependencies: codes are assigned to a document as a set and not individually. Furthermore, the code distribution throughout the CMC training documents has a very heavy tail; that is, there are a few heavily-used codes and a large number of codes that are used only occasionally. An ideal approach will work well with both high-frequency and low-frequency codes.

3 Related work

Automated clinical coding has received much attention in the medical informatics literature. Stanfill et al. reviewed 113 studies on automated coding published in the last 40 years (Stanfill et al., 2010). The authors conclude that there exists a variety of tools covering different purposes, healthcare specialties, and clinical document types; however, these tools are not generalizable and neither are their evaluation results. One major obstacle that hinders the progress in this domain is data privacy issues. To overcome this obstacle, the CMC Challenge was organized in 2007. The purpose of the challenge was to provide a common realistic dataset to stimulate the research in the area and to assess the current level of performance on the task. Forty-four teams participated in the challenge. The top-performing system achieved micro-averaged F1-score of 0.8908, and the mean score was 0.7670.

Several teams, including the winner, built pure symbolic (i.e., hand-crafted rule-based) systems (e.g., (Goldstein et al., 2007)). This approach is feasible for the small code set used in the challenge, but it is questionable in real-life settings where thousands of codes need to be considered. Later, the winning team showed how their hand-crafted rules can be built in a semi-automatic way: the initial set of rules adopted from the official coding guidelines were automatically extended with additional synonyms and code dependency rules generated from the training data (Farkas and Szarvas, 2008).

Statistical systems trained on only text-derived features (such as n-grams) did not show good performance due to a wide variety of medical language and a relatively small training set (Goldstein et al., 2007). This led to the creation of hybrid systems: symbolic and statistical classifiers used together in an ensemble or cascade (Aronson et al., 2007; Crammer et al., 2007) or a symbolic component providing features for a statistical component (Patrick et al., 2007; Suominen et al., 2008). Strong competition systems had good answers for dealing with negative and speculative contexts, taking advantage of the competition's limited set of possible code combinations, and handling of low-frequency codes.

Our proposed approach is a combination system as well. We combine a symbolic component that matches lexical strings of a document against a medical dictionary to determine possible codes (Lussier et al., 2000; Kevers and Medori, 2010) and a statistical component that finalizes the assignment of codes to the document. Our statistical component is similar to that of Crammer et al. (2007), in that we train a single model for all codes with code-

specific and generic features. However, Crammer et al. (2007) did not employ our lexical trigger step or our sequence-modeling formulation. In fact, they considered all possible code subsets, which can be infeasible in real-life settings.

4 Method

To address the task of document coding, our lexically-triggered HMM operates using a two-stage procedure:

1. Lexically match text to the dictionary to get a set of candidate codes;
2. Using features derived from the candidates and the document, select the best code subset.

In the first stage, dictionary terms are detected in the document using exact string matching. All codes corresponding to matches become candidate codes, and no other codes can be proposed for this document.

In the second stage, a single classifier is trained to select the best code subset from the matched candidates. By training a single classifier, we use all of the training data to assign binary labels (present or absent) to candidates. This is the key distinction of our method from the traditional statistical approach where a separate classifier is trained for each code. The LT-HMM allows features learned from a document coded with c_i to transfer at test time to predict code c_j, provided their respective triggers appear in similar contexts. Training one common classifier improves our chances to reliably predict codes that have few training instances, and even codes that do not appear at all in the training data.

4.1 Trigger Detection

We have manually assembled a dictionary of terms for each of the 45 codes used in the CMC challenge.[2] The dictionaries were built by collecting relevant medical terminology from UMLS, the ICD-9-CM coding guidelines, and the CMC training data. The test data was not consulted during dictionary construction. The dictionaries contain 440 terms, with 9.78 terms per code on average. Given these dictionaries, the exact-matching of terms to input documents is straightforward. In our experiments, this process finds on average 1.83 distinct candidate codes per document.

The quality of the dictionary significantly affects the prediction performance of the proposed two-stage approach. Especially important is the coverage of the dictionary. If a trigger term is missing from the dictionary and, as the result, the code is not selected as a candidate code, it will not be recovered in the following stage, resulting in a false negative. Preliminary experiments show that our dictionary recovers 94.42% of the codes in the training set and 93.20% in the test set. These numbers provide an upper bound on recall for the overall approach.

4.2 Sequence Construction

After trigger detection, we view the input document as a sequence of candidate codes, each corresponding to a detected trigger (see Figure 1). By tagging these candidates in sequence, we can label each candidate code as present or absent and use previous tagging decisions to model code interactions. The final code subset is constructed by collecting all candidate codes tagged as present.

Our training data consists of [document, code set] pairs, augmented with the trigger terms detected through dictionary matching. We transform this into a sequence to be tagged using the following steps:

Ordering: The candidate code sequence is presented in reverse chronological order, according to when their corresponding trigger terms appear in the document. That is, the last candidate to be detected by the dictionary will be the first code to appear in our candidate sequence. Reverse order was chosen because clinical documents often close with a final (and informative) diagnosis.

Merging: Each detected trigger corresponds to exactly one code; however, several triggers may be detected for the same code throughout a document. If a code has several triggers, we keep only the last occurrence. When possible, we collect relevant features (such as negation information) of all occurrences and associate them with this last occurrence.

Labelling: Each candidate code is assigned a binary label (present or absent) based on whether it appears in the gold-standard code set. Note that this

[2] Online at https://sites.google.com/site/colinacherry/ICD9CM_ACL11.txt

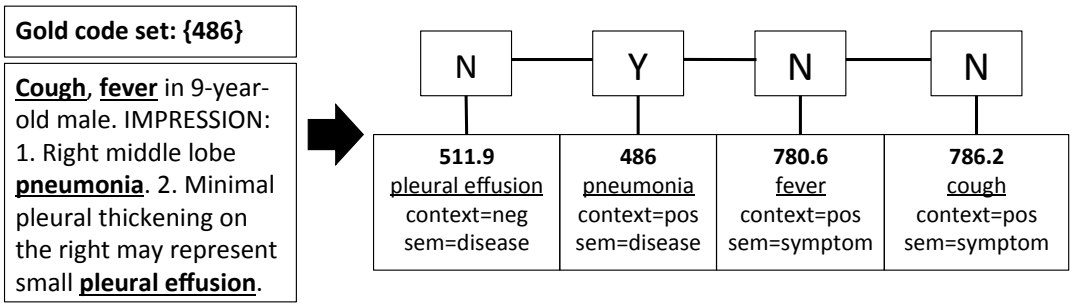

Figure 1: An example document and its corresponding gold-standard tag sequence. The top binary layer is the correct output tag sequence, which confirms or rejects the presence of candidate codes. The bottom layer shows the candidate code sequence derived from the text, with corresponding trigger phrases and some prominent features.

process can not introduce gold-standard codes that were not proposed by the dictionary.

The final output of these steps is depicted in Figure 1. To the left, we have an input text with underlined trigger phrases, as detected by our dictionary. This implies an input sequence (bottom right), which consists of detected codes and their corresponding trigger phrases. The gold-standard code set for the document is used to infer a gold-standard label sequence for these codes (top right). At test time, the goal of the classifier is to correctly predict the correct binary label sequence for new inputs. We discuss the construction of the features used to make this prediction in section 4.3.

4.3 Model

We model this sequence data using a discriminative SVM-HMM (Taskar et al., 2003; Altun et al., 2003). This allows us to use rich, over-lapping features of the input while also modeling interactions between labels. A discriminative HMM has two major categories of features: emission features, which characterize a candidate's tag in terms of the input document x, and transition features, which characterize a tag in terms of the tags that have come before it. We describe these two feature categories and then our training mechanism. All feature engineering discussed below was carried out using 10-fold cross-validation on the training set.

Transition Features

The transition features are modeled as simple indicators over n-grams of present codes, for values of n up to 10, the largest number of codes proposed by our dictionary in the training set.[3] This allows the system to learn sequences of codes that are (and are not) likely to occur in the gold-standard data.

We found it useful to pad our n-grams with "beginning of document" tokens for sequences when fewer than n codes have been labelled as present, but found it harmful to include an end-of-document tag once labelling is complete. We suspect that the small training set for the challenge makes the system prone to over-fit when modeling code-set length.

Emission Features

The vast majority of our training signal comes from emission features, which carefully model both the trigger term's local context and the document as a whole. For each candidate code, three types of features are generated: document features, ConText features, and code-semantics features (Table 1).

Document: Document features include indicators on all individual words, 2-grams, 3-grams, and 4-grams found in the document. These *n-gram features* have the candidate code appended to them, making them similar to features traditionally used in multiclass document categorization.

ConText: We take advantage of the ConText algorithm's output. ConText is publicly available software that determines the presence of negated, hypothetical, historical, and family-related context for a given phrase in a clinical text (Harkema et al., 2009).

[3] We can easily afford such a long history because input sequences are generally short and the tagging is binary, resulting in only a small number of possible histories for a document.

Features	gen.	spec.
Document		
n-gram		x
ConText		
current match		
context	x	x
only in context	x	x
more than once in context	x	x
other matches		
present	x	x
present in context = pos	x	x
code present in context	x	x
Code Semantics		
current match		
sem_type	x	
other matches		
sem_type, context = pos	x	x

Table 1: The emission features used in LT-HMM. Typeset words represent variables replaced with specific values, i.e. context $\in$ {pos,neg}, sem_type $\in$ {symptom,disease}, code is one of 45 challenge codes, n-gram is a document n-gram. Features can come in generic and/or code-specific version.

The algorithm is based on regular expression matching of the context to a precompiled list of context indicators. Regardless of its simplicity, the algorithm has shown very good performance on a variety of clinical document types. We run ConText for each trigger term located in the text and produce two types of features: features related to the candidate code in question and features related to other candidate codes of the document. Negated, hypothetical, and family-related contexts are clustered into a single *negative* context for the term. Absence of the negative context implies the *positive* context.

We used the following ConText derived indicator features: for the current candidate code, if there is at least one trigger term found in a positive (negative) context, if all trigger terms for this code are found in a positive (negative) context, if there are more than one trigger terms for the code found in a positive (negative) context; for other candidate codes of the document, if there is at least one other candidate code, if there is another candidate code with at least one trigger term found in a positive context, if there is a trigger term for candidate code c_i found in a positive (negative) context.

Code Semantics: We include features that indicate if the code itself corresponds to a disease or a symptom. This assignment was determined based on the UMLS semantic type of the code. Like the ConText features, code features come in two types: those regarding the candidate code in question and those regarding other candidate codes from the same document.

Generic versus Specific: Most of our features come in two versions: generic and code-specific. Generic features are concerned with classifying any candidate as present or absent based on characteristics of its trigger or semantics. Code-specific features append the candidate code to the feature. For example, the feature context=pos represents that the current candidate has a trigger term in a positive context, while context=pos:486 adds the information that the code in question is 486. Note that n-grams features are only code-specific, as they are not connected to any specific trigger term.

To an extent, code-specific features allow us to replicate the traditional classification approach, which focuses on one code at a time. Using these features, the classifier is free to build complex submodels for a particular code, provided that this code has enough training examples. Generic versions of the features, on the other hand, make it possible to learn common rules applicable to all codes, including low-frequency ones. In this way, even in the extreme case of having zero training examples for a particular code, the model can still potentially assign the code to new documents, provided it is detected by our dictionary. This is impossible in a traditional document-classification setting.

Training

We train our SVM-HMM with the objective of separating the correct tag sequence from all others by a fixed margin of 1, using a primal stochastic gradient optimization algorithm that follows Shalev-Shwartz et al. (2007). Let S be a set of training points (x, y), where x is the input and y is the corresponding gold-standard tag sequence. Let $\phi(x, y)$ be a function that transforms complete input-output pairs into feature vectors. We also use $\phi(x, y', y)$ as shorthand for the difference in features between

begin
Input: S, λ, n
Initialize: Set w_0 to the 0 vector
for $t = 1, 2 \ldots, n|S|$
Choose $(x, y) \in S$ at random
Set the learning rate: $\eta_t = \frac{1}{\lambda t}$
Search:
$y' = \arg\max_{y''} \left[\delta(y, y'') + w_t \cdot \phi(x, y'')\right]$
Update:
$w_{t+1} = w_t + \eta_t\big(\phi(x, y, y') - \lambda w_t\big)$
Adjust:
$w_{t+1} = w_{t+1} \cdot \min\left[1, \frac{1/\sqrt{\lambda}}{\|w_{t+1}\|}\right]$
end
Output: $w_{n|S|+1}$
end

Figure 2: Training an SVM-HMM

two outputs: $\phi(x, y', y) = \phi(x, y') - \phi(x, y)$. With this notation in place, the SVM-HMM minimizes the regularized hinge-loss:

$$\min_w \frac{\lambda}{2} w^2 + \frac{1}{|S|} \sum_{(x,y) \in S} \ell(w;\ (x, y)) \qquad (1)$$

where

$$\ell(w;\ (x, y)) = \max_{y'} \left[\delta(y, y') + w \cdot \phi(x, y', y)\right] \qquad (2)$$

and where $\delta(y, y') = 0$ when $y = y'$ and 1 otherwise.[4] Intuitively, the objective attempts to find a small weight vector w that separates all incorrect tag sequences y' from the correct tag sequence y by a margin of 1. λ controls the trade-off between regularization and training hinge-loss.

The stochastic gradient descent algorithm used to optimize this objective is shown in Figure 2. It bears many similarities to perceptron HMM training (Collins, 2002), with theoretically-motivated alterations, such as selecting training points at random[5] and the explicit inclusion of a learning rate η and a regularization term λ. The search step can be carried out with a two-best version of the Viterbi algorithm; if the one-best answer y'_1 matches the gold-standard y, that is $\delta(y, y'_1) = 0$, then y'_2 is checked to see if its loss is higher.

We tune two hyper-parameters using 10-fold cross-validation: the regularization parameter λ and a number of passes n through the training data. Using F1 as measured by 10-fold cross-validation on the training set, we found values of $\lambda = 0.1$ with $n = 5$ to prove optimal. Training time is less than one minute on modern hardware.

[4] We did not experiment with structured versions of δ that account for the number of incorrect tags in the label sequence y', as a fixed margin was already working very well. We intend to explore structured costs in future work.

[5] Like many implementations, we make n passes through S, shuffling S before each pass, rather than sampling from S with replacement $n|S|$ times.

Table 2: The training and test set characteristics.

5 Experiments

5.1 Data

For testing purposes, we use the CMC Challenge dataset. The data consists of 978 training and 976 test medical records labelled with one or more ICD-9-CM codes from a set of 45 codes. The data statistics are presented in Table 2. The training and test sets have similar, very imbalanced distributions of codes. In particular, all codes in the test set have at least one training example. Moreover, for any code subset assigned to a test document there is at least one training document labelled with the same code subset. Notably, more than half of the codes have less than 10 instances in both training and test sets. Following the challenge's protocol, we use micro-averaged F1-measure for evaluation.

5.2 Baseline

As the first baseline for comparison, we built a one-classifier-per-code statistical system. A document's code subset is implied by the set of classifiers that assign it a positive label. The classifiers use a feature set designed to mimic our LT-HMM as closely as possible, including n-grams, dictionary matches, ConText output, and symptom/disease se-

mantic types. Each classifier is trained as an SVM with a linear kernel.

Unlike our approach, this baseline cannot share features across codes, and it does not allow coding decisions for a document to inform one another. It also cannot propose codes that have not been seen in the training data as it has no model for these codes. However, one should note that it is a very strong baseline. Like our proposed system, it is built with many features derived from dictionary matches and their contexts, and thus it shares many of our system's strengths. In fact, this baseline system outperforms all published statistical approaches tested on the CMC data.

Our second baseline is a symbolic system, designed to evaluate the quality of our rule-based components when used alone. It is based on the same hand-crafted dictionary, filtered according to the ConText algorithm and four code dependency rules from (Farkas and Szarvas, 2008). These rules address the problem of overcoding: some symptom codes should be omitted when a specific disease code is present.[6]

This symbolic system has access to the same hand-crafted resources as our LT-HMM and, therefore, has a good chance of predicting low-frequency and unseen codes. However, it lacks the flexibility of our statistical solution to accept or reject code candidates based on the whole document text, which prevents it from compensating for dictionary or ConText errors. Similarly, the structure of the code dependency rules may not provide the same flexibility as our features that look at other detected triggers and previous code assignments.

5.3 Coding Accuracy

We evaluate the proposed approach on both the training set (using 10-fold cross-validation) and the test set (Table 3). The experiments demonstrate the superiority of the proposed LT-HMM approach over the one-per-code statistical scheme as well as our symbolic baseline. Furthermore, the new approach shows the best results ever achieved on the dataset, beating the top-performing system in the challenge, a symbolic method.

[6]Note that we do not match the performance of the Farkas and Szarvas system, likely due to our use of a different (and simpler) dictionary.

	Cross-fold	**Test**

-ConText & Transition	86.91	85.39	86.14

Table 4: Results on the CMC test data with each major component removed.

5.4 Ablation

Our system employs a number of emission feature templates. We measure the impact of each by removing the template, re-training, and testing on the challenge test data, as shown in Table 4. By far the most important component of our system is the output of the ConText algorithm.

We also tested a version of the system that does not create a parallel code-specific feature set by appending the candidate code to emission features. This system tags code-candidates without any code-specific components, but it still does very well, outperforming the baselines.

Removing the sequence-based transition features from our system has only a small impact on accuracy. This is because several of our emission features look at features of other candidate codes. This provides a strong approximation to the actual tagging decisions for these candidates. If we remove the ConText features, the HMM's transition features become more important (compare line 2 of Table 4 to line 7).

5.5 Low-frequency codes

As one can see from Table 2, more than half of the available codes appear fewer than 10 times in the

System	Prec.	Rec.	F1

Symbolic baseline	60.00	80.00	68.57
All training data	72.92	74.47	73.68
One code held out	79.31	48.94	60.53

Table 6: Results on the CMC test set when all instances of a low-frequency code are held-out during training.

training documents. This does not provide much training data for a one-classifier-per-code approach, which has been a major motivating factor in the design of our LT-HMM. In Table 5, we compare our system to the baselines on the CMC test set, considering only these low-frequency codes. We show a 15-point gain in F1 over the statistical baseline on these hard cases, brought on by an substantial increase in recall. Similarly, we improve over the symbolic baseline, due to a much higher precision. In this way, the LT-HMM captures the strengths of both approaches.

Our system also has the ability to predict codes that have not been seen during training, by labelling a dictionary match for a code as present according to its local context. We simulate this setting by dropping training data. For each low-frequency code c, we hold out all training documents that include c in their gold-standard code set. We then train our system on the reduced training set and measure its ability to detect c on the unseen test data. 11 of the 24 low-frequency codes have no dictionary matches in our test data; we omit them from our analysis as we are unable to predict them. The micro-averaged results for the remaining 13 low-frequency codes are shown in Table 6, with the results from the symbolic baseline and from our system trained on the complete training data provided for comparison.

We were able to recover 49% of the test-time occurrences of codes withheld from training, while maintaining our full system's precision. Considering that traditional statistical strategies would lead to recall dropping uniformly to 0, this is a vast improvement. However, the symbolic baseline recalls 80% of occurrences in aggregate, indicating that we are not yet making optimal use of the dictionary for cases when a code is missing from the training data. By holding out only *correct* occurrences of a code c, our system becomes biased against it: all trigger terms for c that are found in the training data *must* be labelled absent. Nonetheless, out of the 13 codes with dictionary matches, there were 9 codes that we were able to recall at a rate of 50% or more, and 5 codes that achieved 100% recall.

6 Conclusion

We have presented the lexically-triggered HMM, a novel and effective approach for clinical document coding. The LT-HMM takes advantage of lexical triggers for clinical codes by operating in two stages: first, a lexical match is performed against a trigger term dictionary to collect a set of candidates codes for a document; next, a discriminative HMM selects the best subset of codes to assign to the document. Using both generic and code-specific features, the LT-HMM outperforms a traditional one-per-code statistical classification method, with substantial improvements on low-frequency codes. Also, it achieves the best ever performance on a common testbed, beating the top-performer of the 2007 CMC Challenge, a hand-crafted rule-based system. Finally, we have demonstrated that the LT-HMM can correctly predict codes never seen in the training set, a vital characteristic missing from previous statistical methods.

In the future, we would like to augment our dictionary-based matching component with entity-recognition technology. It would be interesting to model triggers as latent variables in the document coding process, in a manner similar to how latent subjective sentences have been used in document-level sentiment analysis (Yessenalina et al., 2010). This would allow us to employ a learned matching component that is trained to compliment our classification component.

Abstract

In this work we address the task of computer-assisted assessment of short student answers. We combine several graph alignment features with lexical semantic similarity measures using machine learning techniques and show that the student answers can be more accurately graded than if the semantic measures were used in isolation. We also present a first attempt to align the dependency graphs of the student and the instructor answers in order to make use of a structural component in the automatic grading of student answers.

1 Introduction

One of the most important aspects of the learning process is the assessment of the knowledge acquired by the learner. In a typical classroom assessment (e.g., an exam, assignment or quiz), an instructor or a grader provides students with feedback on their answers to questions related to the subject matter. However, in certain scenarios, such as a number of sites worldwide with limited teacher availability, online learning environments, and individual or group study sessions done outside of class, an instructor may not be readily available. In these instances, students still need some assessment of their knowledge of the subject, and so, we must turn to computer-assisted assessment (CAA).

While some forms of CAA do not require sophisticated text understanding (e.g., multiple choice or true/false questions can be easily graded by a system if the correct solution is available), there are also student answers made up of free text that may require textual analysis. Research to date has concentrated on two subtasks of CAA: grading essay responses, which includes checking the style, grammaticality, and coherence of the essay (Higgins et al., 2004), and the assessment of short student answers (Leacock and Chodorow, 2003; Pulman and Sukkarieh, 2005; Mohler and Mihalcea, 2009), which is the focus of this work.

An automatic short answer grading system is one that automatically assigns a grade to an answer provided by a student, usually by comparing it to one or more correct answers. Note that this is different from the related tasks of paraphrase detection and textual entailment, since a common requirement in student answer grading is to provide a grade on a certain scale rather than make a simple yes/no decision.

In this paper, we explore the possibility of improving upon existing bag-of-words (BOW) approaches to short answer grading by utilizing machine learning techniques. Furthermore, in an attempt to mirror the ability of humans to understand structural (e.g. syntactic) differences between sentences, we employ a rudimentary dependency-graph alignment module, similar to those more commonly used in the textual entailment community.

Specifically, we seek answers to the following questions. **First**, to what extent can machine learning be leveraged to improve upon existing approaches to short answer grading. **Second**, does the dependency parse structure of a text provide clues that can be exploited to improve upon existing BOW methodologies?

Portland, Oregon, June 19-24, 2011.

2 Related Work

Several state-of-the-art short answer grading systems (Sukkarieh et al., 2004; Mitchell et al., 2002) require manually crafted patterns which, if matched, indicate that a question has been answered correctly. If an annotated corpus is available, these patterns can be supplemented by learning additional patterns semi-automatically. The Oxford-UCLES system (Sukkarieh et al., 2004) bootstraps patterns by starting with a set of keywords and synonyms and searching through windows of a text for new patterns. A later implementation of the Oxford-UCLES system (Pulman and Sukkarieh, 2005) compares several machine learning techniques, including inductive logic programming, decision tree learning, and Bayesian learning, to the earlier pattern matching approach, with encouraging results.

C-Rater (Leacock and Chodorow, 2003) matches the syntactical features of a student response (i.e., subject, object, and verb) to that of a set of correct responses. This method specifically disregards the BOW approach to take into account the difference between "dog bites man" and "man bites dog" while still trying to detect changes in voice (i.e., "the man was bitten by the dog").

Another short answer grading system, AutoTutor (Wiemer-Hastings et al., 1999), has been designed as an immersive tutoring environment with a graphical "talking head" and speech recognition to improve the overall experience for students. AutoTutor eschews the pattern-based approach entirely in favor of a BOW LSA approach (Landauer and Dumais, 1997). Later work on AutoTutor(Wiemer-Hastings et al., 2005; Malatesta et al., 2002) seeks to expand upon their BOW approach which becomes less useful as causality (and thus word order) becomes more important.

A text similarity approach was taken in (Mohler and Mihalcea, 2009), where a grade is assigned based on a measure of relatedness between the student and the instructor answer. Several measures are compared, including knowledge-based and corpus-based measures, with the best results being obtained with a corpus-based measure using Wikipedia combined with a "relevance feedback" approach that iteratively augments the instructor answer by integrating the student answers that receive the highest grades.

In the dependency-based classification component of the Intelligent Tutoring System (Nielsen et al., 2009), instructor answers are parsed, enhanced, and manually converted into a set of content-bearing dependency triples or facets. For each facet of the instructor answer each student's answer is labelled to indicate whether it has addressed that facet and whether or not the answer was contradictory. The system uses a decision tree trained on part-of-speech tags, dependency types, word count, and other features to attempt to learn how best to classify an answer/facet pair.

Closely related to the task of short answer grading is the task of textual entailment (Dagan et al., 2005), which targets the identification of a directional inferential relation between texts. Given a pair of two texts as input, typically referred to as *text* and *hypothesis*, a textual entailment system automatically finds if the hypothesis is entailed by the text.

In particular, the entailment-related works that are most similar to our own are the graph matching techniques proposed by Haghighi et al. (2005) and Rus et al. (2007). Both input texts are converted into a graph by using the dependency relations obtained from a parser. Next, a matching score is calculated, by combining separate vertex- and edge-matching scores. The vertex matching functions use word-level lexical and semantic features to determine the quality of the match while the the edge matching functions take into account the types of relations and the difference in lengths between the aligned paths.

Following the same line of work in the textual entailment world are (Raina et al., 2005), (MacCartney et al., 2006), (de Marneffe et al., 2007), and (Chambers et al., 2007), which experiment variously with using diverse knowledge sources, using a perceptron to learn alignment decisions, and exploiting natural logic.

3 Answer Grading System

We use a set of syntax-aware graph alignment features in a three-stage pipelined approach to short answer grading, as outlined in Figure 1.

In the first stage (Section 3.1), the system is provided with the dependency graphs for each pair of instructor (A_i) and student (A_s) answers. For each

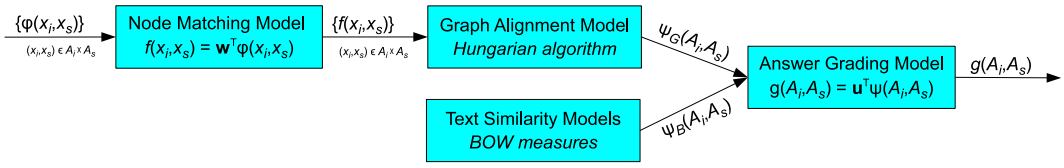

Figure 1: Pipeline model for scoring short-answer pairs.

node in the instructor's dependency graph, we compute a similarity score for each node in the student's dependency graph based upon a set of lexical, semantic, and syntactic features applied to both the pair of nodes and their corresponding subgraphs. The scoring function is trained on a small set of manually aligned graphs using the averaged perceptron algorithm.

In the second stage (Section 3.2), the node similarity scores calculated in the previous stage are used to weight the edges in a bipartite graph representing the nodes in A_i on one side and the nodes in A_s on the other. We then apply the Hungarian algorithm to find both an optimal matching and the score associated with such a matching. In this stage, we also introduce question demoting in an attempt to reduce the advantage of parroting back words provided in the question.

In the final stage (Section 3.4), we produce an overall grade based upon the alignment scores found in the previous stage as well as the results of several semantic BOW similarity measures (Section 3.3). Using each of these as features, we use Support Vector Machines (SVM) to produce a combined real-number grade. Finally, we build an Isotonic Regression (IR) model to transform our output scores onto the original [0,5] scale for ease of comparison.

3.1 Node to Node Matching

Dependency graphs for both the student and instructor answers are generated using the Stanford Dependency Parser (de Marneffe et al., 2006) in collapse/propagate mode. The graphs are further post-processed to propagate dependencies across the "APPOS" (apposition) relation, to explicitly encode negation, part-of-speech, and sentence ID within each node, and to add an overarching ROOT node governing the main verb or predicate of each sentence of an answer. The final representation is a list of (relation,governor,dependent) triples, where governor and dependent are both tokens described by the tuple (sentenceID:token:POS:wordPosition). For example: **(nsubj, 1:provide:VBZ:4, 1:program:NN:3)** indicates that the noun "program" is a subject in sentence 1 whose associated verb is "provide."

If we consider the dependency graphs output by the Stanford parser as directed (minimally cyclic) graphs,[1] we can define for each node x a set of nodes N_x that are reachable from x using a subset of the relations (i.e., edge types)[2]. We variously define "reachable" in four ways to create four subgraphs defined for each node. These are as follows:

- N_x^0 : All edge types may be followed
- N_x^1 : All edge types except for subject types, ADVCL, PURPCL, APPOS, PARATAXIS, ABBREV, TMOD, and CONJ
- N_x^2 : All edge types except for those in N_x^1 plus object/complement types, PREP, and RCMOD
- N_x^3 : No edge types may be followed (This set is the single starting node x)

Subgraph similarity (as opposed to simple node similarity) is a means to escape the rigidity involved in aligning parse trees while making use of as much of the sentence structure as possible. Humans intuitively make use of modifiers, predicates, and subordinate clauses in determining that two sentence entities are similar. For instance, the entity-describing phrase "men who put out fires" matches well with "firemen," but the words "men" and "firemen" have

[1]The standard output of the Stanford Parser produces rooted trees. However, the process of collapsing and propagating dependences violates the tree structure which results in a tree with a few cross-links between distinct branches.

[2]For more information on the relations used in this experiment, consult the Stanford Typed Dependencies Manual at http://nlp.stanford.edu/software/dependencies_manual.pdf

less inherent similarity. It remains to be determined how much of a node's subgraph will positively enrich its semantics. In addition to the complete N_x^0 subgraph, we chose to include N_x^1 and N_x^2 as tightening the scope of the subtree by first removing more abstract relations, then sightly more concrete relations.

We define a total of 68 features to be used to train our machine learning system to compute node-node (more specifically, subgraph-subgraph) matches. Of these, 36 are based upon the semantic similarity of four subgraphs defined by $N_x^{[0..3]}$. All eight WordNet-based similarity measures listed in Section 3.3 plus the LSA model are used to produce these features. The remaining 32 features are lexico-syntactic features[3] defined only for N_x^3 and are described in more detail in Table 2.

We use $\phi(x_i, x_s)$ to denote the feature vector associated with a pair of nodes $\langle x_i, x_s \rangle$, where x_i is a node from the instructor answer A_i and x_s is a node from the student answer A_s. A matching score can then be computed for any pair $\langle x_i, x_s \rangle \in A_i \times A_s$ through a linear scoring function $f(x_i, x_s) = \mathbf{w}^T \phi(x_i, x_s)$. In order to learn the parameter vector $\mathbf{w}$, we use the averaged version of the perceptron algorithm (Freund and Schapire, 1999; Collins, 2002).

As training data, we randomly select a subset of the student answers in such a way that our set was roughly balanced between good scores, mediocre scores, and poor scores. We then manually annotate each node pair $\langle x_i, x_s \rangle$ as matching, i.e. $A(x_i, x_s) = +1$, or not matching, i.e. $A(x_i, x_s) = -1$. Overall, 32 student answers in response to 21 questions with a total of 7303 node pairs (656 matches, 6647 non-matches) are manually annotated. The pseudocode for the learning algorithm is shown in Table 1. After training the perceptron, these 32 student answers are removed from the dataset, not used as training further along in the pipeline, and are not included in the final results. After training for 50 epochs,[4] the matching score $f(x_i, x_s)$ is calculated (and cached) for each node-node pair across all student answers for all assignments.

[3]Note that synonyms include negated antonyms (and vice versa). Hypernymy and hyponymy are restricted to at most two steps).

[4]This value was chosen arbitrarily and was not tuned in anyway

```
0. set w ← 0, w̄ ← 0, n ← 0
1. repeat for T epochs:
2.     foreach ⟨A_i; A_s⟩:
3.         foreach ⟨x_i, x_s⟩ ∈ A_i × A_s:
4.             if sgn(w^T φ(x_i, x_s)) ≠ sgn(A(x_i, x_s)):
5.                 set w ← w + A(x_i, x_s) φ(x_i, x_s)
6.             set w̄ ← w̄ + w, n ← n + 1
7. return w̄/n.
```

Table 1: Perceptron Training for Node Matching.

3.2 Graph to Graph Alignment

Once a score has been computed for each node-node pair across all student/instructor answer pairs, we attempt to find an optimal alignment for the answer pair. We begin with a bipartite graph where each node in the student answer is represented by a node on the left side of the bipartite graph and each node in the instructor answer is represented by a node on the right side. The score associated with each edge is the score computed for each node-node pair in the previous stage. The bipartite graph is then augmented by adding dummy nodes to both sides which are allowed to match any node with a score of zero. An optimal alignment between the two graphs is then computed efficiently using the Hungarian algorithm. Note that this results in an optimal matching, not a mapping, so that an individual node is associated with at most one node in the other answer.

At this stage we also compute several alignment-based scores by applying various transformations to the input graphs, the node matching function, and the alignment score itself.

The first and simplest transformation involves the normalization of the alignment score. While there are several possible ways to normalize a matching such that longer answers do not unjustly receive higher scores, we opted to simply divide the total alignment score by the number of nodes in the instructor answer.

The second transformation scales the node matching score by multiplying it with the idf[5] of the instructor answer node, i.e., replace $f(x_i, x_s)$ with $idf(x_i) * f(x_i, x_s)$.

The third transformation relies upon a certain real-world intuition associated with grading student

[5]Inverse document frequency, as computed from the British National Corpus (BNC)

Name	Type	# features	Description
RootMatch	binary	5	Is a ROOT node matched to: ROOT, N, V, JJ, or Other
Lexical	binary	3	Exact match, Stemmed match, close Levenshtein match

answers – repeating words in the question is easy and is not necessarily an indication of student understanding. With this in mind, we remove any words in the question from both the instructor answer and the student answer.

In all, the application of the three transformations leads to eight different transform combinations, and therefore eight different alignment scores. For a given answer pair (A_i, A_s), we assemble the eight graph alignment scores into a feature vector $\psi_G(A_i, A_s)$.

3.3 Lexical Semantic Similarity

Haghighi et al. (2005), working on the entailment detection problem, point out that finding a good alignment is not sufficient to determine that the aligned texts are in fact entailing. For instance, two identical sentences in which an adjective from one is replaced by its antonym will have very similar structures (which indicates a good alignment). However, the sentences will have opposite meanings. Further information is necessary to arrive at an appropriate score.

In order to address this, we combine the graph alignment scores, which encode syntactic knowledge, with the scores obtained from semantic similarity measures.

Following Mihalcea et al. (2006) and Mohler and Mihalcea (2009), we use eight knowledge-based measures of semantic similarity: shortest path [PATH], Leacock & Chodorow (1998) [LCH], Lesk (1986), Wu & Palmer(1994) [WUP], Resnik (1995) [RES], Lin (1998), Jiang & Conrath (1997) [JCN], Hirst & St. Onge (1998) [HSO], and two corpus-based measures: Latent Semantic Analysis [LSA] (Landauer and Dumais, 1997) and Explicit Semantic Analysis [ESA] (Gabrilovich and Markovitch, 2007).

Briefly, for the knowledge-based measures, we use the maximum semantic similarity – for each open-class word – that can be obtained by pairing it up with individual open-class words in the second input text. We base our implementation on the WordNet::Similarity package provided by Pedersen et al. (2004). For the corpus-based measures, we create a vector for each answer by summing the vectors associated with each word in the answer – ignoring stopwords. We produce a score in the range [0..1] based upon the cosine similarity between the student and instructor answer vectors. The LSA model used in these experiments was built by training Infomap[6] on a subset of Wikipedia articles that contain one or more common computer science terms. Since ESA uses Wikipedia article associations as vector features, it was trained using a full Wikipedia dump.

3.4 Answer Ranking and Grading

We combine the alignment scores $\psi_G(A_i, A_s)$ with the scores $\psi_B(A_i, A_s)$ from the lexical semantic similarity measures into a single feature vector $\psi(A_i, A_s) = [\psi_G(A_i, A_s)|\psi_B(A_i, A_s)]$. The feature vector $\psi_G(A_i, A_s)$ contains the eight alignment scores found by applying the three transformations in the graph alignment stage. The feature vector $\psi_B(A_i, A_s)$ consists of eleven semantic features – the eight knowledge-based features plus LSA, ESA and a vector consisting only of tf*idf weights – both with and without question demoting. Thus, the entire feature vector $\psi(A_i, A_s)$ contains a total of 30 features.

[6] http://Infomap-nlp.sourceforge.net/

An input pair (A_i, A_s) is then associated with a grade $g(A_i, A_s) = \mathbf{u}^T \psi(A_i, A_s)$ computed as a linear combination of features. The weight vector $\mathbf{u}$ is trained to optimize performance in two scenarios:

Regression: An SVM model for regression (SVR) is trained using as target function the grades assigned by the instructors. We use the libSVM [7] implementation of SVR, with tuned parameters.

Ranking: An SVM model for ranking (SVMRank) is trained using as ranking pairs all pairs of student answers (A_s, A_t) such that $grade(A_i, A_s) > grade(A_i, A_t)$, where A_i is the corresponding instructor answer. We use the SVMLight [8] implementation of SVMRank with tuned parameters.

In both cases, the parameters are tuned using a grid-search. At each grid point, the training data is partitioned into 5 folds which are used to train a temporary SVM model with the given parameters. The regression passage selects the grid point with the minimal mean square error (MSE), and the SVMRank package tries to minimize the number of discordant pairs. The parameters found are then used to score the test set – a set not used in the grid training.

3.5 Isotonic Regression

Since the end result of any grading system is to give a student feedback on their answers, we need to ensure that the system's final score has some meaning. With this in mind, we use isotonic regression (Zadrozny and Elkan, 2002) to convert the system scores onto the same [0..5] scale used by the annotators. This has the added benefit of making the system output more directly related to the annotated grade, which makes it possible to report root mean square error in addition to correlation. We train the isotonic regression model on each type of system output (i.e., alignment scores, SVM output, BOW scores).

4 Data Set

To evaluate our method for short answer grading, we created a data set of questions from introductory computer science assignments with answers provided by a class of undergraduate students. The assignments were administered as part of a Data Structures course at the University of North Texas. For each assignment, the student answers were collected via an online learning environment.

The students submitted answers to 80 questions spread across ten assignments and two examinations.[9] Table 3 shows two question-answer pairs with three sample student answers each. Thirty-one students were enrolled in the class and submitted answers to these assignments. The data set we work with consists of a total of 2273 student answers. This is less than the expected $31 \times 80 = 2480$ as some students did not submit answers for a few assignments. In addition, the student answers used to train the perceptron are removed from the pipeline after the perceptron training stage.

The answers were independently graded by two human judges, using an integer scale from 0 (completely incorrect) to 5 (perfect answer). Both human judges were graduate students in the computer science department; one (grader1) was the teaching assistant assigned to the Data Structures class, while the other (grader2) is one of the authors of this paper. We treat the average grade of the two annotators as the gold standard against which we compare our system output.

Difference	Examples	% of examples
0	1294	57.7%
1	514	22.9%
2	231	10.3%
3	123	5.5%
4	70	3.1%
5	9	0.4%

Table 4: Annotator Analysis

The annotators were given no explicit instructions on how to assign grades other than the [0..5] scale. Both annotators gave the same grade 57.7% of the time and gave a grade only 1 point apart 22.9% of the time. The full breakdown can be seen in Table 4. In addition, an analysis of the grading patterns indicate that the two graders operated off of different grading policies where one grader (grader1) was more generous than the other. In fact, when the two differed, grader1 gave the higher grade 76.6% of the time. The average grade given by grader1 is 4.43,

	Sample questions, correct answers, and student answers	Grades
Question:	What is the role of a prototype program in problem solving?	
Correct answer:	To simulate the behavior of portions of the desired software product.	
Student answer 1:	A prototype program is used in problem solving to collect data for the problem.	1, 2
Student answer 2:	It simulates the behavior of portions of the desired software product.	5, 5
Student answer 3:	To find problem and errors in a program before it is finalized.	2, 2
Question:	What are the main advantages associated with object-oriented programming?	
Correct answer:	Abstraction and reusability.	
Student answer 1:	They make it easier to reuse and adapt previously written code and they separate complex programs into smaller, easier to understand classes.	5, 4
Student answer 2:	Object oriented programming allows programmers to use an object with classes that can be changed and manipulated while not affecting the entire object at once.	1, 1
Student answer 3:	Reusable components, Extensibility, Maintainability, it reduces large problems into smaller more manageable problems.	4, 4

Table 3: A sample question with short answers provided by students and the grades assigned by the two human judges

while the average grade given by grader2 is 3.94. The dataset is biased towards correct answers. We believe all of these issues correctly mirror real-world issues associated with the task of grading.

5 Results

We independently test two components of our overall grading system: the node alignment detection scores found by training the perceptron, and the overall grades produced in the final stage. For the alignment detection, we report the precision, recall, and F-measure associated with correctly detecting matches. For the grading stage, we report a single Pearson's correlation coefficient tracking the annotator grades (average of the two annotators) and the output score of each system. In addition, we report the Root Mean Square Error (RMSE) for the full dataset as well as the median RMSE across each individual question. This is to give an indication of the performance of the system for grading a single question in isolation.[10]

5.1 Perceptron Alignment

For the purpose of this experiment, the scores associated with a given node-node matching are converted into a simple yes/no matching decision where positive scores are considered a match and negative scores a non-match. The threshold weight learned from the bias feature strongly influences the point at which real scores change from non-matches to matches, and given the threshold weight learned by the algorithm, we find an F-measure of 0.72, with precision(P) = 0.85 and recall(R) = 0.62. However, as the perceptron is designed to minimize error rate, this may not reflect an optimal objective when seeking to detect matches. By manually varying the threshold, we find a maximum F-measure of 0.76, with P=0.79 and R=0.74. Figure 2 shows the full precision-recall curve with the F-measure overlaid.

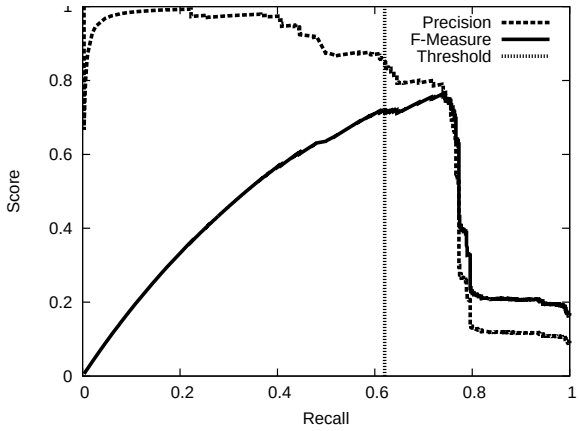

Figure 2: Precision, recall, and F-measure on node-level match detection

5.2 Question Demoting

One surprise while building this system was the consistency with which the novel technique of *question demoting* improved scores for the BOW similarity measures. With this relatively minor change the average correlation between the BOW methods' sim-

[10] We initially intended to report an aggregate of question-level Pearson correlation results, but discovered that the dataset contained one question for which each student received full points – leaving the correlation undefined. We believe that this casts some doubt on the applicability of Pearson's (or Spearman's) correlation coefficient for the short answer grading task. We have retained its use here alongside RMSE for ease of comparison.

ilarity scores and the student grades improved by up to 0.046 with an average improvement of 0.019 across all eleven semantic features. Table 5 shows the results of applying question demoting to our semantic features. When comparing scores using RMSE, the difference is less consistent, yielding an average improvement of 0.002. However, for one measure (tf*idf), the improvement is 0.063 which brings its RMSE score close to the lowest of all BOW metrics. The reasons for this are not entirely clear. As a baseline, we include here the results of assigning the average grade (as determined on the training data) for each question. The average grade was chosen as it minimizes the RMSE on the training data.

	ρ	w/ QD	RMSE	w/ QD	Med. RMSE	w/ QD
Lesk	**0.450**	**0.462**	1.034	1.050	**0.930**	**0.919**

Avg.grade			1.097	1.097	0.973	0.973

Table 5: BOW Features with Question Demoting (QD). Pearson's correlation, root mean square error (RMSE), and median RMSE for all individual questions.

5.3 Alignment Score Grading

Before applying any machine learning techniques, we first test the quality of the eight graph alignment features $\psi_G(A_i, A_s)$ independently. Results indicate that the basic alignment score performs comparably to most BOW approaches. The introduction of *idf* weighting seems to degrade performance somewhat, while introducing question demoting causes the correlation with the grader to increase while increasing RMSE somewhat. The four normalized components of $\psi_G(A_i, A_s)$ are reported in Table 6.

5.4 SVM Score Grading

The SVM components of the system are run on the full dataset using a 12-fold cross validation. Each of the 10 assignments and 2 examinations (for a total of 12 folds) is scored independently with ten of the remaining eleven used to train the machine learning system. For each fold, one additional fold is held out for later use in the development of an isotonic regression model (see Figure 3). The parameters (for cost C and tube width ϵ) were found using a grid search. At each point on the grid, the data from the ten training folds was partitioned into 5 sets which were scored according to the current parameters. SVMRank and SVR sought to minimize the number of discordant pairs and the mean absolute error, respectively.

	Standard	w/ IDF	w/ QD	w/ QD+IDF
Pearson's ρ	0.411	0.277	**0.428**	0.291
RMSE	**1.018**	1.078	1.046	1.076
Median RMSE	**0.910**	0.970	0.919	0.992

Table 6: Alignment Feature/Grade Correlations using Pearson's ρ. Results are also reported when inverse document frequency weighting (IDF) and question demoting (QD) are used.

Both SVM models are trained using a linear kernel.[11] Results from both the SVR and the SVMRank implementations are reported in Table 7 along with a selection of other measures. Note that the RMSE score is computed after performing isotonic regression on the SVMRank results, but that it was unnecessary to perform an isotonic regression on the SVR results as the system was trained to produce a score on the correct scale.

We report the results of running the systems on three subsets of features $\psi(A_i, A_s)$: BOW features $\psi_B(A_i, A_s)$ only, alignment features $\psi_G(A_i, A_s)$ only, or the full feature vector (labeled "Hybrid"). Finally, three subsets of the alignment features are used: only unnormalized features, only normalized features, or the full alignment feature set.

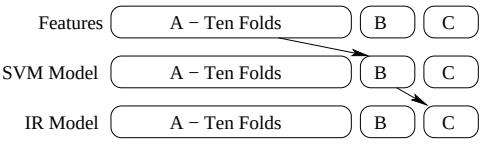

Figure 3: Dependencies of the SVM/IR training stages.

[11] We also ran the SVR system using quadratic and radial-basis function (RBF) kernels, but the results did not show significant improvement over the simpler linear kernel.

						Unnormalized		Normalized		Both	
	IAA	Avg. grade	tf*idf	Lesk	BOW	Align	Hybrid	Align	Hybrid	Align	Hybrid
					SVMRank						
Pearson's ρ	0.586		0.327	0.450	0.480	0.266	0.451	0.447	**0.518**	0.424	0.493
RMSE	0.659	1.097	1.022	1.050	1.042	1.093	1.038	1.015	**0.998**	1.029	1.021
Median RMSE	0.605	0.973	0.918	0.919	0.943	0.974	0.903	**0.865**	0.873	0.904	0.901
					SVR						
Pearson's ρ	0.586		0.327	0.450	0.431	0.167	0.437	0.433	0.459	0.434	**0.464**
RMSE	0.659	1.097	1.022	1.050	0.999	1.133	0.995	1.001	0.982	1.003	**0.978**
Median RMSE	0.605	0.973	0.918	0.919	0.910	0.987	0.893	0.894	0.877	0.886	**0.862**

Table 7: The results of the SVM models trained on the full suite of BOW measures, the alignment scores, and the hybrid model. The terms "normalized", "unnormalized", and "both" indicate which subset of the 8 alignment features were used to train the SVM model. For ease of comparison, we include in both sections the scores for the IAA, the "Average grade" baseline, and two of the top performing BOW metrics – both with question demoting.

6 Discussion and Conclusions

There are three things that we can learn from these experiments. First, we can see from the results that several systems appear better when evaluating on a correlation measure like Pearson's ρ, while others appear better when analyzing error rate. The SVM-Rank system seemed to outperform the SVR system when measuring correlation, however the SVR system clearly had a minimal RMSE. This is likely due to the different objective function in the corresponding optimization formulations: while the ranking model attempts to ensure a correct ordering between the grades, the regression model seeks to minimize an error objective that is closer to the RMSE. It is difficult to claim that either system is superior.

Likewise, perhaps the most unexpected result of this work is the differing analyses of the simple tf*idf measure – originally included only as a baseline. Evaluating with a correlative measure yields predictably poor results, but evaluating the error rate indicates that it is comparable to (or better than) the more intelligent BOW metrics. One explanation for this result is that the skewed nature of this "natural" dataset favors systems that tend towards scores in the 4 to 4.5 range. In fact, 46% of the scores output by the tf*idf measure (after IR) were within the 4 to 4.5 range and only 6% were below 3.5. Testing on a more balanced dataset, this tendency to fit to the average would be less advantageous.

Second, the supervised learning techniques are clearly able to leverage multiple BOW measures to yield improvements over individual BOW metrics. The correlation for the BOW-only SVM model for SVMRank improved upon the best BOW feature from .462 to .480. Likewise, using the BOW-only SVM model for SVR reduces the RMSE by .022 overall compared to the best BOW feature.

Third, the rudimentary alignment features we have introduced here are not sufficient to act as a standalone grading system. However, even with a very primitive attempt at alignment detection, we show that it is possible to improve upon grade learning systems that only consider BOW features. The correlations associated with the hybrid systems (esp. those using normalized alignment data) frequently show an improvement over the BOW-only SVM systems. This is true for both SVM systems when considering either evaluation metric.

Future work will concentrate on improving the quality of the answer alignments by training a model to directly output graph-to-graph alignments. This learning approach will allow the use of more complex alignment features, for example features that are defined on pairs of aligned edges or on larger subtrees in the two input graphs. Furthermore, given an alignment, we can define several phrase-level grammatical features such as negation, modality, tense, person, number, or gender, which make better use of the alignment itself.

Abstract

We investigate whether wording, stylistic choices, and online behavior can be used to predict the age category of blog authors. Our hypothesis is that significant changes in writing style distinguish pre-social media bloggers from post-social media bloggers. Through experimentation with a range of years, we found that the birth dates of students in college at the time when social media such as AIM, SMS text messaging, MySpace and Facebook first became popular, enable accurate age prediction. We also show that internet writing characteristics are important features for age prediction, but that lexical content is also needed to produce significantly more accurate results. Our best results allow for 81.57% accuracy.

1 Introduction

The evolution of the internet has changed the way that people communicate. The introduction of instant messaging, forums, social networking and blogs has made it possible for people of every age to become authors. The users of these social media platforms have created their own form of unstructured writing that is best characterized as informal. Even *how* people communicate has dramatically changed, with multitasking increasing and responses generated immediately. We should be able to exploit those differences to automatically determine from blog posts whether an author is part of a *pre-* or *post-social media* generation. This problem is called *age prediction* and raises two main questions:

- Is there a point in time that proves to be a significantly better dividing line between pre and post-social media generations?
- What features of communication most directly reveal the generation in which a blogger was born?

We hypothesize that the dividing line(s) occur when people in *generation Y*[1], or the *millennial generation*, (born anywhere from the mid-1970s to the early 2000s) were typical college-aged students (18-22). We focus on this generation due to the rise of popular social media technologies such as messaging and online social networks sites that occurred during that time. Therefore, we experimented with binary classification into age groups using all birth dates from 1975 through 1988, thus including students from generation Y who were in college during the emergence of social media technologies. We find five years where binary classification is significantly more accurate than other years: 1977, 1979, and 1982-1984. The appearance of social media technologies such as AOL Instant Messenger (AIM), weblogs, SMS text messaging, Facebook and MySpace occurred when people with these birth dates were in college.

We explore two of these years in more detail, 1979 and 1984, and examine a wide variety of

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 763–772,
Portland, Oregon, June 19-24, 2011.

features that differ between the pre-social media and post-social media bloggers. We examine lexical-content features such as collocations and part-of-speech collocations, lexical-stylistic features such as internet slang and capitalization, and features representing online behavior such as time of post and number of friends. We find that both stylistic and content features have a significant impact on age prediction and show that, for unseen blogs, we are able to classify authors as born before or after 1979 with 80% accuracy and born before or after 1984 with 82% accuracy.

In the remainder of this paper, we first discuss work to date on age prediction for blogs and then present the features that we extracted, which is a larger set than previously explored. We then turn separately to three experiments. In the first, we implement a prior approach to show that we can produce a similar outcome. In the second, we show how the accuracy of age prediction changes over time and pinpoint when major changes occur. In the last experiment, we describe our age prediction experiments in more detail for the most significant years.

2 Related Work

In previous work, Mackinnon (2006) , used LiveJournal data to identify a blogger's age by examining the mean age of his peer group using his social network and not just his immediate friends. They were able to predict the correct age within +/-5 years at 98% accuracy. This approach, however, is very different from ours as it requires access to the age of each of the blogger's friends. Our approach uses only a body of text written by a person along with his blogging behavior to determine which age group he is more closely identified with.

Initial research on predicting age without using the ages of friends focuses on identifying important candidate features, including blogging characteristics (e.g., time of post), text features (e.g., length of post), and profile information (e.g., interests) (Burger and Henderson, 2006). They aimed at binary prediction of age, classifying LiveJournal bloggers as either over or under 18, but were unable to automatically predict age with more accuracy than a baseline model that always chose the majority class. In our study on determining the ideal age split we did not find 18 (bloggers born in 1986 in their dataset) to be significant.

Prior work by Schler et al. (2006) has examined metadata such as gender and age in blogger.com bloggers. In contrast to our work, they examine bloggers based on their age at the time of the experiment, whether in the 10's, 20's or 30's age bracket. They identify interesting changes in content and style features across categories, in which they include blogging words (e.g., "LOL"), all defined by the Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2007). They did not use characteristics of online behavior (e.g., friends). They can distinguish between bloggers in the 10's and in the 30's with relatively high accuracy (above 96%) but many 30s are misclassified as 20s, which results in a overall accuracy of 76.2%. We re-implement Schler et al.'s work in section 5.1 with similar findings. Their work shows that ease of classification is dependent in part on what division is made between age groups and in turn motivates our decision to study whether the creation of social media technologies can be used to find the dividing line(s). Neither Schler et al., nor we, attempt to determine how a person's writing changes over his lifespan (Pennebaker and Stone, 2003; Robins et al., 2002). Goswami et al. (2009) add to Schler et al.'s approach using the same data and have a 4% increase in accuracy. However, the paper is lacking details and it is entirely unclear how they were able to do this with fewer features than Schler et al.

In other work, Tam and Martell (2009) attempt to detect age in the NPS chat corpus between teens and other ages. They use an SVM classifier with only n-grams as features. They achieve $> 90\%$ accuracy when classifying teens vs 30s, 40s, 50s, and all adults and achieve at best 76% when using 3 character gram features in classifying teens vs 20s. This work shows that n-grams are useful features for detecting age and it is difficult to detect differences between consecutive groups such as teens and 20s, and this

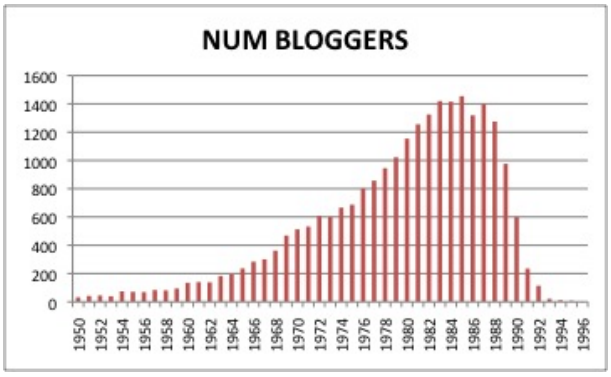

Figure 1: Number of bloggers in 2010 by year of birth from 1950-1996. A minimal amount of data occurred in years not shown.

provides evidence for the need to find a good classification split.

Other researchers have investigated weblogs for differences in writing style depending on gender identification (Herring and Paolillo, 2006; Yan and Yan, 2006; Nowson and Oberlander, 2006). Herring et al (2006) found that the typical gender related features were based on genre and independent of author gender. Yan et al (2006) used text categorization and stylistic web features, such as emoticons, to identify gender and achieved 60% F-measure. Nowson et al (2006) employed dictionary and n-gram based content analysis and achieved 91.5% accuracy using an SVM classifier. We also use a supervised machine learning approach, but classification by gender is naturally a binary classification task, while our work requires determining a natural dividing point.

3 Data Collection

Our corpus consists of blogs downloaded from the virtual community LiveJournal. We chose to use LiveJournal blogs for our corpus because the website provides an easy-to-use format in XML for downloading and crawling their site. In addition, LiveJournal gives bloggers the opportunity to post their age on their profile. We take advantage of this feature by downloading blogs where the user chooses to publicly provide this metadata.

We downloaded approximately 24,500 LiveJournal blogs containing age. We represent age as the year a person was born and not his age at the time of the experiment. Since technology has different effects in different countries, we only analyze the blogs of people who have listed US as their country. It is possible that text written in a language other than English is included in our corpus. However, in a manual check of a small portion of text from 500 blogs, we only found English words. Each blog was written by a unique individual and includes a user profile and up to 25 recent posts written between 2000-2010 with the most recent post being written in 2009-2010. The birth dates of the bloggers range in years from 1940 to 2000 and thus, their age ranges from 10 to 70 in 2010. Figure 1 shows the number of bloggers per age in our group with birth dates from 1950 to 1996. The majority of bloggers on LiveJournal were born between 1978-1989.

4 Methods

We pre-processed the data to add Part-of-Speech tags (POS) and dependencies (de Marneffe et al., 2006) between words using the Stanford Parser (Klein and Manning, 2003a; Klein and Manning, 2003b). The POS and syntactic dependencies were only found for approximately the first 90 words in each sentence. Our classification method investigates 17 different features that fall into three categories: online behavior, lexical-stylistic and lexical-content. All of the features we used are explained in Table 1 along with their trend as age decreases where applicable. Any feature that increased, decreased, or fluctuated should have some positive impact on the accuracy of predicting age.

4.1 Online Behavior and Interests

Online behavior features are blog specific, such as number of *comments* and *friends* as described in Table 1.1. The first feature, *interests*, is our only feature that is specific to LiveJournal. Interests appear in the LiveJournal user profile, but are not found on all blog sites. All other online behavior features are typically available in any blog.

	Feature	Explanation	Example	Trend as Age Decreases
1	Interests	Top[3] interests provided on the profile page[2]	disney	N/A
2	# of Friends	Number of friends the blogger has	45	fluctuates
	# of Posts	Number of downloadable posts (0-25)	23	decrease
	# of Lifetime Posts	Number of posts written in total	821	decrease
	Time	Mode hour (00-23) and day the blogger posts	11/Monday	no change
	Comments	Average number of comments per post	2.64	increase
3	Emoticons	number of emoticons[1]	:)	increase
	Acronyms	number of internet acronyms[1]	lol	increase
	Slang	number of words that are not found in the dictionary[1]	wazzup	increase
	Punctuation	number of stand-alone punctuation[1]	...	increase
	Capitalization	number of words (with length > 1) that are all CAPS[1]	YOU	increase
	Sentence Length	average sentence length	40	decrease
	Links/Images	number of url and image links[1]	www.site.com	fluctuates
4	Collocations	Top[3] Collocations in the age group.	to [] the	N/A
	Syntax Collocations	Top[3] Syntax Collocations in the age group.	best friends	N/A
	POS Collocations	Top[3] Part-of-Speech Collocations in the age group.	this [] [] VB	N/A
	Words	Top[3] words in the age group	his	N/A

Table 1: List of all features used during classification divided into three categories (1,2) online behavior and interests, (3) lexical - content, and (4) lexical - stylistic [1] normalized per sentence per entry, [2] available in LiveJournal only, [3] pruned from top 200 features to include those that do not occur within +/- 10 position in any other age group

We extracted the top 200 interests based on occurrence in the profile page from 1500 random blogs in three age groups. These age groups are used solely to illustrate the differences that occur at different ages and are not used in our classification experiments. We then pruned the list of interests by excluding any interest that occurred within a +/-10 window (based on its position in the list) in multiple age groups. We show the top interests in each age group in Table 2. For example, "disney" is the most popular unique interest in the 18-22 age group with only 39 other non-unique interests in that age group occurring more frequently. "Fanfiction" is a popular interest in all age groups, but it is significantly more popular in the 18-22 age group than in other age groups.

Table 2: Top interests for three different age groups. The top half refers to the top 5 interests that are unique to each age group. The value refers to the *position of the interest in its list*

Amongst the other online behavior features, the number of friends tends to fluctuate but seems to be higher for older bloggers. The number of *lifetime posts* (Figure 2(d)), and *posts* decreases as bloggers get younger which is as one would expect unless younger people were orders of magnitude more prolific than older people. The *mode time* (Figure 2(b)), refers to the most common hour of posting from 00-24 based on GMT time. We didn't compute time based on the time zone because city/state is often not included. We found time to not be a useful feature in this manner and it is difficult to come to any conclusions from its change as year of birth decreases.

4.2 Lexical - Stylistic

The Lexical-Stylistic features in Table 1.2, such as *slang* and *sentence length*, are computed us-

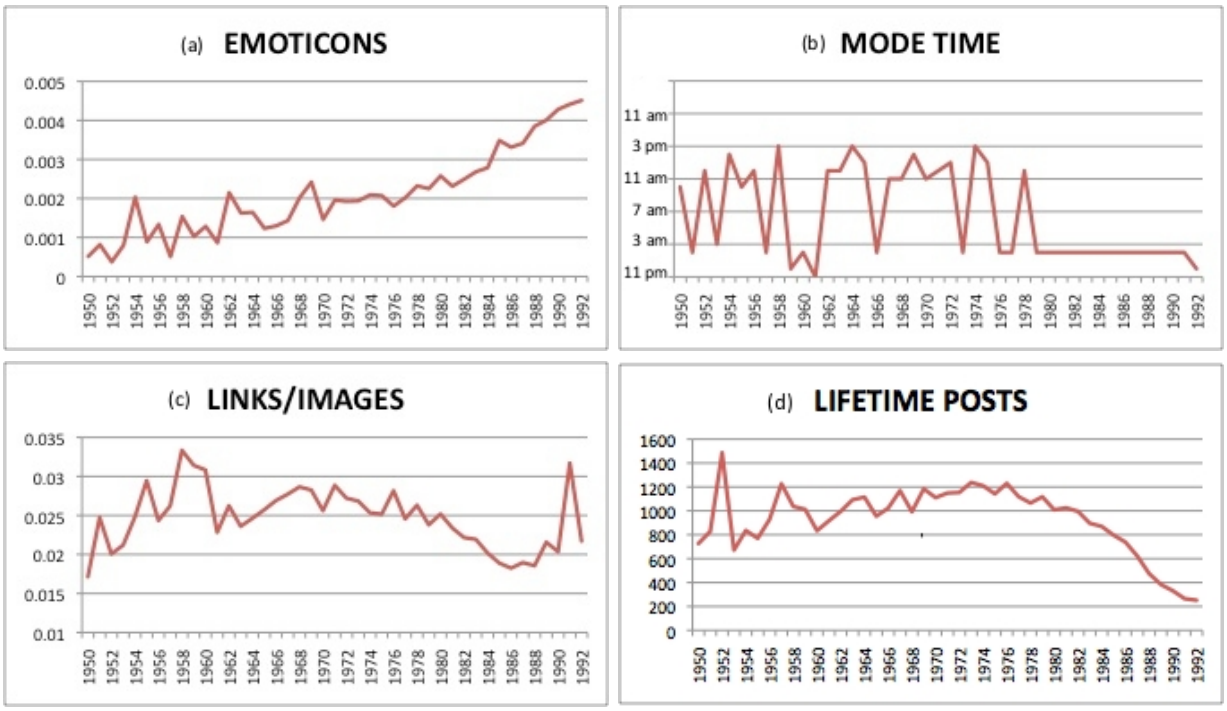

Figure 2: Examples of change to features over time (a) Average number of emoticons in a sentence increases as age decreases (b) The most common time fluctuates until 1982, where it is consistent (c) The number of links/images in a sentence fluctuates (d) The average number of lifetime posts per year decreases as age decreases

ing the text from all of the posts written by the blogger. Other than *sentence length*, they were normalized by sentence and post to keep the numbers consistent between bloggers regardless of whether the user wrote one or many posts in his/her blog. The number of *emoticons* (Figure 2(a)), *acronyms*, and *capital words* increased as bloggers got younger. *Slang* and *punctuation*, which excludes the emoticons and acronyms counted in the other features, increased as well, but not as significantly. The *length of sentences* decreased as bloggers got younger and the number of *links/images* varied across all years as shown in Figure 2(c).

4.3 Lexical - Content

The last category of features described in Table 1.3 consists of collocations and words, which are content based lexical terms. The top words are produced using a typical "bag-of-words" approach. The top collocations are computed using a system called *Xtract* (Smadja, 1993).

We use Xtract to obtain important lexical collocations, syntactic collocations, and POS collocations as features from our text. *Syntactic collocations* refer to significant word pairs that have specific syntactic dependencies such as subject/verb and verb/object. Due to the length of time it takes to run this program, we ran Xtract on 1500 random blogs from each age group and examined the first 1000 words per blog. We looked at 1.5 million words in total and found approximately 2500-2700 words that were repeated more than 50 times.

We extracted the top 200 words and collocations sorted by *post frequency* (pf), which is the number of posts the term occurred in. Then, similarly to interests, we pruned each list to include the features that did not occur within +/-10 window (based on its position in the list) within each age group. Prior to settling on these metrics, we also experimented with other metrics such as the number of times the collocation

18-22		28-32		38-42

Table 4: Statistics for Schler et al.'s data (blogger.com) vs our data (livejournal.com) [1] is approximate amount.

occurred in total, defined as *collocation* or *term frequency* (tf), the number of blogs the collocation occurred in, defined as *blog frequency* (bf), and variations of TF*IDF (Salton and Buckley, 1988) where we tried using inverse blog frequency and inverse post frequency as the value for IDF. In addition, we also experimented with looking at a different number of important words and collocations ranging from the top 100-300 terms and experimented without pruning. None of these variations improved accuracy in our experiments, however, and thus, were dropped from further experimentation.

Table 3 shows the top words for each age group; older people tend to use words such as "house" and "old" frequently and younger people talk about "school".

In our analysis of the top collocations, we found that younger people tend to use first person singular (*I,me*) in subject position while older people tend to use first person plural (*we*) in subject position, both with a variety of verbs.

5 Experiments and Results

We ran three separate experiments to determine how well we can predict age: 1. classifying into three distinct age groups (Schler et al. (2006) experiment), 2. binary classification with the split at each birth year from 1975-1988 and 3. Detailed classification on two significant splits from the second experiment.

We ran all of our experiments in Weka (Hall et al., 2009) using logistic regression over 10 runs of 10-fold cross-validation. All values shown are the averages of the accuracies from the 10 cross-validation runs and all results were compared for statistical significance using the t-test where applicable.

We use logistic regression as our classifier because it has been shown that logistic regression typically has lower asymptotic error than naive Bayes for multiple classification tasks as well as for text classification (Ng and Jordan, 2002). We experimented with an SVM classifier and found logistic regression to do slightly better.

5.1 Age Groups

The first experiment implements a variation of the experiment done by Schler et al. (2006). The differences between the two datasets are shown in Tables 4. The experiment looks at three age groups containing a 5-year gap between each group. Intermediate years were not included to provide clear differentiation between the groups because many of the blogs have been active for several years and this will make it less common for a blogger to have posts that fall into two age groups (Schler et al., 2006).

We did not use the same age groups as Schler et al. because very few blogs on LiveJournal, in 2010, are in the 13-17 age group. Many early demographic studies (Perseus Development, 2004; Herring et al., 2004) show teens as the dominant age group in all blogs. However, more recent studies (Nowson and Oberlander, 2006; Lenhart et al., 2010) show that less teens blog. Furthermore, an early study on the LiveJournal

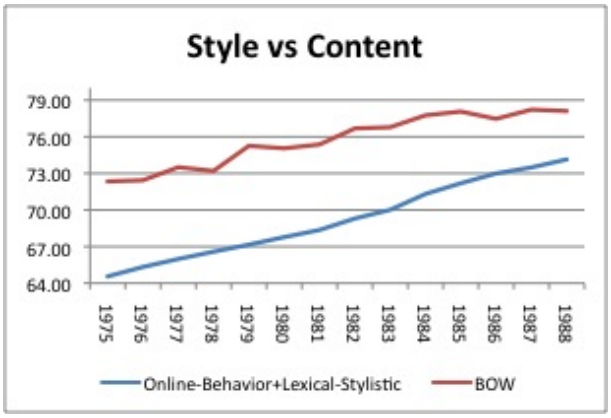

Figure 3: Style vs Content: Accuracy from 1975-1988 for Style (Online-Behavior+Lexical-Stylistic) vs Content (BOW)

demographic (Kumar et al., 2004) reported that 28.6% of blogs are written by bloggers between the ages 13-18 whereas based on the current demographic statistics, in 2010[2], only 6.96% of blogs are written by that age group and the number of bloggers in the 31-36 age group increased from 3.9% to 12.08%. We chose the later age groups because this study is based on blogs updated in 2009-10 which is 5-6 years later and thus, the 13-17 age group is now 18-22 and so on.

We use style-based (lexical-stylistic) and content-based features (BOW, interests) to mimic Schler et al.'s experiment as closely as possible and also experimented with adding online-behavior features. Our experiment with style-based and content-based features had an accuracy of 57%. However, when we added online-behavior, we increased our accuracy to 67%. A more detailed look at the better results show that our accuracies are consistently 7% lower than the original work but we have similar findings; 18-22s are distinguishable from 38-42s with accuracy of 94.5%, and 18-22s are distinguishable from 28-32s with accuracy of 80.5%. However, many 38-42s are misclassified as 28-32s with an accuracy of 72.1%, yielding overall accuracy of 67%. Due to our findings, we believe that adding online-behavior features to Schler et al.'s dataset would improve their results as well.

[2]http://www.livejournal.com/stats.bml

5.2 Social Media and Generation Y

In the first experiment we used the current age of a blogger based on when he wrote his last post. However, the age of a person changes; someone who was in one age group now will be in a different age group in 5 years. Furthermore, a blogger's posts can fall into two categories depending on his age at the time. Therefore, our second experiment looks at year of birth instead of age, as that never changes. In contrast to Schler et al.'s experiment, our division does not introduce a gap between age groups, we do binary classification, and we use significantly less data.

We approach age prediction as attempting to identify a shift in writing style over a 14 year time span from birth years 1975-1988:

For each year X = 1975-1988:

- get 1500 blogs (∼33,000 posts) balanced across years BEFORE X
- get 1500 blogs (∼33,000 posts) balanced across years IN/AFTER X
- Perform binary classification between blogs BEFORE X and IN/AFTER X

The experiment focuses on the range of birth years of bloggers from 1975-1888 to identify at what point in time, if any, shift(s) in writing style occurred amongst college-aged students in generation Y. We were motivated to examine these years due to the emergence of social media technologies during that time. Furthermore, research by Pew Internet (Zickuhr, 2010) has found that this generation (defined as 1977-1992 in their research) uses social networking, blogs, and instant messaging more than their elders. The experiment is balanced to ensure that each birth year is evenly represented. We balance the data by choosing a blogger consecutively from each birth year in the category, repeating these sweeps through the category until we have obtained 1500 blogs. We chose to use 1500 blogs from each group because of processing power, time constraints, and the amount of blogs needed to reasonably sample the age group at each split. Due to the extensive running time, we only examined variations of a combination of

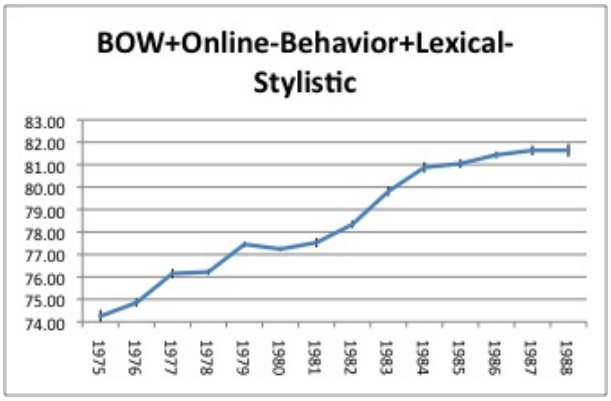

Figure 4: Style and Content: Accuracy from 1975-1988 using BOW, Online Behavior, and Lexical-Stylistic features

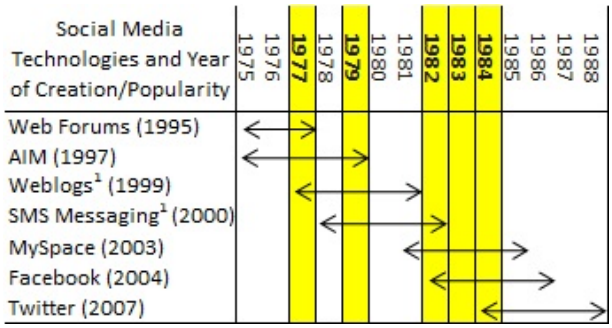

Figure 5: The impact of social media technologies: The arrows correspond to the years that generation Yers were college aged students. The highlighted years represent the significant years. [1]Year it became popular (Urmann, 2009)

online-behavior, lexical-stylistic, and BOW features.

We found accuracy to increase as year of birth increases in various feature experiments which is consistent with the trends we found while examining the distribution of features such as emoticons and lifetime posts in Figure 2. We experimented with style and content features and found that both help improve accuracy. Figure 3 shows that content helps more than style, but style helps more as age decreases. However, as shown in Figure 4, style and content combined provided the best results. We found 5 years to have significant improvement over all prior years for $p \leq .0005$: 1977, 1979, and 1982-1984.

Generation Y is considered the social media generation, so we decided to examine how the creation and/or popularity of social media technologies compared to the years that had a change in writing style. We looked at many popular social media technologies such as weblogs, messaging, and social networking sites. Figure 5 compares the significant years 1977,1979, and 1982-1984 against when each technology was created or became popular amongst college aged students. We find that all the technologies had an effect on one or more of those years. AIM and weblogs coincide with the earlier shifts at 1977 and 1979, SMS messaging coincide with both the earlier and later shifts at 1979 and 1982, and the social networking sites, MySpace and Facebook coincide with the later shifts of 1982-1984. On the other hand, web forums and Twitter each coincide with only one outlying year which suggests that either they had less of an impact on writing style or, in the case of Twitter, the change has not yet been transferred to other writing forms.

5.3 A Closer Look: 1979 and 1984

Our final experiment provides a more detailed explanation of the results using various feature combinations when splitting pre- and post- social media bloggers by year of birth at two of the significant years found in the previous section; 1979 and 1984. The results for all of the experiments described are shown in Table 5.

We experimented against two baselines, online behavior and interests. We chose these two features as baselines because they are both easy to generate and not lexical in nature. We found that we were able to exceed the baselines significantly using a simple bag-of-words (BOW) approach. This means the BOW does a better job of picking topics than interests. We found that including all 17 features did not do well, but we were able to get good results using a subset of the lexical features. We found the best results to have an accuracy of 79.96% and 81.57% for 1979 and 1984 respectively using BOW, interests, online behavior, and all lexical-stylistic features.

In addition, we show accuracy without interests since they are not always available.

Experiment	1979	1984
Online-Behavior	59.66	61.61
Interests	70.22	74.61
Lexical-Stylistic	65.38[2]	67.28[2]
Slang+Emoticons+Acronyms	60.57[2]	62.10[2]
Online-Behavior + Lexical-Stylistic	67.16[2]	71.31[2]
Collocations + Syntax Collocations	53.47[1]	73.45[2]
POS-Collocations + POS-Syntax Collocations	55.54[1]	74.00[2]
BOW	75.26	77.76
BOW+Online-Behavior	76.39	79.22
BOW + Online-Behavior + Lexical-Stylistic	**77.45**	**80.88**
BOW + Online-Behavior + Lexical-Stylistic + Syntax Collocations	74.8	80.36
BOW + Online-Behavior + Lexical-Stylistic + POS-Collocations + POS Syntax Collocations	74.73	80.54
Online-Behavior + Interests + Lexical-Stylistic	74.39	77.20
BOW + Online-Behavior + Interests + Lexical-Stylistic	**79.96**	**81.57**
All Features	71.26	74.07[2]

Table 5: Feature Accuracy. The top portion refers to the baselines. The best accuracies are shown in bold. Unless otherwise marked, all accuracies are statistically significant at p<=.0005 for both baselines. [1] not statistically significant over Online-Behavior and Interests. [2] not statistically significant over Interests.

BOW, online-behavior, and lexical-stylistic features combined did best achieving accuracy of 77.45% and 80.88% in 1979 and 1984 respectively. This indicates that our classification method could work well on blogs from any website. It is interesting to note that collocations and POS-collocations were useful, but only when we use 1984 as the split which implies that bloggers born in 1984 and later are more homogeneous.

6 Conclusion and Future Work

We have shown that it is possible to predict the age group of a person based on style, content, and online behavior features with good accuracy; these are all features that are available in any blog. While features representing writing practices that emerged with social media (e.g., capitalized words, abbreviations, slang) do not significantly impact age prediction on their own, these features have a clear change of value across time, with post-social media bloggers using them more often. We found that the birth years that had a significant change in writing style corresponded to the birth dates of college-aged students at the time of the creation/popularity of social media technologies, AIM, SMS text messaging, weblogs, Facebook and MySpace.

In the future we plan on using age and other metadata to improve results in larger tasks such as identifying opinion, persuasion and power by targeting our approach in those tasks to the identified age of the person. Another approach that we will experiment with is the use of ranking, regression, and/or clustering to create meaningful age groups.

Abstract

Sociolinguists have long argued that social context influences language use in all manner of ways, resulting in *lects*[1]. This paper explores a text classification problem we will call *lect modeling*, an example of what has been termed computational sociolinguistics. In particular, we use machine learning techniques to identify *social power relationships* between members of a social network, based purely on the content of their interpersonal communication. We rely on statistical methods, as opposed to language-specific engineering, to extract features which represent vocabulary and grammar usage indicative of social power lect. We then apply support vector machines to model the social power lects representing superior-subordinate communication in the Enron email corpus. Our results validate the treatment of lect modeling as a text classification problem – albeit a hard one – and constitute a case for future research in computational sociolinguistics.

1 Introduction

Linguists in sociolinguistics, pragmatics and related fields have analyzed the influence of social context on language and have catalogued countless phenomena that are influenced by it, confirming many with qualitative and quantitative studies. Indeed, social context and function influence language at every level – morphologically, lexically, syntactically, and semantically, through discourse structure, and through higher-level abstractions such as pragmatics.

Considered together, the extent to which speakers modify their language for a social context amounts to an identifiable variation on language, which we call a *lect*. *Lect* is a backformation from words such as *dialect* (geographically defined language) and e*thnolect* (language defined by ethnic context).

In this paper, we describe *lect classifiers* for *social power relationships*. We refer to these lects as:

- *UpSpeak*: Communication directed to someone with greater social authority.
- *DownSpeak*: Communication directed to someone with less social authority.
- *PeerSpeak*: Communication to someone of equal social authority.

We call the problem of modeling these lects *Social Power Modeling* (SPM). The experiments reported in this paper focused primarily on modeling UpSpeak and DownSpeak.

Manually constructing tools that effectively model specific linguistic phenomena suggested by sociolinguistics would be a Herculean effort. Moreover, it would be necessary to repeat the effort in every language! Our approach first identifies statistically salient phrases of words and parts of speech – known as *n-grams* – in training texts generated in conditions where the social power

* This work was done while these authors were at SET Corporation, an SAIC Company.

[1] Fields that deal with society and language have inconsistent terminology; "lect" is chosen here because "lect" has no other English definitions and the etymology of the word gives it the sense we consider most relevant.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 773–782,
Portland, Oregon, June 19-24, 2011.

relationship is known. Then, we apply machine learning to train classifiers with groups of these n-grams as features. The classifiers assign the UpSpeak and DownSpeak labels to unseen text. This methodology is a cost-effective approach to modeling social information and requires no language- or culture-specific feature engineering, although we believe sociolinguistics-inspired features hold promise.

When applied to the corpus of emails sent and received by Enron employees (CALO Project 2009), this approach produced solid results, despite a limited number of training and test instances.

This has many implications. Since manually determining the power structure of social networks is a time-consuming process, even for an expert, effective SPM could support data driven sociocultural research and greatly aid analysts doing national intelligence work. Social network analysis (SNA) presupposes a collection of individuals, whereas a social power lect classifier, once trained, would provide useful information about individual author-recipient links. On networks where SNA already has traction, SPM could provide complementary information based on the content of communications.

If SPM were yoked with sentiment analysis, we might identify which opinions belong to respected members of online communities or lay the groundwork for understanding how respect is earned in social networks.

More broadly, computational sociolinguistics is a nascent field with significant potential to aid in modeling and understanding human relationships. The results in this paper suggest that successes to date modeling authorship, sentiment, emotion, and personality extend to social power modeling, and our approach may well be applicable to other dimensions of social meaning.

In the coming sections, we first establish the **Related Work**, primarily from Statistical NLP. We then cover our **Approach,** the **Evaluation**, and, finally, the **Conclusions and Future Research**.

2 Related Work

The feasibility of Social Power Modeling is supported by sociolinguistic research identifying specific ways in which a person's language reflects his relative power over others. Fairclough's classic work *Language and Power* explores how "sociolinguistic conventions . . . arise out of -- and give rise to – particular relations of power" (Fairclough, 1989). Brown and Levinson created a theory of politeness, articulating a set of strategies which people employ to demonstrate different levels of politeness (Brown & Levinson, 1987). Morand drew upon this theory in his analysis of emails sent within a corporate hierarchy; in it, he quantitatively showed that emails from subordinates to superiors are, in fact, perceived as more polite, and that this perceived politeness is correlated with specific linguistic tactics, including ones set out by Brown and Levinson (Morand, 2000). Similarly, Erikson et al identified measurable characteristics of the speech of witnesses in a courtroom setting which were directly associated with the witness's level of social power (Erikson, 1978). Given, then, that there are distinct differences among what we term UpSpeak and DownSpeak, we treat Social Power Modeling as an instance of *text classification* (or *categorization*): we seek to assign a class (UpSpeak or DownSpeak) to a text sample. Closely related natural language processing problems are authorship attribution, sentiment analysis, emotion detection, and personality classification: all aim to extract higher-level information from language.

Authorship attribution in computational linguistics is the task of identifying the author of a text. The earliest modern authorship attribution work was (Mosteller & Wallace, 1964), although forensic authorship analysis has been around much longer. Mosteller and Wallace used statistical language-modeling techniques to measure the similarity of disputed Federalist Papers to samples of known authorship. Since then, authorship identification has become a mature area productively exploring a broad spectrum of features (stylistic, lexical, syntactic, and semantic) and many generative and discriminative modeling approaches (Stamatatos, 2009). The generative models of authorship identification motivated our statistically extracted lexical and grammatical features, and future work should consider these language modeling (a.k.a. compression) approaches.

Sentiment analysis, which strives to determine the attitude of an author from text, has recently garnered much attention (e.g. Pang, Lee, & Vaithyanathan, 2002; Kim & Hovy, 2004; Breck, Choi

& Cardie, 2007). For example, one problem is classifying user reviews as positive, negative or neutral. Typically, polarity lexicons (each term is labeled as positive, negative or neutral) help determine attitudes in text (Hiroya & Takamura, 2005, Ravichandran 2009, Choi & Cardie 2009).

The polarity of an expression can be determined based on the polarity of its component lexical items (Choi & Cardie 2008). For example, the polarity of the expression is determined by the majority polarity of its lexical items or by rules applied to syntactic patterns of expressions on how to determine the polarity from its lexical components. McDonald et al studied models that classify sentiment on multiple levels of granularity: sentence and document-level (McDonald, 2007). Their work jointly classifies sentiment at both levels instead of using independent classifiers for each level or cascaded classifiers. Similar to our techniques, these studies determine the polarity of text based on its component lexical and grammatical sequences. Unlike their works, our text classification techniques take into account the frequency of occurrence of word n-grams and part-of-speech (POS) tag sequences, and other measures of statistical salience in training data.

Text-based emotion prediction is another instance of text classification, where the goal is to detect the emotion appropriate to a text (Alm, Roth & Sproat, 2005) or provoked by an author, for example (Strapparava & Mihalcea, 2008). Alm, Roth, and Sproat explored a broad array of lexical and syntactic features, reminiscent of those of authorship attribution, as well as features related to story structure. A Winnow-based learning algorithm trained on these features convincingly predicted an appropriate emotion for individual sentences of narrative text. Strapparava and Mihalcea try to predict the emotion the author of a headline intends to provoke by leveraging words with known affective sense and by expanding those words' synonyms. They used a Naïve Bayes classifier trained on short blogposts of known emotive sense. The knowledge engineering approaches were generally superior to the Naïve Bayes approach. Our approach is corpus-driven like the Naïve Bayes approach, but we interject statistically driven feature selection between the corpus and the machine learning classifiers.

In personality classification, a person's language is used to classify him on different personality dimensions, such as extraversion or neuroticism (Oberlander & Nowson, 2006; Mairesse & Walker; 2006). The goal is to recover the more permanent traits of a person, rather than fleeting characteristics such as sentiment or emotion. Oberlander and Nowson explore using a Naïve Bayes and an SVM classifier to perform binary classification of text on each personality dimension. For example, one classifier might determine if a person displays a high or low level of extraversion. Their attempt to classify each personality trait as either "high" or "low" echoes early sentiment analysis work that reduced sentiments to either positive or negative (Pang, Lee, & Vaithyanathan, 2002), and supports initially treating Social Power Modeling as a binary classification task. Personality classification seems to be the application of text classification which is the most relevant to Social Power Modeling. As Mairesse and Walker note, certain personality traits are indicative of leaders. Thus, the ability to model personality suggests an ability to model social power lects as well.

Apart from text classification, work from the topic modeling community is also closely related to Social Power Modeling. Andrew McCallum extended Latent Dirichlet Allocation to model the author and recipient dependencies of per-message topic distributions with an Author-Recipient-Topic (ART) model (McCallum, Wang, & Corrada-Emmanuel, 2007). This was the first significant work to model the content and relationships of communication in a social network. McCallum et al applied ART to the Enron email corpus to show that the resulting topics are strongly tied to role. They suggest that clustering these topic distributions would yield roles and argue that the person-to-person similarity matrix yielded by this approach has advantages over those of canonical social network analysis. The same authors proposed several Role-Author-Recipient-Topic (RART) models to model authors, roles and words simultaneously. With a RART modeling roles-per-word, they produced per-author distributions of generated roles that appeared reasonable (e.g. they labeled Role 10 as 'grant issues' and Role 2 as 'natural language researcher').

We have a similar emphasis on statistically modeling language and interpersonal communica-

tion. However, we model social power relationships, not roles or topics, and our approach produces discriminative classifiers, not generative models, which enables more concrete evaluation.

Namata, Getoor, and Diehl effectively applied role modeling to the Enron email corpus, allowing them to infer the social hierarchy structure of Enron (Namata et al., 2006). They applied machine learning classifiers to map individuals to their roles in the hierarchy based on features related to email traffic patterns. They also attempt to identify cases of manager-subordinate relationships within the email domain by ranking emails using traffic-based and content-based features (Diehl et al., 2007). While their task is similar to ours, our goal is to classify any case in which one person has more social power than the other, not just identify instances of direct reporting.

3 Approach

3.1 Feature Set-Up

Previous work in traditional text classification and its variants – such as sentiment analysis – has achieved successful results by using the bag-of-words representation; that is, by treating text as a collection of words with no interdependencies, training a classifier on a large feature set of word unigrams which appear in the corpus. However, our hypothesis was that this approach would not be the best for SPM. Morand's study, for instance, identified specific features that correlate with the direction of communication within a social hierarchy (Morand, 2000). Few of these tactics would be effectively encapsulated by word unigrams. Many would be better modeled by POS tag unigrams (with no word information) or by longer n-grams consisting of either words, POS tags, or a combination of the two. "Uses subjunctive" and "Uses past tense" are examples. Because considering such features would increase the size of the feature space, we suspected that including these features would also benefit from algorithmic means of selecting n-grams that are indicative of particular lects, and even from *binning* these relevant n-grams into sets to be used as features.

Therefore, we focused on an approach where each feature is associated with a set of one or more n-grams. Each n-gram is a sequence of words, POS tags or a combination of words and POS tags ("mixed" n-grams). Let S represent a set $\{n_1, ..., n_k\}$ of n-grams. The feature associated with S on text T would be:

$$f(S,T) = \sum_{i=1}^{k} freq(n_i, T)$$

where $freq(n_i, T)$ is the relative frequency (defined later) of n_i in text T. Let n_i represent the sequence $s_1 \ldots s_m$ where s_j specifies either a word or a POS tag. Let T represent the text consisting of the sequence of tagged-word tokens $t_1 \ldots t_l$. $freq(n_i, T)$ is then defined as follows:

$$freq(n_i, T) = freq(s_1 \ldots s_m, T) = \frac{\left|\left\{t_{b+1} \ldots t_{b+m} : \forall_{1 \le p \le m}(t_{b+p} = s_p)\right\}\right|}{l - m + 1}$$

where:

$$t_i = s_j \leftrightarrow \begin{cases} word(t_i) = s_j \text{ if } s_j \text{ is a word} \\ tag(t_i) = s_j \text{ if } s_j \text{ is a tag} \end{cases}$$

To illustrate, consider the following feature set, a bigram and a trigram (each term in the n-gram either has the form *word* or *^tag*):

{please ^VB, please ^'comma' ^VB}[2]

The tag "VB" denotes a verb. Suppose T consists of the following tokenized and tagged text (sentence initial and final tokens are not shown):

please^RB bring^VB the^DET report^NN to^TO our^PRP$ next^JJ weekly^JJ meeting^NN .^.

The first n-gram of the set, *please ^VB*, would match *please^RB bring^VB* from the text. The frequency of this n-gram in *T* would then be 1/9, where 1 is the number of substrings in *T* that match

[2] To distinguish a comma separating elements of a set with a comma as part of an ngram, we use 'comma' to denote the punctuation mark ',' as part of the ngram.

please ^VB and 9 is the number of bigrams in *T*, excluding sentence initial and final markers. The other n-gram, the trigram *please ^'comma' ^VB,* does not have any match, so the final value of the feature is 1/9.

Defining features in this manner allows us to both explore the bag-of-words representation as well as use groups of n-grams as features, which we believed would be a better fit for this problem.

3.2 N-Gram Selection

To identify n-grams which would be useful features, frequencies of n-grams in only the training set are considered. Different types of frequency measures were explored to capture different types of information about an n-gram's usage. These are:

- *Absolute frequency*: The total number of times a particular n-gram occurs in the text of a given class (social power lect).
- *Relative frequency*: The total number of times a particular n-gram occurs in a given class, divided by the total number of n-grams in that class. Normalization by the size of the class makes relative frequency a better metric for comparing n-gram usage across classes.

We then used the following frequency-based metrics to select n-grams:

- We set a minimum threshold for the absolute frequency of the n-gram in a class. This helps weed out extremely infrequent words and spelling errors.
- We require that the ratio of the relative frequency of the n-gram in one class to its relative frequency in the other class is also greater than a threshold. This is a simple means of selecting n-grams indicative of lect.

In experiments based on the bag-of-words model, we only consider an absolute frequency threshold, whereas in later experiments, we also take into account the relative frequency ratio threshold.

3.3 N-gram Binning

In experiments in which we bin n-grams, selected n-grams are assigned to the class in which their relative frequency is highest. For example, an n-gram whose relative frequency in UpSpeak text is twice that in DownSpeak text would be assigned to the class UpSpeak.

N-grams assigned to a class are then partitioned into sets of n-grams. Each of these sets of n-grams is associated with a feature. This partition is based on the n-gram type, the length of n-grams and the relative frequency ratio of the n-grams. While the n-grams composing a set may themselves be indicative of social power lects, this method of grouping them makes no guarantees as to how indicative the overall set is. Therefore, we experimented with filtering out sets which had a negligible information gain. Information gain is an information theoretic concept measuring how much the probability distributions for a feature differ among the different classes. A small information gain suggests that a feature may not be effective at discriminating between classes.

Although this approach to partitioning is simple and worthy of improvement, it effectively reduced the dimensionality of the feature space.

3.4 Classification

Once features are selected, a classifier is trained on these features. Many features are weak on their own; they either occur rarely or occur frequently but only hint weakly at social information. Therefore, we experimented with classifiers friendly to weak features, such as Adaboost and Logistic Regression (MaxEnt). However, we generally achieved the best results using support vector machines, a machine learning classifier which has been successfully applied to many previous text classification problems. We used Weka's optimized SVMs (SMO) (Witten 2005, Platt 1998) and default parameters, except where noted.

4 Evaluation

4.1 Data

To validate our supervised learning approach, we sought an adequately large English corpus of person-to-person communication labeled with the ground truth. For this, we used the publicly avail-

able Enron corpus. After filtering for duplicates and removing empty or otherwise unusable emails, the total number of emails is 245K, containing roughly 90 million words. However, this total includes emails to non-Enron employees, such as family members and employees of other corporations, emails to multiple people, and emails received from Enron employees without a known corporate role. Because the author-recipient relationships of these emails could not be established, they were not included in our experiments.

Building upon previous annotation done on the corpus, we were able to ascertain the corporate role (CEO, Manager, Employee, etc.) of many email authors and recipients. From this information, we determined the author-recipient relationship by applying general rules about the structure of a corporate hierarchy (an email from an Employee to a CEO, for instance, is UpSpeak). This annotation method does not take into account promotions over time, secretaries speaking on behalf of their supervisors, or other causes of relationship irregularities. However, this misinformation would, if anything, generally hurt our classifiers.

The emails were pre-processed to eliminate text not written by the author, such as forwarded text and email headers. As our approach requires text to be POS-tagged, we employed Stanford's POS tagger (http://nlp.stanford.edu/software/tagger.shtml). In addition, text was regularized by conversion to lower case and tokenized to improve counts.

To create training and test sets, we partitioned the authors of text from the corpus into two sets: A and B. Then, we used text authored by individuals in A as a training set and text authored by individuals in B as a test set. The training set is used to determine discriminating features upon which classifiers are built and applied to the test set. We found that partitioning by authors was necessary to avoid artificially inflated scores, because the classifiers pick up aspects of particular authors' language (idiolect) in addition to social power lect information. It was not necessary to account for recipients because the emails did not contain text from the recipients. Table 1 summarizes the text partitions.

	UpSpeak		**DownSpeak**	
	Links	Words	Links	Words
Training	431	136K	328	63K
Test	232	74K	148	27K

Table 1. Author-based Training and Test partitions. The number of author-recipient pairs (links) and the number of words in text labeled as UpSpeak and DownSpeak are shown.

Because preliminary experiments suggested that smaller text samples were harder to classify, the classifiers we describe in this paper were both trained and tested on a subset of the Enron corpus where at least 500 words of text was communicated from a specific author to a specific recipient. This subset contained 142 links, 40% of which were used as the test set.

Weighting for Cost-Sensitive Learning: The original corpus was not balanced: the number of UpSpeak links was greater than the number of DownSpeak links. Varying the weight given to training instances is a technique for creating a classifier that is cost-sensitive, since a classifier built on an unbalanced training set can be biased towards avoiding errors on the overrepresented class (Witten, 2005). We wanted misclassifying UpSpeak as DownSpeak to have the same cost as misclassifying DownSpeak as UpSpeak. To do this, we assigned weights to each instance in the training set. UpSpeak instances were weighted less than DownSpeak instances, creating a training set that was balanced between UpSpeak and DownSpeak. Balancing the training set generally improved results.

Weighting the test set in the same manner allowed us to evaluate the performance of the classifier in a situation in which the numbers of UpSpeak and DownSpeak instances were equal. A baseline classifier that always predicted the majority class would, on its own, achieve an accuracy of 74% on UpSpeak/DownSpeak classification of unweighted test set instances with a minimum length of 500 words. However, results on the weighted test set are properly compared to a baseline of 50%. We include both approaches to scoring in this paper.

4.2 UpSpeak/DownSpeak Classifiers

In this section, we describe experiments on classification of interpersonal email communication into UpSpeak and DownSpeak. For these experiments, only emails exchanged between two people related by a superior/subordinate power relationship were

	Features	# of features	# of n-grams	Cross-Validation		Test Set (weighted)		Test Set (unweighted)	
				Acc (%)	F-score	Acc (%)	F-score	Acc (%)	F-score
(1)	Word unigrams	3899	3899	55.4	.481	62.1	.567	78.9	.748
(2)	Word bigrams	3740	3740	54.5	.457	56.4	.498	73.7	.693
(3)	Word unigrams + word bigrams	7639	7639	51.8	.398	63.3	.576	80.7	.762
(4)	(3) + tag unigrams + tag bigrams	9014	9014	51.8	.398	58.8	.515	77.2	.719
(5)	Binned n-grams	8	106	83.0	.830	**78.1**	**.781**	77.2	.783
(6)	N-grams from (5), separated	106	106	83.0	.828	60.5	.587	70.2	.698
(7)	(5) + polite imperatives	9	108	83.9	.839	77.1	.771	**78.9**	**.797**

Table 2. Experiment Results. Accuracies/F-Scores with an SVM classifier for 10-fold cross validation on the weighted training set and evaluation against the weighted and unweighted test sets. Note that the baseline accuracy against the unweighted test set is 74%, but 50% for the weighted test set and cross-validation.

Human-Engineered Features: Before examining the data itself, we identified some features which we thought would be predictive of UpSpeak or DownSpeak, and which could be fairly accurately modeled by mixed n-grams. These features included the use of different types of imperatives.

We also thought that the type of greeting or signature used in the email might be reflective of formality, and therefore of UpSpeak and DownSpeak. For example, subordinates might be more likely to use an honorific when addressing a superior, or to sign an email with "Thanks." We preformed some preliminary experiments using these features. While the feature set was too small to produce notable results, we identified which features actually were indicative of lect. One such feature was polite imperatives (imperatives preceded by the word "please"). The polite imperative feature was represented by the n-gram set:

{please ^VB, please ^'comma' ^VB}.

Unigrams and Bigrams: As a different sort of baseline, we considered the results of a bag-of-words based classifier. Features used in these experiments consist of single words which occurred a minimum of four times in the relevant lects (UpSpeak and DownSpeak) of the training set. The results of the SVM classifier, shown in line (1) of Table 2, were fairly poor. We then performed experiments with word bigrams, selecting as features those which occurred at least seven times in the relevant lects of the training set. This threshold for bigram frequency minimized the difference in the number of features between the unigram and bigram experiments. While the bigrams on their own were less successful than the unigrams, as seen in line (2), adding them to the unigram features improved accuracy against the test set, shown in line (3).

As we had speculated that including surface-level grammar information in the form of tag n-grams would be beneficial to our problem, we performed experiments using all tag unigrams and all tag bigrams occurring in the training set as features. The results are shown in line (4) of Table 2. The results of these experiments were not particularly strong, likely owing to the increased sparsity of the feature vectors.

Binning: Next, we wished to explore longer n-grams of words or POS tags and to reduce the sparsity of the feature vectors. We therefore experimented with our method of binning the individual n-grams to be used as features. We binned features by their relative frequency ratios. In addition to binning, we also reduced the total number of n-grams by setting higher frequency thresholds and relative frequency ratio thresholds.

When selecting n-grams for this experiment, we considered only word n-grams and tag n-grams – not mixed n-grams, which are a combination of words and tags. These mixed n-grams, while useful for specifying human-defined features, largely increased the dimensionality of the feature search space and did not provide significant benefit in preliminary experiments. For the word sequences,

we set an absolute frequency threshold that depended on class. The frequency of a word n-gram in a particular class was required to be *0.18 * nrlinks / n*, where *nrlinks* is the number of links in each class (431 for UpSpeak and 328 for DownSpeak), and *n* is the number of words in the class. The relative frequency ratio was required to be at least 1.5. The tag sequences were required to meet an absolute frequency threshold of 20, but the same relative frequency ratio of 1.5.

Binning the n-grams into features was done based on both the length of the n-gram and the relative frequency ratio. For example, one feature might represent the set of all word unigrams which have a relative frequency ratio between 1.5 and 1.6.

We explored possible feature sets with cross validation. Before filtering for low information gain, we used six word n-gram bins per class (relative frequency ratios of 1.5, 1.6 ..., 1.9 and 2.0+), one tag n-gram bin for UpSpeak (2.0+), and three tag n-gram bins for DownSpeak (2.0+, 5.0+, 10.0+). Even with the weighted training set, DownSpeak instances were generally harder to identify and likely benefited from additional representation. Grouping features by length was a simple but arbitrary method for reducing dimensionality, yet sometimes produced small bins of otherwise good features. Therefore, as we explored the feature space, small bins of different n-gram lengths were merged. We then employed Weka's InfoGain feature selection tool to remove those features with a low information gain[3], which removed all but eight features. The results of this experiment are shown in line (5) of Table 2. It far outperforms the bag-of-words baselines, despite significantly fewer features.

To ascertain which feature reduction method had the greatest effect on performance – binning or setting a relative frequency ratio threshold – we performed an experiment in which all the n-grams that we used in the previous experiment were their own features. Line (6) of Table 2 shows that while this approach is an improvement over the basic bag-of-words method, grouping features still improves results.

Our goal was to have successful results using only statistically extracted features; however, we examined the effect of augmenting this feature set with the most indicative of the human-identified feature – polite imperatives. The results, in line (7), show a slight improvement in both the cross validation accuracy, and the accuracy against the unweighted test set increases to **78.9%**[4]. However, among the weighted test sets, the highest accuracy was **78.1%**, with the features in line (5).

We report the scores for cross-validation on the training set for these features; however, because the features were selected with knowledge of their per-class distribution in the training set, these cross-validation scores should not be seen as the classifier's true accuracy.

Self-Training: Besides sparse feature vectors, another factor likely to be hurting our classifier was the limited amount of training data. We attempted to increase the training set size by performing exploratory experiments with self-training, an iterative semi-supervised learning method (Zhu, 2005) with the feature set from (7). On the first iteration, we trained the classifier on the labeled training set, classified the instances of the unlabeled test set, and then added the instances of the test set along with their predicted class to the training set to be used for the next iteration. After three iterations, the accuracy of the classifier when evaluated on the weighted test set improved to **82%**, suggesting that our classifiers would benefit from more data.

Impact of Cost-Sensitive Learning: Without cost-sensitive learning, the classifiers were heavily biased towards UpSpeak, tending to classify both DownSpeak and UpSpeak test instances as UpSpeak. With cost-sensitive training, overall performance improved and classifier performance on DownSpeak instances improved dramatically. In (5) of Table 2, DownSpeak classifier accuracy even edged out the accuracy for UpSpeak. We expect that on a larger dataset behavior with unweighted training and test data would improve.

5 Conclusions and Future Research

We presented a corpus-based statistical learning approach to modeling social power relationships and experimental results for our methods. To our

[3] In Weka, features ('attributes') with a sufficiently low information gain have this value rounded down to "0"; these are the features we removed.

[4] The associated p-value is 6.56E-6.

knowledge, this is the first corpus-based approach to learning social power lects beyond those in direct reporting relationships.

Our work strongly suggests that statistically extracted features are an efficient and effective approach to modeling social information. Our methods exploit many aspects of language use and effectively model social power information while using statistical methods at every stage to tease out the information we seek, significantly reducing language-, culture-, and lect-specific engineering needs. Our feature selection method picks up on indicators suggested by sociolinguistics, and it also allows for the identification of features that are not obviously characteristic of UpSpeak or DownSpeak. Some easily recognizable features include:

Lect	Ngram	Example
UpSpeak	if you	"Let me know *if you* need anything."
		"Please call me *if you* have any questions."
DownSpeak	give me	"Read this over and *give me* a call."
		"Please *give me* your comments next week."

On the other hand, other features are less intuitive:

Lect	Ngram	Example
UpSpeak	I'll, we'll	"*I'll* let you know the final results soon"
		"Everyone is very excited […] and we're confident *we'll* be successful"
DownSpeak	that is, this is	"Neither does any other group but *that is* not my problem"
		"I think *this is* an excellent letter"

We hope to improve our methods for selecting and binning features with information theoretic selection metrics and clustering algorithms.

We also have begun work on 3-way, UpSpeak/DownSpeak/PeerSpeak classification. Training a multiclass SVM on the binned n-gram features from (5) produces **51.6%** cross-validation accuracy on training data and **44.4%** accuracy on the weighted test set (both numbers should be compared to a 33% baseline). That classifier contained no n-gram features selected from the PeerSpeak class. Preliminary experiments incorporating PeerSpeak n-grams yield slightly better numbers. However, early results also suggest that the three-way classification problem is made more tractable with cascaded two-way classifiers; feature selection was more manageable with binary problems. For example, one classifier determines whether an instance is UpSpeak; if it is not, a second classifier distinguishes between DownSpeak and PeerSpeak. Our text classification problem is similar to sentiment analysis in that there are class dependencies; for example, DownSpeak is more closely related to PeerSpeak than to UpSpeak. We might attempt to exploit these dependencies in a manner similar to Pang and Lee (2005) to improve three-way classification.

In addition, we had promising early results for classification of author-recipient links with 200 to 500 words, so we plan to explore performance improvements for links of few words.

In early, unpublished work, we had promising results with generative model-based approach to SPM, and we plan to revisit it; language models are a natural fit for lect modeling. Finally, we hope to investigate how SPM and SNA can enhance one another, and explore other lect classification problems for which the ground truth can be found.

Acknowledgments

Dr. Richard Sproat contributed time, valuable insights, and wise counsel on several occasions during the course of the research. Dr. Lillian Lee and her students in *Natural Language Processing and Social Interaction* reviewed the paper, offering valuable feedback and helpful leads.

Our colleague, Diane Bramsen, created an excellent graphical interface for probing and understanding the results. Jeff Lau guided and advised throughout the project.

We thank our anonymous reviewers for prudent advice.

Bootstrapping Coreference Resolution Using Word Associations

Hamidreza Kobdani, Hinrich Schütze, Michael Schiehlen and **Hans Kamp**
Institute for Natural Language Processing

kobdani@ims.uni-stuttgart.de

Abstract

In this paper, we present an unsupervised framework that bootstraps a complete coreference resolution (CoRe) system from *word associations* mined from a large unlabeled corpus. We show that word associations are useful for CoRe – e.g., the strong association between *Obama* and *President* is an indicator of likely coreference. Association information has so far not been used in CoRe because it is sparse and difficult to learn from small labeled corpora. Since unlabeled text is readily available, our unsupervised approach addresses the sparseness problem. In a self-training framework, we train a decision tree on a corpus that is automatically labeled using word associations. We show that this unsupervised system has better CoRe performance than other learning approaches that do not use manually labeled data.

1 Introduction

Coreference resolution (CoRe) is the process of finding markables (noun phrases) referring to the same real world entity or concept. Until recently, most approaches tried to solve the problem by binary classification, where the probability of a pair of markables being coreferent is estimated from labeled data. Alternatively, a model that determines whether a markable is coreferent with a preceding cluster can be used. For both pair-based and cluster-based models, a well established feature model plays an important role. Typical systems use a *rich feature space* based on lexical, syntactic and semantic knowledge. Most commonly used features are described by Soon et al. (2001).

Most existing systems are supervised systems, trained on human-labeled benchmark data sets for English. These systems use linguistic features based on number, gender, person etc. It is a challenge to adapt these systems to new domains, genres and languages because a significant human labeling effort is usually necessary to get good performance.

To address this challenge, we pursue an *unsupervised self-training approach.* We train a classifier on a corpus that is automatically labeled using association information. Self-training approaches usually include the use of some manually labeled data. In contrast, our self-trained system is not trained on any manually labeled data and is therefore a completely unsupervised system. Although training on automatically labeled data can be viewed as a form of supervision, we reserve the term *supervised system* for systems that are trained on manually labeled data.

The key novelty of our approach is that we bootstrap a competitive CoRe system from association information that is mined from an unlabeled corpus in a completely unsupervised fashion. While this method is shallow, it provides valuable information for CoRe because it considers the actual identity of the words in question. Consider the pair of markables *(Obama, President)*. It is a likely coreference pair, but this information is not accessible to standard CoRe systems because they only use string-based features (often called lexical features), named entity features and semantic word class features (e.g., from WordNet) that do not distinguish,

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 783–792,
Portland, Oregon, June 19-24, 2011.

say, *Obama* from *Hawking*.

In our approach, word association information is used for *clustering markables* in unsupervised learning. Association information is calculated as *association scores between heads of markables* as described below. We view association information as an example of a *shallow feature space* which contrasts with the rich feature space that is generally used in CoRe.

Our experiments are conducted using the MCORE system ("Modular COreference REsolution").[1] MCORE can operate in three different settings: unsupervised (subsystem *A-INF*), supervised (subsystem *SUCRE* (Kobdani and Schütze, 2010)), and self-trained (subsystem *UNSEL*). The unsupervised subsystem A-INF ("Association INFormation") uses the association scores between heads as the distance measure when clustering markables. SUCRE ("SUpervised Coreference REsolution") is trained on a labeled corpus (manually or automatically labeled) similar to standard CoRe systems. Finally, the unsupervised self-trained subsystem UNSEL ("UNsupervised SELf-trained") uses the unsupervised subsystem A-INF to automatically label an unlabeled corpus that is then used as a training set for SUCRE.

Our main contributions in this paper are as follows:

1. We demonstrate that word association information can be used to develop an unsupervised model for shallow coreference resolution (subsystem A-INF).

2. We introduce an unsupervised self-trained method (UNSEL) that takes a two-learner two-feature-space approach. The two learners are A-INF and SUCRE. The feature spaces are the shallow and rich feature spaces.

3. We show that the performance of UNSEL is better than the performance of other unsupervised systems when it is self-trained on the automatically labeled corpus and uses the leveraging effect of a rich feature space.

4. MCORE is a flexible and modular framework that is able to learn from data with different quality and domain. Not only is it able to deal with shallow information spaces (A-INF), but it can also deliver competitive results for rich feature spaces (SUCRE and UNSEL).

This paper is organized as follows. Related work is discussed in Section 2. In Section 3, we present our system architecture. Section 4 describes the experiments and Section 5 presents and discusses our results. The final section presents our conclusions.

2 Related Work

There are three main approaches to CoRe: supervised, semi-supervised (or weakly supervised) and unsupervised. We use the term *semi-supervised* for approaches that use some amount of human-labeled coreference pairs.

Müller et al. (2002) used co-training for coreference resolution, a semi-supervised method. Co-training puts features into disjoint subsets when learning from labeled and unlabeled data and tries to leverage this split for better performance. Ng and Cardie (2003) use self-training in a multiple-learner framework and report performance superior to co-training. They argue that the multiple learner approach is a better choice for CoRe than the multiple view approach of co-training. Our self-trained model combines multiple learners (A-INF and SUCRE) and multiple views (shallow/rich information). A key difference to the work by Müller et al. (2002) and Ng and Cardie (2003) is that we do not use any human-labeled coreference pairs.

Our basic idea of self-training without human labels is similar to (Kehler et al., 2004), but we address the general CoRe problem, not just pronoun interpretation.

Turning to unsupervised CoRe, Haghighi and Klein (2007) proposed a generative Bayesian model with good performance. Poon and Domingos (2008) introduced an unsupervised system in the framework of Markov logic. Ng (2008) presented a generative model that views coreference as an EM clustering process. We will show that our system, which is simpler than prior work, outperforms these systems.

Haghighi and Klein (2010) present an "almost unsupervised" CoRe system. In this paper, we only compare with completely unsupervised approaches,

[1] MCORE can be downloaded from `ifnlp.org/~schuetze/mcore`.

not with approaches that make some limited use of labeled data.

Recent work by Haghighi and Klein (2009), Klenner and Ailloud (2009) and Raghunathan et al. (2010) challenges the appropriateness of machine learning methods for CoRe. These researchers show that a "deterministic" system (essentially a rule-based system) that uses a rich feature space including lexical, syntactic and semantic features can improve CoRe performance. Almost all CoRe systems, including ours, use a limited number of rules or filters, e.g., to implement binding condition A that reflexives must have a close antecedent in some sense of "close". In our view, systems that use a few basic filters are fundamentally different from carefully tuned systems with a large number of complex rules, some of which use specific lexical information. A limitation of complex rule-based systems is that they require substantial effort to encode the large number of deterministic constraints that guarantee good performance. Moreover, these systems are not adaptable (since they are not machine-learned) and may have to be rewritten for each new domain, genre and language. Consequently, we do not compare our performance with deterministic systems.

Ponzetto (2010) extracts metadata from Wikipedia for supervised CoRe. Using such additional resources in our unsupervised system should further improve CoRe performance. Elsner et al. (2009) present an unsupervised algorithm for identifying clusters of entities that belong to the same named entity (NE) class. Determining common membership in an NE class like person is an easier task than determining coreference of two NEs.

3 System Architecture

Figure 1 illustrates the system architecture of our unsupervised self-trained CoRe system (UNSEL). Oval nodes are data, box nodes are processes. We take a self-training approach to coreference resolution: We first label the corpus using the unsupervised model A-INF and then train the supervised model SUCRE on this automatically labeled training corpus. Even though we train on a labeled corpus, the labeling of the corpus is produced in a completely automatic fashion, without recourse to human labeling. Thus, it is an unsupervised approach.

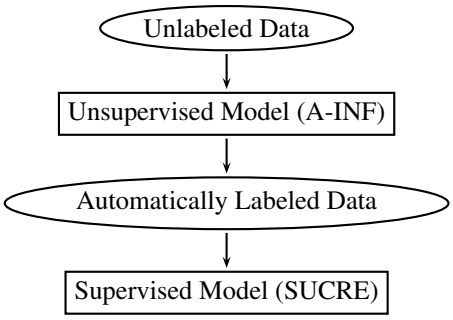

Figure 1: System Architecture of UNSEL (Unsupervised Self-Trained Model).

The MCORE architecture is very flexible; in particular, as will be explained presently, it can be easily adapted for supervised as well as unsupervised settings.

The unsupervised and supervised models have an identical top level architecture; we illustrate this in Figure 2. In *preprocessing*, tokens (words), markables and their attributes are extracted from the input text. The key difference between the unsupervised and supervised approaches is in how *pair estimation* is accomplished — see Sections 3.1 & 3.2 for details.

The main task in *chain estimation* is clustering. Figure 3 presents our clustering method, which is used for both supervised and unsupervised CoRe. We search for the best predicted antecedent (with coreference probability $p \geq 0.5$) from right to left starting from the end of the document. McEnery et al. (1997) showed that in 98.68% of cases the antecedent is within a 10-sentence window; hence we use a window of 10 sentences for search. We have found that limiting the search to a window increases both efficiency and effectiveness.

Filtering. We use a feature definition language to define the templates according to which the filters and features are calculated. These templates are hard constraints that filter out all cases that are clearly disreferent, e.g., *(he, she)* or *(he, they)*. We use the following filters: (i) the antecedent of a reflexive pronoun must be in the same sentence; (ii) the antecedent of a pronoun must occur at a distance of at most 3 sentences; (iii) a coreferent pair of a noun and a pronoun or of two pronouns must not

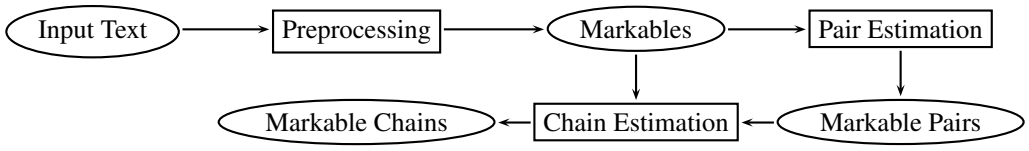

Figure 2: Common architecture of unsupervised (A-INF) and supervised (SUCRE) models.

Chain_Estimation $(M_1, M_2, \ldots, M_n)$
1. $t \leftarrow 1$
2. For each markable M_i: $C_i \leftarrow \{M_i\}$
3. Proceed through the markables from the end of the document. For each M_j, consider each preceding M_i within 10 sentences:
If Pair_Estimation(M_i, M_j)>=t: $C_i \leftarrow C_i \cup C_j$
4. $t \leftarrow t - 0.01$
5. If $t >= 0.5$: go to step 3

Pair_Estimation (M_i, M_j):
If Filtering(M_i, M_j)==FALSE then return 0; else return the probability p (or association score N) of markable pair (M_i, M_j) being coreferent.

Filtering (M_i, M_j):
return TRUE if all filters for (M_i, M_j) are TRUE else FALSE

Figure 3: MCORE chain estimation (clustering) algorithm (test). t is the clustering threshold. C_i refers to the cluster that M_i is a member of.

disagree in number; (iv) a coreferent pair of two pronouns must not disagree in gender. These four filters are used in supervised and unsupervised modes of MCORE.

3.1 Unsupervised Model (A-INF)

Figure 4 (top) shows how A-INF performs pair estimation. First, in the pair generation step, all possible pairs inside 10 sentences are generated. Other steps are separately explained for train and test as follows.

Train. In addition to the filters (i)–(iv) described above, we use the following filter: *(v) If the head of markable M_2 matches the head of the preceding markable M_1, then we ignore all other pairs for M_2 in the calculation of association scores.*

This additional filter is necessary because an approach without some kind of string matching constraint yields poor results, given the importance of string matching for CoRe. As we will show below, even the simple filters (i)–(v) are sufficient to learn high-quality association scores; this means that we do not need the complex features of "deterministic" systems. However, if such complex features are available, then we can use them to improve performance in our self-trained setting.

To learn word association information from an unlabeled corpus (see Section 4), we compute mutual information (MI) scores between heads of markables. We define MI as follows: (Cover and Thomas, 1991)

$$\text{MI}(a,b) = \sum_{i \in \{\bar{a}, a\}} \sum_{j \in \{\bar{b}, b\}} P(i,j) \log_2 \frac{P(i,j)}{P(i)P(j)}$$

E.g., $P(a, \bar{b})$ is the probability of a pair whose two elements are a and a word not equal to b.

Test. A key virtue of our approach is that in the classification of pairs as coreferent/disreferent, the coreference probability p estimated in supervised learning plays exactly the same role as the association information score N (defined below). For p, it is important that we only consider pairs with $p \geq 0.5$ as potentially coreferent (see Figure 3). To be able to impose the same constraint on N, we normalize the MI scores by the maximum values of the two words and take the average:

$$N(a,b) = \frac{1}{2}\left(\frac{\text{MI}(a,b)}{\text{argmax}_x \text{MI}(a,x)} + \frac{\text{MI}(a,b)}{\text{argmax}_x \text{MI}(x,b)}\right)$$

In the above equation, the value of N indicates how strongly two words are associated. N is normalized to ensure $0 \leq N \leq 1$. If a or b did not occur, then we set $N = 0$.

In filtering for test, we use filters (i)–(iv). We then fetch the MI values and calculate N values. The clustering algorithm described in Figure 3 uses these N values in exactly the same way as p: we search for the antecedent with the maximum association score

N greater than 0.5 from right to left starting from the end of the document.

As we will see below, using N scores acquired from an unlabeled corpus as the only source of information for CoRe performs surprising well. However, the weaknesses of this approach are (i) the failure to cover pairs that do not occur in the unlabeled corpus (negatively affecting recall) and (ii) the generation of pairs that are not plausible candidates for coreference (negatively affecting precision). To address these problems, we train a model on a corpus labeled by A-INF in a self-training approach.

3.2 Supervised Model (SUCRE)

Figure 4 (bottom) presents the architecture of pair estimation for the supervised approach (SUCRE).

In the pair generation step for train, we take each coreferent markable pair (M_i, M_j) without intervening coreferent markables and use (M_i, M_j) as a positive training instance and (M_i, M_k), $i < k < j$, as negative training instances. For test, we generate all possible pairs within 10 sentences. After filtering, we then calculate a feature vector for each generated pair that survived filters (i)–(iv).

Our basic features are similar to those described by Soon et al. (2001): string-based features, distance features, span features, part-of-speech features, grammatical features, semantic features, and agreement features. These basic features are engineered with the goal of creating a feature set that will result in good performance. For this purpose we used the relational feature engineering framework which has been presented in (Kobdani et al., 2010). It includes powerful and flexible methods for implementing and extracting new features. It allows systematic and fast search of the space of features and thereby reduces the time and effort needed for defining optimal features. We believe that the good performance of our supervised system SUCRE (tables 1 and 2) is the result of our feature engineering approach.[2]

As our classification method, we use a decision tree[3] (Quinlan, 1993) that is trained on the training set to estimate the coreference probability p for a pair and then applied to the test set. Note that, as is standard in CoRe, filtering and feature calculation are exactly the same for training and test, but that pair generation is different as described above.

4 Experimental Setup

4.1 Data Sets

For computing word association, we used a corpus of about 63,000 documents from the 2009 English *Wikipedia* (the articles that were larger than 200 bytes). This corpus consists of more than 33.8 million tokens; the average document length is 500 tokens. The corpus was parsed using the Berkeley parser (Petrov and Klein, 2007). We ignored all sentences that had no parse output. The number of detected markables (all noun phrases extracted from parse trees) is about 9 million.

We evaluate unsupervised, supervised and self-trained models on *ACE (Phase 2)* (Mitchell et al., 2003).[4] This data set is one of the most widely used CoRe benchmarks and was used by the systems that are most comparable to our approach; in particular, it was used in most prior work on unsupervised CoRe. The corpus is composed of three data sets from three different news sources. We give the number of test documents for each: (i) Broadcast News (BNEWS): 51. (ii) Newspaper (NPAPER): 17. (iii) Newswire (NWIRE): 29. We report results for *true markables* (markables extracted from the answer keys) to be able to compare with other systems that use true markables.

In addition, we use the recently published *OntoNotes* benchmark (Recasens et al., 2010). OntoNotes is an excerpt of news from the OntoNotes Corpus Release 2.0 (Pradhan et al., 2007). The advantage of OntoNotes is that it contains two parallel annotations: (i) a *gold setting*, gold standard manual annotations of the preprocessing information and (ii) an *automatic setting*, automatically predicted annotations of the preprocessing information. The automatic setting reflects the situation a CoRe system

[2] While this is not the focus of this paper, SUCRE has performance comparable to other state-of-the-art supervised systems. E.g., B^3/MUC F_1 are 75.6/72.4 on ACE-2 and 69.4/70.6 on MUC-6 compared to 78.3/66.0 on ACE-2 and 70.9/68.5 on MUC-6 for Reconcile (Stoyanov et al., 2010)

[3] We also tried support vector machines and maximum entropy models, but they did not perform better.

[4] We used two variants of ACE (Phase 2): ACE-2 and ACE2003

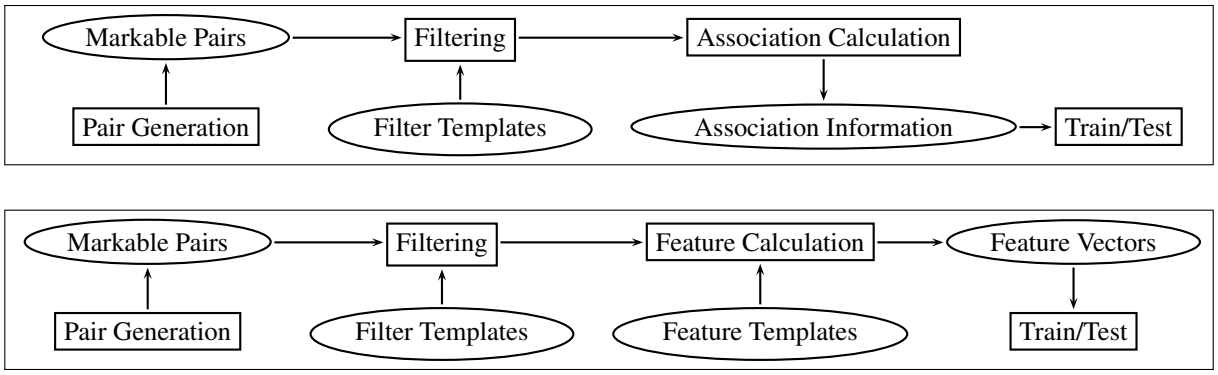

Figure 4: Pair estimation in the unsupervised model A-INF (top) and in the supervised model SUCRE (bottom).

faces in reality; in contrast, the gold setting should be considered less realistic.

The issue of gold vs. automatic setting is directly related to a second important evaluation issue: the influence of markable detection on CoRe evaluation measures. In a real application, we do not have access to true markables, so an evaluation on *system markables* (markables automatically detected by the system) reflects actual expected performance better. However, reporting only CoRe numbers (even for system markables) is not sufficient either since accuracy of markable detection is necessary to interpret CoRe scores. Thus, we need (i) measures of the quality of system markables (i.e., an evaluation of the markable detection subtask) and CoRe performance on system markables as well as (ii) a measure of CoRe performance on true markables. We use OntoNotes in this paper to perform such a, in our view, complete and realistic evaluation of CoRe. The two evaluations correspond to the two evaluations performed at SemEval-2010 (Recasens et al., 2010): the automatic setting with system markables and the gold setting with true markables. Test set size is 85 documents.

In the experiments with A-INF we use Wikipedia to compute association information and then evaluate the model on the test sets of ACE and OntoNotes. For the experiments with UNSEL, we use its unsupervised subsystem A-INF (which uses Wikipedia association scores) to automatically label the training sets of ACE and OntoNotes. Then for each data set, the supervised subsystem of UNSEL (i.e., SUCRE) is trained on its automatically labeled training set and then evaluated on its test set. Finally, for the supervised experiments, we use the manually labeled training sets and evaluate on the corresponding test sets.

4.2 Evaluation Metrics

We report recall, precision, and F_1 for MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and CEAF (Luo, 2005). We selected these three metrics because a single metric is often misleading and because we need to use metrics that were used in previous unsupervised work.

It is well known that MUC by itself is insufficient because it gives misleadingly high scores to the "single-chain" system that puts all markables into one chain (Luo et al., 2004; Finkel and Manning, 2008). However, B^3 and CEAF have a different bias: they give high scores to the "all-singletons" system that puts each markable in a separate chain. On OntoNotes test, we get $B^3 = 83.2$ and CEAF $= 71.2$ for all-singletons, which incorrectly suggests that performance is good; but MUC F_1 is 0 in this case, demonstrating that all-singletons performs poorly. With the goal of performing a complete evaluation, one that punishes all-singletons as well as single-chain, we use one of the following two combinations: (i) MUC and B^3 or (ii) MUC and CEAF. Recasens et al. (2010) showed that B^3 and CEAF are highly correlated (Pearson's $r = 0.91$). Therefore, either combination (i) or combination (ii) fairly characterizes CoRe performance.

5 Results and Discussion

Table 1 compares our unsupervised self-trained model UNSEL and unsupervised model A-INF to

Table 1: Scores for MCORE (A-INF, SUCRE and UNSEL) and three comparable systems on ACE-2 and ACE2003.

P&D (Poon and Domingos, 2008) on ACE-2; and to Ng (Ng, 2008) and H&K[5] (Haghighi and Klein, 2007) on ACE2003. To our knowledge, these three papers are the best and most recent evaluation results for unsupervised learning and they all report results on ACE-2 and ACE-2003. Results on SUCRE will be discussed later in this section.

A-INF scores are below some of the earlier unsupervised work reported in the literature (lines 2, 6, 10) although they are close to competitive on two of the datasets (lines 15 and 20: MUC scores are equal or better, CEAF scores are worse). Given the simplicity of A-INF, which uses nothing but associations mined from a large unannotated corpus, its performance is surprisingly good.

Turning to UNSEL, we see that F_1 is always better for UNSEL than for A-INF, for all three measures (lines 3 vs 2, 7 vs 6, 11 vs 10, 16 vs 15, 21 vs 20). This demonstrates that the self-training step of UNSEL is able to correct many of the errors that A-INF commits. Both precision and recall are improved with two exceptions: recall of B^3 decreases from line 2 to 3 and from 15 to 16.

When comparing the unsupervised system UNSEL to previous unsupervised results, we find that UNSEL's F_1 is higher in all runs (lines 3 vs 1, 7 vs 5, 11 vs 9, 16 vs 13&14, 21 vs 18&19). The differences are large (up to 11%) compared to H&K and

[5]We report numbers for the better performing Pronoun-only Salience variant of H&K proposed by Ng (2008).

Ng. The difference to P&D is smaller, ranging from 2.7% (B^3, lines 11 vs 9) to 0.7% (MUC, lines 7 vs 5). Given that MCORE is a simpler and more efficient system than this prior work on unsupervised CoRe, these results are promising.

In contrast to F_1, there is no consistent trend for precision and recall. For example, P&D is better than UNSEL on MUC recall for BNEWS-ACE-2 (lines 1 vs 3) and H&K is better than UNSEL on CEAF precision for NWIRE-ACE2003 (lines 18 vs 21). But this higher variability for precision and recall is to be expected since every system trades the two measures off differently.

These results show that the application of self-training significantly improves performance. As discussed in Section 3.1, self-training has positive effects on both recall and precision. We now present two simplified examples that illustrate this point.

Example for recall. Consider the markable pair (*Novoselov*[6]*,he*) in the test set. Its N score is 0 because our subset of 2009 Wikipedia sentences has no occurrence of *Novoselov.* However, A-INF finds many similar pairs like (*Einstein,he*) and (*Hawking,he*), pairs that have high N scores. Suppose we represent pairs using the following five features: <sentence distance, string match, type of first markable, type of second markable, number agreement>. Then (*Einstein,he*), (*Hawking,he*) and (*Novoselov,he*) will all be assigned the feature vector <1, No, Proper Noun, Personal Pronoun, Yes>. We can now automatically label Wikipedia using A-INF – this will label (*Einstein,he*) and (*Hawking,he*) as coreferent – and train SUCRE on the resulting training set. SUCRE can then resolve the coreference (*Novoselov,he*) correctly. We call this the *better recall effect*.

Example for precision. Using the same representation of pairs, suppose that for the sequence of markables *Biden, Obama, President* the markable pairs (*Biden,President*) and (*Obama,President*) are assigned the feature vectors <8, No, Proper Noun, Proper Noun, Yes> and <1, No, Proper Noun, Proper Noun, Yes>, respectively. Since both pairs have N scores > 0.5, A-INF incorrectly puts the three markables into one cluster. But as we would expect, A-INF labels many more markable pairs with the second feature vector (distance=1) as coreferent than with the first one (distance=8) in the entire automatically labeled training set. If we now train SUCRE on this training set, it can resolve such cases in the test set correctly even though they are so similar: (*Biden,President*) is classified as disreferent and (*Obama,President*) as coreferent. We call this the *better precision effect*.

[6]The 2010 physics Nobel laureate.

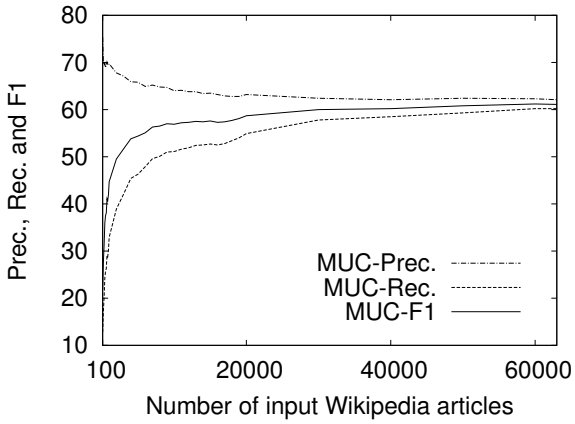

Figure 5: MUC learning curve for A-INF.

Recall that UNSEL has better recall and precision than A-INF in almost all cases (discussion of Table 1). This result shows that better precision and better recall effects do indeed benefit UNSEL.

To summarize, the advantages of our self-training approach are: (i) We cover cases that do not occur in the unlabeled corpus (better recall effect); and (ii) we use the leveraging effect of a rich feature space including distance, person, number, gender etc. to improve precision (better precision effect).

Learning curve. Figure 5 presents MUC scores of A-INF as a function of the number of Wikipedia articles used in unsupervised learning. We can see that a small number of input articles (e.g., 100) results in low recall and high precision. When we increase the number of input articles, recall rapidly increases and precision rapidly decreases up to about 10,000 articles. Increase and decrease continue more slowly after that. F_1 increases throughout because lower precision is compensated by higher recall. This learning curve demonstrates the importance of the size of the corpus for A-INF.

Comparison of UNSEL with SUCRE

Table 2 compares our unsupervised self-trained (UNSEL) and supervised (SUCRE) models with the recently published SemEval-2010 OntoNotes re-

Gold setting + True markables				
System	MD	MUC	B^3	CEAF
Relax	100	33.7	84.5	75.6
$SUCRE_{2010}$	100	60.8	82.4	74.3
SUCRE	100	64.3	87.0	80.1
UNSEL	100	63.0	86.9	79.7
Automatic setting + System markables				
System	MD	MUC	B^3	CEAF
$SUCRE_{2010}$	80.7	52.5	67.1	62.7
Tanl-1	73.9	24.6	61.3	57.3
SUCRE	80.9	55.7	69.7	66.6
UNSEL	80.9	55.0	69.8	66.3

Table 2: F_1 scores for MCORE (SUCRE and UNSEL) and the best comparable systems in SemEval-2010. MD: Markable Detection F_1 (Recasens et al., 2010).

sults (gold and automatic settings). We compare with the scores of the two best systems, Relax and $SUCRE_{2010}$[7] (for the gold setting with true markables) and $SUCRE_{2010}$ and Tanl-1 (for the automatic setting with system markables, 89.9% markable detection (MD) F_1). It is apparent from this table that our supervised and unsupervised self-trained models outperform Relax, $SUCRE_{2010}$ and Tanl-1. We should make clear that we did not use the test set for development to ensure a fair comparison with the participant systems at SemEval-2010.

Table 1 shows that the unsupervised self-trained system (UNSEL) does a lot worse than the supervised system (SUCRE) on ACE.[8] In contrast, UNSEL performs almost as well as SUCRE on OntoNotes (Table 2), for both gold and automatic settings: F_1 differences range from $+.1$ (Automatic, B^3) to -1.3 (Gold, MUC). We suspect that this is partly due to the much higher proportion of singletons in OntoNotes than in ACE-2: 85.2% (OntoNotes) vs. 60.2% (ACE-2). The low recall of the automatic labeling by A-INF introduces a bias for singletons when UNSEL is self-trained. Another reason is that the OntoNotes training set is about 4 times larger than each of BNEWS, NWIRE and NPAPER training sets. With more training data, UNSEL can correct more of its precision and recall errors. For an unsupervised approach, which only needs unlabeled data, there is little cost to creating large training sets. Thus, this comparison of ACE-2/Ontonotes results is evidence that in a realistic scenario using association information in an unsupervised self-trained system is almost as good as a system trained on manually labeled data.

It is important to note that the comparison of SUCRE to UNSEL is the most direct comparison of supervised and unsupervised CoRe learning we are aware of. The two systems are identical with the single exception that they are trained on manual vs. automatic coreference labels.

6 Conclusion

In this paper, we have demonstrated the utility of association information for coreference resolution. We first developed a simple unsupervised model for shallow CoRe that only uses association information for finding coreference chains. We then introduced an unsupervised self-trained approach where a supervised model is trained on a corpus that was automatically labeled by the unsupervised model based on the association information. The results of the experiments indicate that the performance of the unsupervised self-trained approach is better than the performance of other unsupervised learning systems. In addition, we showed that our system is a flexible and modular framework that is able to learn from data with different quality (perfect vs noisy markable detection) and domain; and is able to deliver good results for shallow information spaces and competitive results for rich feature spaces. Finally, our framework is the first CoRe system that is designed to support three major modes of machine learning equally well: supervised, self-trained and unsupervised.

Abstract

Cross-document coreference, the task of grouping all the mentions of each entity in a document collection, arises in information extraction and automated knowledge base construction. For large collections, it is clearly impractical to consider all possible groupings of mentions into distinct entities. To solve the problem we propose two ideas: (a) a *distributed* inference technique that uses parallelism to enable large scale processing, and (b) a *hierarchical* model of coreference that represents uncertainty over multiple granularities of entities to facilitate more effective approximate inference. To evaluate these ideas, we constructed a labeled corpus of 1.5 million disambiguated mentions in Web pages by selecting link anchors referring to Wikipedia entities. We show that the combination of the hierarchical model with distributed inference quickly obtains high accuracy (with error reduction of 38%) on this large dataset, demonstrating the scalability of our approach.

1 Introduction

Given a collection of mentions of entities extracted from a body of text, *coreference* or *entity resolution* consists of clustering the mentions such that two mentions belong to the same cluster if and only if they refer to the same entity. Solutions to this problem are important in semantic analysis and knowledge discovery tasks (Blume, 2005; Mayfield et al., 2009). While significant progress has been made in *within*-document coreference (Ng, 2005; Culotta et al., 2007; Haghighi and Klein, 2007; Bengston and Roth, 2008; Haghighi and Klein, 2009; Haghighi and Klein, 2010), the larger problem of *cross*-document coreference has not received as much attention.

Unlike inference in other language processing tasks that scales linearly in the size of the corpus, the hypothesis space for coreference grows super-exponentially with the number of mentions. Consequently, most of the current approaches are developed on small datasets containing a few thousand mentions. We believe that cross-document coreference resolution is most useful when applied to a very large set of documents, such as all the news articles published during the last 20 years. Such a corpus would have billions of mentions. In this paper we propose a model and inference algorithms that can scale the cross-document coreference problem to corpora of that size.

Much of the previous work in cross-document coreference (Bagga and Baldwin, 1998; Ravin and Kazi, 1999; Gooi and Allan, 2004; Pedersen et al., 2006; Rao et al., 2010) groups mentions into entities with some form of greedy clustering using a pairwise mention similarity or distance function based on mention text, context, and document-level statistics. Such methods have not been shown to scale up, and they cannot exploit cluster features that cannot be expressed in terms of mention pairs. We provide a detailed survey of related work in Section 6.

Other previous work attempts to address some of the above concerns by mapping coreference to inference on an undirected graphical model (Culotta et al., 2007; Poon et al., 2008; Wellner et al., 2004; Wick et al., 2009a). These models contain pairwise factors between all pairs of mentions capturing similarity between them. Many of these models also enforce transitivity and enable features over

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 793–803,
Portland, Oregon, June 19-24, 2011.

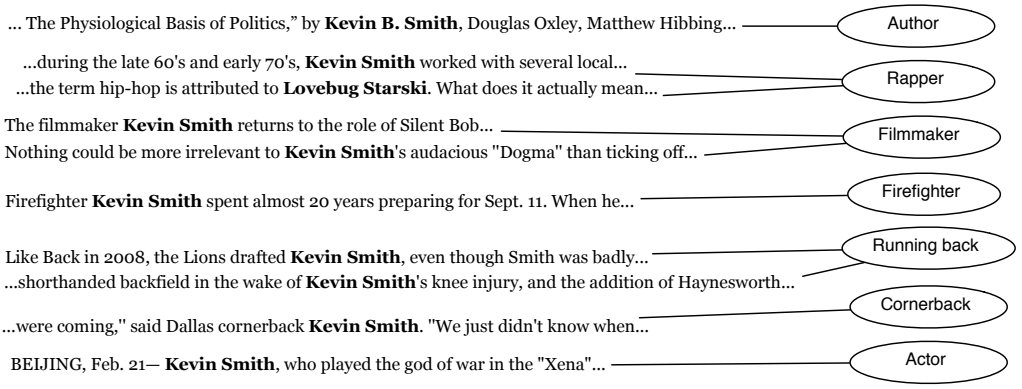

Figure 1: **Cross-Document Coreference Problem:** Example mentions of "Kevin Smith" from New York Times articles, with the true entities shown on the right.

entities by including *set-valued variables*. Exact inference in these models is intractable and a number of approximate inference schemes (McCallum et al., 2009; Rush et al., 2010; Martins et al., 2010) may be used. In particular, *Markov chain Monte Carlo* (MCMC) based inference has been found to work well in practice. However as the number of mentions grows to Web scale, as in our problem of cross-document coreference, even these inference techniques become infeasible, motivating the need for a scalable, parallelizable solution.

In this work we first distribute MCMC-based inference for the graphical model representation of coreference. Entities are distributed across the machines such that the parallel MCMC chains on the different machines use only local proposal distributions. After a fixed number of samples on each machine, we redistribute the entities among machines to enable proposals across entities that were previously on different machines. In comparison to the greedy approaches used in related work, our MCMC-based inference provides better robustness properties.

As the number of mentions becomes large, high-quality samples for MCMC become scarce. To facilitate better proposals, we present a hierarchical model. We add *sub-entity* variables that represent clusters of similar mentions that are likely to be coreferent; these are used to propose composite jumps that move multiple mentions together. We also introduce *super-entity* variables that represent clusters of similar entities; these are used to distribute entities among the machines such that similar entities are assigned to the same machine. These additional levels of hierarchy dramatically increase the probability of beneficial proposals even with a large number of entities and mentions.

To create a large corpus for evaluation, we identify pages that have hyperlinks to Wikipedia, and extract the anchor text and the context around the link. We treat the anchor text as the mention, the context as the document, and the title of the Wikipedia page as the entity label. Using this approach, 1.5 million mentions were annotated with 43k entity labels. On this dataset, our proposed model yields a B^3 (Bagga and Baldwin, 1998) F1 score of 73.7%, improving over the baseline by 16% absolute (corresponding to 38% error reduction). Our experimental results also show that our proposed hierarchical model converges much faster even though it contains many more variables.

2 Cross-document Coreference

The problem of coreference is to identify the sets of mention strings that refer to the same underlying entity. The identities and the number of the underlying entities is not known. In *within-document* coreference, the mentions occur in a single document. The number of mentions (and entities) in each document is usually in the hundreds. The difficulty of the task arises from a large hypothesis space (exponential in the number of mentions) and challenge in resolving nominal and pronominal mentions to the correct named mentions. In most cases, named mentions

are not ambiguous within a document. In *cross-document* coreference, the number of mentions and entities is in the millions, making the combinatorics even more daunting. Furthermore, naming ambiguity is much more common as the same string can refer to multiple entities in different documents, and distinct strings may refer to the same entity in different documents.

We show examples of ambiguities in Figure 1. Resolving the identity of individuals with the *same name* is a common problem in cross-document coreference. This problem is further complicated by the fact that in some situations, these individuals may belong to the same field. Another common ambiguity is that of *alternate* names, in which the same entity is referred to by different names or *aliases* (e.g. "Bill" is often used as a substitute for "William"). The figure also shows an example of the *renaming* ambiguity – "Lovebug Starski" refers to "Kevin Smith", and this is an extreme form of alternate names. Rare *singleton* entities (like the firefighter) that may appear only once in the whole corpus are also often difficult to isolate.

2.1 Pairwise Factor Model

Factor graphs are a convenient representation for a probability distribution over a vector of output variables given observed variables. The model that we use for coreference represents mentions ($\mathbf{M}$) and entities ($\mathbf{E}$) as random variables. Each mention can take an entity as its value, and each entity takes a set of mentions as its value. Each mention also has a feature vector extracted from the observed text mention and its context. More precisely, the probability of a configuration $\mathbf{E} = \mathbf{e}$ is defined by

$$p(\mathbf{e}) \propto \exp \sum_{e \in \mathbf{e}} \left\{ \sum_{m,n \in e, n \neq m} \psi_a(m,n) + \sum_{m \in e, n \notin e} \psi_r(m,n) \right\}$$

where factor ψ_a represents *affinity* between mentions that are coreferent according to $\mathbf{e}$, and factor ψ_r represents *repulsion* between mentions that are not coreferent. Different factors are instantiated for different predicted configurations. Figure 2 shows the model instantiated with five mentions over a two-entity hypothesis.

For the factor potentials, we use cosine similarity of mention context pairs (ϕ_{mn}) such that

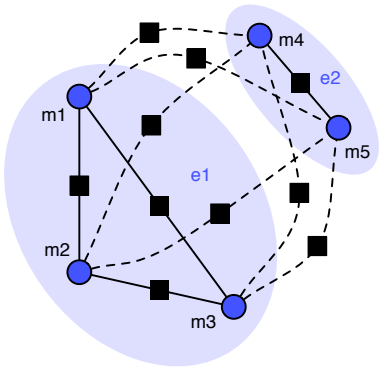

Figure 2: **Pairwise Coreference Model:** Factor graph for a 2-entity configuration of 5 mentions. Affinity factors are shown with solid lines, and repulsion factors with dashed lines.

$\psi_a(m,n) = \phi_{mn} - b$ and $\psi_r(m,n) = -(\phi_{mn} - b)$, where b is the bias. While one can certainly make use of a more sophisticated feature set, we leave this for future work as our focus is to scale up inference. However, it should be noted that this approach is agnostic to the particular set of features used. As we will note in the next section, we do not need to calculate features between all pairs of mentions (as would be prohibitively expensive for large datasets); instead we only compute the features as and when required.

2.2 MCMC-based Inference

Given the above model of coreference, we seek the *maximum a posteriori* (MAP) configuration:

$$\begin{aligned} \hat{\mathbf{e}} &= \arg\max_{\mathbf{e}} p(\mathbf{e}) \\ &= \arg\max_{\mathbf{e}} \sum_{e \in \mathbf{e}} \left\{ \sum_{m,n \in e, n \neq m} \psi_a(m,n) + \sum_{m \in e, n \notin e} \psi_r(m,n) \right\} \end{aligned}$$

Computing $\hat{\mathbf{e}}$ exactly is intractable due to the large space of possible configurations.[1] Instead, we employ MCMC-based optimization to discover the MAP configuration. A proposal function q is used to propose a change $\mathbf{e}'$ to the current configuration $\mathbf{e}$. This jump is accepted with the following Metropolis-Hastings acceptance probability:

$$\alpha(\mathbf{e}, \mathbf{e}') = \min\left(1, \left(\frac{p(\mathbf{e}')}{p(\mathbf{e})}\right)^{1/t} \frac{q(\mathbf{e})}{q(\mathbf{e}')}\right) \quad (1)$$

[1] Number of possible entities is Bell(n) in the number of mentions, i.e. number of partitions of n items

where t is the annealing temperature parameter.

MCMC chains efficiently explore the high-density regions of the probability distribution. By slowly reducing the temperature, we can decrease the entropy of the distribution to encourage convergence to the MAP configuration. MCMC has been used for optimization in a number of related work (McCallum et al., 2009; Goldwater and Griffiths, 2007; Changhe et al., 2004).

The proposal function moves a randomly chosen mention l from its current entity e_s to a randomly chosen entity e_t. For such a proposal, the log-model ratio is:

$$\log \frac{p(\mathbf{e}')}{p(\mathbf{e})} = \sum_{m \in e_t} \psi_a(l, m) + \sum_{n \in e_s} \psi_r(l, n) - \sum_{n \in e_s} \psi_a(l, n) - \sum_{m \in e_t} \psi_r(l, m) \quad (2)$$

Note that since only the factors between mention l and mentions in e_s and e_t are involved in this computation, the acceptance probability of each proposal is calculated efficiently.

In general, the model may contain arbitrarily complex set of features over pairs of mentions, with parameters associated with them. Given labeled data, these parameters can be *learned* by Perceptron (Collins, 2002), which uses the MAP configuration according to the model ($\hat{\mathbf{e}}$). There also exist more efficient training algorithms such as SampleRank (McCallum et al., 2009; Wick et al., 2009b) that update parameters *during* inference. However, we only focus on inference in this work, and the only parameter that we set manually is the bias b, which indirectly influences the number of entities in $\hat{\mathbf{e}}$. Unless specified otherwise, in this work the initial configuration for MCMC is the *singleton* configuration, i.e. all entities have a size of 1.

This MCMC inference technique, which has been used in McCallum and Wellner (2004), offers several advantages over other inference techniques: (a) unlike message-passing-methods, it does not require the full ground graph, (b) we only have to examine the factors that lie within the changed entities to evaluate a proposal, and (c) inference may be stopped at any point to obtain the current best configuration. However, the super exponential nature of the hypothesis space in cross-doc coreference renders this algorithm computationally unsuitable for large scale coreference tasks. In particular, fruitful proposals (that increase the model score) are extremely rare, resulting in a large number of proposals that are not accepted. We describe methods to speed up inference by 1) evaluating multiple proposal simultaneously (Section 3), and 2) by augmenting our model with hierarchical variables that enable better proposal distributions (Section 4).

3 Distributed MAP Inference

The key observation that enables distribution is that the acceptance probability computation of a proposal only examines a few factors that are **not** common to the previous and next configurations (Eq. 2). Consider a pair of proposals, one that moves mention l from entity e_s to entity e_t, and the other that moves mention l' from entity e'_s to entity e'_t. The set of factors to compute acceptance of the first proposal are factors between l and mentions in e_s and e_t, while the set of factors required to compute acceptance of the second proposal lie between l' and mentions in e'_s and e'_t. Since these set of factors are completely disjoint from each other, and the resulting configurations do not depend on each other, these two proposals are *mutually-exclusive*. Different orders of evaluating such proposals are equivalent, and in fact, these proposals can be proposed and evaluated concurrently. This mutual-exclusivity is not restricted only to pairs of proposals; a set of proposals are mutually-exclusive if no two proposals require the same factor for evaluation.

Using this insight, we introduce the following approach to distributed cross-document coreference. We divide the mentions and entities among multiple machines, and propose moves of mentions between entities assigned to the same machine. These jumps are evaluated exactly and accepted without communication between machines. Since acceptance of a mention's move requires examining factors that lie between other mentions in its entity, we ensure that all mentions of an entity are assigned the same machine. Unless specified otherwise, the distribution is performed randomly. To enable exploration of the complete configuration space, rounds of sampling are interleaved by *redistribution* stages, in which the entities are redistributed among the machines (see Figure 3). We use MapReduce (Dean and Ghe-

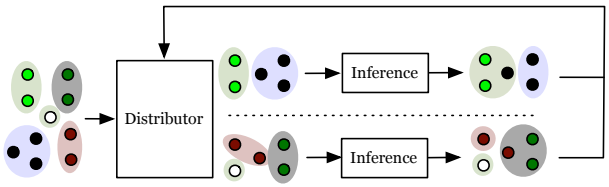

Figure 3: **Distributed MCMC-based Inference**: Distributor divides the entities among the machines, and the machines run inference. The process is repeated by the redistributing the entities.

mawat, 2004) to manage the distributed computation.

This approach to distribution is equivalent to inference with all mentions and entities on a single machine with a restricted proposer, but is faster since it exploits independencies to propose multiple jumps simultaneously. By restricting the jumps as described above, the acceptance probability calculation is exact. Partitioning the entities and proposing local jumps are restrictions to the single-machine proposal distribution; redistribution stages ensure the equivalent Markov chains are still irreducible. See Singh et al. (2010) for more details.

4 Hierarchical Coreference Model

The proposal function for MCMC-based MAP inference presents changes to the current entities. Since we use MCMC to reach high-scoring regions of the hypothesis space, we are interested in the changes that improve the current configuration. But as the number of mentions and entities increases, these *fruitful* samples become extremely rare due to the blowup in the possible space of configurations, resulting in rejection of a large number of proposals. By distributing as described in the previous section, we propose samples in parallel, improving chances of finding changes that result in better configurations. However, due to random redistribution and a naive proposal function within each machine, a large fraction of proposals are still wasted. We address these concerns by adding *hierarchy* to the model.

4.1 Sub-Entities

Consider the task of proposing moves of mentions (within a machine). Given the large number of mentions and entities, the probability that a randomly picked mention that is moved to a random entity results in a better configuration is extremely small. If such a move is accepted, this gives us evidence that the mention did not belong to the previous entity, and we should also move similar mentions from the previous entity simultaneously to the same entity. Since the proposer moves only a single mention at a time, a large number of samples may be required to discover these fruitful moves. To enable *block* proposals that move similar mentions simultaneously, we introduce latent *sub-entity* variables that represent groups of similar mentions within an entity, where the similarity is defined by the model. For inference, we have stages of sampling sub-entities (moving individual mentions) interleaved with stages of entity sampling (moving all mentions within a sub-entity). Even though our configuration space has become larger due to these extra variables, the proposal distribution has also improved since it proposes composite moves.

4.2 Super-Entities

Another issue faced during distributed inference is that random redistribution is often wasteful. For example, if dissimilar entities are assigned to a machine, none of the proposals may be accepted. For a large number of entities and machines, the probability that similar entities will be assigned to the same machine is extremely small, leading to a larger number of wasted proposals. To alleviate this problem, we introduce *super-entities* that represent groups of similar entities. During redistribution, we ensure all entities in the same super-entity are assigned to the same machine. As for sub-entities above, inference switches between regular sampling of entities and sampling of super-entities (by moving entities). Although these extra variables have made the configuration space larger, they also allow more efficient distribution of entities, leading to useful proposals.

4.3 Combined Hierarchical Model

Each of the described levels of the hierarchy are similar to the initial model (Section 2.1): mentions/sub-entities have the same structure as the entities/super-entities, and are modeled using similar factors. To represent the "context" of a sub-entity we take the union of the bags-of-words of the constituent mention contexts. Similarly, we take the union of sub-

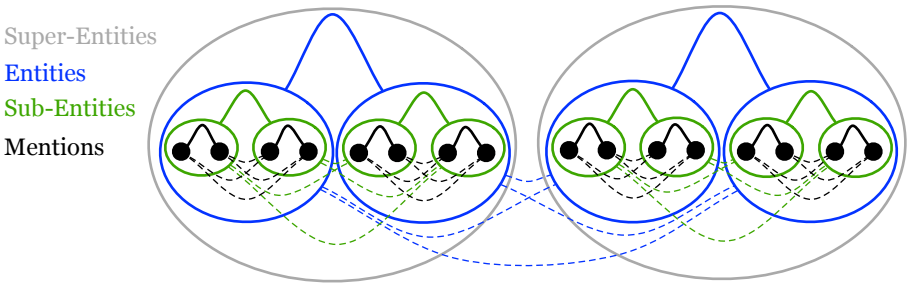

Figure 4: **Combined Hierarchical Model** with factors instantiated for a hypothesis containing 2 super-entities, 4 entities, and 8 sub-entities, shown as colored circles, over 16 mentions. Dotted lines represent repulsion factors and solid lines represent affinity factors (the color denotes the type of variable that the factor touches). The boxes on factors were excluded for clarity.

entity contexts to represent the context of an entity. The factors are instantiated in the same manner as Section 2.1 except that we change the bias factor b for each level (increasing it for sub-entities, and decreasing it for super-entities). The exact values of these biases indirectly determines the number of predicted sub-entities and super-entities.

Since these two levels of hierarchy operate at separate granularities from each other, we combine them into a single hierarchical model that contains both sub- and super-entities. We illustrate this hierarchical structure in Figure 4. Inference for this model takes a round-robin approach by fixing two of the levels of the hierarchy and sampling the third, cycling through these three levels. Unless specified otherwise, the initial configuration is the *singleton* configuration, in which all sub-entities, entities, and super-entities are of size 1.

5 Experiments

We evaluate our models and algorithms on a number of datasets. First, we compare performance on the small, publicly-available "John Smith" dataset. Second, we run the automated *Person-X* evaluation to obtain thousands of mentions that we use to demonstrate accuracy and scalability improvements. Most importantly, we create a large labeled corpus using links to Wikipedia to explore the performance in the large-scale setting.

5.1 John Smith Corpus

To compare with related work, we run an evaluation on the "John Smith" corpus (Bagga and Baldwin, 1998), containing 197 mentions of the name "John Smith" from New York Times articles (labeled to obtain 35 true entities). The bias b for our approach is set to result in the correct number of entities. Our model achieves B^3 F1 accuracy of 66.4% on this dataset. In comparison, Rao et al. (2010) obtains 61.8% using the model most similar to ours, while their best model (which uses sophisticated topic-model features that do not scale easily) achieves 69.7%. It is encouraging to note that our approach, using only a subset of the features, performs competitively with related work. However, due to the small size of the dataset, we require further evaluation before reaching any conclusions.

5.2 Person-X Evaluation

There is a severe lack of labeled corpora for cross-document coreference due to the effort required to evaluate the coreference decisions. Related approaches have used automated *Person-X* evaluation (Gooi and Allan, 2004), in which unique person-name strings are treated as the true entity labels for the mentions. Every mention string is replaced with an "X" for the coreference system. We use this evaluation methodology on 25k person-name mentions from the New York Times corpus (Sandhaus, 2008) each with one of 50 unique strings. As before, we set the bias b to achieve the same number of entities. We use 1 million samples in each round of inference, followed by random redistribution in the flat model, and super-entities in the hierarchical model. Results are averaged over five runs.

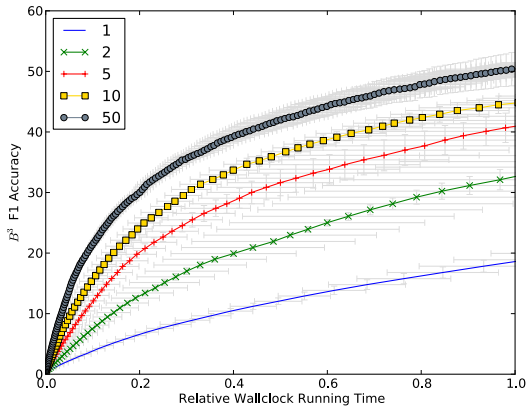

Figure 5: **Person-X Evaluation of Pairwise model**: Performance as number of machines is varied, averaged over 5 runs.

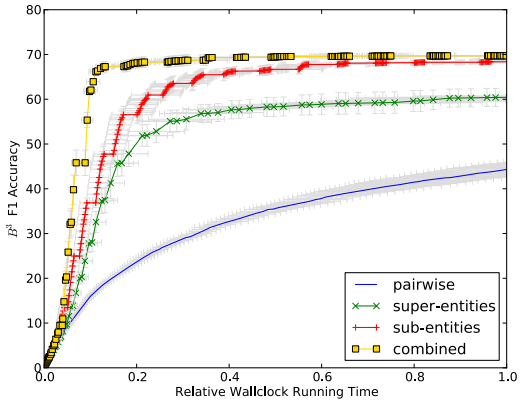

Figure 6: **Person-X Evaluation of Hierarchical Models**: Performance of inference on hierarchical models compared to the pairwise model. Experiments were run using 50 machines.

Number of Entities	43,928
Number of Mentions	1,567,028
Size of Largest Entity	6,096
Average Mentions per Entity	35.7
Variance of Mentions per Entity	5191.7

Table 1: **Wikipedia Link Corpus Statistics**. Size of an entity is the number of mentions of that entity.

Figure 5 shows accuracy compared to relative wallclock running time for distributed inference on the flat, pairwise model. Speed and accuracy improve as additional machines are added, but larger number of machines lead to diminishing returns for this small dataset. Distributed inference on our hierarchical model is evaluated in Figure 6 against inference on the pairwise model from Figure 5. We see that the individual hierarchical models perform much better than the pairwise model; they achieve the same accuracy as the pairwise model in approximately 10% of the time. Moreover, distributed inference on the combined hierarchical model is both faster and more accurate than the individual hierarchical models.

5.3 Wikipedia Link Corpus

To explore the application of the proposed approach to a larger, realistic dataset, we construct a corpus based on the insight that links to Wikipedia that appear on webpages can be treated as mentions, and since the links were added manually by the page author, we use the destination Wikipedia page as the entity the link refers to.

The dataset is created as follows: First, we crawl the web and select hyperlinks on webpages that link to an English Wikipedia page.[2] The anchors of these links form our set of *mentions*, with the surrounding block of clean text (obtained after removing markup, etc.) around each link being its context. We assign the title of the linked Wikipedia page as the *entity* label of that link. Since this set of mentions and labels can be noisy, we use the following filtering steps. All links that have less than 36 words in their block, or whose anchor text has a large string edit distance from the title of the Wikipedia page, are discarded. While this results in cases in which "President" is discarded when linked to the "Barack Obama" Wikipedia page, it was necessary to reduce noise. Further, we also discard links to Wikipedia pages that are concepts (such as "`public_domain`") rather than entities. All entities with less than 6 links to them are also discarded.

Table 1 shows some statistics about our automatically generated data set. We randomly sampled 5% of the entities to create a development set, treating the remaining entities as the test set. Unlike the John Smith and Person-X evaluation, this data set also contains non-person entities such as organizations and locations.

For our models, we augment the factor potentials with mention-string similarity:

[2] e.g. `http://en.wikipedia.org/Hillary_Clinton`

$$\psi_{a/r}(m,n) = \pm\left(\phi_{mn} - b + w\text{STREQ}(m,n)\right)$$

where STREQ is 1 if mentions m and n are string identical (0 otherwise), and w is the weight to this feature.[3] In our experiments we found that setting $w = 0.8$ and $b = 1e-4$ gave the best results on the development set.

Due to the large size of the corpus, existing cross-document coreference approaches could not be applied to this dataset. However, since a majority of related work consists of using clustering after defining a similarity function (Section 6), we provide a baseline evaluation of clustering with *Subsquare* (Bshouty and Long, 2010), a scalable, distributed clustering method. Subsquare takes as input a weighted graph with mentions as nodes and similarity between mentions used as edge weights. Subsquare works by stochastically assigning a vertex to the cluster of one its neighbors if they have significant neighborhood overlap. This algorithm is an efficient form of approximate spectral clustering (Bshouty and Long, 2010), and since it is given the same distances between mentions as our models, we expect it to get similar accuracy. We also generate another baseline clustering by assigning mentions with identical strings to the same entity. This mention-string clustering is also used as the initial configuration of our inference.

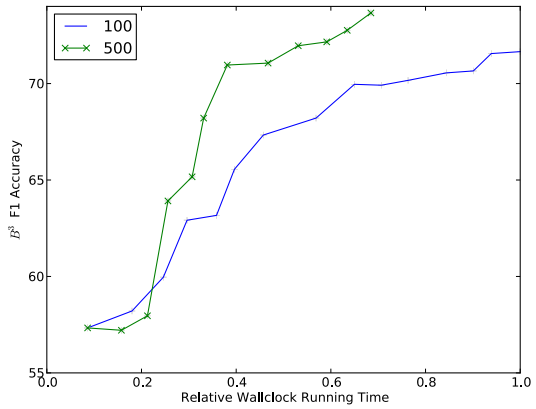

Figure 7: **Wikipedia Link Evaluation**: Performance of inference for different number of machines ($N = 100, 500$). Mention-string match clustering is used as the initial configuration.

[3]Note that we do not use mention-string similarity for John Smith or Person-X as the mention strings are all identical.

Method	Pairwise		B^3 Score	
	P/ R	F1	P/ R	F1
String-Match	30.0 / 66.7	41.5	82.7 / 43.8	57.3
Subsquare	38.2 / 49.1	43.0	87.6 / 51.4	64.8
Our Model	44.2 / 61.4	**51.4**	89.4 / 62.5	**73.7**

Table 2: **F1 Scores on the Wikipedia Link Data**. The results are significant at the 0.0001 level over Subsquare according to the difference of proportions significance test.

Inference is run for 20 rounds of 10 million samples each, distributed over N machines. We use $N = 100, 500$ and the B^3 F1 score results obtained set for each case are shown in Figure 7. It can be seen that $N = 500$ converges to a better solution faster, showing effective use of parallelism. Table 2 compares the results of our approach (at convergence for $N = 500$), the baseline mention-string match and the Subsquare algorithm. Our approach significantly outperforms the competitors.

6 Related Work

Although the cross-document coreference problem is challenging and lacks large labeled datasets, its ubiquitous role as a key component of many knowledge discovery tasks has inspired several efforts.

A number of previous techniques use scoring functions between pairs of contexts, which are then used for clustering. One of the first approaches to cross-document coreference (Bagga and Baldwin, 1998) uses an idf-based cosine-distance scoring function for pairs of contexts, similar to the one we use. Ravin and Kazi (1999) extend this work to be somewhat scalable by comparing pairs of contexts only if the mentions are deemed "ambiguous" using a heuristic. Others have explored multiple methods of context similarity, and concluded that agglomerative clustering provides effective means of inference (Gooi and Allan, 2004). Pedersen et al. (2006) and Purandare and Pedersen (2004) integrate second-order co-occurrence of words into the similarity function. Mann and Yarowsky (2003) use biographical facts from the Web as features for clustering. Niu et al. (2004) incorporate information extraction into the context similarity model, and annotate a small dataset to learn the parameters. A number of other approaches include various forms of

hand-tuned weights, dictionaries, and heuristics to define similarity for name disambiguation (Blume, 2005; Baron and Freedman, 2008; Popescu et al., 2008). These approaches are greedy and differ in the choice of the distance function and the clustering algorithm used. Daumé III and Marcu (2005) propose a generative approach to supervised clustering, and Haghighi and Klein (2010) use entity profiles to assist within-document coreference.

Since many related methods use clustering, there are a number of distributed clustering algorithms that may help scale these approaches. Datta et al. (2006) propose an algorithm for distributed k-means. Chen et al. (2010) describe a parallel spectral clustering algorithm. We use the Subsquare algorithm (Bshouty and Long, 2010) as baseline because it works well in practice. Mocian (2009) presents a survey of distributed clustering algorithms.

Rao et al. (2010) have proposed an online deterministic method that uses a stream of input mentions and assigns them greedily to entities. Although it can resolve mentions from non-trivial sized datasets, the method is restricted to a single machine, which is not scalable to the very large number of mentions that are encountered in practice.

Our representation of the problem as an undirected graphical model, and performing distributed inference on it, provides a combination of advantages not available in any of these approaches. First, most of the methods will not scale to the hundreds of millions of mentions that are present in real-world applications. By utilizing parallelism across machines, our method can run on very large datasets simply by increasing the number of machines used. Second, approaches that use clustering are limited to using pairwise distance functions for which additional supervision and features are difficult to incorporate. In addition to representing features from all of the related work, graphical models can also use more complex entity-wide features (Culotta et al., 2007; Wick et al., 2009a), and parameters can be learned using supervised (Collins, 2002) or semi-supervised techniques (Mann and McCallum, 2008). Finally, the inference for most of the related approaches is *greedy*, and earlier decisions are not revisited. Our technique is based on MCMC inference and simulated annealing, which are able to escape local maxima.

7 Conclusions

Motivated by the problem of solving the coreference problem on billions of mentions from all of the newswire documents from the past few decades, we make the following contributions. First, we introduce distributed version of MCMC-based inference technique that can utilize parallelism to enable scalability. Second, we augment the model with hierarchical variables that facilitate fruitful proposal distributions. As an additional contribution, we use links to Wikipedia pages to obtain a high-quality cross-document corpus. Scalability and accuracy gains of our method are evaluated on multiple datasets.

There are a number of avenues for future work. Although we demonstrate scalability to more than a million mentions, we plan to explore performance on datasets in the billions. We also plan to examine inference on complex coreference models (such as with entity-wide factors). Another possible avenue for future work is that of learning the factors. Since our approach supports parameter estimation, we expect significant accuracy gains with additional features and supervised data. Our work enables cross-document coreference on very large corpora, and we would like to explore the downstream applications that can benefit from it.

Abstract

We present an ILP-based model of zero anaphora detection and resolution that builds on the joint determination of anaphoricity and coreference model proposed by Denis and Baldridge (2007), but revises it and extends it into a three-way ILP problem also incorporating subject detection. We show that this new model outperforms several baselines and competing models, as well as a direct translation of the Denis / Baldridge model, for both Italian and Japanese zero anaphora. We incorporate our model in complete anaphoric resolvers for both Italian and Japanese, showing that our approach leads to improved performance also when not used in isolation, provided that separate classifiers are used for zeros and for explicitly realized anaphors.

1 Introduction

In so-called 'pro-drop' languages such as Japanese and many romance languages including Italian, phonetic realization is not required for anaphoric references in contexts in which in English non-contrastive pronouns are used: e.g., the subjects of Italian and Japanese translations of *buy* in (1b) and (1c) are not explicitly realized. We call these non-realized mandatory arguments **zero anaphors**.

(1) a. [EN] [John]$_i$ went to visit some friends. On the way, [he]$_i$ bought some wine.
b. [IT] [Giovanni]$_i$ andò a far visita a degli amici. Per via, ϕ_i comprò del vino.
c. [JA] [John]$_i$-wa yujin-o houmon-sita. Tochu-de ϕ_i wain-o ka-tta.

The felicitousness of zero anaphoric reference depends on the referred entity being sufficiently salient, hence this type of data–particularly in Japanese and Italian–played a key role in early work in coreference resolution, e.g., in the development of Centering (Kameyama, 1985; Walker et al., 1994; Di Eugenio, 1998). This research highlighted both commonalities and differences between the phenomenon in such languages. Zero anaphora resolution has remained a very active area of study for researchers working on Japanese, because of the prevalence of zeros in such languages[1] (Seki et al., 2002; Isozaki and Hirao, 2003; Iida et al., 2007a; Taira et al., 2008; Imamura et al., 2009; Sasano et al., 2009; Taira et al., 2010). But now the availability of corpora annotated to study anaphora, including zero anaphora, in languages such as Italian (e.g., Rodriguez et al. (2010)), and their use in competitions such as SEMEVAL 2010 Task 1 on Multilingual Coreference (Recasens et al., 2010), is leading to a renewed interest in zero anaphora resolution, particularly at the light of the mediocre results obtained on zero anaphors by most systems participating in SEMEVAL.

Resolving zero anaphora requires the simultaneous decision that one of the arguments of a verb is phonetically unrealized (and which argument exactly–in this paper, we will only be concerned with subject zeros as these are the only type to occur in Italian) and that a particular entity is its antecedent. It is therefore natural to view zero anaphora resolution as a joint inference

[1] As shown in Table 1, 64.3% of anaphors in the NAIST Text Corpus of Anaphora are zeros.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 804–813,
Portland, Oregon, June 19-24, 2011.

task, for which Integer Linear Programming (ILP)– introduced to NLP by Roth and Yih (2004) and successfully applied by Denis and Baldridge (2007) to the task of jointly inferring anaphoricity and determining the antecedent–would be appropriate.

In this work we developed, starting from the ILP system proposed by Denis and Baldridge, an ILP approach to zero anaphora detection and resolution that integrates (revised) versions of Denis and Baldridge's constraints with additional constraints between the values of three distinct classifiers, one of which is a novel one for subject prediction. We demonstrate that treating zero anaphora resolution as a three-way inference problem is successful for both Italian and Japanese. We integrate the zero anaphora resolver with a coreference resolver and demonstrate that the approach leads to improved results for both Italian and Japanese.

The rest of the paper is organized as follows. Section 2 briefly summarizes the approach proposed by Denis and Baldridge (2007). We next present our new ILP formulation in Section 3. In Section 4 we show the experimental results with zero anaphora only. In Section 5 we discuss experiments testing that adding our zero anaphora detector and resolver to a full coreference resolver would result in overall increase in performance. We conclude and discuss future work in Section 7.

2 Using ILP for joint anaphoricity and coreference determination

Integer Linear Programming (ILP) is a method for constraint-based inference aimed at finding the values for a set of variables that maximize a (linear) **objective function** while satisfying a number of constraints. Roth and Yih (2004) advocated ILP as a general solution for a number of NLP tasks that require combining multiple classifiers and which the traditional pipeline architecture is not appropriate, such as entity disambiguation and relation extraction.

Denis and Baldridge (2007) defined the following object function for the joint anaphoricity and coreference determination problem.

$$\min \sum_{\langle i,j\rangle \in P} c^{C}_{\langle i,j\rangle} \cdot x_{\langle i,j\rangle} + c^{-C}_{\langle i,j\rangle} \cdot (1 - x_{\langle i,j\rangle}) + \sum_{j \in M} c^{A}_{j} \cdot y_j + c^{-A}_{j} \cdot (1 - y_j) \quad (2)$$

subject to

$$x_{\langle i,j\rangle} \in \{0,1\} \qquad \forall \langle i,j\rangle \in P$$
$$y_j \in \{0,1\} \qquad \forall j \in M$$

M stands for the set of mentions in the document, and P the set of possible coreference links over these mentions. $x_{\langle i,j\rangle}$ is an indicator variable that is set to 1 if mentions i and j are coreferent, and 0 otherwise. y_j is an indicator variable that is set to 1 if mention j is anaphoric, and 0 otherwise. The costs $c^{C}_{\langle i,j\rangle} = -log(P(\mathrm{COREF}|i,j))$ are (logs of) probabilities produced by an antecedent identification classifier with $-log$, whereas $c^{A}_{j} = -log(P(\mathrm{ANAPH}|j))$, are the probabilities produced by an anaphoricity determination classifier with $-log$. In the Denis & Baldridge model, the search for a solution to antecedent identification and anaphoricity determination is guided by the following three constraints.

Resolve only anaphors: if a pair of mentions $\langle i,j\rangle$ is coreferent ($x_{\langle i,j\rangle} = 1$), then mention j must be anaphoric ($y_j = 1$).

$$x_{\langle i,j\rangle} \leq y_j \qquad \forall \langle i,j\rangle \in P \quad (3)$$

Resolve anaphors: if a mention is anaphoric ($y_j = 1$), it must be coreferent with at least one antecedent.

$$y_j \leq \sum_{i \in M_j} x_{\langle i,j\rangle} \qquad \forall j \in M \quad (4)$$

Do not resolve non-anaphors: if a mention is non-anaphoric ($y_j = 0$), it should have no antecedents.

$$y_j \geq \frac{1}{|M_j|} \sum_{i \in M_j} x_{\langle i,j\rangle} \qquad \forall j \in M \quad (5)$$

3 An ILP-based account of zero anaphora detection and resolution

In the corpora used in our experiments, zero anaphora is annotated using as markable the first verbal form (not necessarily the head) following the position where the argument would have been realized, as in the following example.

(6) [Pahor]$_i$ è nato a Trieste, allora porto principale dell'Impero Austro-Ungarico.
A sette anni [vide]$_i$ l'incendio del Narodni dom,

The proposal of Denis and Baldridge (2007) can be easily turned into a proposal for the task of detecting and resolving zero anaphora in this type of data by reinterpreting the indicator variables as follows:

- y_j is 1 if markable j (a verbal form) initiates a verbal complex whose subject is unrealized, 0 otherwise;
- $x_{\langle i,j \rangle}$ is 1 if the empty mention realizing the subject argument of markable j and markable i are mentions of the same entity, 0 otherwise.

There are however a number of ways in which this direct adaptation can be modified and extended. We discuss them in turn.

3.1 Best First

In the context of zero anaphora resolution, the 'Do not resolve non-anaphors' constraint (5) is too weak, as it allows the redundant choice of more than one candidate antecedent. We developed therefore the following alternative, that blocks selection of more than one antecedent.

Best First (BF):

$$y_j \geq \sum_{i \in M_j} x_{\langle i,j \rangle} \qquad \forall j \in M \qquad (7)$$

3.2 A subject detection model

The greatest difficulty in zero anaphora resolution in comparison to, say, pronoun resolution, is zero anaphora detection. Simply relying for this on the parser is not enough: most dependency parsers are not very accurate at identifying cases in which the verb does not have a subject on syntactic grounds only. Again, it seems reasonable to suppose this is because zero anaphora detection requires a combination of syntactic information and information about the current context. Within the ILP framework, this hypothesis can be implemented by turning the zero anaphora resolution optimization problem into one with *three* indicator variables, with the objective function in (8). The third variable, z_j, encodes the information provided by the parser: it is 1 with cost $c_j^S = -log(P(SUBJ|j))$ if the parser thinks that verb j has an explicit subject with probability $P(SUBJ|j)$, otherwise it is 0.

$$\begin{aligned} \min \sum_{\langle i,j \rangle \in P} & c^C_{\langle i,j \rangle} \cdot x_{\langle i,j \rangle} + c^{-C}_{\langle i,j \rangle} \cdot (1 - x_{\langle i,j \rangle}) \\ & + \sum_{j \in M} c^A_j \cdot y_j + c^{-A}_j \cdot (1 - y_j) \\ & + \sum_{j \in M} c^S_j \cdot z_j + c^{-S}_j \cdot (1 - z_j) \quad (8) \end{aligned}$$

$$\begin{aligned} \text{subject to} \\ x_{\langle i,j \rangle} &\in \{0,1\} && \forall \langle i,j \rangle \in P \\ y_j &\in \{0,1\} && \forall j \in M \\ z_j &\in \{0,1\} && \forall j \in M \end{aligned}$$

The crucial fact about the relation between z_j and y_j is that a verb has either a syntactically realized NP or a zero pronoun as a subject, but not both. This is encoded by the following constraint.

Resolve only non-subjects: if a predicate j syntactically depends on a subject ($z_j = 1$), then the predicate j should have no antecedents of its subject zero pronoun.

$$y_j + z_j \leq 1 \qquad \forall j \in M \qquad (9)$$

4 Experiment 1: zero anaphora resolution

In a first round of experiments, we evaluated the performance of the model proposed in Section 3 on zero anaphora only (i.e., not attempting to resolve other types of anaphoric expressions).

4.1 Data sets

We use the two data sets summarized in Table 1. The table shows that NP anaphora occurs more frequently than zero-anaphora in Italian, whereas in Japanese the frequency of anaphoric zero-anaphors[2] is almost double the frequency of the remaining anaphoric expressions.

Italian For Italian coreference, we used the annotated data set presented in Rodriguez et al. (2010) and developed for the Semeval 2010 task 'Coreference Resolution in Multiple Languages' (Recasens et al., 2010), where both zero-anaphora and NP

[2] In Japanese, like in Italian, zero anaphors are often used non-anaphorically, to refer to situationally introduced entities, as in *I went to John's office, but they told me that he had left.*

					#instances (anaphoric/total)		
language	type	#docs	#sentences	#words	zero-anaphors	others	all
Italian	train	97	3,294	98,304	1,093 / 1,160	6,747 / 27,187	7,840 / 28,347
	test	46	1,478	41,587	792 / 837	3,058 / 11,880	3,850 / 12,717
Japanese	train	1,753	24,263	651,986	18,526 / 29,544	10,206 / 161,124	28,732 / 190,668
	test	696	9,287	250,901	7,877 / 11,205	4,396 / 61,652	12,273 / 72,857

In the 6th column we use the term 'anaphoric' to indicate the number of zero anaphors that have an antecedent in the text, whereas the total figure is the sum of anaphoric and *exophoric* zero-anaphors - zeros with a vague / generic reference.

Table 1: Italian and Japanese Data Sets

coreference are annotated. This dataset consists of articles from Italian Wikipedia, tokenized, POS-tagged and morphologically analyzed using TextPro, a freely available Italian pipeline (Pianta et al., 2008). We parsed the corpus using the Italian version of the DESR dependency parser (Attardi et al., 2007).

In Italian, zero pronouns may only occur as omitted subjects of verbs. Therefore, in the task of zero-anaphora resolution all verbs appearing in a text are considered candidates for zero pronouns, and all gold mentions or system mentions preceding a candidate zero pronoun are considered as candidate antecedents. (In contrast, in the experiments on coreference resolution discussed in the following section, all mentions are considered as both candidate anaphors and candidate antecedents. To compare the results with gold mentions and with system detected mentions, we carried out an evaluation using the mentions automatically detected by the Italian version of the BART system (I-BART) (Poesio et al., 2010), which is freely downloadable.[3]

Japanese For Japanese coreference we used the NAIST Text Corpus (Iida et al., 2007b) version 1.4β, which contains the annotated data about NP coreference and zero-anaphoric relations. We also used the Kyoto University Text Corpus[4] that provides dependency relations information for the same articles as the NAIST Text Corpus. In addition, we also used a Japanese named entity tagger, *CaboCha*[5] for automatically tagging named entity labels. In the NAIST Text Corpus mention boundaries are not annotated, only the heads. Thus, we considered as pseudo-mentions all *bunsetsu* chunks (i.e. base phrases in Japanese) whose head part-of-speech was automatically tagged by the Japanese morphological analyser *Chasen*[6] as either 'noun' or 'unknown word' according to the NAIST-jdic dictionary.[7]

For evaluation, articles published from January 1st to January 11th and the editorials from January to August were used for training and articles dated January 14th to 17th and editorials dated October to December are used for testing as done by Taira et al. (2008) and Imamura et al. (2009). Furthermore, in the experiments we only considered *subject* zero pronouns for a fair comparison to Italian zero-anaphora.

4.2 Models

In these first experiments we compared the three ILP-based models discussed in Section 3: the direct reimplementation of the Denis and Baldridge proposal (i.e., using the same constrains), a version replacing Do-Not-Resolve-Not-Anaphors with Best-First, and a version with Subject Detection as well.

As discussed by Iida et al. (2007a) and Imamura et al. (2009), useful features in intra-sentential zero-anaphora are different from ones in inter-sentential zero-anaphora because in the former problem syntactic information between a zero pronoun and its candidate antecedent is essential, while the latter needs to capture the significance of saliency based on Centering Theory (Grosz et al., 1995). To directly reflect this difference, we created two antecedent identification models; one for intra-sentential zero-anaphora, induced using the training instances which a zero pronoun and its candidate antecedent appear in the same sentences, the other for

[3] http://www.bart-coref.org/

[4] http://www-lab25.kuee.kyoto-u.ac.jp/nl-resource/corpus.html

[5] http://chasen.org˜taku/software/cabocha/

[6] http://chasen-legacy.sourceforge.jp/

[7] http://sourceforge.jp/projects/naist-jdic/

inter-sentential cases, induced from the remaining training instances.

To estimate the feature weights of each classifier, we used MEGAM[8], an implementation of the Maximum Entropy model, with default parameter settings. The ILP-based models were compared with the following baselines.

PAIRWISE: as in the work by Soon et al. (2001), antecedent identification and anaphoricity determination are simultaneously executed by a single classifier.

DS-CASCADE: the model first filters out non-anaphoric candidate anaphors using an anaphoricity determination model, then selects an antecedent from a set of candidate antecedents of anaphoric candidate anaphors using an antecedent identification model.

4.3 Features

The feature sets for antecedent identification and anaphoricity determination are briefly summarized in Table 2 and Table 3, respectively. The agreement features such as NUM_AGREE and GEN_AGREE are automatically derived using TextPro. Such agreement features are not available in Japanese because Japanese words do not contain such information.

4.4 Creating subject detection models

To create a subject detection model for Italian, we used the TUT corpus[9] (Bosco et al., 2010), which contains manually annotated dependency relations and their labels, consisting of 80,878 tokens in CoNLL format. We induced an maximum entropy classifier by using as items all arcs of dependency relations, each of which is used as a positive instance if its label is subject; otherwise it is used as a negative instance.

To train the Japanese subject detection model we used 1,753 articles contained both in the NAIST Text Corpus and the Kyoto University Text Corpus. By merging these two corpora, we can obtain the annotated data including which dependency arc is subject[10]. To create the training instances, any pair of a predicate and its dependent are extracted, each of which is judged as positive if its relation is subject; as negative otherwise.

feature	description
SUBJ_PRE	1 if subject is included in the preceding words of *ZERO* in a sentence; otherwise 0.
TOPIC_PRE*	1 if topic case marker appears in the preceding words of *ZERO* in a sentence; otherwise 0.
NUM_PRE (GEN_PRE)	1 if a candidate which agrees with *ZERO* with regards to number (gender) is included in the set of *NP*; otherwise 0.
FIRST_SENT	1 if ZERO appears in the first sentence of a text; otherwise 0.
FIRST_WORD	1 if the predicate which has *ZERO* is the first word in a sentence; otherwise 0.
POS / LEMMA / DEP_LABEL	part-of-speech / dependency label / lemma of the predicate which has *ZERO*.
D_POS / D_LEMMA / D_DEP_LABEL	part-of-speech / dependency label / lemma of the dependents of the predicate which has *ZERO*.
PATH*	dependency labels (functional words) of words intervening between a *ZERO* and the sentence head

The features marked with '*' used only in Japanese.

Table 3: Features for anaphoricity determination

As features for Italian, we used lemmas, PoS tag of a predicate and its dependents as well as their morphological information (i.e. gender and number) automatically computed by TextPro (Pianta et al., 2008). For Japanese, the head lemmas of predicate and dependent chunks as well as the functional words involved with these two chunks were used as features. One case specially treated is when a dependent is placed as an adnominal constituent of a predicate, as in this case relation estimation of dependency arcs is difficult. In such case we instead use the features shown in Table 2 for accurate estimation.

4.5 Results with zero anaphora only

In zero anaphora resolution, we need to find all predicates that have *anaphoric* unrealized subjects (i.e. zero pronouns which have an antecedent in a text), and then identify an antecedent for each such argument.

The Italian and Japanese test data sets contain 4,065 and 25,467 verbal predicates respectively. The performance of each model at zero-anaphora detection and resolution is shown in Table 4, using recall

[8] http://www.cs.utah.edu/~hal/megam/

[9] http://www.di.unito.it/~tutreeb/

[10] Note that Iida et al. (2007b) referred to this relation as 'nominative'.

feature	description
HEAD_LEMMA	characters of the head lemma in *NP*.
POS	part-of-speech of *NP*.
DEFINITE	1 if *NP* contains the article corresponding to DEFINITE 'the'; otherwise 0.
DEMONSTRATIVE	1 if *NP* contains the article corresponding to DEMONSTRATIVE such as 'that' and 'this'; otherwise 0.
POSSESSIVE	1 if *NP* contains the article corresponding to POSSESSIVE such as 'his' and 'their'; otherwise 0.
CASE_MARKER**	case marker followed by *NP*, such as '*wa* (topic)', '*ga* (subject)', '*o* (object)'.
DEP_LABEL*	dependency label of *NP*.
COOC_MI**	the score of well-formedness model estimated from a large number of triplets ⟨ *NP*, Case, Predicate⟩.
FIRST_SENT	1 if *NP* appears in the first sentence of a text; otherwise 0.
FIRST_MENTION	1 if *NP* first appears in the set of candidate antecedents; otherwise 0.
CL_RANK**	a rank of *NP* in forward looking-center list based on Centering Theory (Grosz et al., 1995)
CL_ORDER**	a order of *NP* in forward looking-center list based on Centering Theory (Grosz et al., 1995)
PATH	dependency labels (functional words) of words intervening between a *ZERO* and *NP*
NUM_(DIS)AGREE	1 if *NP* (dis)agrees with *ZERO* with regards to number; otherwise 0.
GEN_(DIS)AGREE	1 if *NP* (dis)agrees with *ZERO* with regards to gender; otherwise 0.
HEAD_MATCH	1 if *ANA* and *NP* have the same head lemma; otherwise 0.
REGEX_MATCH	1 if the string of NP subsumes the string of ANA; otherwise 0.
COMP_MATCH	1 if *ANA* and *NP* have the same string; otherwise 0.

NP, *ANA* and *ZERO* stand for a candidate antecedent, a candidate anaphor and a candidate zero pronoun respectively. The features marked with '*' are only used in Italian, while the features marked with '**' are only used in Japanese.

Table 2: Features used for antecedent identification

Table 4: Results on zero pronouns

/ precision / F over link detection as a metric (model theoretic metrics do not apply for this task as only subsets of coreference chains are considered). As can be seen from Table 4, the ILP version with Do-Not-Resolve-Non-Anaphors performs no better than the baselines for either languages, but in both languages replacing that constraint with Best-First results in a performance above the baselines; adding Subject Detection results in further improvement for both languages. Notice also that the performance of the models on Italian is quite a bit higher than for Japanese although the dataset is much smaller, possibly meaning that the task is easier in Italian.

5 Experiment 2: coreference resolution for all anaphors

In a second series of experiments we evaluated the performance of our models together with a full coreference system resolving all anaphors, not just zeros.

5.1 Separating vs combining classifiers

Different types of nominal expressions display very different anaphoric behavior: e.g., pronoun resolution involves very different types of information from nominal expression resolution, depending more on syntactic information and on the local context and less on commonsense knowledge. But the most common approach to coreference resolu-

tion (Soon et al., 2001; Ng and Cardie, 2002, etc.) is to use a single classifier to identify antecedents of all anaphoric expressions, relying on the ability of the machine learning algorithm to learn these differences. These models, however, often fail to capture the differences in anaphoric behavior between different types of expressions–one of the reasons being that the amount of training instances is often too small to learn such differences.[11] Using different models would appear to be key in the case of zero-anaphora resolution, which differs even more from the rest of anaphora resolution, e.g., in being particularly sensitive to local salience, as amply discussed in the literature on Centering discussed earlier.

To test the hypothesis that using what we will call *separated models* for zero anaphora and everything else would work better than *combined models* induced from all the learning instances, we manually split the training instances in terms of these two anaphora types and then created two classifiers for antecedent identification: one for zero-anaphora, the other for NP-anaphora, separately induced from the corresponding training instances. Likewise, anaphoricity determination models were separately induced with regards to these two anaphora types.

5.2 Results with all anaphors

In Table 5 and Table 6 we show the (MUC scorer) results obtained by adding the zero anaphoric resolution models proposed in this paper to both a combined and a separated classifier. For the separated classifier, we use the ILP+BF model for explicitly realized NPs, and different ILP models for zeros.

The results show that the separated classifier works systematically better than a combined classifier. For both Italian and Japanese the ILP+BF+SUBJ model works clearly better than the baselines, whereas simply applying the original Denis and Baldridge model unchanged to this case we obtain worse results than the baselines. For Italian we could also compare our results with those obtained on the same dataset by one of the two systems that participated to the Italian section of SEMEVAL, I-BART. I-BART's results are clearly better than those with both baselines, but also clearly inferior to the results obtained with our models. In particular, the effect of introducing the separated model with ILP+BF+SUBJ is more significant when using the system detected mentions; it obtained performance more than 13 points better than I-BART when the model referred to the system detected mentions.

[11] E.g., the entire MUC-6 corpus contains a grand total of 3 reflexive pronouns.

6 Related work

We are not aware of any previous machine learning model for zero anaphora in Italian, but there has been quite a lot of work on Japanese zero-anaphora (Iida et al., 2007a; Taira et al., 2008; Imamura et al., 2009; Taira et al., 2010; Sasano et al., 2009). In work such as Taira et al. (2008) and Imamura et al. (2009), zero-anaphora resolution is considered as a sub-task of predicate argument structure analysis, taking the NAIST text corpus as a target data set. Taira et al. (2008) and Taira et al. (2010) applied decision lists and transformation-based learning respectively in order to manually analyze which clues are important for each argument assignment. Imamura et al. (2009) also tackled to the same problem setting by applying a pairwise classifier for each argument. In their approach, a 'null' argument is explicitly added into the set of candidate argument to learn the situation where an argument of a predicate is 'exophoric'. They reported their model achieved better performance than the work by Taira et al. (2008).

Iida et al. (2007a) also used the NAIST text corpus. They adopted the BACT learning algorithm (Kudo and Matsumoto, 2004) to effectively learn subtrees useful for both antecedent identification and zero pronoun detection. Their model drastically outperformed a simple pairwise model, but it is still performed as a cascaded process. Incorporating

their model into the ILP formulation proposed here looks like a promising further extension.

Sasano et al. (2009) obtained interesting experimental results about the relationship between zero-anaphora resolution and the scale of automatically acquired case frames. In their work, their case frames were acquired from a very large corpus consisting of 100 billion words. They also proposed a probabilistic model to Japanese zero-anaphora in which an argument assignment score is estimated based on the automatically acquired case frames. They concluded that case frames acquired from larger corpora lead to better f-score on zero-anaphora resolution.

In contrast to these approaches in Japanese, the participants to Semeval 2010 task 1 (especially the Italian coreference task) simply solved the problems using one coreference classifier, not distinguishing zero-anaphora from the other types of anaphora (Kobdani and Schütze, 2010; Poesio et al., 2010). On the other hand, our approach shows separating problems contributes to improving performance in Italian zero-anaphora. Although we used gold mentions in our evaluations, mention detection is also essential. As a next step, we also need to take into account ways of incorporating a mention detection model into the ILP formulation.

7 Conclusion

In this paper, we developed a new ILP-based model of zero anaphora detection and resolution that extends the coreference resolution model proposed by Denis and Baldridge (2007) by introducing modified constraints and a subject detection model. We evaluated this model both individually and as part of the overall coreference task for both Italian and Japanese zero anaphora, obtaining clear improvements in performance.

One avenue for future research is motivated by the observation that whereas introducing the subject detection model and the best-first constraint results in higher precision maintaining the recall compared to the baselines, that precision is still low. One of the major source of the errors is that zero pronouns are frequently used in Italian and Japanese in contexts in which in English as so-called *generic they* would be used: "*I walked into the hotel and (they) said ..*". In such case, the zero pronoun detection model is often incorrect. We are considering adding a generic they detection component.

We also intend to experiment with introducing more sophisticated antecedent identification models in the ILP framework. In this paper, we used a very basic pairwise classifier; however Yang et al. (2008) and Iida et al. (2003) showed that the relative comparison of two candidate antecedents leads to obtaining better accuracy than the pairwise model. However, these approaches do not output absolute probabilities, but relative significance between two candidates, and therefore cannot be directly integrated with the ILP-framework. We plan to examine ways of appropriately estimating an absolute score from a set of relative scores for further refinement.

Finally, we would like to test our model with English constructions which closely resemble zero anaphora. One example were studied in the Semeval 2010 'Linking Events and their Participants in Discourse' task, which provides data about *null instan-*

tiation, omitted arguments of predicates like "*We arrived ϕ^{goal} at 8pm.*". (Unfortunately the dataset available for SEMEVAL was very small.) Another interesting area of application of these techniques would be VP ellipsis.

Acknowledgments

Ryu Iida's stay in Trento was supported by the Excellent Young Researcher Overseas Visit Program of the Japan Society for the Promotion of Science (JSPS). Massimo Poesio was supported in part by the Provincia di Trento Grande Progetto LiveMemories, which also funded the creation of the Italian corpus used in this study. We also wish to thank Francesca Delogu, Kepa Rodriguez, Olga Uryupina and Yannick Versley for much help with the corpus and BART.

Coreference Resolution with World Knowledge

Altaf Rahman and **Vincent Ng**

{altaf,vince}@hlt.utdallas.edu

Abstract

While world knowledge has been shown to improve learning-based coreference resolvers, the improvements were typically obtained by incorporating world knowledge into a fairly weak baseline resolver. Hence, it is not clear whether these benefits can carry over to a stronger baseline. Moreover, since there has been no attempt to apply different sources of world knowledge in combination to coreference resolution, it is not clear whether they offer complementary benefits to a resolver. We systematically compare commonly-used and under-investigated sources of world knowledge for coreference resolution by applying them to two learning-based coreference models and evaluating them on documents annotated with two different annotation schemes.

1 Introduction

Noun phrase (NP) coreference resolution is the task of determining which NPs in a text or dialogue refer to the same real-world entity. The difficulty of the task stems in part from its reliance on world knowledge (Charniak, 1972). To exemplify, consider the following text fragment.

Martha Stewart is hoping people don't run out on her. The celebrity indicted on charges stemming from . . .

Having the (world) knowledge that *Martha Stewart* is a *celebrity* would be helpful for establishing the coreference relation between the two NPs. One may argue that employing heuristics such as subject preference or syntactic parallelism (which prefers resolving an NP to a candidate antecedent that has the same grammatical role) in this example would also allow us to correctly resolve *the celebrity* (Mitkov, 2002), thereby obviating the need for world knowledge. However, since these heuristics are not perfect, complementing them with world knowledge would be an important step towards bringing coreference systems to the next level of performance.

Despite the usefulness of world knowledge for coreference resolution, early learning-based coreference resolvers have relied mostly on morpho-syntactic features (e.g., Soon et al. (2001), Ng and Cardie (2002), Yang et al. (2003)). With recent advances in lexical semantics research and the development of large-scale knowledge bases, researchers have begun to employ world knowledge for coreference resolution. World knowledge is extracted primarily from three data sources, web-based encyclopedia (e.g., Ponzetto and Strube (2006), Uryupina et al. (2011)), unannotated data (e.g., Daumé III and Marcu (2005), Ng (2007)), and coreference-annotated data (e.g., Bengtson and Roth (2008)).

While each of these three sources of world knowledge has been shown to improve coreference resolution, the improvements were typically obtained by incorporating world knowledge (as features) into a baseline resolver composed of a rather weak coreference model (i.e., the mention-pair model) and a small set of features (i.e., the 12 features adopted by Soon et al.'s (2001) knowledge-lean approach). As a result, some questions naturally arise. First, can world knowledge still offer benefits when used in combination with a richer set of features? Second, since automatically extracted world knowledge is typically noisy (Ponzetto and Poesio, 2009), are recently-developed coreference models more noise-tolerant than the mention-pair model, and if so, can they profit more from the noisily extracted world knowledge? Finally, while different world knowl-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 814–824,
Portland, Oregon, June 19-24, 2011.

edge sources have been shown to be useful when applied in isolation to a coreference system, do they offer complementary benefits and therefore can further improve a resolver when applied in combination?

We seek answers to these questions by conducting a systematic evaluation of different world knowledge sources for learning-based coreference resolution. Specifically, we (1) derive world knowledge from encyclopedic sources that are under-investigated for coreference resolution, including FrameNet (Baker et al., 1998) and YAGO (Suchanek et al., 2007), in addition to coreference-annotated data and unannotated data; (2) incorporate such knowledge as features into a richer baseline feature set that we previously employed (Rahman and Ng, 2009); and (3) evaluate their utility using two coreference models, the traditional mention-pair model (Soon et al., 2001) and the recently developed cluster-ranking model (Rahman and Ng, 2009).

Our evaluation corpus contains 410 documents, which are coreference-annotated using the ACE annotation scheme as well as the OntoNotes annotation scheme (Hovy et al., 2006). By evaluating on two sets of coreference annotations for the same set of documents, we can determine whether the usefulness of world knowledge sources for coreference resolution is dependent on the underlying annotation scheme used to annotate the documents.

2 Preliminaries

In this section, we describe the corpus, the NP extraction methods, the coreference models, and the evaluation measures we will use in our evaluation.

2.1 Data Set

We evaluate on documents that are coreference-annotated using both the ACE annotation scheme and the OntoNotes annotation scheme, so that we can examine whether the usefulness of our world knowledge sources is dependent on the underlying coreference annotation scheme. Specifically, our data set is composed of the 410 English newswire articles that appear in both OntoNotes-2 and ACE 2004/2005. We partition the documents into a training set and a test set following a 80/20 ratio.

ACE and OntoNotes employ different guidelines to annotate coreference chains. A major difference between the two annotation schemes is that ACE only concerns establishing coreference chains among NPs that belong to the ACE entity types, whereas OntoNotes does not have this restriction. Hence, the OntoNotes annotation scheme should produce more coreference chains (i.e., non-singleton coreference clusters) than the ACE annotation scheme for a given set of documents. For our data set, the OntoNotes scheme yielded 4500 chains, whereas the ACE scheme yielded only 3637 chains.

Another difference between the two annotation schemes is that singleton clusters are annotated in ACE but not OntoNotes. As discussed below, the presence of singleton clusters may have an impact on NP extraction and coreference evaluation.

2.2 NP Extraction

Following common practice, we employ different methods to extract NPs from the documents annotated with the two annotation schemes.

To extract NPs from the ACE-annotated documents, we train a mention extractor on the training texts (see Section 5.1 of Rahman and Ng (2009) for details), which recalls 83.6% of the NPs in the test set. On the other hand, to extract NPs from the OntoNotes-annotated documents, the same method should not be applied. To see the reason, recall that only the NPs in non-singleton clusters are annotated in these documents. Training a mention extractor on these NPs implies that we are learning to extract *non-singleton NPs*, which are typically much smaller in number than the entire set of NPs. In other words, doing so could substantially simplify the coreference task. Consequently, we follow the approach adopted by traditional learning-based resolvers and employ an NP chunker to extract NPs. Specifically, we use the markable identification system in the Reconcile resolver (Stoyanov et al., 2010) to extract NPs from the training and test texts. This identifier recalls 77.4% of the NPs in the test set.

2.3 Coreference Models

We evaluate the utility of world knowledge using the mention-pair model and the cluster-ranking model.

2.3.1 Mention-Pair Model

The mention-pair (MP) model is a classifier that determines whether two NPs are coreferent or not.

Each instance $\boldsymbol{i}(\text{NP}_j, \text{NP}_k)$ corresponds to NP_j and NP_k, and is represented by a Baseline feature set consisting of 39 features. Linguistically, these features can be divided into four categories: string-matching, grammatical, semantic, and positional. These features can also be categorized based on whether they are relational or not. Relational features capture the relationship between NP_j and NP_k, whereas non-relational features capture the linguistic property of one of these two NPs. Since space limitations preclude a description of these features, we refer the reader to Rahman and Ng (2009) for details.

We follow Soon et al.'s (2001) method for creating training instances: we create (1) a positive instance for each anaphoric NP, NP_k, and its closest antecedent, NP_j; and (2) a negative instance for NP_k paired with each of the intervening NPs, NP_{j+1}, NP_{j+2}, ..., NP_{k-1}. The classification of a training instance is either positive or negative, depending on whether the two NPs are coreferent in the associated text. To train the MP model, we use the SVM learning algorithm from SVM^{light} (Joachims, 2002).[1]

After training, the classifier is used to identify an antecedent for an NP in a test text. Specifically, each NP, NP_k, is compared in turn to each preceding NP, NP_j, from right to left, and NP_j is selected as its antecedent if the pair is classified as coreferent. The process terminates as soon as an antecedent is found for NP_k or the beginning of the text is reached.

Despite its popularity, the MP model has two major weaknesses. First, since each candidate antecedent for an NP to be resolved (henceforth an *active NP*) is considered independently of the others, this model only determines how good a candidate antecedent is relative to the active NP, but not how good a candidate antecedent is relative to other candidates. So, it fails to answer the critical question of which candidate antecedent is most probable. Second, it has limitations in its expressiveness: the information extracted from the two NPs alone may not be sufficient for making a coreference decision.

2.3.2 Cluster-Ranking Model

The cluster-ranking (CR) model addresses the two weaknesses of the MP model by combining the strengths of the *entity-mention* model (e.g., Luo et al. (2004), Yang et al. (2008)) and the *mention-ranking* model (e.g., Denis and Baldridge (2008)). Specifically, the CR model ranks the preceding clusters for an active NP so that the highest-ranked cluster is the one to which the active NP should be linked. Employing a ranker addresses the first weakness, as a ranker allows all candidates to be compared *simultaneously*. Considering preceding clusters rather than antecedents as candidates addresses the second weakness, as *cluster-level* features (i.e., features that are defined over any subset of NPs in a preceding cluster) can be employed. Details of the CR model can be found in Rahman and Ng (2009).

Since the CR model ranks preceding clusters, a training instance $\boldsymbol{i}(c_j, \text{NP}_k)$ represents a preceding cluster, c_j, and an anaphoric NP, NP_k. Each instance consists of features that are computed based solely on NP_k as well as cluster-level features, which describe the relationship between c_j and NP_k. Motivated in part by Culotta et al. (2007), we create cluster-level features from the *relational* features in our feature set using four predicates: NONE, MOST-FALSE, MOST-TRUE, and ALL. Specifically, for each relational feature X, we first convert X into an equivalent set of binary-valued features if it is multi-valued. Then, for each resulting binary-valued feature X_b, we create four binary-valued cluster-level features: (1) NONE-X_b is true when X_b is false between NP_k and each NP in c_j; (2) MOST-FALSE-X_b is true when X_b is true between NP_k and less than half (but at least one) of the NPs in c_j; (3) MOST-TRUE-X_b is true when X_b is true between NP_k and at least half (but not all) of the NPs in c_j; and (4) ALL-X_b is true when X_b is true between NP_k and each NP in c_j.

We train a cluster ranker to jointly learn anaphoricity determination and coreference resolution using SVM^{light}'s ranker-learning algorithm. Specifically, for each NP, NP_k, we create a training instance between NP_k and *each* preceding cluster c_j using the features described above. Since we are learning a joint model, we need to provide the ranker with the option to start a new cluster by creating an additional training instance that contains the non-relational features describing NP_k. The rank value of a training instance $\boldsymbol{i}(c_j, \text{NP}_k)$ created for NP_k is the rank of c_j among the competing clusters. If NP_k is anaphoric, its rank is HIGH if NP_k belongs to c_j, and LOW otherwise. If NP_k is non-anaphoric, its rank is

[1] For this and subsequent uses of the SVM learner in our experiments, we set all parameters to their default values.

LOW unless it is the additional training instance described above, which has rank HIGH.

After training, the cluster ranker processes the NPs in a test text in a left-to-right manner. For each active NP, NP_k, we create test instances for it by pairing it with each of its preceding clusters. To allow for the possibility that NP_k is non-anaphoric, we create an additional test instance as during training. All these test instances are then presented to the ranker. If the additional test instance is assigned the highest rank value, then we create a new cluster containing NP_k. Otherwise, NP_k is linked to the cluster that has the highest rank. Note that the partial clusters preceding NP_k are formed incrementally based on the predictions of the ranker for the first $k-1$ NPs.

2.4 Evaluation Measures

We employ two commonly-used scoring programs, B^3 (Bagga and Baldwin, 1998) and CEAF (Luo, 2005), both of which report results in terms of recall (R), precision (P), and F-measure (F) by comparing the gold-standard (i.e., key) partition, KP, against the system-generated (i.e., response) partition, RP.

Briefly, B^3 computes the R and P values of each NP and averages these values at the end. Specifically, for each NP, NP_j, B^3 first computes the number of common NPs in KP_j and RP_j, the clusters containing NP_j in KP and RP, respectively, and then divides this number by $|KP_j|$ and $|RP_j|$ to obtain the R and P values of NP_j, respectively. On the other hand, CEAF finds the best one-to-one alignment between the key clusters and the response clusters.

A complication arises when B^3 is used to score a response partition containing automatically extracted NPs. Recall that B^3 constructs a mapping between the NPs in the response and those in the key. Hence, if the response is generated using gold-standard NPs, then every NP in the response is mapped to some NP in the key and vice versa. In other words, there are no *twinless* (i.e., unmapped) NPs (Stoyanov et al., 2009). This is not the case when automatically extracted NPs are used, but the original description of B^3 does not specify how twinless NPs should be scored (Bagga and Baldwin, 1998). To address this problem, we set the recall and precision of a twinless NP to zero, regardless of whether the NP appears in the key or the response. Note that CEAF can compare partitions with twinless NPs without any modification, since it operates by finding the best alignment between the clusters in the two partitions.

Additionally, in order not to over-penalize a response partition, we remove all the twinless NPs in the response that are singletons. The rationale is simple: since the resolver has successfully identified these NPs as singletons, it should not be penalized, and removing them avoids such penalty.

Since B^3 and CEAF align NPs/clusters, the lack of singleton clusters in the OntoNotes annotations implies that the resulting scores reflect solely how well a resolver identifies coreference links and do not take into account how well it identifies singleton clusters.

3 Extracting World Knowledge

In this section, we describe how we extract world knowledge for coreference resolution from three different sources: large-scale knowledge bases, coreference-annotated data and unannotated data.

3.1 World Knowledge from Knowledge Bases

We extract world knowledge from two large-scale knowledge bases, YAGO and FrameNet.

3.1.1 Extracting Knowledge from YAGO

We choose to employ YAGO rather than the more popularly-used Wikipedia due to its potentially richer knowledge, which comprises 5 million facts extracted from Wikipedia and WordNet. Each fact is represented as a triple (NP_j, rel, NP_k), where rel is one of the 90 YAGO relation types defined on two NPs, NP_j and NP_k. Motivated in part by previous work (Bryl et al., 2010; Uryupina et al., 2011), we employ the two relation types that we believe are most useful for coreference resolution, TYPE and MEANS. TYPE is essentially an IS-A relation. For instance, the triple (`AlbertEinstein`, TYPE, `physicist`) denotes the fact that *Albert Einstein* is a physicist. MEANS provides different ways of expressing an entity, and therefore allows us to deal with synonymy and ambiguity. For instance, the two triples (`Einstein`, MEANS, `AlbertEinstein`) and (`Einstein`, MEANS, `AlfredEinstein`) denote the facts that *Einstein* may refer to the physicist *Albert Einstein* and the musicologist *Alfred Einstein*, respectively. Hence, the presence of one or

both of these relations between two NPs provides strong evidence that the two NPs are coreferent.

YAGO's unification of the information in Wikipedia and WordNet enables it to extract facts that cannot be extracted with Wikipedia or WordNet alone, such as (`MarthaStewart`, TYPE, `celebrity`). To better appreciate YAGO's strengths, let us see how this fact was extracted. YAGO first heuristically maps each of the Wiki categories in the Wiki page for *Martha Stewart* to its semantically closest WordNet synset. For instance, the Wiki category AMERICAN TELEVISION PERSONALITIES is mapped to the synset corresponding to sense #2 of the word *personality*. Then, given that *personality* is a direct hyponym of *celebrity* in WordNet, YAGO extracts the desired fact. This enables YAGO to extract facts that cannot be extracted with Wikipedia or WordNet alone.

We incorporate the world knowledge from YAGO into our coreference models as a binary-valued feature. If the MP model is used, the YAGO feature for an instance will have the value 1 if and only if the two NPs involved are in a TYPE or MEANS relation. On the other hand, if the CR model is used, the YAGO feature for an instance involving NP_k and preceding cluster c will have the value 1 if and only if NP_k has a TYPE or MEANS relation with any of the NPs in c. Since knowledge extraction from web-based encyclopedia is typically noisy (Ponzetto and Poesio, 2009), we use YAGO to determine whether two NPs have a relation only if one NP is a named entity (NE) of type person, organization, or location according to the Stanford NE recognizer (Finkel et al., 2005) and the other NP is a common noun.

3.1.2 Extracting Knowledge from FrameNet

FrameNet is a lexico-semantic resource focused on semantic frames (Baker et al., 1998). As a schematic representation of a situation, a frame contains the *lexical predicates* that can invoke it as well as the *frame elements* (i.e., semantic roles). For example, the JUDGMENT_COMMUNICATION frame describes situations in which a COMMUNICATOR communicates a judgment of an EVALUEE to an ADDRESSEE. This frame has COMMUNICATOR and EVALUEE as its core frame elements and ADDRESSEE as its non-core frame elements, and can be invoked by more than 40 predicates, such as *acclaim*, *accuse*, *commend*, *decry*, *denounce*, *praise*, and *slam*.

To better understand why FrameNet contains potentially useful knowledge for coreference resolution, consider the following text segment:

Peter Anthony decries program trading as "limiting the game to a few," but he is not sure whether he wants to denounce it because ...

To establish the coreference relation between *it* and *program trading*, it may be helpful to know that *decry* and *denounce* appear in the same frame and the two NPs have the same semantic role.

This example suggests that features encoding both the semantic roles of the two NPs under consideration and whether the associated predicates are "related" to each other in FrameNet (i.e., whether they appear in the same frame) could be useful for identifying coreference relations. Two points regarding our implementation of these features deserve mention. First, since we do not employ verb sense disambiguation, we consider two predicates *related* as long as there is at least one semantic frame in which they both appear. Second, since FrameNet-style semantic role labelers are not publicly available, we use ASSERT (Pradhan et al., 2004), a semantic role labeler that provides PropBank-style semantic roles such as ARG0 (the PROTOAGENT, which is typically the subject of a transitive verb) and ARG1 (the PROTOPATIENT, which is typically its direct object).

Now, assuming that NP_j and NP_k are the arguments of two stemmed predicates, $pred_j$ and $pred_k$, we create 15 features using the knowledge extracted from FrameNet and ASSERT as follows. First, we encode the knowledge extracted from FrameNet as one of three possible values: (1) $pred_j$ and $pred_k$ are in the same frame; (2) they are both predicates in FrameNet but never appear in the same frame; and (3) one or both predicates do not appear in FrameNet. Second, we encode the semantic roles of NP_j and NP_k as one of five possible values: ARG0-ARG0, ARG1-ARG1, ARG0-ARG1, ARG1-ARG0, and OTHERS (the default case).[2] Finally, we create 15 binary-valued features by pairing the 3 possible values extracted from FrameNet and the 5 possible values provided by ASSERT. Since these features

[2] We focus primarily on ARG0 and ARG1 because they are the most important core arguments of a predicate and may provide more useful information than other semantic roles.

are computed over two NPs, we can employ them directly for the MP model. Note that by construction, exactly one of these features will have a non-zero value. For the CR model, we extend their definitions so that they can be computed between an NP, NP_k, and a preceding cluster, c. Specifically, the value of a feature is 1 if and only if its value between NP_k and one of the NPs in c is 1 under its original definition.

The above discussion assumes that the two NPs under consideration serve as predicate arguments. If this assumption fails, we will not create any features based on FrameNet for these two NPs.

To our knowledge, FrameNet has not been exploited for coreference resolution. However, the use of related verbs is similar in spirit to Bean and Riloff's (2004) use of patterns for inducing contextual role knowledge, and the use of semantic roles is also discussed in Ponzetto and Strube (2006).

3.2 World Knowledge from Annotated Data

Since world knowledge is needed for coreference resolution, a human annotator must have employed world knowledge when coreference-annotating a document. We aim to design features that can "recover" such world knowledge from annotated data.

3.2.1 Features Based on Noun Pairs

A natural question is: what kind of world knowledge can we extract from annotated data? We may gather the knowledge that *Barack Obama* is a *U.S. president* if we see these two NPs appearing in the same coreference chain. Equally importantly, we may gather the commonsense knowledge needed for determining *non-coreference*. For instance, we may discover that a *lion* and a *tiger* are unlikely to refer to the same real-world entity after realizing that they never appear in the same chain in a large number of annotated documents. Note that any features computed based on WordNet distance or distributional similarity are likely to incorrectly suggest that *lion* and *tiger* are coreferent, since the two nouns are similar distributionally and according to WordNet.

Given these observations, one may collect the noun pairs from the (coreference-annotated) training data and use them as features to train a resolver. However, for these features to be effective, we need to address *data sparseness*, as many noun pairs in the training data may not appear in the test data.

To improve generalization, we instead create different kinds of *noun-pair-based* features given an annotated text. To begin with, we preprocess each document. A *training* text is preprocessed by randomly replacing 10% of its common nouns with the label UNSEEN. If an NP, NP_k, is replaced with UNSEEN, all NPs that have the same string as NP_k will also be replaced with UNSEEN. A *test* text is preprocessed differently: we simply replace all NPs whose strings are not seen in the training data with UNSEEN. Hence, artificially creating UNSEEN labels from a training text will allow a learner to learn how to handle unseen words in a test text.

Next, we create *noun-pair-based features* for the MP model, which will be used to augment the Baseline feature set. Here, each instance corresponds to two NPs, NP_j and NP_k, and is represented by three groups of *binary-valued* features.

Unseen features are applicable when both NP_j and NP_k are UNSEEN. Either an UNSEEN-SAME feature or an UNSEEN-DIFF feature is created, depending on whether the two NPs are the same string before being replaced with the UNSEEN token.

Lexical features are applicable when neither NP_j nor NP_k is UNSEEN. A lexical feature is an ordered pair consisting of the heads of the NPs. For a pronoun or a common noun, the head is the last word of the NP; for a proper name, the head is the entire NP.

Semi-lexical features aim to improve generalization, and are applicable when neither NP_j nor NP_k is UNSEEN. If exactly one of NP_j and NP_k is tagged as a NE by the Stanford NE recognizer, we create a semi-lexical feature that is identical to the lexical feature described above, except that the NE is replaced with its NE label. On the other hand, if both NPs are NEs, we check whether they are the same string. If so, we create a *NE*-SAME feature, where *NE* is replaced with the corresponding NE label. Otherwise, we check whether they have the same NE tag *and* a word-subset match (i.e., whether the word tokens in one NP appears in the other's list of word tokens). If so, we create a *NE*-SUBSAME feature, where *NE* is replaced with their NE label. Otherwise, we create a feature that is the concatenation of the NE labels of the two NPs.

The noun-pair-based features for the CR model can be generated using essentially the same method. Specifically, since each instance now corresponds to

an NP, NP_k, and a preceding cluster, c, we can generate a noun-pair-based feature by applying the above method to NP_k and each of the NPs in c, and its value is the number of times it is applicable to NP_k and c.

3.2.2 Features Based on Verb Pairs

As discussed above, features encoding the semantic roles of two NPs and the relatedness of the associated verbs could be useful for coreference resolution. Rather than encoding verb relatedness, we may replace verb relatedness with the verbs themselves in these features, and have the learner learn directly from coreference-annotated data whether two NPs serving as the objects of *decry* and *denounce* are likely to be coreferent or not, for instance.

Specifically, assuming that NP_j and NP_k are the arguments of two stemmed predicates, $pred_j$ and $pred_k$, in the training data, we create five features as follows. First, we encode the semantic roles of NP_j and NP_k as one of five possible values: ARG0-ARG0, ARG1-ARG1, ARG0-ARG1, ARG1-ARG0, and OTHERS (the default case). Second, we create five binary-valued features by pairing each of these five values with the two stemmed predicates. Since these features are computed over two NPs, we can employ them directly for the MP model. Note that by construction, exactly one of these features will have a non-zero value. For the CR model, we extend their definitions so that they can be computed between an NP, NP_k, and a preceding cluster, c. Specifically, the value of a feature is 1 if and only if its value between NP_k and one of the NPs in c is 1 under its original definition.

The above discussion assumes that the two NPs under consideration serve as predicate arguments. If this assumption fails, we will not create any features based on verb pairs for these two NPs.

3.3 World Knowledge from Unannotated Data

Previous work has shown that syntactic appositions, which can be extracted using heuristics from unannotated documents or parse trees, are a useful source of world knowledge for coreference resolution (e.g., Daumé III and Marcu (2005), Ng (2007), Haghighi and Klein (2009)). Each extraction is an NP pair such as <*Barack Obama*, *the president*> and <*Eastern Airlines*, *the carrier*>, where the first NP in the pair is a proper name and the second NP is a common NP. Low-frequency extractions are typically assumed to be noisy and discarded.

We combine the extractions produced by Fleischman et al. (2003) and Ng (2007) to form a database consisting of 1.057 million NP pairs, and create a binary-valued feature for our coreference models using this database. If the MP model is used, this feature will have the value 1 if and only if the two NPs appear as a pair in the database. On the other hand, if the CR model is used, the feature for an instance involving NP_k and preceding cluster c will have the value 1 if and only if NP_k and at least one of the NPs in c appears as a pair in the database.

4 Evaluation

4.1 Experimental Setup

As described in Section 2, we use as our evaluation corpus the 411 documents that are coreference-annotated using the ACE and OntoNotes annotation schemes. Specifically, we divide these documents into five (disjoint) folds of roughly the same size, training the MP model and the CR model using SVM^{light} on four folds and evaluate their performance on the remaining fold. The linguistic features, as well as the NPs used to create the training and test instances, are computed automatically. We employ B^3 and CEAF as described in Section 2.3 to score the output of a coreference system.

4.2 Results and Discussion

4.2.1 Baseline Models

Since our goal is to evaluate the effectiveness of the features encoding world knowledge for learning-based coreference resolution, we employ as our baselines the MR model and the CR model trained on the Baseline feature set, which does not contain any features encoding world knowledge. For the MP model, the Baseline feature set consists of the 39 features described in Section 2.3.1; for the CR model, the Baseline feature set consists of the cluster-level features derived from the 39 features used in the Baseline MP model (see Section 2.3.2).

Results of the MP model and the CR model employing the Baseline feature set are shown in rows 1 and 8 of Table 1, respectively. Each row contains the B^3 and CEAF results of the corresponding coreference model when it is evaluated using the ACE and

Table 2: Results obtained by adding different types of features incrementally to the Baseline system.

OntoNotes annotations as the gold standard. As we can see, the MP model achieves F-measure scores of 62.4 (B^3) and 60.0 (CEAF) on ACE and 53.3 (B^3) and 51.5 (CEAF) on OntoNotes, and the CR model achieves F-measure scores of 66.1 (B^3) and 63.8 (CEAF) on ACE and 56.2 (B^3) and 54.0 (CEAF) on OntoNotes. Also, the results show that the CR model is stronger than the MP model, corroborating previous empirical findings (Rahman and Ng, 2009).

4.2.2 Incorporating World Knowledge

Next, we examine the usefulness of world knowledge for coreference resolution. The remaining rows in Table 1 show the results obtained when different types of features encoding world knowledge are applied to the Baseline system in isolation. The best result for each combination of data set, evaluation measure, and coreference model is boldfaced.

Two points deserve mention. First, each type of features improves the Baseline, regardless of the coreference model, the evaluation measure, and the annotation scheme used. This suggests that all these feature types are indeed useful for coreference resolution. It is worth noting that in all but a few cases involving the FrameNet-based and appositive-based features, the rise in F-measure is accompanied by a

1.	The Bush White House is breeding non-duck ducks the same way the **Nixon** White House did: It hops on an issue that is unopposable – cleaner air, better treatment of the disabled, better child care. **The President** came up with a good bill, but now may end up signing the awful bureaucratic creature hatched on Capitol Hill.
2.	**The tumor**, he suggested, developed when the second, normal copy also was damaged. He believed **colon cancer** might also arise from multiple "hits" on cancer suppressor genes, as it often seems to develop in stages.

Table 3: Examples errors introduced by YAGO and FrameNet.

simultaneous rise in recall and precision. This is perhaps not surprising: as the use of world knowledge helps discover coreference links, recall increases; and as more (relevant) knowledge is available to make coreference decisions, precision increases.

Second, the feature types that yield the best improvement over the Baseline are YAGO TYPE and Noun Pairs. When the MP model is used, the best coreference system improves the Baseline by 1–1.3% (B^3) and 1.3–2.8% (CEAF) in F-measure. On the other hand, when the CR model is used, the best system improves the Baseline by 2.3–2.6% (B^3) and 1.7–2.2% (CEAF) in F-measure.

Table 2 shows the results obtained when the different types of features are added to the Baseline one after the other. Specifically, we add the feature types in this order: YAGO TYPE, YAGO MEANS, Noun Pairs, FrameNet, Verb Pairs, and Appositives. In comparison to the results in Table 1, we can see that better results are obtained when the different types of features are applied to the Baseline in combination than in isolation, regardless of the coreference model, the evaluation measure, and the annotation scheme used. The best-performing system, which employs all but the Appositive features, outperforms the Baseline by 3.1–3.3% in F-measure when the MR model is used and by 4.1–4.8% in F-measure when the CR model is used. In both cases, the gains in F-measure are accompanied by a simultaneous rise in recall and precision. Overall, these results seem to suggest that the CR model is making more effective use of the available knowledge than the MR model, and that the different feature types are providing complementary information for the two coreference models.

4.3 Example Errors

While the different types of features we considered improve the performance of the Baseline primarily via the establishment of coreference links, some of these links are spurious. Sentences 1 and 2 of Table 3 show the spurious coreference links introduced by the CR model when YAGO and FrameNet are used, respectively. In sentence 1, while *The President* and *Bush* are coreferent, YAGO caused the CR model to establish the spurious link between *The President* and *Nixon* owing to the proximity of the two NPs and the presence of this NP pair in the YAGO TYPE relation. In sentence 2, FrameNet caused the CR model to establish the spurious link between *The tumor* and *colon cancer* because these two NPs are the ARG0 arguments of *develop* and *arise*, which appear in the same semantic frame in FrameNet.

5 Conclusions

We have examined the utility of three major sources of world knowledge for coreference resolution, namely, large-scale knowledge bases (YAGO, FrameNet), coreference-annotated data (Noun Pairs, Verb Pairs), and unannotated data (Appositives), by applying them to two learning-based coreference models, the mention-pair model and the cluster-ranking model, and evaluating them on documents annotated with the ACE and OntoNotes annotation schemes. When applying the different types of features in isolation to a Baseline system that does not employ world knowledge, we found that all of them improved the Baseline regardless of the underlying coreference model, the evaluation measure, and the annotation scheme, with YAGO TYPE and Noun Pairs yielding the largest performance gains. Nevertheless, the best results were obtained when they were applied in combination to the Baseline system. We conclude from these results that the different feature types we considered are providing complementary world knowledge to the coreference resolvers, and while each of them provides fairly small gains, their cumulative benefits can be substantial.

Acknowledgments

How to train your multi bottom-up tree transducer

Andreas Maletti
Universität Stuttgart, Institute for Natural Language Processing
Azenbergstraße 12, 70174 Stuttgart, Germany
andreas.maletti@ims.uni-stuttgart.de

Abstract

The local multi bottom-up tree transducer is introduced and related to the (non-contiguous) synchronous tree sequence substitution grammar. It is then shown how to obtain a weighted local multi bottom-up tree transducer from a bilingual and biparsed corpus. Finally, the problem of non-preservation of regularity is addressed. Three properties that ensure preservation are introduced, and it is discussed how to adjust the rule extraction process such that they are automatically fulfilled.

1 Introduction

A (formal) translation model is at the core of every machine translation system. Predominantly, statistical processes are used to instantiate the formal model and derive a specific translation device. Brown et al. (1990) discuss automatically trainable translation models in their seminal paper. However, the IBM models of Brown et al. (1993) are string-based in the sense that they base the translation decision on the words and their surrounding context. Contrary, in the field of syntax-based machine translation, the translation models have full access to the syntax of the sentences and can base their decision on it. A good exposition to both fields is presented in (Knight, 2007).

In this paper, we deal exclusively with syntax-based translation models such as synchronous tree substitution grammars (STSG), multi bottom-up tree transducers (MBOT), and synchronous tree-sequence substitution grammars (STSSG). Chiang (2006) gives a good introduction to STSG, which originate from the syntax-directed translation schemes of Aho and Ullman (1972). Roughly speaking, an STSG has rules in which two linked nonterminals are replaced (at the same time) by two corresponding trees containing terminal and nonterminal symbols. In addition, the nonterminals in the two replacement trees are linked, which creates new linked nonterminals to which further rules can be applied. Henceforth, we refer to these two trees as input and output tree. MBOT have been introduced in (Arnold and Dauchet, 1982; Lilin, 1981) and are slightly more expressive than STSG. Roughly speaking, they allow one replacement input tree and several output trees in a single rule. This change and the presence of states yields many algorithmically advantageous properties such as closure under composition, efficient binarization, and efficient input and output restriction [see (Maletti, 2010)]. Finally, STSSG, which have been derived from rational tree relations (Raoult, 1997), have been discussed by Zhang et al. (2008a), Zhang et al. (2008b), and Sun et al. (2009). They are even more expressive than the local variant of the multi bottom-up tree transducer (LMBOT) that we introduce here and can have several input and output trees in a single rule.

In this contribution, we restrict MBOT to a form that is particularly relevant in machine translation. We drop the general state behavior of MBOT and replace it by the common locality tests that are also present in STSG, STSSG, and STAG (Shieber and Schabes, 1990; Shieber, 2007). The obtained device is the local MBOT (LMBOT).

Maletti (2010) argued the algorithmical advantages of MBOT over STSG and proposed MBOT as an implementation alternative for STSG. In particular, the training procedure would train STSG; i.e., it would not utilize the additional expressive power

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 825–834,
Portland, Oregon, June 19-24, 2011.

of MBOT. However, Zhang et al. (2008b) and Sun et al. (2009) demonstrate that the additional expressivity gained from non-contiguous rules greatly improves the translation quality. In this contribution we address this separation and investigate a training procedure for LMBOT that allows non-contiguous fragments while preserving the algorithmic advantages of MBOT. To this end, we introduce a rule extraction and weight training method for LMBOT that is based on the corresponding procedures for STSG and STSSG. However, general LMBOT can be too expressive in the sense that they allow translations that do not preserve regularity. Preservation of regularity is an important property for efficient representations and efficient algorithms [see (May et al., 2010)]. Consequently, we present 3 properties that ensure that an LMBOT preserves regularity. In addition, we shortly discuss how these properties could be enforced in the rule extraction procedure.

2 Notation

The set of nonnegative integers is $\mathbb{N}$. We write $[k]$ for the set $\{i \mid 1 \leq i \leq k\}$. We treat functions as special relations. For every relation $R \subseteq A \times B$ and $S \subseteq A$, we write

$$R(S) = \{b \in B \mid \exists a \in S\colon (a,b) \in R\}$$
$$R^{-1} = \{(b,a) \mid (a,b) \in R\} \ ,$$

where R^{-1} is called the *inverse* of R.

Given an alphabet Σ, the set of all words (or sequences) over Σ is Σ^*, of which the empty word is ε. The concatenation of two words u and w is simply denoted by the juxtaposition uw. The length of a word $w = \sigma_1 \cdots \sigma_k$ with $\sigma_i \in \Sigma$ for all $i \in [k]$ is $|w| = k$. Given $1 \leq i \leq j \leq k$, the (i,j)-*span* $w[i,j]$ of w is $\sigma_i \sigma_{i+1} \cdots \sigma_j$.

The set T_Σ of all Σ-*trees* is the smallest set T such that $\sigma(\mathbf{t}) \in T$ for all $\sigma \in \Sigma$ and $\mathbf{t} \in T^*$. We generally use bold-face characters (like $\mathbf{t}$) for sequences, and we refer to their elements using subscripts (like t_i). Consequently, a tree t consists of a labeled root node σ followed by a sequence $\mathbf{t}$ of its children. To improve readability we sometimes write a sequence $t_1 \cdots t_k$ as $t_1, \ldots, t_k$.

The *positions* $\mathrm{pos}(t) \subseteq \mathbb{N}^*$ of a tree $t = \sigma(\mathbf{t})$ are inductively defined by $\mathrm{pos}(t) = \{\varepsilon\} \cup \mathrm{pos}(\mathbf{t})$, where

$$\mathrm{pos}(\mathbf{t}) = \bigcup_{1 \leq i \leq |\mathbf{t}|} \{ip \mid p \in \mathrm{pos}(t_i)\} \ .$$

Note that this yields an undesirable difference between $\mathrm{pos}(t)$ and $\mathrm{pos}(\mathbf{t})$, but it will always be clear from the context whether we refer to a single tree or a sequence. Note that positions are ordered via the (standard) lexicographic ordering. Let $t \in T_\Sigma$ and $p \in \mathrm{pos}(t)$. The label of t at position p is $t(p)$, and the subtree rooted at position p is $t|_p$. Formally, they are defined by

$$t(p) = \begin{cases} \sigma & \text{if } p = \varepsilon \\ \mathbf{t}(p) & \text{otherwise} \end{cases} \qquad \mathbf{t}(ip) = t_i(p)$$

$$t|_p = \begin{cases} t & \text{if } p = \varepsilon \\ \mathbf{t}|_p & \text{otherwise} \end{cases} \qquad \mathbf{t}|_{ip} = t_i|_p$$

for all $t = \sigma(\mathbf{t})$ and $1 \leq i \leq |\mathbf{t}|$. As demonstrated, these notions are also used for sequences. A position $p \in \mathrm{pos}(t)$ is a *leaf* (in t) if $p1 \notin \mathrm{pos}(t)$. Given a subset $\mathrm{NT} \subseteq \Sigma$, we let

$$\downarrow_{\mathrm{NT}}(t) = \{p \in \mathrm{pos}(t) \mid t(p) \in \mathrm{NT},\ p \text{ leaf in } t\} \ .$$

Later NT will be the set of nonterminals, so that the elements of $\downarrow_{\mathrm{NT}}(t)$ will be the *leaf nonterminals* of t. We extend the notion to sequences $\mathbf{t}$ by

$$\downarrow_{\mathrm{NT}}(\mathbf{t}) = \bigcup_{1 \leq i \leq |\mathbf{t}|} \{ip \mid p \in \downarrow_{\mathrm{NT}}(t_i)\} \ .$$

We also need a substitution that replaces subtrees. Let $p_1, \ldots, p_n \in \mathrm{pos}(t)$ be pairwise incomparable positions and $t_1, \ldots, t_n \in T_\Sigma$. Then $t[p_i \leftarrow t_i \mid 1 \leq i \leq n]$ denotes the tree that is obtained from t by replacing (in parallel) the subtrees at p_i by t_i for every $i \in [k]$.

Finally, let us recall regular tree languages. A *finite tree automaton* M is a tuple (Q, Σ, δ, F) such that Q is a finite set, $\delta \subseteq Q^* \times \Sigma \times Q$ is a finite relation, and $F \subseteq Q$. We extend δ to a mapping $\underline{\delta}\colon T_\Sigma \to 2^Q$ by

$$\underline{\delta}(\sigma(\mathbf{t})) = \{q \mid (\mathbf{q}, \sigma, q) \in \delta, \forall i \in [\,|\mathbf{t}|\,]\colon q_i \in \underline{\delta}(t_i)\}$$

for every $\sigma \in \Sigma$ and $\mathbf{t} \in T_\Sigma^*$. The finite tree automaton M recognizes the tree language

$$L(M) = \{t \in T_\Sigma \mid \underline{\delta}(t) \cap F \neq \emptyset\} \ .$$

A tree language $L \subseteq T_\Sigma$ is *regular* if there exists a finite tree automaton M such that $L = L(M)$.

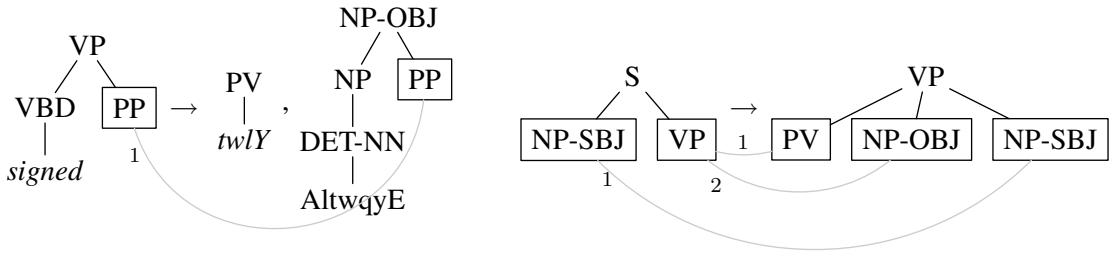

Figure 1: Sample LMBOT rules.

3 The model

In this section, we recall particular multi bottom-up tree transducers, which have been introduced by Arnold and Dauchet (1982) and Lilin (1981). A detailed (and English) presentation of the general model can be found in Engelfriet et al. (2009) and Maletti (2010). Using the nomenclature of Engelfriet et al. (2009), we recall a variant of *linear and nondeleting extended multi bottom-up tree transducers* (MBOT) here. Occasionally, we will refer to general MBOT, which differ from the local variant discussed here because they have explicit states.

Throughout the article, we assume sets Σ and Δ of input and output symbols, respectively. Moreover, let $\mathrm{NT} \subseteq \Sigma \cup \Delta$ be the set of designated nonterminal symbols. Finally, we avoid weights in the formal development to keep it simple. It is straightforward to add weights to our model.

Essentially, the model works on pairs $\langle t, \mathbf{u} \rangle$ consisting of an input tree $t \in T_\Sigma$ and a sequence $\mathbf{u} \in T_\Delta^*$ of output trees. Each such pair is called a *pre-translation* and the rank $\mathrm{rk}(\langle t, \mathbf{u} \rangle)$ the pre-translation $\langle t, \mathbf{u} \rangle$ is $|\mathbf{u}|$. In other words, the rank of a pre-translation equals the number of output trees stored in it. Given a pre-translation $\langle t, \mathbf{u} \rangle \in T_\Sigma \times T_\Delta^k$ and $i \in [k]$, we call u_i the i^{th} translation of t. An alignment for the pre-translation $\langle t, \mathbf{u} \rangle$ is an injective mapping $\psi \colon \downarrow_{\mathrm{NT}}(\mathbf{u}) \to \downarrow_{\mathrm{NT}}(t) \times \mathbb{N}$ such that $(p, j) \in \psi(\downarrow_{\mathrm{NT}}(\mathbf{u}))$ for every $(p, i) \in \psi(\downarrow_{\mathrm{NT}}(\mathbf{u}))$ and $j \in [i]$. In other words, an alignment should request each translation of a particular subtree at most once and if it requests the i^{th} translation, then it should also request all previous translations.

Definition 1 *A* local multi bottom-up tree transducer *(*LMBOT*) is a finite set R of* rules *such that every rule, written $l \to_\psi \mathbf{r}$, contains a pre-translation $\langle l, \mathbf{r} \rangle$ and an alignment ψ for it.*

The component l is the *left-hand side*, $\mathbf{r}$ is the *right-hand side*, and ψ is the *alignment* of a rule $l \to_\psi \mathbf{r} \in R$. The rules of an LMBOT are similar to the rules of an STSG (synchronous tree substitution grammar) of Eisner (2003) and Shieber (2004), but right-hand sides of LMBOT contain a sequence of trees instead of just a single tree as in an STSG. In addition, the alignments in an STSG rule are bijective between leaf nonterminals, whereas our model permits multiple alignments to a single leaf nonterminal in the left-hand side. A model that is even more powerful than LMBOT is the non-contiguous version of STSSG (synchronous tree-sequence substitution grammar) of Zhang et al. (2008a), Zhang et al. (2008b), and Sun et al. (2009), which allows sequences of trees on both sides of rules [see also (Raoult, 1997)]. Figure 1 displays sample rules of an LMBOT using a graphical representation of the trees and the alignment.

Next, we define the semantics of an LMBOT R. To avoid difficulties[1], we explicitly exclude rules like $l \to_\psi \mathbf{r}$ where $l \in \mathrm{NT}$ or $\mathbf{r} \in \mathrm{NT}^*$; i.e., rules where the left- or right-hand side are only leaf nonterminals. We first define the traditional bottom-up semantics. Let $\rho = l \to_\psi \mathbf{r} \in R$ be a rule and $p \in \downarrow_{\mathrm{NT}}(l)$. The p-rank $\mathrm{rk}(\rho, p)$ of ρ is $\mathrm{rk}(\rho, p) = |\{i \in \mathbb{N} \mid (p, i) \in \psi(\downarrow_{\mathrm{NT}}(\mathbf{r}))\}|$.

Definition 2 *The set $\tau(R)$ of pre-translations of an* LMBOT *R is inductively defined to be the smallest set such that: If $\rho = l \to_\psi \mathbf{r} \in R$ is a rule, $\langle t_p, \mathbf{u}_p \rangle \in \tau(R)$ is a pre-translation of R for every $p \in \downarrow_{\mathrm{NT}}(l)$, and*

- $\mathrm{rk}(\rho, p) = \mathrm{rk}(\langle t_p, \mathbf{u}_p \rangle)$,
- $l(p) = t_p(\varepsilon)$, *and*

[1] Actually, difficulties arise only in the weighted setting.

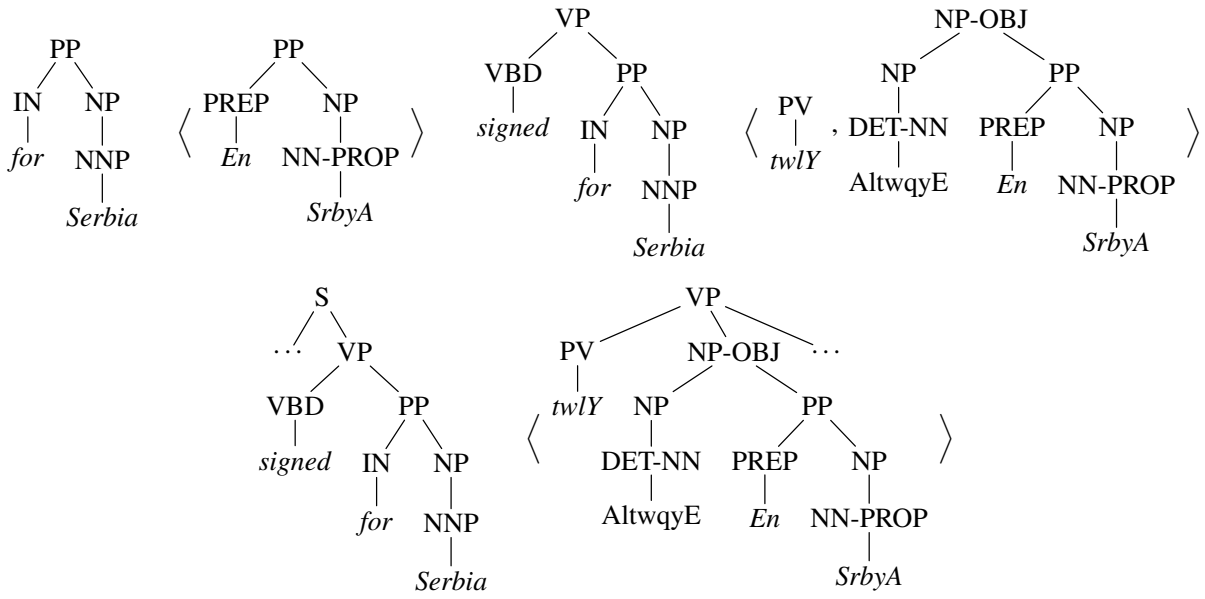

Figure 2: Top left: (a) Initial pre-translation; Top right: (b) Pre-translation obtained from the left rule of Fig. 1 and (a); Bottom: (c) Pre-translation obtained from the right rule of Fig. 1 and (b).

- $\mathbf{r}(p') = \mathbf{u}_{p''}(i)$ *with* $\psi(p') = (p'', i)$

for every $p' \in \downarrow_{\mathrm{NT}}(\mathbf{r})$*, then* $\langle t, \mathbf{u}\rangle \in \tau(R)$ *where*

- $t = l[p \leftarrow t_p \mid p \in \downarrow_{\mathrm{NT}}(l)]$ *and*
- $\mathbf{u} = \mathbf{r}[p' \leftarrow (\mathbf{u}_{p''})_i \mid p' \in \psi^{-1}(p'', i)]$.

In plain words, each nonterminal leaf p in the left-hand side of a rule ρ can be replaced by the input tree t of a pre-translation $\langle t, \mathbf{u}\rangle$ whose root is labeled by the same nonterminal. In addition, the rank $\mathrm{rk}(\rho, p)$ of the replaced nonterminal should match the rank $\mathrm{rk}(\langle t, \mathbf{u}\rangle)$ of the pre-translation and the nonterminals in the right-hand side that are aligned to p should be replaced by the translation that the alignment requests, provided that the nonterminal matches with the root symbol of the requested translation. The main benefit of the bottom-up semantics is that it works exclusively on pre-translations. The process is illustrated in Figure 2.

Using the classical bottom-up semantics, we simply obtain the following theorem by Maletti (2010) because the MBOT constructed there is in fact an LMBOT.

Theorem 3 *For every* STSG*, an equivalent* LMBOT *can be constructed in linear time, which in turn yields a particular* MBOT *in linear time.*

Finally, we want to relate LMBOT to the STSSG of Sun et al. (2009). To this end, we also introduce the top-down semantics for LMBOT. As expected, both semantics coincide. The top-down semantics is introduced using rule compositions, which will play an important rule later on.

Definition 4 *The set* R^k *of* k*-fold composed rules is inductively defined as follows:*

- $R^1 = R$ *and*
- $\ell \to_\varphi \mathbf{s} \in R^{k+1}$ *for all* $\rho = l \to_\psi \mathbf{r} \in R$ *and* $\rho_p = l_p \to_{\psi_p} \mathbf{r}_p \in R^k$ *such that*
  - $\mathrm{rk}(\rho, p) = \mathrm{rk}(\langle l_p, \mathbf{r}_p\rangle)$,
  - $l(p) = l_p(\varepsilon)$*, and*
  - $\mathbf{r}(p') = \mathbf{r}_{p''}(i)$ *with* $\psi(p') = (p'', i)$

  for every $p \in \downarrow_{\mathrm{NT}}(l)$ *and* $p' \in \downarrow_{\mathrm{NT}}(\mathbf{r})$ *where*
  - $\ell = l[p \leftarrow l_p \mid p \in \downarrow_{\mathrm{NT}}(l)]$,
  - $\mathbf{s} = \mathbf{r}[p' \leftarrow (\mathbf{r}_{p''})_i \mid p' \in \psi^{-1}(p'', i)]$*, and*
  - $\varphi(p'p) = p''\psi_{p''}(ip)$ *for all positions* $p' \in \psi^{-1}(p'', i)$ *and* $ip \in \downarrow_{\mathrm{NT}}(\mathbf{r}_{p''})$.

The rule closure $R^{\leq\infty}$ *of* R *is* $R^{\leq\infty} = \bigcup_{i\geq 1} R^i$*. The top-down pre-translation of* R *is*

$$\tau_{\mathrm{t}}(R) = \{\langle l, \mathbf{r}\rangle \mid l \to_\psi \mathbf{r} \in R^{\leq\infty}, \downarrow_{\mathrm{NT}}(l) = \emptyset\} \ .$$

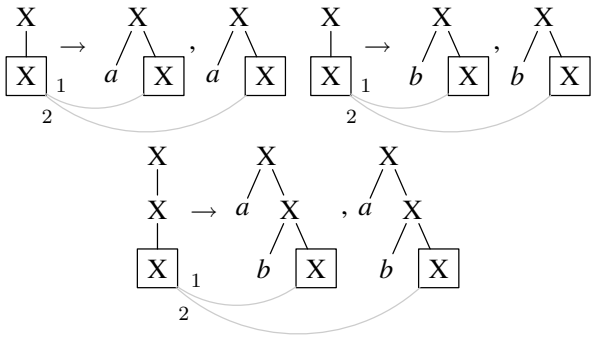

Figure 3: Composed rule.

The composition of the rules, which is illustrated in Figure 3, in the second item of Definition 4 could also be represented as $\rho(\rho_1, \ldots, \rho_k)$ where $\rho_1, \ldots, \rho_k$ is an enumeration of the rules $\{\rho_p \mid p \in \downarrow_{\mathrm{NT}}(l)\}$ used in the item. The following theorem is easy to prove.

Theorem 5 *The bottom-up and top-down semantics coincide; i.e.,* $\tau(R) = \tau_{\mathrm{t}}(R)$.

Chiang (2005) and Graehl et al. (2008) argue that STSG have sufficient expressive power for syntax-based machine translation, but Zhang et al. (2008a) show that the additional expressive power of tree-sequences helps the translation process. This is mostly due to the fact that smaller (and less specific) rules can be extracted from bi-parsed word-aligned training data. A detailed overview that focusses on STSG is presented by Knight (2007).

Theorem 6 *For every* LMBOT*, an equivalent* STSSG *can be constructed in linear time.*

4 Rule extraction and training

In this section, we will show how to automatically obtain an LMBOT from a bi-parsed, word-aligned parallel corpus. Essentially, the process has two steps: *rule extraction* and *training*. In the rule extraction step, an (unweighted) LMBOT is extracted from the corpus. The rule weights are then set in the training procedure.

The two main inspirations for our rule extraction are the corresponding procedures for STSG (Galley et al., 2004; Graehl et al., 2008) and for STSSG (Sun et al., 2009). STSG are always contiguous in both the left- and right-hand side, which means that they (completely) cover a single span of input or output words. On the contrary, STSSG rules can be non-contiguous on both sides, but the extraction procedure of Sun et al. (2009) only extracts rules that are contiguous on the left- or right-hand side. We can adjust its 1^{st} phase that extracts rules with (potentially) non-contiguous right-hand sides. The adjustment is necessary because LMBOT rules cannot have (contiguous) tree sequences in their left-hand sides. Overall, the rule extraction process is sketched in Algorithm 1.

Algorithm 1 Rule extraction for LMBOT

Require: word-aligned tree pair (t, u)
Return: LMBOT rules R such that $(t, u) \in \tau(R)$
  while there exists a maximal non-leaf node $p \in \mathrm{pos}(t)$ and minimal $p_1, \ldots, p_k \in \mathrm{pos}(u)$ such that $t|_p$ and $(u|_{p_1}, \ldots, u|_{p_k})$ have a consistent alignment (i.e., no alignments from within $t|_p$ to a leaf outside $(u|_{p_1}, \ldots, u|_{p_k})$ and vice versa)
  do
2: add rule $\rho = t|_p \to_\psi (u_{p_1}, \ldots, u_{p_k})$ to R with the nonterminal alignments ψ
      `// excise rule` ρ `from` (t, u)
4: $t \leftarrow t[p \leftarrow t(p)]$
    $u \leftarrow u[p_i \leftarrow u(p_i) \mid i \in \{1, \ldots, k\}]$
6: establish alignments according to position
  end while

The requirement that we can only have one input tree in LMBOT rules indeed might cause the extraction of bigger and less useful rules (when compared to the corresponding STSSG rules) as demonstrated in (Sun et al., 2009). However, the stricter rule shape preserves the good algorithmic properties of LMBOT. The more powerful STSSG rules can cause nonclosure under composition (Raoult, 1997; Radmacher, 2008) and parsing to be less efficient.

Figure 4 shows an example of biparsed aligned parallel text. According to the method of Galley et al. (2004) we can extract the (minimal) STSG rule displayed in Figure 5. Using the more liberal format of LMBOT rules, we can decompose the STSG rule of Figure 5 further into the rules displayed in Figure 1. The method of Sun et al. (2009) would also extract the rule displayed in Figure 6.

Let us reconsider Figures 1 and 2. Let ρ_1 be the top left rule of Figure 2 and ρ_2 and ρ_3 be the

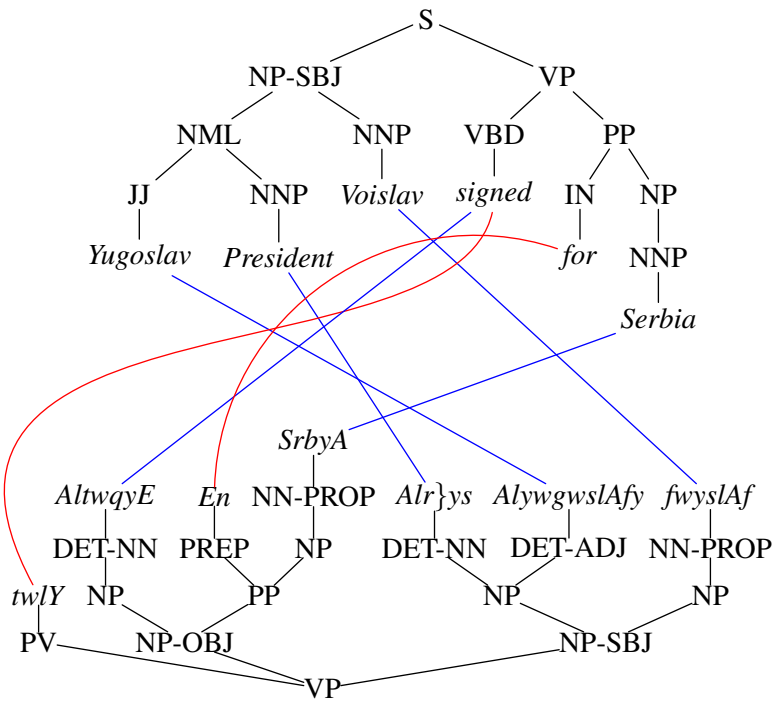

Figure 4: Biparsed aligned parallel text.

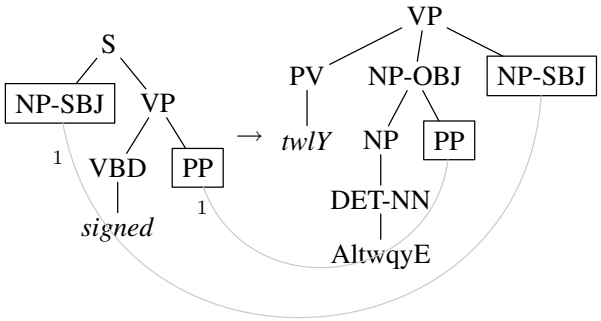

Figure 5: Minimal STSG rule.

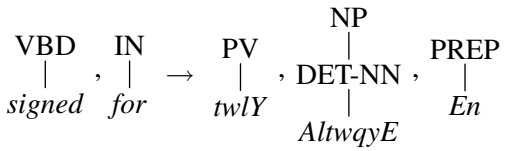

Figure 6: Sample STSSG rule.

left and right rule of Figure 1, respectively. We can represent the lower pre-translation of Figure 2 by $\rho_3(\cdots, \rho_2(\rho_1))$, where $\rho_2(\rho_1)$ represents the upper right pre-translation of Figure 2. If we name all rules of R, then we can represent each pre-translation of $\tau(R)$ symbolically by a tree containing rule names. Such trees containing rule names are often called *derivation trees*. Overall, we obtain the following result, for which details can be found in (Arnold and Dauchet, 1982).

Theorem 7 *The set $D(R)$ is a regular tree language for every* LMBOT *R, and the set of derivations is also regular for every* MBOT.

Moreover, using the input and output product constructions of Maletti (2010) we obtain that even the set $D_{t,u}(R)$ of derivations for a specific input tree t and output tree u is regular. Since $D_{t,u}(R)$ is regular, we can compute the inside and outside weight of each (weighted) rule of R following the method of Graehl et al. (2008). Similarly, we can adjust the training procedure of Graehl et al. (2008), which yields that we can automatically obtain a weighted LMBOT from a bi-parsed parallel corpus. Details on the run-time can be found in (Graehl et al., 2008).

5 Preservation of regularity

Clearly, LMBOT are not symmetric. Although, the backwards application of an LMBOT preserves regularity, this property does not hold for forward application. We will focus on forward application here. Given a set $\mathcal{T}$ of pre-translations and a tree language

$L \subseteq T_\Sigma$, we let

$$\mathcal{T}_{\mathrm{c}}(L) = \{u_i \mid (u_1, \ldots, u_k) \in \mathcal{T}(L), i \in [k]\} \ ,$$

which collects all translations of input trees in L. We say that $\mathcal{T}$ *preserves regularity* if $\mathcal{T}_{\mathrm{c}}(L)$ is regular for every regular tree language $L \subseteq T_\Sigma$. Correspondingly, an LMBOT R preserves regularity if its set $\tau(R)$ of pre-translations preserves regularity.

As mentioned, an LMBOT does not necessarily preserve regularity. The rules of an LMBOT have only alignments between the left-hand side (input tree) and the right-hand side (output tree), which are also called *inter-tree* alignments. However, several alignments to a single nonterminal in the left-hand side can transitively relate two different nonterminals in the output side and thus simulate an *intra-tree* alignment. For example, the right rule of Figure 1 relates a 'PV' and an 'NP-OBJ' node to a single 'VP' node in the left-hand side. This could lead to an intra-tree alignment (synchronization) between the 'PV' and 'NP-OBJ' nodes in the right-hand side.

Figure 7 displays the rules R of an LMBOT that does not preserve regularity. This can easily be seen on the leaf (word) languages because the LMBOT can translate the word x to any element of $L = \{wcwc \mid w \in \{a, b\}^*\}$. Clearly, this word language L is not context-free. Since the leaf language of every regular tree language is context-free and regular tree languages are closed under intersection (needed to single out the translations that have the symbol Y at the root), this also proves that $\tau(R)_{\mathrm{c}}(T_\Sigma)$ is not regular. Since T_Σ is regular, this proves that the LMBOT does not preserve regularity.

Preservation of regularity is an important property for a number of translation model manipulations. For example, the bucket-brigade and the on-the-fly method for the efficient inference described in (May et al., 2010) essentially build on it. Moreover, a regular tree grammar (i.e., a representation of a regular tree language) is an efficient representation. More complex representations such as context-free tree grammars [see, e.g., (Fujiyoshi, 2004)] have worse algorithmic properties (e.g., more complex parsing and problematic intersection).

In this section, we investigate three syntactic restrictions on the set R of rules that guarantees that the obtained LMBOT preserves regularity. Then we shortly discuss how to adjust the rule extraction algorithm, so that the extracted rules automatically have these property. First, we quickly recall the notion of composed rules from Definition 4 because it will play an essential role in all three properties. Figure 3 shows a composition of two rules from Figure 7. Mind that R^2 might not contain all rules of R, but it contains all those without leaf nonterminals.

Definition 8 *An* LMBOT R *is* finitely collapsing *if there is* $n \in \mathbb{N}$ *such that* $\psi\colon \downarrow_{\mathrm{NT}}(\mathbf{r}) \to \downarrow_{\mathrm{NT}}(l) \times \{1\}$ *for every rule* $l \to_\psi \mathbf{r} \in R^n$.

The following statement follows from a more general result of Raoult (1997), which we will introduce with our second property.

Theorem 9 *Every finitely collapsing* LMBOT *preserves regularity.*

Often the simple condition 'finitely collapsing' is fulfilled after rule extraction. In addition, it is automatically fulfilled in an LMBOT that was obtained from an STSG using Theorem 3. It can also be ensured in the rule extraction process by introducing *collapsing points* for output symbols that can appear recursively in the corpus. For example, we could enforce that all extracted rules for clause-level output symbols (assuming that there is no recursion not involving a clause-level output symbols) should have only 1 output tree in the right-hand side.

However, 'finitely collapsing' is a rather strict property. Finitely collapsing LMBOT have only slightly more expressive power than STSG. In fact, they could be called STSG with input desynchronization. This is due to the fact that the alignment in composed rules establishes an injective relation between leaf nonterminals (as in an STSG), but it need not be bijective. Consequently, there can be leaf nonterminals in the left-hand side that have no aligned leaf nonterminal in the right-hand side. In this sense, those leaf nonterminals are desynchronized. This feature is illustrated in Figure 8 and such an LMBOT can compute the transformation $\{(t, a) \mid t \in T_\Sigma\}$, which cannot be computed by an STSG (assuming that T_Σ is suitably rich). Thus STSG with input desynchronization are more expressive than STSG, but they still compute a class of transformations that is not closed under composition.

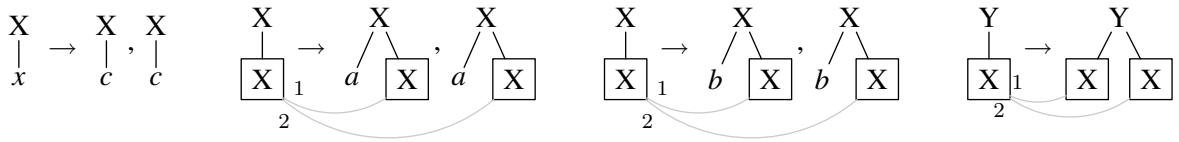

Figure 7: Output subtree synchronization (intra-tree).

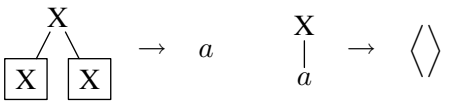

Figure 8: Finitely collapsing LMBOT.

Theorem 10 *For every* STSG*, we can construct an equivalent finitely collapsing* LMBOT *in linear time. Moreover, finitely collapsing* LMBOT *are strictly more expressive than* STSG*.*

Next, we investigate a weaker property by Raoult (1997) that still ensures preservation of regularity.

Definition 11 *An* LMBOT R *has* finite synchronization *if there is* $n \in \mathbb{N}$ *such that for every rule* $l \to_\psi \mathbf{r} \in R^n$ *and* $p \in \downarrow_{\mathrm{NT}}(l)$ *there exists* $i \in \mathbb{N}$ *with* $\psi^{-1}(\{p\} \times \mathbb{N}) \subseteq \{iw \mid w \in \mathbb{N}^*\}$.

In plain terms, multiple alignments to a single leaf nonterminal at p in the left-hand side are allowed, but all leaf nonterminals of the right-hand side that are aligned to p must be in the same tree. Clearly, an LMBOT with finite synchronization is finitely collapsing. Raoult (1997) investigated this restriction in the context of *rational tree relations*, which are a generalization of our LMBOT. Raoult (1997) shows that finite synchronization can be decided. The next theorem follows from the results of Raoult (1997).

Theorem 12 *Every* LMBOT *with finite synchronization preserves regularity.*

MBOT can compute arbitrary compositions of STSG (Maletti, 2010). However, this no longer remains true for MBOT (or LMBOT) with finite synchronization.[2] In Figure 9 we illustrate a translation that can be computed by a composition of two STSG, but that cannot be computed by an MBOT (or LMBOT) with finite synchronization. Intuitively, when processing the chain of 'X's of the transformation depicted in Figure 9, the first and second successor of the 'Z'-node at the root on the output side must be aligned to the 'X'-chain. This is necessary because those two mentioned subtrees must reproduce t_1 and t_2 from the end of the 'X'-chain. We omit the formal proof here, but obtain the following statement.

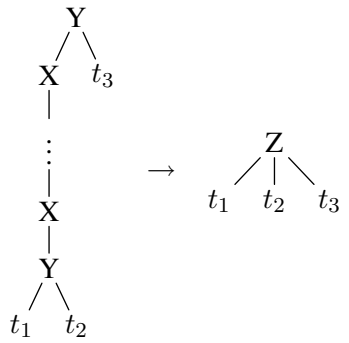

Figure 9: Transformation that cannot be computed by an MBOT with finite synchronization.

Theorem 13 *For every* STSG*, we can construct an equivalent* LMBOT *with finite synchronization in linear time.* LMBOT *and* MBOT *with finite synchronization are strictly more expressive than* STSG *and compute classes that are not closed under composition.*

Again, it is straightforward to adjust the rule extraction algorithm by the introduction of *synchronization points* (for example, for clause level output symbols). We can simply require that rules extracted for those selected output symbols fulfill the condition mentioned in Definition 11.

Finally, we introduce an even weaker version.

Definition 14 *An* LMBOT R *is* copy-free *if there is* $n \in \mathbb{N}$ *such that for every rule* $l \to_\psi \mathbf{r} \in R^n$ *and* $p \in \downarrow_{\mathrm{NT}}(l)$ *we have (i)* $\psi^{-1}(\{p\} \times \mathbb{N}) \subseteq \mathbb{N}$*, or (ii)* $\psi^{-1}(\{p\} \times \mathbb{N}) \subseteq \{iw \mid w \in \mathbb{N}^*\}$ *for an* $i \in \mathbb{N}$*.*

Intuitively, a copy-free LMBOT has rules whose right hand sides may use all leaf nonterminals that are aligned to a given leaf nonterminal in the left-hand side directly at the root (of one of the trees

[2]This assumes a straightforward generalization of the 'finite synchronization' property for MBOT.

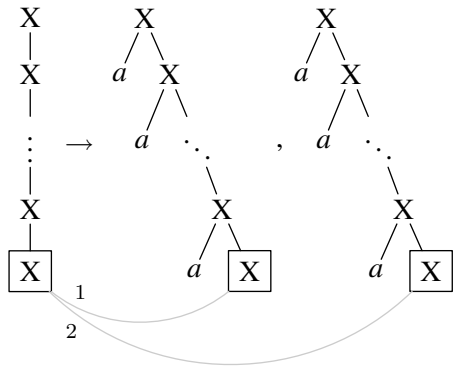

Figure 10: Composed rule that is not copy-free.

in the right-hand side forest) or group all those leaf nonterminals in a single tree in the forest. Clearly, the LMBOT of Figure 7 is not copy-free because the second rule composes with itself (see Figure 10) to a rule that does not fulfill the copy-free condition.

Theorem 15 *Every copy-free* LMBOT *preserves regularity.*

Proof sketch: Let n be the integer of Definition 14. We replace the LMBOT with rules R by the equivalent LMBOT M with rules R^n. Then all rules have the form required in Definition 14. Moreover, let $L \subseteq T_\Sigma$ be a regular tree language. Then we can construct the input product of $\tau(M)$ with L. In this way, we obtain an MBOT M', whose rules still fulfill the requirements (adapted for MBOT) of Definition 14 because the input product does not change the structure of the rules (it only modifies the state behavior). Consequently, we only need to show that the range of the MBOT M' is regular. This can be achieved using a decomposition into a relabeling, which clearly preserves regularity, and a deterministic finite-copying top-down tree transducer (Engelfriet et al., 1980; Engelfriet, 1982). □

Figure 11 shows some relevant rules of a copy-free LMBOT that computes the transformation of Figure 9. Clearly, copy-free LMBOT are more general than LMBOT with finite synchronization, so we again can obtain copy-free LMBOT from STSG. In addition, we can adjust the rule extraction process using synchronization points as for LMBOT with finite synchronization using the restrictions of Definition 14.

Theorem 16 *For every* STSG*, we can construct an equivalent copy-free* LMBOT *in linear time.*

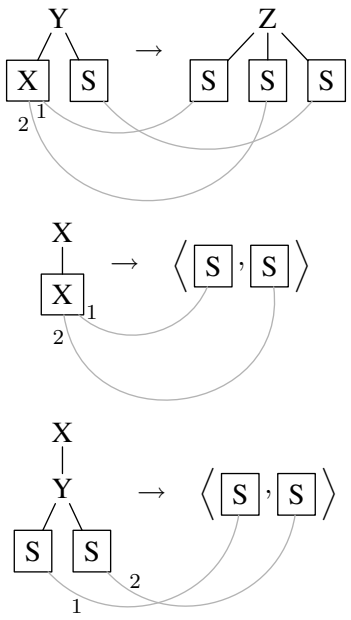

Figure 11: Copy-free LMBOT for the transformation of Figure 9.

Copy-free LMBOT *are strictly more expressive than* LMBOT *with finite synchronization.*

6 Conclusion

We have introduced a simple restriction of multi bottom-up tree transducers. It abstracts from the general state behavior of the general model and only uses the locality tests that are also present in STSG, STSSG, and STAG. Next, we introduced a rule extraction procedure and a corresponding rule weight training procedure for our LMBOT. However, LMBOT allow translations that do not preserve regularity, which is an important property for efficient algorithms. We presented 3 properties that ensure that regularity is preserved. In addition, we shortly discussed how these properties could be enforced in the presented rule extraction procedure.

Abstract

Tree-to-string translation is syntax-aware and efficient but sensitive to parsing errors. Forest-to-string translation approaches mitigate the risk of propagating parser errors into translation errors by considering a forest of alternative trees, as generated by a source language parser. We propose an alternative approach to generating forests that is based on combining sub-trees within the first best parse through binarization. Provably, our binarization forest can cover any non-consitituent phrases in a sentence but maintains the desirable property that for each span there is at most one nonterminal so that the grammar constant for decoding is relatively small. For the purpose of reducing search errors, we apply the synchronous binarization technique to forest-to-string decoding. Combining the two techniques, we show that using a fast shift-reduce parser we can achieve significant quality gains in NIST 2008 English-to-Chinese track (1.3 BLEU points over a phrase-based system, 0.8 BLEU points over a hierarchical phrase-based system). Consistent and significant gains are also shown in WMT 2010 in the English to German, French, Spanish and Czech tracks.

1 Introduction

In recent years, researchers have explored a wide spectrum of approaches to incorporate syntax and structure into machine translation models. The unifying framework for these models is *synchronous grammars* (Chiang, 2005) or *tree transducers* (Graehl and Knight, 2004). Depending on whether or not monolingual parsing is carried out on the source side or the target side for inference, there are four general categories within the framework:

- *string-to-string* (Chiang, 2005; Zollmann and Venugopal, 2006)
- *string-to-tree* (Galley et al., 2006; Shen et al., 2008)
- *tree-to-string* (Lin, 2004; Quirk et al., 2005; Liu et al., 2006; Huang et al., 2006; Mi et al., 2008)
- *tree-to-tree* (Eisner, 2003; Zhang et al., 2008)

In terms of search, the string-to-x models explore all possible source parses and map them to the target side, while the tree-to-x models search over the subspace of structures of the source side constrained by an input tree or trees. Hence, tree-to-x models are more constrained but more efficient. Models such as Huang et al. (2006) can match multi-level tree fragments on the source side which means larger contexts are taken into account for translation (Poutsma, 2000), which is a modeling advantage. To balance efficiency and accuracy, forest-to-string models (Mi et al., 2008; Mi and Huang, 2008) use a compact representation of exponentially many trees to improve tree-to-string models. Traditionally, such forests are obtained through hyper-edge pruning in the k-best search space of a monolingual parser (Huang, 2008). The pruning parameters that control the size of forests are normally hand-tuned. Such forests encode both syntactic variants and structural variants. By syntactic variants, we refer to the fact that a parser can parse a substring into either a noun phrase or verb phrase in certain cases.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 835–845,
Portland, Oregon, June 19-24, 2011.

We believe that structural variants which allow more source spans to be explored during translation are more important (DeNeefe et al., 2007), while syntactic variants might improve word sense disambiguation but also introduce more spurious ambiguities (Chiang, 2005) during decoding. To focus on structural variants, we propose a family of binarization algorithms to expand one single constituent tree into a packed forest of binary trees containing combinations of adjacent tree nodes. We control the freedom of tree node binary combination by restricting the distance to the lowest common ancestor of two tree nodes. We show that the best results are achieved when the distance is two, i.e., when combining tree nodes sharing a common grand-parent. In contrast to conventional parser-produced-forest-to-string models, in our model:

- Forests are not generated by a parser but by combining sub-structures using a tree binarizer.
- Instead of using arbitary pruning parameters, we control forest size by an integer number that defines the degree of tree structure violation.
- There is at most one nonterminal per span so that the grammar constant is small.

Since GHKM rules (Galley et al., 2004) can cover multi-level tree fragments, a synchronous grammar extracted using the GHKM algorithm can have synchronous translation rules with more than two nonterminals regardless of the branching factor of the source trees. For the first time, we show that similar to string-to-tree decoding, synchronous binarization significantly reduces search errors and improves translation quality for forest-to-string decoding.

To summarize, the whole pipeline is as follows. First, a parser produces the highest-scored tree for an input sentence. Second, the parse tree is restructured using our binarization algorithm, resulting in a binary packed forest. Third, we apply the forest-based variant of the GHKM algorithm (Mi and Huang, 2008) on the new forest for rule extraction. Fourth, on the translation forest generated by all applicable translation rules, which is not necessarily binary, we apply the synchronous binarization algorithm (Zhang et al., 2006) to generate a binary translation forest. Finally, we use a bottom-up decoding algorithm with intergrated LM intersection using the cube pruning technique (Chiang, 2005).

The rest of the paper is organized as follows. In Section 2, we give an overview of the forest-to-string models. In Section 2.1, we introduce a more efficient and flexible algorithm for extracting composed GHKM rules based on the same principle as cube pruning (Chiang, 2007). In Section 3, we introduce our source tree binarization algorithm for producing binarized forests. In Section 4, we explain how to do synchronous rule factorization in a forest-to-string decoder. Experimental results are in Section 5.

2 Forest-to-string Translation

Forest-to-string models can be described as

$$e = \mathcal{Y}(\underset{d \in D(T),\, T \in F(f)}{\arg\max} P(d|T)) \qquad (1)$$

where f stands for a source string, e stands for a target string, F stands for a forest, D stands for a set of synchronous derivations on a given tree T, and $\mathcal{Y}$ stands for the target side yield of a derivation. The search problem is finding the derivation with the highest probability in the space of all derivations for all parse trees for an input sentence. The log probability of a derivation is normally a linear combination of local features which enables dynamic programming to find the optimal combination efficiently. In this paper, we focus on the models based on the Synchronous Tree Substitution Grammars (STSG) defined by Galley et al. (2004). In contrast to a tree-to-string model, the introduction of F augments the search space systematically. When the first-best parse is wrong or no good translation rules are applicable to the first-best parse, the model can recover good translations from alternative parses.

In STSG, local features are defined on tree-to-string rules, which are synchronous grammar rules defining how a sequence of terminals and nonterminals on the source side translates to a sequence of target terminals and nonterminals. One-to-one mapping of nonterminals is assumed. But terminals do not necessarily need to be aligned. Figure 1 shows a typical English-Chinese tree-to-string rule with a reordering pattern consisting of two nonterminals and different numbers of terminals on the two sides.

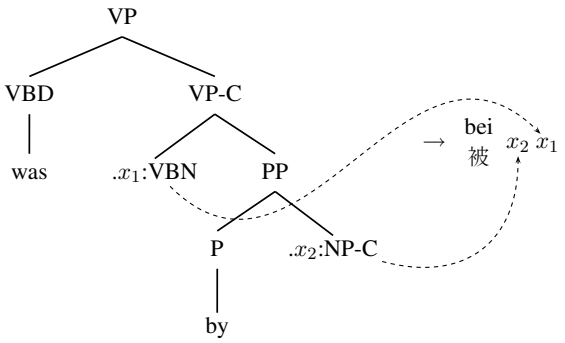

Figure 1: An example tree-to-string rule.

Forest-to-string translation has two stages. The first stage is rule extraction on word-aligned parallel texts with source forests. The second stage is rule enumeration and DP decoding on forests of input strings. In both stages, at each tree node, the task on the source side is to generate a list of tree fragments by composing the tree fragments of its children. We propose a cube-pruning style algorithm that is suitable for both rule extraction during training and rule enumeration during decoding.

At the highest level, our algorithm involves three steps. In the first step, we label each node in the input forest by a boolean variable indicating whether it is a site of interest for tree fragment generation. If it is marked true, it is an *admissible* node. In the case of rule extraction, a node is admissible if and only if it corresponds to a phrase pair according to the underlying word alignment. In the case of decoding, every node is admissible for the sake of completeness of search. An initial one-node tree fragment is placed at each admissible node for seeding the tree fragment generation process. In the second step, we do cube-pruning style bottom-up combinations to enumerate a pruned list of tree fragments at each tree node. In the third step, we extract or enumerate-and-match tree-to-string rules for the tree fragments at the admissible nodes.

2.1 A Cube-pruning-inspired Algorithm for Tree Fragment Composition

Galley et al. (2004) defined minimal tree-to-string rules. Galley et al. (2006) showed that tree-to-string rules made by composing smaller ones are important to translation. It can be understood by the analogy of going from word-based models to phrase-based models. We relate composed rule extraction to cube-pruning (Chiang, 2007). In cube-pruning, the process is to keep track of the k-best sorted language model states at each node and combine them bottom-up with the help of a priority queue. We can imagine substituting k-best LM states with k composed rules at each node and composing them bottom-up. We can also borrow the cube pruning trick to compose multiple lists of rules using a priority queue to lazily explore the space of combinations starting from the top-most element in the cube formed by the lists.

We need to define a ranking function for composed rules. To simulate the breadth-first expansion heuristics of Galley et al. (2006), we define the figure of merit of a tree-to-string rule as a tuple $m = (h, s, t)$, where h is the height of a tree fragment, s is the number of frontier nodes, i.e., bottom-level nodes including both terminals and non-terminals, and t is the number of terminals in the set of frontier nodes. We define an additive operator $+$:

$$\begin{aligned} & m_1 + m_2 \\ & \quad = (\ \max\{h_1, h_2\} + 1,\ s_1 + s_2,\ t_1 + t_2\ ) \end{aligned}$$

and a $\min$ operator based on the order $<$:

$$m_1 < m_2 \iff \begin{cases} h_1 < h_2 \vee \\ h_1 = h_2 \ \wedge\ s_1 < s_2 \vee \\ h_1 = h_2 \ \wedge\ s_1 = s_2 \ \wedge\ t_1 < t_2 \end{cases}$$

The $+$ operator corresponds to rule compositions. The $<$ operator corresponds to ranking rules by their sizes. A concrete example is shown in Figure 2, in which case the monotonicity property of $(+, <)$ holds: if $m_a < m_b$, $m_a + m_c < m_b + m_c$. However, this is not true in general for the operators in our definition, which implies that our algorithm is indeed like cube-pruning: an approximate k-shortest-path algorithm.

3 Source Tree Binarization

The motivation of tree binarization is to factorize large and rare structures into smaller but frequent ones to improve generalization. For example, Penn Treebank annotations are often flat at the phrase level. Translation rules involving flat phrases are unlikely to generalize. If long sequences are binarized,

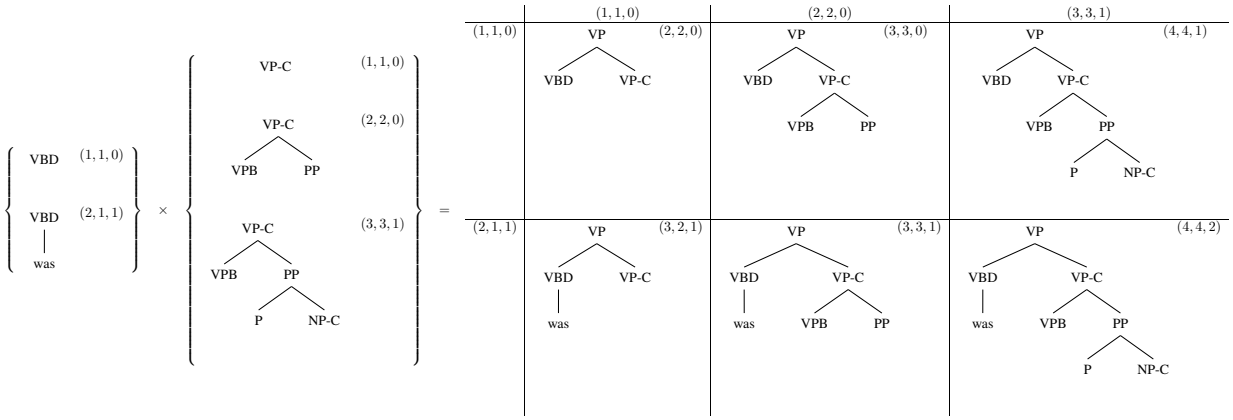

Figure 2: Tree-to-string rule composition as cube-pruning. The left shows two lists of composed rules sorted by their geometric measures $(height, \#\ frontiers, \#\ frontier\ terminals)$, under the gluing rule of VP $\rightarrow$ VBD VP$-$C. The right part shows a cube view of the combination space. We explore the space from the top-left corner to the neighbors.

the commonality of subsequences can be discovered. For example, the simplest binarization methods *left-to-right*, *right-to-left*, and *head-out* explore sharing of prefixes or suffixes. Among exponentially many binarization choices, these algorithms pick a single bracketing structure for a sequence of sibling nodes. To explore all possible binarizations, we use a CYK algorithm to produce a packed forest of binary trees for a given sibling sequence.

With CYK binarization, we can explore any span that is nested within the original tree structure, but still miss all cross-bracket spans. For example, translating from English to Chinese, The phrase "There is" should often be translated into one verb in Chinese. In a correct English parse tree, however, the subject-verb boundary is between "There" and "is". As a result, tree-to-string translation based on constituent phrases misses the good translation rule.

The CYK-n binarization algorithm shown in Algorithm 1 is a parameterization of the basic CYK binarization algorithm we just outlined. The idea is that binarization can go beyond the scope of parent nodes to more distant ancestors. The CYK-n algorithm first annotates each node with its n nearest ancestors in the source tree, then generates a binarization forest that allows combining any two nodes with common ancestors. The ancestor chain labeled at each node licenses the node to only combine with nodes having common ancestors in the past n generations.

The algorithm creates new tree nodes on the fly. New tree nodes need to have their own states indicated by a node label representing what is covered internally by the node and an ancestor chain representing which nodes the node attaches to externally. Line 22 and Line 23 of Algorithm 1 update the label and ancestor annotations of new tree nodes. Using the parsing semiring notations (Goodman, 1999), the ancestor computation can be summarized by the $(\cap, \cup)$ pair. $\cap$ produces the ancestor chain of a hyper-edge. $\cup$ produces the ancestor chain of a hyper-node. The node label computation can be summarized by the $(\mathrm{concatenate}, \mathrm{min})$ pair. $\mathrm{concatenate}$ produces a concatenation of node labels. min yields the label with the shortest length. A *tree-sequence* (Liu et al., 2007) is a sequence of sub-trees covering adjacent spans. It can be proved that the final label of each new node in the forest corresponds to the tree sequence which has the minimum length among all sequences covered by the node span. The ancestor chain of a new node is the common ancestors of the nodes in its minimum tree sequence.

For clarity, we do full CYK loops over all $O(|w|^2)$ spans and $O(|w|^3)$ potential hyper-edges, where $|w|$ is the length of a source string. In reality, only descendants under a shared ancestor can combine. If we assume trees have a bounded branching factor b, the number of descendants after n generations is still bounded by a constant $c = b^n$. The algorithm is $O(c^3 \cdot |w|)$, which is still linear to the size of input sentence when the parameter n is a constant.

Figure 3: Alternative binary parses created for the original tree fragment in Figure 1 through CYK-2 binarization (a and b) and CYK-3 binarization (c and d). In the chart representation at the bottom, cells with labels containing the concatenation symbol $+$ hold nodes created through binarization.

Figure 3 shows some examples of alternative trees generated by the CYK-n algorithm. In this example, standard CYK binarization will not create any new trees since the input is already binary. The CYK-2 and CYK-3 algorithms discover new trees with an increasing degree of freedom.

4 Synchronous Binarization for Forest-to-string Decoding

In this section, we deal with binarization of translation forests, also known as translation hypergraphs (Mi et al., 2008). A translation forest is a packed forest representation of all synchronous derivations composed of tree-to-string rules that match the source forest. Tree-to-string decoding algorithms work on a translation forest, rather than a source forest. A binary source forest does not necessarily always result in a binary translation forest. In the tree-to-string rule in Figure 4, the source tree is already

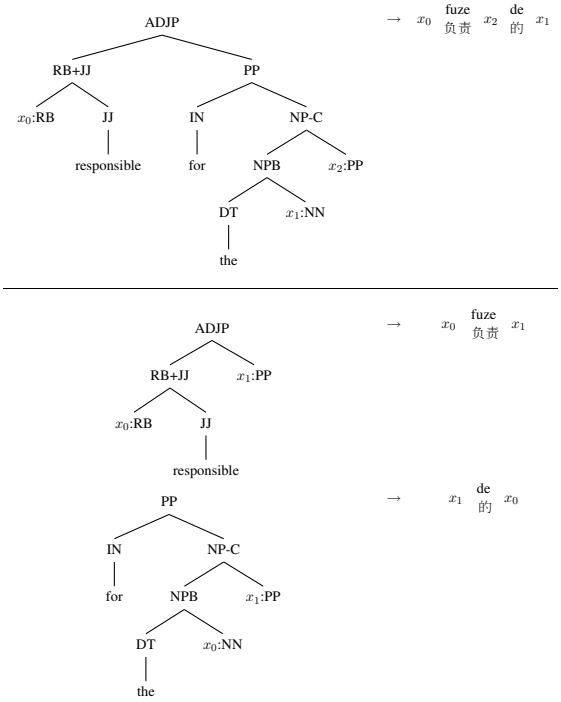

Figure 4: Synchronous binarization for a tree-to-string rule. The top rule can be binarized into two smaller rules.

binary with the help of source tree binarization, but the translation rule involves three variables in the set of frontier nodes. If we apply synchronous binarization (Zhang et al., 2006), we can factorize it into two smaller translation rules each having two variables. Obviously, the second rule, which is a common pattern, is likely to be shared by many translation rules in the derivation forest. When beams are fixed, search goes deeper in a factorized translation forest.

The challenge of synchronous binarization for a forest-to-string system is that we need to first match large tree fragments in the input forest as the first step of decoding. Our solution is to do the matching using the original rules and then run synchronous binarization to break matching rules down to factor rules which can be shared in the derivation forest. This is different from the offline binarization scheme described in (Zhang et al., 2006), although the core algorithm stays the same.

5 Experiments

We ran experiments on public data sets for English to Chinese, Czech, French, German, and Spanish

translation to evaluate our methods.

5.1 Setup

For English-to-Chinese translation, we used all the allowed training sets in the NIST 2008 constrained track. For English to the European languages, we used the training data sets for WMT 2010 (Callison-Burch et al., 2010). For NIST, we filtered out sentences exceeding 80 words in the parallel texts. For WMT, the filtering limit is 60. There is no filtering on the test data set. Table 1 shows the corpus statistics of our bilingual training data sets.

	Source Words	Target Words
English-Chinese	287M	254M
English-Czech	66M	57M
English-French	857M	996M
English-German	45M	43M
English-Spanish	216M	238M

Table 1: The Sizes of Parallel Texts.

At the word alignment step, we did 6 iterations of IBM Model-1 and 6 iterations of HMM. For English-Chinese, we ran 2 iterations of IBM Model-4 in addition to Model-1 and HMM. The word alignments are symmetrized using the "union" heuristics. Then, the standard phrase extraction heuristics (Koehn et al., 2003) were applied to extract phrase pairs with a length limit of 6. We ran the hierarchical phrase extraction algorithm with the standard heuristics of Chiang (2005). The phrase-length limit is interpreted as the maximum number of symbols on either the source side or the target side of a given rule. On the same aligned data sets, we also ran the tree-to-string rule extraction algorithm described in Section 2.1 with a limit of 16 rules per tree node.

The default parser in the experiments is a shift-reduce dependency parser (Nivre and Scholz, 2004). It achieves 87.8% labelled attachment score and 88.8% unlabeled attachment score on the standard Penn Treebank test set. We convert dependency parses to constituent trees by propagating the part-of-speech tags of the head words to the corresponding phrase structures.

We compare three systems: a phrase-based system (Och and Ney, 2004), a hierarchical phrase-based system (Chiang, 2005), and our forest-to-string system with different binarization schemes. In the phrase-based decoder, jump width is set to 8. In the hierarchical decoder, only the glue rule is applied

to spans longer than 10. For the forest-to-string system, we do not have such length-based reordering constraints.

We trained two 5-gram language models with Kneser-Ney smoothing for each of the target languages. One is trained on the target side of the parallel text, the other is on a corpus provided by the evaluation: the Gigaword corpus for Chinese and news corpora for the others. Besides standard features (Och and Ney, 2004), the phrase-based decoder also uses a Maximum Entropy phrasal reordering model (Zens and Ney, 2006). Both the hierarchical decoder and the forest-to-string decoder only use the standard features. For feature weight tuning, we do Minimum Error Rate Training (Och, 2003). To explore a larger n-best list more efficiently in training, we adopt the hypergraph-based MERT (Kumar et al., 2009).

To evaluate the translation results, we use BLEU (Papineni et al., 2002).

5.2 Translation Results

Table 2 shows the scores of our system with the best binarization scheme compared to the phrase-based system and the hierarchical phrase-based system. Our system is consistently better than the other two systems in all data sets. On the English-Chinese data set, the improvement over the phrase-based system is 1.3 BLEU points, and 0.8 over the hierarchical phrase-based system. In the tasks of translating to European languages, the improvements over the phrase-based baseline are in the range of 0.5 to 1.0 BLEU points, and 0.3 to 0.5 over the hierarchical phrase-based system. All improvements except the *bf2s* and *hier* difference in English-Czech are significant with confidence level above 99% using the bootstrap method (Koehn, 2004). To demonstrate the strength of our systems including the two baseline systems, we also show the reported best results on these data sets from the 2010 WMT workshop. Our forest-to-string system (*bf2s*) outperforms or ties with the best ones in three out of four language pairs.

		BLEU dev	BLEU test
English-Chinese	pb	29.7	39.4
	hier	31.7	38.9
	bf2s	31.9	40.7**
English-Czech	*wmt best*	-	*15.4*
	pb	14.3	15.5
	hier	14.7	16.0
	bf2s	14.8	16.3*
English-French	*wmt best*	-	*27.6*
	pb	24.1	26.1
	hier	23.9	26.1
	bf2s	24.5	26.6**
English-German	*wmt best*	-	*16.3*
	pb	14.5	15.5
	hier	14.9	15.9
	bf2s	15.2	16.3**
English-Spanish	*wmt best*	-	*28.4*
	pb	24.1	27.9
	hier	24.2	28.4
	bf2s	24.9	28.9**

Table 2: Translation results comparing *bf2s*, the binarized-forest-to-string system, *pb*, the phrase-based system, and *hier*, the hierarchical phrase-based system. For comparison, the best scores from WMT 2010 are also shown. ** indicates the result is significantly better than both *pb* and *hier*. * indicates the result is significantly better than *pb* only.

5.3 Different Binarization Methods

The translation results for the *bf2s* system in Table 2 are based on the *cyk* binarization algorithm with bracket violation degree 2. In this section, we vary the degree to generate forests that are incrementally augmented from a single tree. Table 3 shows the scores of different tree binarization methods for the English-Chinese task.

It is clear from reading the table that *cyk*-2 is the optimal binarization parameter. We have verified this is true for other language pairs on non-standard data sets. We can explain it from two angles. At degree 2, we allow phrases crossing at most one bracket in the original tree. If the parser is reasonably good, crossing just one bracket is likely to cover most interesting phrases that can be translation units. From another point of view, enlarging the forests entails more parameters in the resulting translation model, making over-fitting likely to happen.

5.4 Binarizer or Parser?

A natural question is how the binarizer-generated forests compare with parser-generated forests in translation. To answer this question, we need a

	rules	BLEU dev	BLEU test
no binarization	378M	28.0	36.3
head-out	408M	30.0	38.2
cyk-1	527M	31.6	40.5
cyk-2	803M	31.9	40.7
cyk-3	1053M	32.0	40.6
cyk-∞	1441M	32.0	40.3

Table 3: Comparing different source tree binarization schemes for English-Chinese translation, showing both BLEU scores and model sizes. The rule counts include normal phrases which are used at the leaf level during decoding.

parser that can generate a packed forest. Our fast deterministic dependency parser does not generate a packed forest. Instead, we use a CRF constituent parser (Finkel et al., 2008) with state-of-the-art accuracy. On the standard Penn Treebank test set, it achieves an F-score of 89.5%. It uses a CYK algorithm to do full dynamic programming inference, so is much slower. We modified the parser to do hyperedge pruning based on posterior probabilities. The parser preprocesses the Penn Treebank training data through binarization. So the packed forest it produces is also a binarized forest. We compare two systems: one is using the *cyk*-2 binarizer to generate forests; the other is using the CRF parser with pruning threshold e^{-p}, where $p = 2$ to generate forests.[1] Although the parser outputs binary trees, we found cross-bracket *cyk*-2 binarization is still helpful.

	BLEU dev	BLEU test
cyk-2	14.9	16.0
parser	14.7	15.7

Table 4: Binarized forests versus parser-generated forests for forest-to-string English-German translation.

Table 4 shows the comparison of binarization forest and parser forest on English-German translation. The results show that *cyk*-2 forest performs slightly better than the parser forest. We have not done full exploration of forest pruning parameters to fine-tune the parser-forest. The speed of the constituent parser is the efficiency bottleneck. This actually demonstrates the advantage of the binarizer plus forest-to-string scheme. It is flexible, and works with any parser that generates projective parses. It does not require hand-tuning of forest pruning parameters for training.

[1]All hyper-edges with negative log posterior probability larger than p are pruned. In Mi and Huang (2008), the threshold is $p = 10$. The difference is that they do the forest pruning on a forest generated by a k-best algorithm, while we do the forest-pruning on the full CYK chart. As a result, we need more aggressive pruning to control forest size.

5.5 Synchronous Binarization

In this section, we demonstrate the effect of synchronous binarization for both tree-to-string and forest-to-string translation. The experiments are on the English-Chinese data set. The baseline systems use k-way cube pruning, where k is the branching factor, i.e., the maximum number of nonterminals on the right-hand side of any synchronous translation rule in an input grammar. The competing system does online synchronous binarization as described in Section 4 to transform the grammar intersected with the input sentence to the minimum branching factor k' ($k' < k$), and then applies k'-way cube pruning. Typically, k' is 2.

		BLEU dev	BLEU test
head-out	cube pruning	29.2	37.0

Table 5 shows that synchronous binarization does help reduce search errors and find better translations consistently in all settings.

6 Related Work

The idea of concatenating adjacent syntactic categories has been explored in various syntax-based models. Zollmann and Venugopal (2006) augmented hierarchial phrase based systems with joint syntactic categories. Liu et al. (2007) proposed tree-sequence-to-string translation rules but did not provide a good solution to place joint subtrees into connection with the rest of the tree structure. Zhang et

al. (2009) is the closest to our work. But their goal was to augment a k-best forest. They did not binarize the tree sequences. They also did not put constraint on the tree-sequence nodes according to how many brackets are crossed.

Wang et al. (2007) used target tree binarization to improve rule extraction for their string-to-tree system. Their binarization forest is equivalent to our *cyk*-1 forest. In contrast to theirs, our binarization scheme affects decoding directly because we match tree-to-string rules on a binarized forest.

Different methods of translation rule binarization have been discussed in Huang (2007). Their argument is that for tree-to-string decoding target side binarization is simpler than synchronous binarization and works well because creating discontinous source spans does not explode the state space. The forest-to-string senario is more similar to string-to-tree decoding in which state-sharing is important. Our experiments show that synchronous binarization helps significantly in the forest-to-string case.

7 Conclusion

We have presented a new approach to tree-to-string translation. It involves a source tree binarization step and a standard forest-to-string translation step. The method renders it unnecessary to have a k-best parser to generate a packed forest. We have demonstrated state-of-the-art results using a fast parser and a simple tree binarizer that allows crossing at most one bracket in each binarized node. We have also shown that reducing search errors is important for forest-to-string translation. We adapted the synchronous binarization technqiue to improve search and have shown significant gains. In addition, we also presented a new cube-pruning-style algorithm for rule extraction. In the new algorithm, it is easy to adjust the figure-of-merit of rules for extraction. In the future, we plan to improve the learning of translation rules with binarized forests.

Abstract

We propose a novel technique of learning how to transform the source parse trees to improve the translation qualities of syntax-based translation models using synchronous context-free grammars. We transform the source tree phrasal structure into a set of simpler structures, expose such decisions to the decoding process, and find the least expensive transformation operation to better model word reordering. In particular, we integrate synchronous binarizations, verb regrouping, removal of redundant parse nodes, and incorporate a few important features such as translation boundaries. We learn the structural preferences from the data in a generative framework. The syntax-based translation system integrating the proposed techniques outperforms the best Arabic-English unconstrained system in NIST-08 evaluations by 1.3 absolute BLEU, which is statistically significant.

1 Introduction

Most syntax-based machine translation models with synchronous context free grammar (SCFG) have been relying on the off-the-shelf monolingual parse structures to learn the translation equivalences for string-to-tree, tree-to-string or tree-to-tree grammars. However, state-of-the-art monolingual parsers are not necessarily well suited for machine translation in terms of both labels and chunks/brackets. For instance, in Arabic-to-English translation, we find only 45.5% of Arabic NP-SBJ structures are mapped to the English NP-SBJ with machine alignment and parse trees, and only 60.1% of NP-SBJs are mapped with human alignment and parse trees as in § 2. The chunking is of more concern; at best only 57.4% source chunking decisions are translated contiguously on the target side. To translate the rest of the chunks one has to frequently *break* the original structures. The main issue lies in the strong assumption behind SCFG-style nonterminals – each nonterminal (or variable) assumes a source chunk should be rewritten into a *contiguous* chunk in the target. Without integrating techniques to modify the parse structures, the SCFGs are not to be effective even for translating NP-SBJ in linguistically distant language-pairs such as Arabic-English.

Such problems have been noted in previous literature. Zollmann and Venugopal (2006) and Marcu et al. (2006) used broken syntactic fragments to augment their grammars to increase the rule coverage; while we learn optimal tree fragments transformed from the original ones via a generative framework, they enumerate the fragments available from the original trees without learning process. Mi and Huang (2008) introduced parse forests to blur the chunking decisions to a certain degree, to expand search space and reduce parsing errors from 1-best trees (Mi et al., 2008); others tried to use the parse trees as soft constraints on top of unlabeled grammar such as Hiero (Marton and Resnik, 2008; Chiang, 2010; Huang et al., 2010; Shen et al., 2010) without sufficiently leveraging rich tree context. Recent works tried more complex approaches to integrate both parsing and decoding in one *single* search space as in (Liu and Liu, 2010), at the cost of huge search space. In (Zhang et al., 2009), combinations of tree forest and *tree-sequence* (Zhang et al., 2008) based approaches were carried out by adding pseudo nodes and hyper edges into the forest. Overall, the forest-based translation can reduce the risks from upstream parsing errors and expand the search space, but it cannot sufficiently address the syntactic divergences between various language-pairs. The tree sequence approach adds pseudo nodes and hyper edges to the forest, which makes the forest even denser and harder for navigation and search. As trees thrive in the search space, especially with the pseudo nodes and edges being added to the already dense forest, it is becoming harder to wade through the deep forest for the best derivation path out.

We propose to simplify suitable subtrees to a reasonable level, at which the correct reordering can be easily identified. The transformed structure should be frequent enough to have rich statistics for learning a model. Instead of creating pseudo nodes and edges and make the forest dense, we transform a tree with a few simple operators; only meaningful frontier nodes, context nodes and edges are kept to induce the correct reordering; such operations also enable the model to share the statistics among all similar subtrees.

On the basis of our study on investigating the language divergence between Arabic-English with human aligned and parsed data, we integrate several simple statistical operations, to transform parse trees adaptively to serve the

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 846–855,
Portland, Oregon, June 19-24, 2011.

translation purpose better. For each source span in the given sentence, a subgraph, corresponding to an elementary tree (in Eqn. 1), is proposed for PSCFG translation; we apply a few operators to transform the subgraph into some frequent subgraphs seen in the whole training data, and thus introduce alternative similar translational equivalences to explain the same source span with enriched statistics and features. For instance, if we regroup two adjacent nodes IV and NP-SBJ in the tree, we can obtain the correct reordering pattern for verb-subject order, which is not easily available otherwise. By finding a set of similar elementary trees derived from the original elementary trees, statistics can be shared for robust learning.

We also investigate the features using the context beyond the phrasal subtree. This is to further disambiguate the transformed subgraphs so that informative neighboring nodes and edges can influence the reordering preferences for each of the transformed trees. For instance, at the beginning and end of a sentence, we do not expect dramatic long distance reordering to happen; or under SBAR context, the clause may prefer monotonic reordering for verb and subject. Such boundary features were treated as hard constraints in previous literature in terms of re-labeling (Huang and Knight, 2006) or re-structuring (Wang et al., 2010). The boundary cases were not addressed in the previous literature for trees, and here we include them in our feature sets for learning a MaxEnt model to predict the transformations. We integrate the neighboring context of the subgraph in our transformation preference predictions, and this improve translation qualities further.

The rest of the paper is organized as follows: in section 2, we analyze the projectable structures using human aligned and parsed data, to identify the problems for SCFG in general; in section 3, our proposed approach is explained in detail, including the statistical operators using a MaxEnt model; in section 4, we illustrate the integration of the proposed approach in our decoder; in section 5, we present experimental results; in section 6, we conclude with discussions and future work.

2 The Projectable Structures

A context-free style nonterminal in PSCFG rules means the source span governed by the nonterminal should be translated into a contiguous target chunk. A "projectable" phrase-structure means that it is translated into a contiguous span on the target side, and thus can be generalized into a nonterminal in our PSCFG rule. We carried out a controlled study on the projectable structures using human annotated parse trees and word alignment for 5k Arabic-English sentence-pairs.

In Table 1, the unlabeled F-measures with machine alignment and parse trees show that, for only 48.71% of the time, the boundaries introduced by the source parses

Alignment	Parse	Labels	Accuracy
H	H	NP-SBJ	0.6011
		PP	0.3436
		NP	0.4832
		unlabel	0.5739

		PP	0.2765
		NP	0.3959
		unlabel	0.5305
M	M	NP-SBJ	0.4555
		PP	0.1935
		NP	0.3556
		unlabel	0.4871

Table 1: The labeled and unlabeled F-measures for projecting the source nodes onto the target side via alignments and parse trees; unlabeled F-measures show the bracketing accuracies for translating a source span contiguously. H: human, M: machine.

are real translation boundaries that can be explained by a nonterminal in PSCFG rule. Even for human parse and alignment, the unlabeled F-measures are still as low as 57.39%. Such statistics show that we should not blindly learn tree-to-string grammar; additional transformations to manipulate the bracketing boundaries and labels accordingly have to be implemented to guarantee the reliability of source-tree based syntax translation grammars. The transformations could be as simple as merging two adjacent nonterminals into one bracket to accommodate non-contiguity on the target side, or lexicalizing those words which have fork-style, many-to-many alignment, or unaligned content words to enable the rest of the span to be generalized into nonterminals. We illustrate several cases using the tree in Figure 1.

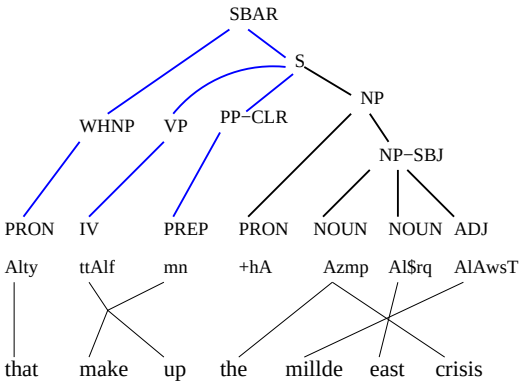

Figure 1: Non-projectable structures in an SBAR tree with human parses and alignment; there are non-projectable structures: the deleted nonterminals PRON (+hA), the many-to-many alignment for IV(ttAlf) PREP(mn), fork-style alignment for NOUN (Azmp).

In Figure 1, several non-projectable nodes were illus-

trated: the deleted nonterminals PRON (+hA), the many-to-many alignment for IV(ttAlf) PREP(mn), fork-style alignment for NOUN (Azmp). Intuitively, it would be good to glue the nodes NOUN(Al$rq) ADJ(AlAwsT) under the node of NP, because it is more frequent for moving ADJ before NOUN in our training data. It should be easier to model the swapping of (NOUN ADJ) using the tree (NP NOUN, ADJ) instead of the original bigger tree of (NP-SBJ Azmp, NOUN, ADJ) with one lexicalized node.

Approaches in tree-sequence based grammar (Zhang et al., 2009) tried to address the bracketing problem by using arbitrary pseudo nodes to weave a new "tree" back into the forest for further grammar extractions. Such approach may improve grammar coverage, but the pseudo node labels would be arguably a worse choice to split the already sparse data. Some of the interior nodes connecting the frontier nodes might be very informative for modeling reordering. Also, due to the introduced pseudo nodes, it would need *exponentially* many nonterminals to keep track of the matching tree-structures for translations. The created pseudo node could easily block the informative neighbor nodes associated with the subgraph which could change the reordering nature. For instance, IV and NP-SBJ tends to swap at the beginning of a sentence, but it may prefer monotone if they share a common parent of SBAR for a subclause. In this case, it is unnecessary to create a pseudo node "IV+SBJ" to block useful factors.

We propose to navigate through the forest, via simplifying trees by grouping the nodes, cutting the branches, and attaching connected neighboring informative nodes to further disambiguate the derivation path. We apply explicit translation motivated operators, on a given monolingual elementary tree, to transform it into similar but simpler trees, and expose such statistical preferences to the decoding process to select the best rewriting rule from the *enriched* grammar rule sets, for generating target strings.

3 Elementary Trees to String Grammar

We propose to use variations of an elementary tree, which is a connected subgraph fitted in the original monolingual parse tree. The subgraph is connected so that the frontiers (two or more) are connected by their *immediate common parent*. Let γ be a source elementary tree:

$$\gamma =< \ell; v^f, v^i, E >, \tag{1}$$

where v^f is a set of *frontier nodes* which contain nonterminals or words; v^i are the *interior nodes* with source labels/symbols; E is the set of *edges* connecting the nodes $v = v^f + v^i$ into a connected *subgraph* fitted in the source parse tree; ℓ is the *immediate common parent* of the frontier nodes v^f. Our proposed grammar rule is formulated as follows:

$$< \gamma; \alpha; \sim; \bar{m}; \bar{t} >, \tag{2}$$

where α is the target string, containing the terminals and/or nonterminals in a target language; $\sim$ is the one-to-one alignment of the nonterminals between γ and α; $\bar{t}$ contains possible sequence of transform operations (to be explained later in this section) associated with each rule; $\bar{m}$ is a function of enumerating the neighborhood of the source elementary tree γ, and certain tree context (nodes and edges) can be used to further disambiguate the reordering or the given lexical choices. The interior nodes of $\gamma.v^i$, however, are not necessarily informative for the reordering decisions, like the unary nodes WHNP,VP, and PP-CLR in Figure 1; while the frontier nodes $\gamma.v^f$ are the ones directly executing the reordering decisions. We can selectively cut off the interior nodes, which have no or only weak causal relations to the reordering decisions. This will enable the frequency or derived probabilities for executing the reordering to be more focused. We call such *transformation operators* $\bar{t}$. We specified a few operators for transforming an elementary tree γ, including flattening tree operators such as removing interior nodes in v^i, or grouping the children via binarizations.

Let's use the trigram "Alty ttAlf mn" in Figure 1 as an example, the immediate common parent for the span is SBAR: $\gamma.\ell$ = SBAR; the interior nodes are $\gamma.v^i$ = {WHNP VP S PP-CLR}; the frontier nodes are $\gamma.v^f$ = (x:PRON x:IV x:PREP). The edges $\gamma.E$ (as highlighted in Figure 1) connect $\gamma.v^i$ and $\gamma.v^f$ into a subgraph for the given source ngram.

For any source span, we look up one elementary tree γ covering the span, then we select an operator $\bar{t} \in T$, to explore a set of similar elementary trees $\bar{t}(\gamma, \bar{m}) = \{\gamma'\}$ as simplified alternatives for translating that source tree (span) γ into an optimal target string α^* accordingly. Our generative model is summarized in Eqn. 3:

$$\begin{aligned} \alpha^* = \underset{\bar{t}\in T;\gamma'\in\bar{t}(\gamma,\bar{m})}{\arg\max} \quad & p_a(\alpha'|\gamma')\times \\ & p_b(\gamma'|\bar{t},\gamma,\bar{m})\times \\ & p_c(\bar{t}|\gamma,\bar{m}). \end{aligned} \tag{3}$$

In our generative scheme, for a given elementary tree γ, we sample an operator (or a combination of operations) $\bar{t}$ with the probability of $p_c(\bar{t}|\gamma)$; with operation $\bar{t}$, we transform γ into a set of simplified versions $\gamma' \in \bar{t}(\gamma, \bar{m})$ with the probability of $p_b(\gamma'|\bar{t}, \gamma)$; finally we select the transformed version γ' to generate the target string α' with a probability of $p_a(\alpha'|\gamma')$. Note here, γ' and γ share the same immediate common parent ℓ, but not necessarily the frontier, or interior, or even neighbors. The frontier nodes can be merged, lexicalized, or even deleted in the tree-to-string rule associated with γ', as long as the alignment for the nonterminals are book-kept in the derivations. To simplify the model, one can choose the operator $\bar{t}$ to be only one level, and the model using a single operator $\bar{t}$ is to be deterministic. Thus, the final set of models

to learn are $p_a(\alpha'|\gamma')$ for rule alignment, and the preference model $p_b(\gamma'|\bar{t},\gamma,\bar{m})$, and the operator proposal model $p_c(\bar{t}|\gamma,\bar{m})$, which in our case is a maximum entropy model— the key model in our proposed approach in this paper for transforming the original elementary tree into similar trees for evaluating the reordering probabilities.

Eqn. 3 significantly enriches reordering powers for syntax-based machine translation. This is because it uses all *similar* set of elementary trees to generate the best target strings. In the next section, we'll first define the operators conceptually, and then explain how we learn each of the models.

3.1 Model $p_a(\alpha'|\gamma')$

A log linear model is applied here to approximate $p_a(\alpha'|\gamma') \propto \exp(\bar{\lambda}\cdot\overline{ff})$ via weighted combination ($\bar{\lambda}$) of feature functions $\overline{ff}(\alpha',\gamma')$, including relative frequencies in both directions, and IBM Model-1 scores in both directions as γ' and α' have lexical items within them. We also employed a few binary features listed in the following table.

γ' is observed less than 2 times
(α',γ') deletes a src content word
(α',γ') deletes a src function word
(α',γ') over generates a tgt content word
(α',γ') over generates a tgt function word

Table 2: Additional 5 Binary Features for $p_a(\alpha'|\gamma')$

3.2 Model $p_b(\gamma'|\bar{t},\gamma,\bar{m})$

$p_b(\gamma'|\bar{t},\gamma,\bar{m})$ is our preference model. For instance using the operator $\bar{t}$ of cutting an unary interior node in $\gamma.v^i$, if $\gamma.v^i$ has more than one unary interior node, like the SBAR tree in Figure 1, having three unary interior node: WHNP, VP and PP-CLR, $p_b(\gamma'|\bar{t},\gamma,\bar{m})$ specifies which one should have more probabilities to be cut. In our case, to make model simple, we simply choose histogram/frequency for modeling the choices.

3.3 Model $p_c(\bar{t}|\gamma,\bar{m})$

$p_c(\bar{t}|\gamma,\bar{m})$ is our operator proposal model. It ranks the operators which are valid to be applied for the given source tree γ together with its neighborhood $\bar{m}$. Here, in our approach, we applied a Maximum Entropy model, which is also employed to train our Arabic parser: $p_c(\bar{t}|\gamma,\bar{m}) \propto \exp\bar{\lambda}\cdot\overline{ff}(\bar{t},\gamma,\bar{m})$. The feature sets we use here are almost the same set we used to train our Arabic parser; the only difference is the future space here is operator categories, and we check bag-of-nodes for interior nodes and frontier nodes. The key feature categories we used are listed as in the Table 3. The headtable used in our training is manually built for Arabic.

bag-of-nodes $\gamma.v^i$
bag-of-nodes and ngram of $\gamma.v^f$
chunk-level features: left-child, right-child, etc.
lexical features: unigram and bigram
pos features: unigram and bigram
contextual features: surrounding words

Table 3: Feature Features for learning $p_c(\bar{t}|\gamma,\bar{m})$

3.4 $\bar{t}$: Tree Transformation Function

Obvious systematic linguistic divergences between language-pairs could be handled by some simple operators such as using binarization to re-group contiguously aligned children. Here, we start from the human aligned and parsed data as used in section 2 to explore potential useful operators.

3.4.1 Binarizations

One of the simplest way for transforming a tree is via binarization. Monolingual binarization chooses to re-group children into smaller subtree with a suitable label for the newly created root. We choose a function mapping to select the *top-frequent* label as the root for the grouped children; if such label is not found we simply use the label of the immediate common parent for γ. In decoding time, we need to select trees from all possible binarizations, while in the training time, we restrict the choices allowed with the alignment constraint, that every grouped children should be aligned contiguously on the target side. Our goal is to simulate the synchronous binarization as much as we can. In this paper, we applied the four basic operators for binarizing a tree: left-most, right-most and additionally head-out left and head-out right for more than three children. Two examples are given in Table 4, in which we used LDC style representation for the trees.

With the proper binarization, the structure becomes rich in sub-structures which allow certain reordering to happen more likely than others. For instance for the subtree (VP PV NP-SBJ), one would apply stronger statistics from training data to support the swap of NP-SBJ and PV for translation.

3.4.2 Regrouping verbs

Verbs are keys for reordering especially for Araic-English with VSO translated into SVO. However, if the verb and its relevant arguments for reordering are at different levels in the tree, the reordering is difficult to model as more interior nodes combinations will distract the distributions and make the model less focused. We provide the following two operations specific for verb in VP trees as in Table 5.

3.4.3 Removing interior nodes and edges

For reordering patterns, keeping the deep tree structure might not be the best choice. Sometimes it is not even

Binarization Operations	Examples
right-most	$(\text{NP}\ \ X_{\text{noun}}\ X_{\text{adj}_1}\ X_{\text{adj}_2}) \mapsto (\text{NP}\ \ X_{\text{noun}}\ (\text{ADJP}\ X_{\text{adj}_1}\ X_{\text{adj}_2}))$
left-most	$(\text{VP}\ \ X_{\text{pv}}\ X_{\text{NP-SBJ}}\ X_{\text{SBAR}}) \mapsto (\text{VP}\ \ (\text{VP}\ \ X_{\text{pv}}\ X_{\text{NP-SBJ}})\ X_{\text{SBAR}})$

Operators for regroup verbs	Examples
regroup verb	$(VP_1\ X_v\ (VP_2\ Y)) \mapsto (VP_1\ (VP_2\ X_v\ Y))$
regroup verb and remove the top level VP	$(R\ \ (VP_1\ X_v\ (R_2\ Y))) \mapsto (R\ \ (R_2\ X_v Y))$

Table 5: Operators for manipulating the trees

possible due to the many-to-many alignment, insertions and deletions of terminals. So, we introduce the operators to remove the interior nodes $\gamma.v^i$ selectively; this way, we can flatten the tree, remove irrelevant nodes and edges, and can use more frequent observations of simplified structures to capture the reordering patterns. We use two operators as shown in Table 6.

The second operator deletes all the interior nodes, labels and edges; thus reordering will become a Hiero-alike (Chiang, 2007) *unlabeled rule*, and additionally a special glue rule: $X_1X_2 \rightarrow X_1X_2$. This operator is necessary, we need a scheme to automatically back off to the meaningful glue or Hiero-alike rules, which may lead to a cheaper derivation path for constructing a partial hypothesis, at the decoding time.

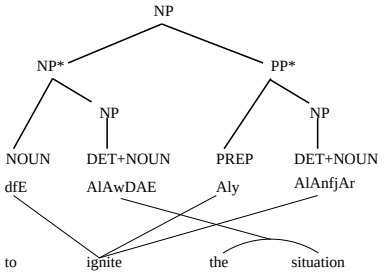

Figure 2: A NP tree with an "inside-out" alignment. The nodes "NP*" and "PP*" are not suitable for generalizing into NTs used in PSCFG rules.

As shown in Table 1, NP brackets has only 35.56% of time to be translated contiguously as an NP in machine aligned & parsed data. The NP tree in Figure 2 happens to be an "inside-out" style alignment, and context free grammar such as ITG (Wu, 1997) can not explain this structure well without necessary lexicalization. Actually, the Arabic tokens of "dfE Aly AlAnfjAr" form a combination and is turned into English word "ignite" in an idiomatic way. With lexicalization, a Hiero style rule "dfE X Aly AlAnfjAr $\mapsto$ to ignite X" is potentially a better alternative for translating the NP tree. Our operators allow us to back off to such Hiero-style rules to construct derivations, which share the immediate common parent NP, as defined for the elementary tree, for the given source span.

3.5 $\bar{m}$: Neighboring Function

For a given elementary tree, we use function $\bar{m}$ to check the context beyond the subgraph. This includes looking the nodes and edges connected to the subgraph. Similar to the features used in (Dyer et al., 2009), we check the following three cases.

3.5.1 Sentence boundaries

When the tree γ frontier sets contain the left-most token, right-most token, or both sides, we will add to the neighboring nodes the corresponding decoration tags L (left), R (right), and B (both), respectively. These decorations are important especially when the reordering patterns for the same trees are depending on the context. For instance, at the beginning or end of a sentence, we do not expect dramatic reordering – moving a token too far away in the middle of the sentences.

3.5.2 SBAR/IP/PP/FRAG boundaries

We check siblings of the root for γ for a few special labels, including SBAR, IP, PP, and FRAG. These labels indicate a partial sentence or clause, and the reordering patterns may get different distributions due to the position relative to these nodes. For instance, the PV and SBJ nodes under SBAR tends to have more monotone preference for word reordering (Carpuat et al., 2010). We mark the boundaries with position markers such as L-PP, to indicate having a left sibling PP, R-IP for having a right sibling IP, and C-SBAR to indicate the elementary tree is a child of SBAR. These labels are selected mainly based on our linguistic intuitions and errors in our translation system. A data-driven approach might be more promising for identifying useful markups w.r.t specific reordering patterns.

3.5.3 Translation boundaries

In the Figure 2, there are two special nodes under NP: NP* and PP*. These two nodes are aligned in a "inside-out" fashion, and none of them can be generalized into a nonterminal to be rewritten in a PSCFG rule. In other words, the phrasal brackets induced from NP* and PP*

operators for removing nodes/edges	Examples
remove unary nodes	$(R\ \ X_{t_1}(R_1\ \ (R2\ \ X_{t_2}))) \mapsto (R\ \ X_{t_1}(R2\ \ X_{t_2}))$
remove all labels	$(R\ \ (R_1\ \ X_{t_1}(R_2\ \ X_{t_2}))) \mapsto\ \ (R\ \ X_{t_2}X_{t_1})$

Table 6: Operators for simplifying the trees

are not *translation boundaries*, and to avoid translation errors we should identify them by applying a PSCFG rule on top of them. During training, we label nodes with translation boundaries, as one additional *function tag*; during decoding, we employ the MaxEnt model to predict the translation boundary label probability for each span associated with a subgraph γ, and discourage derivations accordingly for using nonterminals over the non-translation boundary span. The translation boundaries over elementary trees have much richer representation power. The previous works as in Xiong et al. (2010), defined translation boundaries on phrase-decoder style derivation trees due to the nature of their shift-reduce algorithm, which is a special case in our model.

4 Decoding

Decoding using the proposed elementary tree to string grammar naturally resembles bottom up chart parsing algorithms. The key difference is at the grammar querying step. Given a grammar G, and the input source parse tree π from a monolingual parser, we first construct the elementary tree for a source span, and then retrieve all the relevant subgraphs seen in the given grammar through the proposed operators. This step is called populating, using the proposed operators to find all relevant elementary trees γ which may have contributed to explain the source span, and put them in the corresponding cells in the chart. There would have been exponential number of relevant elementary trees to search if we do not have any restrictions in the populating step; we restrict the maximum number of interior nodes $|\gamma.v^i|$ to be 3, and the size of frontier nodes $|\gamma.v^f|$ to be less than 6; additional pruning for less frequent elementary trees is carried out.

After populating the elementary trees, we construct the partial hypotheses bottom up, by rewriting the frontier nodes of each elementary tree with the probabilities(costs) for $\gamma \rightarrow \alpha*$ as in Eqn. 3. Our decoder (Zhao and Al-Onaizan, 2008) is a template-based chart decoder in C++. It generalizes over the dotted-product operator in Earley style parser, to allow us to leverage many operators $\bar{t} \in T$ as above-mentioned, such as binarizations, at different levels for constructing partial hypothesis.

5 Experiments

In our experiments, we built our system using most of the parallel training data available to us: 250M Arabic running tokens, corresponding to the "unconstrained" condition in NIST-MT08. We chose the testsets of *newswire* and *weblog* genres from MT08 and DEV10[1]. In particular, we choose MT08 to enable the comparison of our results to the reported results in NIST evaluations. Our training and test data is summarized in Table 5. For testings, we have 129,908 tokens in our testsets. For language models (LM), we used 6-gram LM trained with 10.3 billion English tokens, and also a shrinkage-based LM (Chen, 2009) – "ModelM" (Chen and Chu, 2010; Emami et al., 2010) with 150 word-clusters learnt from 2.1 million tokens.

From the parallel data, we extract phrase pairs(blocks) and elementary trees to string grammar in various configurations: basic tree-to-string rules (Tr2str), elementary tree-to-string rules with boundaries $\bar{t}$(elm2str+$\bar{m}$), and with both $\bar{t}$ and $\bar{m}$ (elm2str+$\bar{t}$ + $\bar{m}$). This is to evaluate the operators' effects at different levels for decoding. To learn our MaxEnt models defined in § 3.3, we collect the events during extracting elm2str grammar in training time, and learn the model using improved iterative scaling. We use the same training data as that used in training our Arabic parser. There are 16 thousand human parse trees with human alignment; additional 1 thousand human parse and aligned sent-pairs are used as unseen test set to verify our MaxEnt models and parsers. For our Arabic parser, we have a labeled F-measure of 78.4%, and POS tag accuracy 94.9%. In particular, we'll evaluate model $p_c(\bar{t}|\gamma, \bar{m})$ in Eqn. 3 for predicting the translation boundaries in § 3.5.3 for projectable spans as detailed in § 5.1.

Our decoder (Zhao and Al-Onaizan, 2008) supports grammars including monotone, ITG, Hiero, tree-to-string, string-to-tree, and several mixtures of them (Lee et al., 2010). We used 19 feature functions, mainly from those used in phrase-based decoder like Moses (Koehn et al., 2007), including two language models (one for a 6-gram LM, one for ModelM, one brevity penalty, IBM Model-1 (Brown et al., 1993) style alignment probabilities in both directions, relative frequency in both directions, word/rule counts, content/function word mismatch, together with features on tr2str rule probabilities. We use BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) to evaluate translation qualities. Our baseline used basic elementary tree to string grammar without any manipulations and boundary markers in the model,

[1]DEV10 are unseen testsets used in our GALE project. It was selected from recently released LDC data LDC2010E43.v3.

Data	Train	MT08-NW	MT08-WB	Dev10-NW	Dev10-WB
# Sents	8,032,837	813	547	1089	1059
# Tokens	349M(ar)/230M(en)	25,926	19,654	41,240	43,088

Table 7: Training and test data; using all training parallel training data for 4 test sets

and we achieved a BLEUr4n4 55.01 for MT08-NW, or a cased BLEU of 53.31, which is close to the best officially reported result 53.85 for unconstrained systems.[2] We expose the statistical decisions in Eqn. 3 as the rule probability as one of the 19 dimensions, and use Simplex Downhill algorithm with Armijo line search (Zhao and Chen, 2009) to optimize the weight vector for decoding. The algorithm moves all dimensions at the same time, and empirically achieved more stable results than MER(Och, 2003) in many of our experiments.

5.1 Predicting Projectable Structures

The projectable structure is important for our proposed elementary tree to string grammar (elm2str). When a span is predicted not to be a translation boundary, we want the decoder to prefer alternative derivations outside of the immediate elementary tree, or more aggressive manipulation of the trees, such as deleting interior nodes, to explore unlabeled grammar such as Hiero style rules, with proper costs. We test separately on predicting the projectable structures, like predicting function tags in § 3.5.3, for each node in syntactic parse tree. We use one thousand test sentences with two conditions: human parses and machine parses. There are totally 40,674 nodes excluding the sentence-level node. The results are shown in Table 8. It showed our MaxEnt model is very accurate using human trees: 94.5% of accuracy, and about 84.7% of accuracy for using the machine parsed trees. Our accuracies are higher compared with the 71+% accuracies reported in (Xiong et al., 2010) for their phrasal decoder.

Setups	Accuracy
Human Parses	94.5%
Machine Parses	84.7%

Table 8: Accuracies of predicting projectable structures

We zoom in the translation boundaries for MT08-NW, in which we studied a few important frequent labels including VP and NP-SBJ as in Table 9. According to our MaxEnt model, 20% of times we should discourage a VP tree to be translated contiguously; such VP trees have an average span length of 16.9 tokens in MT08-NW. Similar statistics are 15.9% for S-tree with an average span of 13.8 tokens.

[2]See link: http://www.itl.nist.gov/iad/mig/tests/mt/2008/doc/mt08_official_results_v0.html

Labels	total	NonProj	Percent	Avg.len
VP*	4479	920	20.5%	16.9
NP*	14164	825	5.8%	8.12
S*	3123	495	15.9%	13.8
NP-SBJ*	1284	53	4.12%	11.9

Table 9: The predicted projectable structures in MT08-NW

Using the predicted projectable structures for elm2str grammar, together with the probability defined in Eqn. 3 as additional cost, the translation results in Table 11 show it helps BLEU by 0.29 BLEU points (56.13 v.s. 55.84). The boundary decisions penalize the derivation paths using nonterminals for non-projectable spans for partial hypothesis construction.

Setups	TER	BLEUr4n4
Baseline	39.87	55.01
right-binz (rbz)	39.10	55.19
left-binz (lbz)	39.67	55.31
Head-out-left (hlbz)	39.56	55.50
Head-out-right (hrbz)	39.52	55.53
+all binzation (abz)	39.42	55.60
+regroup-verb	39.29	55.72
+deleting interior nodes $\gamma.v^i$	38.98	55.84

Table 10: TER and BLEU for MT08-NW, using only $\bar{t}(\gamma)$

5.2 Integrating $\bar{t}$ and $\bar{m}$

We carried out a series of experiments to explore the impacts using $\bar{t}$ and $\bar{m}$ for elm2str grammar. We start from transforming the trees via simple operator $\bar{t}(\gamma)$, and then expand the function with more tree context to include the neighboring functions: $\bar{t}(\gamma, \bar{m})$.

Setups	TER	BLEUr4n4
Baseline w/ $\bar{t}$	38.98	55.84
+ TM Boundaries	38.89	56.13
+ SENT Bound	38.63	56.46
all $\bar{t}(\gamma, \bar{m})$	38.61	56.87

Table 11: TER and BLEU for MT08-NW, using $\bar{t}(\gamma, \bar{m})$.

Experiments in Table 10 focus on testing operators especially binarizations for transforming the trees. In Table 10, the four possible binarization methods all improve

Data	MT08-NW	MT08-WB	Dev10-NW	Dev10-WB
Tr2Str	55.01	39.19	37.33	41.77
elm2str+$\bar{t}$	55.84	39.43	38.02	42.70
elm2str+$\bar{m}$	55.57	39.60	37.67	42.54
elm2str+$\bar{t}(\gamma, \bar{m})$	56.87	39.82	38.62	42.75

Table 12: BLEU scores on various test sets; comparing elementary tree-to-string grammar (tr2str), transformation of the trees (elm2str+$\bar{t}$), using the neighboring function for boundaries (elm2str+$\bar{m}$), and combination of all together (elm2str+$\bar{t}(\gamma, \bar{m})$). MT08-NW and MT08-WB have four references; Dev10-WB has three references, and Dev10-NW has one reference. BLEUn4 were reported.

over the baseline from +0.18 (via right-most binarization) to +0.52 (via head-out-right) BLEU points. When we combine all binarizations (abz), we did not see additive gains over the best individual case – hrbz. Because during our decoding time, we do not frequently see large number of children (maximum at 6), and for smaller trees (with three or four children), these operators will largely generate same transformed trees, and that explains the differences from these individual binarization are small. For other languages, these binarization choices might give larger differences. Additionally, regrouping the verbs is marginally helpful for BLEU and TER. Upon close examinations, we found it is usually beneficial to group verb (PV or IV) with its neighboring nodes for expressing phrases like "have to do" and "will not only". Deleting the interior nodes helps on shrinking the trees, so that we can translate it with more statistics and confidences. It helps more on TER than BLEU for MT08-NW.

Table 11 extends Table 10 with neighboring function to further disambiguate the reordering rule using the tree context. Besides the translation boundary, the reordering decisions should be different with regard to the positions of the elementary tree relative to the sentence. At the sentence-beginning one might expect more for monotone decoding, while in the middle of the sentence, one might expect more reorderings. Table 11 shows when we add such boundary markups in our rules, an improvement of 0.33 BLEU points were obtained (56.46 v.s. 56.13) on top of the already improved setups. A close check up showed that the sentence-begin/end markups significantly reduced the leading "and" (from Arabic word w#) in the decoding output. Also, the verb subject order under SBAR seems to be more like monotone with a leading pronoun, rather than the general strong reordering of moving verb after subject. Overall, our results showed that such boundary conditions are helpful for executing the correct reorderings. We conclude the investigation with full function $\bar{t}(\gamma, \bar{m})$, which leads to a BLEUr4n4 of 56.87 (cased BLEUr4n4c 55.16), a significant improvement of 1.77 BLEU point over a already strong baseline.

We apply the setups for several other NW and WEB datasets to further verify the improvement. Shown in Table 12, we apply separately the operators for $\bar{t}$ and $\bar{m}$ first, then combine them as the final results. Varied improvements were observed for different genres. On DEV10-NW, we observed 1.29 BLEU points improvement, and about 0.63 and 0.98 improved BLEU points for MT08-WB and DEV10-WB, respectively. The improvements for newwire are statistically significant. The improvements for weblog are, however, only marginally better. One possible reason is the parser quality for web genre is reliable, as our training data is all in newswire. Regarding to the individual operators proposed in this paper, we observed consistent improvements of applying them across all the datasets. The generative model in Eqn. 3 leverages the operators further by selecting the best transformed tree form for executing the reorderings.

5.3 A Translation Example

To illustrate the advantages of the proposed grammar, we use a testing case with long distance word reordering and the source side parse trees. We compare the translation from a strong phrasal decoder (DTM2) (Ittycheriah and Roukos, 2007), which is one of the top systems in NIST-08 evaluation for Arabic-English. The translations from both decoders with the same training data (LM+TM) are in Table 13. The highlighted parts in Figure 3 show that, the rules on partial trees are effectively selected and applied for capturing long-distance word reordering, which is otherwise rather difficult to get correct in a phrasal system even with a MaxEnt reordering model.

6 Discussions and Conclusions

We proposed a framework to learn models to predict how to transform an elementary tree into its simplified forms for better executing the word reorderings. Two types of operators were explored, including (a) transforming the trees via binarizations, grouping or deleting interior nodes to change the structures; and (b) neighboring boundary context to further disambiguate the reordering decisions. Significant improvements were observed on top of a strong baseline system, and consistent improvements were observed across genres; we achieved a cased BLEU of 55.16 for MT08-NW, which is significantly better than the officially reported results in NIST MT08 Arabic-English evaluations.

Table 13: A translation example, comparing with phrasal decoder.

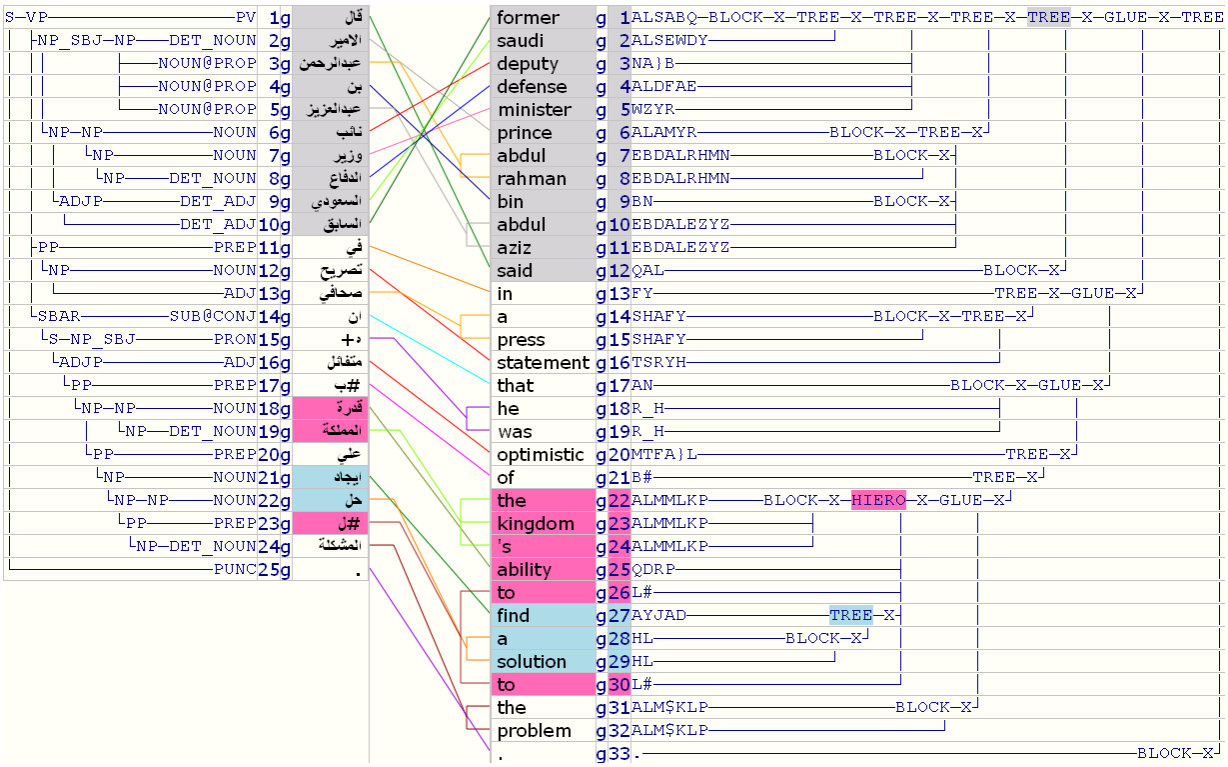

Figure 3: A testing case: illustrating the derivations from chart decoder. The left panel is source parse tree for the Arabic sentence — the input to our decoder; the right panel is the English translation together with the simplified derivation tree and alignment from our decoder output. Each "X" is a nonterminal in the grammar rule; a "Block" means a phrase pair is applied to rewrite a nonterminal; "Glue" and "Hiero" means the unlabeled rules were chosen to explain the span as explained in § 3.4.3 ; "Tree" means a labeled rule is applied for the span. For instance, for the source span [1,10], a rule is applied on a partial tree with PV and NP-SBJ; for the span [18,23], a rule is backed off to an unlabeled rule (Hiero-alike); for the span [21,22], it is another partial tree of NPs.

Within the proposed framework, we also presented several special cases including the translation boundaries for nonterminals in SCFG for translation. We achieved a high accuracy of 84.7% for predicting such boundaries using MaxEnt model on machine parse trees. Future works aim at transforming such non-projectable trees into projectable form (Eisner, 2003), driven by translation rules from aligned data(Burkett et al., 2010), and informative features form both the source [3] and the target sides (Shen et al., 2008) to enable the system to leverage more isomorphic trees, and avoid potential detour errors. We are exploring the incremental decoding framework, like (Huang and Mi, 2010), to improve pruning and speed.

Abstract

Most statistical machine translation systems rely on *composed rules* (rules that can be formed out of smaller rules in the grammar). Though this practice improves translation by weakening independence assumptions in the translation model, it nevertheless results in huge, redundant grammars, making both training and decoding inefficient. Here, we take the opposite approach, where we only use *minimal rules* (those that cannot be formed out of other rules), and instead rely on a *rule Markov model* of the derivation history to capture dependencies between minimal rules. Large-scale experiments on a state-of-the-art tree-to-string translation system show that our approach leads to a slimmer model, a faster decoder, yet the same translation quality (measured using B) as composed rules.

1 Introduction

Statistical machine translation systems typically model the translation process as a sequence of translation steps, each of which uses a translation rule, for example, a phrase pair in phrase-based translation or a tree-to-string rule in tree-to-string translation. These rules are usually applied independently of each other, which violates the conventional wisdom that translation should be done in context. To alleviate this problem, most state-of-the-art systems rely on *composed rules*, which are larger rules that can be formed out of smaller rules (including larger phrase pairs that can be formerd out of smaller phrase pairs), as opposed to *minimal rules*, which are rules that cannot be formed out of other rules. Although this approach does improve translation quality dramatically by weakening the independence assumptions in the translation model, they suffer from two main problems. First, composition can cause a combinatorial explosion in the number of rules. To avoid this, ad-hoc limits are placed during composition, like upper bounds on the number of nodes in the composed rule, or the height of the rule. Under such limits, the grammar size is manageable, but still much larger than the minimal-rule grammar. Second, due to large grammars, the decoder has to consider many more hypothesis translations, which slows it down. Nevertheless, the advantages outweigh the disadvantages, and to our knowledge, all top-performing systems, both phrase-based and syntax-based, use composed rules. For example, Galley et al. (2004) initially built a syntax-based system using only minimal rules, and subsequently reported (Galley et al., 2006) that composing rules improves B by 3.6 points, while increasing grammar size 60-fold and decoding time 15-fold.

The alternative we propose is to replace composed rules with a *rule Markov model* that generates rules conditioned on their context. In this work, we restrict a rule's context to the vertical chain of ancestors of the rule. This ancestral context would play the same role as the context formerly provided by rule composition. The dependency treelet model developed by Quirk and Menezes (2006) takes such an approach within the framework of dependency translation. However, their study leaves unanswered whether a rule Markov model can take the place of composed rules. In this work, we investigate the use of rule Markov models in the context of tree-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 856–864,
Portland, Oregon, June 19-24, 2011.

to-string translation (Liu et al., 2006; Huang et al., 2006). We make three new contributions.

First, we carry out a detailed comparison of rule Markov models with composed rules. Our experiments show that, using trigram rule Markov models, we achieve an improvement of 2.2 B over a baseline of minimal rules. When we compare against *vertically* composed rules, we find that our rule Markov model has the same accuracy, but our model is much smaller and decoding with our model is 30% faster. When we compare against *full* composed rules, we find that our rule Markov model still often reaches the same level of accuracy, again with savings in space and time.

Second, we investigate methods for pruning rule Markov models, finding that even very simple pruning criteria actually improve the accuracy of the model, while of course decreasing its size.

Third, we present a very fast decoder for tree-to-string grammars with rule Markov models. Huang and Mi (2010) have recently introduced an efficient incremental decoding algorithm for tree-to-string translation, which operates top-down and maintains a derivation history of translation rules encountered. This history is exactly the vertical chain of ancestors corresponding to the contexts in our rule Markov model, which makes it an ideal decoder for our model.

We start by describing our rule Markov model (Section 2) and then how to decode using the rule Markov model (Section 3).

2 Rule Markov models

Our model which conditions the generation of a rule on the vertical chain of its ancestors, which allows it to capture interactions between rules.

Consider the example Chinese-English tree-to-string grammar in Figure 1 and the example derivation in Figure 2. Each row is a derivation step; the tree on the left is the derivation tree (in which each node is a rule and its children are the rules that substitute into it) and the tree pair on the right is the source and target derived tree. For any derivation node r, let $anc_1(r)$ be the parent of r (or ϵ if it has no parent), $anc_2(r)$ be the grandparent of node r (or ϵ if it has no grandparent), and so on. Let $anc_1^n(r)$ be the chain of ancestors $anc_1(r) \cdots anc_n(r)$.

The derivation tree is generated as follows. With probability $\mathrm{P}(r_1 \mid \epsilon)$, we generate the rule at the root node, r_1. We then generate rule r_2 with probability $\mathrm{P}(r_2 \mid r_1)$, and so on, always taking the leftmost open substitution site on the English derived tree, and generating a rule r_i conditioned on its chain of ancestors with probability $\mathrm{P}(r_i \mid anc_1^n(r_i))$. We carry on until no more children can be generated. Thus the probability of a derivation tree T is

$$\mathrm{P}(T) = \prod_{r \in T} \mathrm{P}(r \mid anc_1^n(r)) \quad (1)$$

For the minimal rule derivation tree in Figure 2, the probability is:

$$\begin{aligned}\mathrm{P}(T) = \mathrm{P}(r_1 \mid \epsilon) \cdot \mathrm{P}(r_2 \mid r_1) \cdot \mathrm{P}(r_3 \mid r_1) \\ \cdot \mathrm{P}(r_4 \mid r_1, r_3) \cdot \mathrm{P}(r_6 \mid r_1, r_3, r_4) \\ \cdot \mathrm{P}(r_7 \mid r_1, r_3, r_4) \cdot \mathrm{P}(r_5 \mid r_1, r_3) \quad (2)\end{aligned}$$

Training We run the algorithm of Galley et al. (2004) on word-aligned parallel text to obtain a single derivation of minimal rules for each sentence

pair. (Unaligned words are handled by attaching them to the highest node possible in the parse tree.) The rule Markov model

can then be trained on the path set of these derivation trees.

Smoothing We use interpolation with absolute discounting (Ney et al., 1994):

$$\begin{aligned}\mathrm{P}_{abs}(r \mid anc_1^n(r)) = \frac{\max\left\{c(r \mid anc_1^n(r)) - D_n, 0\right\}}{\sum_{r'} c(r' \mid anc_1^n(r'))} \\ + \ (1 - \lambda_n)\mathrm{P}_{abs}(r \mid anc_1^{n-1}(r)), \quad (3)\end{aligned}$$

where $c(r \mid anc_1^n(r))$ is the number of times we have seen rule r after the vertical context $anc_1^n(r)$, D_n is the discount for a context of length n, and $(1 - \lambda_n)$ is set to the value that makes the smoothed probability distribution sum to one.

We experiment with bigram and trigram rule Markov models. For each, we try different values of D_1 and D_2, the discount for bigrams and trigrams, respectively. Ney et al. (1994) suggest using the following value for the discount D_n:

$$D_n = \frac{n_1}{n_1 + n_2} \quad (4)$$

rule id	translation rule
r_1	IP(x_1:NP x_2:VP) → x_1 x_2
r_2	NP(Bùshí) → Bush
r_3	VP(x_1:PP x_2:VP) → x_2 x_1
r_4	PP(x_1:P x_2:NP) → x_1 x_2
r_5	VP(VV(jǔxíng) AS(le) NPB(huìtán)) → held talks
r_6	P(yǔ) → with
r'_6	P(yǔ) → and
r_7	NP(Shālóng) → Sharon

Figure 1: Example tree-to-string grammar.

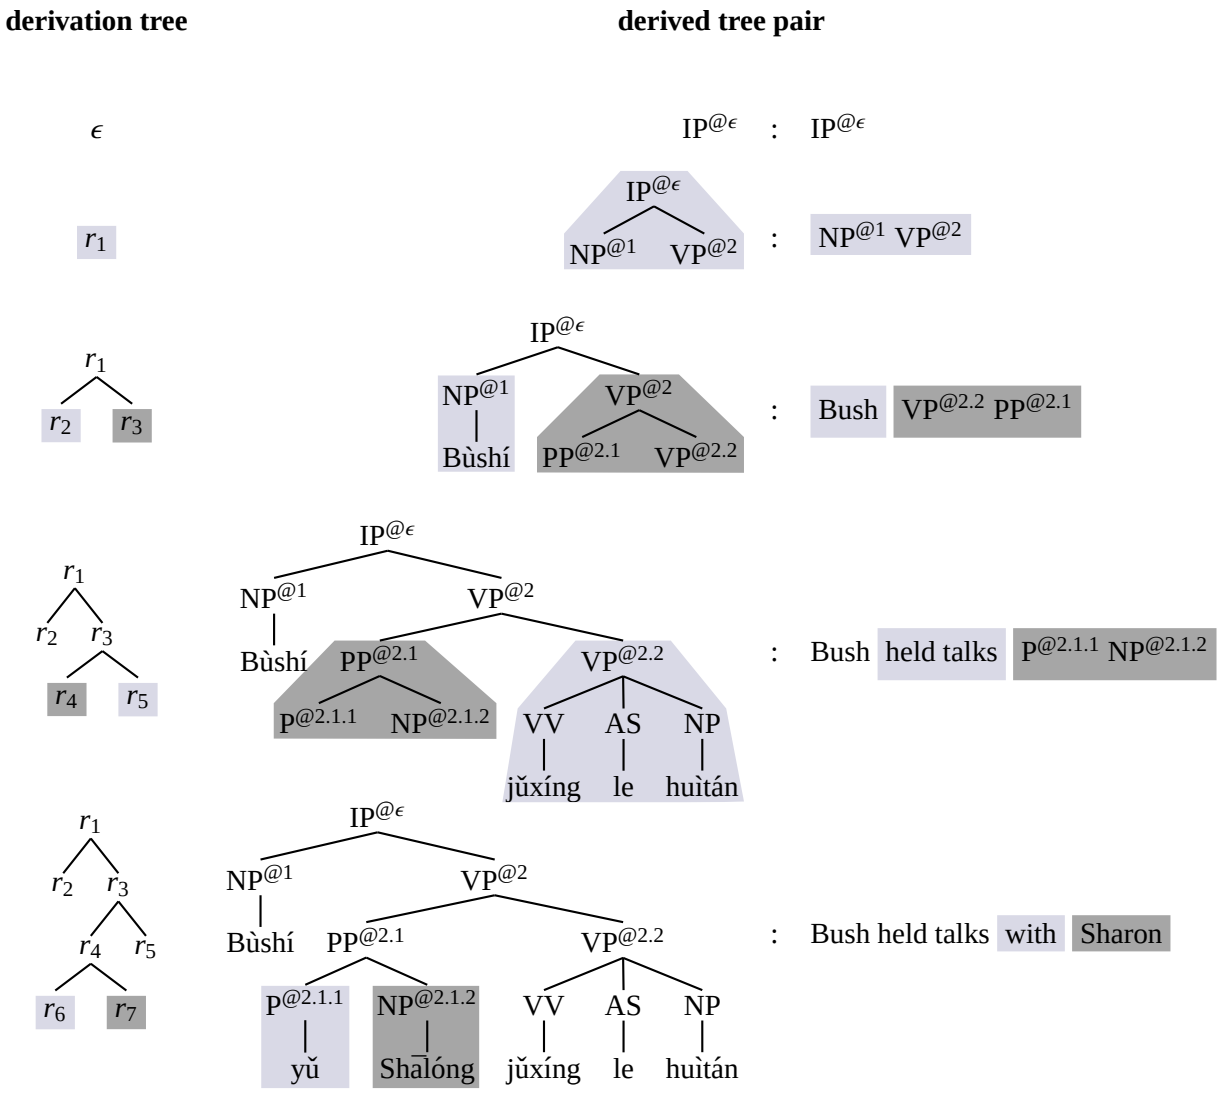

Figure 2: Example tree-to-string derivation. Each row shows a rewriting step; at each step, the leftmost nonterminal symbol is rewritten using one of the rules in Figure 1.

Here, n_1 and n_2 are the total number of n-grams with exactly one and two counts, respectively. For our corpus, $D_1 = 0.871$ and $D_2 = 0.902$. Additionally, we experiment with 0.4 and 0.5 for D_n.

Pruning In addition to full n-gram Markov models, we experiment with three approaches to build smaller models to investigate if pruning helps. Our results will show that smaller models indeed give a higher B score than the full bigram and trigram models. The approaches we use are:

- RM-A: We keep only those contexts in which more than P unique rules were observed. By optimizing on the development set, we set $P = 12$.
- RM-B: We keep only those contexts that were observed more than P times. Note that this is a superset of RM-A. Again, by optimizing on the development set, we set $P = 12$.
- RM-C: We try a more principled approach for learning variable-length Markov models inspired by that of Bejerano and Yona (1999), who learn a Prediction Suffix Tree (PST). They grow the PST in an iterative manner by starting from the root node (no context), and then add contexts to the tree. A context is added if the KL divergence between its predictive distribution and that of its parent is above a certain threshold and the probability of observing the context is above another threshold.

3 Tree-to-string decoding with rule Markov models

In this paper, we use our rule Markov model framework in the context of tree-to-string translation. Tree-to-string translation systems (Liu et al., 2006; Huang et al., 2006) have gained popularity in recent years due to their speed and simplicity. The input to the translation system is a source parse tree and the output is the target string. Huang and Mi (2010) have recently introduced an efficient incremental decoding algorithm for tree-to-string translation. The decoder operates top-down and maintains a derivation history of translation rules encountered. The history is exactly the vertical chain of ancestors corresponding to the contexts in our rule Markov model. This

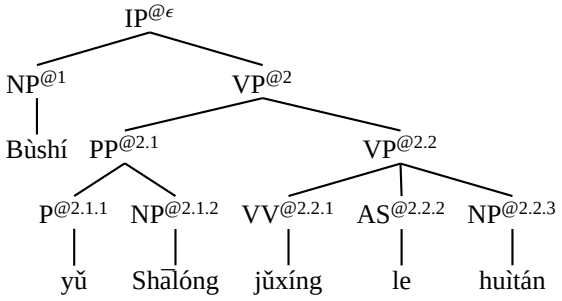

Figure 3: Example input parse tree with tree addresses.

makes incremental decoding a natural fit with our generative story. In this section, we describe how to integrate our rule Markov model into this incremental decoding algorithm. Note that it is also possible to integrate our rule Markov model with other decoding algorithms, for example, the more common non-incremental top-down/bottom-up approach (Huang et al., 2006), but it would involve a non-trivial change to the decoding algorithms to keep track of the vertical derivation history, which would result in significant overhead.

Algorithm Given the input parse tree in Figure 3, Figure 4 illustrates the search process of the incremental decoder with the grammar of Figure 1. We write $X^{@\eta}$ for a tree node with label X at tree address η (Shieber et al., 1995). The root node has address ϵ, and the ith child of node η has address $\eta.i$. At each step, the decoder maintains a stack of active rules, which are rules that have not been completed yet, and the rightmost $(n-1)$ English words translated thus far (the hypothesis), where n is the order of the word language model (in Figure 4, $n = 2$). The stack together with the translated English words comprise a state of the decoder. The last column in the figure shows the rule Markov model probabilities with the conditioning context. In this example, we use a trigram rule Markov model.

After initialization, the process starts at step 1, where we *predict* rule r_1 (the shaded rule) with probability $\mathrm{P}(r_1 \mid \epsilon)$ and push its English side onto the stack, with variables replaced by the corresponding tree nodes: x_1 becomes $\mathrm{NP}^{@1}$ and x_2 becomes $\mathrm{VP}^{@2}$. This gives us the following stack:

$$s = [\mathbf{.}\ \mathrm{NP}^{@1}\ \mathrm{VP}^{@2}]$$

The dot (**.**) indicates the next symbol to process in

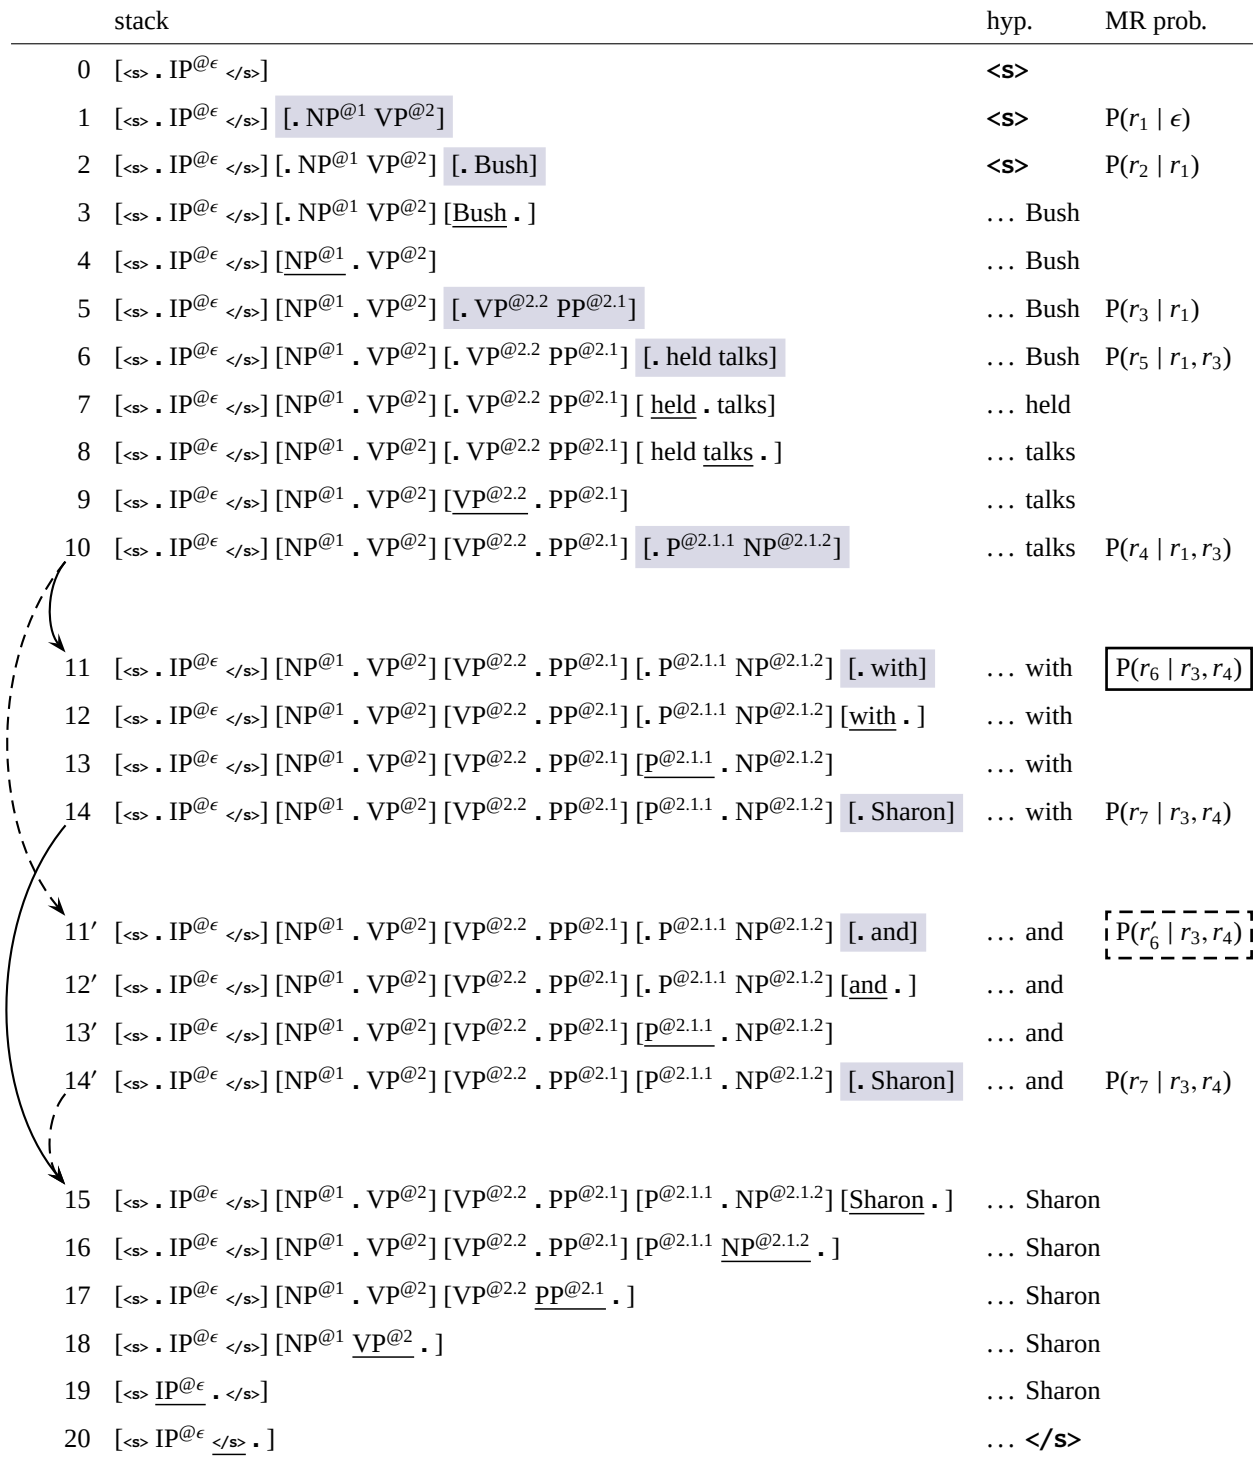

Figure 4: Simulation of incremental decoding with rule Markov model. The solid arrows indicate one path and the dashed arrows indicate an alternate path.

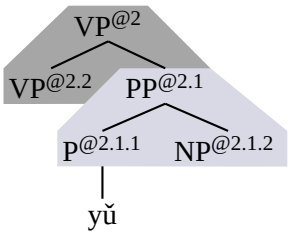

Figure 5: Vertical context r_3 r_4 which allows the model to correctly translate *yǔ* as *with*.

the English word order. We expand node $\text{NP}^{@1}$ first with English word order. We then predict lexical rule r_2 with probability $\text{P}(r_2 \mid r_1)$ and push rule r_2 onto the stack:

$$[\text{. NP}^{@1}\ \text{VP}^{@2}\ ]\ [\text{. Bush}]$$

In step 3, we perform a *scan* operation, in which we append the English word just after the dot to the current hypothesis and move the dot after the word. Since the dot is at the end of the top rule in the stack, we perform a *complete* operation in step 4 where we pop the finished rule at the top of the stack. In the *scan* and *complete* steps, we don't need to compute rule probabilities.

An interesting branch occurs after step 10 with two competing lexical rules, r_6 and r'_6. The Chinese word *yǔ* can be translated as either a preposition *with* (leading to step 11) or a conjunction *and* (leading to step 11′). The word *n*-gram model does not have enough information to make the correct choice, *with*. As a result, good translations might be pruned because of the beam. However, our rule Markov model has the correct preference because of the conditioning ancestral sequence (r_3, r_4), shown in Figure 5. Since $\text{VP}^{@2.2}$ has a preference for *yǔ* translating to *with*, our corpus statistics will give a higher probability to $\text{P}(r_6 \mid r_3, r_4)$ than $\text{P}(r'_6 \mid r_3, r_4)$. This helps the decoder to score the correct translation higher.

Complexity analysis With the incremental decoding algorithm, adding rule Markov models does not change the time complexity, which is $O(nc|V|^{g-1})$, where n is the sentence length, c is the maximum number of incoming hyperedges for each node in the translation forest, V is the target-language vocabulary, and g is the order of the n-gram language model (Huang and Mi, 2010). However, if one were to use rule Markov models with a conventional CKY-style bottom-up decoder (Liu et al., 2006), the complexity would increase to $O(nC^{m-1}|V|^{4(g-1)})$, where C is the maximum number of outgoing hyperedges for each node in the translation forest, and m is the order of the rule Markov model.

4 Experiments and results

4.1 Setup

The training corpus consists of 1.5M sentence pairs with 38M/32M words of Chinese/English, respectively. Our development set is the newswire portion of the 2006 NIST MT Evaluation test set (616 sentences), and our test set is the newswire portion of the 2008 NIST MT Evaluation test set (691 sentences).

We word-aligned the training data using GIZA++ followed by link deletion (Fossum et al., 2008), and then parsed the Chinese sentences using the Berkeley parser (Petrov and Klein, 2007). To extract tree-to-string translation rules, we applied the algorithm of Galley et al. (2004). We trained our rule Markov model on derivations of minimal rules as described above. Our trigram word language model was trained on the target side of the training corpus using the SRILM toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing. The base feature set for all systems is similar to the set used in Mi et al. (2008). The features are combined into a standard log-linear model, which we trained using minimum error-rate training (Och, 2003) to maximize the B score on the development set.

At decoding time, we again parse the input sentences using the Berkeley parser, and convert them into translation forests using rule pattern-matching (Mi et al., 2008). We evaluate translation quality using case-insensitive IBM B -4, calculated by the script `mteval-v13a.pl`.

4.2 Results

Table 1 presents the main results of our paper. We used grammars of minimal rules and composed rules of maximum height 3 as our baselines. For decoding, we used a beam size of 50. Using the best bigram rule Markov models and the minimal rule grammar gives us an improvement of 1.5 B over the minimal rule baseline. Using the best trigram rule Markov model brings our gain up to 2.3 B .

grammar	rule Markov model	max rule height	parameters ($\times 10^6$) full	parameters ($\times 10^6$) dev+test	B test	time (sec/sent)
minimal	None	3	4.9	0.3	24.2	1.2
	RM-B bigram	3	4.9+4.7	0.3+0.5	25.7	1.8
	RM-A trigram	3	4.9+7.6	0.3+0.6	26.5	2.0
vertical composed	None	7	176.8	1.3	26.5	2.9
composed	None	3	17.5	1.6	26.4	2.2
	None	7	448.7	3.3	27.5	6.8
	RM-A trigram	7	448.7+7.6	3.3+1.0	28.0	9.2

Table 1: Main results. Our trigram rule Markov model strongly outperforms minimal rules, and performs at the same level as composed and vertically composed rules, but is smaller and faster. The number of parameters is shown for both the full model and the model filtered for the concatenation of the development and test sets (dev+test).

These gains are statistically significant with $p < 0.01$, using bootstrap resampling with 1000 samples (Koehn, 2004). We find that by just using bigram context, we are able to get at least 1 B point higher than the minimal rule grammar. It is interesting to see that using just bigram rule interactions can give us a reasonable boost. We get our highest gains from using trigram context where our best performing rule Markov model gives us 2.3 B points over minimal rules. This suggests that using longer contexts helps the decoder to find better translations.

We also compared rule Markov models against composed rules. Since our models are currently limited to conditioning on vertical context, the closest comparison is against *vertically* composed rules. We find that our approach performs equally well using much less time and space.

Comparing against *full* composed rules, we find that our system matches the score of the baseline composed rule grammar of maximum height 3, while using many fewer parameters. (It should be noted that a parameter in the rule Markov model is just a floating-point number, whereas a parameter in the composed-rule system is an entire rule; therefore the difference in memory usage would be even greater.) Decoding with our model is 0.2 seconds faster per sentence than with composed rules.

These experiments clearly show that rule Markov models with minimal rules increase translation quality significantly and with lower memory requirements than composed rules. One might wonder if the best performance can be obtained by combining composed rules with a rule Markov model. This is straightforward to implement: the rule Markov model is still defined over derivations of minimal rules, but in the decoder's prediction step, the rule Markov model's value on a composed rule is calculated by decomposing it into minimal rules and computing the product of their probabilities. We find that using our best trigram rule Markov model with composed rules gives us a 0.5 B gain on top of the composed rule grammar, statistically significant with $p < 0.05$, achieving our highest score of 28.0.[1]

rule Markov model	D_1	B dev	time (sec/sent)
RM-A	0.871	29.2	1.8
RM-B	0.4	29.9	1.8
RM-C	0.871	29.8	1.8
RM-Full	0.4	29.7	1.9

Table 2: For rule bigrams, RM-B with $D_1 = 0.4$ gives the best results on the development set.

rule Markov model	D_1	D_2	B dev	time (sec/sent)
RM-A	0.5	0.5	30.3	2.0
RM-B	0.5	0.5	29.9	2.0
RM-C	0.5	0.5	30.1	2.0
RM-Full	0.4	0.5	30.1	2.2

Table 3: For rule bigrams, RM-A with $D_1, D_2 = 0.5$ gives the best results on the development set.

parameters ($\times 10^6$) dev+test	B dev	test	time (sec/sent)
1.2	30.2	26.1	2.8
1.3	30.1	26.5	2.9
1.3	30.1	26.2	3.2

Table 5: Comparison of vertically composed rules using various settings (maximum rule height 7).

respectively. It is interesting that the full bigram and trigram rule Markov models do not give our highest B scores; pruning the models not only saves space but improves their performance. We think that this is probably due to overfitting.

Table 4 shows that the RM-A trigram model does fairly well under all the settings of D_n we tried. Table 5 shows the performance of *vertically* composed rules at various settings. Here we have chosen the setting that gives the best performance on the test set for inclusion in Table 1.

Table 6 shows the performance of *fully* composed rules and fully composed rules with a rule Markov Model at various settings.[2] In the second line (2.9 million rules), the drop in B score resulting from adding the rule Markov model is not statistically significant.

5 Related Work

Besides the Quirk and Menezes (2006) work discussed in Section 1, there are two other previous efforts both using a rule bigram model in machine translation, that is, the probability of the current rule only depends on the immediate previous rule in the vertical context, whereas our rule Markov model can condition on longer and sparser derivation histories. Among them, Ding and Palmer (2005) also use a dependency treelet model similar to Quirk and Menezes (2006), and Liu and Gildea (2008) use a tree-to-string model more like ours. Neither compared to the scenario with composed rules.

Outside of machine translation, the idea of weakening independence assumptions by modeling the derivation history is also found in parsing (Johnson, 1998), where rule probabilities are conditioned on parent and grand-parent nonterminals. However, besides the difference between parsing and translation, there are still two major differences. First, our work conditions rule probabilities on parent and grandparent *rules*, not just nonterminals. Second, we compare against a composed-rule system, which is analogous to the Data Oriented Parsing (DOP) approach in parsing (Bod, 2003). To our knowledge, there has been no direct comparison between a history-based PCFG approach and DOP approach in the parsing literature.

6 Conclusion

In this paper, we have investigated whether we can eliminate composed rules without any loss in translation quality. We have developed a rule Markov model that captures vertical bigrams and trigrams of minimal rules, and tested it in the framework of tree-to-string translation. We draw three main conclusions from our experiments. First, our rule Markov models dramatically improve a grammar of minimal rules, giving an improvement of 2.3 B . Second, when we compare against *vertically* composed rules we are able to get about the same B score, but our model is much smaller and decoding with our

[2] For these experiments, a beam size of 100 was used.

model is faster. Finally, when we compare against full composed rules, we find that we can reach the same level of performance under some conditions, but in order to do so consistently, we believe we need to extend our model to condition on horizontal context in addition to vertical context. We hope that by modeling context in both axes, we will be able to completely replace composed-rule grammars with smaller minimal-rule grammars.

Abstract

In this work we address the problem of unsupervised part-of-speech induction by bringing together several strands of research into a single model. We develop a novel hidden Markov model incorporating sophisticated smoothing using a hierarchical Pitman-Yor processes prior, providing an elegant and principled means of incorporating lexical characteristics. Central to our approach is a new type-based sampling algorithm for hierarchical Pitman-Yor models in which we track fractional table counts. In an empirical evaluation we show that our model consistently out-performs the current state-of-the-art across 10 languages.

1 Introduction

Unsupervised part-of-speech (PoS) induction has long been a central challenge in computational linguistics, with applications in human language learning and for developing portable language processing systems. Despite considerable research effort, progress in fully unsupervised PoS induction has been slow and modern systems barely improve over the early Brown et al. (1992) approach (Christodoulopoulos et al., 2010). One popular means of improving tagging performance is to include supervision in the form of a tag dictionary or similar, however this limits portability and also comprimises any cognitive conclusions. In this paper we present a novel approach to fully unsupervised PoS induction which uniformly outperforms the existing state-of-the-art across all our corpora in 10 different languages. Moreover, the performance of our unsupervised model approaches that of many existing semi-supervised systems, despite our method not receiving any human input.

In this paper we present a Bayesian hidden Markov model (HMM) which uses a non-parametric prior to infer a latent tagging for a sequence of words. HMMs have been popular for unsupervised PoS induction from its very beginnings (Brown et al., 1992), and justifiably so, as the most discriminating feature for deciding a word's PoS is its local syntactic context.

Our work brings together several strands of research including Bayesian non-parametric HMMs (Goldwater and Griffiths, 2007), Pitman-Yor language models (Teh, 2006b; Goldwater et al., 2006b), tagging constraints over word types (Brown et al., 1992) and the incorporation of morphological features (Clark, 2003). The result is a non-parametric Bayesian HMM which avoids overfitting, contains no free parameters, and exhibits good scaling properties. Our model uses a hierarchical Pitman-Yor process (PYP) prior to affect sophisicated smoothing over the transition and emission distributions. This allows the modelling of sub-word structure, thereby capturing tag-specific morphological variation. Unlike many existing approaches, our model is a principled generative model and does not include any hand tuned language specific features.

Inspired by previous successful approaches (Brown et al., 1992), we develop a new type-level inference procedure in the form of an MCMC sampler with an approximate method for incorporating the complex dependencies that arise between jointly sampled events. Our experimental evaluation demonstrates that our model, particularly when restricted to a single tag per type, produces

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 865–874,
Portland, Oregon, June 19-24, 2011.

state-of-the-art results across a range of corpora and languages.

2 Background

Past research in unsupervised PoS induction has largely been driven by two different motivations: a task based perspective which has focussed on inducing word classes to improve various applications, and a linguistic perspective where the aim is to induce classes which correspond closely to annotated part-of-speech corpora. Early work was firmly situtated in the task-based setting of improving generalisation in language models. Brown et al. (1992) presented a simple first-order HMM which restricted word types to always be generated from the same class. Though PoS induction was not their aim, this restriction is largely validated by empirical analysis of treebanked data, and moreover conveys the significant advantage that all the tags for a given word type can be updated at the same time, allowing very efficient inference using the exchange algorithm. This model has been popular for language modelling and bilingual word alignment, and an implementation with improved inference called `mkcls` (Och, 1999)[1] has become a standard part of statistical machine translation systems.

The HMM ignores orthographic information, which is often highly indicative of a word's part-of-speech, particularly so in morphologically rich languages. For this reason Clark (2003) extended Brown et al. (1992)'s HMM by incorporating a character language model, allowing the modelling of limited morphology. Our work draws from these models, in that we develop a HMM with a one class per tag restriction and include a character level language model. In contrast to these previous works which use the maximum likelihood estimate, we develop a Bayesian model with a rich prior for smoothing the parameter estimates, allowing us to move to a trigram model.

A number of researchers have investigated a semi-supervised PoS induction task in which a tag dictionary or similar data is supplied a priori (Smith and Eisner, 2005; Haghighi and Klein, 2006; Goldwater and Griffiths, 2007; Toutanova and Johnson, 2008; Ravi and Knight, 2009). These systems achieve much higher accuracy than fully unsupervised systems, though it is unclear whether the tag dictionary assumption has real world application. We focus solely on the fully unsupervised scenario, which we believe is more practical for text processing in new languages and domains.

Recent work on unsupervised PoS induction has focussed on encouraging sparsity in the emission distributions in order to match empirical distributions derived from treebank data (Goldwater and Griffiths, 2007; Johnson, 2007; Gao and Johnson, 2008). These authors took a Bayesian approach using a Dirichlet prior to encourage sparse distributions over the word types emitted from each tag. Conversely, Ganchev et al. (2010) developed a technique to optimize the more desirable reverse property of the word types having a sparse posterior distribution over tags. Recently Lee et al. (2010) combined the one class per word type constraint (Brown et al., 1992) in a HMM with a Dirichlet prior to achieve both forms of sparsity. However this work approximated the derivation of the Gibbs sampler (omitting the interdependence between events when sampling from a collapsed model), resulting in a model which underperformed Brown et al. (1992)'s one-class HMM.

Our work also seeks to enforce both forms of sparsity, by developing an algorithm for type-level inference under the one class constraint. This work differs from previous Bayesian models in that we explicitly model a complex backoff path using a hierachical prior, such that our model jointly infers distributions over tag trigrams, bigrams and unigrams and whole words and their character level representation. This smoothing is critical to ensure adequate generalisation from small data samples.

Research in language modelling (Teh, 2006b; Goldwater et al., 2006a) and parsing (Cohn et al., 2010) has shown that models employing Pitman-Yor priors can significantly outperform the more frequently used Dirichlet priors, especially where complex hierarchical relationships exist between latent variables. In this work we apply these advances to unsupervised PoS tagging, developing a HMM smoothed using a Pitman-Yor process prior.

[1] Available from `http://fjoch.com/mkcls.html`.

3 The PYP-HMM

We develop a trigram hidden Markov model which models the joint probability of a sequence of latent tags, $\mathbf{t}$, and words, $\mathbf{w}$, as

$$P_\theta(\mathbf{t}, \mathbf{w}) = \prod_{l=1}^{L+1} P_\theta(t_l|t_{l-1}, t_{l-2}) P_\theta(w_l|t_l)\,,$$

where $L = |\mathbf{w}| = |\mathbf{t}|$ and $t_0 = t_{-1} = t_{L+1} = \$$ are assigned a sentinel value to denote the start or end of the sentence. A key decision in formulating such a model is the smoothing of the tag trigram and emission distributions, which would otherwise be too difficult to estimate from small datasets. Prior work in unsupervised PoS induction has employed simple smoothing techniques, such as additive smoothing or Dirichlet priors (Goldwater and Griffiths, 2007; Johnson, 2007), however this body of work has overlooked recent advances in smoothing methods used for language modelling (Teh, 2006b; Goldwater et al., 2006b). Here we build upon previous work by developing a PoS induction model smoothed with a sophisticated non-parametric prior. Our model uses a hierarchical Pitman-Yor process prior for both the transition and emission distributions, encoding a backoff path from complex distributions to succesSsively simpler ones. The use of complex distributions (e.g., over tag trigrams) allows for rich expressivity when sufficient evidence is available, while the hierarchy affords a means of backing off to simpler and more easily estimated distributions otherwise. The PYP has been shown to generate distributions particularly well suited to modelling language (Teh, 2006a; Goldwater et al., 2006b), and has been shown to be a generalisation of Kneser-Ney smoothing, widely recognised as the best smoothing method for language modelling (Chen and Goodman, 1996).

The model is depicted in the plate diagram in Figure 1. At its centre is a standard trigram HMM, which generates a sequence of tags and words,

$$\begin{aligned} t_l|t_{l-1}, t_{l-2}, T &\sim T_{t_{l-1},t_{l-2}} \\ w_l|t_l, E &\sim E_{t_l}\,. \end{aligned}$$

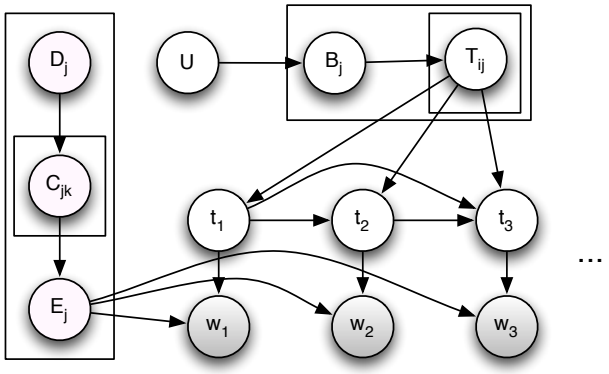

Figure 1: Plate diagram representation of the trigram HMM. The indexes i and j range over the set of tags and k ranges over the set of characters. Hyper-parameters have been omitted from the figure for clarity.

The trigram transition distribution, T_{ij}, is drawn from a hierarchical PYP prior which backs off to a bigram B_j and then a unigram U distribution,

$$\begin{aligned} T_{ij}|a^T, b^T, B_j &\sim \text{PYP}(a^T, b^T, B_j) \\ B_j|a^B, b^B, U &\sim \text{PYP}(a^B, b^B, U) \\ U|a^U, b^U &\sim \text{PYP}(a^U, b^U, \text{Uniform})\,, \end{aligned}$$

where the prior over U has as its base distribition a uniform distribution over the set of tags, while the priors for B_j and T_{ij} back off by discarding an item of context. This allows the modelling of trigram tag sequences, while smoothing these estimates with their corresponding bigram and unigram distributions. The degree of smoothing is regulated by the hyper-parameters a and b which are tied across each length of n-gram; these hyper-parameters are inferred during training, as described in 3.1.

The tag-specific emission distributions, E_j, are also drawn from a PYP prior,

$$E_j|a^E, b^E, C \sim \text{PYP}(a^E, b^E, C_j)\,.$$

We consider two different settings for the base distribution C_j: 1) a simple uniform distribution over the vocabulary (denoted HMM for the experiments in section 4); and 2) a character-level language model (denoted HMM+LM). In many languages morphological regularities correlate strongly with a word's part-of-speech (e.g., suffixes in English), which we hope to capture using a basic character language model. This model was inspired by Clark (2003)

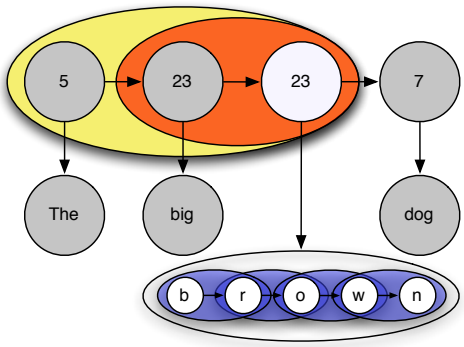

Figure 2: The conditioning structure of the hierarchical PYP with an embedded character language models.

who applied a character level distribution to the single class HMM (Brown et al., 1992). We formulate the character-level language model as a bigram model over the character sequence comprising word w_l,

$$\begin{aligned} w_{lk}|w_{lk-1}, t_l, C &\sim C_{t_l w_{lk-1}} \\ C_{jk}|a^C, b^C, D_j &\sim \text{PYP}(a^C, b^C, D_j) \\ D_j|a^D, b^D &\sim \text{PYP}(a^D, b^D, \text{Uniform})\,, \end{aligned}$$

where k indexes the characters in the word and, in a slight abuse of notation, the character itself, w_0 and is set to a special sentinel value denoting the start of the sentence (ditto for a final end of sentence marker) and the uniform base distribution ranges over the set of characters. We expect that the HMM+LM model will outperform the uniform HMM as it can capture many consistent morphological affixes and thereby better distinguish between different parts-of-speech. The HMM+LM is shown in Figure 2, illustrating the decomposition of the tag sequence into n-grams and a word into its component character bigrams.

3.1 Training

In order to induce a tagging under this model we use Gibbs sampling, a Markov chain Monte Carlo (MCMC) technique for drawing samples from the posterior distribution over the tag sequences given observed word sequences. We present two different sampling strategies: First, a simple Gibbs sampler which randomly samples an update to a single tag given all other tags; and second, a type-level sampler which updates all tags for a given word under a one-tag-per-word-type constraint. In order to extract a single tag sequence to test our model against the gold standard we find the tag at each site with maximum marginal probability in the sample set.

Following standard practice, we perform inference using a collapsed sampler whereby the model parameters U, B, T, E and C are marginalised out. After marginalisation the posterior distribution under a PYP prior is described by a variant of the Chinese Restaurant Process (CRP). The CRP is based around the analogy of a restaurant with an infinite number of tables, with customers entering one at a time and seating themselves at a table. The choice of table is governed by

$$P(z_l = k|\mathbf{z}_{-l}) = \begin{cases} \frac{n_k^- - a}{l-1+b} & 1 \le k \le K^- \\ \frac{K^- a + b}{l-1+b} & k = K^- + 1 \end{cases} \quad (1)$$

where z_l is the table chosen by the lth customer, $\mathbf{z}_{-l}$ is the seating arrangement of the $l-1$ previous customers, n_k^- is the number of customers in $\mathbf{z}_{-l}$ who are seated at table k, $K^- = K(\mathbf{z}_{-l})$ is the total number of tables in $\mathbf{z}_{-l}$, and $z_1 = 1$ by definition. The arrangement of customers at tables defines a clustering which exhibits a power-law behavior controlled by the hyperparameters a and b.

To complete the restaurant analogy, a dish is then served to each table which is shared by all the customers seated there. This corresponds to a draw from the base distribution, which in our case ranges over tags for the transition distribution, and words for the observation distribution. Overall the PYP leads to a distribution of the form

$$P^T(t_l = i|\mathbf{z}_{-l}, \mathbf{t}_{-l}) = \frac{1}{n_{\mathbf{h}}^- + b^T} \times \quad (2)$$
$$\left(n_{\mathbf{h}i}^- - K_{\mathbf{h}i}^- a^T + \left(K_{\mathbf{h}}^- a^T + b^T\right) P^B(i|\mathbf{z}_{-l}, \mathbf{t}_{-l})\right),$$

illustrating the trigram transition distribution, where $\mathbf{t}_{-l}$ are all previous tags, $\mathbf{h} = (t_{l-2}, t_{l-1})$ is the conditioning bigram, $n_{\mathbf{h}i}^-$ is the count of the trigram $\mathbf{h}i$ in $\mathbf{t}_{-l}$, $n_{\mathbf{h}}^-$ the total count over all trigrams beginning with $\mathbf{h}$, $K_{\mathbf{h}i}^-$ the number of tables served dish i and $P^B(\cdot)$ is the base distribution, in this case the bigram distribution.

A hierarchy of PYPs can be formed by making the base distribution of a PYP another PYP, following a

semantics whereby whenever a customer sits at an empty table in a restaurant, a new customer is also said to enter the restaurant for its base distribution. That is, each table at one level is equivalent to a customer at the next deeper level, creating the invariants: $K^-_{\mathbf{h}i} = n^-_{\mathbf{u}i}$ and $K^-_{\mathbf{u}i} = n^-_i$, where $\mathbf{u} = t_{l-1}$ indicates the unigram backoff context of $\mathbf{h}$. The recursion terminates at the lowest level where the base distribution is static. The hierarchical setting allows for the modelling of elaborate backoff paths from rich and complex structure to successively simpler structures.

Gibbs samplers Both our Gibbs samplers perform the same calculation of conditional tag distributions, and involve first decrementing all trigrams and emissions affected by a sampling action, and then reintroducing the trigrams one at a time, conditioning their probabilities on the updated counts and table configurations as we progress.

The first local Gibbs sampler (PYP-HMM) updates a single tag assignment at a time, in a similar fashion to Goldwater and Griffiths (2007). Changing one tag affects three trigrams, with posterior

$$P(t_l|\mathbf{z}_{-l}, \mathbf{t}_{-l}, \mathbf{w}) \propto P(\mathbf{t}_{l\pm2}, w_l|\mathbf{z}_{-l\pm2}, \mathbf{t}_{-l\pm2}) \,,$$

where $l\pm2$ denotes the range $l-2, l-1, l, l+1, l+2$. The joint distribution over the three trigrams contained in $\mathbf{t}_{l\pm2}$ can be calculated using the PYP formulation. This calculation is complicated by the fact that these events are not independent; the counts of one trigram can affect the probability of later ones, and moreover, the table assignment for the trigram may also affect the bigram and unigram counts, of particular import when the same tag occurs twice in a row such as in Figure 2.

Many HMMs used for inducing word classes for language modelling include the restriction that all occurrences of a word type always appear with the same class throughout the corpus (Brown et al., 1992; Och, 1999; Clark, 2003). Our second sampler (PYP-1HMM) restricts inference to taggings which adhere to this one tag per type restriction. This restriction permits efficient inference techniques in which all tags of all occurrences of a word type are updated in parallel. Similar techniques have been used for models with Dirichlet priors (Liang et al., 2010), though one must be careful to manage the dependencies between multiple draws from the posterior.

The dependency on table counts in the conditional distributions complicates the process of drawing samples for both our models. In the non-hierarchical model (Goldwater and Griffiths, 2007) these dependencies can easily be accounted for by incrementing customer counts when such a dependence occurs. In our model we would need to sum over all possible table assignments that result in the same tagging, at all levels in the hierarchy: tag trigrams, bigrams and unigrams; and also words, character bigrams and character unigrams. To avoid this rather onerous marginalisation[2] we instead use expected table counts to calculate the conditional distributions for sampling. Unfortunately we know of no efficient algorithm for calculating the expected table counts, so instead develop a novel approximation

$$\mathrm{E}_{n+1}\left[K_i\right] \approx \mathrm{E}_n\left[K_i\right] + \frac{(a^U \mathrm{E}_n\left[K\right] + b^U) P_0(i)}{(n - \mathrm{E}_n\left[K_i\right] b^U) + (a^U \mathrm{E}_n\left[K\right] + b^U) P_0(i)} \,, \quad (3)$$

where K_i is the number of tables for the tag unigram i of which there are $n+1$ occurrences, $\mathrm{E}_n\left[\cdot\right]$ denotes an expectation after observing n items and $\mathrm{E}_n\left[K\right] = \sum_j \mathrm{E}_n\left[K_j\right]$. This formulation defines a simple recurrence starting with the first customer seated at a table, $\mathrm{E}_1\left[K_i\right] = 1$, and as each subsequent customer arrives we *fractionally* assign them to a new table based on their conditional probability of sitting alone. These fractional counts are then carried forward for subsequent customers.

This approximation is tight for small n, and therefore it should be effective in the case of the local Gibbs sampler where only three trigrams are being resampled. For the type based resampling where large numbers of n are involved (consider resampling *the*), this approximation can deviate from the actual value due to errors accumulated in the recursion. Figure 3 illustrates a simulation demonstrating that the approximation is a close match for small a and n but underestimates the true value for high a

[2] Marginalisation is intractable in general, i.e. for the 1HMM where many sites are sampled jointly.

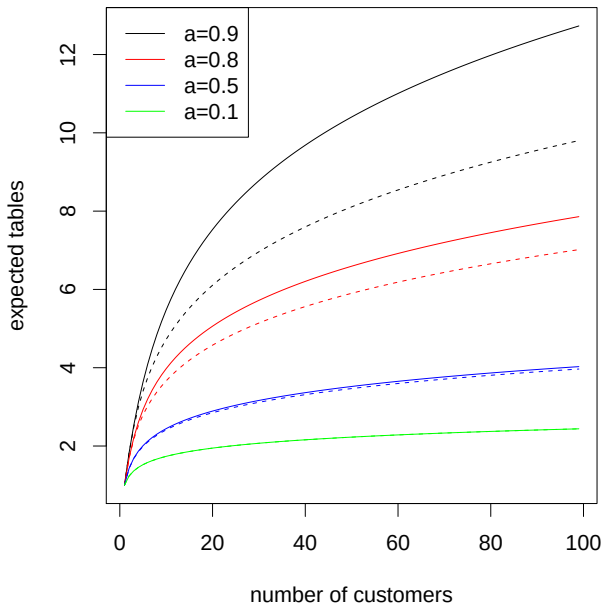

Figure 3: Simulation comparing the expected table count (solid lines) versus the approximation under Eq. 3 (dashed lines) for various values of a. This data was generated from a single PYP with $b = 1, P_0(i) = \frac{1}{4}$ and $n = 100$ customers which all share the same tag.

and n. The approximation was much less sensitive to the choice of b (not shown).

To resample a sequence of trigrams we start by removing their counts from the current restaurant configuration (resulting in $\mathbf{z}_-$). For each tag we simulate adding back the trigrams one at a time, calculating their probability under the given $\mathbf{z}_-$ plus the fractional table counts accumulated by Equation 3. We then calculate the expected table count contribution from this trigram and add it to the accumulated counts. The fractional table count from the trigram then results in a fractional customer entering the bigram restaurant, and so on down to unigrams. At each level we must update the expected counts before moving on to the next trigram. After performing this process for all trigrams under consideration and for all tags, we then normalise the resulting tag probabilities and sample an outcome. Once a tag has been sampled, we then add all the trigrams to the restaurants sampling their tables assignments explicitly (which are no longer fractional), recorded in $\mathbf{z}$. Because we do not marginalise out the table counts and our expectations are only approximate, this sampler will be biased. We leave to future work properly accounting for this bias, e.g., by devising a Metropolis Hastings acceptance test.

Sampling hyperparameters We treat the hyper-parameters $\{(a^x, b^x), x \in (U, B, T, E, C)\}$ as random variables in our model and infer their values. We place prior distributions on the PYP discount a^x and concentration b^x hyperparamters and sample their values using a slice sampler. For the discount parameters we employ a uniform Beta distribution ($a^x \sim \text{Beta}(1, 1)$), and for the concentration parameters we use a vague gamma prior ($b^x \sim \text{Gamma}(10, 0.1)$). All the hyper-parameters are resampled after every 5th sample of the corpus.

The result of this hyperparameter inference is that there are no user tunable parameters in the model, an important feature that we believe helps explain its consistently high performance across test settings.

4 Experiments

We perform experiments with a range of corpora to both investigate the properties of our proposed models and inference algorithms, as well as to establish their robustness across languages and domains. For our core English experiments we report results on the entire Penn. Treebank (Marcus et al., 1993), while for other languages we use the corpora made available for the CoNLL-X Shared Task (Buchholz and Marsi, 2006). We report results using the many-to-one (M-1) and v-measure (VM) metrics considered best by the evaluation of Christodoulopoulos et al. (2010). M-1 measures the accuracy of the model after mapping each predicted class to its most frequent corresponding tag, while VM is a variant of the F-measure which uses conditional entropy analogies of precision and recall. The log-posterior for the HMM sampler levels off after a few hundred samples, so we report results after five hundred. The 1HMM sampler converges more quickly so we use two hundred samples for these models. All reported results are the mean of three sampling runs.

An important detail for any unsupervised learning algorithm is its initialisation. We used slightly different initialisation for each of our inference strategies. For the unrestricted HMM we randomly assigned each word token to a class. For the restricted 1HMM we use a similar initialiser to

Model	M-1	VM

Table 1: WSJ performance comparing previous work to our own model. The columns display the many-to-1 accuracy and the V measure, both averaged over 5 independent runs. Our model was run with the local sampler (HMM), the type-level sampler (1HMM) and also with the character LM (1HMM-LM). Also shown are results using Dirichlet Process (DP) priors by fixing $\mathbf{a} = 0$. The system abbreviations are CGS10 (Christodoulopoulos et al., 2010), BBDK10 (Berg-Kirkpatrick et al., 2010) and GG07 (Goldwater and Griffiths, 2007). Starred entries denote results reported in CGS10.

Clark (2003), assigning each of the k most frequent word types to its own class, and then randomly dividing the rest of the types between the classes.

As a baseline we report the performance of `mkcls` (Och, 1999) on all test corpora. This model seems not to have been evaluated in prior work on unsupervised PoS tagging, which is surprising given its consistently good performance.

First we present our results on the most frequently reported evaluation, the WSJ sections of the Penn. Treebank, along with a number of state-of-the-art results previously reported (Table 1). All of these models are allowed 45 tags, the same number of tags as in the gold-standard. The performance of our models is strong, particularly the 1HMM. We also see that incorporating a character language model (1HMM-LM) leads to further gains in performance, improving over the best reported scores under both M-1 and VM. We have omitted the results for the HMM-LM as experimentation showed that the local Gibbs sampler became hopelessly stuck, failing to mix due to the model's deep structure (its peak performance was $\approx 55\%$).

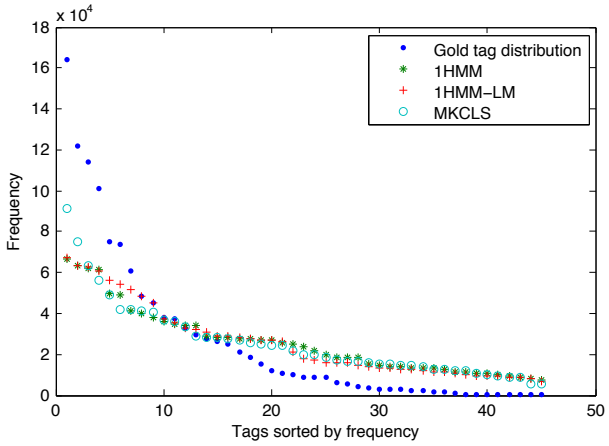

Figure 4: Sorted frequency of tags for WSJ. The gold standard distribution follows a steep exponential curve while the induced model distributions are more uniform.

To evaluate the effectiveness of the PYP prior we include results using a Dirichlet Process prior (DP). We see that for all models the use of the PYP provides some gain for the HMM, but diminishes for the 1HMM. This is perhaps a consequence of the expected table count approximation for the type-sampled PYP-1HMM: the DP relies less on the table counts than the PYP.

If we restrict the model to bigrams we see a considerable drop in performance. Note that the bigram PYP-HMM outperforms the closely related BHMM (the main difference being that we smooth tag bigrams with unigrams). It is also interesting to compare the bigram PYP-1HMM to the closely related model of Lee et al. (2010). That model incorrectly assumed independence of the conditional sampling distributions, resulting in a accuracy of 66.4%, well below that of our model.

Figures 4 and 5 provide insight into the behavior of the sampling algorithms. The former shows that both our models and `mkcls` induce a more uniform distribution over tags than specified by the treebank. It is unclear whether it is desirable for models to exhibit behavior closer to the treebank, which dedicates separate tags to very infrequent phenomena while lumping the large range of noun types into a single category. The graph in Figure 5 shows that the type-based 1HMM sampler finds a good tagging extremely quickly and then sticks with it,

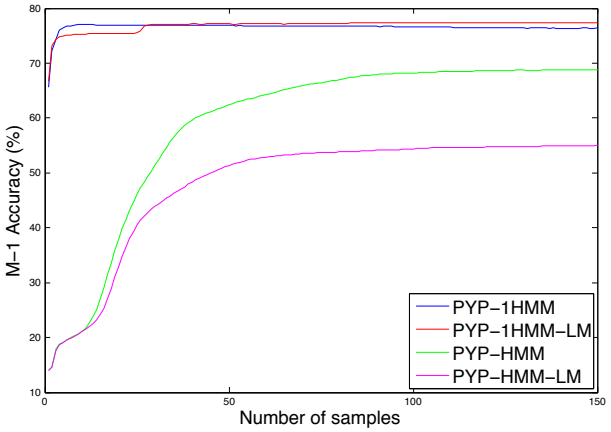

Figure 5: M-1 accuracy vs. number of samples.

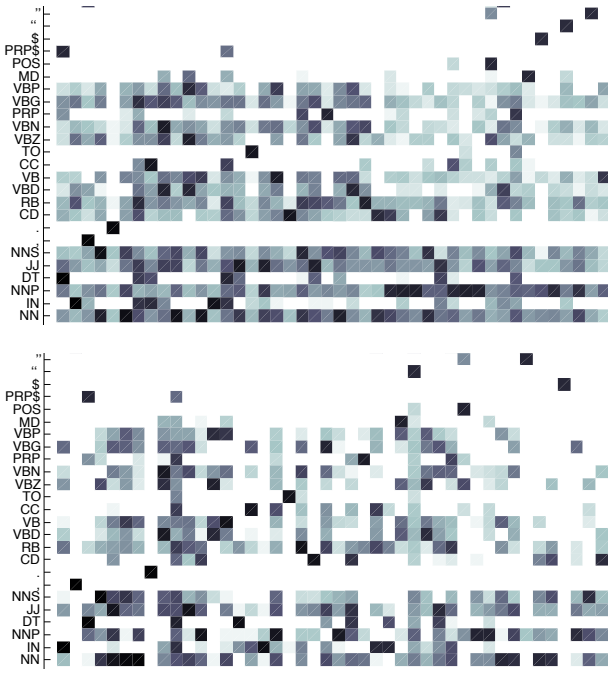

Figure 6: Cooccurence between frequent gold (y-axis) and predicted (x-axis) tags, comparing `mkcls` (top) and PYP-1HMM-LM (bottom). Both axes are sorted in terms of frequency. Darker shades indicate more frequent cooccurence and columns represent the induced tags.

save for the occasional step change demonstrated by the 1HMM-LM line. The locally sampled model is far slower to converge, rising slowly and plateauing well below the other models.

In Figure 6 we compare the distributions over WSJ tags for `mkcls` and the PYP-1HMM-LM. On the macro scale we can see that our model induces a sparser distribution. With closer inspection we can identify particular improvements our model makes. In the first column for `mkcls` and the third column for our model we can see similar classes with significant counts for DTs and PRPs, indicating a class that the models may be using to represent the start of sentences (informed by start transitions or capitalisation). This column exemplifies the sparsity of the PYP model's posterior.

We continue our evaluation on the CoNLL multilingual corpora (Table 2). These results show a highly consistent story of performance for our models across diverse corpora. In all cases the PYP-1HMM outperforms the PYP-HMM, which are both outperformed by the PYP-1HMM-LM. The character language model provides large gains in performance on a number of corpora, in particular those with rich morphology (Arabic +5%, Portuguese +5%, Spanish +4%). We again note the strong performance of the `mkcls` model, significantly beating recently published state-of-the-art results for both Dutch and Swedish. Overall our best model (PYP-1HMM-LM) outperforms both the state-of-the-art, where previous work exists, as well as `mkcls` consistently across all languages.

5 Discussion

The hidden Markov model, originally developed by Brown et al. (1992), continues to be an effective modelling structure for PoS induction. We have combined hierarchical Bayesian priors with a trigram HMM and character language model to produce a model with consistently state-of-the-art performance across corpora in ten languages. However our analysis indicates that there is still room for improvement, particularly in model formulation and developing effective inference algorithms.

Induced tags have already proven their usefulness in applications such as Machine Translation, thus it will prove interesting as to whether the improvements seen from our models can lead to gains in downstream tasks. The continued successes of models combining hierarchical Pitman-Yor priors with expressive graphical models attests to this framework's enduring attraction, we foresee continued interest in applying this technique to other NLP tasks.

Language	mkcls	HMM	1HMM	1HMM-LM	Best pub.	Tokens	Tag types

Using Deep Morphology to Improve Automatic Error Detection in Arabic Handwriting Recognition

Nizar Habash and **Ryan M. Roth**
Center for Computational Learning Systems
Columbia University
{habash,ryanr}@ccls.columbia.edu

Abstract

Arabic handwriting recognition (HR) is a challenging problem due to Arabic's connected letter forms, consonantal diacritics and rich morphology. In this paper we isolate the task of identification of erroneous words in HR from the task of producing corrections for these words. We consider a variety of linguistic (morphological and syntactic) and non-linguistic features to automatically identify these errors. Our best approach achieves a roughly $\sim$15% absolute increase in F-score over a simple but reasonable baseline. A detailed error analysis shows that linguistic features, such as lemma (i.e., citation form) models, help improve HR-error detection precisely where we expect them to: semantically incoherent error words.

1 Introduction

After years of development, optical character recognition (OCR) for Latin-character languages, such as English, has been refined greatly. Arabic, however, possesses a complex orthography and morphology that makes OCR more difficult (Märgner and Abed, 2009; Halima and Alimi, 2009; Magdy and Darwish, 2006). Because of this, only a few systems for Arabic OCR of printed text have been developed, and these have not been thoroughly evaluated (Märgner and Abed, 2009). OCR of Arabic handwritten text (handwriting recognition, or HR), whether online or offline, is even more challenging compared to printed Arabic OCR, where the uniformity of letter shapes and other factors allow for easier recognition (Biadsy et al., 2006; Natarajan et al., 2008; Saleem et al., 2009).

OCR and HR systems are often improved by performing post-processing; these are attempts to evaluate whether each word, phrase or sentence in the OCR/HR output is legal and/or probable. When an illegal word or phrase is discovered (error detection), these systems usually attempt to generate a legal alternative (error correction). In this paper, we present a HR error *detection* system that uses deep lexical and morphological feature models to locate possible "problem zones" – words or phrases that are likely incorrect – in Arabic HR output. We use an off-the-shelf HR system (Natarajan et al., 2008; Saleem et al., 2009) to generate an N-best list of hypotheses for each of several scanned segments of Arabic handwriting. Our problem zone detection (PZD) system then tags the potentially erroneous (problem) words. A subsequent HR post-processing system can then focus its effort on these words when generating additional alternative hypotheses. We only discuss the PZD system and not the task of new hypothesis generation; the evaluation is on error/problem identification. PZD can also be useful in highlighting erroneous text for human post-editors.

This paper is structured as follows: Section 2 provides background on the difficulties of the Arabic HR task. Section 3 presents an analysis of HR errors and defines what is considered a problem zone to be tagged. The experimental features, data and other variables are outlined in Section 4. The experiments are presented and discussed in Section 5. We discuss and compare to some related work in detail in Section 6. Conclusions and suggested avenues of for future progress are presented in Section 7.

2 Arabic Handwriting Recognition Challenges

Arabic has several orthographic and morphological properties that make HR challenging (Darwish and Oard, 2002; Magdy and Darwish, 2006; Märgner and Abed, 2009).

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 875–884,
Portland, Oregon, June 19-24, 2011.

2.1 Arabic Orthography Challenges

The use of cursive, connected script creates problems in that it becomes more difficult for a machine to distinguish between individual characters. This is certainly not a property unique to Arabic; methods developed for other cursive script languages (such as Hidden Markov Models) can be applied successfully to Arabic (Natarajan et al., 2008; Saleem et al., 2009; Märgner and Abed, 2009; Lu et al., 1999).

Arabic writers often make use of elongation (tatweel/kashida) to beautify the script. Arabic also contains certain ligature constructions that require consideration during OCR/HR (Darwish and Oard, 2002). Sets of dots and optional diacritic markers are used to create character distinctions in Arabic. However, trace amounts of dust or dirt on the original document scan can be easily mistaken for these markers (Darwish and Oard, 2002). Alternatively, these markers in handwritten text may be too small, light or closely-spaced to readily distinguish, causing the system to drop them entirely. While Arabic disconnective letters may make it hard to determine word boundaries, they could plausibly contribute to reduced ambiguity of otherwise similar shapes.

2.2 Arabic Morphology Challenges

Arabic words can be described in terms of their morphemes. In addition to concatenative prefixes and suffixes, Arabic has templatic morphemes called *roots* and *patterns*. For example, the word وكمكاتبهم *wkmkAtbhm*[1] (*w+k+mkAtb+hm*) 'and like their offices' has two prefixes and one suffix, in addition to a stem composed of the root كتب *k-t-b* 'writing related' and the pattern *m1A23*.[2] Arabic words can also be described in terms of lexemes and inflectional features. The set of word forms that only vary inflectionally among each other is called the *lexeme*. A *lemma* is a particular word form used to represent the lexeme word set – a citation form that stands in for the class (Habash, 2010). For instance, the lemma مكتب *mktb* 'office' represents the class of all forms sharing the core meaning 'office': مكاتب *mkAtb* 'offices' (irregular plural), المكتب *Almktb* 'the office', لمكتبها *lmktbhA* 'for her office', and so on.

Just as the lemma abstracts over inflectional morphology, the root abstracts over both inflectional and derivational morphology and thus provides a very high level of lexical abstraction, indicating the "core" meaning of the word. The Arabic root كتب *k-t-b* 'writing related', e.g., relates words like مكتب *mktb* 'office', مكتوب *mktwb* 'letter', and كتيبة *ktybħ* 'military unit (of conscripts)'.

Arabic morphology allows for tens of billions of potential, legal words (Magdy and Darwish, 2006; Moftah et al., 2009). The large potential vocabulary size by itself complicates HR methods that rely on conventional, word-based dictionary lookup strategies. In this paper we consider the value of morpho-lexical and morpho-syntactic features such as lemmas and part-of-speech tags, respectively, that may allow machine learning algorithms to learn generalizations. We do not consider the root since it has been shown to be too general for NLP purposes (Larkey et al., 2007). Other researchers have used stems for OCR correction (Magdy and Darwish, 2006); we discuss their work and compare to it in Section 6, but we do not present a direct experimental comparison.

3 Problem Zones in Handwriting Recognition

3.1 HR Error Classifications

We can classify three types of HR errors: substitutions, insertions and deletions. Substitutions involve replacing the correct word by another incorrect form. Insertions are words that are incorrectly added into the HR hypothesis. An insertion error is typically paired with a substitution error, where the two errors reflect a mis-identification of a single word as two words. Deletions are simply missing words. Examples of these different types of errors appear in Table 1. In the dev set that we study here (see Section 4.1), 25.8% of the words are marked as problematic. Of these, 87.2% are letter-based words (henceforth words), as opposed to 9.3% punctuation and 3.5% digits.

Orthogonally, 81.4% of all problem words are substitution errors, 10.6% are insertion errors and 7.9% are deletion errors. Whereas punctuation symbols are 9.3% of all errors, they represent over 38%

[1] All Arabic transliterations are presented in the HSB transliteration scheme (Habash et al., 2007).

[2] The digits in the pattern correspond to positions where root radicals are inserted.

REF	!	الجودة	عالية	زبدة		علبة	تصنعوا	أن	والأندلس		وفارس	القسطنطينية	يافاتحي	المسلمون	أيها	أعجزتم

Table 1: An example highlighting the different types of Arabic HR errors. The first row shows the reference sentence (right-to-left). The second row shows an automatically generated hypothesis of the same sentence. The last row shows which words in the hypothesis are marked as *problematic* (PROB) by the system and the specific category of the problem (illustrative, not used by system): SUB (substituted), ORTH (substituted by an orthographic variant), DOTS (substituted by a word with different dotting), INS (inserted), and DELX (adjacent to a deleted word). The remaining words are tagged as OK. The reference translates as '*Are you unable O'Moslems, you who conquered Constantinople and Persia and Andalusia, to manufacture a tub of high quality butter!*'. The hypothesis roughly translates as '*I loan then O'Moslems Pattani Constantinople, and Persia and taking from whom that you spend on him N Yeoh high quality*'.

of all deletion errors, almost 22% of all insertion errors and less than 5% of substitution errors. Similarly digits, which are 3.5% of all errors, are almost 14% of deletions, 7% of insertions and just over 2% of all substitutions. Punctuation and digits bring different challenges: whereas punctuation marks are a small class, their shape is often confusable with Arabic letters or letter components, e.g., إ *Ǎ* and **!** or ر *r* and **,**. Digits on the other hand are a hard class to language model since the vocabulary (of multi-digit numbers) is infinite. Potentially this can be addressed using a pattern-based model that captures forms of digit sequences (such as date and currency formats); we leave this as future work.

Words (non-digit, non-punctuation) still constitute the majority in every category of error: 47.7% of deletions, 71.3% of insertions and over 93% of substitutions. Among substitutions, 26.5% are simple orthographic variants that are often normalized in Arabic NLP because they result from frequent inconsistencies in spelling: Alef Hamza forms (ٱأإآ *A/Â/Ǎ/Ā*) and Ya/Alef-Maqsura (ى/ي *y/ý*). If we consider whether the lemma of the correct word and its incorrect form are matchable, an additional 6.9% can be added to the orthographic variant sum (since all of these cases can share the same lemmas). The rest of the cases, or 59.7% of the words, involve complex orthographic errors. Simple dot misplacement can only account for 2.4% of all substitution errors. The HR system output does not contain any illegal non-words since its vocabulary is restricted by its training data and language models. The large proportion of errors involving lemma differences is consistent with the perception that most OCR/HR errors create semantically incoherent sentences. This suggests that lemma models can be helpful in identifying such errors.

3.2 Problem Zone Definition

Prior to developing a model for PZD, it is necessary to define what is considered a 'problem'. Once a definition is chosen, gold problem tags can be generated for the training and test data by comparing the hypotheses to their references.[3] We decided in this paper to use a simple binary *problem* tag: a hypothesis word is tagged as "PROB" if it is the result of an insertion or substitution of a word. Deleted words in a hypothesis, which cannot be tagged themselves, cause their adjacent words to be marked as PROB instead. In this way, a subsequent HR post-processing system can be alerted to the possibility of a missing word via its surroundings (hence the idea of a problem 'zone'). Any words not marked as PROB are given an "OK" tag (see the PZD row of Table 1). We describe in Section 5.6 some preliminary experiments we conducted using more fine-grained tags.

4 Experimental Settings

4.1 Training and Evaluation Data

The data used in this paper is derived from image scans provided by the Linguistic Data Consortium (LDC) (Strassel, 2009). This data consists of high-resolution (600 dpi) handwriting scans of Arabic text taken from newswire articles, web logs and

[3]For clarity, we refer to these tags as 'gold', whereas the correct segment for a given hypothesis set is called the 'reference'.

newsgroups, along with ground truth annotations and word bounding box information. The scans include variations in scribe demographic background, writing instrument, paper and writing speed.

The BBN Byblos HR system (Natarajan et al., 2008; Saleem et al., 2009) is then used to process these scanned images into sequences of *segments* (sentence fragments). The system generates a ranked N-best list of hypotheses for each segment, where N could be as high as 300. On average, a segment has 6.87 words (including punctuation).

We divide the N-best list data into training, development (dev) and test sets.[4] For training, we consider two sets of size 2000 and 4000 segments (S) with the 10 top-ranked hypotheses (H) for each segment to provide additional variations.[5] The references are also included in the training sets to provide examples of perfect text. The dev and test sets use 500 segments with one top-ranked hypothesis each {H=1}. We can construct a trivial PZD baseline by assuming all the input words are PROBs; this results in baseline % Precision/Recall/F-scores of 25.8/100/41.1 and 26.0/100/41.2 for the dev and test sets, respectively. Note that in this paper we eschew these baselines in favor of comparison to a non-trivial baseline generated by a simple PZD model.

4.2 PZD Models and Features

The PZD system relies on a set of SVM classifiers trained using morphological and lexical features. The SVM classifiers are built using Yamcha (Kudo and Matsumoto, 2003). The SVMs use a quadratic polynomial kernel. For the models presented in this paper, the static feature window context size is set to +/- 2 words; the previous two (dynamic) classifications (i.e. targets) are also used as features. Experiments with smaller window sizes result in poorer performance, while a larger window size (+/- 6 words) yields roughly the same performance at the expense of an order-of-magnitude increase in required training time. Over 30 different combinations of features were considered. Table 2 shows the individual feature definitions.

Simple	**Description**
`word`	The surface word form
`nw`	Normalized word: the word after Alef, Ya and digit normalization
`pos`	The part-of-speech (POS) of the word
`lem`	The lemma of the word
`na`	No-analysis: a binary feature indicating whether the morphological analyzer produced any analyses for the word
Binned	**Description**
`nw` N-grams	Normword 1/2/3-gram probabilities
`lem` N-grams	Lemma 1/2/3-gram probabilities
`pos` N-grams	POS 1/2/3-gram probabilities
`conf`	Word confidence: the ratio of the number of hypotheses in the N-best list that contain the word over the total number of hypotheses

Table 2: PZD model features. Simple features are used directly by the PZD SVM models, whereas Binned features' (numerical) values are reduced to a small, labeled category set whose labels are used as model features.

In order to obtain the morphological features, all of the training and test data is passed through MADA 3.0, a software tool for Arabic morphological analysis disambiguation (Habash and Rambow, 2005; Roth et al., 2008; Habash et al., 2010). For these experiments, MADA provides the `pos` (using MADA's native 34-tag set) and the lemma for each word. Occasionally MADA will not be able to produce any interpretations (analyses) for a word; since this is often a sign that the word is misspelled or uncommon, we define a binary `na` feature to indicate when MADA fails to generate analyses.

In addition to using the MADA features directly, we also develop a set of nine N-gram models (where N=1, 2, and 3) for the `nw`, `pos`, and `lem` features defined in Table 2. We train these models using 220M words from the Arabic Gigaword 3 corpus (Graff, 2007) which had also been run through MADA 3.0 to extract the `pos` and `lem` information. The models are built using the SRI Language Modeling Toolkit (Stolcke, 2002). Each word in a hypothesis can then be assigned a probability by each of these nine models. We reduce these probabilities into one of nine bins, with each successive bin representing an order of magnitude drop in probability (the final bin is re-

[4] Naturally, we do not use data that the BBN Byblos HR system was trained on.

[5] We conducted additional experiments where we varied the number of segments and hypotheses and found that the system benefited from added variety of segments more than hypotheses. We also modified training composition in terms of the ratio of problem/non-problem words; this did not help performance.

served for word N-grams which did not appear in the models). The bin labels are used as the SVM features.

Finally, we also use a word confidence (`conf`) feature, which is aimed at measuring the frequency with which a given word is chosen by the HR system for a given segment scan. The `conf` is defined here as the ratio of the number of hypotheses in the N-best list that the word appears in to the total number of hypotheses. These numbers are calculated using the original N-best hypothesis list, before the data is trimmed to H={1, 10}. Like the N-grams, this number is binned; in this case there are 11 bins, with 10 spread evenly over the [0,1) range, and an extra bin for values of exactly 1 (i.e., when the word appears in every hypothesis in the set).

5 Results

We describe next different experiments conducted by varying the features used in the PZD model. We present the results in terms of F-score only for simplicity; we then conduct an error analysis that examines precision and recall.

5.1 Effect of Feature Set Choice

Selecting an appropriate set of features for PZD requires extensive testing. Even when only considering the few features described in Table 2, the parameter space is quite large. Rather then exhaustively test every possible feature combination, we selectively choose feature subsets that can be compared to gain a sense of the incremental benefit provided by individual features.

5.1.1 Simple Features

Table 3 illustrates the result of taking a baseline feature set (containing `word` as the only feature) and adding a single feature from the Simple set to it. The result of combining all the Simple features is also indicated. From this, we see that Simple features, even collectively, provide only minor improvements.

5.1.2 Binned Features

Table 4 shows models which include both Simple and Binned features. First, Table 4 shows the effect of adding `nw` N-grams of successively higher orders to the `word` baseline. Here we see that even a simple unigram provides a significant benefit (compared to the improvements gained in Table 3). The largest improvement comes with the addition of the bigram (thus introducing context into the model), but the trigram provides only a slight improvement above that. This implies that pursuing higher order N-grams will result in negligible returns.

In the next part of Table 4, we see that the single feature (`pos`) which provided the highest single-feature benefit in Table 3 does not provide similar improvements under these combinations, and in fact seems detrimental. We also note that using all the features in one model is outperformed by more selective choices. Here, the best performer is the model which utilizes the `word`, `nw` N-grams,

Feature Set	**F-score**	*%Imp*
`word`	43.85	–
`word+nw`	43.86	∼0
`word+na`	44.78	2.1
`word+lem`	45.85	4.6
`word+pos`	45.91	4.7
`word+nw+pos+lem+na`	**46.34**	**5.7**

Table 3: PZD F-scores for simple feature combinations. The training set used was {S=2000, H=10} and the models were evaluated on the dev set. The improvement over the **word** baseline case is also indicated. *%Imp* is the relative improvement over the first row.

Feature Set	**F-score**	*%Imp*
`word`	43.85	–
`word+nw` 1-gram	49.51	12.9
`word+nw` 1-gram+`nw` 2-gram	59.26	35.2
`word+nw` N-grams	59.33	35.3
+`pos`	58.50	33.4
+`pos` N-grams	57.35	30.8
+`lem+lem` N-grams	59.63	36.0
+`lem+lem` N-grams+`na`	59.93	36.7
+`lem+lem` N-grams+`na+nw`	59.77	36.3
+`lem`	**60.92**	**38.9**
+`lem+na`	60.47	37.9
+`lem+lem` N-grams	60.44	37.9

Table 4: PZD F-scores for models that include Binned features. The training set used was {S=2000, H=10} and the models were evaluated on the dev set. The improvement over the **word** baseline case is also indicated. The label "N-grams" following a Binned feature refers to using 1, 2 *and* 3-grams of that feature. Indentation marks accumulative features in model. The best performing row (with bolded score) is *word+nw N-grams+lem*.

Base Feature Set	F-score		%Imp
		+conf	
word	43.85	55.83	27.3
+nw N-grams	59.33	61.71	4.0
+lem	**60.92**	62.60	2.8
+lem+na	60.47	**63.14**	4.4
+lem+lem N-grams	60.44	62.88	4.0
+pos+pos N-grams +na+nw (**all** system)	59.77	62.44	4.5

Table 5: PZD F-scores for models when word confidence is added to the feature set. The training set used was {S=2000, H=10} and the models were evaluated on the dev set. The improvement generated by including word confidence is indicated. The label "N-grams" following a Binned feature refers to using 1, 2 *and* 3-grams of that feature. Indentation marks accumulative features in model. *%Imp* is the relative improvement gained by adding the *conf* feature.

Feature Set	S = 2000 F-score	S = 4000 F-score	%Imp
word	43.85	52.08	18.8
word+conf	55.83	57.50	3.0
word+nw N-grams+lem +conf (**best** system)	62.60	**66.34**	6.0
+na	**63.14**	66.21	4.9
+lem N-grams	62.88	64.43	2.5
all	62.44	65.62	5.1

Table 6: PZD F-scores for selected models when the number of training segments (S) is doubled. The training set used was {S=2000, H=10} and {S=4000, H=10}, and the models were evaluated on the dev set. The label "N-grams" following a Binned feature refers to using 1, 2 *and* 3-grams of that feature. Indentation marks accumulative features in model.

and lem as the only features. However, the differences among this model and the other models using lem Table 4 are not statistically significant. The differences between this model and the other lower performing models are statistically significant ($p<0.05$).

5.1.3 Word Confidence

The conf feature deserves special consideration because it is the only feature which draws on information from across the entire hypothesis set. In Table 5, we show the effect of adding conf as a feature to several base feature sets taken from Table 4. Except for the baseline case, conf provides a relatively consistent benefit. The large (27.3%) improvement gained by adding conf to the **word** baseline shows that conf is a valuable feature, but the smaller improvements in the other models indicate that the information it provides largely overlaps with the information already present in those models. The differences among the last four models (all including lem) in Table 5 are not statistically significant. The differences between these four models and the first two are statistically significant ($p<0.05$).

5.2 Effect of Training Data Size

In order to allow for rapid examination of multiple feature combinations, we restricted the size of the training set (S) to maintain manageable training times. With this decision comes the implicit assumption that the results obtained will scale with additional training data. We test this assumption by taking the best-performing feature sets from Table 5 and training new models using twice the training data {S=4000}. The results are shown in Table 6. In each case, the improvements are relatively consistent (and on the order of the gains provided by the inclusion of conf as seen in Table 5), indicating that the model performance does scale with data size. However, these improvements come with a cost of a roughly 4-7x increase in training time. We note that the value of doubling S is roughly 3-6x times greater for the **word** baseline than the others; however, simply adding conf to the baseline provides an even greater improvement than doubling S. The differences between the final four models in Table 6 are not statistically significant. The differences between these models and the first two models in the table are statistically significant ($p<0.05$). For convenience, in the next section we refer to the third model listed in Table 6 as the **best** system (because it has the highest absolute F-score on the large data set), but readers should recall that these four models are roughly equivalent in performance.

5.3 Error Analysis

In this section, we look closely at the performance of a subset of systems on different types of problem words. We compare the following model settings: for {S=4000} training, we use word, word + conf, the best system from Table 6 and the model

(a)	S=4000				S=2000
	word	**wconf**	**best**	**all**	**all**
Precision	54.7	59.5	67.1	**67.4**	62.4
Recall	49.7	55.7	**65.6**	64.0	62.5
F-score	52.1	57.5	**66.3**	65.6	62.4
Accuracy	76.4	78.7	**82.8**	82.7	80.6

(b)	**%Prob**	**word**	**wconf**	**best**	**all**	**all**
Words	87.2	51.8	57.3	**68.5**	67.1	64.9
Punc.	9.3	39.5	44.7	**50.0**	46.1	40.8
Digits	3.5	24.1	44.8	34.5	34.5	**62.1**
INS	10.6	46.0	49.4	**62.1**	**62.1**	55.2
DEL	7.9	**29.2**	20.0	24.6	21.5	27.7
SUB	81.4	52.2	60.0	**70.0**	68.4	66.9
Ortho	21.6	**63.3**	51.4	52.5	53.7	48.6
Lemma	5.6	45.7	52.2	**63.0**	52.2	54.4
Semantic	54.2	48.4	64.2	**77.7**	75.9	75.5

Table 7: Error analysis results comparing the performance of multiple systems over different metrics (a) and word/error types (b). %Prob shows the distribution of problem words into different word types (word, punctuation and digit) and error types. INS, DEL and SUB stand for insertion, deletion and substitution error types, respectively. *Ortho* stands for orthographic variant. *Lemma* stands for 'shared lemma'. The columns to the right of the %Prob column show recall percentage for each word/error type.

using all possible features (**word**, **wconf**, **best** and **all**, respectively); and we also use **all** trained with {S=2000}. We consider the performance in terms of precision and recall in addition to F-score – see Table 7 (a). We also consider the percentage of recall per error type, such as word/punctuation/digit or deletion/insertion/substitution and different types of substitution errors – see Table 7 (b). The second column in this table (**%Prob**) shows the distribution of gold-tagged problem words into word and error type categories.

Overall, there is no major tradeoff between precision and recall across the different settings; although we can observe the following: (i) adding more training data helps precision more than recall (over three times more) – compare the last two columns in Table 7 (a); and (ii) the best setting has a slightly lower precision than **all** features, although a much better recall – compare columns 4 and 5 in Table 7 (a).

The performance of different settings on words is generally better than punctuation and that is better than digits. The only exceptions are in the digit category, which may be explained by that category's small count which makes it prone to large percentage fluctuations.

In terms of error type, the performance on substitutions is better than insertions, which is in turn better than deletions, for all systems compared. This makes sense since deletions are rather hard to detect and they are marked on possibly correct adjacent words, which may confuse the classifiers. One insight for future work is to develop systems for different types of errors. Considering substitutions in more detail, we see that surprisingly, the simple approach of using the word feature only (without `conf`) correctly recalls a bigger proportion of problems involving orthographic variants than other settings. It seems that the more complex the model, the harder it is to model these cases correctly. Error types that include semantic variations (different lemmas) or shared lemmas (but not explained by orthographic variation), are by contrast much harder for the simple models. The more complex models do quite well recalling errors involving semantically incoherent substitutions (around 77.7% of those cases) and words that share the same lemma but vary in inflectional features (63% of those cases). These two results are quite a jump from the basic word baseline (around 29% and 18% respectively).

The simple addition of data seems to contribute more towards the orthographic variation errors and less towards semantic errors. The different settings we use (training size and features) show some degree of complementarity in how they identify errors. We try to exploit this fact in Section 5.5 exploring some simple system combination ideas.

5.4 Blind Test Set

Table 8 shows the results of applying the same models described in Table 7 to a blind test set of yet unseen data. As mentioned in Section 4.1, the trivial baseline of the test set is comparable to the dev set. However, the test set is harder to tag than the dev set; this can be seen in the overall lower F-scores. That said, the relative order of performing features is the same as with the dev set, confirming that our **best** model is optimal for test too. On further study, we noticed that the reason for the test set difference is that the overlap in word forms between test and

	word	wconf	best	all
Precision	37.55	51.48	**57.01**	55.46
Recall	51.73	53.39	**61.97**	60.44
F-score	43.51	52.42	**59.39**	57.84
Accuracy	65.13	74.83	**77.99**	77.13

Table 8: Results on test set of 500 segments with one hypothesis each. The models were trained on the {S=4000, H=10} training set.

train is less than dev and train: 63% versus 81%, respectively on {S=4000}.

5.5 Preliminary Combination Analysis

In a preliminarily investigation of the value of complementarity across these different systems, we tried two simple model combination techniques. We restricted the search to the systems in the error analysis (Table 7).

First, we considered a sliding voting scheme where a word is marked as problematic if at least n systems agreed to that. Naturally, as n increases, precision increases and recall decreases, providing multiple tradeoff options. The range spans 49.1/83.2/61.8 (% Precision/Recall/F-score) at one end ($n = 1$) to 80.4/27.5/41.0 on the other ($n = all$). The best F-score combination was with $n = 2$ (any two agree) producing 62.8/72.4/67.3, an almost 1% higher than our best system.

In a different combination exploration, we exhaustively sought the best three systems from which any agreement (2 or 3) can produce an even better system. The best combination included the **word** model, the **best** model (both in {S=4000} training) and the **all** model (in {S=2000}). This combination yields 70.2/64.0/66.9, a lower F-score than the best general voting approach discussed above, but with a different bias towards better precision.

These basic exploratory experiments show that there is a lot of value in pursuing combinations of systems, if not for overall improvement, then at least to benefit from tradeoffs in precision and recall that may be appropriate for different applications.

5.6 Preliminary Tag Set Exploration

In all of the experiments described so far, the PZD models tag words using a binary tag set of PROB/OK. We may also consider more complex tag sets based on problem subtypes, such as SUB/INS/DEL/OK (where all the problem subtypes are differentiated), SUB/INS/OK (ignores deletions), and SUB/OK (ignores deletions and insertions). Care must be taken when comparing these systems, because the differences in tag set definition results in different baselines. Therefore we compare the % error reduction over the trivial baseline achieved in each case.

For an **all** model trained on the {S=2000, H=10} set, using the PROB/OK tag set results in a 36.3% error reduction over its trivial baseline (using the dev set). The corresponding SUB/INS/DEL/OK tag set only achieves a 34.8% error reduction. The SUB/INS/OK tag set manages a 40.1% error reduction, however. The SUB/OK tag set achieves a 38.9% error reduction. We suspect that the very low relative number of deletions (7.9% in the dev data) and the awkwardness of a DEL tag indicating a neighboring deletion (rather than the current word) may be confusing the models, and so ignoring them seems to result in a clearer picture.

6 Related Work

Common OCR/HR post-processing strategies are similar to spelling correction solutions involving dictionary lookup (Kukich, 1992; Jurafsky and Martin, 2000) and morphological restrictions (Domeij et al., 1994; Oflazer, 1996). Error detection systems using dictionary lookup can sometimes be improved by adding entries representing morphological variations of root words, particularly if the language involved has a complex morphology (Pal et al., 2000). Alternatively, morphological information can be used to construct supplemental lexicons or language models (Sari and Sellami, 2002; Magdy and Darwish, 2006).

In comparison to (Magdy and Darwish, 2006), our paper is about error detection only (done in using discriminative machine learning); whereas their work is on error correction (done in a standard generative manner (Kolak and Resnik, 2002)) with no assumptions of some cases being correct or incorrect. In essence, their method of detection is the same as our trivial baseline. The morphological features they use are *shallow* and restricted to breaking up a word into *prefix*+*stem*+*suffix*; whereas we analyze words into their lemmas, abstracting away over a large number of variations. We also made use of

part-of-speech tags, which they do not use, but suggest may help. In their work, the morphological features did not help (and even hurt a little), whereas for us, the lemma feature actually helped. Their hypothesis that their large language model (16M words) may be responsible for why the word-based models outperformed stem-based (morphological) models is challenged by the fact that our language model data (220M words) is an order of magnitude larger, but we are still able to show benefit for using morphology. We cannot directly compare to their results because of the different training/test sets and target (correction vs detection); however, we should note that their starting error rate was quite high (39% on Alef/Ya normalized words), whereas our starting error rate is almost half of that ($\sim$26% with unnormalized Alef/Yas, which account for almost 5% absolute of the errors). Perhaps a combination of the two kinds of efforts can push the perfomance on correction even further by biasing towards problematic words and avoiding incorrectly changing correct words. Magdy and Darwish (2006) do not report on percentages of words that they incorrectly modify.

7 Conclusions and Future Work

We presented a study with various settings (linguistic and non-linguistic features and learning curve) for automatically detecting problem words in Arabic handwriting recognition. Our best approach achieves a roughly $\sim$15% absolute increase in F-score over a simple baseline. A detailed error analysis shows that linguistic features, such as lemma models, help improve HR-error detection specifically where we expect them to: identifying semantically inconsistent error words.

In the future, we plan to continue improving our system by considering smarter trainable combination techniques and by separating the training for different types of errors, particularly deletions from insertions and substitutions. We would also like to conduct an extended evaluation comparing other types of morphological features, such as roots and stems, directly. One additional idea is to implement a lemma-confidence feature that examines lemma use in hypotheses across the document. This could potentially provide valuable semantic information at the document level.

We also plan to integrate our system with a system for producing correction hypotheses. We also will consider different uses for the basic system setup we developed to identify other types of text errors, such as spelling errors or code-switching between languages and dialects.

Abstract

Most previous studies of morphological disambiguation and dependency parsing have been pursued independently. Morphological taggers operate on n-grams and do not take into account syntactic relations; parsers use the "pipeline" approach, assuming that morphological information has been separately obtained.

However, in morphologically-rich languages, there is often considerable interaction between morphology and syntax, such that neither can be disambiguated without the other. In this paper, we propose a discriminative model that jointly infers morphological properties and syntactic structures. In evaluations on various highly-inflected languages, this joint model outperforms both a baseline tagger in morphological disambiguation, and a pipeline parser in head selection.

1 Introduction

To date, studies of morphological analysis and dependency parsing have been pursued more or less independently. Morphological taggers disambiguate morphological attributes such as part-of-speech (POS) or case, without taking syntax into account (Hakkani-Tür et al., 2000; Hajič et al., 2001); dependency parsers commonly assume the "pipeline" approach, relying on morphological information as part of the input (Buchholz and Marsi, 2006; Nivre et al., 2007). This approach serves many languages well, especially those with less morphological ambiguity. In English, for example, accuracy of POS tagging has risen above 97% (Toutanova et al., 2003), and that of dependency parsing has reached the low nineties (Nivre et al., 2007). For these languages, there may be little to be gained to justify the computational cost of incorporating syntactic inference during the morphological tagging task; conversely, it is doubtful that errorful morphological information is a main cause of errors in English dependency parsing.

However, the pipeline approach seems more problematic for morphologically-rich languages with substantial interactions between morphology and syntax (Tsarfaty, 2006). Consider the Latin sentence, *Una dies omnis potuit praecurrere amantis*, 'One day was able to make up for all the lovers'[1]. As shown in Table 1, the adjective *omnis* ('all') is ambiguous in number, gender, and case; there are seven valid analyses. From the perspective of a finite-state morphological tagger, the most attractive analysis is arguably the singular nominative, since *omnis* is immediately followed by the singular verb *potuit* ('could'). Indeed, the baseline tagger used in this study did make this decision. Given its nominative case, the pipeline parser assigned the verb *potuit* to be its head; the two words form the typical subject-verb relation, agreeing in number.

Unfortunately, as shown in Figure 1, the word *omnis* in fact modifies the noun *amantis*, at the end of the sentence. As a result, despite the distance between them, they must agree in number, gender and case, i.e., both must be plural masculine (or feminine) accusative. The pipeline parser, acting on the input that *omnis* is nominative, naturally did not see

Latin	*Una*		*dies*		*omnis*			*potuit*	*praecurrere*	*amantis*	
English	one		day		all			could	to surpass	lovers	
Number	**sg**	pl	**sg**	pl	sg	sg	**pl**	**sg**	**-**	sg	**pl**
Gender	**f**	n	m/**f**	m/f	m/f	m/f/n	**m**/f	**-**	**-**	m/f/n	**m**/f
Case	**nom**/ab	nom/acc	**nom**	nom/acc	nom	gen	**acc**	**-**	**-**	gen	**acc**

Table 1: The Latin sentence "*Una dies omnis potuit praecurrere amantis*", meaning 'One day was able to make up for all the lovers', shown with glosses and possible morphological analyses. The correct analyses are shown in bold. The word *omnis* has 7 possible combinations of number, gender and case, while *amantis* has 5. Disambiguation partly depends on establishing *amantis* as the head of *omnis*, and so the two must agree in all three attributes.

this agreement, and therefore did not consider this syntactic relation likely.

Such a dilemma is not uncommon in languages with relatively free word order. On the one hand, it appears difficult to improve morphological tagging accuracy on words like *omnis* without syntactic knowledge; on the other hand, a parser cannot reliably disambiguate syntax unless it has accurate morphological information, in this example the agreement in number, gender, and case.

In this paper we propose to attack this chicken-and-egg problem with a discriminative model that jointly infers morphological and syntactic properties of a sentence, given its words as input. In evaluations on various highly-inflected languages, the model outperforms both a baseline tagger in morphological disambiguation, and a pipeline parser in head selection.

After a description of previous work (§2), the joint model (§3) will be contrasted with the baseline pipeline model (§4). Experimental results (§5-6) will then be presented, followed by conclusions and future directions.

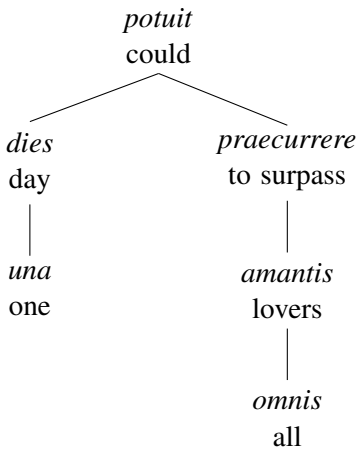

Figure 1: Dependency tree for the sentence "*Una dies omnis potuit praecurrere amantis*". The word *omnis* is an adjective modifying the noun *amantis*. This information is key to the morphological disambiguation of both words, as shown in Table 1.

2 Previous Work

Since space does not allow a full review of the vast literature on morphological analysis and parsing, we focus only on past research involving joint morphological and syntactic inference (§2.1); we then discuss Latin (§2.2), a language representative of the challenges that motivated our approach.

2.1 Joint Morphological and Syntactic Inference

Most previous work in morphological disambiguation, even when applied on morphologically complex languages with relatively free word order, such as Turkish (Hakkani-Tür et al., 2000) and Czech (Hajič et al., 2001), did not consider syntactic relationships between words. In the literature on data-driven parsing, two recent studies attempted joint inference on morphology and syntax, and both considered phrase-structure trees for Modern Hebrew (Cohen and Smith, 2007; Goldberg and Tsarfaty, 2008).

The primary focus of morphological processing in Modern Hebrew is splitting orthographic words into morphemes: clitics such as prepositions, pronouns, and the definite article must be separated from the core word. Each of the resulting morphemes is then tagged with an atomic "part-of-speech" to indicate word class and some morphological features. Similarly, the English POS tags in the Penn Treebank combine word class information with morphologi-

cal attributes such as "plural" or "past tense".

Cohen and Smith (2007) separately train a discriminative conditional random field (CRF) for segmentation and tagging, and a generative probabilistic context-free grammar (PCFG) for parsing. At decoding time, the two models are combined as a product of experts. Goldberg and Tsarfaty (2008) propose a generative joint model. This paper is the first to use a fully discriminative model for joint morphological and syntactic inference on dependency trees.

2.2 Latin

Unlike Modern Hebrew, Latin does not require extensive morpheme segmentation[2]. However, it does have a relatively free word order, and is also highly inflected, with each word having up to nine morphological attributes, listed in Table 2. In addition to its absolute numbers of cases, moods, and tenses, Latin morphology is *fusional*. For instance, the suffix *−is* in *omnis* cannot be segmented into morphemes that separately indicate gender, number, and case. According to the Latin morphological database encoded in MORPHEUS (Crane, 1991), 30% of Latin nouns can be parsed as another part-of-speech, and on average each has 3.8 possible morphological interpretations.

We know of only one previous attempt in data-driven dependency parsing for Latin (Bamman and Crane, 2008), with the goal of constructing a dynamic lexicon for a digital library. Parsing is performed using the usual pipeline approach, first with the TreeTagger analyzer (Schmid, 1994) and then with a state-of-the-art dependency parser (McDonald et al., 2005). Head selection accuracy was 61.49%, and rose to 64.99% with oracle morphological tags. Of the nine morphological attributes, gender and especially case had the lowest accuracy. This observation echoes the findings for Czech (Smith et al., 2005), where case was also the most difficult to disambiguate.

Attribute	Values
Part-of-speech (POS)	noun, verb, participle, adjective, adverb, conjunction, preposition, pronoun, numeral, interjection, exclamation, punctuation
Person	first, second, third
Number	singular, plural
Tense	present, imperfect, perfect, pluperfect, future perfect, future
Mood	indicative, subjunctive, infinitive, imperative, participle, gerund, gerundive, supine
Voice	active, passive
Gender	masculine, feminine, neuter
Case	nominative, genitive, dative, accusative, ablative, vocative, locative
Degree	comparative, superlative

Table 2: Morphological attributes and values for Latin. Ancient Greek has the same attributes; Czech and Hungarian lack some of them. In all categories except POS, a value of *null* ('-') may also be assigned. For example, a noun has '-' for the tense attribute.

3 Joint Model

This section describes a model that jointly infers morphological and syntactic properties of a sentence. It will be presented as a graphical model, starting with the variables and then the factors, which represents constraints on the variables. Let n be the number of words and m be the number of possible values for a morphological attribute. The variables are:

- WORD: the n words w_1,...,w_n of the input sentence, all observed.
- TAG: $O(nm)$ boolean variables[3] $T_{a,i,v}$, corresponding to each value of the morphological attributes listed in Table 2. $T_{a,i,v} = true$ when the word w_i has value v as its morphological attribute a. In Figure 2, CASE$_{3,acc}$ is the shorthand representing the variable $T_{case,3,acc}$. It is set to $true$ since the word w_3 has the accusative case.
- LINK: $O(n^2)$ boolean variables $L_{i,j}$ corresponding to a possible link between each pair

[2]Except for enclitics such as *-que*, *-ve*, and *-ne*, but their segmentation is rather straightforward compared to Modern Hebrew or other Semitic languages.

[3]The TAG variables were actually implemented as multinomials, but are presented here as booleans for ease of understanding.

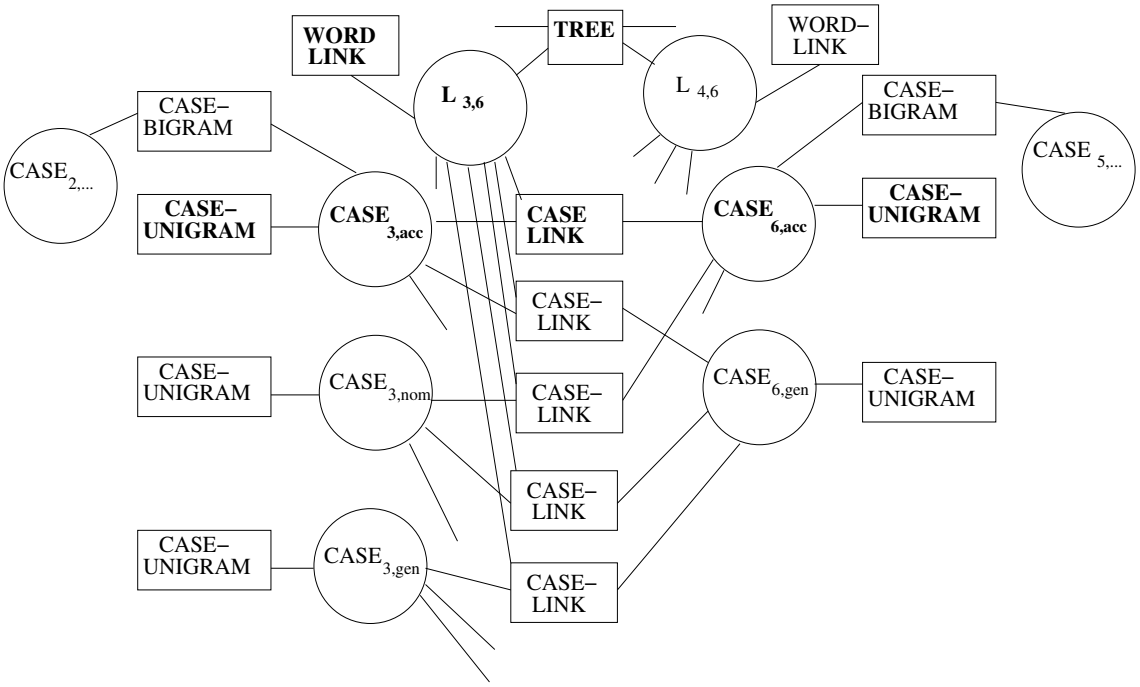

Figure 2: The joint model (§3) depicted as a graphical model. The variables, all boolean, are represented by circles and are bolded if their correct values are $true$. Factors are represented by rectangles and are bolded if they fire. For clarity, this graph shows only those variables and factors associated with one pair of words (i.e., w_3=*omnis* and w_6=*amantis*) and with one morphological attribute (i.e., case). The variables $L_{3,6}$, CASE$_{3,acc}$ and CASE$_{6,acc}$ are bolded, indicating that w_3 and w_6 are linked and both have the accusative case. The ternary factor CASE-LINK, that connects to these three variable, therefore fires.

of words[4]. $L_{i,j} = true$ when there is a dependency link from the word w_i to the word w_j. In Figure 2, the variable $L_{3,6}$ is set to $true$ since there is a dependency link between the words w_3 and w_6.

We define a probability distribution over all joint assignments $\mathcal{A}$ to the above variables,

$$p(\mathcal{A}) = \frac{1}{Z} \prod_k F_k(\mathcal{A}) \quad (1)$$

where Z is a normalizing constant. The assignment $\mathcal{A}$ is subject to a hard constraint, represented in Figure 2 as TREE, requiring that the values of the LINK variables must yield a tree, which may be non-projective. The factors $F_k(\mathcal{A})$ represent soft constraints evaluating various aspects of the "goodness" of the tree structure implied by $\mathcal{A}$. We say a factor "fires" when all its neighboring variables are $true$ and it evaluates to a non-negative real number; otherwise, it evaluates to 1 and has no effect on the product in equation (1). Soft constraints in the model are divided into **local** and **link** factors, to which we now turn.

3.1 Local Factors

The local factors consult either one word or two neighboring words, and their morphological attributes. These factors express the desirability of the assignments of morphological attributes based on local context. There are three types:

- TAG-UNIGRAM: There are $O(nm)$ such unary factors, each instance of which is connected to a TAG variable. The factor fires when $T_{a,i,v}$ is $true$. The features consist of the value v of the morphological attribute concerned, combined with the word identity of w_i, with backoff using all suffixes of the word. The CASE-UNIGRAM factors shown in Figure 2 are examples of this family of factors.

[4]Variables for link labels can be integrated in a straightforward manner, if desired.

- TAG-BIGRAM: There are $O(nm^2)$ of such binary factors, each connected to the TAG variables of a pair of neighboring words. The factor fires when T_{a,i,v_1} and $T_{a,i+1,v_2}$ are both $true$. The CASE-BIGRAM factors shown in Figure 2 are examples of this family of factors.

- TAG-CONSISTENCY: For each word, the TAG variables representing the possible POS values are connected to those representing the values of other morphological attributes, yielding $O(nm^2)$ binary factors. They fire when T_{pos,i,v_1} and T_{a,i,v_2} are both $true$. These factors are intended to discourage inconsistent assignments, such as a non-null tense for a noun.

It is clear that so far, none of these factors are aware of the morphological agreement between *omnis* and *amantis*, crucial for inferring their syntactic relation. We now turn our attention to link factors, which serve this purpose.

3.2 Link Factors

The link factors consult all pairs of words, possibly separated by a long distance, that may have a dependency link. These factors model the likelihood of such a link based on the word identities and their morphological attributes:

- WORD-LINK: There are $O(n^2)$ such unary factors, each connected to a LINK variable, as shown in Figure 2. The factor fires when $L_{i,j}$ is $true$. Features include various combinations of the word identities of the parent w_i and child w_j, and 5-letter prefixes of these words, replicating the so-called "basic features" used by McDonald et al. (2005).

- POS-LINK: There are $O(n^2m^2)$ such ternary factors, each connected to the variables $L_{i,j}$, T_{i,pos,v_i} and T_{j,pos,v_j}. It fires when all three are $true$ or, in other words, when the parent word w_i has POS v_i, and the child w_j has POS v_j. Features replicate all the so-called "basic features" used by McDonald et al. (2005) that involve POS. These factors are not shown in Figure 2, but would have exactly the same structure as the CASE-LINK factors.

  Beyond these basic features, McDonald et al. (2005) also utilize POS trigrams and POS 4-grams. Both include the POS of two linked words, w_i and w_j. The third component in the trigrams is the POS of each word w_k located between w_i and w_j, $i < k < j$. The two additional components that make up the 4-grams are subsets of the POS of words located to the immediate left and right of w_i and w_j.

  If fully implemented in our joint model, these features would necessitate two separate families of link factors: $O(n^3m^3)$ factors for the POS trigrams, and $O(n^2m^4)$ factors for the POS 4-grams. To avoid this substantial increase in model complexity, these features are instead approximated: the POS of all words involved in the trigrams and 4-grams, except those of w_i and w_j, are regarded as fixed, their values being taken from the output of a morphological tagger (§4.1), rather than connected to the appropriate TAG variables. This approximation allows these features to be incorporated in the POS-LINK factors.

- MORPH-LINK: There are $O(n^2m^2)$ such ternary factors, each connected to the variables $L_{i,j}$, T_{i,a,v_i} and T_{j,a,v_j}, for every attribute a other than POS. The factor fires when all three variables are $true$, and both v_i and v_j are non-null; i.e., it fires when the parent word w_i has v_i as its morphological attribute a, and the child w_j has v_j. Features include the combination of v_i and v_j themselves, and agreement between them. The CASE-LINK factors in Figure 2 are an example of this family of factors.

4 Baselines

To ensure a meaningful comparison with the joint model, our two baselines are both implemented in the same graphical model framework, and trained with the same machine-learning algorithm. Roughly speaking, they divide up the variables and factors of the joint model and train them separately. For morphological disambiguation, we use the baseline tagger described in §4.1. For dependency parsing, our baseline is a "pipeline" parser (§4.2) that infers syntax upon the output of the baseline tagger.

4.1 Baseline Morphological Tagger

The tagger is a graphical model with the WORD and TAG variables, connected by the local factors TAG-UNIGRAM, TAG-BIGRAM, and TAG-CONSISTENCY, all used in the joint model (§3).

4.2 Baseline Dependency Parser

The parser has no local factors, but has the same variables as the joint model and the same features from all three families of link factors (§3). However, since it takes as input the morphological attributes predicted by the tagger, the TAG variables are now observed. This leads to a change in the structure of the link factors — all features from the POS-LINK factors now belong to the WORD-LINK factors, since the POS of all words are observed. In short, the features of the parser are a replication of (McDonald et al., 2005), but also extended beyond POS to the other morphological attributes, with the features in the MORPH-LINK factors incorporated into WORD-LINK for similar reasons.

5 Experimental Set-up

5.1 Data

Our evaluation focused on the Latin Dependency Treebank (Bamman and Crane, 2006), created at the Perseus Digital Library by tailoring the Prague Dependency Treebank guidelines for the Latin language. It consists of excerpts from works by eight Latin authors. We randomly divided the 53K-word treebank into 10 folds of roughly equal sizes, with an average of 5314 words (347 sentences) per fold. We used one fold as the development set and performed cross-validation on the other nine.

To measure how well our model generalizes to other highly-inflected, relatively free-word-order languages, we considered Ancient Greek, Hungarian, and Czech. Their respective datasets consist of 8000 sentences from the Ancient Greek Dependency Treebank (Bamman et al., 2009), 5800 from the Hungarian Szeged Dependency Treebank (Vincze et al., 2010), and a subset of 3100 from the Prague Dependency Treebank (Böhmová et al., 2003).

5.2 Training

We define each factor in (1) as a log-linear function:

$$F_k(\mathcal{A}) = \exp \sum_h \theta_h f_h(\mathcal{A}, W, k) \qquad (2)$$

Given an assignment $\mathcal{A}$ and words W, f_h is an indicator function describing the presence or absence of the feature, and θ_h is the corresponding set of weights learned using stochastic gradient ascent, with the gradients inferred by loopy belief propagation (Smith and Eisner, 2008). The variance of the Gaussian prior is set to 1. The other two parameters in the training process, the number of belief propagation iterations and the number of training rounds, were tuned on the development set.

5.3 Decoding

The output of the joint model is the assignment to the TAG and LINK variables. Loopy belief propagation (BP) was used to calculate the posterior probabilities of these variables. For TAG, we emit the tag with the highest posterior probability as computed by sum-product BP. We produced head attachments by first calculating the posteriors of the LINK variables with BP and then passing them to an edge-factored tree decoder. This is equivalent to minimum Bayes risk decoding (Goodman, 1996), which is used by Cohen and Smith (2007) and Smith and Eisner (2008). This MBR decoding procedure enforces the hard constraint that the output be a tree but sums over possible morphological assignments.[5]

5.4 Reducing Model Complexity

In principle, the joint model should consider every possible combination of morphological attributes for every word. In practice, to reduce the complexity of the model, we used a pre-existing morphological database, MORPHEUS (Crane, 1991), to constrain the range of possible values of the attributes listed in Table 2; more precisely, we add a hard constraint, requiring that assignments to the TAG variables be compatible with MORPHEUS. This constraint significantly reduces the value of m in the big-O notation

[5] This approach to nuisance variables has also been used effectively for parsing with tree-substitution grammars, where several derived trees may correspond to each derivation tree, and parsing with PCFGs with latent annotations.

Model Attr. ↓	Tagger all	Joint all	Tagger non-null	Joint non-null
POS	94.4	94.5	94.4	94.5
Person	99.4	99.5	97.1	97.6
Number	95.3	95.9	93.7	94.5
Tense	98.0	98.2	93.2	93.9
Mood	98.1	98.3	93.8	94.4
Voice	98.5	98.6	95.3	95.7
Gender	93.1	93.9	87.7	89.1
Case	89.3	90.0	79.9	81.2
Degree	99.9	99.9	86.4	90.8
UAS	61.0	61.9	—	—

Table 3: **Latin** morphological disambiguation and parsing. For some attributes, such as degree, a substantial portion of words have the *null* value. The non-null columns provides a sharper picture by excluding these "easy" cases. Note that POS is never *null*.

for the number of variables and factors described in §3. To illustrate the effect, the graphical model of the sentence in Table 1, whose six words are all covered by the database, has 1,866 factors; without the benefit of the database, the full model would have 31,901 factors.

The MORPHEUS database was automatically generated from a list of stems, inflections, irregular forms and morphological rules. It covers about 99% of the distinct words in the Latin Dependency Treebank. At decoding time, for each fold, the database is further augmented with tags seen in training data. After this augmentation, an average of 44 words are "unseen" in each fold.

Similarly, we constructed morphological dictionaries for Czech, Ancient Greek, and Hungarian from words that occurred at least five times in the training data; words that occurred fewer times were unrestricted in the morphological attributes they could take on.

6 Experimental Results

We compare the performance of the pipeline model (§4) and the joint model (§3) on morphological disambiguation and unlabeled dependency parsing.

Model Attr. ↓	Tagger all	Joint all	Tagger non-null	Joint non-null
POS	95.5	95.7	95.5	95.7
Person	98.4	98.8	93.5	95.6
Number	91.2	92.3	87.0	88.4
Tense	98.4	98.8	92.7	96.1
Voice	98.5	98.7	93.2	95.8
Gender	86.6	87.9	75.6	78.0
Case	84.1	85.6	74.3	76.5
Degree	97.9	98.0	90.1	90.1
UAS	67.4	68.7	—	—

Table 4: **Czech** morphological disambiguation and parsing. As with Latin, the model is least accurate with noun/adjective categories of gender number, and case, particularly when considering only words whose true value is non-null for those attributes. Joint inference with syntactic features improves accuracy across the board.

Model Attr. ↓	Tagger all	Joint all	Tagger non-null	Joint non-null
POS	94.9	95.7	94.9	95.7
Person	98.7	99.0	92.2	94.6
Number	97.4	97.9	96.5	97.1
Tense	96.8	97.2	84.1	86.8
Mood	97.9	98.3	91.4	93.2
Voice	97.8	98.0	91.3	92.4
Gender	95.4	96.1	90.7	91.9
Case	95.9	96.3	92.0	92.6
Degree	99.8	99.9	33.3	55.6
UAS	68.0	70.5	—	—

Table 5: **Ancient Greek** morphological disambiguation and parsing. Noun/adjective morphology is more accurate, but verbal morphology is more problematic.

Model Attr. ↓	Tagger all	Joint all	Tagger non-null	Joint non-null
POS	95.8	95.8	95.8	95.8
Person	98.5	98.6	94.9	94.1
Number	97.4	97.5	96.8	96.6
Tense	98.9	99.3	97.2	97.3
Mood	98.7	99.2	95.8	97.3
Case	96.7	97.0	94.5	94.9
Degree	97.9	98.1	87.5	88.6
UAS	78.2	78.8	—	—

Table 6: **Hungarian** morphological disambiguation and parsing. The agglutinative morphological system makes local cues more effective, but syntactic information helps in almost all categories.

6.1 Morphological Disambiguation

As seen in Table 3, the joint model outperforms[6] the baseline tagger in all attributes in Latin morphological disambiguation. Among words not covered by the morphological database, accuracy in POS is slightly better, but lower for case, gender and number.

The joint model made the most gains on adjectives and participles. Both parts-of-speech are particularly ambiguous: according to MORPHEUS, 43% of the adjectives can be interpreted as another POS, most frequently nouns; while participles have an average of 5.5 morphological interpretations. Both also often have identical forms for different genders, numbers and cases. In these situations, syntactic considerations help nudge the joint model to the correct interpretations.

Experiments on the other three languages bear out similar results: the joint model improves morphological disambiguation. The performance of Czech (Table 4) exhibits the closest analogue to Latin: gender, number, and case are much less accurately predicted than are the other morphological attributes. Like Latin, Czech lacks definite and indefinite articles to provide high-confidence cues for noun phrase boundaries.

The Ancient Greek treebank comprises both archaic texts, before the development of a definite article, and later classic Greek, which has a definite article; Hungarian has both a definite and an indefinite article. In both languages (Tables 5 and 6), noun and adjective gender, number, and case are more accurately predicted than in Czech and Latin. The verbal system of ancient Greek, in contrast, is more complex than that of the other languages, so mood, voice, and tense accuracy are lower.

6.2 Dependency Parsing

In addition to morphological disambiguation, we also measured the performance of the joint model on dependency parsing of Latin and the other languages. The baseline pipeline parser (§4.2) yielded 61.00% head selection accuracy (i.e., unlabeled attachment score, UAS), outperformed[7] by the joint model at 61.88%. The joint model showed similar improvements in Ancient Greek, Hungarian, and Czech.

Wrong decisions made by the baseline tagger often misled the pipeline parser. For adjectives, the example shown in Table 1 and Figure 1 is a typical scenario, where an accusative adjective was tagged as nominative, and was then misanalyzed by the parser as modifying a verb (as a subject) rather than modifying an accusative noun. For participles modifying a noun, the wrong noun was often chosen based on inaccurate morphological information. In these cases, the joint model, entertaining all morphological possibilities, was able to find the combination of links and morphological analyses that are collectively more likely.

The accuracy figures of our baselines are comparable, but not identical, to their counterparts reported in (Bamman and Crane, 2008). The differences may partially be attributed to the different morphological tagger used, and the different learning algorithm, namely Margin Infused Relaxed Algorithm (MIRA) in (McDonald et al., 2005) rather than maximum likelihood. More importantly, the Latin Dependency Treebank has grown from about 30K at the time of the previous work to 53K at present, resulting in significantly different training and testing material.

Gold Pipeline Parser When given perfect morphological information, the Latin parser performs at 65.28% accuracy in head selection. Despite the oracle morphology, the head selection accuracy is still below other languages. This is hardly surprising, given the relatively small training set, and that the "the most difficult languages are those that combine a relatively free word order with a high degree of inflection", as observed at the recent dependency parsing shared task (Nivre et al., 2007); both of these are characteristics of Latin.

A particularly troublesome structure is coordination; the most frequent link errors all involve either a parent or a child as a conjunction. In a list of words, all words and coordinators depend on the final coordinator. Since the factors in our model consult only one link at a time, they do not sufficiently capture this kind of structures. Higher-order features, particularly those concerned with links with grandparents and siblings, have been shown to benefit dependency

[6] The differences are statistically significant in all ($p < 0.01$ by McNemar's Test) but POS ($p = 0.5$).

[7] Significant at $p < e^{-11}$ by McNemar's Test.

parsing (Smith and Eisner, 2008) and may be able to address this issue.

7 Conclusions and Future Work

We have proposed a discriminative model that jointly infers morphological properties and syntactic structures. In evaluations on various highly-inflected languages, this joint model outperforms both a baseline tagger in morphological disambiguation, and a pipeline parser in head selection.

This model may be refined by incorporating richer features and improved decoding. In particular, we would like to experiment with higher-order features (§6), and with maximum *a posteriori* decoding, via max-product BP or (relaxed) integer linear programming. Further evaluation on other morphological systems would also be desirable.

Abstract

This paper describes an unsupervised dynamic graphical model for morphological segmentation and bilingual morpheme alignment for statistical machine translation. The model extends Hidden Semi-Markov chain models by using factored output nodes and special structures for its conditional probability distributions. It relies on morpho-syntactic and lexical source-side information (part-of-speech, morphological segmentation) while learning a morpheme segmentation over the target language. Our model outperforms a competitive word alignment system in alignment quality. Used in a monolingual morphological segmentation setting it substantially improves accuracy over previous state-of-the-art models on three Arabic and Hebrew datasets.

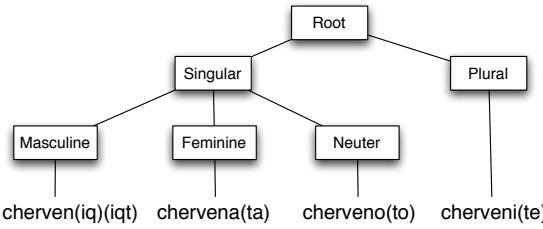
1 Introduction

An enduring problem in statistical machine translation is sparsity. The word alignment models of modern MT systems attempt to capture $p(e_i|f_j)$, the probability that token e_i is a translation of f_j. Underlying these models is the assumption that the word-based tokenization of each sentence is, if not optimal, at least appropriate for specifying a conceptual mapping between the two languages.

However, when translating between unrelated languages – a common task – disparate morphological systems can place an asymmetric conceptual burden on words, making the lexicon of one language much more coarse. This intensifies the problem of sparsity as the large number of word forms created through morphologically productive processes hinders attempts to find concise mappings between concepts.

For instance, Bulgarian adjectives may contain markings for gender, number, and definiteness. The following tree illustrates nine realized forms of the Bulgarian word for *red*, with each leaf listing the definite and indefinite markings.

Table 1: Bulgarian forms of *red*



Contrast this with English, in which this information is marked either on the modified word or by separate function words.

In comparison to a language which isn't morphologically productive on adjectives, the alignment model must observe nine times as much data (assuming uniform distribution of the inflected forms) to yield a comparable statistic. In an area of research where the amount of data available plays a large role in a system's overall performance, this sparsity can be extremely problematic. Further complications are created when lexical sparsity is compounded with the desire to build up alignments over increasingly larger contiguous phrases.

To address this issue we propose an alternative to word alignment: *morpheme alignment*, an alignment that operates over the smallest meaningful subsequences of words. By striving to keep a direct 1-to-1 mapping between corresponding semantic units across languages, we hope to find better estimates

Portland, Oregon, June 19-24, 2011.

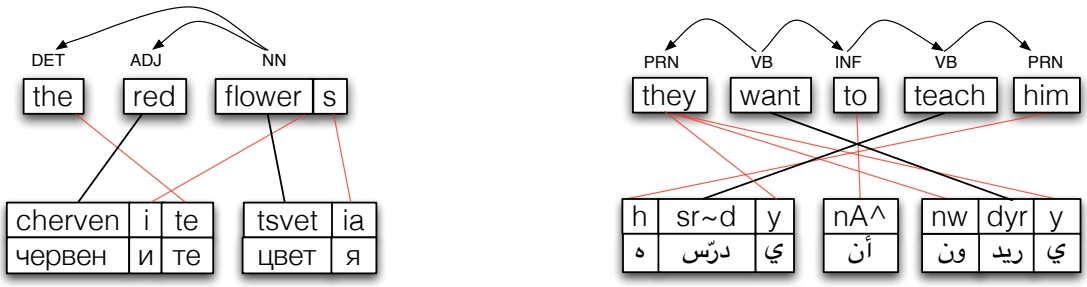

Figure 1: A depiction of morpheme-level alignment. Here dark lines indicate the more stem-focused alignment strategy of a traditional word or phrasal alignment model, while thin lines indicate a more fine-grained alignment across morphemes. In the alignment between English and Bulgarian (a) the morpheme-specific alignment reduces sparsity in the adjective and noun (*red flowers*) by isolating the stems from their inflected forms. Despite Arabic exhibiting templatic morphology, there are still phenomena which can be accounted for with a simpler segmentational approach. The Arabic alignment (b) demonstrates how the plural marker on English *they* would normally create sparsity by being marked in three additional places, two of them inflections in larger wordforms.

for the alignment statistics. Our results show that this improves alignment quality.

In the following sections we describe an unsupervised dynamic graphical model approach to monolingual morphological segmentation and bilingual morpheme alignment using a linguistically motivated statistical model. In a bilingual setting, the model relies on morpho-syntactic and lexical source-side information (part-of-speech, morphological segmentation, dependency analysis) while learning a morpheme segmentation over the target language. In a monolingual setting we introduce effective use of context by feature-rich modeling of the probabilities of morphemes, morpheme-transitions, and word boundaries. These additional sources of information provide powerful bias for unsupervised learning, without increasing the asymptotic running time of the inference algorithm.

Used as a monolingual model, our system significantly improves the state-of-the-art segmentation performance on three Arabic and Hebrew datasets. Used as a bilingual model, our system outperforms the state-of-the-art WDHMM (He, 2007) word alignment model as measured by alignment error rate (AER).

In agreement with some previous work on tokenization/morpheme segmentation for alignment (Chung and Gildea, 2009; Habash and Sadat, 2006), we find that the best segmentation for alignment does not coincide with the gold-standard segmentation and our bilingual model does not outperform our monolingual model in segmentation F-Measure.

2 Model

Our model defines the probability of a target language sequence of words (each consisting of a sequence of morphemes), and alignment from target to source morphemes, given a source language sequence of words (each consisting of a sequence of morphemes).

An example morpheme segmentation and alignment of phrases in English-Arabic and English-Bulgarian is shown in Figure 1. In our task setting, the words of the source and target language as well as the morpheme segmentation of the source (English) language are given. The morpheme segmentation of the target language and the alignments between source and target morphemes are hidden.

The source-side input, which we assume to be English, is processed with a gold morphological segmentation, part-of-speech, and dependency tree analysis. While these tools are unavailable in resource-poor languages, they are often available for at least one of the modeled languages in common translation tasks. This additional information then provides a source of features and conditioning information for the translation model.

Our model is derived from the hidden-markov model for word alignment (Vogel et al., 1996; Och and Ney, 2000). Based on it, we define a dynamic

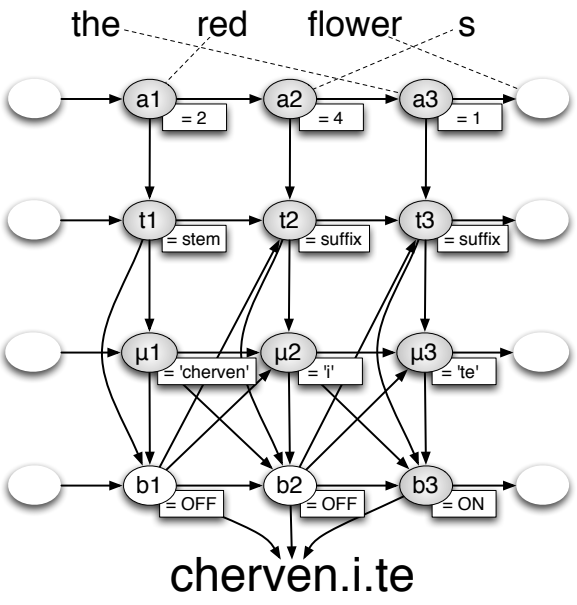

Figure 2: A graphical depiction of the model generating the transliteration of the first Bulgarian word from Figure 1. Trigram dependencies and some incoming/outgoing arcs have been omitted for clarity.

graphical model which lets us encode more linguistic intuition about morpheme segmentation and alignment: (*i*) we extend it to a hidden semi-markov model to account for hidden target morpheme segmentation; (*ii*) we introduce an additional observation layer to model observed word boundaries and thus truly represent target sentences as words composed of morphemes, instead of just a sequence of tokens; (*iii*) we employ hierarchically smoothed models and log-linear models to capture broader context and to better represent the morpho-syntactic mapping between source and target languages. (*iv*) we enrich the hidden state space of the model to encode morpheme types {prefix,suffix,stem}, in addition to morpheme alignment and segmentation information.

Before defining our model formally, we introduce some notation. Each possible morphological segmentation and alignment for a given sentence pair can be described by the following random variables:

Let $\mu_1\mu_2 \ldots \mu_I$ denote I morphemes in the segmentation of the target sentence. For the Example in Figure 1 (a) I=5 and μ_1=*cherven*, μ_2=*i* $\ldots$, and μ_5=*ia*. Let $b_1, b_2, \ldots b_I$ denote Bernoulli variables indicating whether there is a word boundary after morpheme μ_i. For our example, $b_3 = 1$, $b_5 = 1$, and the other b_i are 0. Let $c_1, c_2, \ldots, c_T$ denote the non-space characters in the target string, and $wb_1, \ldots, wb_T$ denote Bernoulli variables indicating whether there is a word boundary after the corresponding target character. For our example, $T = 14$ (for the Cyrillic version) and the only wb variables that are on are wb_9 and wb_{14}. The c and wb variables are observed. Let $s_1 s_2 \ldots s_T$ denote Bernoulli segmentation variables indicating whether there is a morpheme boundary after the corresponding character. The values of the hidden segmentation variables s together with the values of the observed c and wb variables uniquely define the values of the morpheme variables μ_i and the word boundary variables b_i. Naturally we enforce the constraint that a given word boundary $wb_t = 1$ entails a segmentation boundary $s_t = 1$. If we use bold letters to indicate a vector of corresponding variables, we have that $\mathbf{c}, \mathbf{wb}, \mathbf{s}{=}\boldsymbol{\mu}, \mathbf{b}$. We will define the assumed parametric form of the learned distribution using the $\boldsymbol{\mu}, \mathbf{b}$ but the inference algorithms are implemented in terms of the $\mathbf{s}$ and $\mathbf{wb}$ variables.

We denote the observed source language morphemes by $e_1 \ldots e_J$. Our model makes use of additional information from the source which we will mention when necessary.

The last part of the hidden model state represents the alignment between target and source morphemes and the type of target morphemes. Let $ta_i = [a_i, t_i]$, $i = 1 \ldots I$ indicate a factored state where a_i represents one of the J source words (or NULL) and t_i represents one of the three morpheme types {prefix,suffix,stem}. a_i is the source morpheme aligned to μ_i and t_i is the type of μ_i.

We are finally ready to define the desired probability of target morphemes, morpheme types, alignments, and word boundaries given source:

$$P(\boldsymbol{\mu}, \mathbf{ta}, \mathbf{b}|\mathbf{e}) = \prod_{i=1}^{I} P_T(\mu_i|ta_i, b_{i-1}, b_{i-2}, \mu_{i-1}, \mathbf{e}) \cdot P_B(b_i|\mu_i, \mu_{i-1}, ta_i, b_{i-1}, b_{i-2}, \mathbf{e}) \cdot P_D(ta_i|ta_{i-1}, b_{i-1}, \mathbf{e}) \cdot LP(|\mu_i|)$$

We now describe each of the factors used by our model in more detail. The formulation makes explicit the full extent of dependencies we have explored in this work. By simplifying the factors

we can recover several previously used models for monolingual segmentation and bilingual joint segmentation and alignment. We discuss the relationship of this model to prior work and study the impact of the novel components in our experiments.

When the source sentence is assumed to be empty (and thus contains no morphemes to align to) our model turns into a monolingual morpheme segmentation model, which we show exceeds the performance of previous state-of-the-art models. When we remove the word boundary component, reduce the order of the alignment transition, omit the morphological type component of the state space, and retain only minimal dependencies in the morpheme translation model, we recover the joint tokenization and alignment model based on IBM Model-1 proposed by (Chung and Gildea, 2009).

2.1 Morpheme Translation Model

In the model equation, P_T denotes the morpheme translation probability. The standard dependence on the aligned source morpheme is represented as a dependence on the state ta_i and the whole annotated source sentence $\mathbf{e}$. We experimented with multiple options for the amount of conditioning context to be included. When most context is used, there is a bigram dependency of target language morphemes as well as dependence on two previous boundary variables and dependence on the aligned source morpheme e_{a_i} as well as its POS tag.

When multiple conditioning variables are used we assume a special linearly interpolated backoff form of the model, similar to models routinely used in language modeling.

As an example, suppose we estimate the morpheme translation probability as $P_T(\mu_i|e_{a_i}, t_i)$. We estimate this in the M-step, given expected joint counts $c(\mu_i, e_{a_i}, t_i)$ and marginal counts derived from these as follows:

$P_T(\mu_i|e_{a_i}, t_i) = \frac{c(\mu_i, e_{a_i}, t_i) + \alpha_2 P_2(\mu_i|t_i)}{c(e_{a_i}, t_i) + \alpha_2}$

The lower order distributions are estimated recursively in a similar way:

$P_2(\mu_i|t_i) = \frac{c(\mu_i, t_i) + \alpha_1 P_1(\mu_i)}{c(t_i) + \alpha_1}$

$P_1(\mu_i) = \frac{c(\mu_i) + \alpha_0 P_0(\mu_i)}{c(.) + \alpha_0}$

For P_0 we used a unigram character language model. This hierarchical smoothing can be seen as an approximation to hierarchical Dirichlet priors with maximum aposteriori estimation.

Note how our explicit treatment of word boundary variables b_i allows us to use a higher order dependence on these variables. If word boundaries are treated as morphemes on their own, we would need to have a four-gram model on target morphemes to represent this dependency which we are now representing using only a bigram model on hidden morphemes.

2.2 Word Boundary Generation Model

The P_B distribution denotes the probability of generating word boundaries. As a sequence model of sentences the basic hidden semi-markov model completely ignores word boundaries. However, they can be powerful predictors of morpheme segments (by for example, indicating that common prefixes follow word boundaries, or that common suffixes precede them). The log-linear model of (Poon et al., 2009) uses word boundaries as observed left and right context features, and Morfessor (Creutz and Lagus, 2007) includes boundaries as special boundary symbols which can inform about the morpheme state of a morpheme (but not its identity).

Our model includes a special generative process for boundaries which is conditioned not only on the previous morpheme state but also the previous two morphemes and other boundaries. Due to the fact that boundaries are observed their inclusion in the model does not increase the complexity of inference.

The inclusion of this distribution lets us estimate the likelihood of a word consisting of one,two,three, or more morphemes. It also allows the estimation of likelihood that particular morphemes are in the beginning/middle/end of words. Through the included factored state variable ta_i word boundaries can also inform about the likelihood of a morpheme aligned to a source word of a particular pos tag to end a word. We discuss the particular conditioning context for this distribution we found most helpful in our experiments.

Similarly to the P_T distribution, we make use of multiple context vectors by hierarchical smoothing of distributions of different granularities.

2.3 Distortion Model

P_D indicates the distortion modeling distribution we use. [1] Traditional distortion models represent $P(a_j|a_{j-1}, \mathbf{e})$, the probability of an alignment given the previous alignment, to bias the model away from placing large distances between the aligned tokens of consecutively sequenced tokens. In addition to modeling a larger state space to also predict morpheme types, we extend this model by using a special log-linear model form which allows the integration of rich morpho-syntactic context. Log-linear models have been previously used in unsupervised learning for local multinomial distributions like this one in e.g. (Berg-Kirkpatrick et al., 2010), and for global distributions in (Poon et al., 2009).

The special log-linear form allows the inclusion of features targeted at learning the transitions among morpheme types and the transitions between corresponding source morphemes. The set of features with example values for this model is depicted in Table 3. The example is focussed on the features firing for the transition from the Bulgarian suffix *te* aligned to the first English morpheme $\mu_{i-1} = te$, t_{i-1}=suffix, a_{i-1}=1, to the Bulgarian root *tsvet* aligned to the third English morpheme $\mu_i = tsvet$, t_i=root, a_i=3. The first feature is the absolute difference between a_i and $a_{i-1} + 1$ and is similar to information used in other HMM word alignment models (Och and Ney, 2000) as well as phrase-translation models (Koehn, 2004). The alignment positions a_i are defined as indices of the aligned source morphemes. We additionally compute distortion in terms of distance in number of source words that are skipped. This distance corresponds to the feature name WORD DISTANCE. Looking at both kinds of distance is useful to capture the intuition that consecutive morphemes in the same target word should prefer to have a higher proximity of their aligned source words, as compared to consecutive morphemes which are not part of the same target word. The binned distances look at the sign of the distortion and bin the jumps into 5 bins, pooling the distances greater than 2 together. The feature SAME TARGET WORD indicates whether the two consecutive morphemes are part of the same word. In this case, they are not. This feature is not useful on its own because it does not distinguish between different alignment possibilities for ta_i, but is useful in conjunction with other features to differentiate the transition behaviors within and across target words. The DEP RELATION feature indicates the direct dependency relation between the source words containing the aligned source morphemes, if such relationship exists. We also represent alignments to null and have one null for each source word, similarly to (Och and Ney, 2000) and have a feature to indicate null. Additionally, we make use of several feature conjunctions involving the null, same target word, and distance features.

Feature	Value
MORPH DISTANCE	*1*
WORD DISTANCE	*1*
BINNED MORPH DISTANCE	*fore1*
BINNED WORD DISTANCE	*fore1*
MORPH STATE TRANSITION	suffix-root
SAME TARGET WORD	*False*

DEP RELATION	*DET←NN*
NULL ALIGNMENT	*False*
conjunctions	...

Figure 3: Features in log-linear distortion model firing for the transition from *te*:suffix:1 to *tsvet*:root:3 in the example sentence pair in Figure 1a.

2.4 Length Penalty

Following (Chung and Gildea, 2009) and (Liang and Klein, 2009) we use an exponential length penalty on morpheme lengths to bias the model away from the maximum likelihood under-segmentation solution. The form of the penalty is:

$LP(|\mu_i|) = \frac{1}{e^{|\mu_i|^{lp}}}$

Here lp is a hyper-parameter indicating the power that the morpheme length is raised to. We fit this parameter using an annotated development set, to optimize morpheme-segmentation F1. The model is extremely sensitive to this value and performs quite poorly if such penalty is not used.

2.5 Inference

We perform inference by EM training on the aligned sentence pairs. In the E-step we compute expected

[1] To reduce complexity of exposition we have omitted the final transition to a special state beyond the source sentence end after the last target morpheme.

counts of all hidden variable configurations that are relevant for our model. In the M-step we re-estimate the model parameters (using LBFGS in the M-step for the distortion model and using count interpolation for the translation and word-boundary models).

The computation of expectations in the E-step is of the same order as an order two semi-markov chain model using hidden state labels of cardinality ($J \times 3$ = number of source morphemes times number of target morpheme types). The running time of the forward and backward dynamic programming passes is $T \times l^2 \times (3J)^2$, where T is the length of the target sentence in characters, J is the number of source morphemes, and l is the maximum morpheme length. Space does not permit the complete listing of the dynamic programming solution but it is not hard to derive by starting from the dynamic program for the IBM-1 like tokenization model of (Chung and Gildea, 2009) and extending it to account for the higher order on morphemes and the factored alignment state space.

Even though the inference algorithm is low polynomial it is still much more expensive than the inference for an HMM model for word-alignment without segmentation. To reduce the running time of the model we limit the space of considered morpheme boundaries as follows:

Given the target side of the corpus, we derive a list of K most frequent prefixes and suffixes using a simple trie-based method proposed by (Schone and Jurafsky, 2000).[2] After we determine a list of allowed prefixes and suffixes we restrict our model to allow only segmentations of the form : ((*p**)*r*(*s**))+ where *p* and *s* belong to the allowed prefixes and suffixes and *r* can match any substring.

We determine the number of prefixes and suffixes to consider using the maximum recall achievable by limiting the segmentation points in this way. Restricting the allowable segmentations in this way not only improves the speed of inference but also leads to improvements in segmentation accuracy.

[2]Words are inserted into a trie with each complete branch naturally identifying a potential suffix, inclusive of its sub-branches. The list comprises of the K most frequent of these complete branches. Inserting the reversed words will then yield potential *prefixes*.

3 Evaluation

For a majority of our testing we borrow the parallel phrases corpus used in previous work (Snyder and Barzilay, 2008), which we refer to as S&B. The corpus consists of 6,139 short phrases drawn from English, Hebrew, and Arabic translations of the Bible. We use an unmodified version of this corpus for the purpose of comparing morphological segmentation accuracy. For evaluating morpheme alignment accuracy, we have also augmented the English/Arabic subset of the corpus with a gold standard alignment between morphemes. Here morphological segmentations were obtained using the previously-annotated gold standard Arabic morphological segmentation, while the English was preprocessed with a morphological analyzer and then further hand annotated with corrections by two native speakers. Morphological alignments were manually annotated. Additionally, we evaluate monolingual segmentation models on the full Arabic Treebank (ATB), also used for unsupervised morpheme segmentation in (Poon et al., 2009).

4 Results

4.1 Morpheme Segmentation

We begin by evaluating a series of models which are simplifications of our complete model, to assess the impact of individual modeling decisions. We focus first on a monolingual setting, where the source sentence aligned to each target sentence is empty.

Unigram Model with Length Penalty

The first model we study is the unigram monolingual segmentation model using an exponential length penalty as proposed by (Liang and Klein, 2009; Chung and Gildea, 2009), which has been shown to be quite accurate. We refer to this model as Model-UP (for unigram with penalty). It defines the probability of a target morpheme sequence as follows: $(\mu_1 \dots \mu_I) = (1-\theta) \prod_{i=1}^{I} \theta P_T(\mu_i) LP(|\mu_i|)$

This model can be (almost) recovered as a special case of our full model, if we drop the transition and word boundary probabilities, do not model morpheme types, and use no conditioning for the morpheme translation model. The only parameter not present in our model is the probability θ of generating a morpheme as opposed to stopping to gener-

ate morphemes (with probability $1 - \theta$). We experimented with this additional parameter, but found it had no significant impact on performance, and so we do not report results including it.

We select the value of the length penalty power by a gird search in the range 1.1 to 2.0, using .1 increments and choosing the values resulting in best performance on a development set containing 500 phrase pairs for each language. We also select the optimal number of prefixes/suffixes to consider by measuring performance on the development set. [3]

Morpheme Type Models

The next model we consider is similar to the unigram model with penalty, but introduces the use of the hidden ta states which indicate only morpheme types in the monolingual setting. We use the ta states and test different configurations to derive the best set of features that can be used in the distortion model utilizing these states, and the morpheme translation model. We consider two variants: (1) Model-HMMP-basic (for HMM model with length penalty), which includes the hidden states but uses them with a simple uniform transition matrix $P(ta_i|ta_{i-1}, b_{i-1})$ (uniform over allowable transitions but forbidding the prefixes from transitioning directly to suffixes, and preventing suffixes from immediately following a word boundary), and (2) a richer model Model-HMMP which is allowed to learn a log-linear distortion model and a feature rich translation model as detailed in the model definition. This model is allowed to use word boundary information for conditioning (because word boundaries are observed), but does not include the P_B predictive word boundary distribution.

Full Model with Word Boundaries

Finally we consider our full monolingual model which also includes the distribution predicting word boundary variables b_i. We term this model Model-FullMono. We detail the best context features for the conditional P_D distribution for each language. We initialize this model with the morpheme translation unigram distribution of ModelHMMP-basic, trained for 5 iterations.

Table 4 details the test set results of the different model configurations, as well as previously reported results on these datasets. For our main results we use the automatically derived list of prefixes and suffixes to limit segmentation points. The names of models that use such limited lists are prefixed by Dict in the Table. For comparison, we also report the results achieved by models that do not limit the segmentation points in this way.

As we can see the unigram model with penalty, Dict-Model-UP, is already very strong, especially on the S&B Arabic dataset. When the segmentation points are not limited, its performance is much worse. The introduction of hidden morpheme states in Dict-HMMP-basic gives substantial improvement on Arabic and does not change results much on the other datasets. A small improvement is observed for the unconstrained models.[4] When our model includes all components except word boundary prediction, Dict-Model-HMMP, the results are substantially improved on all languages. Model-HMMP is also the first unconstrained model in our sequence to approach or surpass previous state-of-the-art segmentation performance.

Finally, when the full model Dict-MonoFull is used, we achieve a substantial improvement over the previous state-of-the-art results on all three corpora, a 6.5 point improvement on Arabic, 6.2 point improvement on Hebrew, and a 9.3 point improvement on ATB. The best configuration of this model uses the same distortion model for all languages: using the morph state transition and boundary features. The translation models used only t_i for Hebrew and ATB and t_i and μ_{i-1} for Arabic. Word boundary was predicted using t_i in Arabic and Hebrew, and additionally using b_{i-1} and b_{i-2} for ATB. The unconstrained models without affix dictionaries are also very strong, outperforming previous state-of-the-art models. For ATB, the unconstrained model slightly outperforms the constrained one.

The segmentation errors made by this system shed light on how it might be improved. We find the dis-

[3] For the S&B Arabic dataset, we selected to use seven prefixes and seven suffixes, which correspond to maximum achievable recall of 95.3. For the S&B Hebrew dataset, we used six prefixes and six suffixes, for a maximum recall of 94.3. The Arabic treebank data required a larger number of affixes: we used seven prefixes and 20 suffixes, for a maximum recall of 98.3.

[4] Note that the inclusion of states in HMMP-basic only serves to provide a different distribution over the number of morphemes in a word, so it is interesting it can have a positive impact.

	Arabic			Hebrew			ATB		
	P	R	F1	P	R	F1	P	R	F1

S&B-Best	67.8	77.3	72.2	64.9	62.9	63.9	–	–	–
Morfessor	71.1	60.5	65.4	65.4	57.7	61.3	77.4	72.6	74.9

Figure 4: Results on morphological segmentation achieved by monolingual variants of our model (top) with results from prior work are included for comparison (bottom). Results from models with a small, automatically-derived list of possible prefixes and suffixes are labeled as "Dict-" followed by the model name.

tributions over the frequencies of particular errors follow a Zipfian skew across both S&B datasets, with the Arabic being more pronounced (the most frequent error being made 27 times, with 627 errors being made just once) in comparison with the Hebrew (with the most frequent error being made 19 times, and with 856 isolated errors). However, in both the Arabic and Hebrew S&B tasks we find that a tendency to over-segment certain characters off of their correct morphemes and on to other frequently occurring, yet incorrect, particles is actually the cause of many of these isolated errors. In Arabic the system tends to over segment the character *aleph* (totally about 300 errors combined). In Hebrew the source of error is not as overwhelmingly directed at a single character, but *yod* and *he*, the latter functioning quite similarly to the problematic Arabic character and frequently turn up in the corresponding places of cognate words in Biblical texts.

We should note that our models select a large number of hyper-parameters on an annotated development set, including length penalty, hierarchical smoothing parameters α, and the subset of variables to use in each of three component sub-models. This might in part explain their advantage over previous-state-of-the-art models, which might use fewer (e.g. (Poon et al., 2009) and (Snyder and Barzilay, 2008)) or no specifically tuned for these datasets hyper-parameters (Morfessor (Creutz and Lagus, 2007)).

4.2 Alignment

Next we evaluate our full bilingual model and a simpler variant on the task of word alignment. We use the morpheme-level annotation of the S&B English-Arabic dataset and project the morpheme alignments to word alignments. We can thus compare alignment performance of the results of different segmentations. Additionally, we evaluate against a state-of-the-art word alignment system WDHMM (He, 2007), which performs comparably or better than IBM-Model4. The table in Figure 5 presents the results. In addition to reporting alignment error rate for different segmentation models, we report their morphological segmentation F1.

The word-alignment WDHMM model performs best when aligning English words to Arabic words (using Arabic as source). In this direction it is able to capture the many-to-one correspondence between English words and arabic morphemes. When we combine alignments in both directions using the standard grow-diag-final method, the error goes up.

We compare the (Chung and Gildea, 2009) model (termed Model-1) to our full bilingual model. We can recover Model-1 similarly to Model-UP, except now every morpheme is conditioned on an aligned source morpheme. Our full bilingual model outperforms Model-1 in both AER and segmentation F1. The specific form of the full model was selected as in the previous experiments, by choosing the model with best segmentations of the development set.

For Arabic, the best model conditions target mor-

	Arabic						Hebrew		
	Align P	Align R	AER	P	R	F1	P	R	F1
Model-1 (C&G 09)	91.6	81.2	13.9	72.4	76.2	74.3	61.0	71.8	65.9
Bilingual full	91.0	88.3	10.3	90.0	72.0	80.0	63.3	71.2	67.0
WDHMM E-to-A	82.4	96.7	11.1						
WDHMM GDF	82.1	94.6	12.1						

Figure 5: Alignment Error Rate (AER) and morphological segmentation F1 achieved by bilingual variants of our model. AER performance of WDHMM is also reported. Gold standard alignments are not available for the Hebrew data set.

phemes on source morphemes only, uses the boundary model with conditioning on number of morphemes in the word, aligned source part-of-speech, and type of target morpheme. The distortion model uses both morpheme and word-based absolute distortion, binned distortion, morpheme types of states, and aligned source-part-of-speech tags. Our best model for Arabic outperforms WDHMM in word alignment error rate. For Hebrew, the best model uses a similar boundary model configuration but a simpler uniform transition distortion distribution.

Note that the bilingual models perform worse than the monolingual ones in segmentation F1. This finding is in line with previous work showing that the best segmentation for MT does not necessarily agree with a particular linguistic convention about what morphemes should contain (Chung and Gildea, 2009; Habash and Sadat, 2006), but contradicts other results (Snyder and Barzilay, 2008). Further experimentation is required to make a general claim.

We should note that the Arabic dataset used for word-alignment evaluation is unconventionally small and noisy (the sentences are very short phrases, automatically extracted using GIZA++). Thus the phrases might not be really translations, and the sentence length is much smaller than in standard parallel corpora. This warrants further model evaluation in a large-scale alignment setting.

5 Related Work

This work is most closely related to the unsupervised tokenization and alignment models of Chung and Gildea (2009), Xu et al. (2008), Snyder and Barzilay (2008), and Nguyen et al. (2010).

Chung & Gildea (2009) introduce a unigram model of tokenization based on IBM Model-1,which is a special case of our model. Snyder and Barzilay (2008) proposes a hierarchical Bayesian model that combines the learning of monolingual segmentations and a cross-lingual alignment; their model is very different from ours.

Incorporating morphological information into MT has received reasonable attention. For example, Goldwater & McClosky (2005) show improvements when preprocessing Czech input to reflect a morphological decomposition using combinations of lemmatization, pseudowords, and morphemes. Yeniterzi and Oflazer (2010) bridge the morphological disparity between languages in a unique way by effectively aligning English syntactic elements (function words connected by dependency relations) to Turkish morphemes, using rule-based postprocessing of standard word alignment. Our work is partly inspired by that work and attempts to automate both the morpho-syntactic alignment and morphological analysis tasks.

6 Conclusion

We have described an unsupervised model for morpheme segmentation and alignment based on Hidden Semi-Markov Models. Our model makes use of linguistic information to improve alignment quality. On the task of monolingual morphological segmentation it produces a new state-of-the-art level on three datasets. The model shows quantitative improvements in both word segmentation and word alignment, but its true potential lies in its finer-grained interpretation of word alignment, which will hopefully yield improvements in translation quality.

Abstract

Spelling correction for keyword-search queries is challenging in restricted domains such as personal email (or desktop) search, due to the scarcity of query logs, and due to the specialized nature of the domain. For that task, this paper presents an algorithm that is based on statistics from the corpus data (rather than the query log). This algorithm, which employs a simple graph-based approach, can incorporate different types of data sources with different levels of reliability (e.g., email subject vs. email body), and can handle complex spelling errors like splitting and merging of words. An experimental study shows the superiority of the algorithm over existing alternatives in the email domain.

1 Introduction

An abundance of applications require *spelling correction*, which (at the high level) is the following task. The user intends to type a chunk $\mathbf{q}$ of text, but types instead the chunk $\mathbf{s}$ that contains *spelling errors* (which we discuss in detail later), due to uncareful typing or lack of knowledge of the exact spelling of $\mathbf{q}$. The goal is to restore $\mathbf{q}$, when given $\mathbf{s}$. Spelling correction has been extensively studied in the literature, and we refer the reader to comprehensive summaries of prior work (Peterson, 1980; Kukich, 1992; Jurafsky and Martin, 2000; Mitton, 2010). The focus of this paper is on the special case where $\mathbf{q}$ is a *search query*, and where $\mathbf{s}$ instead of $\mathbf{q}$ is submitted to a search engine (with the goal of retrieving documents that match the search query $\mathbf{q}$). Spelling correction for search queries is important, because a significant portion of posed queries may be misspelled (Cucerzan and Brill, 2004). Effective spelling correction has a major effect on the experience and effort of the user, who is otherwise required to ensure the exact spellings of her queries. Furthermore, it is critical when the exact spelling is unknown (e.g., person names like *Schwarzenegger*).

1.1 Spelling Errors

The more common and studied type of spelling error is *word-to-word* error: a single word w is misspelled into another single word w'. The specific spelling errors involved include omission of a character (e.g., `atachment`), inclusion of a redundant character (e.g., `attachement`), and replacement of characters (e.g., `attachemnt`). The fact that w' is a misspelling of (and should be corrected to) w is denoted by $w' \rightarrow w$ (e.g., `atachment` $\rightarrow$ `attachment`).

Additional common spelling errors are *splitting* of a word, and *merging* two (or more) words:

- `attach ment` $\rightarrow$ `attachment`
- `emailattachment` $\rightarrow$ `email attachment`

Part of our experiments, as well as most of our examples, are from the domain of (personal) email search. An email from the *Enron email collection* (Klimt and Yang, 2004) is shown in Figure 1. Our running example is the following misspelling of a search query, involving multiple types of errors.

`sadeep kohli excellatach ment` $\rightarrow$
`sandeep kohli excel attachment` (1)

In this example, correction entails fixing `sadeep`, splitting `excellatach`, fixing `excell`, merging `atach ment`, and fixing `atachment`. Beyond the complexity of errors, this example also illustrates other challenges in spelling correction for search. We need to identify not only that `sadeep` is misspelled, but also that `kohli` is correctly spelled. Just having `kohli` in a dictionary is not enough.

Vince/Stinson,

Please find below two attachemnts. The Excell spreadsheet shows some calculations... The seond attachement (Word) has the wordings that I think we can send in to the press...

I am availabel on mobile if you have questions o clarifications...

Regards,
Sandeep.

Figure 1: Enron email (misspelled words are underlined)

For example, in `kohli coupons` the user may very well mean `kohls coupons` if Sandeep Kohli has nothing to do with coupons (in contrast to the store chain Kohl's). A similar example is the word `nail`, which is a legitimate English word, but in the context of email the query `nail box` is likely to be a misspelling of `mail box` (unless nail boxes are indeed relevant to the user's email collection). Finally, while the word `kohli` is relevant to some email users (e.g., Kohli's colleagues), it may have no meaning at all to other users.

1.2 Domain Knowledge

The common approach to spelling correction utilizes statistical information (Kernighan et al., 1990; Schierle et al., 2007; Mitton, 2010). As a simple example, if we want to avoid maintaining a manually-crafted dictionary to accommodate the wealth of new terms introduced every day (e.g., `ipod` and `ipad`), we may decide that `atachment` is a misspelling of `attachment` due to both the (relative) proximity between the words, and the fact that `attachment` is significantly more popular than `atachment`. As another example, the fact that the expression `sandeep kohli` is frequent in the domain increases our confidence in `sadeep kohli` $\rightarrow$ `sandeep kohli` (rather than, e.g., `sadeep kohli` $\rightarrow$ `sudeep kohli`). One can further note that, in email search, the fact that Sandeep Kohli sent multiple excel attachments increases our confidence in `excell` $\rightarrow$ `excel`.

A source of statistics widely used in prior work is the query log (Cucerzan and Brill, 2004; Ahmad and Kondrak, 2005; Li et al., 2006a; Chen et al., 2007; Sun et al., 2010). However, while query logs are abundant in the context of Web search, in many other search applications (e.g. email search, desktop search, and even small-enterprise search) query logs are too scarce to provide statistical information that is sufficient for effective spelling correction. Even an email provider of a massive scale (such as GMail) may need to rely on the (possibly tiny) query log of the single user at hand, due to privacy or security concerns; moreover, as noted earlier about `kohli`, the statistics of one user may be relevant to one user, while irrelevant to another.

The focus of this paper is on spelling correction for search applications like the above, where query-log analysis is impossible or undesirable (with email search being a prominent example). Our approach relies mainly on the corpus data (e.g., the collection of emails of the user at hand) and external, generic dictionaries (e.g., English). As shown in Figure 1, the corpus data may very well contain misspelled words (like query logs do), and such noise is a part of the challenge. Relying on the corpus has been shown to be successful in spelling correction for *text cleaning* (Schierle et al., 2007). Nevertheless, as we later explain, our approach can still incorporate query-log data as features involved in the correction, as well as means to refine the parameters.

1.3 Contribution and Outline

As said above, our goal is to devise spelling correction that relies on the corpus. The corpus often contains various types of information, with different levels of reliability (e.g., n-grams from email subjects and sender information, vs. those from email bodies). The major question is how to effectively exploit that information while addressing the various types of spelling errors such as those discussed in Section 1.1. The key contribution of this work is a novel graph-based algorithm, MaxPaths, that handles the different types of errors and incorporates the corpus data in a uniform (and simple) fashion. We describe MaxPaths in Section 2. We evaluate the effectiveness of our algorithm via an experimental study in Section 3. Finally, we make concluding remarks and discuss future directions in Section 4.

2 Spelling-Correction Algorithm

In this section, we describe our algorithm for spelling correction. Recall that given a search query

$\mathbf{s}$ of a user who intends to phrase $\mathbf{q}$, the goal is to find $\mathbf{q}$. Our corpus is essentially a collection $\mathbf{D}$ of unstructured or *semistructured documents*. For example, in email search such a document is an email with a title, a body, one or more recipients, and so on. As conventional in spelling correction, we devise a scoring function $\text{score}_{\mathbf{D}}(\mathbf{r} \mid \mathbf{s})$ that estimates our confidence in $\mathbf{r}$ being the correction of $\mathbf{s}$ (i.e., that $\mathbf{r}$ is equal to $\mathbf{q}$). Eventually, we suggest a sequence $\mathbf{r}$ from a set $\mathcal{C}_{\mathbf{D}}(\mathbf{s})$ of *candidates*, such that $\text{score}_{\mathbf{D}}(\mathbf{r} \mid \mathbf{s})$ is maximal among all the candidates in $\mathcal{C}_{\mathbf{D}}(\mathbf{s})$. In this section, we describe our graph-based approach to finding $\mathcal{C}_{\mathbf{D}}(\mathbf{s})$ and to determining $\text{score}_{\mathbf{D}}(\mathbf{r} \mid \mathbf{s})$.

We first give some basic notation. We fix an alphabet $\mathbf{\Sigma}$ of *characters* that does not include any of the conventional whitespace characters. By $\mathbf{\Sigma}^*$ we denote the set of all the *words*, namely, finite sequences over $\mathbf{\Sigma}$. A *search query* $\mathbf{s}$ is a sequence $w_1, \ldots, w_n$, where each w_i is a word. For convenience, in our examples we use whitespace instead of comma (e.g., `sandeep kohli` instead of `sandeep, kohli`). We use the *Damerau-Levenshtein* edit distance (as implemented by the *Jazzy* tool) as our primary edit distance between two words $r_1, r_2 \in \mathbf{\Sigma}^*$, and we denote this distance by $ed(r_1, r_2)$.

2.1 Word-Level Correction

We first handle a restriction of our problem, where the search query is a single word w (rather than a general sequence $\mathbf{s}$ of words). Moreover, we consider only candidate suggestions that are words (rather than sequences of words that account for the case where w is obtained by merging keywords). Later, we will use the solution for this restricted problem as a basic component in our algorithm for the general problem.

Let $\mathbf{U}_{\mathbf{D}} \subseteq \mathbf{\Sigma}^*$ be a finite *universal lexicon*, which (conceptually) consists of all the words in the corpus $\mathbf{D}$. (In practice, one may want add to $\mathbf{D}$ words of auxiliary sources, like English dictionary, and to filter out noisy words; we did so in the site-search domain that is discussed in Section 3.) The set $\mathcal{C}_{\mathbf{D}}(w)$ of candidates is defined by

$$\mathcal{C}_{\mathbf{D}}(w) \stackrel{\text{def}}{=} \{w\} \cup \{w' \in \mathbf{U}_{\mathbf{D}} \mid ed(w, w') \leq \delta\}\,.$$

for some fixed number δ. Note that $\mathcal{C}_{\mathbf{D}}(w)$ contains w even if w is misspelled; furthermore, $\mathcal{C}_{\mathbf{D}}(w)$ may contain other misspelled words (with a small edit distance to w) that appear in $\mathbf{D}$.

Table 1: Feature set $\mathsf{WF}_{\mathbf{D}}$ in email search

Basic Features
$ed(w, w')$: weighted Damerau-Levenshtein edit distance
$ph(w, w')$: 1 if w and w' are phonetically equal, 0 otherwise
$\text{english}(w')$: 1 is w' is in English, 0 otherwise
Corpus-Based Features
$logfreq(w')$): logarithm of #occurrences of w' in the corpus
Domain-Specific Features
$\text{subject}(w')$: 1 if w' is in some "Subject" field, 0 otherwise
$\text{from}(w')$: 1 if w' is in some "From" field, 0 otherwise
$\text{xfrom}(w')$: 1 if w' is in some "X-From" field, 0 otherwise

We now define $\text{score}_{\mathbf{D}}(w' \mid w)$. Here, our corpus $\mathbf{D}$ is translated into a set $\mathsf{WF}_{\mathbf{D}}$ of *word features*, where each feature $f \in \mathsf{WF}_{\mathbf{D}}$ gives a scoring function $\text{score}_f(w' \mid w)$. The function $\text{score}_{\mathbf{D}}(w' \mid w)$ is simply a linear combination of the $\text{score}_f(w' \mid w)$:

$$\text{score}_{\mathbf{D}}(w' \mid w) \stackrel{\text{def}}{=} \sum_{f \in \mathsf{WF}_{\mathbf{D}}} a_f \cdot \text{score}_f(w' \mid w)$$

As a concrete example, the features of $\mathsf{WF}_{\mathbf{D}}$ we used in the email domain are listed in Table 1; the resulting $\text{score}_f(w'|w)$ is in the spirit of the *noisy channel model* (Kernighan et al., 1990). Note that additional features could be used, like ones involving the *stems* of w and w', and even query-log statistics (when available). Rather than manually tuning the parameters a_f, we learned them using the well known *Support Vector Machine*, abbreviated *SVM* (Cortes and Vapnik, 1995), as also done by Schaback and Li (2007) for spelling correction. We further discuss this learning step in Section 3.

We fix a natural number k, and in the sequel we denote by $\text{top}_{\mathbf{D}}(w)$ a set of k words $w' \in \mathcal{C}_{\mathbf{D}}(w)$ with the highest $\text{score}_{\mathbf{D}}(w' \mid w)$. If $|\mathcal{C}_{\mathbf{D}}(w)| < k$, then $\text{top}_{\mathbf{D}}(w)$ is simply $\mathcal{C}_{\mathbf{D}}(w)$.

2.2 Query-Level Correction: MaxPaths

We now describe our algorithm, MaxPaths, for spelling correction. The input is a (possibly misspelled) search query $\mathbf{s} = s_1, \ldots, s_n$. As done in the word-level correction, the algorithm produces a set $\mathcal{C}_{\mathbf{D}}(\mathbf{s})$ of suggestions and determines the values

Algorithm 1 MaxPaths

Input: a search query $\mathbf{s}$
Output: a set $\mathcal{C}_\mathbf{D}(\mathbf{s})$ of candidate suggestions $\mathbf{r}$, ranked by $\text{score}_\mathbf{D}(\mathbf{r} \mid \mathbf{s})$

1: Find the *strongly plausible tokens*
2: Construct the *correction graph*
3: Find top-k *full paths* (with the largest weights)
4: Re-rank the paths by *word correlation*

$\text{score}_\mathbf{D}(\mathbf{r} \mid \mathbf{s})$, for all $\mathbf{r} \in \mathcal{C}_\mathbf{D}(\mathbf{s})$, in order to rank $\mathcal{C}_\mathbf{D}(\mathbf{s})$. A high-level overview of MaxPaths is given in the pseudo-code of Algorithm 1. In the rest of this section, we will detail each of the four steps in Algorithm 1. The name MaxPaths will become clear towards the end of this section.

We use the following notation. For a word $w = c_1 \cdots c_m$ of m characters c_i and integers $i < j$ in $\{1, \ldots, m+1\}$, we denote by $w_{[i,j)}$ the word $c_i \cdots c_{j-1}$. For two words $w_1, w_2 \in \mathbf{\Sigma}^*$, the word $w_1 w_2 \in \mathbf{\Sigma}^*$ is obtained by concatenating w_1 and w_2. Note that for the search query $\mathbf{s} = s_1, \ldots, s_n$ it holds that $s_1 \cdots s_n$ is a single word (in $\mathbf{\Sigma}^*$). We denote the word $s_1 \cdots s_n$ by $\lfloor \mathbf{s} \rfloor$. For example, if $s_1 =$ `sadeep` and $s_2 =$ `kohli`, then $\mathbf{s}$ corresponds to the query `sadeep kohli` while $\lfloor \mathbf{s} \rfloor$ is the word `sadeepkohli`; furthermore, $\lfloor \mathbf{s} \rfloor_{[1,7)} =$ `sadeep`.

2.2.1 Plausible Tokens

To support merging and splitting, we first identify the possible *tokens* of the given query $\mathbf{s}$. For example, in `excellatach ment` we would like to identify `excell` and `atach ment` as tokens, since those are indeed the tokens that the user has in mind. Formally, suppose that $\lfloor \mathbf{s} \rfloor = c_1 \cdots c_m$. A *token* is a word $\lfloor \mathbf{s} \rfloor_{[i,j)}$ where $1 \leq i < j \leq m+1$. To simplify the presentation, we make the (often false) assumption that a token $\lfloor \mathbf{s} \rfloor_{[i,j)}$ uniquely identifies i and j (that is, $\lfloor \mathbf{s} \rfloor_{[i,j)} \neq \lfloor \mathbf{s} \rfloor_{[i',j')}$ if $i \neq i'$ or $j \neq j'$); in reality, we should define a token as a triple $(\lfloor \mathbf{s} \rfloor_{[i,j)}, i, j)$. In principle, every token $\lfloor \mathbf{s} \rfloor_{[i,j)}$ could be viewed as a possible word that user meant to phrase. However, such liberty would require our algorithm to process a search space that is too large to manage in reasonable time. Instead, we restrict to *strongly plausible tokens*, which we define next.

A token $w = \lfloor \mathbf{s} \rfloor_{[i,j)}$ is *plausible* if w is a word of $\mathbf{s}$, or there is a word $w' \in \mathcal{C}_\mathbf{D}(w)$ (as defined in Section 2.1) such that $\text{score}_\mathbf{D}(w' \mid w) > \epsilon$ for some fixed number ϵ. Intuitively, w is plausible if it is an original token of $\mathbf{s}$, or we have a high confidence in our word-level suggestion to correct w (note that the suggested correction for w can be w itself). Recall that $\lfloor \mathbf{s} \rfloor = c_1 \cdots c_m$. A *tokenization* of $\mathbf{s}$ is a sequence $j_1, \ldots, j_l$, such that $j_1 = 1$, $j_l = m+1$, and $j_i < j_{i+1}$ for $1 \leq i < l$. The tokenization $j_1, \ldots, j_l$ *induces* the tokens $\lfloor \mathbf{s} \rfloor_{[j_1,j_2)}, \ldots, \lfloor \mathbf{s} \rfloor_{[j_{l-1},j_l)}$. A tokenization is *plausible* if each of its induced tokens is plausible. Observe that a plausible token is not necessarily induced by any plausible tokenization; in that case, the plausible token is useless to us. Thus, we define a *strongly plausible token*, abbreviated *sp-token*, which is a token that is induced by some plausible tokenization. As a concrete example, for the query `excellatach ment`, the sp-tokens in our implementation include `excellatach`, `ment`, `excell`, and `atachment`.

As the first step (line 1 in Algorithm 1), we find the sp-tokens by employing an efficient (and fairly straightforward) dynamic-programming algorithm.

2.2.2 Correction Graph

In the next step (line 2 in Algorithm 1), we construct the *correction graph*, which we denote by $\mathcal{G}_\mathbf{D}(\mathbf{s})$. The construction is as follows.

We first find the set $\text{top}_\mathbf{D}(w)$ (defined in Section 2.1) for each sp-token w. Table 2 shows the sp-tokens and suggestions thereon in our running example. This example shows the actual execution of our implementation within email search, where $\mathbf{s}$ is the query `sadeep kohli excellatach ment`; for clarity of presentation, we omitted a few sp-tokens and suggested corrections. Observe that some of the corrections in the table are actually misspelled words (as those naturally occur in the corpus).

A node of the graph $\mathcal{G}_\mathbf{D}(\mathbf{s})$ is a pair $\langle w, w' \rangle$, where w is an sp-token and $w' \in \text{top}_\mathbf{D}(w)$. Recall our simplifying assumption that a token $\lfloor \mathbf{s} \rfloor_{[i,j)}$ uniquely identifies the indices i and j. The graph $\mathcal{G}_\mathbf{D}(\mathbf{s})$ contains a (directed) edge from a node $\langle w_1, w_1' \rangle$ to a node $\langle w_2, w_2' \rangle$ if w_2 immediately follows w_1 in $\lfloor \mathbf{q} \rfloor$; in other words, $\mathcal{G}_\mathbf{D}(\mathbf{s})$ has an edge from $\langle w_1, w_1' \rangle$ to $\langle w_2, w_2' \rangle$ whenever there exist indices i, j and k, such that $w_1 = \lfloor \mathbf{s} \rfloor_{[i,j)}$ and $w_2 = \lfloor \mathbf{s} \rfloor_{[j,k)}$. Observe that $\mathcal{G}_\mathbf{D}(\mathbf{s})$ is a *directed acyclic graph* (DAG).

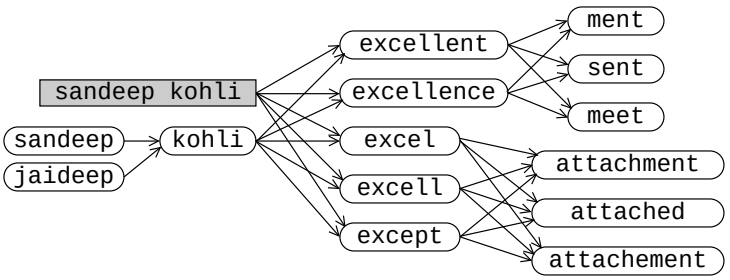

Figure 2: The graph $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$

For example, Figure 2 shows $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$ for the query `sadeep kohli excellatach ment`, with the sp-tokens w and the sets $\text{top}_{\mathbf{D}}(w)$ being those of Table 2. For now, the reader should ignore the node in the grey box (containing `sandeep kohli`) and its incident edges. For simplicity, in this figure we depict each node $\langle w, w' \rangle$ by just mentioning w'; the word w is in the first row of Table 2, above w'.

2.2.3 Top-k Paths

Let $P = \langle w_1, w'_1 \rangle \rightarrow \cdots \rightarrow \langle w_k, w'_k \rangle$ be a path in $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$. We say that P is *full* if $\langle w_1, w'_1 \rangle$ has no incoming edges in $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$, and $\langle w_k, w'_k \rangle$ has no outgoing edges in $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$. An easy observation is that, since we consider only strongly plausible tokens, if P is full then $w_1 \cdots w_k = \lfloor \mathbf{s} \rfloor$; in that case, the sequence $w'_1, \ldots, w'_k$ is a suggestion for spelling correction, and we denote it by $crc(P)$. As an example, Figure 3 shows two full paths P_1 and P_2 in the graph $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$ of Figure 2. The corrections $crc(P_i)$, for $i = 1, 2$, are `jaideep kohli excellent ment` and `sandeep kohli excel attachement`, respectively.

To obtain corrections $crc(P)$ with high quality, we produce a set of k full paths with the largest weights, for some fixed k; we denote this set by $\text{topPaths}_{\mathbf{D}}(\mathbf{s})$. The *weight* of a path P, denoted $\text{weight}(P)$, is the sum of the weights of all the nodes and edges in P, and we define the weights of nodes and edges next. To find these paths, we use a well known efficient algorithm (Eppstein, 1994).

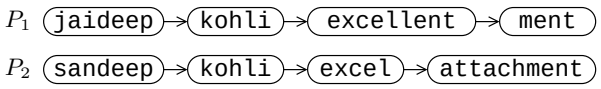

Figure 3: Full paths in the graph $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$ of Figure 2

Consider a node $u = \langle w, w' \rangle$ of $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$. In the construction of $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$, zero or more merges of (part of) original tokens have been applied to obtain the token w; let $\#\text{merges}(w)$ be that number. Consider an edge e of $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$ from a node $u_1 = \langle w_1, w'_1 \rangle$ to $u_2 = \langle w_2, w'_2 \rangle$. In $\mathbf{s}$, either w_1 and w_2 belong to different words (i.e., there is a whitespace between them) or not; in the former case define $\#\text{splits}(e) = 0$, and in the latter $\#\text{splits}(e) = 1$. We define:

$$\text{weight}(u) \stackrel{\text{def}}{=} \text{score}_{\mathbf{D}}(w' \mid w) + a_m \cdot \#\text{merges}(w)$$
$$\text{weight}(e) \stackrel{\text{def}}{=} a_s \cdot \#\text{splits}(e)$$

Note that a_m and a_s are negative, as they penalize for merges and splits, respectively. Again, in our implementations, we learned a_m and a_s by means of SVM.

Recall that $\text{topPaths}_{\mathbf{D}}(\mathbf{s})$ is the set of k full paths (in the graph $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$) with the largest weights. From $\text{topPaths}_{\mathbf{D}}(\mathbf{s})$ we get the set $\mathcal{C}_{\mathbf{D}}(\mathbf{s})$ of candidate suggestions:

$$\mathcal{C}_{\mathbf{D}}(\mathbf{s}) \stackrel{\text{def}}{=} \{crc(P) \mid P \in \text{topPaths}_{\mathbf{D}}(\mathbf{s})\}.$$

2.2.4 Word Correlation

To compute $\text{score}_{\mathbf{D}}(\mathbf{r}|\mathbf{s})$ for $\mathbf{r} \in \mathcal{C}_{\mathbf{D}}(\mathbf{s})$, we incorporate *correlation* among the words of $\mathbf{r}$. Intuitively, we would like to reward a candidate with pairs of words that are likely to co-exist in a query. For that, we assume a (symmetric) numerical function $crl(w'_1, w'_2)$ that estimates the extent to which the words w'_1 and w'_2 are correlated. As an example, in the email domain we would like $crl(\texttt{kohli}, \texttt{excel})$ to be high if Kohli sent many emails with excel attachments. Our implementation of $crl(w'_1, w'_2)$ essentially employs *pointwise mutual information* that has also been used in (Schierle et al., 2007), and that

Table 2: $\text{top}_{\mathbf{D}}(w)$ for sp-tokens w

sadeep	kohli	excellatach	ment	excell	atachment
sandeep	kohli	excellent	ment	excel	attachment
jaideep		excellence	sent	excell	attached
			meet	except	attachement

compares the number of documents (emails) containing w'_1 and w'_2 separately and jointly.

Let $P \in \text{topPaths}_{\mathbf{D}}(\mathbf{s})$ be a path. We denote by $crl(P)$ a function that aggregates the numbers $crl(w'_1, w'_2)$ for nodes $\langle w_1, w'_1 \rangle$ and $\langle w_2, w'_2 \rangle$ of P (where $\langle w_1, w'_1 \rangle$ and $\langle w_2, w'_2 \rangle$ are not necessarily neighbors in P). Over the email domain, our $crl(P)$ is the minimum of the $crl(w'_1, w'_2)$. We define $\text{score}_{\mathbf{D}}(P) = \text{weight}(P) + crl(P)$. To improve the performance, in our implementation we learned again (re-trained) all the parameters involved in $\text{score}_{\mathbf{D}}(P)$.

Finally, as the top suggestions we take $crc(P)$ for full paths P with highest $\text{score}_{\mathbf{D}}(P)$. Note that $crc(P)$ is not necessarily injective; that is, there can be two full paths $P_1 \neq P_2$ satisfying $crc(P_1) = crc(P_2)$. Thus, in effect, $\text{score}_{\mathbf{D}}(\mathbf{r} \mid \mathbf{s})$ is determined by the best evidence of $\mathbf{r}$; that is,

$$\text{score}_{\mathbf{D}}(\mathbf{r} \mid \mathbf{s}) \stackrel{\text{def}}{=} \max\{\text{score}_{\mathbf{D}}(P) \mid crc(P) = \mathbf{r} \wedge P \in \text{topPaths}_{\mathbf{D}}(\mathbf{s})\}.$$

Note that our final scoring function essentially views P as a *clique* rather than a path. In principle, we could define $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$ in a way that we would extract the maximal cliques directly without finding $\text{topPaths}_{\mathbf{D}}(\mathbf{s})$ first. However, we chose our method (finding top paths first, and then re-ranking) to avoid the inherent computational hardness involved in finding maximal cliques.

2.3 Handling Expressions

We now briefly discuss our handling of frequent n-grams (expressions). We handle n-grams by introducing new nodes to the graph $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$; such a new node u is a pair $\langle \mathbf{t}, \mathbf{t}' \rangle$, where $\mathbf{t}$ is a sequence of n consecutive sp-tokens and $\mathbf{t}'$ is a n-gram. The weight of such a node u is rewarded for constituting a frequent or important n-gram. An example of such a node is in the grey box of Figure 2, where `sandeep kohli` is a bigram. Observe that `sandeep kohli` may be deemed an important bigram because it occurs as a sender of an email, and not necessarily because it is frequent.

An advantage of our approach is avoidance of over-scoring due to *conflicting n-grams*. For example, consider the query `textile import expert`, and assume that both `textile import` and `import export` (with an "o" rather than an "e") are frequent bigrams. If the user referred to the bigram `textile import`, then `expert` is likely to be correct. But if she meant for `import export`, then `expert` is misspelled. However, only one of these two options can hold true, and we would like `textile import export` to be rewarded only once—for the bigram `import export`. This is achieved in our approach, since a full path in $\mathcal{G}_{\mathbf{D}}(\mathbf{s})$ may contain either a node for `textile import` or a node for `import export`, but it cannot contain nodes for both of these bigrams.

Finally, we note that our algorithm is in the spirit of that of Cucerzan and Brill (2004), with a few inherent differences. In essence, a node in the graph they construct corresponds to what we denote here as $\langle w, w' \rangle$ in the special case where w is an actual word of the query; that is, no re-tokenization is applied. They can split a word by comparing it to a bigram. However, it is not clear how they can split into non-bigrams (without a huge index) and to handle simultaneous merging and splitting as in our running example (1). Furthermore, they translate bigram information into edge weights, which implies that the above problem of over-rewarding due to conflicting bigrams occurs.

3 Experimental Study

Our experimental study aims to investigate the effectiveness of our approach in various settings, as we explain next.

3.1 Experimental Setup

We first describe our experimental setup, and specifically the datasets and general methodology.

Datasets. The focus of our experimental study is on *personal email search*; later on (Section 3.6), we will consider (and give experimental results for) a totally different setting—site search over `www.ibm.com`, which is a massive and open domain. Our dataset (for the email domain) is obtained from

the Enron email collection (Bekkerman et al., 2004; Klimt and Yang, 2004). Specifically, we chose the three users with the largest number of emails. We refer to the three email collections by the last names of their owners: *Farmer*, *Kaminski* and *Kitchen*. Each user mailbox is a separate domain, with a separate corpus $\mathbf{D}$, that one can search upon. Due to the absence of real user queries, we constructed our dataset by conducting a user study, as described next.

For each user, we randomly sampled 50 emails and divided them into 5 disjoint sets of 10 emails each. We gave each 10-email set to a unique human subject that was asked to phrase two search queries for each email: one for the entire email content (*general query*), and the other for the `From` and `X-From` fields (*sender query*). (Figure 1 shows examples of the `From` and `X-From` fields.) The latter represents queries posed against a specific field (e.g., using "advanced search"). The participants were not told about the goal of this study (i.e., spelling correction), and the collected queries have no spelling errors. For generating spelling errors, we implemented a typo generator.[1] This generator extends an online typo generator (Seobook, 2010) that produces a variety of spelling errors, including skipped letter, doubled letter, reversed letter, skipped space (merge), missed key and inserted key; in addition, our generator produces inserted space (split). When applied to a search query, our generator adds random typos to each word, independently, with a specified probability p that is 50% by default. For each collected query (and for each considered value of p) we generated 5 misspelled queries, and thereby obtained 250 instances of misspelled general queries and 250 instances of misspelled sender queries.

Methodology. We compared the accuracy of MaxPaths (Section 2) with three alternatives. The first alternative is the open-source *Jazzy*, which is a widely used spelling-correction tool based on (weighted) edit distance. The second alternative is the spelling correction provided by *Google*. We provided Jazzy with our unigram index (as a dictionary). However, we were not able to do so with Google, as we used remote access via its Java API (Google, 2010); hence, the Google tool is unaware of our domain, but is rather based on its own statistics (from the World Wide Web). The third alternative is what we call WordWise, which applies word-level correction (Section 2.1) to each input query term, independently. More precisely, WordWise is a simplified version of MaxPaths, where we forbid splitting and merging of words (i.e., only the original tokens are considered), and where we do not take correlation into account.

Our emphasis is on *correcting misspelled queries*, rather than *recognizing correctly spelled queries*, due to the role of spelling in a search engine: we wish to provide the user with the correct query upon misspelling, but there is no harm in making a suggestion for correctly spelled queries, except for visual discomfort. Hence, by default *accuracy* means the number of properly corrected queries (within the top-k suggestions) divided by the number of the misspelled queries. An exception is in Section 3.5, where we study the accuracy on correct queries.

Since MaxPaths and WordWise involve parameter learning (SVM), the results for them are consistently obtained by performing 5-folder *cross validation* over each collection of misspelled queries.

3.2 Fixed Error Probability

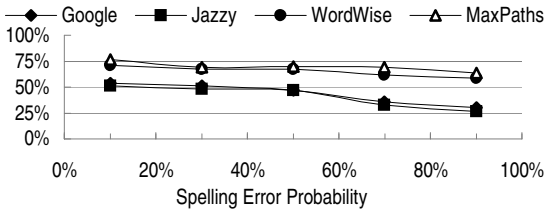
Here, we compare MaxPaths to the alternatives when the error probability p is fixed (0.5). We consider only the Kaminski dataset; the results for the other two datasets are similar. Figure 4(a) shows the accuracy, for general queries, of top-k suggestions for $k = 1$, $k = 3$ and $k = 10$. Note that we can get only one (top-1) suggestion from Google. As can be seen, MaxPaths has the highest accuracy in all cases. Moreover, the advantage of MaxPaths over the alternatives increases as k increases, which indicates potential for further improving MaxPaths.

Figure 4(b) shows the accuracy of top-k suggestions for sender queries. Overall, the results are similar to those of Figure 4(a), except that top-1 of both WordWise and MaxPaths has a higher accuracy in sender queries than in general queries. This is due to the fact that the dictionaries of person names and email addresses extracted from the `X-From` and `From` fields, respectively, provide strong features for the scoring function, since a sender query refers to these two fields. In addition, the accuracy of MaxPaths is further enhanced by exploiting the cor-

[1] The queries and our typo generator are publicly available at `https://dbappserv.cis.upenn.edu/spell/`.

(a) General queries (Kaminski)

(b) Sender queries (Kaminski)



(c) Varying error probability (Kaminski)

Figure 4: Accuracy for Kaminski (misspelled queries)

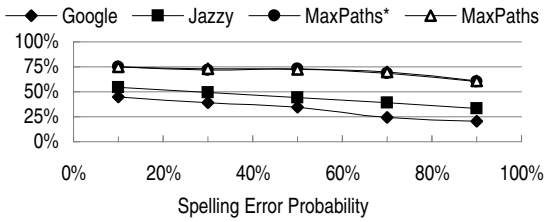
relation between the first and last name of a person.

3.3 Impact of Error Probability

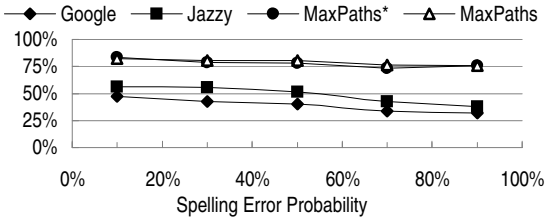
We now study the impact of the complexity of spelling errors on our algorithm. For that, we measure the accuracy while the error probability p varies from 10% to 90% (with gaps of 20%). The results are in Figure 4(c). Again, we show the results only for Kaminski, since we get similar results for the other two datasets. As expected, in all examined methods the accuracy decreases as p increases. Now, not only does MaxPaths outperform the alternatives, its decrease (as well as that of WordWise) is the mildest—13% as p increases from 10% to 90% (while Google and Jazzy decrease by 23% or more). We got similar results for the sender queries (and for each of the three users).

3.4 Adaptiveness of Parameters

Obtaining the labeled data needed for parameter learning entails a nontrivial manual effort. Ideally, we would like to learn the parameters of MaxPaths in one domain, and use them in similar domains.



(a) General queries (Farmer)



(b) Sender queries (Farmer)

Figure 5: Accuracy for Farmer (misspelled queries)

More specifically, our desire is to use the parameters learned over one corpus (e.g., the email collection of one user) on a second corpus (e.g., the email collection of another user), rather than learning the parameters again over the second corpus. In this set of experiments, we examine the feasibility of that approach. Specifically, we consider the user Farmer and observe the accuracy of our algorithm with two sets of parameters: the first, denoted by MaxPaths in Figures 5(a) and 5(b), is learned within the Farmer dataset, and the second, denoted by MaxPaths*, is learned within the Kaminski dataset. Figures 5(a) and 5(b) show the accuracy of the top-1 suggestion for general queries and sender queries, respectively, with varying error probabilities. As can be seen, these results mean good news—the accuracies of MaxPaths* and MaxPaths are extremely close (their curves are barely distinguishable, as in most cases the difference is smaller than 1%). We repeated this experiment for Kitchen and Kaminski, and got similar results.

3.5 Accuracy for Correct Queries

Next, we study the accuracy on *correct* queries, where the task is to recognize the given query as correct by returning it as the top suggestion. For each of the three users, we considered the $50 + 50$ (general + sender) collected queries (having no spelling errors), and measured the *accuracy*, which is the percentage of queries that are equal to the top sug-

Table 3: Accuracy for Correct Queries

Dataset	Google	Jazzy	MaxPaths
Kaminski (general)	90%	98%	94%
Kaminski (sender)	94%	98%	94%
Farmer (general)	96%	98%	96%
Farmer (sender)	96%	96%	92%
Kitchen (general)	86%	100%	92%
Kitchen (sender)	94%	100%	98%

gestion. Table 3 shows the results. Since Jazzy is based on edit distance, it almost always gives the input query as the top suggestion; the misses of Jazzy are for queries that contain a word that is not the corpus. MaxPaths is fairly close to the upper bound set by Jazzy. Google (having no access to the domain) also performs well, partly because it returns the input query if no reasonable suggestion is found.

3.6 Applicability to Large-Scale Site Search

Up to now, our focus has been on email search, which represents a restricted (closed) domain with specialized knowledge (e.g., sender names). In this part, we examine the effectiveness of our algorithm in a totally different setting—*large-scale site search* within `www.ibm.com`, a domain that is popular on a world scale. There, the accuracy of Google is very high, due to this domain's popularity, scale, and full accessibility on the Web. We crawled 10 million documents in that domain to obtain the corpus. We manually collected 1348 misspelled queries from the log of search issued against developerWorks (`www.ibm.com/developerworks/`) during a week. To facilitate the manual collection of these queries, we inspected each query with two or fewer search results, after applying a random permutation to those queries. Figure 6 shows the accuracy of top-k suggestions. Note that the performance of MaxPaths is very close to that of Google—only 2% lower for top-1. For $k = 3$ and $k = 10$, MaxPaths outperforms Jazzy and the top-1 of Google (from which we cannot obtain top-k for $k > 1$).

Figure 6: Accuracy for site search

3.7 Summary

To conclude, our experiments demonstrate various important qualities of MaxPaths. First, it outperforms its alternatives, in both accuracy (Section 3.2) and robustness to varying error complexities (Section 3.3). Second, the parameters learned in one domain (e.g., an email user) can be applied to similar domains (e.g., other email users) with essentially no loss in performance (Section 3.4). Third, it is highly accurate in recognition of correct queries (Section 3.5). Fourth, even when applied to large (open) domains, it achieves a comparable performance to the state-of-the-art Google spelling correction (Section 3.6). Finally, the higher performance of MaxPaths on top-3 and top-10 corrections suggests a potential for further improvement of top-1 (which is important since search engines often restrict their interfaces to only one suggestion).

4 Conclusions

We presented the algorithm MaxPaths for spelling correction in domain-centric search. This algorithm relies primarily on corpus statistics and domain knowledge (rather than on query logs). It can handle a variety of spelling errors, and can incorporate different levels of spelling reliability among different parts of the corpus. Our experimental study demonstrates the superiority of MaxPaths over existing alternatives in the domain of email search, and indicates its effectiveness beyond that domain.

In future work, we plan to explore how to utilize additional domain knowledge to better estimate the correlation between words. Particularly, from available auxiliary data (Fagin et al., 2010) and tools like *information extraction* (Chiticariu et al., 2010), we can infer and utilize *type* information from the corpus (Li et al., 2006b; Zhu et al., 2007). For instance, if `kohli` is of type person, and `phone` is highly correlated with person instances, then `phone` is highly correlated with `kohli` even if the two words do not frequently co-occur. We also plan to explore aspects of corpus maintenance in dynamic (constantly changing) domains.

[2]Department of Computer Science, National University of Singapore
{danielhe,nght}@comp.nus.edu.sg

Abstract

We present a novel approach to grammatical error correction based on Alternating Structure Optimization. As part of our work, we introduce the *NUS Corpus of Learner English (NUCLE)*, a fully annotated one million words corpus of learner English available for research purposes. We conduct an extensive evaluation for article and preposition errors using various feature sets. Our experiments show that our approach outperforms two baselines trained on non-learner text and learner text, respectively. Our approach also outperforms two commercial grammar checking software packages.

1 Introduction

Grammatical error correction (GEC) has been recognized as an interesting as well as commercially attractive problem in natural language processing (NLP), in particular for learners of English as a foreign or second language (EFL/ESL).

Despite the growing interest, research has been hindered by the lack of a large annotated corpus of learner text that is available for research purposes. As a result, the standard approach to GEC has been to train an off-the-shelf classifier to re-predict words in non-learner text. Learning GEC models directly from annotated learner corpora is not well explored, as are methods that combine learner and non-learner text. Furthermore, the evaluation of GEC has been problematic. Previous work has either evaluated on artificial test instances as a substitute for real learner errors or on proprietary data that is not available to other researchers. As a consequence, existing methods have not been compared on the same test set, leaving it unclear where the current state of the art really is.

In this work, we aim to overcome both problems. First, we present a novel approach to GEC based on Alternating Structure Optimization (ASO) (Ando and Zhang, 2005). Our approach is able to train models on annotated learner corpora while still taking advantage of large non-learner corpora. Second, we introduce the *NUS Corpus of Learner English (NUCLE)*, a fully annotated one million words corpus of learner English available for research purposes. We conduct an extensive evaluation for article and preposition errors using six different feature sets proposed in previous work. We compare our proposed ASO method with two baselines trained on non-learner text and learner text, respectively. To the best of our knowledge, this is the first extensive comparison of different feature sets on real learner text which is another contribution of our work. Our experiments show that our proposed ASO algorithm significantly improves over both baselines. It also outperforms two commercial grammar checking software packages in a manual evaluation.

The remainder of this paper is organized as follows. The next section reviews related work. Section 3 describes the tasks. Section 4 formulates GEC as a classification problem. Section 5 extends this to the ASO algorithm. The experiments are presented in Section 6 and the results in Section 7. Section 8 contains a more detailed analysis of the results. Section 9 concludes the paper.

2 Related Work

In this section, we give a brief overview on related work on article and preposition errors. For a more comprehensive survey, see (Leacock et al., 2010).

The seminal work on grammatical error correction was done by Knight and Chander (1994) on article errors. Subsequent work has focused on designing better features and testing different classifiers, including memory-based learning (Minnen et al., 2000), decision tree learning (Nagata et al., 2006; Gamon et al., 2008), and logistic regression (Lee, 2004; Han et al., 2006; De Felice, 2008). Work on preposition errors has used a similar classification approach and mainly differs in terms of the features employed (Chodorow et al., 2007; Gamon et al., 2008; Lee and Knutsson, 2008; Tetreault and Chodorow, 2008; Tetreault et al., 2010; De Felice, 2008). All of the above works only use non-learner text for training.

Recent work has shown that training on annotated learner text can give better performance (Han et al., 2010) and that the observed word used by the writer is an important feature (Rozovskaya and Roth, 2010b). However, training data has either been small (Izumi et al., 2003), only partly annotated (Han et al., 2010), or artificially created (Rozovskaya and Roth, 2010b; Rozovskaya and Roth, 2010a).

Almost no work has investigated ways to combine learner and non-learner text for training. The only exception is Gamon (2010), who combined features from the output of logistic-regression classifiers and language models trained on non-learner text in a meta-classifier trained on learner text. In this work, we show a more direct way to combine learner and non-learner text in a single model.

Finally, researchers have investigated GEC in connection with web-based models in NLP (Lapata and Keller, 2005; Bergsma et al., 2009; Yi et al., 2008). These methods do not use classifiers, but rely on simple n-gram counts or page hits from the Web.

3 Task Description

In this work, we focus on article and preposition errors, as they are among the most frequent types of errors made by EFL learners.

3.1 Selection vs. Correction Task

There is an important difference between training on annotated learner text and training on non-learner text, namely whether the observed word can be used as a feature or not. When training on non-learner text, the observed word cannot be used as a feature. The word choice of the writer is "blanked out" from the text and serves as the correct class. A classifier is trained to re-predict the word given the surrounding context. The *confusion set* of possible classes is usually pre-defined. This *selection task* formulation is convenient as training examples can be created "for free" from any text that is assumed to be free of grammatical errors. We define the more realistic *correction task* as follows: given a particular word and its context, propose an appropriate correction. The proposed correction can be identical to the observed word, i.e., no correction is necessary. The main difference is that the word choice of the writer can be encoded as part of the features.

3.2 Article Errors

For article errors, the classes are the three articles *a*, *the*, and the *zero-article*. This covers article insertion, deletion, and substitution errors. During training, each noun phrase (NP) in the training data is one training example. When training on learner text, the correct class is the article provided by the human annotator. When training on non-learner text, the correct class is the observed article. The context is encoded via a set of feature functions. During testing, each NP in the test set is one test example. The correct class is the article provided by the human annotator when testing on learner text or the observed article when testing on non-learner text.

3.3 Preposition Errors

The approach to preposition errors is similar to articles but typically focuses on preposition substitution errors. In our work, the classes are 36 frequent English prepositions (*about, along, among, around, as, at, beside, besides, between, by, down, during, except, for, from, in, inside, into, of, off, on, onto, outside, over, through, to, toward, towards, under, underneath, until, up, upon, with, within, without*), which we adopt from previous work. Every prepositional phrase (PP) that is governed by one of the

36 prepositions is one training or test example. We ignore PPs governed by other prepositions.

4 Linear Classifiers for Grammatical Error Correction

In this section, we formulate GEC as a classification problem and describe the feature sets for each task.

4.1 Linear Classifiers

We use classifiers to approximate the unknown relation between articles or prepositions and their contexts in learner text, and their valid corrections. The articles or prepositions and their contexts are represented as feature vectors $\mathbf{X} \in \mathcal{X}$. The corrections are the classes $Y \in \mathcal{Y}$.

In this work, we employ binary linear classifiers of the form $\mathbf{u}^T\mathbf{X}$ where $\mathbf{u}$ is a weight vector. The outcome is considered $+1$ if the score is positive and -1 otherwise. A popular method for finding $\mathbf{u}$ is *empirical risk minimization* with *least square regularization*. Given a training set $\{\mathbf{X}_i, Y_i\}_{i=1,\ldots,n}$, we aim to find the weight vector that minimizes the empirical loss on the training data

$$\hat{\mathbf{u}} = \arg\min_{\mathbf{u}} \left(\frac{1}{n} \sum_{i=1}^{n} L(\mathbf{u}^T\mathbf{X}_i, Y_i) + \lambda \, ||\mathbf{u}||^2 \right), \quad (1)$$

where L is a loss function. We use a modification of Huber's robust loss function. We fix the regularization parameter λ to 10^{-4}. A multi-class classification problem with m classes can be cast as m binary classification problems in a *one-vs-rest* arrangement. The prediction of the classifier is the class with the highest score $\hat{Y} = \arg\max_{Y \in \mathcal{Y}} (\mathbf{u}_Y^T\mathbf{X})$. In earlier experiments, this linear classifier gave comparable or superior performance compared to a logistic regression classifier.

4.2 Features

We re-implement six feature extraction methods from previous work, three for articles and three for prepositions. The methods require different linguistic pre-processing: chunking, CCG parsing, and constituency parsing.

4.2.1 Article Errors

- **DeFelice** The system in (De Felice, 2008) for article errors uses a CCG parser to extract a rich set of syntactic and semantic features, including part of speech (POS) tags, hypernyms from WordNet (Fellbaum, 1998), and named entities.
- **Han** The system in (Han et al., 2006) relies on shallow syntactic and lexical features derived from a chunker, including the words before, in, and after the NP, the head word, and POS tags.
- **Lee** The system in (Lee, 2004) uses a constituency parser. The features include POS tags, surrounding words, the head word, and hypernyms from WordNet.

4.2.2 Preposition Errors

- **DeFelice** The system in (De Felice, 2008) for preposition errors uses a similar rich set of syntactic and semantic features as the system for article errors. In our re-implementation, we do not use a subcategorization dictionary, as this resource was not available to us.
- **TetreaultChunk** The system in (Tetreault and Chodorow, 2008) uses a chunker to extract features from a two-word window around the preposition, including lexical and POS n-grams, and the head words from neighboring constituents.
- **TetreaultParse** The system in (Tetreault et al., 2010) extends (Tetreault and Chodorow, 2008) by adding additional features derived from a constituency and a dependency parse tree.

For each of the above feature sets, we add the observed article or preposition as an additional feature when training on learner text.

5 Alternating Structure Optimization

This section describes the ASO algorithm and shows how it can be used for grammatical error correction.

5.1 The ASO algorithm

Alternating Structure Optimization (Ando and Zhang, 2005) is a multi-task learning algorithm that takes advantage of the *common structure* of multiple related problems. Let us assume that we have m binary classification problems. Each classifier $\mathbf{u}_i$ is a

weight vector of dimension p. Let Θ be an orthonormal $h \times p$ matrix that captures the common structure of the m weight vectors. We assume that each weight vector can be decomposed into two parts: one part that models the particular i-th classification problem and one part that models the common structure

$$\mathbf{u}_i = \mathbf{w}_i + \Theta^T \mathbf{v}_i. \quad (2)$$

The parameters $[\{\mathbf{w}_i, \mathbf{v}_i\}, \Theta]$ can be learned by *joint empirical risk minimization*, i.e., by minimizing the joint empirical loss of the m problems on the training data

$$\sum_{l=1}^{m} \left(\frac{1}{n} \sum_{i=1}^{n} L\left(\left(\mathbf{w}_l + \Theta^T \mathbf{v}_l\right)^T \mathbf{X}_i^l, Y_i^l \right) + \lambda \left|\left|\mathbf{w}_l\right|\right|^2 \right). \quad (3)$$

The key observation in ASO is that the problems used to find Θ do not have to be same as the *target problems* that we ultimately want to solve. Instead, we can automatically create *auxiliary problems* for the sole purpose of learning a better Θ.

Let us assume that we have k target problems and m auxiliary problems. We can obtain an approximate solution to Equation 3 by performing the following algorithm (Ando and Zhang, 2005):

1. Learn m linear classifiers $\mathbf{u}_i$ independently.
2. Let $U = [\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_m]$ be the $p \times m$ matrix formed from the m weight vectors.
3. Perform Singular Value Decomposition (SVD) on U: $U = V_1 D V_2^T$. The first h column vectors of V_1 are stored as rows of Θ.
4. Learn $\mathbf{w}_j$ and $\mathbf{v}_j$ for each of the target problems by minimizing the empirical risk:
$$\frac{1}{n} \sum_{i=1}^{n} L\left(\left(\mathbf{w}_j + \Theta^T \mathbf{v}_j\right)^T \mathbf{X}_i, Y_i \right) + \lambda \left|\left|\mathbf{w}_j\right|\right|^2.$$
5. The weight vector for the j-th target problem is:
$$\mathbf{u}_j = \mathbf{w}_j + \Theta^T \mathbf{v}_j.$$

5.2 ASO for Grammatical Error Correction

The key observation in our work is that the selection task on non-learner text is a highly informative *auxiliary problem* for the correction task on learner text. For example, a classifier that can predict the presence or absence of the preposition *on* can be helpful for correcting wrong uses of *on* in learner text, e.g., if the classifier's confidence for *on* is low but the writer used the preposition *on*, the writer might have made a mistake. As the auxiliary problems can be created automatically, we can leverage the power of very large corpora of non-learner text.

Let us assume a grammatical error correction task with m classes. For each class, we define a binary auxiliary problem. The feature space of the auxiliary problems is a restriction of the original feature space $\mathcal{X}$ to all features except the observed word: $\mathcal{X} \backslash \{X_{obs}\}$. The weight vectors of the auxiliary problems form the matrix U in Step 2 of the ASO algorithm from which we obtain Θ through SVD. Given Θ, we learn the vectors $\mathbf{w}_j$ and $\mathbf{v}_j$, $j = 1, \ldots, k$ from the annotated learner text using the complete feature space $\mathcal{X}$.

This can be seen as an instance of *transfer learning* (Pan and Yang, 2010), as the auxiliary problems are trained on data from a different domain (non-learner text) and have a slightly different feature space ($\mathcal{X} \backslash \{X_{obs}\}$). We note that our method is general and can be applied to any classification problem in GEC.

6 Experiments

6.1 Data Sets

The main corpus in our experiments is the *NUS Corpus of Learner English (NUCLE)*. The corpus consists of about 1,400 essays written by EFL/ESL university students on a wide range of topics, like environmental pollution or healthcare. It contains over one million words which are completely annotated with error tags and corrections. All annotations have been performed by professional English instructors. We use about 80% of the essays for training, 10% for development, and 10% for testing. We ensure that no sentences from the same essay appear in both the training and the test or development data. NUCLE is available to the community for research purposes.

On average, only 1.8% of the articles and 1.3% of the prepositions in NUCLE contain an error. This figure is considerably lower compared to other learner corpora (Leacock et al., 2010, Ch. 3) and shows that our writers have a relatively high proficiency of English. We argue that this makes the task considerably more difficult. Furthermore, to keep the task as realistic as possible, we do not filter the

test data in any way.

In addition to NUCLE, we use a subset of the New York Times section of the Gigaword corpus[1] and the Wall Street Journal section of the Penn Treebank (Marcus et al., 1993) for some experiments. We pre-process all corpora using the following tools: We use NLTK[2] for sentence splitting, OpenNLP[3] for POS tagging, YamCha (Kudo and Matsumoto, 2003) for chunking, the C&C tools (Clark and Curran, 2007) for CCG parsing and named entity recognition, and the Stanford parser (Klein and Manning, 2003a; Klein and Manning, 2003b) for constituency and dependency parsing.

6.2 Evaluation Metrics

For experiments on non-learner text, we report accuracy, which is defined as the number of correct predictions divided by the total number of test instances. For experiments on learner text, we report F_1-measure

$$F_1 = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$$

where precision is the number of suggested corrections that agree with the human annotator divided by the total number of proposed corrections by the system, and recall is the number of suggested corrections that agree with the human annotator divided by the total number of errors annotated by the human annotator.

6.3 Selection Task Experiments on WSJ Test Data

The first set of experiments investigates predicting articles and prepositions in non-learner text. This primarily serves as a reference point for the correction task described in the next section. We train classifiers as described in Section 4 on the Gigaword corpus. We train with up to 10 million training instances, which corresponds to about 37 million words of text for articles and 112 million words of text for prepositions. The test instances are extracted from section 23 of the WSJ and no text from the WSJ is included in the training data. The observed article or preposition choice of the writer is the class we want to predict. Therefore, the article or preposition cannot be part of the input features. Our proposed ASO method is not included in these experiments, as it uses the observed article or preposition as a feature which is only applicable when testing on learner text.

6.4 Correction Task Experiments on NUCLE Test Data

The second set of experiments investigates the primary goal of this work: to automatically correct grammatical errors in learner text. The test instances are extracted from NUCLE. In contrast to the previous selection task, the observed word choice of the writer can be different from the correct class and the observed word is available during testing. We investigate two different baselines and our ASO method.

The first baseline is a classifier trained on the Gigaword corpus in the same way as described in the selection task experiment. We use a simple thresholding strategy to make use of the observed word during testing. The system only flags an error if the difference between the classifier's confidence for its first choice and the confidence for the observed word is higher than a threshold t. The threshold parameter t is tuned on the NUCLE development data for each feature set. In our experiments, the value for t is between 0.7 and 1.2.

The second baseline is a classifier trained on NUCLE. The classifier is trained in the same way as the Gigaword model, except that the observed word choice of the writer is included as a feature. The correct class during training is the correction provided by the human annotator. As the observed word is part of the features, this model does not need an extra thresholding step. Indeed, we found that thresholding is harmful in this case. During training, the instances that do not contain an error greatly outnumber the instances that do contain an error. To reduce this imbalance, we keep all instances that contain an error and retain a random sample of q percent of the instances that do not contain an error. The undersample parameter q is tuned on the NUCLE development data for each data set. In our experiments, the value for q is between 20% and 40%.

Our ASO method is trained in the following way. We create binary auxiliary problems for articles or prepositions, i.e., there are 3 auxiliary problems for

[1] LDC2009T13

[2] www.nltk.org

[3] opennlp.sourceforge.net

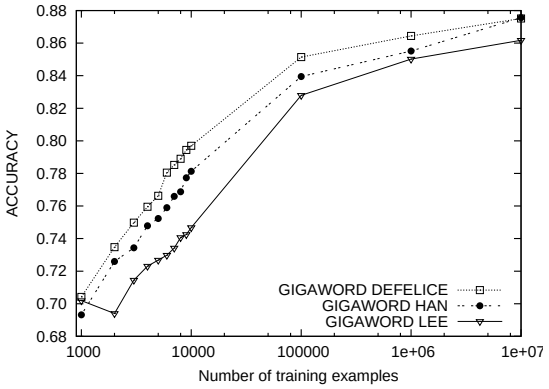
articles and 36 auxiliary problems for prepositions. We train the classifiers for the auxiliary problems on the complete 10 million instances from Gigaword in the same ways as in the selection task experiment. The weight vectors of the auxiliary problems form the matrix U. We perform SVD to get $U = V_1 D V_2^T$. We keep all columns of V_1 to form Θ. The target problems are again binary classification problems for each article or preposition, but this time trained on NUCLE. The observed word choice of the writer is included as a feature for the target problems. We again undersample the instances that do not contain an error and tune the parameter q on the NUCLE development data. The value for q is between 20% and 40%. No thresholding is applied.

We also experimented with a classifier that is trained on the concatenated data from NUCLE and Gigaword. This model always performed worse than the better of the individual baselines. The reason is that the two data sets have different feature spaces which prevents simple concatenation of the training data. We therefore omit these results from the paper.

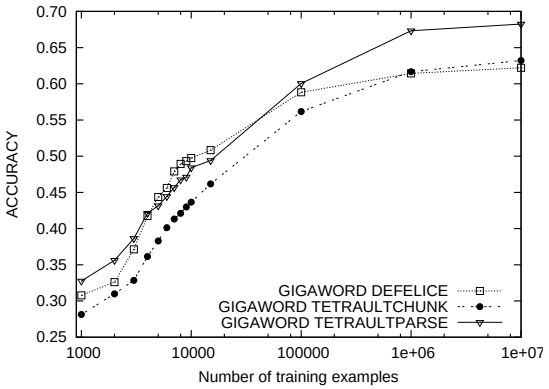
7 Results

The learning curves of the selection task experiments on WSJ test data are shown in Figure 1. The three curves in each plot correspond to different feature sets. Accuracy improves quickly in the beginning but improvements get smaller as the size of the training data increases. The best results are 87.56% for articles (Han) and 68.25% for prepositions (TetreaultParse). The best accuracy for articles is comparable to the best reported results of 87.70% (Lee, 2004) on this data set.

The learning curves of the correction task experiments on NUCLE test data are shown in Figure 2 and 3. Each sub-plot shows the curves of three models as described in the last section: ASO trained on NUCLE and Gigaword, the baseline classifier trained on NUCLE, and the baseline classifier trained on Gigaword. For ASO, the x-axis shows the number of target problem training instances. The first observation is that high accuracy for the selection task on non-learner text does not automatically entail high F_1-measure on learner text. We also note that feature sets with similar performance on non-learner text can show very different performance on



(a) Articles



(b) Prepositions

Figure 1: Accuracy for the selection task on WSJ test data.

learner text. The second observation is that training on annotated learner text can significantly improve performance. In three experiments (articles DeFelice, Han, prepositions DeFelice), the NUCLE model outperforms the Gigaword model trained on 10 million instances. Finally, the ASO models show the best results. In the experiments where the NUCLE models already perform better than the Gigaword baseline, ASO gives comparable or slightly better results (articles DeFelice, Han, Lee, prepositions DeFelice). In those experiments where neither baseline shows good performance (TetreaultChunk, TetreaultParse), ASO results in a large improvement over either baseline. The best results are 19.29% F_1-measure for articles (Han) and 11.15% F_1-measure for prepositions (TetreaultParse) achieved by the ASO model.

(a) DeFelice (b) TetreaultChunk (c) TetreaultParse

Figure 3: F_1-measure for the preposition correction task on NUCLE test data. Each plot shows ASO and two baselines for a particular feature set.

8 Analysis

In this section, we analyze the results in more detail and show examples from our test set for illustration.

Table 1 shows precision, recall, and F_1-measure for the best models in our experiments. ASO achieves a higher F_1-measure than either baseline. We use the sign-test with bootstrap re-sampling for statistical significance testing. The sign-test is a non-parametric test that makes fewer assumptions than parametric tests like the t-test. The improvements in F_1-measure of ASO over either baseline are statistically significant ($p < 0.001$) for both articles and prepositions.

The difficulty in GEC is that in many cases, more than one word choice can be correct. Even with a threshold, the Gigaword baseline model suggests too many corrections, because the model cannot make use of the observed word as a feature. This results in low precision. For example, the model replaces **as** with **by** in the sentence *"This group should be categorized **as the vulnerable group**"*, which is wrong.

Articles			
Model	**Prec**	**Rec**	**F_1**
Gigaword (Han)	10.33	**21.81**	14.02
NUCLE (Han)	**29.48**	12.91	17.96
ASO (Han)	26.44	15.18	**19.29**
Prepositions			
Model	**Prec**	**Rec**	**F_1**
Gigaword (TetreaultParse)	4.77	**14.81**	7.21
NUCLE (DeFelice)	13.84	5.55	7.92
ASO (TetreaultParse)	**18.30**	8.02	**11.15**

Table 1: Best results for the correction task on NUCLE test data. Improvements for ASO over either baseline are statistically significant ($p < 0.001$) for both tasks.

In contrast, the NUCLE model learns a bias towards the observed word and therefore achieves higher precision. However, the training data is

smaller and therefore recall is low as the model has not seen enough examples during training. This is especially true for prepositions which can occur in a large variety of contexts. For example, the preposition **in** should be **on** in the sentence *"... psychology had an impact **in** the way we process and manage technology"*. The phrase *"impact on the way"* does not appear in the NUCLE training data and the NUCLE baseline fails to detect the error.

The ASO model is able to take advantage of both the annotated learner text and the large non-learner text, thus achieving overall high F_1-measure. The phrase *"impact on the way"*, for example, appears many times in the Gigaword training data. With the common structure learned from the auxiliary problems, the ASO model successfully finds and corrects this mistake.

8.1 Manual Evaluation

We carried out a manual evaluation of the best ASO models and compared their output with two commercial grammar checking software packages which we call *System A* and *System B*. We randomly sampled 1000 test instances for articles and 2000 test instances for prepositions and manually categorized each test instance into one of the following categories: *(1) Correct* means that both human and system flag an error and suggest the same correction. If the system's correction differs from the human but is equally acceptable, it is considered *(2) Both Ok*. If the system identifies an error but fails to correct it, we consider it *(3) Both Wrong*, as both the writer and the system are wrong. *(4) Other Error* means that the system's correction does not result in a grammatical sentence because of another grammatical error that is outside the scope of article or preposition errors, e.g., a noun number error as in *"all **the** dog"*. If the system corrupts a previously correct sentence it is a *(5) False Flag*. If the human flags an error but the system does not, it is a *(6) Miss*. *(7) No Flag* means that neither the human annotator nor the system flags an error. We calculate precision by dividing the count of category (1) by the sum of counts of categories (1), (3), and (5), and recall by dividing the count of category (1) by the sum of counts of categories (1), (3), and (6). The results are shown in Table 2. Our ASO method outperforms both commercial software packages. Our evaluation shows that even commercial software packages achieve low F_1-measure for article and preposition errors, which confirms the difficulty of these tasks.

Articles			
	ASO	**System A**	**System B**
(1) Correct	4	1	1
(2) Both Ok	16	12	18
(3) Both Wrong	0	1	0
(4) Other Error	1	0	0
(5) False Flag	1	0	4
(6) Miss	3	5	6
(7) No Flag	975	981	971
Precision	**80.00**	50.00	20.00
Recall	**57.14**	14.28	14.28
F_1	**66.67**	22.21	16.67
Prepositions			
	ASO	**System A**	**System B**
(1) Correct	3	3	0
(2) Both Ok	35	39	24
(3) Both Wrong	0	2	0
(4) Other Error	0	0	0
(5) False Flag	5	11	1
(6) Miss	12	11	15
(7) No Flag	1945	1934	1960
Precision	**37.50**	18.75	0.00
Recall	**20.00**	18.75	0.00
F_1	**26.09**	18.75	0.00

Table 2: Manual evaluation and comparison with commercial grammar checking software.

9 Conclusion

We have presented a novel approach to grammatical error correction based on Alternating Structure Optimization. We have introduced the NUS Corpus of Learner English (NUCLE), a fully annotated corpus of learner text. Our experiments for article and preposition errors show the advantage of our ASO approach over two baseline methods. Our ASO approach also outperforms two commercial grammar checking software packages in a manual evaluation.

Algorithm Selection and Model Adaptation for ESL Correction Tasks

Alla Rozovskaya and Dan Roth

Abstract

We consider the problem of correcting errors made by English as a Second Language (ESL) writers and address two issues that are essential to making progress in ESL error correction - algorithm selection and model adaptation to the first language of the ESL learner.

A variety of learning algorithms have been applied to correct ESL mistakes, but often comparisons were made between incomparable data sets. We conduct an extensive, fair comparison of four popular learning methods for the task, reversing conclusions from earlier evaluations. Our results hold for different training sets, genres, and feature sets.

A second key issue in ESL error correction is the adaptation of a model to the first language of the writer. Errors made by non-native speakers exhibit certain regularities and, as we show, models perform much better when they use knowledge about error patterns of the non-native writers. We propose a novel way to adapt a learned algorithm to the first language of the writer that is both cheaper to implement and performs better than other adaptation methods.

1 Introduction

There has been a lot of recent work on correcting writing mistakes made by English as a Second Language (ESL) learners (Izumi et al., 2003; Eeg-Olofsson and Knuttson, 2003; Han et al., 2006; Felice and Pulman, 2008; Gamon et al., 2008; Tetreault and Chodorow, 2008; Elghaari et al., 2010; Tetreault et al., 2010; Gamon, 2010; Rozovskaya and Roth, 2010c). Most of this work has focused on correcting mistakes in article and preposition usage, which are some of the most common error types among non-native writers of English (Dalgish, 1985; Bitchener et al., 2005; Leacock et al., 2010). Examples below illustrate some of these errors:

1. "They listen to *None*/the* lecture carefully."
2. "He is an engineer with a passion *to*/for* what he does."

In (1) the definite article is incorrectly omitted. In (2), the writer uses an incorrect preposition.

Approaches to correcting preposition and article mistakes have adopted the methods of the *context-sensitive spelling correction task*, which addresses the problem of correcting spelling mistakes that result in legitimate words, such as confusing *their* and *there* (Carlson et al., 2001; Golding and Roth, 1999). A *candidate set* or a *confusion set* is defined that specifies a list of confusable words, e.g., {*their, there*}. Each occurrence of a confusable word in text is represented as a vector of features derived from a context window around the target, e.g., words and part-of-speech tags. A classifier is trained on text assumed to be error-free. At decision time, for each word in text, e.g. *there*, the classifier predicts the most likely candidate from the corresponding confusion set {*their, there*}.

Models for correcting article and preposition errors are similarly trained on error-free native English text, where the confusion set includes all articles or prepositions (Izumi et al., 2003; Eeg-Olofsson and Knuttson, 2003; Han et al., 2006; Felice and Pulman, 2008; Gamon et al., 2008; Tetreault and Chodorow, 2008; Tetreault et al., 2010).

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 924–933,
Portland, Oregon, June 19-24, 2011.

Although the choice of a particular learning algorithm differs, with the exception of decision trees (Gamon et al., 2008), all algorithms used are linear learning algorithms, some discriminative (Han et al., 2006; Felice and Pulman, 2008; Tetreault and Chodorow, 2008; Rozovskaya and Roth, 2010c; Rozovskaya and Roth, 2010b), some probabilistic (Gamon et al., 2008; Gamon, 2010), or "counting" (Bergsma et al., 2009; Elghaari et al., 2010).

While model comparison has not been the goal of the earlier studies, it is quite common to compare systems, even when they are trained on different data sets and use different features. Furthermore, since there is no shared ESL data set, systems are also evaluated on data from different ESL sources or even on native data. Several conclusions have been made when comparing systems developed for ESL correction tasks. A *language model* was found to outperform a *maximum entropy classifier* (Gamon, 2010). However, the language model was trained on the Gigaword corpus, $17 \cdot 10^9$ words (Linguistic Data Consortium, 2003), a corpus several orders of magnitude larger than the corpus used to train the classifier. Similarly, web-based models built on Google Web1T 5-gram Corpus (Bergsma et al., 2009) achieve better results when compared to a maximum entropy model that uses a corpus $10,000$ times smaller (Chodorow et al., 2007)[1].

In this work, we compare four popular learning methods applied to the problem of correcting preposition and article errors and evaluate on a common ESL data set. We compare two probabilistic approaches – *Naïve Bayes* and *language modeling*; a discriminative algorithm *Averaged Perceptron*; and a count-based method *SumLM* (Bergsma et al., 2009), which, as we show, is very similar to Naïve Bayes, but with a different free coefficient. We train our models on data from several sources, varying training sizes and feature sets, and show that there are significant differences in the performance of these algorithms. Contrary to previous results (Bergsma et al., 2009; Gamon, 2010), we find that when trained on the same data with the same features, Averaged Perceptron achieves the best performance, followed by Naïve Bayes, then the language model, and finally the count-based approach. Our results hold for training sets of different sizes, genres, and feature sets. We also explain the performance differences from the perspective of each algorithm.

The second important question that we address is that of adapting the decision to the source language of the writer. Errors made by non-native speakers exhibit certain regularities. Adapting a model so that it takes into consideration the specific error patterns of the non-native writers was shown to be extremely helpful in the context of discriminative classifiers (Rozovskaya and Roth, 2010c; Rozovskaya and Roth, 2010b). However, this method requires generating new training data and training a separate classifier for each source language. Our key contribution here is a novel, simple, and elegant adaptation method within the framework of the Naïve Bayes algorithm, which yields even greater performance gains. Specifically, we show how the error patterns of the non-native writers can be viewed as *a different distribution on candidate priors* in the confusion set. Following this observation, we train Naïve Bayes in a traditional way, regardless of the source language of the writer, and then, only at decision time, change the prior probabilities of the model from the ones observed in the native training data to the ones corresponding to error patterns in the non-native writer's source language (Section 4). A related idea has been applied in Word Sense Disambiguation to adjust the model priors to a new domain with different sense distributions (Chan and Ng, 2005).

The paper has two main contributions. First, we conduct a fair comparison of four learning algorithms and show that the discriminative approach Averaged Perceptron is the best performing model (Sec. 3). Our results do not support earlier conclusions with respect to the performance of count-based models (Bergsma et al., 2009) and language models (Gamon, 2010). In fact, we show that SumLM is comparable to Averaged Perceptron trained with a *10 times* smaller corpus, and language model is comparable to Averaged Perceptron trained with a *2 times* smaller corpus.

The second, and most significant, of our contributions is a novel way to adapt a model to the source language of the writer, *without re-training the model* (Sec. 4). As we show, adapting to the source language of the writer provides significant performance improvement, and our new method also performs

[1] These two models also use different features.

better than previous, more complicated methods.

Section 2 presents the theoretical component of the linear learning framework. In Section 3, we describe the experiments, which compare the four learning models. Section 4 presents the key result of this work, a novel method of adapting the model to the source language of the learner.

2 The Models

The standard approach to preposition correction is to cast the problem as a multi-class classification task and train a classifier on features defined on the surrounding context[2]. The model selects the most likely candidate from the confusion set, where the set of candidates includes the top n most frequent English prepositions. Our confusion set includes the top ten prepositions[3]: $ConfSet = \{$*on, from, for, of, about, to, at, in, with, by*$\}$. We use p to refer to a candidate preposition from $ConfSet$.

Let *preposition context* denote the preposition and the window around it. For instance, "a passion *to* what he" is a context for window size 2. We use three feature sets, varying window size from 2 to 4 words on each side (see Table 1). All feature sets consist of word n-grams of various lengths spanning p and all the features are of the form $s^{-k}ps^{+m}$, where s^{-k} and s^{+m} denote k words before and m words after p; we show two 3-gram features for illustration:

1. a passion *p*
2. passion *p* what

We implement four linear learning models: the discriminative method *Averaged Perceptron* (AP); two probabilistic methods – *a language model* (LM) and *Naïve Bayes* (NB); and a "counting" method *SumLM* (Bergsma et al., 2009).

Each model produces a score for a candidate in the confusion set. Since all of the models are linear, the hypotheses generated by the algorithms differ only in the weights they assign to the features

[2]We also report one experiment on the article correction task. We take the preposition correction task as an example; the article case is treated in the same way.

[3]This set of prepositions is also considered in other works, e.g. (Rozovskaya and Roth, 2010b). The usage of the ten most frequent prepositions accounts for 82% of all preposition errors (Leacock et al., 2010).

Feature set	Preposition context	N-gram lengths
Win2	a passion [to] what he	2,3,4
Win3	with a passion [to] what he does	2,3,4
Win4	engineer with a passion [to] what he does .	2,3,4,5

Table 1: **Description of the three feature sets** used in the experiments. All feature sets consist of word n-grams of various lengths spanning the preposition and vary by n-gram length and window size.

Method	Free Coefficient	Feature weights
AP	bias parameter	mistake-driven
LM	$\lambda \cdot prior(p)$	$\sum_{v_l \circ v_r} \lambda_{v_r} \cdot log(P(u\|v_r))$
NB	$log(prior(p))$	$log(P(f\|p))$
SumLM	$\|F(S,p)\| \cdot log(C(p))$	$log(P(f\|p))$

Table 2: **Summary of the learning methods**. $C(p)$ denotes the number of times preposition p occurred in training. λ is a smoothing parameter, u is the rightmost word in f, $v_l \circ v_r$ denotes all concatenations of substrings v_l and v_r of feature f without u.

(Roth, 1998; Roth, 1999). Thus a score computed by each of the models for a preposition p in the context S can be expressed as follows:

$$g(S,p) = C(p) + \sum_{f \in F(S,p)} w_a(f), \qquad (1)$$

where $F(S,p)$ is the set of features active in context S relative to preposition p, $w_a(f)$ is the weight algorithm a assigns to feature $f \in F$, and $C(p)$ is a free coefficient. Predictions are made using the winner-take-all approach: $argmax_p g(S,p)$. The algorithms make use of the same feature set F and differ only by how the weights $w_a(f)$ and $C(p)$ are computed. Below we explain how the weights are determined in each method. Table 2 summarizes the four approaches.

2.1 Averaged Perceptron

Discriminative classifiers represent the most common learning paradigm in error correction. AP (Freund and Schapire, 1999) is a discriminative mistake-driven online learning algorithm. It maintains a vector of feature weights w and processes one training example at a time, updating w if the current weight assignment makes a mistake on the training example. In the case of AP, the $C(p)$ coefficient refers to the bias parameter (see Table 2).

We use the regularized version of AP in Learning Based Java[4] (LBJ, (Rizzolo and Roth, 2007)). While classical Perceptron comes with a generalization bound related to the margin of the data, Averaged Perceptron also comes with a PAC-like generalization bound (Freund and Schapire, 1999). This linear learning algorithm is known, both theoretically and experimentally, to be among the best linear learning approaches and is competitive with SVM and Logistic Regression, while being more efficient in training. It also has been shown to produce state-of-the-art results on many natural language applications (Punyakanok et al., 2008).

2.2 Language Modeling

Given a feature $f = s^{-k}ps^{+m}$, let u denote the rightmost word in f and $v_l \circ v_r$ denote all concatenations of substrings v_l and v_r of feature f without u. The language model computes several probabilities of the form $P(u|v_r)$. If f ="with a passion *p* what", then u ="what", and $v_r \in$ {"with a passion *p*", "a passion *p*", "passion *p*", "*p*" }. In practice, these probabilities are smoothed and replaced with their corresponding log values, and the total weight contribution of f to the scoring function of p is $\sum_{v_l \circ v_r} \lambda_{v_r} \cdot log(P(u|v_r))$. In addition, this scoring function has a coefficient that only depends on p: $C(p) = \lambda \cdot prior(p)$ (see Table 2). The *prior* probability of a candidate p is:

$$prior(p) = \frac{C(p)}{\sum_{q \in ConfSet} C(q)}, \qquad (2)$$

where $C(p)$ and $C(q)$ denote the number of times preposition p and q, respectively, occurred in the training data. We implement a count-based LM with Jelinek-Mercer linear interpolation as a smoothing method[5] (Chen and Goodman, 1996), where each n-gram length, from 1 to n, is associated with an interpolation smoothing weight λ. Weights are optimized on a held-out set of ESL sentences.

Win2 and Win3 features correspond to 4-gram LMs and Win4 to 5-gram LMs. Language models are trained with SRILM (Stolcke, 2002).

[4]LBJ can be downloaded from `http://cogcomp.cs.illinois.edu`.

[5]Unlike other LM methods, this approach allows us to train LMs on very large data sets. Although we found that backoff LMs may perform slightly better, they still maintain the same hierarchy in the order of algorithm performance.

2.3 Naïve Bayes

NB is another linear model, which is often hard to beat using more sophisticated approaches. NB architecture is also particularly well-suited for adapting the model to the first language of the writer (Section 4). Weights in NB are determined, similarly to LM, by the feature counts and the *prior* probability of each candidate p (Eq. (2)). For each candidate p, NB computes the joint probability of p and the feature space F, assuming that the features are conditionally independent given p:

$$\begin{aligned} g(S,p) &= log\{prior(p) \cdot \prod_{f \in F(S,p)} P(f|p)\} \\ &= log(prior(p)) + \\ &+ \sum_{f \in F(S,p)} log(P(f|p)) \qquad (3) \end{aligned}$$

NB weights and its free coefficient are also summarized in Table 2.

2.4 SumLM

For candidate p, SumLM (Bergsma et al., 2009)[6] produces a score by summing over the logs of all feature counts:

$$\begin{aligned} g(S,p) &= \sum_{f \in F(S,p)} log(C(f)) \\ &= \sum_{f \in F(S,p)} log(P(f|p)C(p)) \\ &= |F(S,p)|C(p) + \sum_{f \in F(S,p)} log(P(f|p)) \end{aligned}$$

where $C(f)$ denotes the number of times n-gram feature f was observed with p in training. It should be clear from equation 3 that SumLM is very similar to NB, with a different free coefficient (Table 2).

3 Comparison of Algorithms

3.1 Evaluation Data

We evaluate the models using a corpus of ESL essays, annotated[7] by native English speakers (Rozovskaya and Roth, 2010a). For each preposition

[6]SumLM is one of several related methods proposed in this work; its accuracy on the preposition selection task on native English data nearly matches the best model, SuperLM (73.7% vs. 75.4%), while being much simpler to implement.

[7]The annotation of the ESL corpus can be downloaded from `http://cogcomp.cs.illinois.edu`.

Source language	Prepositions		Articles	
	Total	Incorrect	Total	Incorrect
Chinese	953	144	1864	150
Czech	627	28	575	55
Italian	687	43	-	-
Russian	1210	85	2292	213
Spanish	708	52	-	-
All	4185	352	4731	418

Table 3: **Statistics on prepositions and articles in the ESL data.** Column *Incorrect* denotes the number of cases judged to be incorrect by the annotator.

(article) used incorrectly, the annotator indicated the correct choice. The data include sentences by speakers of five first languages. Table 3 shows statistics by the source language of the writer.

3.2 Training Corpora

We use two training corpora. The first corpus, *WikiNYT*, is a selection of texts from English Wikipedia and the New York Times section of the Gigaword corpus and contains 10^7 preposition contexts. We build models of 3 sizes[8]: 10^6, $5 \cdot 10^6$, and 10^7.

To experiment with larger data sets, we use the Google Web1T 5-gram Corpus, which is a collection of n-gram counts of length one to five over a corpus of 10^{12} words. The corpus contains $2.6 \cdot 10^{10}$ prepositions. We refer to this corpus as *GoogleWeb*.

We stress that *GoogleWeb* does not contain complete sentences, but only n-gram counts. Thus, we cannot generate training data for AP for feature sets Win3 and Win4: Since the algorithm does not assume feature independence, we need to have 7 and 9-word sequences, respectively, with a preposition in the middle (as shown in Table 1) and their corpus frequencies. The other three models can be evaluated with the n-gram counts available. For example, we compute NB scores by obtaining the count of each feature independently, e.g. the count for left context 5-gram "engineer with a passion p" and right context 5-gram "p what he does .", due to the conditional independence assumption that NB makes. On *GoogleWeb*, we train NB, SumLM, and LM with three feature sets: Win2, Win3, and Win4.

From *GoogleWeb*, we also generate a smaller training set of size 10^8: We use 5-grams with a preposition in the middle and generate a new count, proportional to the size of the smaller corpus[9]. For instance, a preposition 5-gram with a count of 2600 in *GoogleWeb*, will have a count of 10 in $GoogleWeb$-10^8.

3.3 Results

Our key results of the fair comparison of the four algorithms are shown in Fig. 1 and summarized in Table 4. The table shows that AP trained on $5 \cdot 10^6$ preposition contexts performs as well as NB trained on 10^7 (i.e., with twice as much data; the performance of LM trained on 10^7 contexts is better than that of AP trained with 10 times less data (10^6), but not as good as that of AP trained with half as much data ($5 \cdot 10^6$); AP outperforms SumLM, when the latter uses 10 times more data. Fig. 1 demonstrates the performance results reported in Table 4; it shows the behavior of different systems with respect to *precision* and *recall* on the error correction task. We generate the curves by varying the decision threshold on the confidence of the classifier (Carlson et al., 2001) and propose a correction only when the confidence of the classifier is above the threshold. A higher precision and a lower recall are obtained when the decision threshold is high, and vice versa.

Key results
$AP > NB > LM > SumLM$
$AP \sim 2 \cdot NB$
$5 \cdot AP > 10 \cdot LM > AP$
$AP > 10 \cdot SumLM$

Table 4: **Key results on the comparison of algorithms**. $2 \cdot NB$ refers to NB trained with twice as much data as AP; $10 \cdot LM$ refers to LM trained with 10 times more data as AP; $10 \cdot SumLM$ refers to $SumLM$ trained with 10 times more data as AP. These results are also shown in Fig. 1.

We now show a fair comparison of the four algorithms for different window sizes, training data and training sizes. Figure 2 compares the models trained on $WikiNYT$-10^7 corpus for Win4. AP is the superior model, followed by NB, then LM, and finally SumLM.

Results for other training sizes and feature[10] set

[8] *Training size* refers to the number of preposition contexts.

[9] Scaling down $GoogleWeb$ introduces some bias but we believe that it should not have an effect on our experiments.

[10] We have also experimented with additional POS-based features that are commonly used in these tasks and observed similar behavior.

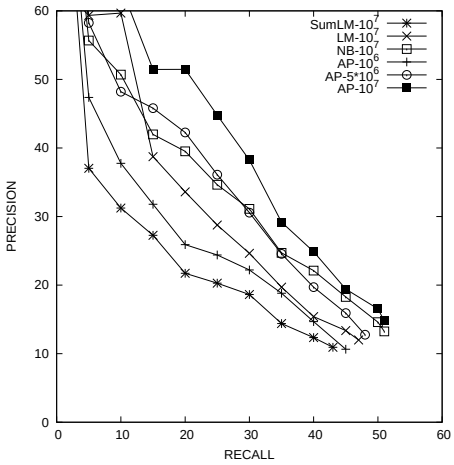

Figure 1: **Algorithm comparison across different training sizes.** (*WikiNYT, Win3*). AP (10^6 preposition contexts) performs as well as SumLM with 10 times more data, and LM requires at least twice as much data to achieve the performance of AP.

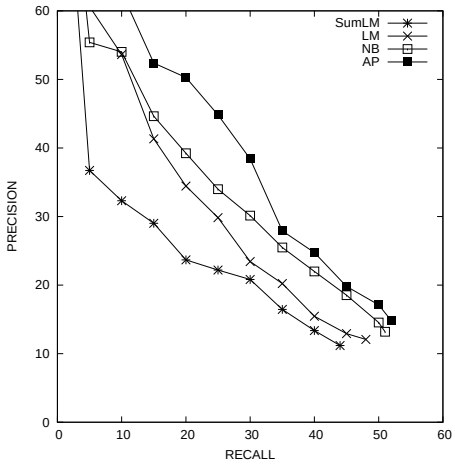

Figure 2: **Model Comparison for training data of the same size**: Performance of models for feature set *Win4* trained on $WikiNYT$-10^7.

configurations show similar behavior and are reported in Table 5, which provides model comparison in terms of *Average Area Under Curve* (AAUC, (Hanley and McNeil, 1983)). AAUC is a measure commonly used to generate a summary statistic and is computed here as an average precision value over 12 recall points (from 5 to 60):

$$AAUC = \frac{1}{12} \cdot \sum_{i=1}^{12} Precision(i \cdot 5)$$

The Table also shows results on the *article correction task*[11].

Training data	**Feature set**	**Performance** ($AAUC$)			
		AP	NB	LM	SumLM
$WikiNYT$-$5 \cdot 10^6$	$Win3$	**26**	22	20	13
$WikiNYT$-10^7	$Win4$	**33**	28	24	16
$GoogleWeb$-10^8	$Win2$	**30**	29	28	15
$GoogleWeb$	$Win4$	-	**44**	41	32
Article $WikiNYT$-$5 \cdot 10^6$	$Win3$	**40**	39	-	30

Table 5: **Performance Comparison** of the four algorithms for different training data, training sizes, and window sizes. Each row shows results for training data of the same size. The last row shows performance on the *article correction* task. All other results are for prepositions.

[11]We do not evaluate the LM approach on the article correction task, since with LM it is difficult to handle missing article errors, one of the most common error types for articles, but the expectation is that it will behave as it does for prepositions.

3.3.1 Effects of Window Size

We found that expanding window size from 2 to 3 is helpful for all of the models, but expanding window to 4 is only helpful for the models trained on *GoogleWeb* (Table 6). Compared to *Win3*, *Win4* has five additional 5-gram features. We look at the proportion of features in the ESL data that occurred in two corpora: $WikiNYT$-10^7 and *GoogleWeb* (Table 7). We observe that only 4% of test 5-grams occur in $WikiNYT$-10^7. This number goes up 7 times to 28% for *GoogleWeb*, which explains why increasing the window size is helpful for this model. By comparison, a set of native English sentences (different from the training data) has 50% more 4-grams and about 3 times more 5-grams, because ESL sentences often contain expressions not common for native speakers.

Training data	**Performance** ($AAUC$)		
	Win2	Win3	Win4
$GoogleWeb$	35	39	44

Table 6: **Effect of Window Size** in terms of $AAUC$. Performance improves, as the window increases.

4 Adapting to Writer's Source Language

In this section, we discuss adapting error correction systems to the first language of the writer. Non-native speakers make mistakes in a systematic manner, and errors often depend on the first language of the writer (Lee and Seneff, 2008; Rozovskaya and

Test	Train	N-gram length			
		2	3	4	5
ESL	$WikiNYT\text{-}10^7$	98%	66%	22%	4%
Native	$WikiNYT\text{-}10^7$	98%	67%	32%	13%
ESL	*GoogleWeb*	99%	92%	64%	28%
Native-*B09*	*GoogleWeb*	-	99%	93%	70%

Table 7: **Feature coverage for ESL and native data**. Percentage of test n-gram features that occurred in training. *Native* refers to data from Wikipedia and NYT. *B09* refers to statistics from Bergsma et al. (2009).

Roth, 2010a). For instance, a Chinese learner of English might say "congratulations *to* this achievement" instead of "congratulations *on* this achievement", while a Russian speaker might say "congratulations *with* this achievement".

A system performs much better when it makes use of knowledge about typical errors. When trained on annotated ESL data instead of native data, systems improve both precision and recall (Han et al., 2010; Gamon, 2010). Annotated data include both the writer's preposition and the intended (correct) one, and thus the knowledge about typical errors is made available to the system.

Another way to adapt a model to the first language is to generate in native training data artificial errors mimicking the typical errors of the non-native writers (Rozovskaya and Roth, 2010c; Rozovskaya and Roth, 2010b). Henceforth, we refer to this method, proposed within the discriminative framework AP, as *AP-adapted*. To determine typical mistakes, error statistics are collected on a small set of annotated ESL sentences. However, for the model to use these language-specific error statistics, a separate classifier for each source language needs to be trained.

We propose a novel adaptation method, which shows performance improvement over *AP-adapted*. Moreover, this method is much simpler to implement, since there is no need to train per source language; only one classifier is trained. The method relies on the observation that error regularities can be viewed as a *distribution on priors over the correction candidates*. Given a preposition *s* in text, the *prior* for candidate p is the probability that p is the correct preposition for *s*. If a model is trained on native data without adaptation to the source language, candidate priors correspond to the relative frequencies of the candidates in the native training data. More importantly, these priors remain the same regardless of the source language of the writer or of the preposition used in text. From the model's perspective, it means that a correction candidate, for example *to*, is equally likely given that the author's preposition is *for* or *from*, which is clearly incorrect and disagrees with the notion that errors are regular and language-dependent.

We use the annotated ESL data and define *adapted* candidate priors that are dependent on the author's preposition and the author's source language. Let *s* be a preposition appearing in text by a writer of source language L_1, and *p* a correction candidate. Then the *adapted* prior of *p* given *s* is:

$$prior(p, s, L_1) = \frac{C_{L_1}(s,p)}{C_{L_1}(s)},$$

where $C_{L_1}(s)$ denotes the number of times *s* appeared in the ESL data by L_1 writers, and $C_{L_1}(s,p)$ denotes the number of times *p* was the correct preposition when *s* was used by an L_1 writer.

Table 8 shows adapted candidate priors for two author's choices – when an ESL writer used *on* and *at* – based on the data from Chinese learners. One key distinction of the adapted priors is the high probability assigned to the author's preposition: the new prior for *on* given that it is also the preposition found in text is 0.70, vs. the 0.07 prior based on the native data. The adapted prior of preposition p, when p is used, is always high, because the majority of prepositions are used correctly. Higher probabilities are also assigned to those candidates that are most often observed as corrections for the author's preposition. For example, the adapted prior for *at* when the writer chose *on* is 0.10, since *on* is frequently incorrectly chosen instead of *at*.

To determine a mechanism to inject the adapted priors into a model, we note that while all of our models use priors in some way, NB architecture directly specifies the prior probability as one of its parameters (Sec. 2.3). We thus train NB in a traditional way, on native data, and then replace the prior component in Eq. (3) with the adapted prior, language and preposition dependent, to get the score for *p* of the *NB-adapted* model:

$$g(S,p) = log\{prior(p, s, L_1) \cdot \prod_{f \in F(S,p)} P(f|p)\}$$

Candidate	Global prior	Adapted prior			
		author's choice	prior	author's choice	prior
of	0.25	on	0.03	at	0.02
to	0.22	on	0.06	at	0.00
in	0.15	on	0.04	at	0.16
for	0.10	on	0.00	at	0.03
on	0.07	on	**0.70**	at	0.09
by	0.06	on	0.00	at	0.02
with	0.06	on	0.04	at	0.00
at	0.04	on	0.10	at	**0.75**
from	0.04	on	0.00	at	0.02
about	0.01	on	0.03	at	0.00

Table 8: **Examples of *adapted* candidate priors for two author's choices – *on* and *at* – based on the errors made by Chinese learners**. *Global prior* denotes the probability of the candidate in the standard model and is based on the relative frequency of the candidate in native training data. *Adapted priors* are dependent on the author's preposition and the author's first language. Adapted priors for the author's choice are very high. Other candidates are given higher priors if they often appear as corrections for the author's choice.

We stress that in the new method there is no need to train per source language, as with previous adaption methods. Only one model is trained, and only at decision time, we change the prior probabilities of the model. Also, while we need a lot of data to train the model, only one parameter depends on annotated data. Therefore, with rather small amounts of data, it is possible to get reasonably good estimates of these prior parameters.

In the experiments below, we compare four models: *AP*, *NB AP-adapted* and *NB-adapted*. *AP-adapted* is the adaptation through artificial errors and *NB-adapted* is the method proposed here. Both of the adapted models use the same error statistics in k-fold cross-validation (CV): We randomly partition the ESL data into k parts, with each part tested on the model that uses error statistics estimated on the remaining $k-1$ parts. We also remove all preposition errors that occurred only once (23% of all errors) to allow for a better evaluation of the adapted models. Although we observe similar behavior on all the data, the models especially benefit from the adapted priors when a particular error occurred more than once. Since the majority of errors are not due to chance, we focus on those errors that the writers will make repeatedly.

Fig. 3 shows the four models trained on $WikiNYT$-10^7. First, we note that the adapted

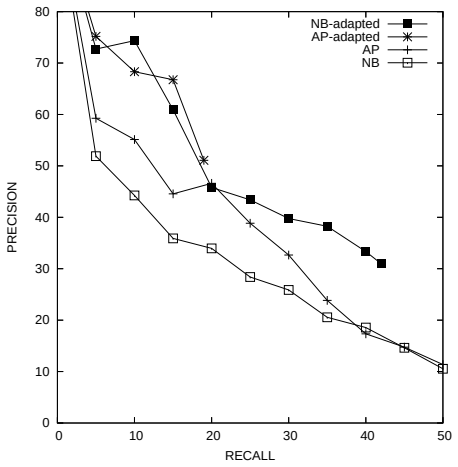

Figure 3: **Adapting to Writer's Source Language**. *NB-adapted* is the method proposed here. *AP-adapted* and *NB-adapted* results are obtained using 2-fold CV, with 50% of the ESL data used for estimating the new priors. All models are trained on $WikiNYT$-10^7.

models outperform their non-adapted counterparts with respect to precision. Second, for the recall points less than 20%, the adapted models obtain very similar precision values. This is interesting, especially because *NB* does not perform as well as *AP*, as we also showed in Sec. 3.3. Thus, *NB-adapted* not only improves over *NB*, but its gap compared to the latter is much wider than the gap between the AP-based systems. Finally, an important performance distinction between the two adapted models is the loss in recall exhibited by *AP-adapted* – its curve is shorter because *AP-adapted* is very conservative and does not propose many corrections. In contrast, *NB-adapted* succeeds in improving its precision over *NB* with almost no recall loss.

To evaluate the effect of the size of the data used to estimate the new priors, we compare the performance of *NB-adapted* models in three settings: *2-fold CV*, *10-fold CV*, and *Leave-One-Out* (Figure 4). In *2-fold CV*, priors are estimated on 50% of the ESL data, in *10-fold* on 90%, and in *Leave-One-Out* on all data but the testing example. Figure 4 shows the averaged results over 5 runs of CV for each setting. The model converges very quickly: there is almost no difference between *10-fold CV* and *Leave-One-Out*, which suggests that we can get a good estimate of the priors using just a little annotated data.

Table 9 compares *NB* and *NB-adapted* for two corpora: $WikiNYT$-10^7 and $GoogleWeb$. Since

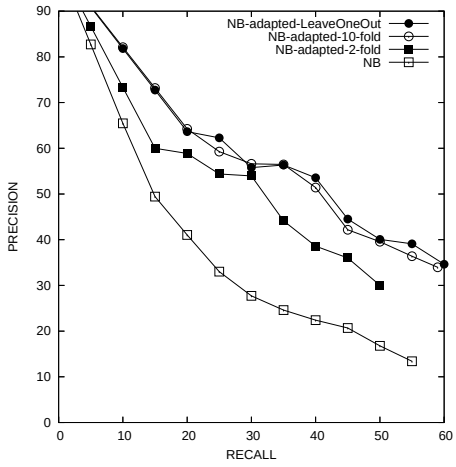

Figure 4: **How much data are needed to estimate adapted priors**. Comparison of *NB-adapted* models trained on *GoogleWeb* that use different amounts of data to estimate the new priors. In *2-fold CV*, priors are estimated on 50% of the data; in *10-fold* on 90% of the data; in *Leave-One-Out*, the new priors are based on all the data but the testing example.

$GoogleWeb$ is several orders of magnitude larger, the adapted model behaves better for this corpus.

So far, we have discussed performance in terms of precision and recall, but we can also discuss it in terms of accuracy, to see how well the algorithm is performing compared to the *baseline* on the task. Following Rozovskaya and Roth (2010c), we consider as the baseline the accuracy of the ESL data before applying the model[12], or *the percentage of prepositions used correctly* in the test data. From Table 3, the baseline is 93.44%[13]. Compared to this high baseline, NB trained on $WikiNYT$-10^7 achieves an accuracy of 93.54, and *NB-adapted* achieves an accuracy of 93.93[14].

Training data	Algorithms	
	NB	NB-adapted
$WikiNYT$-10^7	29	**53**
$GoogleWeb$	38	**62**

Table 9: **Adapting to writer's source language.** Results are reported in terms of $AAUC$. *NB-adapted* is the model with adapted priors. Results for *NB-adapted* are based on 10-fold CV.

[12]Note that this baseline is different from the *majority* baseline used in the preposition *selection* task, since here we have the author's preposition in text.

[13]This is the baseline after removing the singleton errors.

[14]We select the best accuracy among different values that can be achieved by varying the decision threshold.

5 Conclusion

We have addressed two important issues in ESL error correction, which are essential to making progress in this task. First, we presented an extensive, fair comparison of four popular linear learning models for the task and demonstrated that there are significant performance differences between the approaches. Since all of the algorithms presented here are linear, the only difference is in how they learn the weights. Our experiments demonstrated that the discriminative approach (AP) is able to generalize better than any of the other models. These results correct earlier conclusions, made with incomparable data sets. The model comparison was performed using two popular tasks – correcting errors in article and preposition usage – and we expect that our results will generalize to other ESL correction tasks.

The second, and most important, contribution of the paper is a novel method that allows one to adapt the learned model to the source language of the writer. We showed that error patterns can be viewed as a distribution on priors over the correction candidates and proposed a method of injecting the adapted priors into the learned model. In addition to performing much better than the previous approaches, this method is also very cheap to implement, since it does not require training a separate model for each source language, but adapts the system to the writer's language at decision time.

Abstract

Automated grammar correction techniques have seen improvement over the years, but there is still much room for increased performance. Current correction techniques mainly focus on identifying and correcting a specific type of error, such as verb form misuse or preposition misuse, which restricts the corrections to a limited scope. We introduce a novel technique, based on a noisy channel model, which can utilize the whole sentence context to determine proper corrections. We show how to use the EM algorithm to learn the parameters of the noise model, using only a data set of erroneous sentences, given the proper language model. This frees us from the burden of acquiring a large corpora of corrected sentences. We also present a cheap and efficient way to provide automated evaluation results for grammar corrections by using BLEU and METEOR, in contrast to the commonly used manual evaluations.

1 Introduction

The process of editing written text is performed by humans on a daily basis. Humans work by first identifying the writer's intent, and then transforming the text so that it is coherent and error free. They can read text with several spelling errors and grammatical errors and still easily identify what the author originally meant to write. Unfortunately, current computer systems are still far from such capabilities when it comes to the task of recognizing incorrect text input. Various approaches have been taken, but to date it seems that even many spell checkers such as Aspell do not take context into consideration, which prevents them from finding misspellings which have the same form as valid words. Also, current grammar correction systems are mostly rule-based, searching the text for defined types of rule violations in the English grammar. While this approach has had some success in finding various grammatical errors, it is confined to specifically defined errors.

In this paper, we approach this problem by modeling various types of human errors using a noisy channel model (Shannon, 1948). Correct sentences are produced by a predefined generative probabilistic model, and lesioned by the noise model. We learn the noise model parameters using an expectation-maximization (EM) approach (Dempster et al., 1977; Wu, 1983). Our model allows us to deduce the original intended sentence by looking for the the highest probability parses over the entire sentence, which leads to automated whole sentence spelling and grammar correction based on contextual information.

In Section 2, we discuss previous work, followed by an explanation of our model and its implementation in Sections 3 and 4. In Section 5 we present a novel technique for evaluating the task of automated grammar and spelling correction, along with the data set we collected for our experiments. Our experiment results and discussion are in Section 6. Section 7 concludes this paper.

2 Background

Much of the previous work in the domain of automated grammar correction has focused on identi-

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 934–944,
Portland, Oregon, June 19-24, 2011.

fying grammatical errors. Chodorow and Leacock (2000) used an unsupervised approach to identifying grammatical errors by looking for contextual cues in a ± 2 word window around a target word. To identify errors, they searched for cues which did not appear in the correct usage of words. Eeg-olofsson and Knutsson (2003) used rule-based methods to approach the problem of discovering preposition and determiner errors of L2 writers, and various classifier-based methods using Maximum Entropy models have also been proposed (Izumi et al., 2003; Tetreault and Chodorow, 2008; De Felice and Pulman, 2008). Some classifier-based methods can be used not only to identify errors, but also to determine suggestions for corrections by using the scores or probabilities from the classifiers for other possible words. While this is a plausible approach for grammar correction, there is one fundamental difference between this approach and the way humans edit. The output scores of classifiers do not take into account the observed erroneous word, changing the task of editing into a fill-in-the-blank selection task. In contrast, editing makes use of the writer's erroneous word which often encompasses information neccessary to correctly deduce the writer's intent.

Generation-based approaches to grammar correction have also been taken, such as Lee and Seneff (2006), where sentences are paraphrased into an over-generated word lattice, and then parsed to select the best rephrasing. As with the previously mentioned approaches, these approaches often have the disadvantage of ignoring the writer's selected word when used for error correction instead of just error detection.

Other work which relates to automated grammar correction has been done in the field of machine translation. Machine translation systems often generate output which is grammatically incorrect, and automated post-editing systems have been created to address this problem. For instance, when translating Japanese to English, the output sentence needs to be edited to include the correct articles, since the Japanese language does not contain articles. Knight and Chander (1994) address the problem of selecting the correct article for MT systems. These types of systems could also be used to facilitate grammar correction.

While grammar correction can be used on the output of MT systems, note that the task of grammar correction itself can also be thought of as a machine translation task, where we are trying to 'translate' a sentence from an 'incorrect grammar' language to a 'correct grammar' language. Under this idea, the use of statistical machine translation techniques to correct grammatical errors has also been explored. Brockett et al. (2006) uses phrasal SMT techniques to identify and correct mass noun errors of ESL students. Désilets and Hermet (2009) use a round-trip translation from L2 to L1 and back to L2 to correct errors using an SMT system, focusing on errors which link back to the writer's native language.

Despite the underlying commonality between the tasks of machine translation and grammar correction, there is a practical difference in that the field of grammar correction suffers from a lack of good quality parallel corpora. While machine translation has taken advantage of the plethora of translated documents and books, from which various corpora have been built, the field of grammar correction does not have this luxury. Annotated corpora of grammatical errors do exist, such as the NICT Japanese Learner of English corpus and the Chinese Learner English Corpus (Shichun and Huizhong, 2003), but the lack of definitive corpora often makes obtaining data for use in training models a task within itself, and often limits the approaches which can be taken.

Using classification or rule-based systems for grammatical error detection has proven to be successful to some extent, but many approaches are not sufficient for real-world automated grammar correction for various of reasons. First, as we have already mentioned, classification systems and generation-based systems do not make full use of the given data when trying to make a selection. This limits the system's ability to make well-informed edits which match the writer's original intent. Second, many of the systems start with the assumption that there is only one type of error. However, ESL students often make several combined mistakes in one sentence. These combined mistakes can throw off error detection/correction schemes which assume that the rest of the sentence is correct. For example, if a student erroneously writes 'much poeple' instead of 'many people', a system trying to correct 'many/much' errors may skip correction of much to many because it does not have any reference to the misspelled word

'poeple'. Thus there are advantages in looking at the sentence as a whole, and creating models which allow several types of errors to occur within the same sentence. We now present our model, which supports the addition of various types of errors into one combined model, and derives its response by using the whole of the observed sentence.

3 Base Model

Our noisy channel model consists of two main components, a base language model and a noise model. The base language model is a probabilistic language model which generates an 'error-free' sentence[1] with a given probability. The probabilistic noise model then takes this sentence and decides whether or not to make it erroneous by inserting various types of errors, such as spelling mistakes, article choice errors, wordform choice errors, etc., based on its parameters (see Figure 1 for example). Using this model, we can find the posterior probability $p(S_{orig}|S_{obs})$ using Bayes rule where S_{orig} is the original sentence created by our base language model, and S_{obs} is the observed erroneous sentence.

$$p(S_{orig}|S_{obs}) = \frac{p(S_{obs}|S_{orig})p(S_{orig})}{p(S_{obs})}$$

For the language model, we can use various known probabilistic models which already have defined methods for learning the parameters, such as n-gram models or PCFGs. For the noise model, we need some way to learn the parameters for the mistakes that a group of specified writers (such as Korean ESL students) make. We address this issue in Section 4.

Using this model, we can find the highest likelihood error-free sentence for an observed output sentence by tracing all possible paths from the language model through the noise model and ending in the observed sentence as output.

4 Implementation

To actually implement our model, we use a bigram model for the base language model, and various noise models which introduce spelling errors, article choice errors, preposition choice errors, etc.

[1] In reality, the language model will most likely produce sentences with errors as seen by humans, but from the modeling perspective, we assume that the language model is a perfect representation of the language for our task.

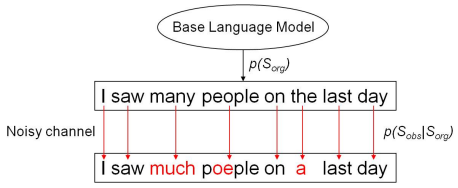

Figure 1: Example of noisy channel model

All models are implemented using weighted finite-state tranducers (wFST). For operations on the wFSTs, we use OpenFST (Allauzen et al., 2007), along with expectation semiring code supplied by Markus Dryer for Dreyer et al. (2008).

4.1 Base language model

The base language model is a bigram model implemented by using a weighted finite-state transducer (wFST). The model parameters are learned from the British National Corpus modified to use American English spellings with Kneser-Ney smoothing. To lower our memory usage, only bigrams whose words are found in the observed sentences, or are determined to be possible candidates for the correct words of the original sentence (due to the noise models) are used. While we use a bigram model here for simplicity, any probabilistic language model having a tractable intersection with wFSTs could be used. For the bigram model, each state in the wFST represents a bigram context, except the end state. The arcs of the wFST are set so that the weight is the bigram probability of the output word given the context specified by the from state, and the output word is a word of the vocabulary. Thus, given a set of n words in the vocabulary, the language model wFST had one start state, from which n arcs extended to each of their own context states. From each of these nodes, $n + 1$ arcs extend to each of the n context states and the end state. Thus the number of states in the language model is $n + 2$ and the number of arcs is $O(n^2)$.

4.2 Noise models

For our noise model, we created a weighted finite-state transducer (wFST) which accepts error-free input, and outputs erroneous sentences with a specified probability. To model various types of human errors, we created several different noise models and

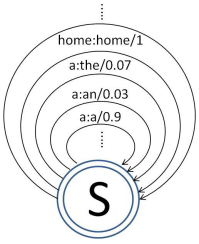

Figure 2: Example of noise model

composed them together, creating a layered noise model. The noise models we implement are spelling errors, article choice errors, preposition choice errors, and insertion errors, which we will explain in more detail later in this section.

The basic design of each noise wFST starts with an initial state, which is also the final state of the wFST. For each word found in the language model, an arc going from the initial state to itself is created, with the input and output values set as the word. These arcs model the case of no error being made. In addition to these arcs, arcs representing prediction errors are also inserted. For example, in the article choice error model, an arc is added for each possible (*input, output*) article pair, such as *a*:*an* for making the mistake of writing *an* instead of *a*. The weights of the arcs are the probabilities of introducing errors, given the input word from the language model. For example, the noise model shown in Figure 2 shows a noise model in which *a* will be written correctly with a probability of 0.9, and will be changed to *an* or *the* with probabilities 0.03 and 0.07, respectively. For this model to work correctly, the setting of the probabilities for each error is required. How this is done is explained in Section 4.3.

4.2.1 Spelling errors

The spelling error noise model accounts for spelling errors made by writers. For spelling errors, we allowed all spelling errors which were a Damerau-Levenshtein distance of 1 (Damerau, 1964; Levenshtein, 1966). While allowing a DL distance of 2 or higher may likely have better performance, the model was constrained to a distance of 1 due to memory constraints. We specified one parameter λ_n for each possible word length n. This parameter is the total probability of making a spelling error for a given word length. For each word length we distributed the probability of each possible spelling error equally. Thus for word length n, we have n deletion errors, $25n$ substitution errors, $n-1$ transposition errors, and $26(n+1)$ insertion errors, and the probability for each possible error is $\frac{\lambda_n}{n+25n+n-1+26(n+1)}$. We set the maximum word length for spelling errors to 22, giving us 22 parameters.

4.2.2 Article choice errors

The article choice error noise model simulates incorrect selection of articles. In this model we learn $n(n-1)$ parameters, one for each article pair. Since there are only 3 articles (*a, an, the*), we only have 6 parameters for this model.

4.2.3 Preposition choice errors

The preposition choice error noise model simulates incorrect selection of prepositions. We take the 12 most commonly misused prepositions by ESL writers (Gamon et al., 2009) and specify one parameter for each preposition pair, as we do in the article choice error noise model, giving us a total of 132 parameters.

4.2.4 Wordform choice errors

The wordform choice error noise model simulates choosing the incorrect wordform of a word. For example, choosing the incorrect tense of a verb (e.g. *went→go*), or the incorrect number marking on a noun or verb (e.g. *are→is*) would be a part of this model. This error model has one parameter for every number of possible inflections, up to a maximum of 12 inflections, giving us 12 parameters. The parameter is the total probability of choosing the wrong inflection of a word, and the probability is spread evenly between each possible inflection. We used CELEX (Baayen et al., 1995) to find all the possible wordforms of each observed word.

4.2.5 Word insertion errors

The word insertion error model simulates the addition of extraneous words to the original sentence. We create a list of words by combining the prepositions and articles found in the article choice and preposition choice errors. We assume that the words on the list have a probability of being inserted erroneously. There is a parameter for each word, which

is the probability of that word being inserted. Thus we have 15 parameters for this noise model.

4.3 Learning noise model parameters

To achieve maximum performance, we wish to learn the parameters of the noise models. If we had a large set of erroneous sentences, along with a hand-annotated list of the specific errors and their corrections, it would be possible to do some form of supervised learning to find the parameters. We looked at the NICT Japanese Learner of English (JLE) corpus, which is a corpus of transcripts of 1,300 Japanese learners' English oral proficiency interview. This corpus has been annotated using an error tagset (Izumi et al., 2004). However, because the JLE corpus is a set of transcribed sentences, it is in a different domain from our task. The Chinese Learner English Corpus (CLEC) contains erroneous sentences which have been annotated, but the CLEC corpus had too many manual errors, such as typos, as well as many incorrect annotations, making it very difficult to automate the processing. Many of the corrections themselves were also incorrect. We were not able to find of a set of annotated errors which fit our task, nor are we aware that such a set exists. Instead, we collected a large data set of possibly erroneous sentences from Korean ESL students (Section 5.1). Since these sentences are not annotated, we need to use an unsupervised learning method to learn our parameters.

To learn the parameters of the noise models, we assume that the collected sentences are random output of our model, and train our model using the EM algorithm. This was done by making use of the V-expectation semiring (Eisner, 2002). The V-expectation semiring is a semiring in which the weight is defined as $\mathbb{R}_{\geq 0} \times V$, where $\mathbb{R}$ can be used to keep track of the probability, and V is a vector which can be used to denote arc traversal counts or feature counts. The weight for each of the arcs in the noise models was set so that the real value was the probability and the vector V denoted which choice (having a specified error or not) was made by selecting the arc. We create a generative language-noise model by composing the language model wFST with the noise model wFSTs, as shown in Figure 3. By using the expectation semiring, we can keep track of the probability of each path going over an erroneous arc or non-erroneous arc.

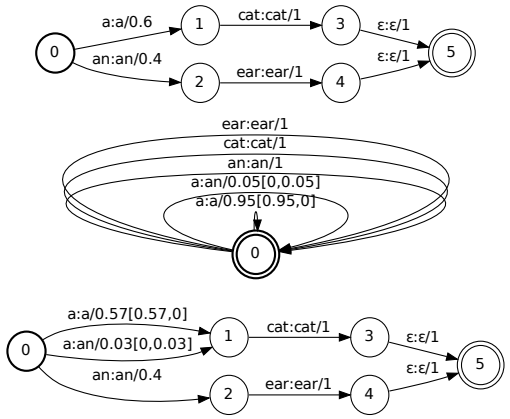

Figure 3: Example of language model (top) and noise model (middle) wFST composition. The vector of the V-expectation semiring weight is in brackets. The first value of the vector denotes no error being made on writing 'a' and the second value denotes the error of writing 'an' instead of 'a'

Once our model is set up for the E step using the initial parameters, we must compute the expected number of noise model arc traversals for use in calculating our new parameters. To do this, we need to find all possible paths resulting in the observed sentence as output, for each observed sentence. Then, for each possible path, we need to calculate the probability of the path given the output sentence, and get the expected counts of going over each erroneous and error-free arc to learn the parameters of the noise model. To find a wFST with just the possible paths for each observed sentence, we can compose the language-noise wFST with the observed sentence wFST. The observed sentence wFST is created in the following manner. Given an observed sentence, an initial state is created. For each word in the sentence, in the order appearing in the sentence, a new state is added, and an arc is created going from the previously added state to the newly added state. The new arc takes the observed word as input and also uses it as output. The weight/probability for each arc is set to 1. Composing the sentence wFST with the language-noise wFST has the effect of restricting the new wFST to only have sentences which output the observed sentence from the language-noise wFST. We now have a new wFST where all valid paths are the paths which can produce the observed

sentence. To find the total weight of all paths, we first change all input and output symbols into the empty string. Since all arcs in this wFST are epsilon arcs, we can use the epsilon-removal operation (Mohri, 2002), which will reduce the wFST to one state with no arcs. This operation combines the total weight of all paths into the final weight of the sole state, giving us the total expectation value for that sentence. By doing this for each sentence, and adding the expectation values for each sentence, we can easily compute the expectation step, from which we can find the maximizing parameters and update our parameters accordingly.

4.4 Finding the maximum likelihood correction

Once the parameters are learned, we can use our model to find the maximum likelihood error-free sentence. This is done by again creating the language model and noise model with the learned parameters, but this time we set the weights of the noise model to just the probabilities, using the log semiring, since we do not need to keep track of expected values. We also set the language model input for each arc to be the same word as the output, instead of using an empty string. Once again, we compose the language model with the noise models. We create a sentence wFST using the observed sentence we wish to correct, the same way the observed sentence wFST for training was created. This is now composed with the language-noise wFST. Now all we need to do is find the shortest path (when using minus-log probabilities) of the new wFST, and the input to that path will be our corrected sentence.

5 Experiment

We now present the data set and evaluation technique used for our experiments.

5.1 Data Set

To train our noise models, we collected around 25,000 essays comprised of 478,350 sentences written by Korean ESL students preparing for the TOEFL writing exam. These were collected from open web postings by Korean ESL students asking for advice on their writing samples. In order to automate the process, a program was written to download the posts, and discard the posts that were deemed too short to be TOEFL writing samples. Also discarded were the posts that had a "[re" or "re.." in the title. Next, all sentences containing Korean were removed, after which some characters were changed so that they were in ASCII form. The remaining text was separated into sentences solely by punctuation marks ., *!*, and *?*. This resulted in the 478,350 sentences stated above. Due to the process, some of the sentences collected are actually sentence fragments, where punctuation had been misused. For training and evaluation purposes, the data set was split into a test set with 504 randomly selected sentences, an evaluation set of 1017 randomly selected sentences, and a training set composed of the remaining sentences.

5.2 Evaluation technique

In the current literature, grammar correction tasks are often manually evaluated for each output correction, or evaluated by taking a set of proper sentences, artificially introducing some error, and seeing how well the algorithm fixes the error. Manual evaluation of automatic corrections may be the best method for getting a more detailed evaluation, but to do manual evaluation for every test output requires a large amount of human resources, in terms of both time and effort. In the case where artificial lesioning is introduced, the lesions may not always reflect the actual errors found in human data, and it is difficult to replicate the actual tendency of humans to make a variety of different mistakes in a single sentence. Thus, this method of evaluation, which may be suitable for evaluating the correction performance of specific grammatical errors, would not be fit for evaluating our model's overall performance. For evaluation of the given task, we have incorporated evaluation techniques based on current evaluation techniques used in machine translation, BLEU (Papineni et al., 2002) and METEOR (Lavie and Agarwal, 2007).

Machine translation addresses the problem of changing a sentence in one language to a sentence of another. The task of correcting erroneous sentences can also be thought of as translating a sentence from a given language A, to another language B, where A is a broken language, and B is the correct language. Under this context, we can apply machine translation evaluation techniques to evaluate the performance of our system. Our model's sentence correc-

tions can be thought of as the output translation to be evaluated. In order to use BLEU and METEOR, we need to have reference translations on which to score our output. As we have already explained in section 5.1, we have a collection of erroneous sentences, but no corrections. To obtain manually corrected sentences for evaluation, the test and evaluation set sentences and were put on Amazon Mechanical Turk as a correction task. Workers residing in the US were asked to manually correct the sentences in the two sets. Workers had a choice of selecting 'Impossible to understand', 'Correct sentence', or 'Incorrect sentence', and were asked to correct the sentences so no spelling errors, grammatical errors, or punctuation errors were present. Each sentence was given to 8 workers, giving us a set of 8 or fewer corrected sentences for each erroneous sentence. We asked workers not to completely rewrite the sentences, but to maintain the original structure as much as possible. Each hit was comprised of 6 sentences, and the reward for each hit was 10 cents. To ensure the quality of our manually corrected sentences, a native English speaker research assistant went over each of the 'corrected' sentences and marked them as correct or incorrect. We then removed all the incorrect 'corrections'.

Using our manually corrected reference sentences, we evaluate our model's correction performance using METEOR and BLEU. Since METEOR and BLEU are fully automated after we have our reference translations (manual corrections), we can run evaluation on our tests without any need for further manual input. While these two evaluation methods were created for machine translation, they also have the potential of being used in the field of grammar correction evaluation. One difference between machine translation and our task is that finding the right lemma is in itself something to be rewarded in MT, but is not sufficient for our task. In this respect, evaluation of grammar correction should be more strict. Thus, for METEOR, we used the 'exact' module for evaluation.

To validate our evaluation method, we ran a simple test by calculating the METEOR and BLEU scores for the observed sentences, and compared them with the scores for the manually corrected sentences, to test for an expected increase. The scores for each correction were evaluated using the set of corrected sentences minus the correction sentence being evaluated. For example, let us say we have the observed sentence o, and correction sentences c_1, c_2, c_3 and c_4 from Mechanical Turk. We run METEOR and BLEU on both o and c_1 using c_2, c_3 and c_4 as the reference set. We repeat the process for o and c_2, using c_1, c_3 and c_4 as the reference, and so on, until we have run METEOR and BLEU on all 4 correction sentences. With a set of 100 manually labeled sentences, the average METEOR score for the ESL sentences was 0.8327, whereas the corrected sentences had an average score of 0.9179. For BLEU, the average scores were 0.7540 and 0.8786, respectively, as shown in Table 1. Thus, we have confirmed that the corrected sentences score higher than the ESL sentence. It is also notable that finding corrections for the sentences is a much easier task than finding various correct translations, since the task of editing is much easier and can be done by a much larger set of qualified people.

	METEOR	BLEU
Original ESL sentences	0.8327	0.7540
Manual corrections	0.9179	0.8786

Table 1: BLEU and METEOR scores for ESL sentences vs manual corrections on 100 randomly chosen sentences

	METEOR	BLEU
Aspell	0.824144	0.719713
Spelling noise model	0.825001	0.722383

Table 2: Aspell vs Spelling noise model

6 Results

For our experiments, we used 2000 randomly selected sentences for training, and a set of 1017 annotated sentences for evaluation. We also set aside a set of 504 annotated sentences as a development set. With the 2000 sentence training, the performance generally converged after around 10 iterations of EM.

6.1 Comparison with Aspell

To check how well our spelling error noise model is doing, we compared the results of using the spelling error noise model with the output results of using the GNU Aspell 0.60.6 spelling checker. Since we

	METEOR	↑	↓	BLEU	↑	↓
ESL Baseline	0.821000			0.715634		
Spelling only	0.825001	49	5	0.722383	53	8
Spelling, Article	0.825437	55	6	0.723022	59	9
Spelling, Preposition	0.824157	52	17	0.720702	55	19
Spelling, Wordform	0.825654	81	25	0.723599	85	27
Spelling, Insertion	0.825041	52	5	0.722564	56	8

Table 3: Average evaluation scores for various noise models run on 1017 sentences, along with counts of sentences with increased (↑) and decreased (↓) scores. All improvements are significant by the binomial test at $p < 0.001$

are using METEOR and BLEU for our evaluation metric, we needed to get a set of corrected sentences for using Aspell. Aspell lists the suggested spelling corrections of misspelled words in a ranked order, so we replaced each misspelled word found by Aspell with the word with the highest rank (lowest score) for the Aspell corrections. One difference between Aspell and our model is that Aspell only corrects words which do not appear in the dictionary, while our method looks at all words, even those found in the dictionary. Thus our model can correct words which look correct by themselves, but seem to be incorrect due to the bigram context. Another difference is that Aspell has the capability to split words, whereas our model does not allow the insertion of spaces. A comparison of the scores is shown in Table 2. We can see that our model has better performance, due to better word selection, despite the advantage that Aspell has by using phonological information to find the correct word, and the disadvantage that our model is restricted to spellings which are within a Damerau-Levenstein distance of 1. This is due to the fact that our model is context-sensitive, and can use other information in addition to the misspelled word. For example, the sentence 'In contast, high prices of products would be the main reason for dislike.' was edited in Aspell by changing 'contast' to 'contest', while our model correctly selected 'contrast'. The sentence 'So i can reach the theater in ten minuets by foot' was not edited by Aspell, but our model changed 'minuets' to 'minutes'. Another difference that can be seen by looking through the results is that Aspell changes every word not found in the dictionary, while our algorithm allows words it has not seen by treating them as unknown tokens. Since we are using smoothing, these tokens are left in place if there is no other high probability bigram to take its place. This helps leave intact the proper nouns and words not in the vocabulary.

6.2 Noise model performance and output

Our next experiment was to test the performance of our model on various types of errors. Table 3 shows the BLEU and METEOR scores of our various error models, along with the number of sentences achieving improved and reduced scores. As we have already seen in section 6.1, the spelling error model increases the evaluation scores from the ESL baseline. Adding in the article choice error model and the word insertion error models in addition to the spelling error noise model increases the BLEU score performance of finding corrections. Upon observing the outputs of the corrections on the development set, we found that the corrections changing *a* to *an* were all correct. Changes between *a* and *the* were sometimes correct, and sometimes incorrect. For example, 'which makes me know a existence about' was changed to 'which makes me know *the* existence about', 'when I am in a trouble.' was changed to 'when I am in *the* trouble.', and 'many people could read a nonfiction books' was changed to 'many people could read *the* nonfiction books'. For the last correction, the manual corrections all changed the sentence to contain 'many people could read a nonfiction book', bringing down the evaluation score. Overall, the article corrections which were being made seemed to change the sentence for the better, or left it at the same quality.

The preposition choice error model decreased the performance of the system overall. Looking through the development set corrections, we found that many correct prepositions were being changed to incorrect prepositions. For example, in the sentence 'Distrust about desire between two have been growing in their

relationship.', *about* was changed to *of*, and in 'As time goes by, ...', *by* was changed to *on*. Since these changes were not found in the manual corrections, the scores were decreased.

For wordform errors, the BLEU and METEOR scores both increased. While the wordform choice noise model had the most sentences with increased scores, it also had the most sentences with decreased scores. Overall, it seems that to correct wordform errors, more context than just the preceding and following word are needed. For example, in the sentence 'There are a lot of a hundred dollar phones in the market.', *phones* was changed to *phone*. To infer which is correct, you would have to have access to the previous context 'a lot of'. Another example is '..., I prefer being indoors to going outside ...', where *going* was changed to *go*. These types of cases illustrate the restrictions of using a bigram model as the base language model.

The word insertion error model was restricted to articles and 12 prepositions, and thus did not make many changes, but was correct when it did. One thing to note is that since we are using a bigram model for the language model, the model itself is biased towards shorter sentences. Since we only included words which were needed when they were used, we did not run into problems with this bias. When we tried including a large set of commonly used words, we found that many of the words were being erased because of the bigrams models probabilistic preference for shorter sentences.

6.3 Limitations of the bigram language model

Browsing through the development set data, we found that many of our model's incorrect 'corrections' were the result of using a bigram model as our language model. For example, '.., I prefer being indoors to going outside in that...' was changed to '.., I prefer being indoors to *go* outside in that...'. From the bigram model, the probabilities $p(go \mid to)$ and $p(outside|go)$ are both higher than $p(going|to)$ and $p(outside \mid going)$, respectively. To infer that going is actually correct, we would need to know the previous context, that we are comparing 'being indoors' to 'going outside'. Unfortunately, since we are using a bigram model, this is not possible. These kind of errors are found throughout the corrections. It seems likely that making use of a language model which can keep track of this kind of information would increase the performance of the correction model by preventing these kinds of errors.

7 Conclusion and future work

We have introduced a novel way of finding grammar and spelling corrections, which uses the EM algorithm to train the parameters of our noisy channel approach. One of the benefits of this approach is that it does not require a parallel set of erroneous sentences and their corrections. Also, our model is not confined to a specific error, and various error models may be added on. For training our noise model, all that is required is finding erroneous data sets. Depending on which domain you are training on, this can also be quite feasible as we have shown by our collection of Korean ESL students' erroneous writing samples. Our data set could have been for ESL students of any native language, or could also be a data set of other groups such as young native English speakers, or the whole set of English speakers for grammar correction. Using only these data sets, we can train our noisy channel model, as we have shown using a bigram language model, and a wFST for our noise model. We have also shown how to use weighted finite-state transducers and the expectation semiring, as well as wFST algorithms implemented in OpenFST to train the model using EM. For evaluation, we have introduced a novel way of evaluating grammar corrections, using MT evaluation methods, which we have not seen in other grammar correction literature. The produced corrections show the restrictions of using a bigram language model. For future work, we plan to use a more accurate language model, and add more types of complex error models, such as word deletion and word ordering error models to improve performance and address other types of errors.

Acknowledgments

We are grateful to Randy West for his input and assistance, and to Markus Dreyer who provided us with his expectation semiring code. We would also like to thank the San Diego Supercomputer Center for use of their DASH high-performance computing system.

Abstract

Linking entities with knowledge base (entity linking) is a key issue in bridging the textual data with the structural knowledge base. Due to the name variation problem and the name ambiguity problem, the entity linking decisions are critically depending on the heterogenous knowledge of entities. In this paper, we propose a generative probabilistic model, called *entity-mention model*, which can leverage heterogenous entity knowledge (including *popularity knowledge*, *name knowledge* and *context knowledge*) for the entity linking task. In our model, each name mention to be linked is modeled as a sample generated through a three-step generative story, and the entity knowledge is encoded in the distribution of entities in document *P(e)*, the distribution of possible names of a specific entity *P(s|e)*, and the distribution of possible contexts of a specific entity *P(c|e)*. To find the referent entity of a name mention, our method combines the evidences from all the three distributions *P(e)*, *P(s|e)* and *P(c|e)*. Experimental results show that our method can significantly outperform the traditional methods.

1 Introduction

In recent years, due to the proliferation of knowledge-sharing communities like *Wikipedia* [1] and the many research efforts for the automated knowledge base population from Web like the *Read the Web*[2] project, more and more large-scale knowledge bases are available. These knowledge bases contain rich knowledge about the world's entities, their semantic properties, and the semantic relations between each other. One of the most notorious examples is *Wikipedia*: its 2010 English version contains more than 3 million entities and 20 million semantic relations. Bridging these knowledge bases with the textual data can facilitate many different tasks such as entity search, information extraction and text classification. For example, as shown in Figure 1, knowing the word *Jordan* in the document refers to a basketball player and the word *Bulls* refers to a NBA team would be helpful in classifying this document into the *Sport/Basketball* class.

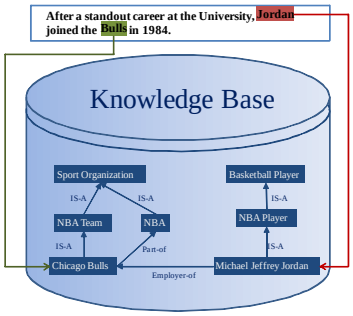

Figure 1. A Demo of Entity Linking

A key issue in bridging the knowledge base with the textual data is linking the entities in a document with their referents in a knowledge base, which is usually referred to as the *Entity Linking* task. Given a set of name mentions $M = \{m_1, m_2, \ldots, m_k\}$ contained in documents and a knowledge base *KB* containing a set of entities $E = \{e_1, e_2, \ldots, e_n\}$, an entity linking system is a function $\sigma : M \rightarrow E$ which links these name mentions to their referent entities in *KB*. For example, in Figure 1 an entity linking system should link the name mention *Jordan* to the entity *Michael Jeffrey Jordan* and the name mention *Bulls* to the entity *Chicago Bulls*.

The entity linking task, however, is not trivial due to the name variation problem and the name ambiguity problem. Name variation means that an entity can be mentioned in different ways such as *full name*, *aliases*, *acronyms* and *misspellings*. For

[1] http://www.wikipedia.org/
[2] http://rtw.ml.cmu.edu/

example, the entity *Michael Jeffrey Jordan* can be mentioned using more than 10 names, such as *Michael Jordan*, *MJ* and *Jordan*. The name ambiguity problem is related to the fact that a name may refer to different entities in different contexts. For example, the name *Bulls* can refer to more than 20 entities in Wikipedia, such as the NBA team *Chicago Bulls*, the football team *Belfast Bulls* and the cricket team *Queensland Bulls*.

Complicated by the name variation problem and the name ambiguity problem, the entity linking decisions are critically depending on the knowledge of entities (Li et al., 2004; Bunescu & Pasca, 2006; Cucerzan, 2007; Milne & Witten, 2008 and Fader et al., 2009). Based on the previous work, we found that the following three types of entity knowledge can provide critical evidence for the entity linking decisions:

- **Popularity Knowledge**. The popularity knowledge of entities tells us the likelihood of an entity appearing in a document. In entity linking, the entity popularity knowledge can provide a *priori* information to the possible referent entities of a name mention. For example, without any other information, the popularity knowledge can tell that in a Web page the name "*Michael Jordan*" will more likely refer to the notorious basketball player *Michael Jeffrey Jordan*, rather than the less popular Berkeley professor *Michael I. Jordan*.
- **Name Knowledge**. The name knowledge tells us the possible names of an entity and the likelihood of a name referring to a specific entity. For example, we would expect the name knowledge tells that both the "*MJ*" and "*Michael Jordan*" are possible names of the basketball player *Michael Jeffrey Jordan*, but the "*Michael Jordan*" has a larger likelihood. The name knowledge plays the central role in resolving the name variation problem, and is also helpful in resolving the name ambiguity problem.
- **Context Knowledge**. The context knowledge tells us the likelihood of an entity appearing in a specific context. For example, given the context "*__wins NBA MVP*", the name "*Michael Jordan*" should more likely refer to the basketball player *Michael Jeffrey Jordan* than the Berkeley professor *Michael I. Jordan*. Context knowledge is crucial in solving the name ambiguities.

Unfortunately, in entity linking system, the modeling and exploitation of these types of entity knowledge is not straightforward. As shown above, these types of knowledge are heterogenous, making it difficult to be incorporated in the same model. Furthermore, in most cases the knowledge of entities is not explicitly given, making it challenging to extract the entity knowledge from data.

To resolve the above problems, this paper proposes a generative probabilistic model, called *entity-mention model*, which can leverage the heterogeneous entity knowledge (including popularity knowledge, name knowledge and context knowledge) for the entity linking task. In our model, each name mention is modeled as a sample generated through a three-step generative story, where the entity knowledge is encoded in three distributions: the entity popularity knowledge is encoded in the distribution of entities in document $P(e)$, the entity name knowledge is encoded in the distribution of possible names of a specific entity $P(s|e)$, and the entity context knowledge is encoded in the distribution of possible contexts of a specific entity $P(c|e)$. The $P(e)$, $P(s|e)$ and $P(c|e)$ are respectively called the *entity popularity model*, the *entity name model* and the *entity context model*. To find the referent entity of a name mention, our method combines the evidences from all the three distributions $P(e)$, $P(s|e)$ and $P(c|e)$. We evaluate our method on both Wikipedia articles and general newswire documents. Experimental results show that our method can significantly improve the entity linking accuracy.

Our Contributions. Specifically, the main contributions of this paper are as follows:

1) We propose a new generative model, the *entity-mention model*, which can leverage heterogenous entity knowledge (including popularity knowledge, name knowledge and context knowledge) for the entity linking task;

2) By modeling the entity knowledge as probabilistic distributions, our model has a statistical foundation, making it different from most previous *ad hoc* approaches.

This paper is organized as follows. The entity-mention model is described in Section 2. The model estimation is described in Section 3. The experimental results are presented and discussed in Section 4. The related work is reviewed in Section 5. Finally we conclude this paper in Section 6.

2 The Generative Entity-Mention Model for Entity Linking

In this section we describe the generative entity-mention model. We first describe the generative story of our model, then formulate the model and show how to apply it to the entity linking task.

2.1 The Generative Story

In the entity mention model, each name mention is modeled as a generated sample. For demonstration, Figure 2 shows two examples of name mention generation. As shown in Figure 2, the generative story of a name mention is composed of three steps, which are detailed as follows:

(i) Firstly, the model chooses the referent entity *e* of the name mention from the given knowledge base, according to the distribution of entities in document *P(e)*. In Figure 2, the model chooses the entity "*Michael Jeffrey Jordan*" for the first name mention, and the entity "*Michael I. Jordan*" for the second name mention;

(ii) Secondly, the model outputs the name *s* of the name mention according to the distribution of possible names of the referent entity *P(s|e)*. In Figure 2, the model outputs "*Jordan*" as the name of the entity "*Michael Jeffrey Jordan*", and the "*Michael Jordan*" as the name of the entity "*Michael I. Jordan*";

(iii) Finally, the model outputs the context *c* of the name mention according to the distribution of possible contexts of the referent entity *P(c|e)*. In Figure 2, the model outputs the context "*joins Bulls in 1984*" for the first name mention, and the context "*is a professor in UC Berkeley*" for the second name mention.

2.2 Model

Based on the above generative story, the probability of a name mention *m* (its context is *c* and its name is *s*) referring to a specific entity *e* can be expressed as the following formula (here we assume that *s* and *c* are independent given *e*):

$$P(m,e) = P(s,c,e) = P(e)P(s\,|\,e)P(c\,|\,e)$$

This model incorporates the three types of entity knowledge we explained earlier: *P(e)* corresponds to the popularity knowledge, *P(s|e)* corresponds to the name knowledge and *P(c|e)* corresponds to the context knowledge.

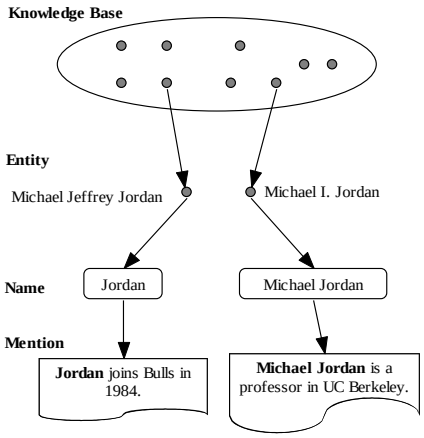

Figure 2. Two examples of name mention generation

Given a name mention *m*, to perform entity linking, we need to find the entity *e* which maximizes the probability *P(e|m)*. Then we can resolve the entity linking task as follows:

$$e = \arg\max_{e} \frac{P(m,e)}{P(m)} = \arg\max_{e} P(e)P(s\,|\,e)P(c\,|\,e)$$

Therefore, the main problem of entity linking is to estimate the three distributions *P(e)*, *P(s|e)* and *P(c|e)*, i.e., to extract the entity knowledge from data. In Section 3, we will show how to estimate these three distributions.

Candidate Selection. Because a knowledge base usually contains millions of entities, it is time-consuming to compute all *P(m,e)* scores between a name mention and all the entities contained in a knowledge base. To reduce the time required, the entity linking system employs a candidate selection process to filter out the impossible referent candidates of a name mention. In this paper, we adopt the candidate selection method of *NLPR_KBP* system (Han and Zhao, 2009), the main idea of which is first building a name-to-entity dictionary using the *redirect links*, *disambiguation pages*, *anchor texts* of Wikipedia, then the candidate entities of a name mention are selected by finding its name's corresponding entry in the dictionary.

3 Model Estimation

Section 2 shows that the entity mention model can decompose the entity linking task into the estimation of three distributions $P(e)$, $P(s|e)$ and $P(c|e)$. In this section, we describe the details of the estimation of these three distributions. We first

introduce the training data, then describe the estimation methods.

3.1 Training Data

In this paper, the training data of our model is a set of annotated name mentions $M = \{m_1, m_2, \ldots, m_n\}$. Each annotated name mention is a triple $m=\{s, e, c\}$, where s is the name, e is the referent entity and c is the context. For example, two annotated name mentions are as follows:

- *Jordan* | **Michael Jeffrey Jordan** | *… wins his first NBA MVP in 1991.*
- *NBA* | **National Basketball Association** | *… is the pre-eminent men's professional basketball league.*

In this paper, we focus on the task of linking entities with Wikipedia, even though the proposed method can be applied to other resources. We will only show how to get the training data from Wikipedia. In Wikipedia, a hyperlink between two articles is an annotated name mention (Milne & Witten, 2008): its anchor text is the name and its target article is the referent entity. For example, in following hyperlink (in Wiki syntax), the *NBA* is the name and the *National Basketball Association* is the referent entity.

"*He won his first* **[[National Basketball Association | NBA]]** *championship with the Bulls*"

Therefore, we can get the training data by collecting all annotated name mentions from the hyperlink data of Wikipedia. In total, we collected more than 23,000,000 annotated name mentions.

3.2 Entity Popularity Model

The distribution $P(e)$ encodes the popularity knowledge as a distribution of entities, i.e., the $P(e_1)$ should be larger than $P(e_2)$ if e_1 is more popular than e_2. For example, on the Web the *P(Michael Jeffrey Jordan)* should be higher than the *P(Michael I. Jordan)*. In this section, we estimate the distribution $P(e)$ using a model called *entity popularity model*.

Given a knowledge base *KB* which contains N entities, in its simplest form, we can assume that all entities have equal popularity, and the distribution $P(e)$ can be estimated as:

$$P(e) = 1/N$$

However, this does not reflect well the real situation because some entities are obviously more popular than others. To get a more precise estimation, we observed that a more popular entity usually appears more times than a less popular entity in a large text corpus, i.e., more name mentions refer to this entity. For example, in Wikipedia the NBA player *Michael Jeffrey Jordan* appears more than 10 times than the Berkeley professor *Michael I. Jordan*. Based on the above observation, our entity popularity model uses the entity frequencies in the name mention data set M to estimate the distribution $P(e)$ as follows:

$$P(e) = \frac{Count(e)+1}{|M|+N}$$

where $Count(e)$ is the count of the name mentions whose referent entity is e, and the $|M|$ is the total name mention size. The estimation is further smoothed using the simple *add-one smoothing* method for the zero probability problem. For illustration, Table 1 shows three selected entities' popularity.

Entity	Popularity
National Basketball Association	$1.73*10^{-5}$
Michael Jeffrey Jordan(NBA player)	$8.21*10^{-6}$
Michael I. Jordan(Berkeley Professor)	$7.50*10^{-8}$

Table 1. Three examples of entity popularity

3.3 Entity Name Model

The distribution $P(s|e)$ encodes the name knowledge of entities, i.e., for a specific entity e, its more frequently used name should be assigned a higher $P(s|e)$ value than the less frequently used name, and a zero $P(s|e)$ value should be assigned to those never used names. For instance, we would expect the *P*(*Michael Jordan*|*Michael Jeffrey Jordan*) to be high, *P*(*MJ*|*Michael Jeffrey Jordan*) to be relative high and *P*(*Michael I. Jordan*|*Michael Jeffrey Jordan*) to be zero.

Intuitively, the name model can be estimated by first collecting all (entity, name) pairs from the name mention data set, then using the maximum likelihood estimation:

$$P(s|e) = \frac{Count(e,s)}{\sum_s Count(e,s)}$$

where the $Count(e,s)$ is the count of the name mentions whose referent entity is e and name is s. However, this method does not work well because it cannot correctly deal with an unseen entity or an unseen name. For example, because the name "*MJ*" doesn't refer to the *Michael Jeffrey Jordan* in Wikipedia, the name model will not be able to identify "*MJ*" as a name of him, even "*MJ*" is a popular name of *Michael Jeffrey Jordan* on Web.

To better estimate the distribution *P(s|e)*, this paper proposes a much more generic model, called *entity name model*, which can capture the variations (including *full name*, *aliases*, *acronyms* and *misspellings*) of an entity's name using a statistical translation model. Given an entity's name *s*, our model assumes that it is a translation of this entity's full name *f* using the IBM model 1 (Brown, et al., 1993). Let Σ be the vocabulary containing all words may be used in the name of entities, the entity name model assumes that a word in Σ can be translated through the following four ways:

1) It is retained (translated into itself);
2) It is translated into its acronym;
3) It is omitted(translated into the word *NULL*);
4) It is translated into another word (misspelling or alias).

In this way, all name variations of an entity are captured as the possible translations of its full name. To illustrate, Figure 3 shows how the full name "*Michael Jeffrey Jordan*" can be transalted into its misspelling name "*Micheal Jordan*".

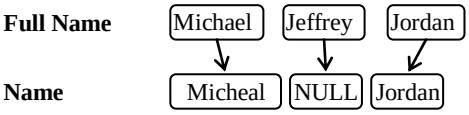

Figure 3. The translation from *Michael Jefferey Jordan* to *Micheal Jordan*

Based on the translation model, *P(s|e)* can be written as:

$$P(s \mid e) = \frac{\varepsilon}{(l_f + 1)^{l_s}} \prod_{j=1}^{l_s} \sum_{i=0}^{l_f} t(s_i \mid f_j)$$

where ε is a normalization factor, *f* is the full name of entity *e*, l_f is the length of *f*, l_s is the length of the name *s*, s_i the i^{th} word of *s*, f_j is the j^{th} word of *f* and $t(s_i|f_j)$ is the lexical translation probability which indicates the probability of a word f_j in the full name will be written as s_i in the output name.

Now the main problem is to estimate the lexical translation probability $t(s_i|f_j)$. In this paper, we first collect the (*name*, *entity full name*) pairs from all annotated name mentions, then get the lexical translation probability by feeding this data set into an IBM model 1 training system (we use the GIZA++ Toolkit[3]).

Table 2 shows several resulting lexical translation probabilities through the above process. We can see that the entity name model can capture the different name variations, such as the acronym (*Michael*→*M*), the misspelling (*Michael*→*Micheal*) and the omission (*St.* → *NULL*).

Full name word	Name word	Probability
Michael	*Michael*	*0.77*
Michael	*M*	*0.008*
Michael	*Micheal*	$2.64*10^{-4}$
Jordan	*Jordan*	*0.96*
Jordan	*J*	$6.13*10^{-4}$
St.	*NULL*	*0.14*
Sir	*NULL*	*0.02*

Table 2. Several lexical translation probabilities

3.4 Entity Context Model

The distribution *P(c|e)* encodes the context knowledge of entities, i.e., it will assign a high *P(c|e)* value if the entity *e* frequently appears in the context *c*, and will assign a low *P(c|e)* value if the entity *e* rarely appears in the context *c*. For example, given the following two contexts:

C1: *__wins NBA MVP.*

C2: *__is a researcher in machine learning.*

Then *P(C1|Michael Jeffrey Jordan)* should be high because the NBA player *Michael Jeffrey Jordan* often appears in C1 and the *P(C2|Michael Jeffrey Jordan)* should be extremely low because he rarely appears in C2.

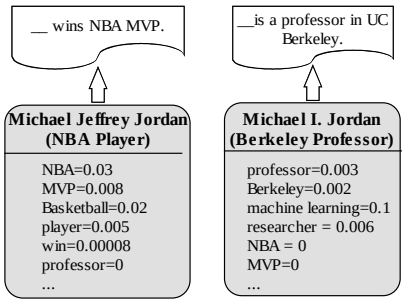

Figure 4. Two entity context models

To estimate the distribution *P(c|e)*, we propose a method based on language modeling, called *entity context model*. In our model, the context of each name mention *m* is the word window surrounding *m*, and the window size is set to 50 according to the experiments in (Pedersen et al., 2005). Specifically, the context knowledge of an entity *e* is encoded in an unigram language model:

$$M_e = \{P_e(t)\}$$

where $P_e(t)$ is the probability of the term *t* appearing in the context of *e*. In our model, the term may indicate a word, a named entity (extracted using the *Stanford Named Entity*

[3] http://fjoch.com/GIZA++.html

Recognizer[4]) or a Wikipedia concept (extracted using the method described in (Han and Zhao, 2010)). Figure 4 shows two entity context models and the contexts generated using them.

Now, given a context c containing n terms $t_1t_2...t_n$, the entity context model estimates the probability $P(c|e)$ as:

$$P(c \mid e) = P(t_1 t_2 ... t_n \mid M_e) = P_e(t_1)P_e(t_2)....P_e(t_n)$$

So the main problem is to estimate $P_e(t)$, the probability of a term t appearing in the context of the entity e.

Using the annotated name mention data set M, we can get the maximum likelihood estimation of $P_e(t)$ as follows:

$$P_{e\_ML}(t) = \frac{Count_e(t)}{\sum_t Count_e(t)}$$

where $Count_e(t)$ is the frequency of occurrences of a term t in the contexts of the name mentions whose referent entity is e.

Because an entity e's name mentions are usually not enough to support a robust estimation of $P_e(t)$ due to the sparse data problem (Chen and Goodman, 1999), we further smooth $P_e(t)$ using the Jelinek-Mercer smoothing method (Jelinek and Mercer, 1980):

$$P_e(t) = \lambda P_{e\_ML}(t) + (1-\lambda)P_g(t)$$

where $P_g(t)$ is a general language model which is estimated using the whole Wikipedia data, and the optimal value of λ is set to 0.2 through a learning process shown in Section 4.

3.5 The NIL Entity Problem

By estimating $P(e)$, $P(s|e)$ and $P(c|e)$, our method can effectively link a name mention to its referent entity contained in a knowledge base. Unfortunately, there is still the *NIL entity problem* (McNamee and Dang, 2009), i.e., the referent entity may not be contained in the given knowledge base. In this situation, the name mention should be linked to the NIL entity. Traditional methods usually resolve this problem with an additional classification step (Zheng et al. 2010): a classifier is trained to identify whether a name mention should be linked to the NIL entity.

Rather than employing an additional step, our entity mention model seamlessly takes into account the NIL entity problem. The start assumption of our solution is that "If a name mention refers to a specific entity, then the probability of this name mention is generated by the specific entity's model should be significantly higher than the probability it is generated by a general language model". Based on the above assumption, we first add a pseudo entity, the NIL entity, into the knowledge base and assume that the NIL entity generates a name mention according to the general language model P_g, without using any entity knowledge; then we treat the NIL entity in the same way as other entities: if the probability of a name mention is generated by the NIL entity is higher than all other entities in Knowledge base, we link the name mention to the NIL entity. Based on the above discussion, we compute the three probabilities of the NIL entity: $P(e)$, $P(s|e)$ and $P(c|e)$ as follows:

$$P(NIL) = \frac{1}{|M| + N}$$

$$P(s \mid NIL) = \prod_{t \in s} P_g(t)$$

$$P(c \mid NIL) = \prod_{t \in c} P_g(t)$$

4 Experiments

In this section, we assess the performance of our method and compare it with the traditional methods. In following, we first explain the experimental settings in Section 4.1, 4.2 and 4.3, then evaluate and discuss the results in Section 4.4.

4.1 Knowledge Base

In our experiments, we use the Jan. 30, 2010 English version of Wikipedia as the knowledge base, which contains over 3 million distinct entities.

4.2 Data Sets

To evaluate the entity linking performance, we adopted two data sets: the first is *WikiAmbi*, which is used to evaluate the performance on Wikipedia articles; the second is *TAC_KBP*, which is used to evaluate the performance on general newswire documents. In following, we describe these two data sets in detail.

WikiAmbi: The *WikiAmbi* data set contains 1000 annotated name mentions which are randomly selected from Wikipedia hyperlinks data set (as shown in Section 3.1, the hyperlinks between Wikipedia articles are manually annotated name mentions). In *WikiAmbi*, there were 207 distinct

[4] http://nlp.stanford.edu/software/CRF-NER.shtml

names and each name contains at least two possible referent entities (on average 6.7 candidate referent entities for each name) [5]. In our experiments, the name mentions contained in the *WikiAmbi* are removed from the training data.

TAC_KBP: The *TAC_KBP* is the standard data set used in the Entity Linking task of the TAC 2009 (McNamee and Dang, 2009). The *TAC_KBP* contains 3904 name mentions which are selected from English newswire articles. For each name mention, its referent entity in Wikipedia is manually annotated. Overall, 57% (2229 of 3904) name mentions's referent entities are missing in Wikipedia, so *TAC_KBP* is also suitable to evaluate the NIL entity detection performance.

The above two data sets can provide a standard testbed for the entity linking task. However, there were still some limitations of these data sets: First, these data sets only annotate the salient name mentions in a document, meanwhile many NLP applications need all name mentions are linked. Second, these data sets only contain well-formed documents, but in many real-world applications the entity linking often be applied to noisy documents such as product reviews and microblog messages. In future, we want to develop a data set which can reflect these real-world settings.

4.3 Evaluation Criteria

We adopted the standard performance metrics used in the Entity Linking task of the TAC 2009 (McNamee and Dang, 2009). These metrics are:

- Micro-Averaged Accuracy (**Micro-Accuracy**): measures entity linking accuracy averaged over all the name mentions;
- Macro-Averaged Accuracy (**Macro-Accuracy)**: measures entity linking accuracy averaged over all the target entities.

As in TAC 2009, we used **Micro-Accuracy** as the primary performance metric.

4.4 Experimental Results

We compared our method with three baselines: (1) The first is the traditional *Bag of Words* based method (Cucerzan, 2007): a name mention's referent entity is the entity which has the highest cosine similarity with its context – we denoted it as *BoW*; (2) The second is the method described in (Medelyan et al., 2008), where a name mention's referent entity is the entity which has the largest average semantic relatedness with the name mention's unambiguous context entities – we denoted it as *TopicIndex*. (3) The third one is the same as the method described in (Milne & Witten, 2008), which uses learning techniques to balance the semantic relatedness, commoness and context quality – we denoted it as *Learning2Link.*

4.4.1 Overall Performance

We conduct experiments on both ***WikiAmbi*** and ***TAC_KBP*** datasets with several methods: the baseline *BoW*; the baseline *TopicIndex;* the baseline *Learning2Link*; the proposed method using only popularity knowledge (***Popu***), i.e., the $P(m,e)=P(e)$; the proposed method with one component of the model is ablated(this is used to evaluate the independent contributions of the three components), correspondingly ***Popu+Name***(i.e., the $P(m,e)=P(e)P(s|e)$), ***Name+Context***(i.e., the $P(m,e)=P(c|e)P(s|e)$) and ***Popu+Context*** (i.e., the $P(m,e)=P(e)P(c|e)$); and the full entity mention model (***Full Model***). For all methods, the parameters were configured through 10-fold cross validation. The overall performance results are shown in Table 3 and 4.

	Micro-Accuracy	**Macro-Accuracy**
BoW	*0.60*	*0.61*
TopicIndex	*0.66*	*0.49*
Learning2Link	*0.70*	*0.54*
Popu	*0.39*	*0.24*
Popu + Name	*0.50*	*0.31*
Name+Context	*0.70*	*0.68*
Popu+Context	*0.72*	*0.73*
Full Model	***0.80***	***0.77***

Table 3. The overall results on *WikiAmbi* dataset

	Micro-Accuracy	**Macro-Accuracy**
BoW	*0.72*	*0.75*
TopicIndex	*0.80*	*0.76*
Learning2Link	*0.83*	*0.79*
Popu	*0.60*	*0.53*
Popu + Name	*0.63*	*0.59*
Name+Context	*0.81*	*0.78*
Popu+Context	*0.84*	*0.83*
Full Model	***0.86***	***0.88***

Table 4. The overall results on *TAC-KBP* dataset

From the results in Table 3 and 4, we can make the following observations:

1) Compared with the traditional methods, our entity mention model can achieve a significant

[5] This is because we want to create a highly ambiguous test data set

performance improvement: In *WikiAmbi* and *TAC_KBP* datasets, compared with the *BoW* baseline, our method respectively gets 20% and 14% micro-accuracy improvement; compared with the *TopicIndex* baseline, our method respectively gets 14% and 6% micro-accuracy improvement; compared with the *Learning2Link* baseline, our method respectively gets 10% and 3% micro-accuracy improvement.

2) By incorporating more entity knowledge, our method can significantly improve the entity linking performance: When only using the popularity knowledge, our method can only achieve 49.5% micro-accuracy. By adding the name knowledge, our method can achieve 56.5% micro-accuracy, a 7% improvement over the *Popu*. By further adding the context knowledge, our method can achieve 83% micro-accuracy, a 33.5% improvement over *Popu* and a 26.5% improvement over *Popu+Name*.

3) All three types of entity knowledge contribute to the final performance improvement, and the context knowledge contributes the most: By respectively ablating the popularity knowledge, the name knowledge and the context knowledge, the performance of our model correspondingly reduces 7.5%, 5% and 26.5%.

NIL Entity Detection Performance. To compare the performances of resolving the NIL entity problem, Table 5 shows the micro-accuracies of different systems on the *TAC_KBP* data set (where **All** is the whole data set, **NIL** only contains the name mentions whose referent entity is NIL, **InKB** only contains the name mentions whose referent entity is contained in the knowledge base). From Table 5 we can see that our method can effectively detect the NIL entity meanwhile retaining the high InKB accuracy.

	All	**NIL**	**InKB**

Table 5. The NIL entity detection performance on the *TAC_KBP* data set

4.4.2 Optimizing Parameters

Our model needs to tune one parameter: the Jelinek-Mercer smoothing parameter λ used in the entity context model. Intuitively, a smaller λ means that the general language model plays a more important role. Figure 5 plots the tradeoff. In both *WikiAmbi* and *TAC_KBP* data sets, Figure 5 shows that a λ value 0.2 will result in the best performance.

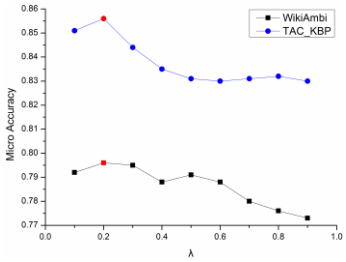

Figure 5. The micro-accuracy vs. λ

4.4.3 Detailed Analysis

To better understand the reasons why and how the proposed method works well, in this Section we analyze our method in detail.

The Effect of Incorporating Heterogenous Entity Knowledge. The first advantage of our method is the entity mention model can incorporate heterogeneous entity knowledge. The Table 3 and 4 have shown that, by incorporating heterogenous entity knowledge (including the name knowledge, the popularity knowledge and the context knowledge), the entity linking performance can obtain a significant improvement.

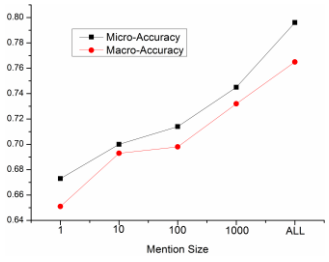

Figure 6. The performance vs. training mention size on *WikiAmbi* data set

The Effect of Better Entity Knowledge Extraction. The second advantage of our method is that, by representing the entity knowledge as probabilistic distributions, our model has a statistical foundation and can better extract the entity knowledge using more training data through the *entity popularity model*, the *entity name model* and the *entity context model*. For instance, we can train a better entity context model *P(c|e)* using more name mentions. To find whether a better

entity knowledge extraction will result in a better performance, Figure 6 plots the micro-accuray along with the size of the training data on name mentions for *P(c|e)* of each entity *e*. From Figure 6, we can see that when more training data is used, the performance increases.

4.4.4 Comparision with State-of-the-Art Performance

We also compared our method with the state-of-the-art entity linking systems in the TAC 2009 KBP track (McNamee and Dang, 2009). Figure 7 plots the comparison with the top five performances in TAC 2009 KBP track. From Figure 7, we can see that our method can outperform the state-of-the-art approaches: compared with the best ranking system, our method can achieve a 4% performance improvement.

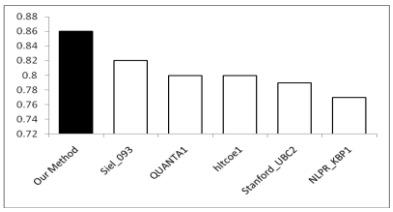

Figure 7. A comparison with top 5 TAC 2009 KBP systems

5 Related Work

In this section, we briefly review the related work. To the date, most entity linking systems employed the context similarity based methods. The essential idea was to extract the discriminative features of an entity from its description, then link a name mention to the entity which has the largest context similarity with it. Cucerzan (2007) proposed a *Bag of Words* based method, which represents each target entity as a vector of terms, then the similarity between a name mention and an entity was computed using the cosine similarity measure. Mihalcea & Csomai (2007), Bunescu & Pasca (2006), Fader et al. (2009) extended the *BoW* model by incorporating more entity knowledge such as popularity knowledge, entity category knowledge, etc. Zheng et al. (2010), Dredze et al. (2010), Zhang et al. (2010) and Zhou et al. (2010) employed the learning to rank techniques which can further take the relations between candidate entities into account. Because the context similarity based methods can only represent the entity knowledge as features, the main drawback of it was the difficulty to incorporate heterogenous entity knowledge.

Recently there were also some entity linking methods based on inter-dependency. These methods assumed that the entities in the same document are related to each other, thus the referent entity of a name mention is the entity which is most related to its contextual entities. Medelyan et al. (2008) found the referent entity of a name mention by computing the weighted average of semantic relatedness between the candidate entity and its unambiguous contextual entities. Milne and Witten (2008) extended Medelyan et al. (2008) by adopting learning-based techniques to balance the semantic relatedness, commoness and context quality. Kulkarni et al. (2009) proposed a method which collectively resolves the entity linking tasks in a document as an optimization problem. The drawback of the inter-dependency based methods is that they are usually specially designed to the leverage of semantic relations, doesn't take the other types of entity knowledge into consideration.

6 Conclusions and Future Work

This paper proposes a generative probabilistic model, the *entity-mention model*, for the entity linking task. The main advantage of our model is it can incorporate multiple types of heterogenous entity knowledge. Furthermore, our model has a statistical foundation, making the entity knowledge extraction approach different from most previous ad hoc approaches. Experimental results show that our method can achieve competitive performance.

In our method, we did not take into account the dependence between entities in the same document. This aspect could be complementary to those we considered in this paper. For our future work, we can integrate such dependencies in our model.

Abstract

We investigate automatic *geolocation* (i.e. identification of the location, expressed as latitude/longitude coordinates) of documents. Geolocation can be an effective means of summarizing large document collections and it is an important component of geographic information retrieval. We describe several simple supervised methods for document geolocation using only the document's raw text as evidence. All of our methods predict locations in the context of geodesic grids of varying degrees of resolution. We evaluate the methods on geotagged Wikipedia articles and Twitter feeds. For Wikipedia, our best method obtains a median prediction error of just 11.8 kilometers. Twitter geolocation is more challenging: we obtain a median error of 479 km, an improvement on previous results for the dataset.

1 Introduction

There are a variety of applications that arise from connecting linguistic content—be it a word, phrase, document, or entire corpus—to geography. Leidner (2008) provides a systematic overview of geography-based language applications over the previous decade, with a special focus on the problem of *toponym resolution*—identifying and disambiguating the references to locations in texts. Perhaps the most obvious and far-reaching application is geographic information retrieval (Ding et al., 2000; Martins, 2009; Andogah, 2010), with applications like MetaCarta's geographic text search (Rauch et al., 2003) and NewsStand (Teitler et al., 2008); these allow users to browse and search for content through a geo-centric interface. The Perseus project performs automatic toponym resolution on historical texts in order to display a map with each text showing the locations that are mentioned (Smith and Crane, 2001); Google Books also does this for some books, though the toponyms are identified and resolved quite crudely. Hao et al (2010) use a location-based topic model to summarize travelogues, enrich them with automatically chosen images, and provide travel recommendations. Eisenstein et al (2010) investigate questions of dialectal differences and variation in regional interests in Twitter users using a collection of geotagged tweets.

An intuitive and effective strategy for summarizing geographically-based data is identification of the location—a specific latitude and longitude—that forms the primary focus of each document. Determining a *single* location of a document is only a well-posed problem for certain documents, generally of fairly small size, but there are a number of natural situations in which such collections arise. For example, a great number of articles in Wikipedia have been manually geotagged; this allows those articles to appear in their geographic locations while geobrowsing in an application like Google Earth.

Overell (2009) investigates the use of Wikipedia as a source of data for article geolocation, in addition to article classification by category (location, person, etc.) and toponym resolution. Overell's main goal is toponym resolution, for which geolocation serves as an input feature. For document geolocation, Overell uses a simple model that makes use only of the metadata available (article title, incoming and outgoing links, etc.)—the actual article text

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 955–964,
Portland, Oregon, June 19-24, 2011.

is not used at all. However, for many document collections, such metadata is unavailable, especially in the case of recently digitized historical documents.

Eisenstein et al. (2010) evaluate their geographic topic model by geolocating USA-based Twitter users based on their tweet content. This is essentially a document geolocation task, where each document is a concatenation of all the tweets for a single user. Their geographic topic model receives supervision from many documents/users and predicts locations for unseen documents/users.

In this paper, we tackle document geolocation using several simple supervised methods on the textual content of documents and a geodesic grid as a discrete representation of the earth's surface. Our approach is similar to that of Serdyukov et al. (2009), who geolocate Flickr images using their associated textual tags.[1] Essentially, the task is cast similarly to language modeling approaches in information retrieval (Ponte and Croft, 1998). Discrete cells representing areas on the earth's surface correspond to documents (with each cell-document being a concatenation of all actual documents that are located in that cell); new documents are then geolocated to the most similar cell according to standard measures such as Kullback-Leibler divergence (Zhai and Lafferty, 2001). Performance is measured both on geotagged Wikipedia articles (Overell, 2009) and tweets (Eisenstein et al., 2010). We obtain high accuracy on Wikipedia using KL divergence, with a median error of just 11.8 kilometers. For the Twitter data set, we obtain a median error of 479 km, which improves on the 494 km error of Eisenstein et al. An advantage of our approach is that it is far simpler, is easy to implement, and scales straightforwardly to large datasets like Wikipedia.

2 Data

Wikipedia As of April 15, 2011, Wikipedia has some 18.4 million content-bearing articles in 281 language-specific encyclopedias. Among these, 39 have over 100,000 articles, including 3.61 million articles in the English-language edition alone. Wikipedia articles generally cover a single subject; in addition, most articles that refer to geographically fixed subjects are *geotagged* with their coordinates. Such articles are well-suited as a source of supervised content for document geolocation purposes. Furthermore, the existence of versions in multiple languages means that the techniques in this paper can easily be extended to cover documents written in many of the world's most common languages.

Wikipedia's geotagged articles encompass more than just cities, geographic formations and landmarks. For example, articles for events (like the shooting of JFK) and vehicles (such as the frigate USS *Constitution*) are geotagged. The latter type of article is actually quite challenging to geolocate based on the text content: though the ship is moored in Boston, most of the page discusses its role in various battles along the eastern seaboard of the USA. However, such articles make up only a small fraction of the geotagged articles.

For the experiments in this paper, we used a full dump of Wikipedia from September 4, 2010.[2] Included in this dump is a total of 10,355,226 articles, of which 1,019,490 have been geotagged. Excluding various types of special-purpose articles used primarily for maintaining the site (specifically, redirect articles and articles outside the main namespace), the dump includes 3,431,722 content-bearing articles, of which 488,269 are geotagged.

It is necessary to process the raw dump to obtain the plain text, as well as metadata such as geotagged coordinates. Extracting the coordinates, for example, is not a trivial task, as coordinates can be specified using multiple templates and in multiple formats. Automatically-processed versions of the English-language Wikipedia site are provided by Metaweb,[3] which at first glance promised to significantly simplify the preprocessing. Unfortunately, these versions still need significant processing and they incorrectly eliminate some of the important metadata. In the end, we wrote our own code to process the raw dump. It should be possible to extend this code to handle other languages with little difficulty. See Lieberman and Lin (2009) for more discussion of a related effort to extract and use the geotagged articles in Wikipedia.

The entire set of articles was split 80/10/10 in

[1] We became aware of Serdyukov et al. (2009) during the writing of the camera-ready version of this paper.

[2] `http://download.wikimedia.org/enwiki/20100904/pages-articles.xml.bz2`

[3] `http://download.freebase.com/wex/`

round-robin fashion into training, development, and testing sets after randomizing the order of the articles, which preserved the proportion of geotagged articles. Running on the full data set is time-consuming, so development was done on a subset of about 80,000 articles (19.9 million tokens) as a training set and 500 articles as a development set. Final evaluation was done on the full dataset, which includes 390,574 training articles (97.2 million tokens) and 48,589 test articles. A full run with all the six strategies described below (three baseline, three non-baseline) required about 4 months of computing time and about 10-16 GB of RAM when run on a 64-bit Intel Xeon E5540 CPU; we completed such jobs in under two days (wall clock) using the Longhorn cluster at the Texas Advanced Computing Center.

Geo-tagged Microblog Corpus As a second evaluation corpus on a different domain, we use the corpus of geotagged tweets collected and used by Eisenstein et al. (2010).[4] It contains 380,000 messages from 9,500 users tweeting within the 48 states of the continental USA.

We use the train/dev/test splits provided with the data; for these, the tweets of each user (a feed) have been concatenated to form a single document, and the location label associated with each document is the location of the first tweet by that user. This is generally a fair assumption as Twitter users typically tweet within a relatively small region. Given this setup, we will refer to Twitter users as documents in what follows; this keeps the terminology consistent with Wikipedia as well. The training split has 5,685 documents (1.58 million tokens).

Replication Our code (part of the TextGrounder system), our processed version of Wikipedia, and instructions for replicating our experiments are available on the TextGrounder website.[5]

3 Grid representation for connecting texts to locations

Geolocation involves identifying some spatial region with a unit of text—be it a word, phrase, or document. The earth's surface is continuous, so a natural approach is to predict locations using a continuous distribution. For example, Eisenstein et al. (2010) use Gaussian distributions to model the locations of Twitter users in the United States of America. This appears to work reasonably well for that restricted region, but is likely to run into problems when predicting locations for anywhere on earth—instead, spherical distributions like the von Mises-Fisher distribution would need to be employed.

We take here the simpler alternative of discretizing the earth's surface with a geodesic grid; this allows us to predict locations with a variety of standard approaches over discrete outcomes. There are many ways of constructing geodesic grids. Like Serdyukov et al. (2009), we use the simplest strategy: a grid of square cells of *equal degree*, such as 1° by 1°. This produces variable-size regions that shrink latitudinally, becoming progressively smaller and more elongated the closer they get towards the poles. Other strategies, such as the quaternary triangular mesh (Dutton, 1996), preserve *equal area*, but are considerably more complex to implement. Given that most of the populated regions of interest for us are closer to the equator than not and that we use cells of quite fine granularity (down to 0.05°), the simple grid system was preferable.

With such a discrete representation of the earth's surface, there are four distributions that form the core of all our geolocation methods. The first is a standard multinomial distribution over the vocabulary for every cell in the grid. Given a grid G with cells c_i and a vocabulary V with words w_j, we have $\theta_{c_i j} = P(w_j|c_i)$. The second distribution is the equivalent distribution for a single test document d_k, i.e. $\theta_{d_k j} = P(w_j|d_k)$. The third distribution is the reverse of the first: for a given word, its distribution over the earth's cells, $\kappa_{ji} = P(c_i|w_j)$. The final distribution is over the cells, $\gamma_i = P(c_i)$.

This grid representation ignores all higher level regions, such as states, countries, rivers, and mountain ranges, but it is consistent with the geocoding in both the Wikipedia and Twitter datasets. Nonetheless, note that the κ_{ji} for words referring to such regions is likely to be much flatter (spread out) but with most of the mass concentrated in a set of connected cells. Those for highly focused point-locations will jam up in a few disconnected cells—in the extreme case, toponyms like *Spring-*

[4] http://www.ark.cs.cmu.edu/GeoText/

[5] http://code.google.com/p/textgrounder/wiki/WingBaldridge2011

field which are connected to many specific point locations around the earth.

We use grids with cell sizes of varying granularity $d \times d$ for $d = 0.1^\circ, 0.5^\circ, 1^\circ, 5^\circ, 10^\circ$. For example, with d=0.5°, a cell at the equator is roughly 56x55 km and at 45° latitude it is 39x55 km. At this resolution, there are a total of 259,200 cells, of which 35,750 are non-empty when using our Wikipedia training set. For comparison, at the equator a cell at d=5° is about 557x553 km (2,592 cells; 1,747 non-empty) and at d=0.1° a cell is about 11.3x10.6 km (6,480,000 cells; 170,005 non-empty).

The geolocation methods predict a cell $\hat{c}$ for a document, and the latitude and longitude of the degree-midpoint of the cell is used as the predicted location. Prediction error is the great-circle distance from these predicted locations to the locations given by the gold standard. The use of cell midpoints provides a fair comparison for predictions with different cell sizes. This differs from the evaluation metrics used by Serdyukov et al. (2009), which are all computed relative to a given grid size. With their metrics, results for different granularities cannot be directly compared because using larger cells means less ambiguity when choosing $\hat{c}$. With our distance-based evaluation, large cells are penalized by the distance from the midpoint to the actual location even when that location is in the same cell. Smaller cells reduce this penalty and permit the word distributions $\theta_{c_i j}$ to be much more specific for each cell, but they are harder to predict exactly and suffer more from sparse word counts compared to courser granularity. For large datasets like Wikipedia, fine-grained grids work very well, but the trade-off between resolution and sufficient training material shows up more clearly for the smaller Twitter dataset.

4 Supervised models for document geolocation

Our methods use only the text in the documents; predictions are made based on the distributions θ, κ, and ρ introduced in the previous section. No use is made of metadata, such as links/followers and infoboxes.

4.1 Supervision

We acquire θ and κ straightforwardly from the training material. The unsmoothed estimate of word w_j's probability in a test document d_k is:[6]

$$\tilde{\theta}_{d_k j} = \frac{\#(w_j, d_k)}{\sum_{w_l \in V} \#(w_l, d_k)} \quad (1)$$

Similarly for a cell c_i, we compute the unsmoothed word distribution by aggregating all of the documents located within c_i:

$$\tilde{\theta}_{c_i j} = \frac{\sum_{d_k \in c_i} \#(w_j, d_k)}{\sum_{d_k \in c_i} \sum_{w_l \in V} \#(w_l, d_k)} \quad (2)$$

We compute the global distribution θ_{Dj} over the set of all documents D in the same fashion.

The word distribution of document d_k backs off to the global distribution θ_{Dj}. The probability mass α_{d_k} reserved for unseen words is determined by the empirical probability of having seen a word once in the document, motivated by Good-Turing smoothing. (The cell distributions are treated analogously.) That is:[7]

$$\alpha_{d_k} = \frac{|w_j \in V \, s.t. \, \#(w_j, d_k)=1|}{\sum_{w_j \in V} \#(w_j, d_k)} \quad (3)$$

$$\theta_{Dj}^{(-d_k)} = \frac{\theta_{Dj}}{1 - \sum_{w_l \in d_k} \theta_{Dl}} \quad (4)$$

$$\theta_{d_k j} = \begin{cases} \alpha_{d_k} \theta_{Dj}^{(-d_k)}, & \text{if } \tilde{\theta}_{d_k j} = 0 \\ (1-\alpha_{d_k}) \tilde{\theta}_{d_k j}, & \text{o.w.} \end{cases} \quad (5)$$

The distributions over cells for each word simply renormalizes the $\theta_{c_i j}$ values to achieve a proper distribution:

$$\kappa_{ji} = \frac{\theta_{c_i j}}{\sum_{c_i \in G} \theta_{c_i j}} \quad (6)$$

A useful aspect of the κ distributions is that they can be plotted in a geobrowser using thematic mapping

[6] We use $\#()$ to indicate the count of an event.

[7] $\theta_{Dj}^{(-d_k)}$ is an adjusted version of θ_{Dj} that is normalized over the subset of words not found in document d_k. This adjustment ensures that the entire distribution is properly normalized.

techniques (Sandvik, 2008) to inspect the spread of a word over the earth. We used this as a simple way to verify the basic hypothesis that words that do not name locations are still useful for geolocation. Indeed, the Wikipedia distribution for *mountain* shows high density over the Rocky Mountains, Smokey Mountains, the Alps, and other ranges, while *beach* has high density in coastal areas. Words without inherent locational properties also have intuitively correct distributions: e.g., *barbecue* has high density over the south-eastern United States, Texas, Jamaica, and Australia, while *wine* is concentrated in France, Spain, Italy, Chile, Argentina, California, South Africa, and Australia.[8]

Finally, the cell distributions are simply the relative frequency of the number of documents in each cell: $\gamma_i = \frac{|c_i|}{|D|}$.

A standard set of stop words are ignored. Also, all words are lowercased except in the case of the most-common-toponym baselines, where uppercase words serve as a fallback in case a toponym cannot be located in the article.

4.2 Kullback-Leibler divergence

Given the distributions for each cell, θ_{c_i}, in the grid, we use an information retrieval approach to choose a location for a test document d_k: compute the similarity between its word distribution θ_{d_k} and that of each cell, and then choose the closest one. Kullback-Leibler (KL) divergence is a natural choice for this (Zhai and Lafferty, 2001). For distribution P and Q, KL divergence is defined as:

$$KL(P||Q) = \sum_i P(i) \log \frac{P(i)}{Q(i)} \tag{7}$$

This quantity measures how good Q is as an encoding for P – the smaller it is the better. The best cell $\hat{c}_{KL}$ is the one which provides the best encoding for the test document:

$$\hat{c}_{KL} = \arg\min_{c_i \in G} KL(\theta_{d_k}||\theta_{c_i}) \tag{8}$$

The fact that KL is not symmetric is desired here: the other direction, $KL(\theta_{c_i}||\theta_{d_k})$, asks which cell the test document is a good encoding for. With $KL(\theta_{d_k}||\theta_{c_i})$, the log ratio of probabilities for each word is weighted by the probability of the word in the test document, $\boldsymbol{\theta_{d_k j}} \log \frac{\theta_{d_k j}}{\theta_{c_i j}}$, which means that the divergence is more sensitive to the document rather than the overall cell.

As an example for why non-symmetric KL in this order is appropriate, consider geolocating a page in a densely geotagged cell, such as the page for the Washington Monument. The distribution of the cell containing the monument will represent the words from many other pages having to do with museums, US government, corporate buildings, and other nearby memorials and will have relatively small values for many of the words that are highly indicative of the monument's location. Many of those words appear only once in the monument's page, but this will still be a higher value than for the cell and will weight the contribution accordingly.

Rather than computing $KL(\theta_{d_k}||\theta_{c_i})$ over the entire vocabulary, we restrict it to only the words in the document to compute KL more efficiently:

$$KL(\theta_{d_k}||\theta_{c_i}) = \sum_{w_j \in V_{d_k}} \theta_{d_k j} \log \frac{\theta_{d_k j}}{\theta_{c_i j}} \tag{9}$$

Early experiments showed that it makes no difference in the outcome to include the rest of the vocabulary. Note that because θ_{c_i} is smoothed, there are no zeros, so this value is always defined.

4.3 Naive Bayes

Naive Bayes is a natural generative model for the task of choosing a cell, given the distributions θ_{c_i} and γ: to generate a document, choose a cell c_i according to γ and then choose the words in the document according to θ_{c_i}:

$$\begin{aligned}
\hat{c}_{NB} &= \arg\max_{c_i \in G} P_{NB}(c_i|d_k) \\
&= \arg\max_{c_i \in G} \frac{P(c_i)P(d_k|c_i)}{P(d_k)} \\
&= \arg\max_{c_i \in G} \gamma_i \prod_{w_j \in V_{d_k}} \theta_{c_i j}^{\#(w_j, d_k)}
\end{aligned} \tag{10}$$

[8] This also acts as an exploratory tool. For example, due to a big spike on Cebu Province in the Philippines we learned that Cebuanos take barbecue very, very seriously.

This method maximizes the combination of the *likelihood* of the document $P(d_k|c_i)$ and the cell prior probability γ_i.

4.4 Average cell probability

For each word, κ_{ji} gives the probability of each cell in the grid. A simple way to compute a distribution for a document d_k is to take a weighted average of the distributions for all words to compute the average cell probability (ACP):

$$\begin{aligned}\hat{c}_{ACP} &= \arg\max_{c_i \in G} P_{ACP}(c_i|d_k) \\ &= \arg\max_{c_i \in G} \frac{\sum_{w_j \in V_{d_k}} \#(w_j, d_k)\kappa_{ji}}{\sum_{c_l \in G} \sum_{w_j \in V_{d_k}} \#(w_j, d_k)\kappa_{jl}} \\ &= \arg\max_{c_i \in G} \sum_{w_j \in V_{d_k}} \#(w_j, d_k)\kappa_{ji} \qquad (11)\end{aligned}$$

This method, despite its conceptual simplicity, works well in practice. It could also be easily modified to use different weights for words, such as TF/IDF or relative frequency ratios between geolocated documents and non-geolocated documents, which we intend to try in future work.

4.5 Baselines

There are several natural baselines to use for comparison against the methods described above.

Random Choose $\hat{c}_{rand}$ randomly from a uniform distribution over the entire grid G.

Cell prior maximum Choose the cell with the highest prior probability according to γ: $\hat{c}_{cpm} = \arg\max_{c_i \in G} \gamma_i$.

Most frequent toponym Identify the most frequent toponym in the article and the geotagged Wikipedia articles that match it. Then identify which of those articles has the most incoming links (a measure of its prominence), and then choose $\hat{c}_{mft}$ to be the cell that contains the geotagged location for that article. This is a strong baseline method, but can only be used with Wikipedia.

Note that a toponym matches an article (or equivalently, the article is a candidate for the toponym) either if the toponym is the same as the article's title, or the same as the title after a parenthetical tag or comma-separated higher-level division is removed. For example, the toponym *Tucson* would match articles named *Tucson*, *Tucson (city)* or *Tucson, Arizona*. In this fashion, the set of toponyms, and the list of candidates for each toponym, is generated from the set of all geotagged Wikipedia articles.

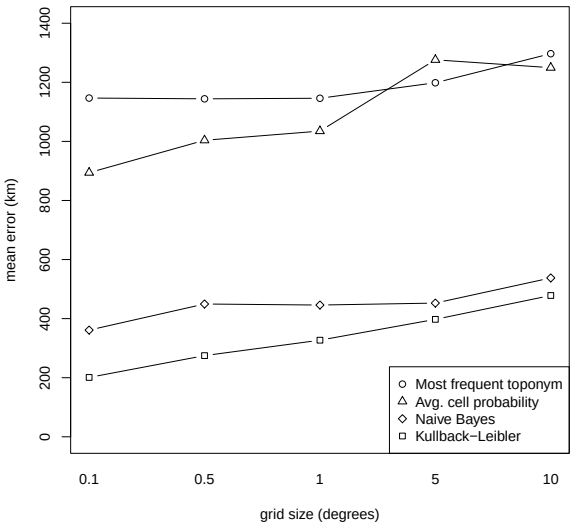

Figure 1: Plot of grid resolution in degrees versus mean error for each method on the Wikipedia dev set.

5 Experiments

The approaches described in the previous section are evaluated on both the geotagged Wikipedia and Twitter datasets. Given a predicted cell $\hat{c}$ for a document, the prediction error is the great-circle distance between the true location and the center of $\hat{c}$, as described in section 3.

Grid resolution and thresholding The major parameter of all our methods is the grid resolution. For both Wikipedia and Twitter, preliminary experiments on the development set were run to plot the prediction error for each method for each level of resolution, and the optimal resolution for each method was chosen for obtaining test results. For the Twitter dataset, an additional parameter is a threshold on the number of feeds each word occurs in: in the preprocessed splits of Eisenstein et al. (2010), all vocabulary items that appear in fewer than 40 feeds are ignored. This thresholding takes away a lot of very useful material; e.g. in the first feed, it removes

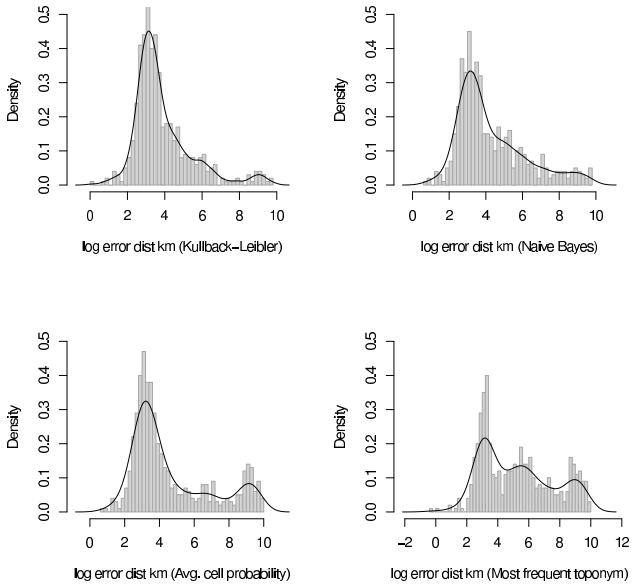

Figure 2: Histograms of distribution of error distances (in km) for grid size 0.5° for each method on the Wikipedia dev set.

both "kirkland" and "redmond" (towns in the Eastside of Lake Washington near Seattle), very useful information for geolocating that user. This suggests that a lower threshold would be better, and this is borne out by our experiments.

Figure 1 graphs the mean error of each method for different resolutions on the Wikipedia dev set, and Figure 2 graphs the distribution of error distances for grid size 0.5° for each method on the Wikipedia dev set. These results indicate that a grid size even smaller than 0.1° might be beneficial. To test this, we ran experiments using a grid size of 0.05° and 0.01° using KL divergence. The mean errors on the dev set increased slightly, from 323 km to 348 and 329 km, respectively, indicating that 0.1° is indeed the minimum.

For the Twitter dataset, we considered both grid size and vocabulary threshold. We recomputed the distributions using several values for both parameters and evaluated on the development set. Table 1 shows mean prediction error using KL divergence, for various combinations of threshold and grid size. Similar tables were constructed for the other strategies. Clearly, the larger grid size of 5° is more optimal than the 0.1° best for Wikipedia. This is unsurprising, given the small size of the corpus. Overall, there is a less clear trend for the other methods

	Grid size (degrees)				
Thr.	0.1	0.5	1	5	10
0	1113.1	996.8	1005.1	969.3	1052.5
2	1018.5	959.5	944.6	911.2	1021.6
3	1027.6	940.8	954.0	913.6	1026.2
5	1011.7	951.0	954.2	**892.0**	1013.0
10	1011.3	968.8	938.5	929.8	1048.0
20	1032.5	987.3	966.0	940.0	1070.1
40	1080.8	1031.5	998.6	981.8	1127.8

Table 1: Mean prediction error (km) on the Twitter dev set for various combinations of vocabulary threshold (in feeds) and grid size, using the KL divergence strategy.

in terms of optimal resolution. Our interpretation of this is that there is greater sparsity for the Twitter dataset, and thus it is more sensitive to arbitrary aspects of how different user feeds are captured in different cells at different granularities.

For the non-baseline strategies, a threshold between about 2 and 5 was best, although no one value in this range was clearly better than another.

Results Based on the optimal resolutions for each method, Table 2 provides the median and mean errors of the methods for both datasets, when run on the test sets. The results clearly show that KL divergence does the best of all the methods considered, with Naive Bayes a close second. Prediction on Wikipedia is very good, with a median value of 11.8 km. Error on Twitter is much higher at 479 km. Nonetheless, this beats Eisenstein et al.'s (2010) median results, though our mean is worse at 967. Using the same threshold of 40 as Eisenstein et al., our results using KL divergence are slightly worse than theirs: median error of 516 km and mean of 986 km.

The difference between Wikipedia and Twitter is unsurprising for several reasons. Wikipedia articles tend to use a lot of toponyms and words that correlate strongly with particular places while many, perhaps most, tweets discuss quotidian details such as what the user ate for lunch. Second, Wikipedia articles are generally longer and thus provide more text to base predictions on. Finally, there are orders of magnitude more training examples for Wikipedia, which allows for greater grid resolution and thus more precise location predictions.

	Wikipedia			Twitter			
Strategy	Degree	Median	Mean	Threshold	Degree	Median	Mean
Kullback-Leibler	0.1	11.8	221	5	5	479	967
Naive Bayes	0.1	15.5	314	5	5	528	989
Avg. cell probability	0.1	24.1	1421	2	10	659	1184
Most frequent toponym	0.5	136	1927	-	-	-	-
Cell prior maximum	5	2333	4309	N/A	0.1	726	1141
Random	0.1	7259	7192	20	0.1	1217	1588
Eisenstein et al.	-	-	-	40	N/A	494	900

Table 2: Prediction error (km) on the Wikipedia and Twitter test sets for each of the strategies using the optimal grid resolution and (for Twitter) the optimal threshold, as determined by performance on the corresponding development sets. Eisenstein et al. (2010) used a fixed Twitter threshold of 40. Threshold makes no difference for cell prior maximum.

Ships One of the most difficult types of Wikipedia pages to disambiguate are those of ships that either are stored or had sunk at a particular location. These articles tend to discuss the exploits of these ships, not their final resting places. Location error on these is usually quite large. However, prediction is quite good for ships that were sunk in particular battles which are described in detail on the page; examples are the USS *Gambier Bay*, USS *Hammann* (DD-412), and the HMS *Majestic* (1895). Another situation that gives good results is when a ship is retired in a location where it is a prominent feature and is thus mentioned in the training set at that location. An example is the USS *Turner Joy*, which is in Bremerton, Washington and figures prominently in the page for Bremerton (which is in the training set).

Another interesting aspect of geolocating ship articles is that ships tend to end up sunk in remote battle locations, such that their article is the only one located in the cell covering the location in the training set. Ship terminology thus dominates such cells, with the effect that our models often (incorrectly) geolocate test articles about other ships to such locations (and often about ships with similar properties). This also leads to generally more accurate geolocation of HMS ships over USS ships; the former seem to have been sunk in more concentrated regions that are themselves less spread out globally.

6 Related work

Lieberman and Lin (2009) also work with geotagged Wikipedia articles, but they do in order so to analyze the likely locations of users who edit such articles. Other researchers have investigated the use of Wikipedia as a source of data for other supervised NLP tasks. Mihalcea and colleagues have investigated the use of Wikipedia in conjunction with word sense disambiguation (Mihalcea, 2007), keyword extraction and linking (Mihalcea and Csomai, 2007) and topic identification (Coursey et al., 2009; Coursey and Mihalcea, 2009). Cucerzan (2007) used Wikipedia to do named entity disambiguation, i.e. identification and coreferencing of named entities by linking them to the Wikipedia article describing the entity.

Some approaches to document geolocation rely largely or entirely on non-textual metadata, which is often unavailable for many corpora of interest, Nonetheless, our methods could be combined with such methods when such metadata is available. For example, given that both Wikipedia and Twitter have a linked structure between documents, it would be possible to use the link-based method given in Backstrom et al. (2010) for predicting the location of Facebook users based on their friends' locations. It is possible that combining their approach with our text-based approach would provide improvements for Facebook, Twitter and Wikipedia datasets. For example, their method performs poorly for users with few geolocated friends, but results improved by combining link-based predictions with IP address predictions. The text written users' updates could be an additional aid for locating such users.

7 Conclusion

We have shown that automatic identification of the location of a document based only on its text can be performed with high accuracy using simple supervised methods and a discrete grid representation of the earth's surface. All of our methods are simple to implement, and both training and testing can be easily parallelized. Our most effective geolocation strategy finds the grid cell whose word distribution has the smallest KL divergence from that of the test document, and easily beats several effective baselines. We predict the location of Wikipedia pages to a median error of 11.8 km and mean error of 221 km. For Twitter, we obtain a median error of 479 km and mean error of 967 km. Using naive Bayes and a simple averaging of word-level cell distributions also both worked well; however, KL was more effective, we believe, because it weights the words in the document most heavily, and thus puts less importance on the less specific word distributions of each cell.

Though we only use text, link-based predictions using the follower graph, as Backstrom et al. (2010) do for Facebook, could improve results on the Twitter task considered here. It could also help with Wikipedia, especially for buildings: for example, the page for Independence Hall in Philadelphia links to geotagged "friend" pages for Philadelphia, the Liberty Bell, and many other nearby locations and buildings. However, we note that we are still primarily interested in geolocation with only text because there are a great many situations in which such linked structure is unavailable. This is especially true for historical corpora like those made available by the Perseus project.[9]

The task of identifying a single location for an entire document provides a convenient way of evaluating approaches for connecting texts with locations, but it is not fully coherent in the context of documents that cover multiple locations. Nonetheless, both the average cell probability and naive Bayes models output a distribution over all cells, which could be used to assign multiple locations. Furthermore, these cell distributions could additionally be used to define a document level prior for resolution of individual toponyms.

[9] www.perseus.tufts.edu/

Though we treated the grid resolution as a parameter, the grids themselves form a hierarchy of cells containing finer-grained cells. Given this, there are a number of obvious ways to combine predictions from different resolutions. For example, given a cell of the finest grain, the average cell probability and naive Bayes models could successively back off to the values produced by their coarser-grained containing cells, and KL divergence could be summed from finest-to-coarsest grain. Another strategy for making models less sensitive to grid resolution is to smooth the per-cell word distributions over neighboring cells; this strategy improved results on Flickr photo geolocation for Serdyukov et al. (2009).

An additional area to explore is to remove the bag-of-words assumption and take into account the ordering between words. This should have a number of obvious benefits, among which are sensitivity to multi-word toponyms such as *New York*, collocations such as *London, Ontario* or *London in Ontario*, and highly indicative terms such as *egg cream* that are made up of generic constituents.

Piggyback: Using Search Engines for Robust Cross-Domain Named Entity Recognition

Abstract

We use search engine results to address a particularly difficult cross-domain language processing task, the adaptation of named entity recognition (NER) from news text to web queries. The key novelty of the method is that we submit a token with context to a search engine and use similar contexts in the search results as additional information for correctly classifying the token. We achieve strong gains in NER performance on news, in-domain and out-of-domain, and on web queries.

1 Introduction

As statistical Natural Language Processing (NLP) matures, NLP components are increasingly used in real-world applications. In many cases, this means that some form of cross-domain adaptation is necessary because there are distributional differences between the labeled training set that is available and the real-world data in the application. To address this problem, we propose a new type of features for NLP data, features extracted from *search engine results*. Our motivation is that search engine results can be viewed as a *substitute for the world knowledge* that is required in NLP tasks, but that can only be extracted from a standard training set or precompiled resources to a limited extent. For example, a named entity (NE) recognizer trained on news text may tag the NE *London* in an out-of-domain web query like *London Klondike gold rush* as a location. But if we train the recognizer on features derived from search results for the sentence to be tagged, correct classification as person is possible. This is because the search results for *London Klondike gold rush* contain snippets in which the first name *Jack* precedes *London*; this is a sure indicator of a last name and hence an NE of type person.

We call our approach *piggyback* and search result-derived features *piggyback features* because we piggyback on a search engine like Google for solving a difficult NLP task.

In this paper, we use piggyback features to address a particularly hard cross-domain problem, the application of an NER system trained on news to web queries. This problem is hard for two reasons. First, the most reliable cue for NEs in English, as in many languages, is *capitalization.* But queries are generally lowercase and even if uppercase characters are used, they are not consistent enough to be reliable features. Thus, applying NER systems trained on news to web queries requires a robust cross-domain approach.

News to queries adaptation is also hard because queries provide *limited context* for NEs. In news text, the first mention of a word like *Ford* is often a fully qualified, unambiguous name like *Ford Motor Corporation* or *Gerald Ford*. In a short query like *buy ford* or *ford pardon*, there is much less context than in news. The lack of context and capitalization, and the noisiness of real-world web queries (tokenization irregularities and misspellings) all make NER hard. The low annotator agreement we found for queries (Section 5) also confirms this point.

The correct identification of NEs in web queries can be crucial for providing relevant pages and ads to users. Other domains have characteristics similar to web queries, e.g., automatically transcribed speech, social communities like Twitter, and SMS. Thus, NER for short, noisy text fragments, in the absence of capitalization, is of general importance.

Proceedings of the 49th Annual Meeting of the Association for Computational Linguistics, pages 965–975,
Portland, Oregon, June 19-24, 2011.

NER performance is to a large extent determined by the quality of the feature representation. Lexical, part-of-speech (PoS), shape and gazetteer features are standard. While the impact of different types of features is well understood for standard NER, fundamentally different types of features can be used when leveraging search engine results. Returning to the NE *London* in the query *London Klondike gold rush*, the feature "proportion of search engine results in which a first name precedes the token of interest" is likely to be useful in NER. Since using search engine results for cross-domain robustness is a new approach in NLP, the design of appropriate features is crucial to its success. A significant part of this paper is devoted to feature design and evaluation.

This paper is organized as follows. Section 2 discusses related work. We describe standard NER features in Section 3. One main contribution of this paper is the large array of piggyback features that we propose in Section 4. We describe the data sets we use and our experimental setup in Sections 5–6. The results in Section 7 show that piggyback features significantly increase NER performance. This is the second main contribution of the paper. We discuss challenges of using piggyback features – due to the cost of querying search engines – and present our conclusions and future work in Section 8.

2 Related work

Barr et al. (2008) found that capitalization of NEs in web queries is inconsistent and not a reliable cue for NER. Guo et al. (2009) exploit query logs for NER in queries. This is also promising, but the context in search results is richer and potentially more informative than that of other queries in logs.

The insight that search results provide useful additional context for natural language expressions is not new. Perhaps the oldest and best known application is pseudo-relevance feedback which uses words and phrases from search results for query expansion (Rocchio, 1971; Xu and Croft, 1996). Search counts or search results have also been used for sentiment analysis (Turney, 2002), for transliteration (Grefenstette et al., 2004), candidate selection in machine translation (Lapata and Keller, 2005), text similarity measurements (Sahami and Heilman, 2006), incorrect parse tree filtering (Yates et al., 2006), and paraphrase evaluation (Fujita and Sato, 2008). The specific NER application we address is most similar to the work of Farkas et al. (2007), but they mainly used frequency statistics as opposed to what we view as the main strength of search results: the ability to get additional contextually similar uses of the token that is to be classified.

Lawson et al. (2010), Finin et al. (2010), and Yetisgen-Yildiz et al. (2010) investigate how to best use Amazon Mechanical Turk (AMT) for NER. We use AMT as a tool, but it is not our focus.

NLP settings where training and test sets are from different domains have received considerable attention in recent years. These settings are difficult because many machine learning approaches assume that source and target are drawn from the same distribution; this is not the case if they are from different domains. Systems applied out of domain typically incur severe losses in accuracy; e.g., Poibeau and Kosseim (2000) showed that newswire-trained NER systems perform poorly when applied to email data (a drop of F_1 from .9 to .5). Recent work in machine learning has made substantial progress in understanding how cross-domain features can be used in effective ways (Ben-David et al., 2010). The development of such features however is to a large extent an empirical problem. From this perspective, one of the most successful approaches to adaptation for NER is based on generating shared feature representations between source and target domains, via unsupervised methods (Ando, 2004; Turian et al., 2010). Turian et al. (2010) show that adapting from CoNLL to MUC-7 (Chinchor, 1998) data (thus between different newswire sources), the best unsupervised feature (Brown clusters) improves F_1 from .68 to .79. Our approach fits within this line of work in that it empirically investigates features with good cross-domain generalization properties. The main contribution of this paper is the design and evaluation of a novel family of features extracted from the largest and most up-to-date repository of world knowledge, the web.

Another source of world knowledge for NER is Wikipedia: Kazama and Torisawa (2007) show that pseudocategories extracted from Wikipedia help for in-domain NER. Cucerzan (2007) uses Wikipedia and web search frequencies to improve NE disambiguation, including simple web search frequencies

	BASE: lexical and input-text part-of-speech features	
1	WORD(k,i)	binary: $w_k = w^i$
2	POS(k,t)	binary: w_k has part-of-speech t
3	SHAPE(k,i)	binary: w_k has (regular expression) shape regexp_i
4	PREFIX(j)	binary: w_0 has prefix j (analogously for suffixes)
	GAZ: gazetteer features	
5	GAZ-B$_l$(k,i)	binary: w_k is the initial word of a phrase, consisting of l words, whose gaz. category is i
6	GAZ-I$_l$(k,i)	binary: w_k is a non-initial word in a phrase, consisting of l words, whose gaz. category is i

	MISC: shape, search part-of-speech, and title features	
12	UPPERCASE	N(s_0 is uppercase)/N(s_0)
13	ALLCAPS	N(s_0 is all-caps)/N(s_0)
14	SPECIAL	binary: w_0 contains special character
15	SPECIAL-TITLE	N(s_{-1} or s_1 in title contains special character)/(N(s_{-1})+N(s_1))
16	TITLE-WORD	N(s_0 occurs in title)/N(title)
17	NOMINAL-POS	N(s_0 is tagged with nominal PoS)/N(s_0)
18	CONTEXT(k)	N(s_k is typical neighbor at position k of named entity)/N(s_0)
19	PHRASE-HIT(k)	N($w_k = s_k$, i.e., word at position k occurs in snippet)/N(s_0)
20	ACRONYM	N($w_{-1}w_0$ or w_0w_1 or $w_{-1}w_0w_1$ occur as acronym)/N(s_0)
21	EMPTY	binary: search result is empty

Table 1: NER features used in this paper. BASE and GAZ are standard features. URL, LEX, BOW and MISC are piggyback (search engine-based) features. See text for explanation of notation. The definitions of URL-MI, LEX-MI, and BOW-MI for LOC, ORG and O are analogous to those for PER. For better readability, we write $\sum$[[x]] for $\sum_x$.

for compound entities.

3 Standard NER features

As is standard in supervised NER, we train an NE tagger on a dataset where each token is represented as a feature vector. In this and the following section we present the features used in our study divided in groups. We will refer to the *target token* – the token we define the feature vector for – as w_0. Its left neighbor is w_{-1} and its right neighbor w_1. Table 1 provides a summary of all features.

Feature group BASE. The first class of features, BASE, is standard in NER. The binary feature WORD(k,i) (line 1) is 1 iff w^i, the i^{th} word in the dictionary, occurs at position k with respect to w_0. The dictionary consists of all words in the training set. The analogous feature for part of speech, POS(k,t) (line 2), is 1 iff w_k has been tagged with PoS t, as determined by TnT tagger (Brants, 2000). We also encode surface properties of the word with simple regular expressions, e.g., *x-ray* is encoded as *x-x* and *9/11* as *d/dd* (SHAPE, line 3). For these features, $k \in \{-1, 0, 1\}$. Finally, we encode prefixes and suffixes, up to three characters long, for w_0 (line 4).

Feature group GAZ. Gazetteer features (lines 5 & 6) are an efficient and effective way of building world knowledge into an NER model. A gazetteer is simply a list of phrases that belong to a particular semantic category. We use gazetteers from (i) GATE (Cunningham et al., 2002): countries, first/last names, trigger words; (ii) WordNet: the 46 lexicographical labels (food, location, person etc.); and (iii) Fortune 500: company names. The two gazetteer features are the binary features GAZ-B$_l$(k,i) and GAZ-I$_l$(k,i). GAZ-B$_l$ (resp. GAZ-I$_l$) is 1

iff w_k occurs as the first (resp. non-initial or internal) word in a phrase of length l that the gazetteer lists as belonging to category i where $k \in \{-1, 0, 1\}$.

4 Piggyback features

Feature groups URL, LEX, BOW, and MISC are piggyback features. We produce these by segmenting the input text into overlapping trigrams $w_1w_2w_3$, $w_2w_3w_4$, $w_3w_4w_5$ etc. Each trigram $w_{i-1}w_iw_{i+1}$ is submitted as a query to the search engine. For all experiments we used the publicly accessible Google Web Search API.[1] The search engine returns a *search result* for the query consisting of, in most cases, 10 *snippets*,[2] each of which contains 0, 1 or more *hits* of the search term w_i. We then compute features for the vector representation of w_i based on the snippets. We again refer to the target token and its neighbors (i.e., the search string) as $w_{-1}w_0w_1$. w_0 is the token that is to be classified (PER, LOC, ORG, or O) and the previous word and the next word serve as context that the search engine can exploit to provide snippets in which w_0 is used in the same NE category as in the input text. O is the tag of a token that is neither LOC, ORG nor PER.

In the definition of the features, we refer to the word in the snippet that matches w_0 as s_0, where the match is determined based on edit distance. The word immediately to the left (resp. right) of s_0 in a snippet is called s_{-1} (resp. s_1).

For non-binary features, we first calculate real values and then binarize them into 10 quantile bins.

Feature group URL. This group exploits NE information in URLs. The feature URL-SUBPART (line 7) is the fraction of URLs in the search result containing w_0 as a substring. To avoid spurious matches, we set the feature to 0 if $\text{length}(w_0) \leq 2$.

For URL-MI (line 8), each URL in the search result is split on special characters into parts (e.g., domain and subdomains). We refer to the set of all parts in the search result as URL-parts. The value of $\text{MI}_u(p, \text{PER})$ is computed on the search results of the training set as the mutual information (MI) between (i) w_0 being PER and (ii) p occurring as part of a URL in the search result. MI is defined as follows:

$$\text{MI}(p, \text{PER}) = \sum_{i \in \{\bar{p}, p\}} \sum_{j \in \{\bar{\text{PER}}, \text{PER}\}} P(i, j) \log \frac{P(i, j)}{P(i)P(j)}$$

For example, for the URL-part p = "staff" (e.g., in `bigcorp.com/staff.htm`), $P(\text{staff})$ is the proportion of search results that contain a URL with the part "staff", $P(\text{PER})$ is the proportion of search results where the search token w_0 is PER and $P(\text{staff,PER})$ is the proportion of search results where w_0 is PER and one of the URLs returned by the search engine has part "staff".

The value of the feature URL-MI is the average difference between the MI of PER and the other named entities. The feature is calculated in the same way for LOC, ORG, and O.

Our initial experiments that used binary features for URL parts were not successful. We then designed URL-MI to integrate all URL information specific to an NE class into one measurement in a way that gives higher weight to strong features and lower weight to weak features. The inner sum on line 8 is the sum of the three differences $\text{MI}(\text{PER}) - \text{MI}(\text{O})$, $\text{MI}(\text{PER}) - \text{MI}(\text{ORG})$, and $\text{MI}(\text{PER}) - \text{MI}(\text{LOC})$. Each of the three summands indicates the relative advantage a URL part p gives to PER vs O (or ORG and LOC). By averaging over all URL parts, one then obtains an assessment of the overall strength of evidence (in terms of MI) for the NE class in question.

Feature group LEX. These features assess how appropriate the words occurring in w_0's local contexts in the search result are for an NE class.

For NEIGHBOR (line 9), we calculate for each word v in the British National Corpus (BNC) the count NE-BNC(v, k), the number of times it occurs at position k with respect to an NE; and OTHER-BNC(v, k), the number of times it occurs at position k with respect to a non-NE. We instantiate the feature for $k = -1$ (left neighbor) and $k = 1$ (right neighbor). The value of NEIGHBOR(k) is defined as the average log ratio of NE-BNC(v, k) and OTHER-BNC(v, k), averaged over the set k-neighbors, the set of words that occur at position k with respect to s_0 in the search result.

In the experiments reported in this paper, we use a PoS-tagged version of the BNC, a balanced corpus of 100M words of British English, as a model

[1] Now deprecated in favor of the new Custom Search API.

[2] Less than 0.5% of the queries return fewer than 10 snippets.

of word distribution in general contexts and in NE contexts that is not specific to either target or source domain. In the BNC, NEs are tagged with just one PoS-tag, but there is no differentiation into subcategories. Note that the search engine could be used again for this purpose; for practical reasons we preferred a static resource for this first study where many design variants were explored.

The feature LEX-MI interprets words occurring before or after s_0 as indicators of named entitihood. The parameter d indicates the "direction" of the feature: before or after. $\text{MI}_d(v, \text{PER})$ is computed on the search results of the training set as the MI between (i) w_0 being PER and (ii) v occurring close to s_0 in the search result either to the left ($d = -1$) or to the right ($d = 1$) of s_0. Close refers to a window of 2 words. The value of LEX-MI(PER,d) is then the average difference between the MI of PER and the other NEs. The definition for LEX-MI(PER,d) is given on line 10. The feature is calculated in the same way for LOC, ORG, and O.

Feature group BOW. The features LEX-MI consider a small window for cooccurrence information and distinguish left and right context. For BOW features, we use a larger window and ignore direction. Our aim is to build a bag-of-words representation of the contexts of w_0 in the result snippets.

$\text{MI}_b(v, \text{PER})$ is computed on the search results of the training set as the MI between (i) w_0 being PER and (ii) v occurring anywhere in the search result. The value of BOW-MI(PER) is the average difference between the MI of PER and the other NEs (line 11). The average is computed over all words $v \in$ bow-words that occur in a particular search result. The feature is calculated in the same way for LOC, ORG, and O.

Feature group MISC. We collect the remaining piggyback features in the group MISC.

The UPPERCASE and ALLCAPS features (lines 12&13) compute the fraction of occurrences of w_0 in the search result with capitalization of only the first letter and all letters, respectively. We exclude titles: capitalization in titles is not a consistent clue for NE status.

The SPECIAL feature (line 14) returns 1 iff any character of w_0 is a number or a special character.

NEs are often surrounded by special characters in web pages, e.g., *Janis Joplin - Summertime*. The SPECIAL-TITLE feature (line 15) captures this by counting the occurrences of numbers and special characters in s_{-1} and s_1 in titles of the search result.

The TITLE-WORD feature (line 16) computes the fraction of occurrences of w_0 in the titles of the search result.

The NOMINAL-POS feature (line 17) calculates the proportion of nominal PoS tags (NN, NNS, NP, NPS) of s_0 in the search result, as determined by a PoS tagging of the snippets using TreeTagger (Schmid, 1994).

The basic idea behind the CONTEXT(k) feature (line 18) is that the occurrence of words of certain shapes and with certain parts of speech makes it either more or less likely that w_0 is an NE. For $k = -1$ (the word preceding s_0 in the search result), we test for words that are adjectives, indefinites, possessive pronouns or numerals (partly based on tagging, partly based on a manually compiled list of words). For $k = 1$ (the word following s_0), we test for words that contain numbers and special characters. This feature is complementary to the feature group LEX in that it is based on shape and PoS and does not estimate different parameters for each word.

The feature PHRASE-HIT(-1) (line 19) calculates the proportion of occurrences of w_0 in the search result where the left neighbor in the snippet is equal to the word preceding w_0 in the search string, i.e., $k = -1$: $s_{-1} = w_{-1}$. PHRASE-HIT(1) is the equivalent for the right neighbor. This feature helps identify phrases – search strings containing NEs are more likely to occur as a phrase in search results.

The ACRONYM feature (line 20) computes the proportion of the initials of $w_{-1}w_0$ or w_0w_1 or $w_{-1}w_0w_1$ occurring in the search result. For example, the abbreviation *GM* is likely to occur when searching for *general motors dealers*.

The binary feature EMPTY (line 21) returns 1 iff the search result is empty. This feature enables the classifier to distinguish true zero values (e.g., for the feature ALLCAPS) from values that are zero because the search engine found no hits.

5 Experimental data

In our experiments, we train an NER classifier on an in-domain data set and test it on two different out-of-domain data sets. We describe these data sets in

	CoNLL trn	CoNLL tst	IEER	KDD-D	KDD-T
LOC	4.1	4.1	1.9	11.9	10.6
ORG	4.9	3.7	3.2	8.2	8.3
PER	5.4	6.4	3.8	5.3	5.4
O	85.6	85.8	91.1	74.6	75.7

Table 2: Percentages of NEs in CoNLL, IEER, and KDD.

this section and the NER classifier and the details of the training regime in the next section, Section 6.

As training data for all models evaluated we used the CoNLL 2003 English NER dataset, a corpus of approximately 300,000 tokens of Reuters news from 1992 annotated with person, location, organization and miscellaneous NE labels (Sang and Meulder, 2003). As out-of-domain newswire evaluation data[3] we use the development test data from the NIST 1999 IEER named entity corpus, a dataset of 50,000 tokens of New York Times (NYT) and Associated Press Weekly news.[4] This corpus is annotated with person, location, organization, cardinal, duration, measure, and date labels. CoNLL and IEER are professionally edited and, in particular, properly capitalized news corpora. As capitalization is absent from queries we lowercased both CoNLL and IEER. We also reannotated the lowercased datasets with PoS categories using the retrained TnT PoS tagger (Brants, 2000) to avoid using non-plausible PoS information. Notice that this step is necessary as otherwise virtually no NNP/NNPS categories would be predicted on the query data because the lowercase NEs of web queries never occur in properly capitalized news; this causes an NER tagger trained on standard PoS to underpredict NEs (1–3% positive rate).

The 2005 KDD Cup is a query topic categorization task based on 800,000 queries (Li et al., 2005).[5] We use a random subset of 2000 queries as a source of web queries. By means of simple regular expressions we excluded from sampling queries that looked like urls or emails ($\approx$ 15%) as they are easy to identify and do not provide a significant challenge. We also excluded queries shorter than 10 characters (4%) and longer than 50 characters (2%) to provide annotators with enough context, but not an overly complex task. The annotation procedure was carried out using Amazon Mechanical Turk. We instructed workers to follow the CoNLL 2003 NER guidelines (augmented with several examples from queries that we annotated) and identify up to three NEs in a short text and copy and paste them into a box with associated multiple choice menu with the 4 CoNLL NE labels: LOC, MISC, ORG, and PER. Five workers annotated each query. In a first round we produced 1000 queries later used for development. We call this set KDD-D. We then expanded the guidelines with a few uncertain cases. In a second round, we generated another 1000 queries. This set will be referred to as KDD-T. Because annotator agreement is low on a per-token basis ($\kappa = .30$ for KDD-D, $\kappa = .34$ for KDD-T (Cohen, 1960)), we remove queries with less than 50% agreement, averaged over the tokens in the query. After this filtering, KDD-D and KDD-T contain 777 and 819 queries, respectively. Most of the rater disagreement involves the MISC NE class. This is not surprising as MISC is a sort of place-holder category that is difficult to define and identify in queries, especially by untrained AMT workers. We thus replaced MISC with the null label O. With these two changes, κ was .54 on KDD-D and .64 on KDD-T. This is sufficient for repeatable experiments.[6]

Table 2 shows the distribution of NE types in the 5 datasets. IEER has fewer NEs than CoNLL, KDD has more. PER is about as prevalent in KDD as in CoNLL, but LOC and ORG have higher percentages, reflecting the fact that people search frequently for locations and commercial organizations. These differences between source domain (CoNLL) and target domains (IEER, KDD) add to the difficulty of cross-domain generalization in this case.

6 Experimental setup

Recall that the input features for a token w_0 consist of standard NER features (BASE and GAZ) and features derived from the search result we obtain by

[3] A reviewer points out that we use the terms in-domain and out-of-domain somewhat liberally. We simply use "different domain" as a short-hand for "different distribution" without making any claim about the exact nature of the difference.

[4] `nltk.googlecode.com/svn/trunk/nltk_data`

[5] `www.sigkdd.org/kdd2005/kddcup.html`

[6] The two KDD sets, along with additional statistics on annotator agreement requested by a reviewer, are available at `ifnlp.org/~schuetze/piggyback11`.

running a search for $w_{-1}w_0w_1$ (URL, LEX, BOW, and MISC). Since the MISC NE class is not annotated in IEER and has low agreement on KDD in the experimental evaluation we focus on the four-class (PER, LOC, ORG, O) NER problem on all datasets. We use BIO encoding as in the original CoNLL task (Sang and Meulder, 2003).

Table 3: Evaluation results. l = text lowercased, c = original capitalization preserved. ALL scores significantly different from the best results for the three datasets (lines c7, i8, k7) are marked $*$ (see text).

We use SuperSenseTagger (Ciaramita and Altun, 2006)[7] as our NER tagger. It is a first-order conditional HMM trained with the perceptron algorithm (Collins, 2002), a discriminative model with excellent efficiency-performance trade-off (Sha and Pereira, 2003). The model is regularized by averaging (Freund and Schapire, 1999). For all models we used an appropriate development set for choosing the only hyperparameter, T, the number of training iterations on the source data. T must be tuned separately for each evaluation because different target domains have different overfitting patterns.

We train our NER system on an 80% sample of the CoNLL data. For our *in-domain* evaluation, we tune T on a 10% development sample of the CoNLL data and test on the remaining 10%. For our *out-of-domain* evaluation, we use the IEER and KDD test sets. Here T is tuned on the corresponding development sets. Since we do not train on IEER and KDD, these two data sets do not have training set portions. For each data set, we perform 63 runs, corresponding to the $2^6 - 1 = 63$ different non-empty combinations of the 6 feature groups. We report average F_1, generated by five-trial training and evaluation, with random permutations of the training data. We compute the scores using the original CoNLL phrase-based metric (Sang and Meulder, 2003). As a benchmark we use the baseline model with gazetteer features (BASE and GAZ). The robustness of this simple approach is well documented; e.g., Turian et al. (2010) show that the baseline model (gazetteer features without unsupervised features) produces an F_1 of .778 against .788 of the best unsupervised word representation feature.

7 Results and discussion

Table 3 summarizes the experimental results. In each column, the best numbers within a dataset for the "lowercased" runs are bolded (see below for discussion of the "capitalization" runs on lines c9 and i9). For all experiments, we selected a subset of the combinations of the feature groups. This subset always includes the best results and a number of other combinations where feature groups are added to or removed from the optimal combination.

Results for the CoNLL test set show that the 5 feature groups without LEX achieve optimal performance (line c7). Adding LEX improves performance on PER, but decreases overall performance (line c8). Removing GAZ, URL, BOW and MISC

[7] sourceforge.net/projects/supersensetag

from line c7, causes small comparable decreases in performance (lines c3–c6). These feature groups seem to have about the same importance in this experimental setting, but leaving out BASE decreases F_1 by a larger 6.6% (lines c7 vs c2).

The main result for CoNLL is that using piggyback features (line c7) improves F_1 of a standard NER system that uses only BASE and GAZ (line c1) by 4.2%. Even though the emphasis of this paper is on cross-domain robustness, we can see that our approach also has clear in-domain benefits.

The baseline in line c1 is the "lowercase" baseline as indicated by "l". We also ran a "capitalized" baseline ("c") on text with the original capitalization preserved and PoS-tagged in this unchanged form. Comparing lines c7 and c9, we see that piggyback features are able to recover all the performance that is lost when proper capitalization is unavailable. Lin and Wu (2009) report an F_1 score of 90.90 on the original split of the CoNLL data. Our F_1 scores $> 92\%$ can be explained by a combination of randomly partitioning the data and the fact that the four-class problem is easier than the five-class problem LOC-ORG-PER-MISC-O.

We use the t-test to compute significance on the two sets of five F_1 scores from the two experiments that are being compared (two-tailed, $p < .01$ for $t > 3.36$).[8] CoNLL scores that are significantly different from line c7 are marked with $*$.

For IEER, the system performs best for all six feature groups (line i8). Runs significantly different from i8 are marked $*$. When URL, LEX and BOW are removed from the set, performance does not decrease, or only slightly (lines i4, i5, i6), indicating that these three feature groups are least important. In contrast, there is significant evidence for the importance of BASE, GAZ, and MISC: removing them decreases performance by at least 1% (lines i2, i3, i7). The large increase of ORG F_1 when URL is not used is surprising (41.2% on line i4, best performance). The reason seems to be that URL features (and LEX to a lesser extent) do not generalize for ORG. Locations like *Madrid* in CoNLL are frequently tagged ORG when they refer to sports clubs like *Real Madrid*. This is rare in IEER and KDD.

[8]We make the assumption that the distribution of F_1 scores is approximately normal. See Cohen (1995), Noreen (1989) for a discussion of how this affects the validity of the t-test.

Compared to standard NER (using feature groups BASE and GAZ), our combined feature set achieves a performance that is by more than 10% higher (lines i8 vs i1). This demonstrates that piggyback features have robust cross-domain generalization properties. The comparison of lines i8 and i9 confirms that the features effectively compensate for the lack of capitalization, and perform almost as well as (although statistically worse than) a model trained on capitalized data.

The best run on KDD-D was the run with feature groups BASE, GAZ, URL, LEX and MISC. On line k7, we show results for this run for KDD-T and for runs that differ by one feature group (lines k2–k6, k8).[9] The overall best result (43.8%) is achieved when using all feature groups (line k8). Omitting BOW results in the same score for ALL (line k7). Apparently, the local LEX features already capture most useful cooccurrence information and looking at a wider window (as implemented by BOW) is of limited utility. On lines k2–k6, performance generally decreases on ALL and the three NE classes when dropping one of the five feature groups on line k7. One notable exception is an increase for ORG when feature group URL is dropped (line k4, 25.2%, the best performance for ORG of all runs). This is in line with our discussion of the same effect on IEER.

The key take-away from our results on KDD-T is that piggyback features are again (as for IEER) significantly better than standard feature groups BASE and GAZ. Search engine based adaptation has an advantage of 9.2% compared to standard NER (lines k7 vs k1). An F_1 below 45% may not yet be good enough for practical purposes. But even if additional work is necessary to boost the scores further, our model is an important step in this direction.

The low scores for KDD-T are also partially due to our processing of the AMT data. Our selection procedure is biased towards short entities whereas CoNLL guidelines favor long NEs. We can address this by forcing AMT raters to be more consistent with the CoNLL guidelines in the future.

We summarize the experimental results as follows. Piggyback features consistently improve NER for non-well-edited text when used together with standard NER features. While relative improve-

[9]KDD-D F_1 values were about 1% higher than for KDD-T.

ment due to piggyback features increases as out-of-domain data become more different from the in-domain training set, performance declines in absolute terms from .930 (CoNLL) to .681 (IEER) and .438 (KDD-T).

8 Conclusion

Robust cross-domain generalization is key in many NLP applications. In addition to surface and linguistic differences, differences in world knowledge pose a key challenge, e.g., the fact that *Java* refers to a location in one domain and to coffee in another. We have proposed a new way of addressing this challenge. Because search engines attempt to make optimal use of the context a word occurs in, hits shown to the user usually include other uses of the word in semantically similar snippets. These snippets can be used as a more robust and domain-independent representation of the context of the word/phrase than what is available in the input text.

Our first contribution is that we have shown that this basic idea of using search engines for robust domain-independent feature representations yields solid results for one specific NLP problem, NER. Piggyback features achieved an improvement of F_1 of about 10% compared to a baseline that uses BASE and GAZ features. Even in-domain, we were able to get a smaller, but still noticeable improvement of 4.2% due to piggyback features. These results are also important because there are many application domains with noisy text without reliable capitalization, e.g., automatically transcribed speech, tweets, SMS, social communities and blogs.

Our second contribution is that we address a type of NER that is of particular importance: NER for web queries. The query is the main source of information about the user's information need. Query analysis is important on the web because understanding the query, including the subtask of NER, is key for identifying the most relevant documents and the most relevant ads. NER for domains like Twitter and SMS has properties similar to web queries.

A third contribution of this paper is the release of an annotated dataset for web query NER. We hope that this dataset will foster more research on cross-domain generalization and domain adaptation – in particular for NER – and the difficult problem of web query understanding.

This paper is about cross-domain generalization. However, the general idea of using search to provide rich context information to NLP systems is applicable to a broad array of tasks. One of the main hurdles that NLP faces is that the single context a token occurs in is often not sufficient for reliable decisions, be they about attachment, disambiguation or higher-order semantic interpretation. Search makes dozens of additional relevant contexts available and can thus overcome this bottleneck. In the future, we hope to be able to show that other NLP tasks can also benefit from such an enriched context representation.

Future work. We used a web search engine in the experiments presented in this paper. Latencies when using one of the three main commercial search engines Bing, Google and Yahoo! in our scenario range from 0.2 to 0.5 seconds per token. These execution times are prohibitive for many applications. Search engines also tend to limit the number of queries per user and IP address. To gain widespread acceptance of the piggyback idea of using search results for robust NLP, we therefore must explore alternatives to search engines.

In future work, we plan to develop more efficient methods of using search results for cross-domain generalization to avoid the cost of issuing a large number of queries to search engines. Caching will be of obvious importance in this regard. Another avenue we are pursuing is to build a specialized search system for our application in a way similar to Cafarella and Etzioni (2005). While we need good coverage of a large variety of domains for our approach to work, it is not clear how big the index of the search engine must be for good performance. Conceivably, collections much smaller than those indexed by major search engines (e.g., the Google 1T 5-gram corpus or ClueWeb09) might give rise to features with similar robustness properties. It is important to keep in mind, however, that one of the key factors a search engine allows us to leverage is the notion of relevance which might not be always possible to model as accurately with other data.

Acknowledgments. This research was funded by a Google Research Award. We would like to thank Amir Najmi, John Blitzer, Richárd Farkas, Florian Laws, Slav Petrov and the anonymous reviewers for their comments.

Template-Based Information Extraction without the Templates

Nathanael Chambers and **Dan Jurafsky**

Abstract

Standard algorithms for template-based information extraction (IE) require predefined template schemas, and often labeled data, to learn to extract their slot fillers (e.g., an *embassy* is the *Target* of a *Bombing* template). This paper describes an approach to template-based IE that removes this requirement and performs extraction without knowing the template structure in advance. Our algorithm instead learns the template structure automatically from raw text, inducing template schemas as sets of linked events (e.g., bombings include *detonate*, *set off*, and *destroy* events) associated with semantic roles. We also solve the standard IE task, using the induced syntactic patterns to extract role fillers from specific documents. We evaluate on the MUC-4 terrorism dataset and show that we induce template structure very similar to hand-created gold structure, and we extract role fillers with an F1 score of .40, approaching the performance of algorithms that require full knowledge of the templates.
